For $I = 3.0$, the limiting value for Z was in the range 0.80—0.95, depending on B. Here, as in the dilute medium, the distinction between stable and unstable solutions was sharp.

The data have not been considered accurate enough to justify a similar calculation for the lower limit at $I = 3.0$, nor for the intermediate "instability

range" for $I=3.0$. It seems likely that a similar intermediate range should exist for $I=0.5$ although it has not been met with in the range of B and Z studied.

Although the explanation given here is reasonable and agrees fairly well both with present data and with the results of earlier work, it is not considered that the present constants are a final answer to the question. Attempts will be made to study silicate ions in other media, and with other experimental methods, and also to study some related anions.

Acknowledgements. This work was made possible by a generous grant from Columbia-Southern Chemical Corporation whose permission to publish is very much appreciated. I wish to thank Professor Lars Gunnar Sillén for introducing me to this interesting type of equilibrium studies and for his invaluable help and encouragement throughout the work. I also wish to thank Dr. Franklin Strain and Mr. Björn Holmström for their stimulating interest and Mr. Frans Ericson for his valuable help with experimental equipment.

Studies on the Vitamin B_{12}, Cyanocobalamin-Binding Capacity, Desoxyribosides, and Methionine in Some Commercial Milk Products and Cheese

DANLEY A. CALLIERI

Royal Institute of Technology, Division of Food Chemistry, Stockholm 70, Sweden

1. Part of the vitamin B_{12} in cow milk is destroyed during commercial pasteurization (74°C for 16 sec).

2. There is no "free" vitamin B_{12} (estimated as *E. coli* activity) in unpasteurized cow milk. On the other hand, this activity is considerable in pasteurized milk.

3. The cyanocobalamin-binding capacity of cow milk amounted on a average to 0.29 mμg/ml. Different results were obtained with different samples of milk, the range being 0.15–0.45.

4. Commercially pasteurized cow milk (74°C, 16 sec) has no cyanocobalamin-binding capacity.

5. The cyanocobalamin-binding capacity of cow milk, determined as shown in Table 4, is destroyed by heating to a temperature between 50–60°C.

6. The substance responsible for the cyanocobalamin-binding capacity of cow milk loses this property upon heating, at the same time as the cyanocobalamin is released from the complex.

7. Freezing has no influence on the cyanocobalamin-binding capacity of cow milk.

8. The "total" vitamin B_{12} activity of sour milk and yoghurt is lower than that of the milk from which they have been prepared. This indicates that the vitamin is used by the bacteria during the lactic fermentation of the milk. The total activity in yoghurt is due mainly to methionine and desoxyribosides, both of which are not at all present, or only in very small amounts, in the ultrafiltrate of cow milk.

9. Sour milk has no, or only a very low, cyanocobalamin-binding capacity. This property is on the other hand very high in yoghurt, being in the range 150–190 mμg/ml, *i. e.* about 500–600 times higher than in fresh unpasteurized milk.

10. Preliminary results with saline suspensions of *Lactobacillus bulgaricus* and of *L. thermophilus*, used in the preparation of yoghurt, indicate that these organisms are able to bind cyanocobalamin.

11. Cheddar and Roquefort had on average about the same B_{12} activity (28 and 27 mμg/g fresh basis, respectively), and so had Camembert and Svecia but on a lower level (11.5 and 11.3 mμg/g fresh basis).

The high contents of desoxyribosides made impossible the assay of the "free" vitamin B_{12} in Camembert and Roquefort by the micro-

biological method used here. The results obtained with Cheddar and Svecia show that the vitamin occurs in these cheeses mainly in a bound form.

13. Camembert contained about 400 μg methionine/g fresh basis (*Leuconostoc mesenteroides* activity) while the other varieties had amounts which were 3 to 7 times greater. The *L. delbrückii* activity of Cheddar and Svecia was of the same order of magnitude, 0.75—1.9 μg/g fresh basis, calculated as thymine desoxyriboside. The activity of Camembert and Roquefort was 20—35 times greater.

Numerous articles have been published in different countries on the determination of the content of cyanocobalamin in cow milk and the seasonal variations of this content as well as the influence of the animal diet composition etc. In the present work, determinations of the total vitamin B_{12} activity of cow milk were only made in order to see if the vitamin is destroyed during commercial pasteurization of the milk, and if so, to what extent. The total vitamin B_{12} activity in the whey was also determined as well as the "free vitamin B_{12}" activity in pasteurized and untreated cow milk. The results obtained are summarized in points 1—3 above.

In 1955 Gregory and Holdsworth [2] demonstrated that milk from different animal species possessed the property of binding added cyanocobalamin. The amount of cyanocobalamin which could be bound was different for different species, being greatest for sow milk (240 mμg Cy/ml) and smallest for cow milk (0.5 mμg Cy/ml). It has been found previously in this laboratory by Neujahr *et al.*[3] that dry skim milk powder has no cyanocobalamin-binding capacity and, even if not fully investigated, it was pointed out that also commercially pasteurized milk might have lost the ability to bind cyanocobalamin.

In the present work, the cyanocobalamin-binding capacity of pasteurized and untreated cow milk was further investigated. As it was found that the pasteurized product does not bind cyanocobalamin, an attempt was made to determine at which temperature this property is destroyed by heating. The results are summarized in points 3—7 above.

There seems to be no published data about the vitamin B_{12} activity and cyanocobalamin-binding capacity of yoghurt and sour milk. In the present work, the vitamin B_{12} content of both products was determined and compared with that of the milk used in their preparation. The ability to bind cyanocobalamin was also investigated. The results are summarized in points 8—10 above.

The vitamin B_{12} activity, total as well as "free", and the cyanocobalamin-binding capacity of four different kinds of cheese were determined. The cheese extracts were also analyzed for methionine and desoxyribosides. The results are summarized in points 11—13 above.

PART I. THE VITAMIN B_{12} ACTIVITY, TOTAL AND "FREE", IN PASTEURIZED AND UNPASTEURIZED COW MILK

Experimental

Determination of the vitamin B_{12} content. A 50 ml sample of milk, containing 100 μg/ml of KCN, was autoclaved for 10 min at 120°C. After cooling, the liquid was ultrafiltered and the ultrafiltrate analyzed for vitamin B_{12} using the tube method and *E. coli* 113—3 as test-organism.

The ultrafiltration was carried out using a piece of Visking cellulose tubing (The Visking Corp., Chicago), diameter 1/4 inch, as described by Gregory [1] but modified in the following way: Two small pieces of plastic or rubber tubing (c) were pushed on to the stem of a funnel (a) (Fig. 1) and a short piece of glass tubing (b). A 20—25 cm length of cellulose tubing was moistened with distilled water at both ends and then slipped over the sleeves (c). Cotton thread was tied tightly around the cellulose tubing in order to make both joints secure. Hence, in contrast to the original method, the cellulose tubing did not have a cotton-tied end with which the liquid to be ultrafiltered came into contact. To facilitate the fastening, the tube (b) can first be loosened from the rubber stopper and can then, after the joints have been made secure, be pushed back into its place. The cellulose tube must be carefully moistened in order to prevent it from cracking during the ultrafiltration. This was performed by keeping it overnight, after it had been fastened to the funnel and the glass tube, in a desiccator, the lower compartment of which was half-filled with distilled water. The desiccator was placed in a refrigerator in order to prevent any possible microbiological attack on the cellulose. To perform the ultrafiltration, the cellulose tubing *etc.* was put into a tube (d) which could be evacuated through (e). It was possible to connect several ultrafilters to the same suction device when there were numerous samples to be treated. During the present work, up to 30 simultaneous ultrafiltrations have been run successfully. After autoclaving, a 10 ml sample was poured

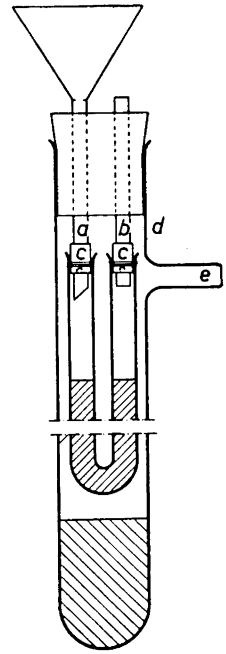

Fig. 1. Ultrafilter.

into the funnel. Suction was applied and then removed when about 1—1.5 ml ultrafiltrate had been collected. This took approximately one hour.

Working with this proportion between the sample and the ultrafiltrate, the amount of free vitamin B_{12} per ml in both of them should be the same [2]. The ultrafiltrate was diluted appropriately and its vitamin B_{12} content determined using the tube method and *E. coli* 113—3 as test organism. To get the standard curve, crystalline cyanocobalamin was added to six sets of tubes in quadruplicate in the following quantities: 0.025, 0.05, 0.1, 0.2, 0.4, and 0.8 mμg per tube. In several cases, the pH of the milk was adjusted to 5 before autoclacing. The whey, thus produced, was ultrafiltered and its vitamin B_{12} content determined. The values were fundamentally the same as those obtained by ultrafiltration of the whole milk, after the above treatment. This is in agreement, with the findings of Neujahr et al [3].

To determine the amount of "free" vitamin B_{12} (as *E. coli* activity), samples of milk were directly ultrafiltered and the ultrafiltrate analyzed.

Bioautography. Spots of the samples were put on sheets of Whatman No. 1 paper and developed in two different solvent systems according to Neujahr [6], the compositions of which are given below, for 24 or 48 h. The spots were made by releasing drops from a capillary. After development, the paper sheets were dried and placed on agar plates seeded with the appropiate test microorganism.

Solvent system I		Solvent system II	
Sec. butanol	75 %	*Sec.* butanol	75 %
Acetic acid (conc.)	1 %	NH_3 (conc.)	1 %
H_2O	24 %	H_2O	24 %
KCN	0.01 %	KCN	0.01 %

Results and discussion

The samples were provided by Mjölkcentralen, Stockholm.

The values found for the total vitamin B_{12}, given as *E. coli* activity, were 3—6 mμg/ml for untreated milk and 2.5—5.3 mμg/ml for pasteurized milk. These results show that a part of the vitamin B_{12} is destroyed during the commercial pasteurization of the milk (16 sec at 74°C). In untreated milk, the "free" B_{12} content is zero, or very low, while in pasteurized milk it is 0.6—0.14 mμg/ml. During pasteurization the milk loses its cyanocobalamin-binding capacity and also a part of the naturally bound vitamin is released. (See Part II).

The results of two typical experiments are shown in Table 1.

Table 1. Total and "free" vitamin B_{12} in pasteurized and unpasteurized cow milk.

Unpasteurized cow milk		Pasteurized cow milk	
Total vitamin B_{12} activity mμg Cy/ml	"Free" vitamin B_{12} activity mμg Cy/ml	Total vitamin B_{12} activity mμg Cy/ml	"Free" vitamin B_{12} activity mμg Cy/ml
6	0.025	5.3	0.56
5.1	0	4.7	0.60

The samples were analyzed also by the bioautographic technique with solvent systems I and II [6] (see Experimental), using *E. coli* 113—3 and *L. leichmannii* 313. In this way, it was shown that the vitamin B_{12} activity was due only to cyanocobalamin.

PART II. CYANOCOBALAMIN-BINDING CAPACITY OF COW MILK. TEMPERATURE AT WHICH THIS PROPERTY IS DESTROYED. EFFECT OF LOW TEMPERATURES ON THE BINDING CAPACITY

Experimental

Determination of cyanocobalamin-binding capacity of pasteurized and unpasteurized cow milk. To four samples of milk from the same batch, 0.25, 1.0, 2.0, and 4.0 mμg cyanocobalamin/ml of milk was added. The samples were kept at 4—7°C for 2 h stirring for 5 min every 30 min. The samples were then ultrafiltered in the usual way, each sample being divided equally between two ultrafilters. In this way, two ultrafiltrates were obtained from each sample and their cyanocobalamin contents were determined separately, the average being taken as the cyanocobalamin content of the sample in question. The cyanocobalamin determination was made using the tube-method with *E. coli* 113—3 and/or *L. leichmannii* 313 A.T.C.C. 7830 as test-organisms. The quantity of cyanocobalamin bound additionally is obtained as the difference between the amount of cyanocobalamin added and that found in the ultrafiltrate. Samples of milk without any added cyanocobalamin were also ultrafiltered to determine the activity of the ultrafiltrate for the test-organism.

Influence of temperature on the cyanocobalamin-binding capacity of cow milk. A 2 l quantity of milk was heated under continuous stirring in a water bath. When the milk reached the desired temperature, a sample was taken. After having kept the milk at the same temperature for a certain time, another sample was taken (Table 4). The milk was then heated until the next temperature was reached and a fresh sample was taken, and so on. The samples were then kept at 4—7°C to permit them to reach a uniform temperature. The binding capacity of the different samples was then determined as above, after adding 2 mμg cyanocobalamin/ml. In the last four samples of assay No 3 taken at 70—85°C, some of the cyanocobalamin naturally present in the milk had been released (contents over the 2 mμg cyanocobalamin added). The remaining part of each sample was kept at —20°C for several days, and then ultrafiltered and analyzed. The results were the same.

Results and discussion

The cyanocobalamin-binding capacity of pasteurized and unpasteurized cow milk was investigated using the ultrafiltration technique (see Experimental). The results show that the pasteurized milk (Table 3) has no binding capacity while the unpasteurized milk (Table 2) does bind cyanocobalamin.

Table 2. Cyanocobalamin-binding capacity of unpasteurized cow milk. The results are given as "coli activity".

Added Cy mμg/ml	Cy found in the ultrafiltrate mμg/ml	Bound Cy mμg/ml	Average
1	0.76	0.24	
2	1.61	0.39	0.29
4	3.77	0.23	

Table 3. Cyanocobalamin-binding capacity of pasteurized cow milk. The results are given as "coli-activity".

Assay No.	Activity of the milk before adding Cy mμg/ml	Cy added mμg/ml	Activity of the ultrafiltrate mμg/ml
1	0.20	0.25	0.5
		1.0	1.11
		2.0	2.10
		4.0	4.10
2	0.28	1.0	1.1
		2.0	2.3
		4.0	4.3
3	0.14	0.25	0.45
		1.0	1.08
		2.0	2.0
		4.0	4.2

This is in agreement with the results of previous investigations in this laboratory performed by Neujahr *et al.*[3] The table shows the average of a large number of determinations using *E. coli* and *L. leichmannii* as test-organisms in the tube method.

The cyanocobalamin-binding capacities of different samples of unpasteurized milk were different, the range being 0.15—0.45 mμg cyanocobalamin/ml. Since the amount of vitamin is small, this variation can be due to the method employed *.

Since pasteurized milk has no binding capacity, the temperature at which this property is destroyed was determined. It was found (Table 4) that, for the conditions under which this work was done (see Experimental), the critical temperature is between 50 and 60°C. Above this temperature the "free" vitamin B_{12} content increases considerably with increasing temperature. This indicates that part of the bound vitamin B_{12} is released by heating over 50—60°C and is thereafter unable to rebind. Hence, this seems to indicate that the substance responsible for the binding of cyanocobalamin in milk is altered by the heating at the moment when the vitamin is released from the complex. To make this conclusion more certain, samples of milk, heated to different temperatures above 50—60°C, were ultrafiltered after they had reached room temperature and also after they had been kept for several days at either 4 or 7°C. It was found that the quantities of vitamin B_{12} in the ultrafiltrates were the same. No recombination of the vitamin took place.

* It it also possible that milk samples from different cows, and even from the same cow on different occasions, have not the same cyanocobalamin-binding capacity. Such possibilities were not especially studied it the present work.

In several assays, the values of which were discarded, a considerable increase in the binding capacity was observed when the amount of cyanocobalamin added was increased. This observation has been made by many authors before, and has been attributed by Gregory [1] to the method of determination of the vitamin.

Table 4. Influence of heating on the cyanocobalamin-binding capacity of cow milk. The results are given as "coli-activity".

	85	1	0	2	3.90	

(a) Samples were taken at the moment at which the milk reached the given temperature.
(b) Samples were taken after keeping for 5 min at the given temperature.

The effect of a low temperature on the cyanocobalamin-binding capacity of cow milk was also studied. Three assays were made with the same sample: before freezing and after keeping at —20°C for 3 days and 10 days. No differences were found.

PART III. VITAMIN B_{12} ACTIVITY AND CYANOCOBALAMIN-BINDING CAPACITY OF SOUR MILK AND YOGHURT. PRELIMINARY STUDY ON BINDING CAPACITY OF *LACTOBACILLUS BULGARICUS* AND *L. TERMOPHILUS*.

Experimental

1. *Determination of "total" vitamin B_{12} activity.* The samples of both sour milk (pH 4.2—4.4) and yoghurt (pH 4.0—4.05) were diluted with an equal amount of distilled water. The pH was adjusted to 5.5 and 100 mμg KCN/ml of diluted sample was added

before autoclaving for 10 min at 120°C. After cooling to room temperature, the solutions were ultrafiltered as usual and the ultrafiltrates analyzed for vitamin B_{12} by the tube method using *E. coli* 113—3 and/or *L. leichmannii* 313 A.T.C.C. 7830 as test-organisms.

2. *Determination of "free" vitamin B_{12} activity.* The samples were diluted with an equal amount of distilled water, ultrafiltered and the ultrafiltrates were assayed as above.

3. *Determination of cyanocobalamin-binding capacity.* This assay was performed as described for milk (see Part II), the appropriate amount of cyanocobalamin being added to the samples after they had been diluted with an equal amount of distilled water.

4. *Chromatography in order to identify methionine* was done on sheets of Whatman No. 1 paper, using a solvent system composed of methylethylketone (55 %), acetone (25 %) and NH_3 conc. (10 %), for 5—8 h. The papers were, after drying, developed by spraying with 0.5 % ninhydrine in acetone [5].

Results and discussion

Yoghurt and sour milk are obtained by the lactic fermentation of milk. Industrially, the milk is first pasteurized and then inoculated with the appropriate microorganism. The vitamin B_{12} activity of these products and also that of the pasteurized milk from which they were prepared was investigated in the present work. As shown above (see Part II), pasteurized milk does not bind cyanocobalamin. The cow milk used for the production of yoghurt and sour milk is treated more rigorously (85°C for 16 sec) than the commercially pasteurized milk (74°C for 16 sec). Any cyanocobalamin-binding capacity in the soured products must therefore be due to changes occurring during the fermentation. The results are shown in Table 5 and can be summarized as follows:

Sour milk. The total B_{12} activity was 30—40 % lower than that of the milk from which the sour milk was prepared. Thus a large part of the vitamin is used by the *Lactobacillus* during the fermentation. Bioautographs were performed using solvent systems I and II (see Part I) and *E. coli*. Only one spot corresponding to cyanocobalamin was obtained. Furthermore, the agreement between the results obtained in assay No 4 with two different test-organisms also indicates that the activity is due to only one factor.

In all assays, the "free" vitamin B_{12} content was found to be greater than that in the milk from which the sour milk was prepared. Bioautographs were, in addition, performed with the ultrafiltrates in which the "free" vitamin B_{12} had been determined. Also here, only one spot, corresponding to cyanocobalamin, was obtained. As before, the results with two different test-organisms (assay No 4) were the same.

The presence of "free" B_{12} would indicate that sour milk has no binding capacity for this vitamin. This seems to be confirmed, in general, by the assays made to study this property. As shown in Table 5, there seems to exist, in some cases and especially in assay No 2, a certain cyanocobalamin-binding capacity since it should be remembered that the solution already contained a certain amount of "free" vitamin B_{12}. In conclusion, it can be said that sour milk has only a very small, or no, cyanocobalamin-binding capacity.

Yoghurt. As can be seen in Table 5, practically all the vitamin B_{12} of the milk was used during the lactic fermentation. Bioautographs were made, in solvent systems I and II (see Experimental Part I) and using *E. coli* 113—3

* See page 744.

as test-organism, with the ultrafiltrates corresponding to the assays of "total" and "free" vitamin B_{12}. Several diffuse spots were obtained in this way, none of them being cyanocobalamin. The different results obtained in the determination of vitamin B_{12} using *E. coli* and *L. leichmannii* as test-organisms in the tube method (assay No 4) also indicate that the activity is due to more than one factor. Hence, a qualitative assay of the ultrafiltrates was made by putting them simultaneously on four agar plates seeded with *E. coli* 113—3, *L. leichmannii* 313 A.T.C.C. 7830, *L. delbrückii* A.T.C.C. 9649, and *Leuconostoc mesenteroides* P. 60 A.T.C.C. 8042 (the first microorganism is sensitive to cyanocobalamin and methionine, the second to cyanocobalamin and desoxyribosides, the third to desoxyribosides and the last one to methionine). This assay showed that the active factors in the ultrafiltrates were mainly methionine and desoxyribosides. Methionine was later also identified by chromatography (see Experimental).

The cyanocobalamin-binding capacity of yoghurt is surprisingly high (Table 5), *viz.* 150—190 mμg/ml.

As mentioned before, yoghurt is prepared from pasteurized cow milk by inoculating with *Lactobacillus bulgaricus* and *L. thermophilus* and fermenting at 45°C. Obviously, the cyanocobalamin-binding capacity of yoghurt appears during this fermentative process and can be due to transformations of the natural constituents of milk and/or can be caused by the substances belonging to the metabolism of the above-named lactobacilli. Hence, preliminary assays were made with suspensions of *L. bulgarius* and of *L. thermophilus* in saline solution. It was found that they are able to bind cyanocobalamin. A further investigation will be carried out on this subject.

PART IV. VITAMIN B_{12} ACTIVITY AND CYANOCOBALAMIN-BINDING CAPACITY OF FOUR DIFFERENT KINDS OF CHEESE. DETERMINATION OF METHIONINE AND DEOXYRIBOSIDES IN THE EXTRACTS USED TO TEST VITAMIN B_{12} CONTENT

Experimental

1. *Determination of total vitamin B_{12} activity.* 200—300 g of cheese was cut into small pieces and mixed, in order to obtain a random sample. Three different methods for the extraction of the vitamin B_{12} were compared:

a) 20 g of cheese was emulsified in a blender for 5 min with 70—75 ml of fresh aqueous emulsifying solution (see below) at 50°C. The volume was adjusted to 100 ml with the same solution. The emulsion was ultrafiltered as usual (see Part I) and the ultrafiltrates diluted and assayed for vitamin B_{12} activity with *Lactobacillus leichmannii* 313 A.T.C.C. 7830 in the tube method. The emulsifying solution had the following composition [4]:

KH_2PO_4	1.36 g
$Na_4P_2O_7$	0.75 g
KCN	0.005 g
H_2O	to 100 ml

b) 20 g of cheese was emulsified as in (a). Before adjusting the volume to 100 ml, KCN was added in order to get a final concentration of 100 μg KCN/ml of emulsion. The emulsion was then autoclaved for 10 min at 120°C, the volume readjusted to 100 ml and the solution ultrafiltered and assayed as before.

c) 20 g of cheese was emulsified as in (a) using, however, glassdistilled water containing 100 μg KCN/ml instead of the emulsifying solution. The volume was adjusted to 100 ml and the pH to 5.5. The emulsion was then autoclaved for 10 min at 120°C, the volume readjusted before ultrafiltering and the ultrafiltrates assayed.

As mentioned before, no appreciable differences in the vitamin B_{12} activity were found when using the methods described. The aqueous extraction (c) was thus adopted.

2. *Determination of "free" vitamin B_{12}.* 20 g of cheese was emulsified in a blender for 5 min with 70—75 ml glass-distilled water at 40—45°C. The emulsion was made up to 100 ml, ultrafiltered and the ultrafiltrate assayed.

3. *Determination of cyanocobalamin-binding capacity.* Emulsions of the cheeses, obtained as described above, were assayed for cyanocobalamin-binding capacity using the ultrafiltration method (see Part II). The activity of the emulsions without addition of cyanocobalamin was also determined after ultrafiltering.

Results and discussion

Several methods for the extraction of vitamin B_{12} from cheese were tested (see Experimental) but no significant difference was found. Consequently, the aqueous extraction method was adopted because of its simplicity.

The determination of the vitamin B_{12} activity was performed by taking the whole of the cheese. The variations in vitamin B_{12} content which may exist in different parts of the same cheese were not tested.

The samples of cheese were extracted (see Experimental) and ultrafiltered. The ultrafiltrates were assayed, using first of all the cup method and *E. coli* 113—3 as test-organism in order to get an approximate idea of the activity. All the four cheeses tested (see below) gave double zones of growth, the inner ring being sharper. This indicates that there was present in the extracts more than one substance which stimulated the growth of *E. coli*. It was thought that the smaller and sharper ring could be due to vitamin B_{12}, and the larger and more diffuse to methionine.

A simultaneous qualitative test was then made using four agar plates, each seeded with a different microorganism (see Part III). The results were as follows:

	Vitamin B_{12}	Methionine	Desoxyribosides
Camembert	+	++	+++
Roquefort	+	++++	+++
Svecia	+	++++	+
Cheddar	+	++++	+

The presence of methionine was confirmed by chromatography and bioautography (see Part III).

The presence of considerable amounts of methionine and desoxyribosides in the extracts made uncertain the use of *E. coli* or *L. leichmannii* for the determination of vitamin B_{12}. It was first necessary to determine these substances quantitatively in order to calculate the appropriate degree of dilution of the extracts required to prevent their interference in the vitamin B_{12} assay. Methionine and desoxyribosides were determined by the tube method using *Leuconostoc mesenteroides* and *Lactobacillus delbrückii*, respectively, as test-organisms. As can be seen in Table 6, all four cheeses have a considerable methionine content, high enough to make the determination of vitamin B_{12}

impossible using *E. coli* as test-organism in the tube method without any special treatment of the extracts.

The amount of desoxyribosides in Cheddar and Svecia is 0.6 — 1.5 μg/g fresh basis. In Camembert and Roquefort the content is 20—40 times higher (*L. delbrückii* activity, calculated as thymine desoxyriboside). Because of the ratio between the quantities of cheese used and the final volume of the extract (see Experimental), the amount of desoxyribosides per ml of extract enabled a direct determination of vitamin B_{12}, using the tube method and *L. leichmannii* as test-organism, provided that the vitamin B_{12} content was not too low, in which case the necessary dilution of the extracts would be impossible.

Preliminary assays were made to determine the approximate vitamin B_{12} activity of the extracts. It was found that, at the dilution necessary in order to prevent the influence of deoxyribosides on the *L. leichmannii* growth, there was sufficient of the vitamin to permit an accurate assay. The results obtained using this microorganism in the tube method are shown in Table 6.

Table 6. Cyanocobalamin, methionine, and desoxyribosides contents of aqueous extracts from four kinds of cheese. The results are given as *L. leichmanii, Leuconostoc mesenteroides* and *L. delbrückii activity*, respectively, each being the average of three different assays.

	Extract from "total vitamin B_{12}" determination			Extract from "free vitamin B_{12}" determination		
	Methionine μg/g fresh basis	Desoxyribosides μg/g fresh basis	Cy mμg/g fresh basis	Methionine μg/g fresh basis	Desoxyribosides μg/g fresh basis	Cy mμg/g fresh basis
Cheddar	1 478	0.75	28	1 635	1.2	1.7
Camembert	390	70	11.5	565	67	*
Roquefort	2 700	42	27	2 515	40	*
Svecia	1 848	1.35	11.3	1 710	1.9	0.8

* The high amount of desoxyribosides present in the extract made impossible the determination of cyanocobalamin by the method used.

An attempt was made to determine whether the vitamin B_{12} is bound or free in the cheese. The samples of cheese were emulsified in a blender with glass-distilled water at 40—45°C, ultrafiltered and assayed for vitamin B_{12}, methionine, and deoxyribosides. As can be seen in Table 6, these last two substances are present more or less in the same amounts as in the ultrafiltrates corresponding to the determination of the total vitamin B_{12} activity. In contrast to this, the "free" vitamin B_{12} content in Cheddar and Svecia is much lower than the values obtained for the total vitamin B_{12}. This indicates that the vitamin is mainly bound in these cheeses. The determination of "free" vitamin B_{12} in Camembert and Roquefort was not possible with the method employed because of the high desoxyriboside concentration.

Table 7. Cyanocobalamin-binding capacity of four kinds of cheese. The results are given as *Lactobacillus leichmannii* activity.

	Natural activity of the ultrafiltrate mμg Cy/ml	Amount of Cy (mμg) added/ml cheese emulsion	Amount of Cy (mμg) found/ml ultra-filtrate
Cheddar	0.3	10	13.7
		20	24.0
Camembert	1.67	10	14.4
		20	23.0
Roquefort	2.5	10	13.0
		20	20.0
Svecia	0.2	10	9.6
		20	23.0

Desoxyribosides were also identified by bioautography in solvent system I and II (see Part I) with *L. delbrückii* as test-organism and thymine desoxyriboside as standard. Further investigations will be made to determine whether the activity detected with L. delbrückii is due only to desoxyribosides.

The cyanocobalamin-binding capacity of the cheeses was also investigated using the ultrafiltration technique (see Experimental).

The mean results obtained are shown in Table 7.

Hence, it can be concluded that none of the cheeses investigated has any cyanocobalamin-binding capacity.

Acknowledgements. The author wishes to thank Professor H. Lundin, Head of the Division, for his great interest in the work and for his provision of valuable laboratory facilities. The author is also indebted to his colleagues in the Institute, in particular Dr. Halina Neujahr and Dr. Arne Bolinder, for their kind advice and many interesting discussions concerning the investigations. Thanks are also due to Mjölkcentralen, Stockholm, for the various samples which were used in this work.

The Structure of Ceroptene

MARTIN NILSSON

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Ceroptene, the yellow pigment of *Pityrogramma triangularis*, has been reinvestigated. The evidence of degradation and synthesis indicates that it is a methyl enol ether of 2-cinnamoyl-6,6-dimethyl*cyclo*hexane-1,3-5-trione (II), either 5-methoxy-2-cinnamoyl-6,6-dimethyl*cyclo*hex-4-ene-1,3-dione (IV) or less probably 3-methoxy-2-cinnamoyl-6,6-dimethyl*cyclo*hex-3-ene-1,5-dione (VI).

On the fronds of many ferns of the family *Pteridaceae* *, and especially on those belonging to the genus *Pityrogramma*, there is a white or yellow secretion on the dorsal surfaces, and these ferns are therefore sometimes cultivated for decorative purposes. In botanical literature the coating is often described as a wax layer (»ceraceous ferns»), but investigations by Blasdale [2] and by Zopf [3] at the beginning of this century show that it contains appreciable amounts of enolic compounds.

The "golden-back fern", *Pityrogramma triangularis*, Kaulf. (earlier known as *Gymnogramme triangularis* and due to some confusion in literature also as *Ceropteris triangularis*), was investigated by Blasdale, who isolated a crystalline, yellow pigment, m.p. 135°, for which he proposed the name ceroptene. He described it as an acidic compound, which analysed for $C_{18}H_{18}O_4$ and gave benzoic acid on oxidation. On treatment of ceroptene with hydroiodic acid he obtained a product, m.p. 182° ($C_{11}H_{11}IO_3$?), which also gave benzoic acid on oxidation, but only ill-defined products on treatment with alkali. Blasdale did not propose any structure for the pigment and no further work on ceroptene appears to have been reported since.

Ceroptene has now been reinvestigated. Fronds of *P. triangularis* were extracted with ether, the extract was freed from lipid material, and eventually the yellow pigment was obtained in fair yield from the alkali-soluble fraction. It melted somewhat unsharply at 137—140° and the analytical data agreed with the composition proposed by Blasdale ($C_{18}H_{18}O_4$). The mass spectrum confirmed the molecular weight as 298.

* Botanical nomenclature according to Copeland [1].

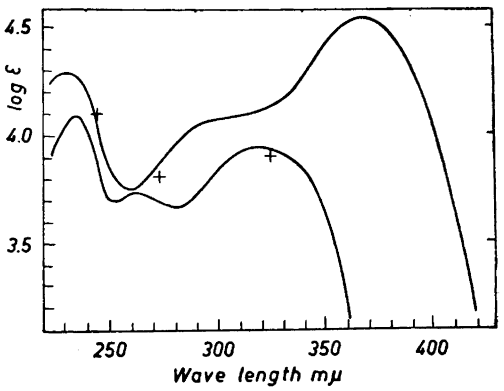

Fig. 1. Ultraviolet spectra of ceroptene (upper curve) and dihydroceroptene (lower curve) in ethanol (99.5 %). The absorption maxima reported for tasmanone [9] are indicated by crosses.

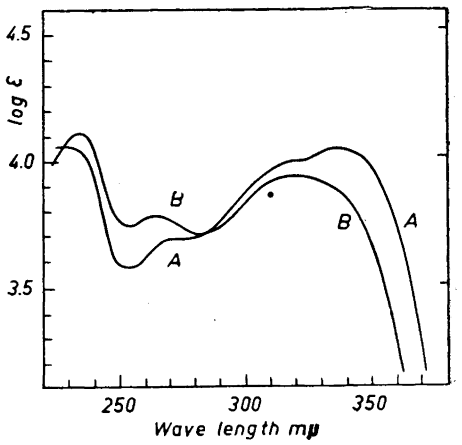

Fig. 2. Ultraviolet spectra of 3-acetylfilicinic acid (A) and O-methyl-3-acetylfilicinic acid (B) in ethanol (99.5 %).

Ceroptene proved to contain one methoxyl group and one active hydrogen atom; the large consumption of Grignard reagent (2.9 mole) in the latter determination indicated the presence of two carbonyl groups also. The C-methyl determination gave 0.4 mole of acetic acid, which suggested the presence of a *gem*-dimethyl group [4].

Ceroptene gave a strong, red colour with iron(III) chloride and a chloroform-soluble copper salt (m.p. 253—257°). This and the infrared absorption (see below) indicated it to be the chelate enol of a β-diketone.

Catalytic hydrogenation or reduction with zinc in acetic acid gave colourless dihydroceroptene, m.p. 98—100°.

The presence of a mono-substituted benzene ring, demonstrated by oxidation of ceroptene to benzoic acid, was evident also in the mass spectrum peak at $m/e = 77$ ($C_6H_5^+$, *cf.* however Ref.[5]). A peak at $m/e = 103$ was interpreted as $C_6H_5—CH=CH^+$ [6]. These peaks were weak in the mass spectrum of dihydroceroptene, which instead gave pronounced peaks at $m/e = 91$ and 105, presumably due to $C_6H_5—CH_2^+$ (rearranged [7]) and $C_6H_5—CH_2—CH_2^+$ [6]. In the infrared spectrum of ceroptene, bands near 3 100, 1 580, 1 310 and 970 cm^{-1}, which did not recur in the spectrum of dihydroceroptene, indicated the presence of a di-substituted, *trans*-ethylenic double bond conjugated with a benzene ring. The mass spectral and infrared data thus indicate that ceroptene contains a Ph—CH=CH- unit.

Degradation of dihydroceroptene by ozonolysis and subsequent oxidation with alkaline hydrogen peroxide gave hydrocinnamic acid and dimethylmalonic acid confirming the presence of the C_6C_2-grouping and also showing the presence of a *gem*-dimethyl group.

The ultraviolet spectrum of ceroptene (Fig. 1) was rather similar to those of chalcones and other arylidene ketones, but did not give very much further information. The spectrum of dihydroceroptene (Fig. 1) was of considerably greater interest because of the strong band near 320 mμ. Since the absorption of the non-conjugated benzene ring is negligible this absorption must be due to the remaining part of the molecule. Comparison with known spectra indicated a close resemblance to 3-acetylfilicinic acid (2-acetyl-6,6-dimethyl*cyclo*hexane-1,3,5-trione, I) [8]. The spectrum of this compound (Fig. 2) is the sum of contributions from various tautomers and enolate ions; the absorption above 300 mμ appears indeed to be made up of two peaks (325 and 340 mμ). The dihydroceroptene maximum is close to the first peak.

Tasmanone [9], isolated from the essential oil of *Eucalyptus risdoni*, has been supposed to be 5-methoxy-2-*iso*butyryl-4,6,6-trimethyl*cyclo*hex-4-ene-1,3- dione. Its ultraviolet absorption (maxima indicated in Fig. 1) is similar to that of dihydroceroptene. A comparison with the methyl ether(s) of 3-acetylfilicinic acid appeared however to be desirable for confirmation of the nature of the chromophore.

3-Acetylfilicinic acid was obtained, albeit in small quantity, by alkaline methylation of phloroacetophenone [8]. On treatment with methyl orthocarbonate [10] it afforded a methyl ether, m.p. 107—109°. The ultraviolet spectrum of this O-methyl-3-acetylfilicinic acid (Fig. 2) was similar to that of tasmanone and almost identical with that of dihydroceroptene. There were also striking similarities between the infrared spectra of O-methyl-3-acetylfilicinic acid and dihydroceroptene.

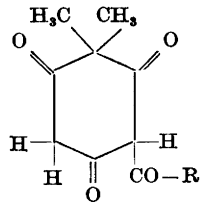
The alkaline cleavage of ceroptene proceeded very slowly, partly due to the poor solubility of the salt(s) in strong alkali and possibly also due to an unfavourable equilibrium. Prolonged heating with dilute aqueous potassium hydroxide with simultaneous, continuous extraction with toluene gave benzaldehyde and a product identical with the synthetic O-methyl-3-acetylfilicinic acid (20 %).

The reverse reaction proceeded smoothly and the condensation of O-methyl-3-acetylfilicinic acid with benzaldehyde using piperidine as a catalyst gave ceroptene in good yield.

The evidence shows that ceroptene is the methyl ether of an enol of 2-cinnamoyl-6,6-dimethyl*cyclo*hexane-1,3,5-trione (II) but does not give any definite evidence about the position of the methoxyl group.

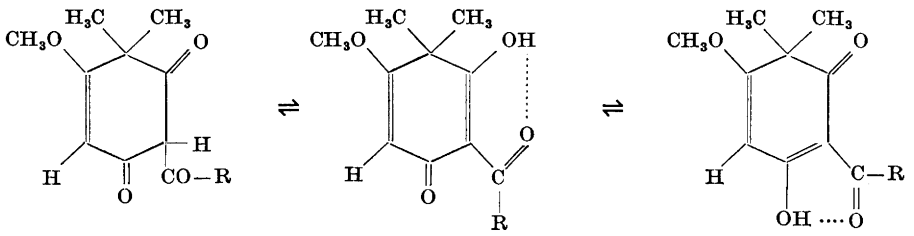
Of the possible methyl ethers of 3-acetylfilicinic acid only III and V should give conjugate chelated enols. The ultraviolet spectrum gives no direct help towards a choice between them because of lack of reference data. The position of the methoxyl group should however be the same as in tasmanone.

The infrared spectra of 2-acyl*cyclo*hexane-1,3-diones show a strong band at 1 540—1 565 cm^{-1}, which has been ascribed to a carbonyl vibration shifted to low frequency by conjugate chelation accentuated by the symmetry of the β-triketone system [11]. Ceroptene, dihydroceroptene and O-methyl-3-acetylfilicinic acid all absorb very strongly near 1 520 cm^{-1}. This band appears to have a similar origin, the shift to lower frequencies presumably being due to additional conjugation. These compounds appear to be completely enolised since the infrared absorption is independent on the concentration and since

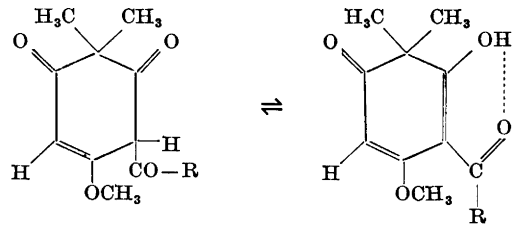


I R = CH_3–

II R = Ph–CH = CH–



III R = CH_3– IV R = Ph–CH=CH–



V R = CH_3– VI R = Ph–CH=CH–

the ultraviolet spectra in *cyclo*hexane and in ethanol are fairly similar. This and the very broad and weak OH-absorption near 2 000 cm^{-1} both support the assignment of the chelate carbonyl frequency. Further work on this subject is published elsewhere [12].

The 2-acyl*cyclo*hexane-1,3-diones also show a band near 1 660 cm^{-1} which is ascribed to the non-chelated carbonyl group [11]. This band recurs in the present spectra. The absorption of dihydroceroptene and O-methyl-3-acetylfilicinic acid at 1 625 and 1 621 cm^{-1}, respectively, is probably due to the enol ether double bond since dimedone methyl ether absorbs at 1 620 cm^{-1} [13]. In ceroptene the peak is observed at 1 625 cm^{-1} and the intensity is increased by the overlapping ethylenic absorption.

Model compounds for prediction of the infrared absorption of 3-methoxy-2-acetyl-6,6-dimethyl*cyclo*hex-3-ene-1,5-dione (V) are lacking but the striking similarity of the present compounds to the 2-acyl*cyclo*hexane-1,3-diones seems to favour structure III (5-methoxy-2-acetyl-6,6-dimethyl*cyclo*hex-4-ene-1,3-dione) for the synthetic O-methyl-3-acetylfilicinic acid.

Ceroptene is therefore probably 5-methoxy-2-cinnamoyl-6,6-dimethyl*cyclo*hex-4-ene-1,3-dione (IV), but structure VI (3-methoxy-2-cinnamoyl-6,6-dimethyl*cyclo*hex-3-ene-1,5-dione) is not excluded.

Ceroptene is a somewhat novel addition to the diversified pattern of naturally occurring phloroglucinol derivatives. It embraces the essential features of a $C_6C_3C_6$ compound but is C-methylated to an extent that precludes aromaticity of the phloroglucinoid nucleus and thus is reminiscent of the large group of alkylated 2-acyl*cyclo*hexane-1,3-diones and -1,3,5-triones. These have recently been reviewed by Hassall [14].

The natural order *Filicales* has given many examples of phloroglucinoid compounds. *Dryopterus Filix mas* (L.) Schott., of the family *Aspidiaceae*, which is perhaps the most carefully investigated species, contains a considerable variety of polymethylphloroacylophenones (*cf.* Ref.[14]). *Matteucia orientalis* (Hooker) Trev.[15] and *Phanerophlebia falcata* (L.) Copel. (also known as *Cyrtomium falcatum*)[16] belong to the same family. They have been found to contain matteucinol (5,7-dihydroxy-4'-methoxy-6,8-dimethylflavanone), desmethoxymatteucinol [15] and 5,7,4'-trihydroxy- and 5,7,3',4'-tetrahydroxy-6,8-dimethylflavanone [16].

Although C-alkylated phloroglucinol derivatives are also known from higher plants the wide variety of compounds of this type found in the natural order *Filicales* appears to offer particular scope for comparative biogenetic studies and for biochemical investigations on the formation and transformations of phloroglucinoid compounds.

It is tempting to speculate on the possible physiological significance of the ceroptene coating of *P. triangularis*. β-Triketones are known to exhibit antibacterial and sometimes insecticidal activity and in some cases have shown an unusual hypermetabolic activity similar to that of 2,4-dinitrophenol [17]. It is interesting to note that the young shoots of the "ceraceous ferns" are almost covered with pigment but the coating of the full-grown plants is confined to the dorsal surfaces of the fronds. Possibly the ceroptene coating acts as a protection during the early growth of the fern.

EXPERIMENTAL

Melting points were determined on a Kofler block. The infrared spectra were recorded on a Perkin Elmer No. 21 instrument fitted with a sodium chloride prism, and the ultraviolet spectra were measured on a Beckman DU instrument. The microanalyses were done in the laboratory of Dr. A. Bernhardt, Mülheim, Germany.

Isolation. Fronds and stems of *Pityrogramma triangularis*, collected in California during summer 1957 (180 g), were washed briefly with ether until the extract was almost colourless. The ether solution was filtered and evaporated giving a semi-crystalline mass, m. p. 119–135° (7.1 g). Further extraction with ether gave a greenish, waxy material (1.8 g), which was not investigated. The first extract was partitioned between dimethyl sulphoxide and light petroleum (b. p. 40–60°). The latter phase on evaporation gave a yellowish wax, m. p. 55–68° (1.5 g). The dimethyl sulphoxide solution was poured into water and the mixture was exhaustively extracted with ether. The ether solution was evaporated to a small volume, washed with water and extracted successively with sodium hydrogen carbonate (sat.), sodium carbonate (sat.) and sodium hydroxide (0.5 M) solutions. On extraction with carbonate the ether solution took on a peculiar greenish colour, probably due to trace metal chelation. If extracted with stronger sodium hydroxide solutions the sodium salt of ceroptene precipitated as an oil.

This fractionation gave: 1) Neutral material, 0.7 g; 2) Hydrogen carbonate soluble fraction, 0.02 g; 3) Carbonate soluble fraction, 0.3 g and 4) Alkali-soluble fraction, 3.9 g.

Fractions 1—3 have not been investigated. Fraction 4 was a crystalline, yellow mass and on recrystallisation from methanol gave ceroptene as lemon-coloured prisms and plates, m. p. 137—140° (3.0 g). Further recrystallisation and sublimation (130°, 0.05 mm) did not improve the m. p. In chloroform solution ceroptene was optically inactive.

Analytical data. Found: C 72.3, 72.2; H 6.4, 6.0; O 21.0; CH_3O 13.8; active H 0.44; CH_3-(C) 2.1. Calc. for $C_{18}H_{18}O_4$: C 72.5; H 6.1; O 21.5; CH_3O (one) 10.4; active H (one) 0.34; CH_3-(C) (one) 5.0; M 298.3.

C-Methylated phloroacetophenones are notorious in giving varying methoxyl analyses[8].

Infrared spectrum (measured in carbon tetrachloride solution with the exception of the italicised figures, which denote absorptions measured on a potassium bromide disc in regions of strong solvent absorption): 3 120 w, 3 080 w, 3 040 w, 3 000 m, 2 960 m, 2 900 w, 2 860 w, 1 655 vs, 1 625 vs, 1 580 s, 1 515 vs, 1 475 vs, 1 450 vs, 1 440 vs, 1 385 vs, 1 355 m, 1 335 m, 1 300 m, 1 286 w, 1 232 vs, 1 200 m, 1 165 s, 1 075 w, 1 040 w, 995 m, 985 m, 979 m, *875* w, *870* m, *838* w, *823* w, *792* w, *760* m, *728* w and 700 cm^{-1} w. In the region 3 100—1 900 cm^{-1} there was a very weak and broad absorption.

The mass spectrum was recorded by Ing. R. Ryhage, Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm, with an apparatus equipped with an all-glass heated inlet system[18]. This system gave a fairly large parent peak but preliminary attempts to use a conventional metal inlet system gave extensive cracking and a very low peak for the unfragmented molecule-ion. Only major peaks and peaks relevant to the discussion are given. The figures in brackets are intensities given as *per cent* of the m/e = 221 peak. 299 (25), 298 (96), 297 (38), 283 (37), 280 (19), 227 (47), 222 (21), *221* (100), 195 (8), 131 (81), 126 (78), 125 (49), 115 (16), 111 (46), 105 (6), 104 (14), 103 (19), 102 (14), 95 (11), 91 (8), 83 (10) and 77 (46).

The copper salt was prepared in aqueous methanol and was recrystallised from chloroform-*cyclo*hexane to give bronze-glistening plates, m. p. 253—257°. (Found: C 64.2; H 5.1; residue 11.0. Calc. for $C_{36}H_{34}CuO_8$: C 65.9; H 5.2; CuO 12.0.) The salt could not be sublimed.

Ceroptene gave a strong red colour with iron(III) chloride in methanol. No reaction was obtained with diazotised benzidine even after addition of sodium carbonate or with 2,4-dinitrophenylhydrazine.

Hydrogenation. Ceroptene (0.30 g) in absolute ethanol (20 ml) on hydrogenation over palladised charcoal (0.08 g, 10 %) absorbed one mole of hydrogen in one hour. After filtration, evaporation and recrystallisation from methanol dihydroceroptene (0.21 g) was obtained as prisms and was finally purified by sublimation, m. p. 98—100°. (Found: C 72.7; H 6.7; CH_3O 10.4. Calc. for $C_{18}H_{20}O_4$: C 72.0; H 6.7; CH_3O 10.3.) Infrared spectrum (in carbon tetrachloride solution and in a potassium bromide disc): 3 070 w, 3 020 m, 2 980 m, 2 920 w, 1 665 vs, 1 625 vs, 1 525 vs, 1 495 vs, 1 480 vs, 1 462 vs, 1 390 vs, 1 360 s, 1 285 m, 1 270 w, 1 230 vs, 1 200 s, 1 165 vs, 1 082 m, 1 060 m, 1 035 w, 1 000 s, 965 m, 845 s, 835 s, *810* w, *750* s, and 695 cm^{-1} m.

Mass spectrum: 301 (21), *300* (100), 286 (16), 285 (91), 282 (13), 267 (15), 196 (11), 195 (35), 181 (17), 169 (16), 168 (98), 153 (11), 126 (22), 125 (20), 111 (16), 105 (13), 104 (6), 103 (6), 95 (7), 91 (28) and 77 (6).

When treated with copper (II) acetate in aqueous methanol dihydroceroptene gave a greenish blue copper salt, m. p. *ca.* 200°, which was not, however, obtained in a state of purity.

Oxidation. Ceroptene was oxidised with potassium permanganate in pyridine-aqueous alkali to give benzoic acid (0.7 mole), m. p. and mixed m. p. 120—123°.

Ozonolysis of dihydroceroptene. Dihydroceroptene (0.16 g) in methylene chloride (20 ml) was treated with ozone at −78° for one hour. The solvent was removed under reduced pressure below room temperature and the residue was oxidised with hydrogen peroxide (30 %, 1 ml) in aqueous alkali (2 M, 5 ml) on the water bath for 0.5 h. The cooled solution was acidified and extracted with ether and the extract was evaporated at room temperature to give an oily mixture. Extraction with cold *cyclo*hexane dissolved part of it leaving a colourless, crystalline material (28 mg), which melted at 190° with effervescence and then gave an odour of *iso*butyric acid. Mixed m. p. with dimethylmalonic acid gave no depression and the infrared spectra were identical. Evaporation of the *cyclo*hexane solution gave a low-melting solid, which was recrystallised from dilute hydro-

chloric acid to give a product with an unsharp melting point (38—48°, 30 mg), the infrared spectrum of which was identical with that of hydrocinnamic acid.

Alkaline cleavage of ceroptene. Ceroptene (50 mg), was dissolved in aqueous potassium hydroxide (1 M, 10 ml). The solution was kept on the water bath under continuous extraction with toluene. Samples were withdrawn at intervals and examined by paper chromatography in the system tetralin, acetic acid, water (10:10:1) [19]. The spots were detected by spraying with iron (III) chloride in methanol. After 50 h the ceroptene (R_F 0.7) had disappeared and the main product had R_F 0.6. There was also a faint spot at R_F 0.3, probably 3-acetyl-filicinic acid. The aqueous solution was acidified and extracted with ether and the ether extract after drying was evaporated to give a solid, m. p. 85—100° (23 mg). Sublimation gave colourless needles, m. p. 90—103° (6 mg). The ultraviolet and infrared (KBr) spectra were identical with those of the synthetic methyl ether of 3-acetylfilicinic acid described below.

The toluene solution was heated with an excess of 2,4-dinitrophenylhydrazine on the water bath for 2 h and was then extracted with dilute hydrochloric acid and evaporated to give an orange solid which was triturated with ethanol to give benzaldehyde 2,4-dinitrophenylhydrazone, m. p. and mixed m. p. 236—239° (8 mg).

Methylation of 3-acetylfilicinic acid. C-Methylation of phloroacetophenone according to Riedl and Risse [8] gave 3-acetylfilicinic acid in 5 % yield, m. p. 178—182°. (Reported yield 4 %, m. p. 174—176°.) The ultraviolet spectrum agreed with that given by these authors and a portion boiled with dilute hydrochloric acid gave filicinic acid, m. p. 216—224° (decomp.). (Reported m. p. 214—216°.)

3-Acetylfilicinic acid (63 mg) and methyl ortocarbonate [20] (0.2 ml) were heated on the water bath for 3 h. Light petroleum (2 ml) was added and after cooling the mixture deposited needles, m. p. 97—105° (47 mg). Sublimation and recrystallisation from light petroleum gave the methyl ether as needles, m. p. 107—109°. (Found: C 63.2; H 6.8; CH_3O 14.6. Calc. for $C_{11}H_{14}O_4$: C 62.8; H 6.7; CH_3O 14.7.)

Infrared spectrum (in carbon tetrachloride): 3 080 w, 2 995 m, 2 950 m, 2 860 w, 1 660 vs, 1 621 vs, 1 525 vs, 1 477 vs, 1 455 vs, 1 385 s, 1 350 m, 1 260 w, 1 230 vs, 1 200 m, 1 167 vs, 1 081 m, 1 030 w, 1 000 m, 962 m, 845 w, 740 m, 676 w.

The copper salt was obtained as blue prisms from aqueous methanol, m. p. *ca.* 240° (some decomposition from 200°). It was not obtained in a state of purity.

Synthesis of ceroptene. Synthetic O-methyl-3-acetylfilicinic acid (11 mg), benzaldehyde (50 mg) and piperidine (5 mg) were heated on the water bath for 0.5 h and then methanol (1 ml) was added. On standing ceroptene separated as prisms, m. p. and mixed m. p. 138—140° (9 mg). The infrared spectrum was identical with that of the natural product (KBr).

Acknowledgements. The present investigation was proposed by Professor H. Erdtman, who collected the initial fern material. For this and for his encouraging interest in the work I wish to express my sincere gratitude. Thanks are also due to Dr. K. Folkers, Rahway, Dr. R. W. Miller, San Francisco, Dr:s Alice and Rolla Tryon, Los Angeles and Professor E. Werdermann, Berlin-Dahlem for generous gifts of material.

I also wish to thank Ing. R. Ryhage for the determination of the mass spectra and discussions on the interpretation, Miss Gurli Hammarberg for skilful assistance in the measurements of infrared and ultraviolet spectra and Dr. B. R. Thomas for linguistic comments.

Equilibrium Studies of Polyanions

IV. Silicate Ions in NaCl Medium

NILS INGRI

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Equilibria in silicate solutions have been studied in 0.5 m (molal) Na(Cl) at 25°C, using emf's with a hydrogen electrode. The data, which cover total silicate concentrations, B, from 0.0025 to 0.080 m, are given in the form of curves Z (log $[OH^-]$)$_B$ as previously. The data indicate, besides the mononuclear $Si(OH)_4$, $SiO(OH)_3^-$, and $SiO_2(OH)_2^{2-}$, the presence of polynuclear species with a fairly low number, three or four, of Si-atoms. Assuming a single predominating polynuclear species in the range studied, the best agreement was obtained with $Si_4O_6(OH)_6^{2-}$, as in previous work (Part III [1]). The equilibrium constants deduced are given in Table 2, and the agreement obtained with them is shown in Fig. 2.

In Part III [1] of this series, Lagerström investigated equilibria in silicate solutions, using 0.5 m and 3.0 m Na(ClO_4) as ionic medium. These data could be explained assuming the mononuclear species $Si(OH)_4$, $SiO(OH)_3^-$, $SiO_2(OH)_2^{2-}$, and one or two tetranuclear complexes. A satisfactory agreement was obtained between calculated and experimental data. Although this was perhaps the most accurate series of equilibrium measurements by modern principles that is as yet available for silicates, it was noted that the range of the data was not as broad as desirable, and that the conclusions thus needed support from other data.

The present work is a direct continuation of Lagerström's work, and the aim has been to find out what difference (if any) it makes if Na(Cl) is substituted for Na(ClO_4) as ionic medium. Thus, an investigation very similar to that in Part III has been made using 0.5 m Na(Cl) as ionic medium, and then the data have been treated by mathematical and graphical methods independent of previous knowledge of the results in Part III. It may be considered as satisfactory that, in the end, the conclusions came out much the same.

For many of the experimental details, and for a survey of pertinent previous work on silicate solutions, the reader is referred to Part III[1]. In this paper, however, possible structures for the complexes will also be discussed.

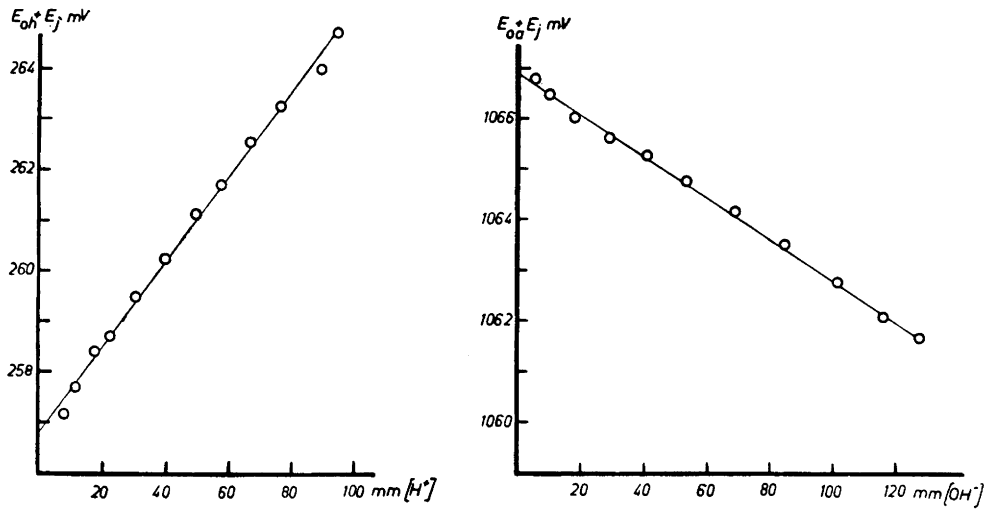

Fig. 1. Diagrams for calculating E_{oa}, E_j and K_w for 0.5 m NaCl medium at 25°C. The values in the two diagrams correspond to the same acid-base titration. The slopes give $E_j h^{-1} = 83$ and $E_j\,[OH^-]^{-1} = 41$ and the intercepts E_{oa} and E_{oh} give $-\log K_w = 13.70$. (See Part II.)

SYMBOLS

The symbols are in general the same as in Parts II[2] and III[1]. Frequently it will be convenient to use the symbol $a = [OH^-]$.

When normalized curves and projection maps have been applied, the normalized quantities B, u and v; corresponding to B, $a = [OH^-]$, and b, have been introduced and defined.

The total concentration B is, in some of the treatments, divided into different parts B_1, $B_2 \ldots B_q \ldots$, each corresponding to complexes A_pB_q with a certain "nuclearity" q. Correspondingly, BZ (the total number of OH^- bound to the $Si(OH)_4$ per liter, or the total charge on the silicate ions per liter), is also divided into the contributions B_1Z_1, $B_2Z_2 \ldots B_qZ_p \ldots$ for the various "nuclearities" present. The functions $f_1 = (1 + \beta_1 a + \beta_2 a^2)$ and $f_Q = \Sigma\beta_{pQ}a^p$ are defined in eqns (3a) and (4a).

Chemical symbols are in Roman type, concentrations in italics. Concentrations and equilibrium constants are expressed in m or mm (moles or millimoles in 1 000 g water).

EXPERIMENTAL

Reagents and apparatus

Sodium chloride, Merck p. a. was used. No Br^- could be detected using the eosin method [3], and the sodium chloride was used after drying at 400°C without further purification.

Hydrochloric acid, Kebo p. a., was standardized against $KHCO_3$ and standard NaOH.

Sodium hydroxide, silicic acid and *alkaline silicate* solutions were prepared and analysed as described in Parts II[2] and III[1], except that solid NaCl was added instead of $NaClO_4$ solution to obtain the ionic medium desired.

Commercial hydrogen gas was used and purified as described in Part II[2]. The *silver-silver chloride* electrodes were prepared [4] by electro-depositing Ag on a Pt foil and afterwards chloridising the silver as anode in dilute HCl.

Following Lagerström's recommendations [1], Jena Geräte glass was used for titration vessels and burets. According to him, during a representative titration, the amount of silica dissolved from the glass-ware will correspond to at most 0.03 mm.

CELL AND PROCEDURE

The same type of *electrode vessel* and *salt bridge* were used as in Part II, except that a different reference electrode was used:

0.5 m NaCl/0.5 m NaCl, saturated with AgCl(s)/AgCl, Ag = SE.

The cell used was thus:

SE/silicate solution/H_2(1 atm), Pt.

The cell including the titration vessel, was kept in an oil thermostat at 25.0 ± 0.1°C, and the whole equipment kept in a thermostated room at 25°C. The emf was measured with a Vernier potentiometer.

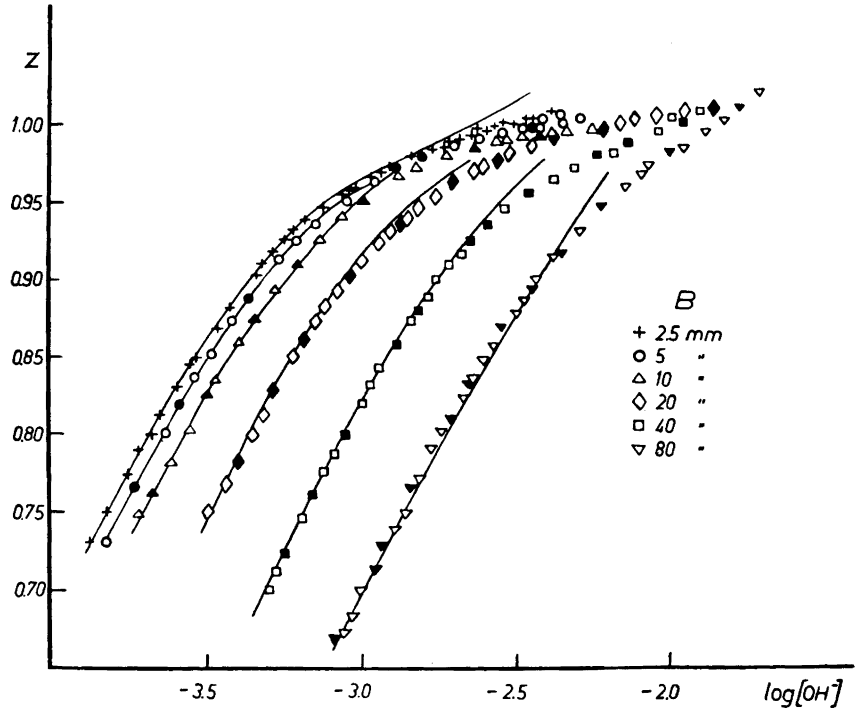

Fig. 2. Experimental data plotted as $Z(\log [OH^-])_B$. Experimental data: points with different symbols for different total concentration B. (See Table 1.) Titrations according to "procedure 1" have filled symbols, those according to procedure 2 open symbols; mm is millimoles in 1000 g water.

Table 1. Data Z (log [OH^-]) for silicates at various total concentrations, B, at 25°C, 0.5 m Na(Cl) ionic medium.

$B = 0.0025$ *m.* Z, $-\log[OH^-]$: 0.731, 3.877; 0.773, 3.7533; 0.801, 3.6777; 0.831, 3.5953; 0.845, 3.5522; 0.868, 3.4634; 0.882, 3.4246; 0.902, 3.3355; 0.931, 3.2202; 0.968, 2.9344; 1.006, 2.3856; (proc. 2) — 0.750, 3.8252; 0.812, 3.6501; 0.917, 3.2902; 0.954, 3.0608; 0.965, 2.9683; 0.996, 2.6238; 0.998, 2.5652; 1.001, 2.4669; (proc. 2) — 0.910, 3.3203; 0.980, 2.8393; 0.983, 2.7702; 0.989. 2.6819; 1.002, 2.4457; (proc. 2) — 0.789, 3.7142; 0.938, 3.1843; 0.956, 3.0409; 0.962, 3.0162; 0.976, 2.8514; 0.994, 2.6755; 0.998, 2.5086; (proc. 2.) — 0.849, 3.5321; 0.925, 3.2501; 0.958, 3.0157; 0.992, 2.6435; 1.000, 2.5401; (proc. 2) — 0.946, 3.1232; 0.972, 2.9115; 0.984, 2.7168; 0.994, 2.5943.

$B = 0.080$ *m.* Z, $-\log[OH^-]$: 0.669, 3.0981; 0.713, 2.9601; 0.810, 2.7121; 0.869, 2.5501; 0.917, 2.3553; 0.982, 1.9991; (proc.1) — 0.672, 3.0593; 0.700, 3.0075; 0.749, 2.8595; 0.791, 2.7763; 0.824, 2.6398; 0.848, 2.6123; 0.886, 2.4756; 0.914, 2.3819; 0.967, 2.0998; 0.984, 1.9545; 1.002, 1.8243; (proc.2) — 0.728, 2.9404; 0.765, 2.8406; 0.833, 2.6519; 0.894, 2.4501; 0.947, 2.2255; 1.010, 1.7761; (proc.1) — 0.683, 3.0344; 0.739, 2.8983; 0.772, 2.8152; 0.802, 2.7444; 0.836, 2.6421; 0.857, 2.5742; 0.878, 2.5015; 0.900, 2.4378; (proc. 2) — 0.930, 2.3004; 0.959, 2.1427; 0.974, 2.0683; 0.994, 1.8864; 1.019, 1.7182 (proc. 2).

Assuming the activity factors to be constant, the emf of the cell can be written

$$E = E_{oa} + 59.15 \log[OH^-] + E_j = E_{oa} + 59.15 \log K_w - 59.15 \log h + E_j \quad (1)$$

Using solutions with known [OH^-], and [H^+], $K_w = 10^{-13.70 \pm 0.02}$ m^2 and $E_j = 41$ [OH^-] mV were obtained. The constant E_{oa} was determined before every titration; for unknown reasons it is slightly different for different hydrogen electrodes. The diagrams in Fig. 1 illustrate this part of the work, which was otherwise quite similar to Part II and Part III.

In the titrations with silicate solutions, the two procedures described by Lagerström as procedure 1 and procedure 2 were used (of course, with Cl^-

instead of ClO_4^-). Thus in each titration, B was kept constant. From the known analytical excess of hydrogen, H, and from the measured $[OH^-]$, Z was obtained from

$$BZ = h - H - K_w h^{-1} = h - H - [OH^-] \quad (2)$$

The data obtained are listed in Table 1, and plotted in Fig. 2 in the usual form, $Z(\log [OH^-])_B$. Within the range shown in Fig. 2, reversible equilibria were obtained, as shown by the fact that points on the same curve were obtained with procedure 1 ($[OH^-]$ decreasing, black points), and procedure 2 ($[OH^-]$ increasing, open symbols).

The experimental range ($Z \sim 0.7$ to 1.0) was limited downwards by the "instability range", and upwards by the fact that at high $[OH^-]$, BZ is obtained as the difference between two large quantities, and thus the accuracy decreases (see eqn. (2)).

The term "instability range", introduced by Lagerström [1], denotes the range where a colloidal precipitate is formed so that stable equilibria, and thus stable emf's cannot be obtained. For $Z < 0.75$, the instability range covers the intermediate total concentrations, B, so that only at low and high values of B, could equilibria be studied.

With titration procedure 1, where, on acidification, part of the solution enters the instability range for a moment, equilibrium was obtained only after some time, whereas with procedure 2 it was obtained practically immediately.

SURVEY OF DATA. CALCULATION OF EQUILIBRIA

In Fig. 2, the data $Z(\log [OH^-])_B$ are seen to give points on different curves for different values of the total concentration, B. This shows that polynuclear complexes must be present. However, with decreasing B the curves seem to approach a limiting curve and one may reasonably assume that the limiting curve has approximately the same shape as the curve for the low B-values. This curve is easily found to fit into a family of curves calculated for a two-step equilibrium [5]. There is every reason to assume that the limiting curve is the one corresponding to equilibria between the three mononuclear species: $Si(OH)_4$, $SiO(OH)_3^-$, $SiO_2(OH)_2^{2-}$, or, in the shorter notation used in Part II and Part III, B, AB and A_2B.

The calculations may be divided into two parts: firstly, the "mononuclear" equilibrium constants were determined as accurately as possible, and secondly an attempt was made to find the formulas and formation equilibrium constants of the most important polynuclear species.

THE EQUILIBRIA WITH MONONUCLEAR SPECIES

It did not prove practicable to get a better approximation to the "mononuclear" curve by making experiments at lower total concentration, B, than about 0.0025 m. At lower B-values, the experimental uncertainty made the data spread so that Z_1 could not be obtained more accurately.

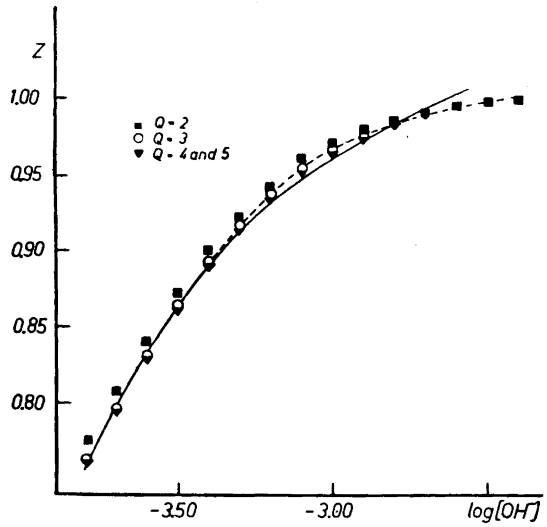

Fig. 3. "Mononuclear curves" $Z_1(\log [OH^-])$ calculated using equation (7) and different values for Q. A full curve: calculated with equilibrium constants in Table 2; a dotted curve, experimental $Z(\log [OH^-])$ curve for $B = 0.0025$ m. The full curve calculated with the constants in Table 2 agrees very well with the points for $Q=4$,

To find the mononuclear curve, $Z_1(\log [OH^-])$, use was made of a method of extrapolation which will now be outlined: It was assumed that the only species formed are the mononuclear B, AB, and A_2B, and the Q-nuclear A_pB_Q, where Q is constant but p may assume several values.

The law of mass action then gives:

$[AB] = \beta_1 ab$; $[A_2B] = \beta_2 a^2 b$; $[A_pB_Q] = \beta_{pQ} a^p b^Q$; and introducing the functions

$$f_1 = 1 + \beta_1 a + \beta_2 a^2 \text{ (3a)} \; ; \; f_1 Z_1 = \beta_1 a + 2\beta_2 a^2 \text{ (3b)} \tag{3}$$

$$f_Q = \Sigma \beta_{pQ} a^p \text{ (4a)} \; ; \; f_Q Z_Q = Q^{-1} \Sigma p \beta_{pQ} a^p \text{ (4b)} \tag{4}$$

we find for the total concentration of B and the total amount of A bound to B per liter:

$$B = b f_1 + b^Q Q f_Q \tag{5a}$$

$$BZ = b f_1 Z_1 + b^Q Q f_Q Z_Q \tag{5b}$$

We notice that Z_Q is the average number of A bound per B in the Q-nuclear complexes. If these are regarded separately, Z_Q, like Z_1 is a function of a only and independent of B.

We may combine (5a) and (5b) to get

$$Z = Z_1 + b^Q Q f_Q (Z_Q - Z_1)(b f_1 + b^Q Q f_Q)^{-1} \tag{6}$$

If a is constant, f_1, f_Q, Z_1 and Z_Q are constant; if B is small, $b \sim B f_1^{-1} \sim B$.constant. Thus, for small B's and constant a we find

$$Z \sim Z_1 + \text{constant } B^{Q-1} \tag{7}$$

Thus one may assume a certain value for Q, and extrapolate a series of plots $Z(B^{Q-1})_a$ to $B = 0$; the intercepts may be used to construct the $Z_1(\log a)$ curve. In Fig 3, the "mononuclear" curve $Z_1(\log a)$ so obtained is plotted for $Q = 2$, 3, 4, and 5. As one extreme, the curve for the lowest B-value used is also given ($B = 0.0025$ m). The equilibrium constants, β_1 and β_2, may be obtained from these curves by the fitting of normalized curves [5]. The following values were obtained (the limits of error indicate the region which might have given an acceptable fit):

	2.5 mM	$Q = 2$	$Q = 3$	$Q = 4$	$Q = 5$	average value
log β_1	4.28	(4.30)	4.29	4.29	4.29	4.29 ± 0.05
log β_2	5.22	(5.34)	5.26	5.24	5.23	5.24 ± 0.15
log K_2	0.94	(1.04)	0.97	0.95	0.94	0.95 ± 0.15

As seen from Fig. 3 a better fit is obtained with $Q=4$ than with $Q=2$ or 3.

POLYNUCLEAR SPECIES

Now that the formulas and equilibrium constants of formation for the mononuclear species were settled, it would have been desirable to apply some general method, such as the integration method used for the borates [2], that would give the average p and q of the polynuclear complexes. Unfortunately, just as in Part III [1], the range of the data is too narrow to allow this method to be applied.

In order to get some information on the formulas of the polynuclear species, an investigation was made to see to what extent the present data could be explained by each of the following three simple assumptions, namely that in addition to the mononuclear species, B, AB, and A_2B, the only species which need be considered are a) a single polynuclear species A_pB_Q, b) a series of complexes A_pB_Q, with p varying but Q constant, and c) a series of uncharged complexes B_q, with q variable.

The assumption c) would mean that all that is formed is a series of polysilicic acids, an idea which has sometimes been suggested; we shall see that it certainly cannot explain the data.

Assumption a) is, of course, a special case of assumption b). The idea that a single value, Q, would predominate is not quite unreasonable, considering that in several hydrolysis systems studied in this Institute (vanadium(V), Rossotti [6]; molybdate, Sasaki [7]; bismuth, Olin [8]) the data quite clearly indicate that in one range the predominating species are a series of complexes with the same number of simple atoms (same Q) but different charges. (In other cases, however, a number of complexes of varying q values have been indicated).

Single polynuclear species, A_pB_Q

Approach with normalized curves. Assuming the species B, AB, A_2B and A_pB_Q, we find from the law of mass action and the definitions of B and BZ:

$$[A_PB_Q] = \beta_{PQ}a^Pb^Q \tag{8}$$

$$B = b + \beta_1 ab + \beta_2 a^2 b + Q\beta_{PQ}a^Pb^Q \tag{9}$$

$$BZ = \beta_1 ab + 2\beta_2 a^2 b + P\beta_{PQ}a^Pb^Q \tag{10}$$

These expressions contain three "unknown" equilibrium constants, two of which (β_1 and β_2) are, however, approximately known. Fixing the ratio

$$l = \beta_2\beta_1^{-2} = 10^{-3.34}$$

at the best value obtained earlier, the two remaining unknowns may be obtained using normalized projection maps (Sillén [9]) obtained by transforming (9) and (10) to the normalized form

$$B = v + uv + lu^2v + Qu^Pv^Q \tag{11}$$

$$BZ = uv + 2lu^2v + Pu^Pv^Q \tag{12}$$

where the normalized variables are

$$u = \beta_1 a \text{ (13a)}; \quad v = b(\beta_1^P\beta_{PQ}^{-1})^{1/1-Q} \text{ (13b)}; \quad B = B(\beta_1^P\beta_{PQ}^{-1})^{1/1-Q} \text{ (13c)} \tag{13}$$

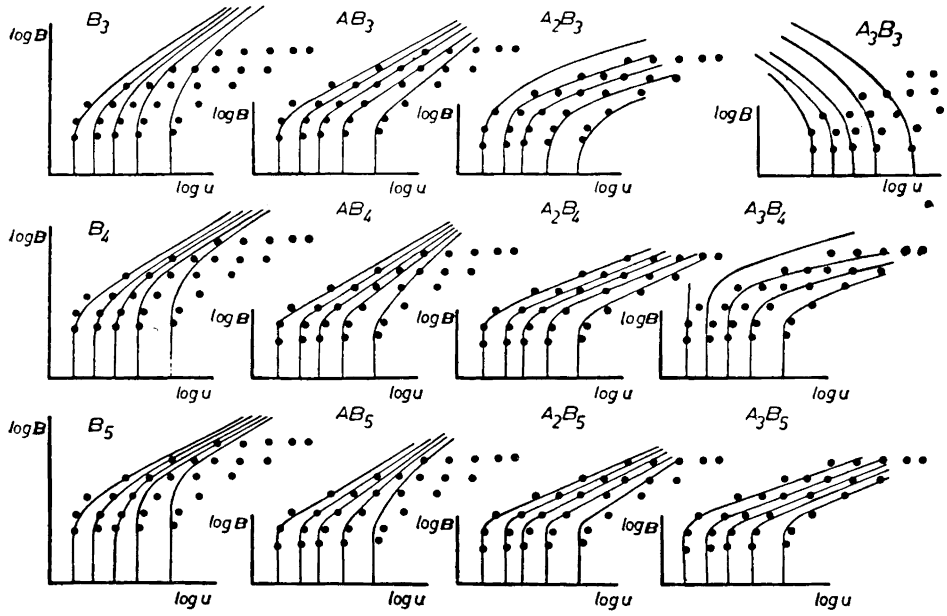

Fig. 4. Projection maps, $B(\log u)_Z$, calculated assuming the single complex A_PB_Q, and various values for P and Q. The experimental data log B (log $[OH^-]$)$_Z$ are in the position of best fit with the calculated projection maps. The experimental points are given for B = 0.0025, 0.005, 0.010, 0.020, 0.040 and 0.080 molal at constant Z. The Z values are from left to right 0.75, 0.80, 0.85, 0.90 and 0.95.

Eliminating v from (11), and (12) we obtain

$$(Q—1)\ \log B = \log [Z(1 + u + lu^2) — (u + 2lu^2)] +$$
$$(Q—1)\ \log [P + (P—Q)\,u + lu^2(P — 2Q)] — P \log u — Q \log (P — QZ) \quad (14)$$

Using eqn. (14) and the value $l = 10^{-3.34}$ obtained earlier, normalized curves log B(log $u)_Z$ have been calculated for a number of sets (P, Q) and moved across the experimental data log B(log [OH^-])$_Z$. Fig. 4 shows the calculated projection maps compared with the experimental data in the position of the best fit, or at least in a position where it is seen that no good fit at all can be obtained. Note that the calculated log B(log $u)_Z$ is vertical for $Z = P/Q$, ($Z = 0.75$ for A_3B_4), and bends to the left for $Z<P/Q$ (all curves for A_3B_3).

The best over-all fit is no doubt obtained with A_2B_4; small deviations at $Z = 0.90$ and $Z = 0.95$ indicate that other polynuclear species may also occur. With A_2B_3 a reasonable fit is obtained for $Z = 0.90$ and 0.95, and with A_2B_5 for $Z = 0.75$ and partly, for $Z = 0.80$; however, neither of these complexes alone would give an acceptable fit for the other end of the diagram. Observing how changes in P and Q affect the slope (Δ log B/Δ log $u)_Z$ and the spacing ($\Delta \log u/\Delta Z)_B$, it is easily seen that no complex outside the range of the (P, Q) sets given in Fig. 4 will be able to give a reasonable agreement with the experimental data.

Our conclusion is thus, just as in Part III[1], that the only single complex which might explain the data in this range is A_2B_4. Assuming this complex, we obtained from log B — log B, and log u — log [OH^-] in the position of best fit, using eqns. (13a) and (13c)

log $\beta_1 = 4.29 \pm 0.05$; log $\beta_{24} = 15.03 \pm 0.20$, log $\beta_2 = 5.24 \pm 0.15$.

The latter comes from the assumed value for l.

Sections at log a = constant. Another approach used the fact that Z_1 and f_1, defined in (3), are functions of a only, and moreover are known approximately. We may write (9) and (10) in the form

$$B = bf_1 + Q\beta_{PQ}a^Pb^Q\ ;\ BZ = bf_1Z_1 + P\beta_{PQ}a^Pb^Q \quad (15)$$

which gives by combination

$$B(Z_1 — Z) = Q(Z_1 — PQ^{-1})\beta_{PQ}a^Pb^Q \quad (16)$$

$$b = Bf_1^{-1}\,(Z — PQ^{-1})\,(Z_1 — PQ^{-1})^{-1} \quad (17)$$

Eliminating b we find

$$B^{Q-1}(Z — PQ^{-1})^Q(Z_1 — Z)^{-1} = f_1^QQ^{-1}\beta_{PQ}^{-1}a^{-P}(Z_1 — PQ_1^{-1})^{Q-1} = \text{function of } a$$

Thus at constant a we would have

$$Q \log (B(Z — PQ^{-1})) = \log [B(Z_1 — Z)] + \text{constant} \quad (18)$$

Plots of log ($B(Z — PQ^{-1})$) against log [$B(Z_1 — Z)$] were made assuming $PQ^{-1} = 0.00$, 0.25, 0.33, 0.50, and 0.67. These plots are given in Fig. 5, except that for $PQ^{-1} = 0.33$.

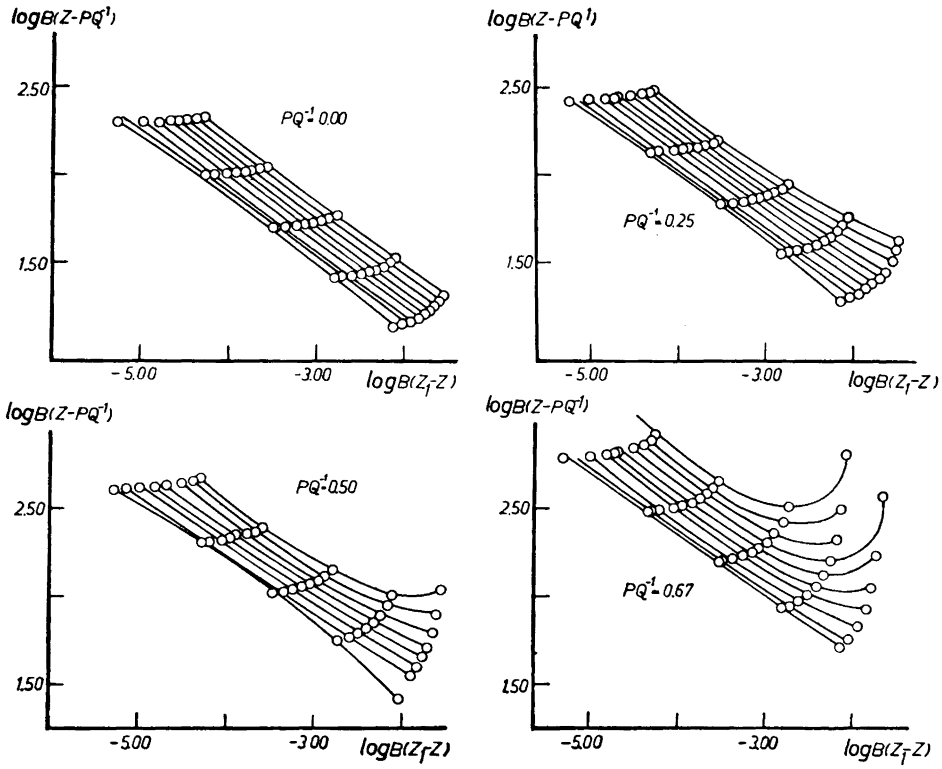

Fig. 5. Plots of $\log(B(Z-PQ^{-1}))$ *versus* $\log(B(Z_1-Z))$ assuming a single complex with various values of PQ^{-1} (compare eqn (18)). The experimental data are given for $-\log [OH^-] = 2.40, 2.50, 2.60, 2.70, 2.80, 2.90, 3.00, 3.10$ and 3.20. For $PQ^{-1} = 0.25$ and 0.67 values for $-\log [OH^-] = 3.30$ are also given and for $PQ^{-1} = 0.5$, $-\log [OH^-] = 2.30$. For $PQ^{-1} = 0.50$ the values for $-\log [OH^-] = 3.10$ and 3.20 have not been calculated.

The complex A_2B_4 would correspond to $PQ^{-1} = 0.50$, and a slope of $Q^{-1} = 0.25$ in the diagrams. As a matter of fact, reasonably straight lines are obtained for all PQ^{-1} lower than 0.67, and the slope of the lines is somewhere between 1/3 and 1/4. This type of plot is less conclusive than the normalized curves, since it pays no attention to the information contained in the distances between the lines. At any rate, it indicates that if any complex predominates, it is a rather small one, with 3 or 4 Si, and with an average charge of less than -1 per Si.

Series of homonuclear complexes A_pB_Q

We have introduced the quantities f_1, Z_1, f_Q, and Z_Q, referring to the mono- and Q-nuclear complexes separately, in connection with the extrapolation method (3), (4). They are all functions of a only. Using them, as before, (9) and (10) take the form

$$B = bf_1 + Qb^Q f_Q \text{ (19a)} ; BZ = Z_1 bf_1 + Z_Q Qb^Q f_Q \text{ (19b) which give} \quad (19)$$

$$b = B(Z - Z_Q)(Z_1 - Z_Q)^{-1} f_1^{-1} \quad (20)$$

Using (19b) and (20) to eliminate b we obtain

$$-Q \log (Z - Z_Q) + \log (Z_1 - Z) + (Q - 1) \log (Z_1 - Z_Q) = \log Q + \log f_Q f_1^{-Q} + (Q - 1) \log B \quad (21)$$

We may normalize (21) to the form

$$\log B = (Q - 1)^{-1} \log Z - Q(Q - 1)^{-1} \log(1 - Z) \quad (22)$$

with the normalized variables

$$\log B = \log B + (Q - 1)^{-1} \log Q + (Q - 1)^{-1} \log f_Q f_1^{-Q} \quad (23)$$

$$\log Z = \log(Z_1 - Z) - \log (Z_1 - Z_Q) \quad (24)$$

If a is constant, Z_1, Z_Q, f_1 and f_Q should keep constant, so that $\log B = \log B +$ constant, $\log Z = \log (Z_1 - Z) +$ constant. For a series of a values experimental curves $\log B(\log(Z_1 - Z))$ were plotted and compared with normalized curves $\log B(\log Z)$, calculated for various values for Q. As shown in Fig. 6, a satisfactory fit could be obtained for $Q = 3$ and 4 (except for $B = 10.00$ mm). For $Q = 2$ and >4, the fit was always poor. For $B \leq 0.010$ m, the curves came too close to the mononuclear one, and the spread in log $(Z_1 - Z)$ made it hard to use (23) and (24). As seen from (23) and (24) the difference $\log B - \log B$, and $\log Z - \log Z$ might be used, for each value of a, to calculate f_Q and Z_Q; in this special case, the accuracy did not permit this to be used as an independent method for determining the several equilibrium constants β_{pQ}; in some other systems it might perhaps prove useful. At any rate, these calculations, like the previous ones, indicate a fairly small complex, with 3 or 4 Si atoms.

Series of uncharged complexes, B_q

If the only species present are A, AB, A_2B, and a series B_q, we would have

$$B = f_1 b + \Sigma q \beta_{oq} b^q ; BZ = f_1 Z_1 b \quad (25)$$

$$\text{Thus } b = BZ f_1^{-1} Z_1^{-1} \quad (26)$$

For each experimental point, BZ, $f_1(a)$, and $Z_1(a)$ are known, so that b can be calculated. A plot $b(B)_a$ was constructed and used for calculating, for a series of round b-values, the function $B - bf_1(a)$.

If the hypothesis were correct, $B - bf_1$ would be $= \Sigma q \beta_{oq} b^q$, and a function of b only. In practice it is found to vary greatly with a, for constant b. Thus it may be concluded that the data cannot be explained assuming the uncharged complexes, B_q, as the only polynuclear complexes.

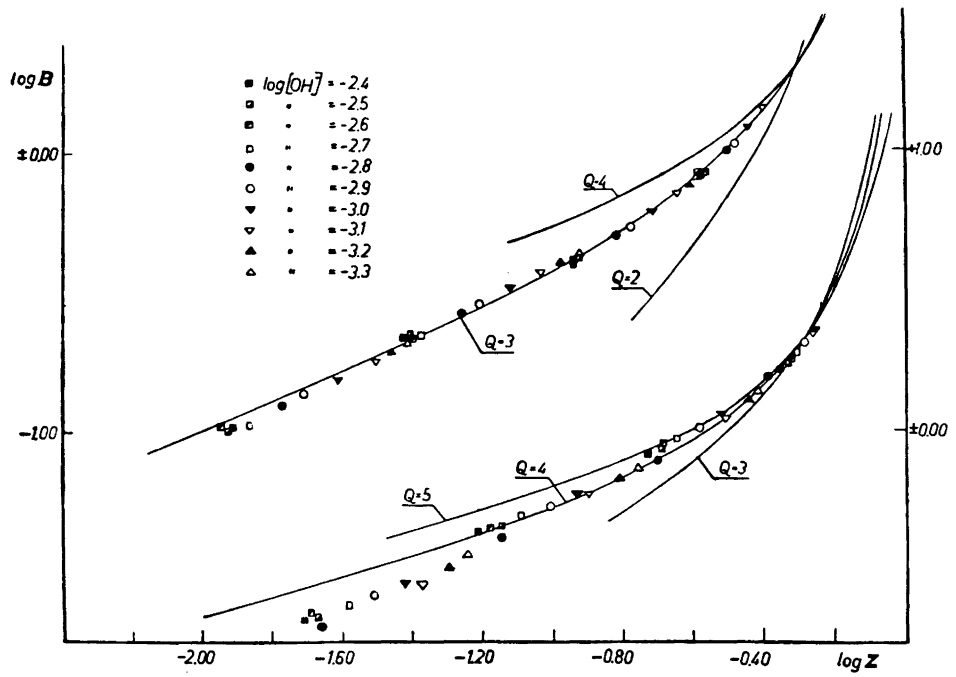

Fig. 6. Series of complexes A_pB_Q. The experimental data log $B(\log (Z_1-Z))_a$ are compared with normalized curves, log B (log $Z)_a$, calculated from (22). In the upper left part of the figure the experimental data are compared with the calculated curve for $Q = 3$ and in the lower right part for $Q = 4$. For comparison, calculated curves for $Q = 2$ and 5 are also given.

CONCLUSIONS

Thus the present data for silicate equilibria in 0.5 NaCl medium, for Z between 0.7 and 1.0, have again given evidence for the existence of the three mononuclear species B, AB, and A_2B, and have given equilibrium constants for their formation. For the polynuclear species, no final and complete picture can be drawn. It is concluded, as in Lagerström's work, that the equilibria with polynuclear species are rapidly obtained, as long as all parts of the solution are kept out of the "instability range". It is also concluded that most or all of the polynuclear ions present are fairly small, with only 3 or 4 Si-atoms. The only single complex that can give a satisfactory agreement with the data is A_2B_4, the same complex as was indicated by Lagerström [1] in $NaClO_4$ medium.

The equilibrium constants are given in Table 2, and the agreement obtained may be studied in Fig. 2.

It seems reasonable to assume, as a working hypothesis, that A_2B_4 is the most important polynuclear silicate ion in the range studied. The small deviations observed indicate that other polysilicate ions, such as A_pB_3 or A_pB_4, are present; the data allow no definite conclusion on their formula

Table 2. Equilibrium constants for silicate reactions at 25°C, 0.5 m Na(Cl) medium, deduced from present data. For comparison, Lagerström's data [1] for 25°C and 0.5 m $Na(ClO_4)$ medium are given.

		0.5 m Na(Cl)	0.5 m $Na(ClO_4)$
$H_2O \rightleftharpoons H^+ + OH^-$	log K_w	$= -13.70 \pm 0.02$	−13.73
$A + B \rightleftharpoons AB$; $OH^- + Si(OH)_4 \rightleftharpoons SiO(OH)_3^- + H_2O$	log β_1	$= 4.29 \pm 0.05$	4.27
$2A + B \rightleftharpoons A_2B$; $2OH^- + Si(OH)_4 \rightleftharpoons SiO_2(OH)_2^{2-} + 2H_2O$	log β_2	$= 5.28 \pm 0.15$	5.44
$A + AB \rightleftharpoons A_2B$; $OH^- + SiO(OH)_3^- \rightleftharpoons SiO_2(OH)_2^{2-} + H_2O$	log K_2	$= 0.99 \pm 0.15$	1.17
$2A + 4B \rightleftharpoons A_2B_4$; $2OH^- + 4Si(OH)_4 \rightleftharpoons Si_4O_6(OH)_6^{2-} + 6H_2O$	log β_{24}	$= 15.03 \pm 0.20$	14.89
$A + B \rightleftharpoons AB$; $Si(OH)_4 \rightleftharpoons SiO(OH)_3^- + H^+$	log $^*\beta_1$	$= -9.51 \pm 0.05$	−9.46
$2A + B \rightleftharpoons A_2B$; $Si(OH)_4 \rightleftharpoons SiO_2(OH)_2^{2-} + 2H^+$	log $^*\beta_2$	$= -22.12 \pm 0.15$	−22.02
$A + AB \rightleftharpoons A_2B$; $SiO(OH)_3^- \rightleftharpoons SiO_2(OH)_2^{2-} + H^+$	log $^*K_2$	$= -12.74 \pm 0.15$	−12.56
$2A + 4B \rightleftharpoons A_2B_4$; $4Si(OH)_4 \rightleftharpoons Si_4O_6(OH)_6^{2-} + 2H^+ + 4H_2O$	log $^*\beta_{24}$	$= -12.37 \pm 0.20$	−12.57

although, of course, an improved agreement probably would be obtained by assuming one or two more complexes, with suitable formation constants.

It seems most desirable to extend the studies of silicate to other media, and also to apply other experimental methods. Work in these directions has been started.

POSSIBLE STRUCTURES FOR SILICATE IONS

Some thought should perhaps be given to the question of what the structures of the silicate ions in solution may be, especially since rather divergent opinions have recently appeared in literature. A short review of the pertinent evidence will be given.

Principles of silicate structures. Beginning with the classical work of the Braggs, the crystal structures have been worked out for a very large number of natural and artificial silicates. They have proved to be built up according to a few simple principles, which are very different from those one might have guessed in the pre-X-ray period of chemistry. This subject has been treated very well in a number of standard text books [10–12].

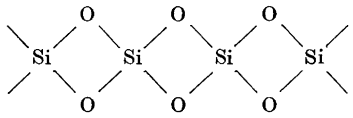
Rule 1: Each Si atom is surrounded by a tetrahedron of 4 O-atoms. The exceptions are very few.

A structure with octahedral coordination Si-6 O has been suggested in SiP_2O_7 (Levi and Peyronel [13]). It is also possible that Si is coordinated to six O's in some organic complexes, such as those with pyrocatechol [14], $Si(O_2C_6H_4)_3^{2-}$, and in a complex with three acetylacetone [15] ($CH_3COCH_2COCH_3 = HA$) acting like a positive ion, SiA_3^+, and forming salts like SiA_3AuCl_4, SiA_3FeCl_4, and $(SiA_3)_2PtCl_6$, soluble in ethanol and acetic acid. A very clear case of 6-coordination around Si is the hexafluorosilicate ion, SiF_6^{2-}, which is octahedral [16].

Although carbon is 3-coordinated in a number of compounds (C_2H_4, CO_3^{2-}, $COCl_2$ etc), no case has been observed with Si coordinated with three O in a crystal structure.

Rule 2: Two SiO_4-tetrahedra can be joined by sharing an oxygen corner. The tetrahedra do not share edges, neither is an oxygen atom shared between more than two Si-atoms.

The only known case of sharing edges seems to be the fibrous form of SiO_2 described by Weiss and Weiss [17]. It seems to have a crystal structure of the same type as SiS_2 (Zintl and Loosen [18]), the SiO_4-tetrahedra forming infinite chains by sharing opposite edges with their neighbors:



We shall disregard these few exceptions and consider instead the overwhelming number of normal structures. In accordance with the two principles given, the SiO_4-tetrahedra can join to form isolated groups, chains (sometimes double chains), sheets and three-dimensional networks. As to detailed descriptions of the structures and references, the reader is referred to the standard texts (*e.g.* Wells [12], p. 569—591).

Anhydrous silicates

Separate SiO_4^{4-} groups are found in a number of minerals and artificial silicates, *e.g.* Mg_2SiO_4. Separate groups, $Si_2O_7^{6-}$, $O_3SiOSiO_3$, are less common, but are found in a few minerals (thortveitite $Sc_2Si_2O_7$; hemimorphite $Zn_4(OH)_2Si_2O_7$; tilleyite [19]). Three-silicon rings, $Si_3O_9^{6-}$, have been reported in the crystal structures of α-and β-wollastonite, $CaSiO_3$, of benitoite, $BaTiSi_3O_9$ and catapleite. Some doubt has been cast upon these rings as Dornberger-Schiff, Liebau and Thilo [20] have reinvestigated the structure of β-wollastonite and found it to contain infinite chains, $(SiO_3)_n$, and not separate rings, $(SiO_3)_3$.

Four-silicon rings, $Si_4O_{12}^{8-}$, seem to exist as independent units in the crystal structure of axinite [21], $Ca_2(Fe, Mn)Al_2(BO_3)(Si_4O_{12})OH$. In the sheet structure of apophyllite, alternate four- and eight-silicon rings occur.

Separate six-silicon rings, $Si_6O_{18}^{12-}$, have been found in beryl, $Be_3Al_2Si_6O_{18}$, and in tourmaline [22]. In the sheet structures of clays, minerals and micas, six-silicon rings are joined to form infinite sheets.

Silicates containing hydrogen

Although a large number of crystalline hydrated silicates are known (see, *e.g.*, Vail [23], *p.* 144—150), very few crystal structures have hitherto been determined. The existence of tetrahedral groups, $HSiO_4^{3-}$, in afwillite [24], ($Ca_3(SiO_3OH)_2(H_2O)_2$) and in $Ca_2(SiO_3OH)OH$ (Heller [25]) seems fairly certain. Thilo and coworkers [26] have concluded from reaction studies that some hydra-

ted Ca and Ca-Na silicates contain $H_2SiO_4^{2-}$, and $HSiO_4^{3-}$ groups, and that crystalline NaH_3SiO_4 contains $H_3SiO_4^-$ groups [27]. Also the latter result was corroborated by the great similarity between the X-ray powder photographs of NaH_3SiO_4 and LiH_2PO_4.

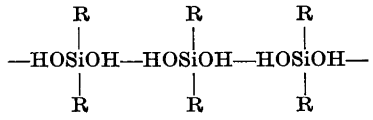
According to a private communication by Machatschki and Preisinger [28] the crystal structure for "sodium metasilicate enneahydrate", really $Na_2(H_2SiO_4)(H_2O)_8$, has been investigated. It contains isolated $H_2SiO_4^{2-}$ groups, and no condensed silicate ions, in contrast to anhydrous Na_2SiO_3 which contains chains, $(SiO_3)_n$, (Grund and Pizy [29]). According to Heide *et al.*[30], dioptase, $Cu_6Si_6O_{18}(H_2O)_6$ contains isolated Si_6O_{18}-rings and H_2O molecules.

Organic Si-O compounds

There are two main series of organic Si compounds, namely silicones and polysilicic acid esters, both of which contain an Si-O skeleton, with R or RO (R = hydrocarbon radical) attached to the remaining corners of the Si tetrahedra.

Silicones are known with straight Si-O chains (2 to 11 Si), with Si-O rings, and also with two rings having one Si atom in common (spiro structures). Rings $(R_2SiO)_n$ with n between 3 and 8 have been prepared and isolated. The 4- and 5-rings seem to be the most stable (Wells [12], p. 562—566). Ring structures $(SiO)_8$ and $(SiO)_4$ have been proved by X-ray studies [31,32] on $((CH_3)_2SiO)_8$ and $((CH_3)_2SiO)_4$. For *polysilicic acid esters*, no structure determination seems to have been made as yet. The compounds $((RO)_2SiO)_n$ with $n = 3$ or 4 are in all probability ring-shaped (Signer and Gross [33]; R = C_6H_{11}, *cyclo*hexyl). Iler [34] claims to have prepared even larger polysilicate ester rings with up to 8 Si (R = C_4H_9). There are also esters known with a lower proportion of R, say $(ROSiO_{1.5})_n$, which may contain a dense Si-O core (several condensed rings), surrounded by R groups (Iler [35], p. 77—78, n around 10 or 12; Sprung and Guenther [36], $n = 6$ and 8).

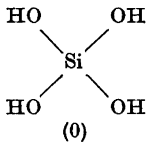
It may be of interest that the methyl and ethyl silanols, R_3SiOH, are, like alcohols, strongly associated in the liquid state and in *cyclo*hexane solution (Grubb and Osthoff [37]). In ROH solutions, R_3SiOH reacts with the ultimate formation of an equilibrium mixture of $R_3SiOSiR_3$, R_3SiOR, and H_2O (Grubb [38]). In crystals, molecules of $R_2Si(OH)_2$ form chains by means of hydrogen bonds (Kakudo and Watase [39], Kasai and Kakudo [40]).



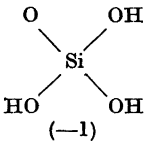
Structures in solutions

It seems plausible that the silicate ions which occur in aqueous solutions are built up on the same principles as have been found in practically all crystalline silicates, namely as SiO_4-tetrahedra, isolated or sharing O atoms, and with

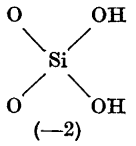
a certain number of protons attached to the unshared O atoms, forming OH groups. The structures of the mononuclear silicate ions would then be,



(0)

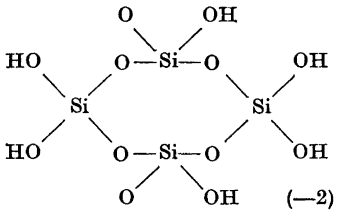


(—1)



(—2)

The present data indicate that complexes with a certain number of Si atoms, namely 4, predominate in the solutions. It seems likely that they contain a ring, so that the structure of A_2B_4 would be

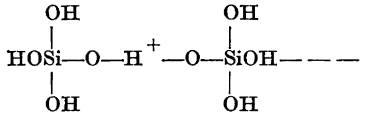


(—2)

If the polysilicate ions had been chain-like, it is hard to understand why, for instance, 4 should be preferred to 2 or 3. One might suggest a still more condensed, tetrahedral structure, $Si_4O_{10}H_2^{2-}$, like P_4O_{10}, however this group has not been found in crystal structures.

Two other hypotheses have been proposed and as far as we can find, are based on insufficient evidence.

Miedreich [41] (p. 14) finds it "very improbable" that Si-O-Si bonds are formed in aqueous solutions, since the equilibria are reached so rapidly in clear solutions. He prefers to think (p. 89) that the polysilicate ions are formed by hydrogen bridging

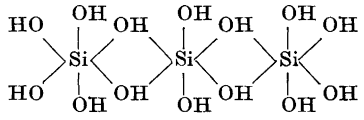


The argument might seem plausible if one makes a comparison only with the polyphosphates; the P-O-P bonds are certainly hydrolyzed only slowly. On the other hand, the formation of O bonds in aqueous solution is a rapidly reversible process for several neighbors of Si in the periodic table. For instance, the polyborate ions undoubtedly contain B-O-B bonds and still give very rapid equilibria [2]. The same is true with the Be-OH-Be bonds formed in the hydrolysis of Be^{2+}, and with quite a number of other O or OH bonds met with in the hydrolysis of positive ions (Kakihana and Sillén[42], Sillén [43]).

With Miedreich's hypothesis it also seems hard to explain the composition of the "X-ray amorphous" precipitates found by Thilo, Wodtcke and Funk [44] on adding Ag^+ to silicate solutions. The general formula, according to them, is $Ag_{n+2}H_nSi_nO_{3n+1}$, with preference for $n = 1$, 2, or 4, whereas Miedreich's

hypothesis demands an average number of 4 O per Si. The formula given by Thilo, Wodtcke and Funk would seem to indicate open-chain ions with 2 or 4 Si. However, as these authors note themselves, it then seems hard to explain why chains with exactly these numbers would be preferred.

Iler [35] (p. 18—30) has followed up a proposal by Weyl [45] that Si is six-coordinated when present as silicate ions in solutions, and that polysilicate ions are formed by sharing two OH's between two adjacent Si-atoms, *e.g.*,



Although the octahedral SiF_6^{2-} ion is well established, there seems to be no structural evidence for the existence of an $Si(OH)_6^{2-}$ ion. On the contrary, as mentioned above, the crystal structure of "$Na_2SiO_3(H_2O)_9$" seems to contain $H_2SiO_4^{2-}$ tetrahedra rather than $Si(OH)_6^{2-}$ octahedra. Nor is there any other evidence to make the existence of such ions very plausible.

The similarity of the Raman spectra of the A_2B silicate ion with $H_2PO_4^-$, (Fortum and Edwards [46]) also suggests strongly a tetrahedral structure $SiO_2(OH)_2^{2-}$.

On the other hand, it may well be that the condensation and breaking of the Si-O-Si bonds in aqueous solution proceeds through some unstable intermediate state with a higher coordination than 4 around Si, and that the rapidity of the reactions is due to the relative ease with which Si can assume a higher coordination number.

Acknowledgements. The present work was carried out thanks to the generous support of Columbia-Southern Chemical Corporation. I am greatly indebted to Professor Lars Gunnar Sillén, who introduced me to these types of equilibrium measurements and for his valuable help during the course of the work. I am also indebted to Drs Franklin Strain and Björn Holmström for valuable advice and support in many ways. I would like to thank Dr. Gösta Lagerström for help and guidance in the beginning of this work, and Mrs. Mina Frydman and Mr. Frans Ericson for valuable help in the experimental parts.

On the Bile Acid Metabolism in the Pig

Bile Acids and Steroids 81

SUNE BERGSTRÖM, HENRY DANIELSSON
and ÅKE GÖRANSSON

Department of Physiological Chemistry, University of Lund, Lund, and the Department of Chemistry, Karolinska Institutet, Stockholm, and Djursjukhuset, Hälsingborg, Sweden

Pig bile, collected from bile fistulas at different times after fistulation, has been analyzed. The main bile acids found in samples collected during the first day after fistulation were chenodeoxycholic, hyocholic and hyodeoxycholic acid, conjugated with glycine and to a small extent with taurine. Bile samples collected later than 24 h after fistulation did not contain hyodeoxycholic acid, indicating that this acid is formed by the action of intestinal microorganisms during the enterohepatic circulation of the bile acids.

This was confirmed by the results of studies on the metabolism of labelled chenodeoxycholic, hyodeoxycholic and hyocholic acid in intact and bile-fistulated pigs.

24-^{14}C-chenodeoxycholic acid was 6α-hydroxylated to hyocholic acid in the fistulated pig, while 24-^{14}C-hyodeoxycholic acid was not metabolized except for conjugation. After circulating enterohepatically in intact pigs for 3 days, 50 % of tritium-labelled hyocholic acid had been transformed into hyodeoxycholic acid.

The metabolism of the main bile acids in the pig could then be summarized as follows:

$$\text{Chenodeoxycholic acid} \xrightarrow{\text{liver}} \text{hyocholic acid}$$

$$\text{Chenodeoxycholic acid} \xrightarrow[\text{microorganisms}]{\text{intestinal}} \text{hyodeoxycholic acid}$$

The main bile acids found in gall-bladder bile of pigs are hyocholic, hyodeoxycholic and chenodeoxycholic acid. They are present as conjugates with glycine and to a small extent with taurine [1]. Hyodeoxycholic (3α, 6α-dihydroxycholanic) acid was identified in 1923 by Windaus and Bohne [2]; the presence of chenodeoxycholic (3α, 7α-dihydroxycholanic) acid was observed in 1939 by Ido and Sakurai [3], but it was not until 1954 that Haslewood and Sjövall [4] demonstrated the presence of considerable amounts of a trihydroxy bile acid. Its structure was shortly thereafter shown to be 3α, 6α, 7α-trihydroxycholanic acid [5,6].

The present investigation is concerned with the metabolism of these three bile acids in the pig. We have prepared labelled hyocholic, hyodeoxycholic and chenodeoxycholic acid and injected them intraperitoneally into pigs. The bile acids were isolated from the bile by chromatography and the identity of the labelled compounds was established by repeated chromatography and cocrystallization with authentic material.

MATERIAL AND METHODS

Labelled compounds. 24-^{14}C-labelled chenodeoxycholic and hyodeoxycholic acid were prepared according to Bergström *et al.*[7] Hyocholic acid was labelled with tritium gas using the method of Wilzbach [8] in the apparatus described by Bergström and Lindstedt [9]. The labelled bile acids were purified by reversed phase partition chromatography in suitable systems (see below) and crystallized to constant specific activity with unlabelled material.

Chromatographic procedures. Reversed phase partition chromatography as described by Sjövall [10] and Norman [11] was used for the separations of the bile acids. The following solvent systems were employed:

	Moving phase	Stationary phase
C.	150 ml methanol	15 ml chloroform
	150 ml water	15 ml *iso*-octanol
D.	300 ml water	100 ml *n*-butanol
F.	165 ml methanol	45 ml chloroform
	135 ml water	5 ml heptane

Hyflo Supercel (Johns Manville and Co., USA) or Hostalene (Farbwerke Hoechst, G.m.b.H., West-Germany) [12] was used as supporting material. The procedure for making Hyflo Supercel hydrophobic has been described [10]. Prior to use, Hostalene was extracted with 95 % ethanol for 48 h in a Soxhlet extractor and then dried at 75°. Columns were prepared as described by Norman [11]. When Hostalene was used as supporting material only 3 ml of stationary phase were used per 4.5 g of this material.

Radioactivity assay. ^{14}C was determined with a Tracerlab end-window counter, tritium with a Tracerlab gas-flow counter.

Animal experiments and procedures for analysis of the bile. The bile acid was injected intraperitoneally in the form of its sodium salt, dissolved in about 10 ml of saline.

Young female pigs weighing about 20 kg were used. Bile fistulas were prepared using trichloroethylene anaesthesia by inserting a polyethylene cannula into the gall-bladder and tying off the ductus choledochus. During the collection of bile from the fistula the animals were restrained in a cage, to which they had previously been conditioned for approximately a week. The animals had free access to drinking water and were fed their normal diet. Bile was collected for 4 h periods into 95 % ethanol. After determination of their radioactivity, the bile samples were diluted with water, acidified with hydrochloric acid and extracted twice with water-saturated butanol. The combined butanol extracts were washed with small volumes of water until neutral and evaporated to dryness *in vacuo*. The residue was chromatographed in phase system C, the effluent was titrated with 0.02 N methanolic sodium hydroxide, and suitable aliquots were assayed for radioactivity. For purpose of further identification the conjugated bile acids were hydrolyzed with N NaOH in a closed steel tube for 6 h at 120°. The saponification mixtures were diluted with water, acidified with hydrochloric acid and extracted twice with ether. The combined ether-extracts, that contained the free bile acids, were washed until neutral with water, and evaporated to dryness. The residue was chromatographed on phase systems C or F, depending upon the acid being purified. The labelled bile acids were diluted with carrier to a weight of approximately 100 mg and crystallized four times from different solvents to a final weight of crystals of about one quarter the original weight. Hyocholic acid was crystallized from ethyl acetate / methanol / heptane, acetone/water, acetic acid/water and acetone/water; hyodeoxycholic acid from ethyl acetate / methanol / heptane, ethyl acetate, acetic acid / water and acetone / water; chenodeoxycholic acid from ethyl acetate / light petroleum, acetic acid / water and ethyl acetate / light petroleum twice.

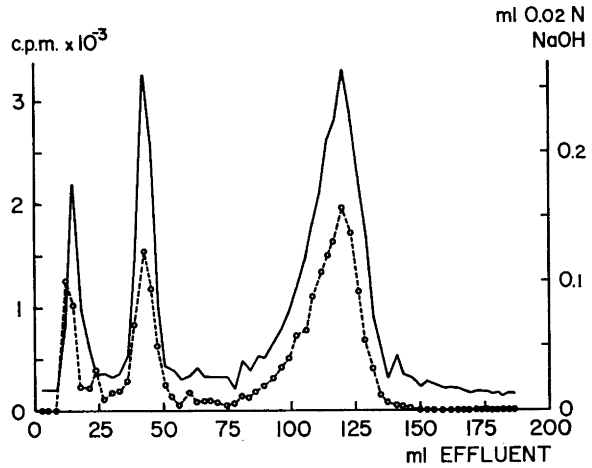

Fig. 1. Chromatogram of unhydrolyzed fistula bile from pig injected i. p. with 24-^{14}C-chenodeoxycholic acid. Fistulation 48 h before the injection. Phase system C. 4.5 g hydrophobic Hyflo Supercel. Solid line: titration. Broken line: c.p.m.

RESULTS

The composition of fistula bile. A sample of pig fistula bile, collected 48 h after the preparation of the fistula, was chromatographed on phase system C, and was found to contain three distinct titration peaks, as illustrated in Fig. 1. The bile acids constituting the first peak were identified as a mixture of taurochenodeoxycholic and taurohyocholic acid by rechromatography on phase system D and after saponification on C and F. The second titration peak was due to glycohyocholic acid, identified in the same manner as described above.

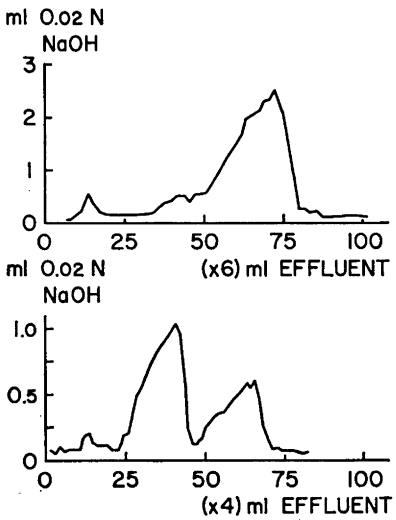

Fig. 2. Chromatogram of hydrolyzed dihydroxycholanic acid band from bile collected 48 h after fistulation (upper curve) and from bile collected immediately after fistulation (lower curve). Phase system F. 27 g hostalene (upper curve), 18 g hostalene (lower curve).

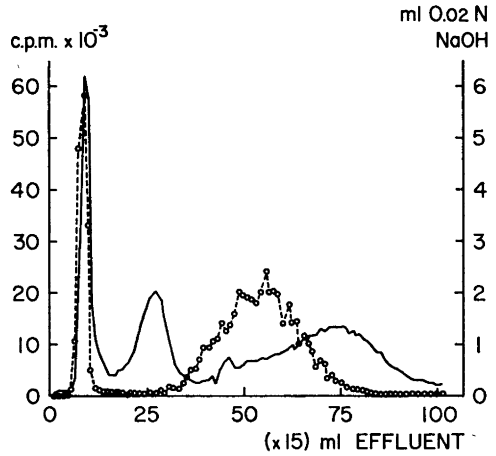

Fig. 3. Chromatogram of unhydrolyzed fistula bile from pig injected i.p. with 24-^{14}C-hyodeoxycholic acid. Fistulation 4 days before injection. Phase system C. 67 g hostalene. Solid line: titration. Broken line: c.p.m.

The third peak, appearing in the usual location for glycodihydroxycholanic acids was hydrolyzed and rechromatographed on phase system F and found to contain only chenodeoxycholic acid, *cf.* Fig. 2. For comparison, there is included in this figure a titration curve of the hydrolyzed glycodihydroxycholanic acids from fistula bile, collected immediately after fistulation, when the bile acids present in the entero-hepatic circulation were being excreted. The presence of a second titration peak, due to hyodeoxycholic acid, is clearly seen. This acid, however, is not present in the bile excreted through the fistula two days later.

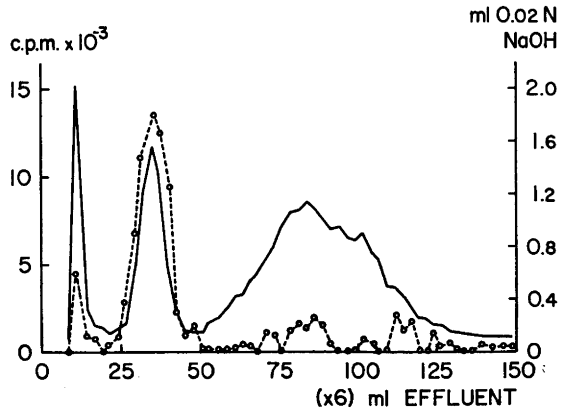

Fig. 4. Chromatogram of unhydrolyzed bile from pig injected i. p. with tritium-labelled hyocholic acid 24 h before sacrifice. Phase system C. 27 g hostalene. Solid line: titration. Broken line: c.p.m.

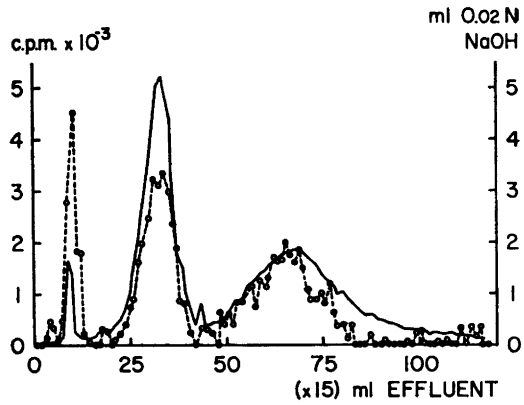

Fig. 5. Chromatogram of unhydrolyzed bile from pig injected i. p. with tritium-labelled hyocholic acid 72 h before collection of bile. Phase system C. 67 g hostalene. Solid line: titration. Broken line: c.p.m.

Injection of 24-^{14}C-chenodeoxycholic acid. Fig. 1. shows a chromatogram of a sample of unhydrolyzed fistula bile from an animal, where the fistula was prepared 2 days prior to the injection of 6×10^6 c.p.m. 24-^{14}C-chenodeoxycholic acid (approx. 40 μC, 2 mg). The radioactivity was found to be distributed in all three titration peaks. 5 % of the radioactivity was retained in the stationary phase and consisted of unchanged chenodeoxycholic acid. More than 90 % of the radioactivity of the first peak was present as taurochenodeoxycholic acid. After hydrolysis and rechromatography on phase system F, this material was diluted with carrier chenodeoxycholic acid, and the specific activity remained constant through four crystallizations. The second radioactive peak was shown to be glycohyocholic acid by rechromatography after saponification on phase system C and crystallization with unlabelled material. The radioactive compound appearing in the third titration peak was in a similar manner shown to be glycochenodeoxycholic acid.

Injection of 24-^{14}C-hyodeoxycholic acid. In Fig. 3 is shown a chromatogram of the unhydrolyzed bile acids from an animal, that had been injected with 9×10^6 c.p.m. 24-^{14}C-hyodeoxycholic acid (3 mg) four days after the preparation of the bile fistula. The radioactivity in the first peak was identified by rechromatography as taurohyodeoxycholic acid. After additional chromatography as the free acid, it was crystallized four times with unlabelled hyodeoxycholic acid, the specific activity remaining constant. The second radioactive elution band was found to be glycohyodeoxycholic acid, the identity of which was confirmed by cocrystallization with authentic hyodeoxycholic acid. 12 % of the radioactivity was retained in the column and consisted of unchanged free hyodeoxycholic acid.

Injection of tritium-labelled hyocholic acid. Two animals were injected each with 1×10^7 c.p.m. hyocholic acid (2 mg). One animal was sacrificed 24 h later and the bile was collected from the gall-bladder. In the other animal a bile fistula was prepared 72 h after the injection and bile was collected for a

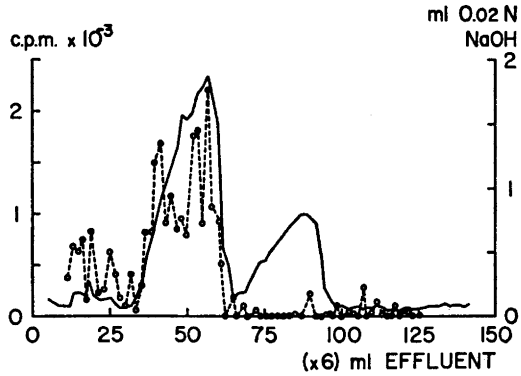

Fig. 6. Rechromatography of dihydroxycholanic acid band (*cf.* fig. 5) after hydrolysis. Phase system F. 27 g hydrophobic Hyflo Supercel. Solid line: titration. Broken line: c.p.m.

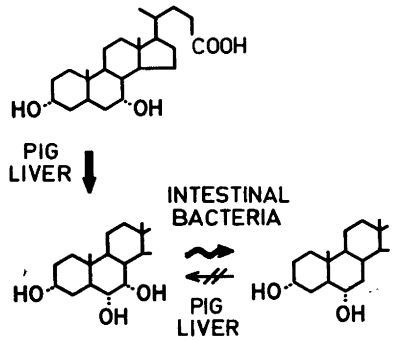
few hours. In Fig. 4 is shown a chromatogram of the non-saponified bile from the former animal, where the labelled hyocholic acid had been present in the entero-hepatic circulation of the bile for a maximum period of 24 h. The injected acid had been conjugated with glycine (second radioactive peak), and to a lesser degree with taurine (first peak). Small amounts of labelled material were found in the glycodihydroxycholanic acid band.

In the chromatogram (Fig. 5) of unhydrolyzed bile from the second animal, that had an intact entero-hepatic circulation for 72 h after the injection of the labelled hyocholic acid, it is seen, that almost half of the radioactivity is present in a band corresponding to a glycine conjugated dihydroxycholanic acid. This material was subsequently saponified and rerun with phase system F (Fig. 6). The radioactivity was found to coincide with the titration peak of hyodeoxycholic acid. The identity of the above-mentioned radioactive compounds was confirmed by cocrystallization with unlabelled material, where the specific activity remained constant through four recrystallizations.

DISCUSSION

The results obtained can be summarized in the following scheme:



The observation that hyodeoxycholic acid was present only in the first portions of the fistula bile but later disappeared, indicated that this acid might be a secondary acid not produced by the liver cells. This was further strengthened by the results with labelled bile acids, that showed that chenodeoxycholic acid was a precursor of hyocholic acid, whereas hyodeoxycholic acid remained unchanged except for its conjugation when injected intraperitoneally into pigs with a functioning bile fistula.

It was established that hyodeoxycholic acid indeed was a secondary product when labelled hyocholic acid was injected into intact pigs. After 24 h some labelled hyodeoxycholic acid had been formed, and after three days about half of the activity was present in the hyodeoxycholic acid formed by elimination of the 7α-hydroxyl group from hyocholic acid.

These results are thus in certain respects very similar to the bile acid metabolism in man [13] and rabbit [14]. In the latter cases intestinal microorganisms eliminate the 7α-hydroxyl from cholic acid resulting in the formation of deoxycholic acid, and in both instances deoxycholic acid — normally present in gallbladder bile of man and rabbit — disappears from the fistula bile, when the bile acids present in the enterohepatic circulation have been excreted.

In the rat the situation is also similar in that deoxycholic acid is formed from cholic acid in the intestine [15,16], but in this case the deoxycholic acid formed is rehydroxylated at position 7α to cholic acid in the liver [17].

In all these cases the intestinal microorganisms thus eliminate a 7α hydroxyl irrespective of whether the other hydroxyls are in position 3α and 12α or 3α and 6α.

A common feature in each of these cases, the rabbit excluded, is that chenodeoxycholic acid occurs in the primary bile, *i. e.* 3α and 7α hydroxyls are present. In most animals the third hydroxyl is then at position 12α, but in the pig it is at 6α, as is apparent from the reviews published by Haslewood [18,19]. There are some exceptions, for example the seals which are reported to have the third hydroxyl at C_{23} (β-phocaecholic acid, 3α, 7α, 23-trihydroxycholanic acid) [20]. Among the animals with trihydroxylated C_{24}-bile acids the only species known to have bile acids unsubstituted at C_7 are the Python and Constrictor snakes. They have pythocholic acid (3α, 12α, 16-trihydroxycholanic acid) as their main bile acid [21]. In these cases the primary bile acids are not known, but considering the long duration of the entero-hepatic circulation in these animals, there appears to be unusually favorable conditions for secondary changes by the intestinal microorganisms, possibly followed by further changes by the liver enzymes.

Earlier work has indicated, that at least some of the changes on the ring system of cholesterol take place before the side chain is degraded. Furthermore, Lindstedt [22] has found that 7α-hydroxycholesterol is transformed rapidly into cholic acid in the rat. It therefore appears possible, that the 7α-hydroxylation of cholesterol is a common and early step in the degradation of cholesterol to bile acids in most higher animals. Further work is needed to clarify the details of these reactions and their possible rôle as rate limiting steps in the degradation of cholesterol to bile acids.

The Kinetics of Crystal Growth in Barium Sulfate Precipitation

II. Temperature Dependence and Mechanism *

ARNE E. NIELSEN

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

The chronometric integrals (chronomals) for precipitation processes with time-independent particle number concentrations are solved, and a table of their numerical values is calculated.

The diffusion coefficient of $BaSO_4$ and the fourth order rate constant of crystal growth in $BaSO_4$ precipitation are determined from experiments at a range of temperatures between 0 and 70°C.

The dissociation of 2–2 electrolytes in aqueous solution is discussed with special regard to $BaSO_4$.

A number of formally possible rate-determining mechanisms are discussed and four of them found to be in agreement with the experiments.

The results are compared with the Volmer-Becker-Döring and the Frank-Cabrera-Burton theories of crystal growth and are found to be in agreement with the former, but not the latter of these, *i. e.* the rate is governed by the formation of surface nuclei requiring a supersaturation ratio of about 10 or more in order to proceed at appreciable speed.

I. THEORETICAL PART; PRECIPITATION CHRONOMALS

1. Introduction. During the precipitation from a supersaturated solution the number of particles may either be constant or change with time. Here we shall only discuss cases where the number of particles is constant [1–10]. It follows that provided the solution is properly stirred the particles will grow with the same rate and be equally large. This has been observed with many sparingly soluble salts.

We shall first derive kinetic equations for precipitation, stating explicitely the constants of proportionality in terms of quantities such as the number of particles, the initial concentrations and the molar volume of the precipitating matter, and fundamental rate-constants. Then we will discuss how these quantities may be obtained from experiment and from theory.

* Part I. of this work, Ref.[1].

These methods will then be applied to the data from experiments on barium sulfate. Several mechanisms are suggested and compared to the experimental results. At last the results of this investigation will be compared to the accepted theories of crystal growth.

2. Derivation of the kinetic equations. If the rate of particle growth during precipitation from a supersaturated solution is controlled by the diffusion from the bulk of the solution to the surface of the particles we have [1,5,6,11].

$$\mathrm{d}r/\mathrm{d}t = vD(\mathrm{d}c/\mathrm{d}\varrho)_{\varrho=r}$$

where r is the radius of the particle or, if it is not a sphere, of a sphere of approximately the same volume as the particle, t the time, v the molar volume of the material, D the diffusion coefficient, c the concentration in mole/cm^3, and ϱ the distance from the center of the particle. Smoluchowski [12] showed that

$$(\mathrm{d}c/\mathrm{d}\varrho)_{\varrho=r} = (c-s)\,/\,r$$

where s is the solubility of the material. If we introduce the degree of reaction α by means of

$$1-\alpha = (c-s)\,/\,(c_0-s)$$

where c_0 is the concentration at $t = 0$, we may write

$$\mathrm{d}r/\mathrm{d}t = vD(c-s)\,/\,r = vD(c_0-s)\;(1-\alpha)\,/\,r$$

Since now

$$r = r_\infty \cdot \alpha^{1/3}$$

where r_∞ is r at $t = \infty$, we have

$$\begin{aligned}
&(\mathrm{d}r/\mathrm{d}t =)\\
&(1/3)r_\infty\alpha^{-2/3}\mathrm{d}\alpha/\mathrm{d}t = vD(c_0-s)\;(1-\alpha)/r_\infty\alpha^{1/3}\\
&\mathrm{d}\alpha/\mathrm{d}t = 3vD(c_0-s)\alpha^{1/3}\;(1-\alpha)/r_\infty^2\\
&\therefore t = r_\infty^2 I_\mathrm{D}/3v(c_0-s)
\end{aligned}$$

where

$$I_\mathrm{D} \equiv \int_0^\alpha \alpha^{-1/3}(1-\alpha)^{-1}\mathrm{d}\alpha$$

If the rate of growth is controlled by a reaction of the order p in the surface of the particle [13–15], with the rate constant k_p (mole/cm^2 · s) (mole/cm^3)$^{-p}$

$$\mathrm{d}r\,/\,\mathrm{d}t = vk_pc^p$$

We then have (when $c \gg s$)

$$\begin{aligned}
&(\mathrm{d}r/\mathrm{d}t =)\;(1/3)r_\infty\alpha^{-2/3}\mathrm{d}\alpha/\mathrm{d}t = vk_pc_0^p(1-\alpha)^p\\
&\therefore t = r_\infty I_p/3vk_pc_0^p
\end{aligned}$$

where

$$I_p \equiv \int_0^\alpha \alpha^{-2/3}(1-\alpha)^{-p}\mathrm{d}\alpha$$

Frisch and Collins [11] solved the problem of mixed diffusion and first order surface reaction. In our terminology the solution may be obtained thus: let the concentration be c' at the surface of the crystal; then

$$\mathrm{d}r/\mathrm{d}t = (1/3)r_\infty\alpha^{-2/3}\mathrm{d}\alpha/\mathrm{d}t = vD(c_0(1-\alpha)-c')/r_\infty\alpha^{1/3} = vk_pc'^p$$

By elimination of c' one gets, for all values of p

$$\frac{d\alpha}{dt} = 3vk_p r_\infty^{-1}\alpha^{1/3}\left[c_0(1-\alpha) - \frac{r_\infty^2}{3vD\alpha^{1/3}}\cdot\frac{d\alpha}{dt}\right]^p$$

For $p = 1$ this can be reduced to

$$\frac{dt}{d\alpha} = \frac{r_\infty^2}{3vDc_0(1-\alpha)\alpha^{1/3}} + \frac{r_\infty}{3vk_1c_0(1-\alpha)\alpha^{1/3}}$$

with the solution

$$t = \frac{r_\infty^2 I_D}{3vDc_0} + \frac{r_\infty I_1}{3vk_1c_0}$$

which is the sum of the solutions to the "pure" problems. For $p \neq 1$ the solution is not simply the sum of the corresponding expressions.

Sometimes it is convenient to use the length l of the edge in a cube of the same volume as the particle rather than r. In case of diffusional rate control it is reasonable to substitute r_∞ by means of

$$(4/3)\pi r^3 = l^3$$

giving

$$t = l_\infty^2 I_D \,/\, \sqrt[3]{48\pi^2}\; vD(c_0-s)$$

In case of a surface reaction we may use

$$dl/dt = 2vk_p c^p$$
$$l = l_\infty \alpha^{1/3}$$

from which follows

$$(dl/dt =)\ (1/3)l_\infty \alpha^{-1/3} d\alpha/dt = 2vk_p c_0^p (1-\alpha)^p$$
$$d\alpha/dt = 6vk_p l^{-1} c_0^p \alpha^{1/3}(1-\alpha)^p$$

and

$$t = l_\infty I_p / 6vk_p c_0^p$$

If the number of particles N per unit volume is known in stead of r_∞ or l_∞ we may use

$$l_\infty^3 = v(c_0-s) \,/\, N$$

and obtain

$$t = I_D \,/\, D\sqrt[3]{48\pi^2 v(c_0-s)N^2}$$

and, respectively (for $c \gg s$)

$$t = I_p \,/\, 6v^{1/3}k_p c_0^{p-1/3}N^{1/3}$$

These two formulae are only exact for spheres and cubes, respectively, but may be applied without serious errors to particles of highly compact shape. In case of thin plates, needles or "star-like" crystals as are often met with in electrolyte precipitation experiments the formulae can be expected to give only the right order of magnitude.

3. Formulae, numerical values. The integrals I_D and I_p have been calculated by numerical integration [5,8]. I_D was expressed by analytic functions by LaMer and Dinegar [6]. The mixed case of I_D and I_1 was similarly solved by Frisch and Collins [11]. Formulae for I_D and I_p (with any positive integer p) may be found by substituting a new variable for $\alpha^{1/3}$, decomposing, and using standard methods of integration. We introduce for brevity the two functions of α

$$L = \ln \frac{\sqrt{1 + \alpha^{1/3} + \alpha^{2/3}}}{1-\alpha^{1/3}} = \tfrac{1}{2} \ln \frac{1-\alpha}{(1-\alpha^{1/3})^3}$$

$$T = \sqrt{3} \operatorname{arctg} \frac{\sqrt{3}}{1 + 2\alpha^{-1/3}}$$

(arctg is the inverse tangent, sometimes denoted $\tan^{-1}$). The integrals can then be written

$$I_D = L - T$$

$$I_1 = L + T$$

$$I_2 = \frac{\alpha^{1/3}}{1-\alpha} + \frac{2}{3} I_1$$

$$I_3 = \frac{\alpha^{1/3}(8-5\alpha)}{6(1-\alpha)^2} + \frac{5}{9} I_1$$

$$I_4 = \frac{\alpha^{1/3}(41-52\alpha + 20\alpha^2)}{27(1-\alpha)^3} + \frac{40}{81} I_1$$

$$I_5 = \frac{\alpha^{1/3}(532-1\,023\alpha + 792\alpha^2-220\alpha^3)}{324(1-\alpha)^4} + \frac{110}{243} I_1$$

$$I_6 = \frac{\alpha^{1/3}(4\,210-10\,885\alpha + 12\,705\alpha^2-7\,084\alpha^3 + 1540\alpha^4)}{2\,430(1-\alpha)^5} + \frac{308}{729} I_1$$

Numerical values of I_D, I_1, I_2, I_3 and I_4 are given in Table 1. L and T may be found from the table by using

$$L = (I_1 + I_D)/2$$
$$T = (I_1 - I_D)/2$$

The coefficients in the general expression for I_p,

$$I_p = \frac{a_{p,1}\alpha^{1/3} + a_{p,2}\alpha^{1+1/3} + \ldots + a_{p,p-1}\alpha^{p-2+1/3}}{(1-\alpha)^{p-1}} + b_p I_1$$

can be found by solving the linear equations

$$\tfrac{1}{3} a_{p,1} = 1 - b_p$$

$$(i-\tfrac{2}{3})a_{p,i} + (p-i+\tfrac{2}{3})a_{p,i-1} = (-1)^i \binom{p-1}{i-1} b_p, \quad i = 2,3 \ldots p-1$$

$$\tfrac{2}{3} a_{p,p-1} = (-1)^p b_p$$

where

$$\binom{p-1}{i-1} = \frac{(p-1) \ldots (p-i+1)}{2 \cdot 3 \ldots (i-1)}$$

0.999	7.64846	9.46189	1 005.97	500 672	333 667 227

The first and the last equation are *not* obtained by letting $i = 1$ and $i = p$ in the formula given for $i = 2, 3, \ldots p-1$.

It is easily proved that for $p > 1$

$$\sum_{i=1}^{p-1} a_{p,i} = \frac{1}{p-1}$$

which constitutes a check on the numerical calculations.

4. The evaluation of kinetic constants. The best method of treating the data is probably to plot I_D or I_p as a function of the (through a) corresponding experimental time [8]. If the measurements are in accordance with the assump-

tions behind the '*I*' chosen a straight line through origo is obtained. In some cases the reaction is diffusion controlled in the beginning and becomes, *e. g.*, fourth order later on. Then a curved curve is obtained which gradually straightens and eventually approaches an asymptote of well defined slope. Both when the whole curve and when only a part of it is a straight line the diffusion coefficient or the rate constant may be calculated by means of the following equations.

$$\begin{aligned} D &= (\mathrm{d}I_D/\mathrm{d}t)l_\infty^2 \,/\, (48\pi^2)^{1/3} v(c_o - s) \\ &= (\mathrm{d}I_D/\mathrm{d}t) \,/\, (48\pi^2 v(c_o - s)\, N^2)^{1/3} \\ &= (\mathrm{d}I_D/\mathrm{d}t) \,/\, 7.795(v(c_o - s)N^2)^{1/3} \\ k_p &= (\mathrm{d}I_p/\mathrm{d}t)l_\infty \,/\, 6vc_o^p \\ &= (\mathrm{d}I_p/\mathrm{d}t) \,/\, 6v^{1/3}c_o^{p-1/3}N^{1/3} \end{aligned}$$

l_∞ may be found by measuring the particles under microscope. In the experiments reported below N was found by counting at least 100 particles on a blood cell counting chamber under microscope. Another possible procedure would be to determine the sedimentation velocity according to Odén [16] or Andreasen [17]. In a certain range of sizes the turbidity may be taken proportional to the surface [18], which would also give the required information if the constant of proportionality is known. It is safest, however, in all cases to examine the particles under microscope in order to be sure whether they are compact enough to justify the assumptions made in deriving the formulae.

II. EXPERIMENTAL PART. THE DIFFUSION COEFFICIENT AND THE RATE CONSTANT FOR $BaSO_4$

1. Introduction. Previously it was found [1] that at 22°C the rate of growth of $BaSO_4$ may be expressed by

$$\mathrm{d}l \,/\, \mathrm{d}t = 630\ c^4\ \mathrm{m}\mu/\mathrm{s} \text{ for } c < 0.3\ \mathrm{mM}$$

where l is the length of the edge in a cube of the same volume as the crystal. Dividing by twice the molar volume we get the rate of depositing matter on a unit of surface. Transforming into c-g-s-units we have

$$k_4 = 6.3 \times 10^{19} \,/\, 2 \times 51.9 = 6.1 \times 10^{17}\ (\mathrm{mole/cm^2 s})\ (\mathrm{cm^3/mole})^4$$

In Table 2 are shown some new and probably more accurate data for a range of temperatures. It was determined to use $c_o = 0.5$ mM because this gave the rates that could be measured best with the apparatus. With this c_o the rate is diffusion controlled in the first part and "surface-reaction"-controlled in the latest part of the experiment. Both D and k_4 can therefore be determined from the same run.

2. Experimental. The reacting aqueous solutions, 40 ml 1.00 mM $BaCl_2$ and 40 ml 1.00 mM Na_2SO_4 *(pro analysi)* were placed in an apparatus shown in Fig. 1, equilibrated in a thermostated water bath, and mixed by pressing the rubber ball. The electric conductance was measured as a function of time. The first reading was obtained 5 s after the moment of mixing. From measurements on solutions having the compositions of the reacting mixture at the degree of reaction a equal to 0.5 and 1.0, together with the value

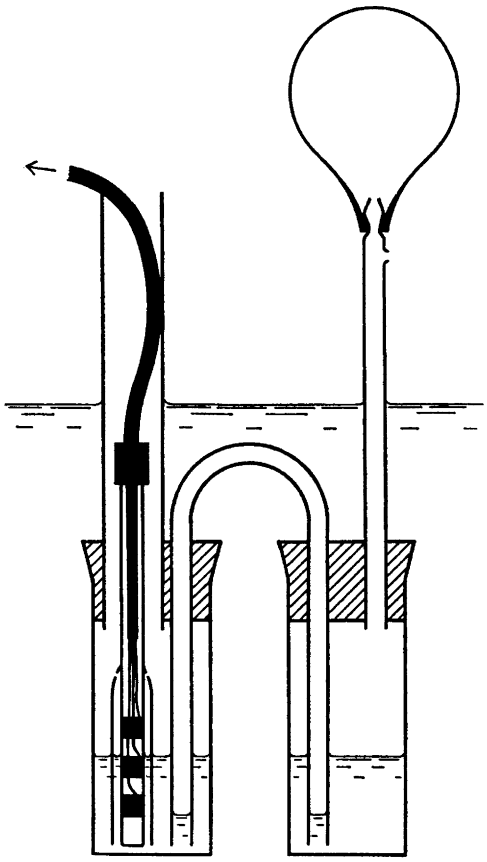

Fig. 1. The apparatus. The solutions were mixed by pressing the rubber ball. The arrow indicates the connection from the conductivity cell to the conductivity meter.

at $a = 0$ obtained in the kinetic experiment, a calibration curve was constructed for converting the electric conductance into a. The calibration curve was almost linear. The solution was frequently stirred by transferring it from one to the other of the two glasses. Afterwards a sample was placed on a counting plate and at least 100 particles were counted under microscope.

3. *Numerical treatment.* D was calculated by means of

$$\begin{aligned} D &= (\mathrm{d}I_\mathrm{D}/\mathrm{d}t) \,/\, (48\pi^2 v(c_\mathrm{o}\text{—}s)N^2)^{1/3} \\ &= (\mathrm{d}I_\mathrm{D}/\mathrm{d}t) \,/\, 7.795(vc_\mathrm{o}N^2)^{1/3} \\ &= (\mathrm{d}I_\mathrm{D}/\mathrm{d}t) \,/\, 0.231\ N^{1/3} \end{aligned}$$

For $\mathrm{d}I_\mathrm{D}/\mathrm{d}t$ was used the initial slope on a graph of I_D *versus* t. See Fig. 2 and Table 3.

k_4 was calculated by means of

$$\begin{aligned} k_4 &= (\mathrm{d}I_4/\mathrm{d}t) \,/\, 6v^{1/3}c_\mathrm{o}^{4-1/3}N^{1/3} \\ &= (\mathrm{d}I_4/\mathrm{d}t) \,/\, 6.58 \times 10^{-22}N^{1/3} \end{aligned}$$

Table 2. Time in seconds (interpolated) as a function of a, from experiments with $c_0 = 0.5$ mM, at different temperatures.

0.80		430	560	420	360	125

where dI_4/dt was found graphically on a plot of I_4 *versus* t, using the straight-line part of the curve for large t. See Fig. 2 and Table 3.

4. Results. In Fig. 3 $\log D$ is plotted as a function of $1/T$. From the slope $d\log D/d(1/T) = -1\,080$ one finds the heat of activation for the diffusion process $\Delta H_D^{\ddagger} = 5\,000 \pm 500$ cal/mole[‡]. In the same figure is also plotted the logarithm of the fluidity of pure water. It is seen that the heat of activation of diffusion is a little greater than that of the fluidity. This is what one would expect, because of the hydration of the ions.

Fig. 3 also shows $\log k_4$ against $1/T$. $-d\log k_4/d(1/T) = 1\,100$ which corresponds to the apparent heat of activation

$$\Delta H_A = 5\,000 \pm 500 \text{ cal/mole.}$$

A ten degree rise in temperature increases k_4 about one-third.

This may be compared to the value for crystal growth in magnesium oxalate precipitation obtained by Lichstein and Brescia [19], $\Delta H_A = 3$ kcal/mole, although they used a different theory [20] involving a first order constant.

Table 3. D and k_4, from N and data in Table 2 (see Fig. 2).

t °C	N $10^6 cm^{-3}$	dI_D/dt s^{-1}	dI_4/dt s^{-1}	D $10^{-6} cm^2/s$	k_4 $10^{18} cm^{10}/s \cdot mole^3$
0	1.81	0.0070	0.051	2.04	0.69
25	3.38	0.0157	0.160	3.02	1.68

70	2.76	0.050	0.544	11.0	5.88

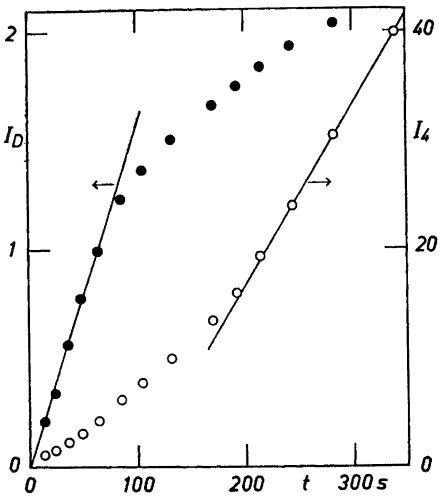

Fig. 2. I_D and I_4 as function of the experimentally determined times at 25°C. From the slope of the straight-line parts of the curves the diffusion coefficient and the fourth-order velocity constant were determined.

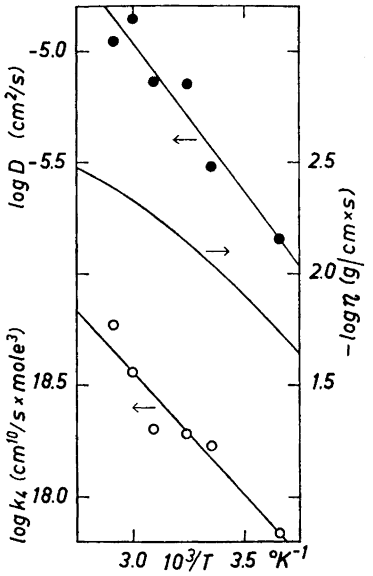

Fig. 3. Diagram for determination of the apparent heat of activation for diffusion of $BaSO_4$ and for the surface reaction of $BaSO_4$ crystal growth. In the middle is plotted for comparison the logarithm of the fluidity ($1/\eta$) of pure water.

III. THE DISSOCIATION OF 2—2 ELECTROLYTES

Before discussing these results we will consider the composition of the system. It is generally recognized that 2—2 electrolytes are only partly dissociated in aqueous solution [21,22]. For sulfates of bivalent metals we define

$$K_1 = (M^{++})\ (SO_4^{--})\ /\ (MSO_4)$$
$$K_2 = (MSO_4)\ (SO_4^{--})\ /\ (M(SO_4)_2^{--})$$
$$K_3 = (M^{++})\ (M(SO_4)_2^{--})\ /\ ((MSO_4)_2)$$
$$K_4 = (M^{++})^2(SO_4^{--})^2\ /\ ((MSO_4)_2) = K_1K_2K_3$$

The interpretation of experimental data from activity-, conductance- or cryoscopic measurements on dilute solutions for finding the K's is very uncertain, since the effects of the interionic forces masks the effects of the incomplete dissociation, and only approximate values of K_1 have been obtained this way.

The difficulty has however been solved by Kenttämaa [23] who measured the freezing point depression of $CuSO_4$, $ZnSO_4$, $NiSO_4$ and $MgSO_4$ in eutectic (cryohydratic) mixtures of water and a salt; the salts used were KNO_3, $KClO_3$ and $KClO_4$. Because of the presence of electrolytes in a roughly constant concentration even in the "pure solvent" the depressions may be extrapolated to infinite dilution of the 'MSO_4' in question without taking the interionic forces

into account. From the law of mass action it follows that if m_s denotes the stoichiometric concentration of the added electrolyte and Σm_i the sum of the concentrations of all the ions and molecules that are not common with those arising from the saturating electrolyte, the function $\bar{\varphi}$ defined by

$$\bar{\varphi} = (2m_s - \Sigma m_i) / (\Sigma m_i - m_s)^2$$

satisfies

$$\bar{\varphi} = 1/K_1 + \Sigma m_i / K_1 K_2$$

Σm_i and thereby also $\bar{\varphi}$ are found from the freezing point depressions.

From a plot of $\bar{\varphi}$ *versus* Σm_i K_1 and K_2 may be obtained. K_1 is strongly dependent on the ionic strength I, whereas K_2 may be regarded — in a first approximation — as independent of the salt concentration. Kenttämaa did not give K_2 explicitely, but it is easily found from the reported values of the coefficient in the linear expression for $\bar{\varphi}$.

All values of K_2 lie between 0.1 and 0.25, most of them close to 0.15 M. At $I = 0$, pK_1 ranges between 2.186 and 2.294 for the four sulfates of bivalent metals investigated by Kenttämaa. In our experiments on $BaSO_4$ precipitation $I = 0.002$ in the part of the experiment which is used for determination of k_4. At $I \cong 0.002$ the correction to pK_1 is about —0.16; we may take $pK_1 = 2.1$, $K_1 = 0.008$ mole/l as a representative value.

Since the dissociation constants seem to be the same for all sulfates of bivalent metals, we may apply them to $BaSO_4$ as well.

This conclusion may seem a little too risky. Since $BaSO_4$ is only 10^{-5} as soluble as the sulfates on which K_1 and K_2 were measured one would perhaps expect it to be appreciably less dissociated. This is however not the case. The calibration curves mentioned in the experimental part of this article turned out to be very near to straight lines. Actually the conductivity at $\alpha = 0.5$ was higher than the arithmetic mean of the conductivities at $\alpha = 0$ and $\alpha = 1$ by about 2.5 % of the total change, *i. e.*

$$e \equiv (\varkappa_{0.5} - (\varkappa_0 + \varkappa_1) / 2) / (\varkappa_0 - \varkappa_1) = 0.025$$

The curvature is due partly to interionic forces and partly to the incompleteness of the dissociation

$$BaSO_4 = Ba^{++} + SO_4^{--}$$

with the dissociation constant

$$K_1 = (Ba^{++})\ (SO_4^{--}) / (BaSO_4) = c\delta^2 / (1-\delta) = c_0\ (1-\alpha)\delta^2 / (1-\delta)$$

where δ is the degree of dissociation. If we neglect for the moment the interionic forces but not the incompleteness of the dissociation we get

$$\begin{aligned}
\varkappa_\alpha &= \Lambda^\circ_{BaSO_4} c_0 (1-\alpha)\delta + \varkappa_1 \\
e &\equiv (\delta_{0.5} - \delta_0) / 2\delta_0 \\
\delta_{0.5}/\delta_0 &= q \equiv 1 + 2e \\
K_1 / c_0 &= \delta_0^2 / (1-\delta_0) = 0.5\delta_{0.5}^2 / (1-\delta_{0.5}) \\
&= q^2\delta_0^2 / 2(1-q\delta_0) \\
\delta_0 &= (2-q^2) / (2q-q^2) \\
K_1 &= c_0(2-q^2)^2 / (2q-q^2)\ (2q-2) \\
&= c_0(1-4e-4e^2)^2 / (1-4e^2)4e \\
&\cong c_0(1/4e-2) = 0.0005 \times 8 = 0.004 \text{ mole/l}
\end{aligned}$$

Since the interionic forces also tend to diminish the electric conductivity and thus contribute positively to e, the value found for K_1 is a minimum value; we therefore only know that for $BaSO_4$

$$K_1 > 0.004 \text{ mole/l}$$

but this is entirely in agreement with the assumption that K_1 has the same value for $BaSO_4$ as for the highly soluble sulfates of bivalent metals, *i. e.* $K_1 = 0.008$ mole/l. It is less certain to put $K_2 = 0.15$ for $BaSO_4$ because it is that much in case of the highly soluble sulfates, but there is no reason to assume it is wrong by more than, *e. g.*, a factor of ten. K_3 is entirely unattainable from Kenttämaas experiments since the function $\bar{\varphi}$ was found to depend lineary on Σm_i. If we assume that the experimental uncertainty allows for a maximum concentration of $(MSO_4)_2$ equal to $M(SO_4)_2^{--}$ at the highest concentration of MSO_4 used, we find from the mass action law

$$K_3 = (M^{++})(M(SO_4)_2^{--}) / ((MSO_4)_2) > (M^{++}) = 0.2 \text{ mole/l}$$

For $BaSO_4$ of course K_3 may be less. For the highly soluble sulfates we have now

$$K_4 = K_1K_2K_3 > 0.008 \times 0.15 \times 0.2 = 2 \times 10^{-4}M^3 = 2 \times 10^{-13} \text{ mole}^3/\text{cm}^9$$

IV. THE RATE-DETERMINING MECHANISM IN $BaSO_4$ CRYSTAL GROWTH

Since the activation energy of the fourth order crystallization reaction is nearly the same as the activation energies of $BaSO_4$ diffusion and of viscous flow of pure water, the rate-determining step is a reaction in which almost any close approach between two molecules of the reactants leads to reaction.

If the collision number of the reactants — when supposed not to react — is Z collisions per unit of volume (or surface) and time, calculated from simple gas theory, we may write the rate of the reaction

$$J = Z\exp(-\Delta G^{\neq}/RT)$$

where $\Delta G^{\neq}$ is the standard activation free energy change, and $\exp(-\Delta G^{\neq}/RT)$ is the ratio between the number of collisions leading to reaction and the number of collisions between the reactant molecules if no reaction took place.

In a liquid two molecules subject to an encounter have a rather large probability of repetitive encounters, performing some sort of oscillations, before a third molecule comes in between. If a reaction of activation free energy less than the activation free energy of diffusion can occur between the two colliding molecules, it is almost certain that it will happen rather than the two molecules depart. Therefore the free energy of activation of the reaction shall be replaced by the free energy of activation for diffusion, and the temperature dependence of the velocity is determined entirely by the enthalpy of activation for diffusion, and the change of Z with temperature. If we neglect any entropy change of activation for diffusion we have

$$J = Z\exp(-\Delta H^{\neq}/RT)$$

where empirically $\Delta H^{\neq} \cong 5\,000$ cal/mole$^{\neq}$ if Z is not strongly temperature dependent; $\exp(-\Delta H^{\neq}/RT) = 10^{-4}$ at 0°C.

We will now discuss the following types of possible rate determining mechanisms.

(i) transport of matter from the solution to the crystal.
(ii) collision between molecules (or ions) from the solution and adsorbed molecules (ions).
(iii) triple collisions between two molecules (ions) and the crystal.
(iv) collision between adsorbed molecules.

Above $c = ca.\ 4 \times 10^{-7}$ mole/cm^3 (= 0.4 mM) the rate determining mechanism has already been shown [1] to be the diffusion of $BaSO_4$ — mostly as ions — from the bulk of the solution to the surface. In the following we are going to discuss $c < 4 \times 10^{-7}$ mole/cm^3. As an example we will estimate the concentrations in a 0.1 mM = 10^{-7} mole/cm^3 solution of $BaSO_4$. (The solubility is *ca.* 10^{-8} mole/cm^3 at 25°C and *ca.* 8×10^{-9} at 0°C; see Seidell [24] for references.)

If we assume the following orders of magnitude (at 0°C):

$$K_1 = 10^{-5},\ K_2 = 10^{-4},\ K_3 = 10^{-4} \text{ mole/cm}^3$$

and, consequently $K_4 = 10^{-13}$ (mole/cm^3)^3 we find for $c = 10^{-7}$ mole/cm^3 the following concentrations:

$$(Ba^{++}) = (SO_4^{--}) = c = 10^{-7},\ (BaSO_4) = 10^{-9},$$
$$(Ba(SO_4)_2^{--}) = 10^{-12} \text{ and } ((BaSO_4)_2) = 10^{-15} \text{ mole/cm}^3.$$

At this concentration we found experimentally $J = k_4 c^4 = 7 \times 10^{-11}$ mole/cm^{2}s.

If the rate is determined by the frequency of collisions between the crystal and molecules of concentration C and molecular weight M (~200 g/mole) the reaction rate per cm^2 is

$$J = C\sqrt{RT/\pi M}\ \exp(-\Delta H^{\neq}/RT) = 0.6 \times C$$

It follows that if this mechanism shall be rate determining

$$C = 7 \times 10^{-11}/0.6 = 10^{-10} \text{ mole/cm}^3$$

Since $((BaSO_4)_2)$ is only 10^{-15} mole/cm^3 it can not be the diffusion of $(BaSO_4)_2$ that is rate determining. It may however be the diffusion of $BaSO_4$-molecules. In order to get the right order (4) of the reaction only collisions with another $BaSO_4$-molecule at the surface may lead to growth. If one-tenth of the surface is covered by adsorbed $BaSO_4$-molecules in adsorption equilibrium with the ionic contents of the solution at $c = 10^{-7}$ mole/cm^3, the observed rate is obtained by this mechanism. Since the molar volume of $BaSO_4$ is 52 cm^3 this corresponds to a concentration of 1/520 mole/cm^3; which is $1/(520 \times 10^{-9}) = 2 \times 10^6$ times as high as in the solution. Another possible mechanism of the same sort is the reaction between a colliding Ba^{++} ion and an adsorbed $Ba(SO_4)_2^{--}$ ion; only $10^{-10}/10^{-7} = 10^{-3}$ of the surface needs be covered by the reactive ionic species. Since the atoms of the (probably) linear $^-SO_4BaSO_4^-$ shall rearrange rather appreciably forming the (probably) square $(BaSO_4)_2$, there must be a rather low entropy of activation so that much more than 10^{-3}

of the surface must be covered, and the concentration at the surface must be more than about $(1/100) \times 10^{-3}/10^{-12} = 10^7$ times the concentration in the solution.

Triple collisions are difficult to define in a generally acceptable way. If we however count any encounter between two molecules or ions closer than a distance λ from the surface of the crystal as a triple collision, we may find the required λ by comparison with the experiment. The encounter may either occur between two $BaSO_4$ molecules or between a Ba^{++} and a $Ba(SO_4)_2^{--}$-ion. We have, respectively, the (simple gas theory) collision numbers

$$Z_{11} = 2n^2d^2\sqrt{\pi RT/M}$$

and

$$Z_{12} = n_1n_2d_{12}^2\sqrt{8\pi RT/\mu_{12}}$$

where

$$d_{12} = (d_1 + d_2)/2, \quad \mu_{12} = M_1M_2 / (M_1 + M_2)$$

With $M = 200$, $\mu = 100$, $d = d_{12} = 5$ Å $= 5 \times 10^{-8}$ cm we find at 0°C

$$Z_{11} = C^2 \times 5 \times 10^{13}$$
$$Z_{12} = C_1C_2 \times 10^{14} \text{ mole/cm}^2\text{s}$$

where C, C_1 and C_2 are measured in mole/cm^3. At $c = 10^{-7}$, $J_{exp} = 7 \times 10^{-11}$ mole/cm^{2}s; but

$$J = \lambda \times Z_{11} \times \exp(-\Delta H^{\neq}/RT)$$
$$= \lambda \times C^2 \times 5 \times 10^{13} \times 10^{-4} \text{ or } = \lambda \times C_1C_2 \times 10^{14} \times 10^{-4}$$

With $C = (BaSO_4) = 10^{-9}$ we find

$$\lambda = 7 \times 10^{-11}/5 \times 10^{-9} = 0.01 \text{ cm}$$

With $C_1 = (Ba^{++}) = 10^{-7}$, $C_2 = (Ba(SO_4)_2^{--}) = 10^{-12}$ we find

$$\lambda = 7 \times 10^{-11}/10^{-9} = 0.1 \text{ cm}$$

None of these mechanisms can therefore give the observed rate with a reasonable value of λ (which must, of course, be of molecular dimensions, *i. e.* $\lambda \sim 1$ Å).

In a two dimensional gas

$$Z_{11} = n^2d\sqrt{\pi RT/M}$$
$$Z_{12} = n_1n_2d_{12}\sqrt{2\pi RT/\mu}$$

where Z_{11} and Z_{12} are the numbers of collisions per cm^2 and s, between similar and different molecules, respectively, and n, n_1, n_2 are the surface concentrations in molecules per cm^2, other symbols having the same meaning as in the case of a three-dimensional gas. With $d = 5 \times 10^{-8}$ cm, $M = 200$, $\mu = 100$ we have

$$Z_{11} = n^2 \times 10^{-3}$$
$$Z_{12} = n_1n_2 \times 2 \times 10^{-3}$$
$$J = 7 \times 10^{-11} = Z_{11}\exp(\Delta H^{\neq}/RT)/N_A = n^2 \times 10^{-3-4}/6 \times 10^{23}$$
$$\therefore n = 2 \times 10^{10} \text{ cm}^{-2}$$

or from Z_{12}

$$\therefore n_1n_2 = 10^{20} \text{ cm}^{-4}$$

In a compact layer of $BaSO_4$ molecules n = thickness × contents in 1 $cm^3 = d \times (1/v) \times N_A = 5 \times 10^{-8} \times 0.02 \times 6 \times 10^{23} = 6 \times 10^{14}$ cm^{-2}. The surface concentration necessary for the rate observed is only the fraction $2 \times 10^{10}/6 \times 10^{14} = 3 \times 10^{-3}$ of that of a compact layer. Calculated as volume concentration it is $2 \times 10^{10}/5 \times 10^{-8} = 4 \times 10^{17}$ molecules/cm^3 = $4 \times 10^{17}/6 \times 10^{23} = 10^{-6}$ mole/cm^3, *i. e.* 1 000 times as high as in the solution. This mechanism seems thus quite reasonable.

Finally, $n_1 n_2 = 10^{20}$ cm^{-4} corresponds to $C_1 C_2 = 10^{20}$ $(6 \times 10^{23})^{-2} = 3 \times 10^{-28}$ $(mole/cm^2)^2 = 3 \times 10^{-28}/(5 \times 10^{-8})^2 = 10^{-11}$ $(mole/cm^3)^2$; in the solution $C_1 C_2 = (Ba^{++})$ $(Ba(SO_4)^{--}) = 10^{-7} \times 10^{-12} = 10^{-19}$ $(mole/cm^3)^2$; we see that if the concentrations in the surface are 10^4 as large as in the solution, this mechanism can give the right rate.

Conclusion. Four of the discussed mechanisms could give a fourth order reaction with the right rate constant.

Reaction			c_{ads}/c_{soln}
(1) $BaSO_4$(soln) + $BaSO_4$(ads)	→	crystal	2×10^6
(2) Ba^{++}(soln) + $Ba(SO_4)_2^{--}$(ads)	→	»	$> 10^7$
(3) 2 $BaSO_4$(ads)	→	»	10^3
(4) Ba^{++}(ads) + $Ba(SO_4)_2^{--}$(ads)	→	»	$> 10^4$

If the differences between the four values of c_{ads}/c_{soln} are significant and if we rate a reaction as more probable than any other requiring a higher adsorption affinity to the crystal surface, in order to have the same velocity, we may point out reaction (3) as the dominating one, (4) as less important and (1) and (2) as practically negligible.

We have assumed that the ("apparent") activation energy $-R\mathrm{d}\ln k_4/\mathrm{d}(1/T)$ was due entirely to the diffusion process. Since

$$k_4 = J/c^4 = (Z/c^4)\exp(-\Delta G^{\ddagger}/RT)$$

any dependence of Z on T will contribute as well. Since the collisions involve complex molecules or ions the enthalpy of association (= minus enthalpy of dissociation) is a part of the "apparent" activation energy. A change by a factor 10 in the ration c_{ads}/c_{soln} is necessary for every $RT\ln 10 = 1\,250$ cal of dissociation enthalpy. The heat of precipitation is about 5 000 cal/mole $BaSO_4$ (Muller [25] found 5 455 at 25°C; from National Bureau of Standards' "Selected Values . . ."[26] one finds 4 630 cal/mole $BaSO_4$ (evolved).) The heat of dissociation of $BaSO_4$ is probably numerically less than this number. It may be zero if the energy change of "hydration" of the ions just compensates the work of the electric attraction forces.

V. COMPARISON WITH THE VOLMER-BECKER-DÖRING AND THE FRANK-CABRERA-BURTON THEORIES OF CRYSTAL GROWTH

1. *Introduction.* The theories of crystal growth have been developed primarily by Volmer and Weber [27,28], Farkas [29], Kaischew and Stranski [30], Becker and Döring [31], Cabrera and Burton [32,33] and Frank [33,34]. If the rate

of crystal growth is controlled by surface two-dimensional nucleation the rate is, according to Cabrera and Burton [32]

$$J = \nu ac \exp(-(U + \tfrac{1}{3}A)/kT)$$

where

ν = "frequency of vibration" or $kT/h = 6 \times 10^{12}$ s^{-1},
a = a molecular dimension (diameter of an ion or thickness of an adsorbed layer),
c = concentration in the supersaturated solution,
U = energy of activation for diffusion,
$A = \gamma'^2\pi/kT\ln\alpha$ = free energy of formation of critical (circular!) surface nucleus,
γ' = edge (free) energy per molecule of the surface nucleus,
k = Boltzmann's constant,
T = temperature,
α = supersaturation ratio (ratio of c to the solubility).

The reason why the energy of activation shall enter in the formula with only one-third of its full value A, is that the bottle-neck of crystal growth rate controlled by surface nucleation is not the nucleus of maximum free energy, because this is formed by collisions between smaller embryos, but rather the formation of embryos of energy about one-third of the nucleus.

Usually an electrolyte crystal will grow with a measurable speed when α is greater than about 1.01 and this observation does not agree at all with the quoted formula. Therefore another mechanism with lower activation energy had to be found, and as shown by Frank [31] this is provided by dislocations. In the case of $BaSO_4$, however, the rate of growth is extremely slow when α is smaller than about 10. This indicates clearly that in $BaSO_4$ growth, surface nucleation may have a chance to be rate determining in stead of the Frank dislocation mechanism.

2. The surface nucleus. In order to examine this possibility we calculate the value of γ' consistent with the experimental J and α.

From the Cabrera-Burton-expression for J we derive

$$\ln J = \ln \nu ac - U/kT - \gamma'^2\pi/3k^2T^2\ln(c/s)$$
$$p = d\ln J/d\ln c = 1 + \gamma'^2\pi/3(kT\ln\alpha)^2 = 1 + n/3$$

where p is the order of the reaction and n the number of ions in the (equilibrium) surface nucleus. With $p = 4$, $T = 298°K$, $\alpha = 25$ we find

$$n = 3(p-1) = 9$$
$$\gamma' = \sqrt{n/\pi}kT\ln\alpha = 2.0 \times 10^{-13} \text{ erg}$$

3. The surface tension. It is crucial to this hypothesis whether the value of γ' is reasonable. This quantity is impossible to measure except through J, and difficult to calculate because the structures of the surface and of the surface nuclei are rather unknown. But perhaps it may be estimated from the surface tension γ by means of

$$\gamma' = a^2\gamma$$

where $a = 3.5$ Å is the distance between the centres of two neighbouring ions in the $BaSO_4$-lattice. This formula corresponds to the view that the free energy of the surface + nucleus can be calculated as the surface tension times the total surface area including that of the vertical wall of the nucleus of heigth a.

The surface tension of an ionic crystal in vacuum may be estimated from Born and Stern's formula [35]

$$\gamma = 0.1166 e^2/\delta^3$$

(e = ionic charge, δ = lattice constant) although it was only derived for a NaCl-type crystal with electrostatic (Coulomb) forces of attraction and repulsion, and with a general repulsion between ions corresponding to a potential energy term proportional to the minus 9th power of distance. Substituting $e = z\varepsilon$, $\delta^3 = 4v/N$, where z = charge number, ε = electronic charge, v = molar volume and N = Avogadro's number we get

$$\gamma = 0.02915\ z^2\varepsilon^2 N/v$$

and for $BaSO_4$ ($z = 2$, $v = 51.9$ cm^3/mole) we obtain

$$\gamma = 312 \text{ erg/cm}^2$$

This value (or, to precise 310) was claimed to agree with experiments on $BaSO_4$ by Bruzs [36], but it is not clear from the article how the agreement is substantiated.

The surface tension of $BaSO_4$ was determined by Hulett [37] and Dundon [38] from the dependence of solubility on particle size. In Hulett's article there were several errors in the calculation, as pointed out by Freundlich [39]. (Freundlichs recalculated value, $\gamma = 4\,000$ erg/cm^2 is, however, also in error. The correct value was given by Dundon [38] and in later editions of Freundlichs book.[40]) According to Dundon, Hulett's measurements give 1 250 and her own 3 000 erg/cm^2, both numbers being rather uncertain, mainly because it is difficult to measure the particle size accurately.

Both Hulett and Dundon did only approach equilibrium through decreasing concentrations (measured by electric conductance), therefore the results may be too high by an unknown amount. There are at least two causes of experimental errors that can keep a too high concentration constant in time, 1) the stirring motion may "wear" on the crystals, so that small bits of higher solubility are broken off leading to a stationary non-equilibrium state with constant concentration, and 2) there may be a practical limiting supersaturation for growth, below which no further precipitation occurs. At low supersaturation $1/\ln a$ in the formulae for nucleus size and for the nucleation free energy becomes very large and the crystal growth becomes extremely slow. This must also lead to higher values than $p = 4$ in the rate equation, at lower concentrations than investigated in the present work.

(One might expect that the critical size and the kinetic order of the reaction both change gradually during the experiment; but since we are dealing with small numbers (< 20) we must pay attention to the fact that certain numbers (*e. g.* 4, 6 or 12) of ions can be arranged in configurations of much lower energy than other numbers (*e. g.* 5). Therefore the critical size must

be a discontinuous function (with large jumps) of the concentration, and may very well be a constant in the whole range investigated kinetically).

The works of Hulett and Dundon have been criticized by several authors; for references see the articles of Cohen and Blekkingh [41], who tried to approach equilibrium from "the other side". They dissolved finely powdered very pure barium sulfate in conductivity water, and claim that they did not succeed in transgressing the solubility of large crystals. (Perhaps they removed the supersaturation during the filtrations before the final measurements?)

As a consequence of these facts we will assume that the best choice for the surface tension of barium sulfate (even in contact with solution) is the theoretical value in vacuum 312 erg/cm^2. Therefore we find

$$\gamma' = 312 \times (3.5 \times 10^{-8})^2 = 3.8 \times 10^{-13} \text{ erg}$$

The disagreement between this value and the 2.0×10^{-13} erg required by the nucleation theory is not sufficient to reject the theory, since both values are calculated using very simplifying assumptions.

4. The temperature dependence. We still have to check whether the temperature dependence is in accord with the surface nucleation theory. The temperature dependence is expressed in the total (apparent) heat of activation.

Assuming γ' but not s independent of T we derive

$$\begin{aligned} \Delta H_A &= k\mathrm{dln}k_p \,/\, \mathrm{d}(1\,/\,T) = -k\mathrm{dln}(J\,/\,c^p) \,/\, \mathrm{d}(1\,/\,T) \\ &= U + 2A\,/\,3 + (p-1)k\mathrm{dln}s \,/\, \mathrm{d}(1\,/\,T) \\ &= kT\ln(vaca^{p-1}\,/\,J) - (p-1)\Delta H_s\,/\,2 \\ &= kT\ln(va\,/\,s^{p-1}k_p) - (p-1)\Delta H_s\,/\,2 \end{aligned}$$

ΔH_s is the heat of solution per molecule of $BaSO_4$. With $a = 3.5 \times 10^{-8}$ cm, $s = 10^{-8}$ mole/cm^3, $p = 4$, $T = 298°$K $k_4 = 1.7 \times 10^{18}$ cm^{10}/s · mole^3, $\Delta H_s = 4\,630$ cal/mole (Rossini *et al.*[26]) we find

$$\begin{aligned} kT\ln(va\,/\,s^{p-1}k_p) &= 7.8 \times 10^{-13} \text{ erg} = 11\,000 \text{ cal/mole} \\ \Delta H_A &= 11\,000 - 7\,000 = 4\,000 \text{ cal/mole} \end{aligned}$$

in good agreement with the measured value, 5 000 cal/mole.

5. The factor 1/3 on the activation energy. As was mentioned earlier in this paper the reason why the energy of activation for surface nucleation shall enter in the formulae with only one-third of its value, is that the bottle-neck of crystal growth rate controlled by surface nucleation is not the formation of the nuclei of maximum free energy, but only of embryos with one-third of the critical energy, because these have greater probability for encounters with similar or larger molecules than for being dissolved. Cabrera and Burton [32] do not give all details of the proof of this essentiel theorem. Since however $BaSO_4$ provides an example of this sort of growth mechanism it is of interest to investigate if the theorem is obeyed. We identify the 'one-third surface nuclei' with adsorbed $(BaSO_4)_2$-molecules. Since adsorbed ionic species such as Ba^{++} and $Ba(SO_4)_2^{--}$ seem to have concentrations 10^4 as high in the adsorption layer as the same ions in the solution, we assume that the concentration of $(BaSO_4)_2$ is 10^8 times as high in the adsorption layer (of thickness 5 Å) as in

the solution. In the case subject to numerical estimates ($c_o = 10^{-7}$ mole/cm^3, 0°C) this amounts to

$$10^8 \times 10^{-15} = 10^{-7} \text{ mole/cm}^3$$

this is equivalent to

$c' = 5 \times 10^{-8} \times 10^{-7} = 5 \times 10^{-15}$ mole per cm^2 of the crystal surface.

The formula for collisions between like molecules in a two-dimensional layer is

$$Z_{11} = n^2 d \sqrt{\pi RT/M}$$

where n = number of molecules per cm^2 of the layer, d = collision diameter $\cong 5 \times 10^{-8}$ cm, M = molecular weight $\cong 200$ g/mole. Substituting $n = Nc'$, dividing by N (Avogadros' number) and multiplying by the activation energy exponential function $\exp(-U/RT)$ for diffusion ($U \cong 5\,000$ cal/mole) we get the rate of collisions between $(BaSO_4)_2$-molecules in the adsorption layer:

$$J = (Z_{11}/N) \exp(-U/RT) = c'^2 \, Nd\sqrt{\pi RT/M} \exp(-U/RT)$$
$$= (5 \times 10^{-15})^2 \times 6 \times 10^{-16} = 1.5 \times 10^{-12} \text{ mole}(BaSO_4)_2/\text{cm}^2\text{s}$$

Since this is of the same order of magnitude as the experimental rate of growth (7×10^{-11} mole $BaSO_4$/cm^{2}s) the theorem has been verified.

VI. CONCLUSION

We have arrived at the following view of crystal growth of barium sulfate. At low concentrations ($c <$ about 0.4 mM) the rate-determining step is the formation of adsorbed double-molecules $(BaSO_4)_2$ on the crystal surface. This is a fourth order reaction, and its rate is determined by the rate of diffusional (or "Brownian") movement of the smaller ionic or molecular species ($Ba^{++} + Ba(SO_4)_2^{--}$ or $BaSO_4 + BaSO_4$) against each other in an adsorbed layer on the crystal surface.

The critical size of the surface nucleus is calculated from simplifying assumptions to be about 9 ions; this is critical with respect to free energy, but not to rate. In contrast to most other crystals whose rate of growth has been investigated, $BaSO_4$ does not grow by the Frank dislocation mechanism, and requires consequently much higher supersaturation ratios ($\alpha > 10$) than the latter ($\alpha > 1.01$).

At high concentrations ($c >$ about 0.4 mM) the rate of growth is controlled by the diffusion of Ba^{++} and SO_4^{--} ions from the bulk of the solution to the crystal surfaces as found in the first part [1] of this work.

The Bacteriostatic Action of Benzoic and Salicylic Acids

I. The Effect on the Oxidation of Glucose and Pyruvic Acid by *Proteus vulgaris*

INGMAR BOSUND*

Swedish Institute for Food Preservation Research, Gothenburg, Sweden

The effect of benzoic and salicylic acids on glucose and pyruvate oxidation by *Proteus vulgaris* was studied by means of Warburg experiments. Neither benzoic nor salicylic acid had any inhibitory influence on the rate of oxygen consumption until the oxidation level of acetate was reached. Further oxidation was specifically stopped in the presence of 0.01 M benzoic, or 0.003 M salicylic acid, at pH 6.0. These concentrations are close to those required for a bacteriostatic effect.

The antimicrobial action of benzoic and salicylic acids has long been known and studied in various respects. Much work [1–17] has been done concerning the effect of these acids on different enzymes, or complex of enzymes, isolated or in intact cells, but the ultimate cause of the growth-inhibiting effect, in terms of metabolic reactions, is still open to discussion. The present work is an attempt to trace the mode of action somewhat further by determining what reactions, vital to the cell, are susceptible to the inhibitors at concentrations suppressing the growth of microorganisms. The experiments presented below are respiration studies with resting cells of *Proteus vulgaris*, in which the conventional Warburg technique has been used.

EXPERIMENTAL

Organism. A strain of *Proteus vulgaris* was selected as testorganism, mainly on account of its rapid growth on different carbon sources in synthetic media. Washed cells of this organism readily oxidize members of the tricarboxylic acid cycle and related compounds, besides glucose and pyruvic acid, especially when aerated during cultivation and harvested in the logarithmic growth phase. Moreover, such suspensions have a very low endogenous respiration, a fact of great value in the present studies. The culture was maintained on nutrient agar and transferred to new agar slants every month.

* Present address: State Dairy Research Station, Alnarp, Sweden.

Medium and growth conditions. The cultivation medium had the following composition, unless otherwise stated: glucose, 10.0 g; NH_4Cl, 1.0 g; K_2HPO_4, 9.5 g; KH_2PO_4, 1.5 g; $MgSO_4 \cdot 7H_2O$, 0.1 g; casein hydrolysate (Difco vitamin-free casamino acids), 1.0 g; nicotinamide, 0.2 mg; distilled water to 1 l; adjusted to pH 7.0. The proper amount of glucose was dissolved in part of the water and autoclaved as a separate solution. Cultures were grown at 37°C, either in Erlenmeyer flasks without shaking, or in Kluyver flasks with sufficient aeration to ensure maximum growth rate. The growth media were inoculated with actively growing cells from a medium of the same composition. In most experiments the cells were harvested at the end of the logarithmic phase, or just after cessation of growth. In these cases, the growth was followed 1—2 h before harvesting by optical density measurements in a Beckman spectrophotometer at 425 mμ with sterile culture medium in the blank cell. Units of cell mass were determined by means of a standard curve for the organism, relating dry weight to optical density. In some experiments the cells were harvested at the beginning of the logarithmic phase of growth. In these cases, the culture medium was inoculated with a heavy suspension of washed cells, the optical density measurements being immediately started and the cells harvested, as soon as the logarithmic phase was established.

Preparation of cell suspensions. The cells were harvested by centrifugation and washed once by resuspension in the approximate growth volume of M/15 phosphate buffer of the same pH as in the actual experiment, usually 6.0. After repeated centrifugation, the cells were again suspended in the buffer, and the cell concentration adjusted to appropriate density. Repeated washings had no effect on cell activity, or endogenous respiration. Of this suspension 2.0 ml were added to each Warburg vessel.

Respiration studies. Oxygen consumption was measured by the conventional Warburg technique. The cell suspension was added to the main compartment of the Warburg vessels, and neutralized solutions of inhibitors and substrates to the side arms. The center well of the flasks contained 0.2 ml of 10 % KOH, absorbed on filter paper. The additions of substrate were so limited that the oxygen uptake could be followed until it had decreased to the value of the endogenous respiration. When necessary, cell activity was terminated by the addition of 0.3 ml of 5 N H_2SO_4 at the end of the experiment. CO_2 evolution, when determined, was measured according to the direct method of Warburg. The data recorded in the figures and tables have been corrected for the endogenous respiration which in no case was more than 10 % of that obtained in the presence of added substrate. All respiration measurements were made at 37°C and pH 6.0, if not otherwise stated.

Analytical procedures. Analyses of the contents of the Warburg vessels were made after removal of the cells by centrifugation. Pyruvic acid was determined as total keto acids with 2,4-dinitrophenylhydrazine, according to Friedemann and Haugen [18]. In the present experiments this method proved to give the same results as polarographic analysis. Acetic acid was determined as volatile acid by fractional steam-distillation. The titration was carried out with 0.1 N NaOH by means of a micrometer syringe. Benzoic acid, when present, distilled over together with acetic acid, and was corrected for by measuring the optical density of the distillate at 230 mμ in a Beckman DU spectrophotometer.

RESULTS

Growth experiments

The first step in this investigation was to determine the concentration of benzoic and salicylic acids required to prevent growth of *P. vulgaris*. As in the case of all weak acids, the biological activity of these compounds depends on the amount of substance present as neutral molecules, probably because these alone, not the ions, can penetrate the semipermeable membrane assumed to surround the bacterial cell. Thus, the activity of a given acid will depend on pH in a predictable manner, increasing with decreasing pH. Most of the

experiments in this investigation were carried out at pH 6.0, since a lower pH in itself would have led to unfavourable conditions for the organism.

The growth-inhibiting effect of benzoic acid on *P. vulgaris* was studied in the medium adjusted to pH 6.0 (Table 1). The main effect seemed to be a lengthening of the lag phase, but at concentrations approaching those required for a bacteriostatic effect, the growth rate in the logarithmic phase was also influenced. A characteristic feature in these experiments was the fact that benzoic acid, even at rather low concentrations, reduced the total amount of growth as compared with the amount obtained without inhibitor. This is easily accounted for by the formation of acid during growth, which resulted in an increasing effect of the benzoic acid and ended with growth being completely suppressed. In fact, a calculation of the actual concentrations of undissociated benzoic acid present at the moment when growth ceased in cultures with varying total amounts of the inhibitor gave the same value in all cases. In cultivation media where pH did not change during the experiment, no effect of benzoic acid on the total amount of growth could be demonstrated. It is evident that benzoic acid at concentrations about 0.01 M completely inhibited growth of *P. vulgaris* at pH 6.0. The same experiment with salicylic acid proved this inhibitor, producing bacteriostasis at concentrations about 0.002 M, to be more effective. However, the good correspondence between the amounts of undissociated acid present when growth ceased, as shown for benzoic acid in Table 1, did not appear when salicylic acid was used as inhibitor.

Table 1. Effect of benzoic acid on the growth of *P. vulgaris*. 50 ml of growth medium in 100-ml Erlenmeyer flasks were inoculated with cells actively growing in medium of the same composition without inhibitor. Different inocula were used in the two experiments. Initial pH, 6.0. Temp. 35°C.

* $10^{-4.20}$ has been used as dissociation constant for benzoic acid in this calculation.

The effect of benzoic and salicylic acids on glucose oxidation

Preliminary respiration studies at pH 6.0, with glucose as substrate, showed that neither inhibitor, at the concentrations mentioned above, had any effect on the rate of oxygen consumption during the first stage of glucose oxidation, and that lower concentrations generally increased the rate somewhat. The results, however, varied with growth conditions and the age of the cells at the time of harvesting.

Experiments with cells grown without shaking or aeration. The cultures were harvested in the stationary phase, generally within 1—2 h after growth had ceased. Warburg experiments with such cells showed that oxygen consumption during glucose oxidation proceeded at a constant rate until a sudden break occurred, after which it continued at a lower, though still constant rate, which, however, was significantly higher than that of the endogenous respiration. At the time of the break, all added glucose had disappeared from the medium. Pyruvate accumulated during the first part of the oxidation and disappeared again after the break (Fig. 1). The maximum amount of pyruvate in the medium, always appearing simultaneously with the break, varied in magnitude with the cell preparations according to some unknown factor, although the experimental conditions were kept as constant as possible.* In

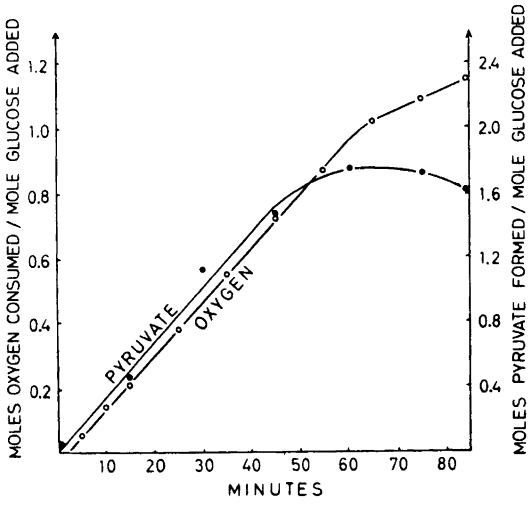

Fig. 1. Pyruvate accumulation during glucose oxidation by *P. vulgaris*. Each vessel contained 2.0 ml of cell suspension, 2.5 μmoles of glucose and 133 μmoles of potassium phosphate in a total volume of 2.5 ml.

* After these experiments were performed, related results have been reported by Jackson[19] who investigated the accumulation of pyruvate in cultures of *P. vulgaris* grown with limiting concentrations of nicotinic acid. Although the concentrations of nicotinamide (0.2 μg/ml) used in the present work hardly can have had a limiting effect on growth, it is still possible that this factor might have been of some significance even in this case.

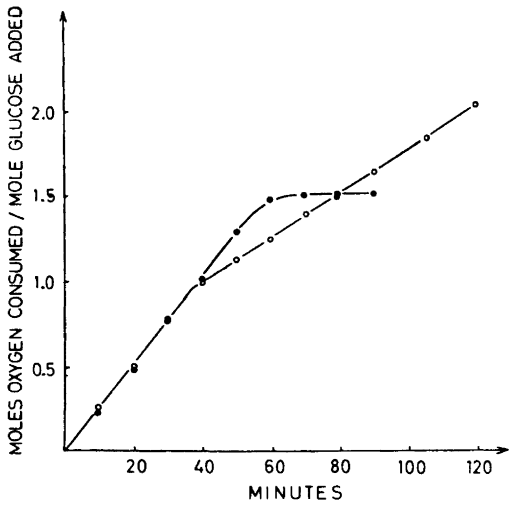

Fig. 2. Effect of benzoic acid on the oxygen consumption during glucose oxidation by *P. vulgaris*. Each vessel contained 2.0 ml of cell suspension, 2.5 μmoles of glucose and 133 μmoles of potassium phosphate. O———O no benzoate, ●———● 0.01 M sodium benzoate. Final volume 2.5 ml.

some experiments, about 90 % of the maximum amount of pyruvate possible, as calculated from the amount of glucose added, had accumulated before the break. In such cases, the break occurred when almost exactly one mole of oxygen had been consumed per mole of glucose added, which seemed to indicate that the oxidation took place in two separate steps, first a conversion of all glucose added into pyruvate, and next a further oxidation of this metabolite.

This picture was completely changed when the oxidation took place in the presence of benzoic acid (Fig. 2). The essential effect of this drug consisted in postponing the break, after which the oxygen consumption was strongly inhibited. This inhibition was complete at the same concentration of benzoic acid as that required to prevent growth of the organism at the pH in question. Under these conditions, accumulation of pyruvate was prevented.

Experiments with cells aerated during growth. The two characteristic features of glucose oxidation with old cells of *P. vulgaris*, the break in the rate of oxygen consumption at a point where about one mole of oxygen had been taken up per mole of glucose added, and the accumulation of pyruvate, seemed to be intimately linked with some factors in the growth conditions. These signs of a disturbed oxidative ability did not appear in cells aerated during growth and harvested in the logarithmic growth phase. The oxygen consumption during glucose oxidation by such cells, and the effect of varying concentrations of benzoic acid, are illustrated in Fig. 3. 0.0035 M benzoic acid slightly stimulated the rate of oxygen uptake, while higher concentrations decreased the rate. The results obtained indicate a specific effect of benzoic acid on the later stages of glucose oxidation, and the amount of oxygen consumed in presence

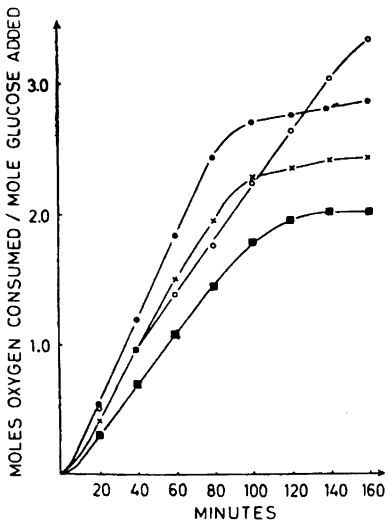

Fig. 3. Effect of benzoic acid on the glucose oxidation by *P. vulgaris*. Each vessel contained 2.0 ml of cell suspension, 2.5 μmoles of glucose and 133 μmoles of potassium phosphate. O——O no benzoate, ●——● 0.0035 M, ×——× 0.0070 M, ■——■ 0.0140 M sodium benzoate. Final volume 2.5 ml.

of 0.014 M benzoic acid, about 2 moles per mole glucose added, suggests that the sensitive point lies at the oxidation level of acetate. Higher concentrations of benzoic acid inhibited the rate of oxygen consumption still more, but had no influence on this minimum amount of oxygen taken up per mole glucose. Essentially the same results were obtained with salicylic acid. This inhibitor, however, was more effective, reducing the oxygen consumption per mole glucose to 2 moles at concentrations about 0.003 M (Fig. 4). The close resemblance between these figures for the two acids and the bacteriostatic concentrations given on page 00 should be noticed. Large amounts of volatile acid were demonstrated in vessels where the oxidation occurred in the presence of benzoic or salicylic acid, whereas only traces were found in vessels without inhibitor.

The inhibition of ammonia assimilation during glucose oxidation by benzoic and salicylic acids

It has already been shown by Bernheim and DeTurk [10] that salicylic acid, benzoic acid, and related compounds, inhibit ammonia assimilation during succinate oxidation in *Pseudomonas aeruginosa*, more than they inhibit the oxidation of succinate itself. A similar specific effect on ammonia assimilation seemed to exist even in *P. vulgaris* (Table 2) when glucose was used as an energy source. Benzoic acid, at a concentration of 0.007 M, actually had a stimulating effect on the rate of oxygen consumption during glucose oxidation in the absence of ammonium ions. The degree of this stimulation varied with the age of the cells, being greater the older the cells were at the time of harvesting. The main results of the four experiments with benzoic acid

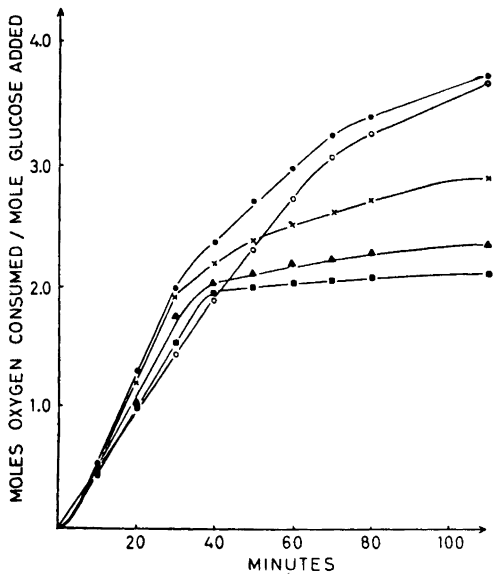

Fig. 4. Effect of salicylic acid on the glucose oxidation by *P. vulgaris*. Each vessel contained 2.0 ml of cell suspension, 5 μmoles of glucose and 133 μmoles of potassium phosphate. O———O no salicylate, ●———● 0.00125 M, ×———× 0.00188 M, ▲———▲ 0.00313 M, ■———■ 0.00500 M sodium salicylate. Final volume 2.5 ml.

were the same, being independent of the growth conditions, *i.e.* the increase in oxidation rate accompanying the presence of ammonium ions was completely abolished. Similar results were obtained with salicylic acid.

The effect of benzoic and salicylic acids on pyruvate oxidation

Bacteria from aerated cultures were used in these experiments. The cells were harvested at the end of logarithmic phase, or just after they had reached

Table 2. Influence of benzoic acid on the rate of glucose oxidation in the presence and absence of ammonium ions (four experiments). Each vessel contained 133 μmoles of potassium phosphate, 5 μmoles of glucose and 5 μmoles of $(NH_4)_2SO_4$ (when added). The final concentration of sodium benzoate was 0.007 M when present.

Additions	Relative rates of oxygen consumption. Rates with glucose as the only addition = 1			
	I	II	III	IV
Glucose	1	1	1	1
Glucose + $(NH_4)_2SO_4$	1.5	1.4	1.6	1.5
Glucose + sodium benzoate	1.3	1.1	1.2	1.4
Glucose + $(NH_4)_2SO_4$ + sodium benzoate	1.3	1.1	1.2	1.4

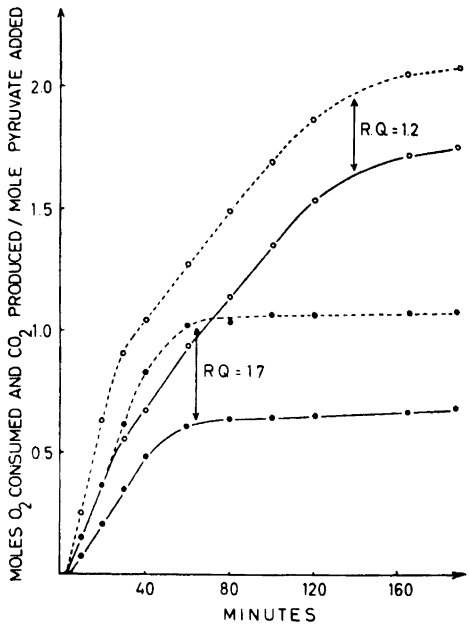

Fig. 5. Effect of benzoic acid on the pyruvate oxidation by *P. vulgaris*. Each vessel contained 2.0 ml of cell suspension, 5 μmoles of sodium pyruvate and 133 μmoles of potassium phosphate. Final volume 2.5 ml. O———O no benzoate, ●———● 0.0083 M sodium benzoate. Solid line, oxygen; dash line, carbon dioxide.

the stationary phase. The growth phase at harvesting did not seem to be critical for the results. As in the case of glucose oxidation, the results (Fig. 5) strongly suggest that the main effect of benzoic acid is close to the oxidation of acetate, or some »active» form of it. The theoretical amounts of oxygen consumed and carbon dioxide produced at a conversion of pyruvate into acetate (or some of its »active» forms) are 0.5 and 1.0 mole per mole pyruvate, respectively. As shown in Fig. 5, the actual values obtained in the presence of 0.0083 M benzoic acid agreed well with these figures. Determination of accumulated volatile acid in the vessels, after the oxygen consumption had practically ceased, supported this interpretation of the data. The results of one such determination are shown in Fig. 6 B, and the corresponding manometric data in Fig. 6 A. Similar experiments with salicylic acid gave corresponding results. The distillation constant calculated from the experimental data agreed with that obtained by distilling a similar solution with known amounts of acetic and benzoic acids, and acetate was demonstrated in the distillate by a method described by Feigl [20]. In other experiments the contents of the Warburg vessels were analysed by chromatographic methods. Apart from benzoic and salicylic acids, only acetic acid could be demonstrated. When the oxidation was carried out without inhibitor, only traces of acid were found (Fig. 6 C).

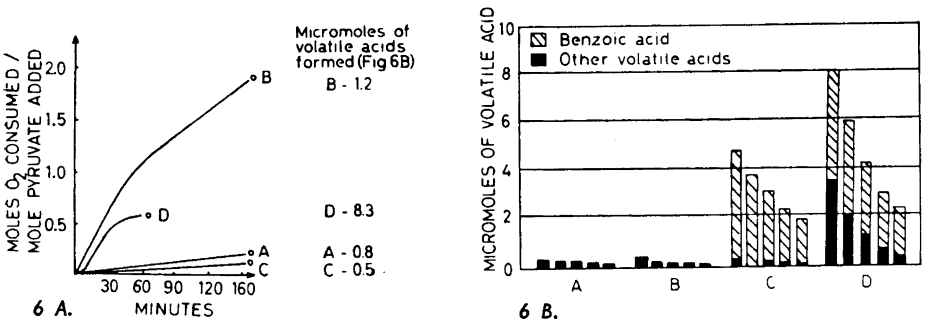

Fig. 6 A. Effect of benzoic acid on oxygen consumption and formation of volatile acids during pyruvate oxidation by *P. vulgaris*. The vessels contained besides 2.0 ml of cell suspension and 133 μmoles of potassium phosphate: A, no further additions; B, 10 μmoles of sodium pyruvate; C, 0.01 M sodium benzoate; D, 10 μmoles of sodium pyruvate and 0.01 M sodium benzoate. Final volume 2.5 ml. The oxidation was stopped, at points indicated, by addition of H_2SO_4 and the amounts of volatile acids determined as shown in Fig. 6B.

Fig. 6 B. Formation of volatile acids during pyruvate oxidation by *P. vulgaris*. Each group of columns represents the amount of volatile acids in the first five fractions of distillate from one Warburg vessel. Indications as in Fig. 6 A. The volume of the fractions was equal to that of the distilling solution.

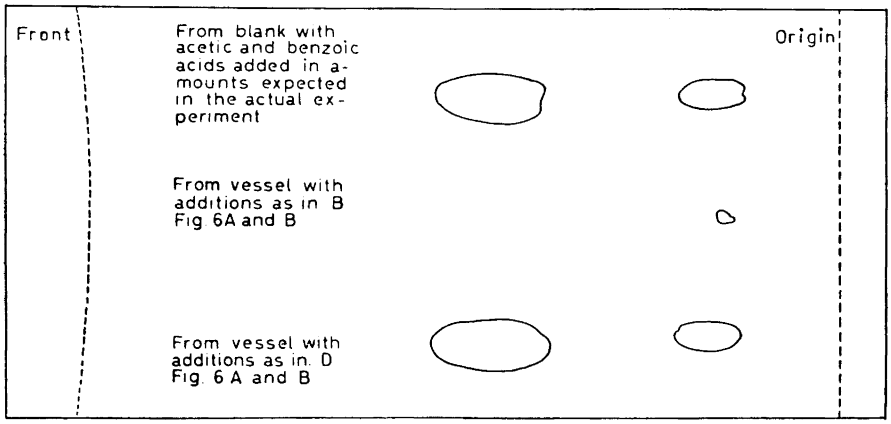

Fig. 6 C. Chromatographic separation of reaction products after an experiment similar to that in Fig. 6 A. The oxidation was stopped by addition of H_2SO_4, the contents in the vessels neutralized and concentrated by evaporation, acidified and extracted with *n*-butanol. Descending solvent: water-saturated *n*-butanol.

DISCUSSION

The experiments described show that the presence of benzoic or salicylic acid during glucose and pyruvate oxidation by *P. vulgaris* causes an accumulation of acetate in the medium. The utilization of this compound, as acetyl-

S-CoA, or in some other activated form, in synthesis of cell material and as an energy source is thereby prevented. The central position of such intermediates in the metabolism of living cells and the fact that benzoic and salicylic acids in the present experiments caused the accumulation of acetate at the same concentrations as those required to suppress growth of *P. vulgaris* suggest that the bacteriostatic effect, at least in part, may be due to an interference with the metabolism of the acetyl group.

Although the net result of the action of the two acids on the oxidation processes studied is relatively clear, the data presented give no information as to the way in which the inhibition is accomplished. Nevertheless, the results may be considered in view of what is known about the pyruvate metabolism in *P. vulgaris*. Apart from the enzyme system transforming pyruvate into metabolic active C_2-compounds, this organism seems to possess a pyruvate oxidase of quite another type. This enzyme has been thoroughly investigated by Stumpf [21] and by Moyed and O'Kane [22] and shown to give rise to acetate from pyruvate, without intermediate formation of any detectable acyl compound. The only cofactors required for the action of this enzyme are divalent ions and cocarboxylase. If the normal way of pyruvate metabolism in *P. vulgaris* is sensitive to benzoic and salicylic acids, and the acetate generating system is not, the presence of these acids during oxidation should lead to the withdrawal of great amounts of C_2-compounds as acetate from the normal metabolic route.

Irrespective of the mechanism of the acetate accumulation, the mere fact that it occurs indicates that the oxidation of acetate in the present experiments is much more sensitive to benzoic and salicylic acids than that of glucose and pyruvate. As the first step in acetate oxidation involves activation in an energy-requiring process, it is possible that the inhibition of this oxidation by benzoic and salicylic acids is related to the effect of these acids on another energy-requiring process, *e.g.* assimilation of ammonium ions. The work by Bernheim and DeTurk [10] already referred to and the experiments described in this paper show that benzoic and salicylic acids specifically inhibit the increased rate of substrate oxidation observed during simultaneous assimilation of ammonium ions. Bernheim and DeTurk suggest that their results are due to an inhibition of the formation, or utilization, of high energy compounds in the presence of salicylic or benzoic acid. In the present experiments such an interpretation would agree well with the stimulation of glucose oxidation, caused by the two acids, as an increase in oxidation rate is often observed in the presence of substances disturbing the energy conservation process. In recent years, inhibition of oxidative phosphorylation in isolated mitochondria by salicylic acid (Penniall, Kalnitsky and Routn [23]) and by salicylic and benzoic acids (Bosund [24]) has been reported. These findings, especially in the case of salicylic acid, bear out the hypothesis that some of the growth-inhibiting effect may be due to an interference with the formation of high energy compounds.

This work is part of an investigation supported by the *Swedish Natural Science Research Council* and the *Swedish Technical Research Council.*

I am greatly indebted to Professor G. Lindeberg, Agricultural College of Norway, Vollebekk, Norway, for introducing me into this field of investigation and for his

patient advice and encouragement throughout the work. I also wish to thank Professor E. Adler, Chalmers University of Technology, Gothenburg, Sweden, for continued interest and helpful criticism.

Structure of Elastin

2. Yellow Coloration

AIMO KÄRKELÄ and EINO KULONEN

Department of Medical Chemistry, University of Turku, Finland

For the investigation of its yellow pigment, elastin was partially hydrolyzed with acids, bases and enzymes under varying conditions and the hydrolyzates submitted to several fractionations. The best result was obtained by hydrolysis in 2 N sulfuric acid for 96 h at +95°C with subsequent adsorption on aluminium oxide and elution with ammonia.

Data on the infra-red absorption spectra of elastin and an enriched yellow preparation are presented. This preparation could not be degraded further without loss of the colour. The yellow pigment is tightly bound to the peptide chain and could not be identified as a bile pigment or by ultraviolet absorption spectrum.

The yellow colour was intensified in an unexplained manner by dialysis or treatment with tungstate.

The yellow pigment of elastin has recently attracted considerable interest [1-3] and several classes of compounds have been suggested as possible chromophores.

The first aim was to isolate the yellow component, but only enriched preparations could be obtained. The elastin was broken down with several enzymes, acids and bases. All methods of hydrolysis were handicapped by the formation of humins. In this respect barium hydroxide and papain were the most favourable agents. A complete hydrolysis of elastin was not achieved without concurrent destruction of the pigment.

The partial hydrolysates were fractionated by dialysis, by ion-exchange chromatography (Dowex-50) using different buffer systems, by preparative silica gel electrophoresis, by adsorption chromatography and by peptide-precipitating agents.

The best yellow fractions were obtained by adsorption on aluminium oxide and elution with ammonia. The yellow color seems to be tightly bound to the peptide chain (*cf.* Partridge and Davis [4]) and it could not be separated from the amino acids. Under certain conditions the colour is intensified, for example during dialysis or after addition of tungstates. This

effect is quite unexplained. An unsaturated bond suggested by Labella [2] is possible.

The main results are the preparation of the enriched fraction, the infra-red data of elastin and analysis of the peptide to which the yellow component is attached. It seems that there exists a yellow "core" which is gradually broken down to smaller non-coloured fragments, of which some amino acids were identified.

The attempts to identify the yellow component as a bile pigment or porphyrin derivative were not successful.

Material and preparation

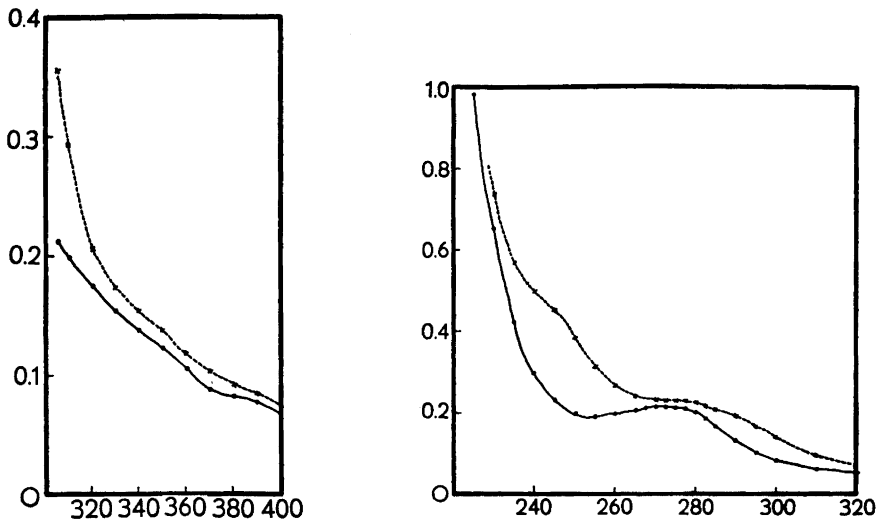
The preparation of elastin has been described in our earlier paper on the structure of elastin [5].

The *best enriched yellow preparation* was designated as R-5/Al_2O_3 and obtained as follows: Fifty g of elastin was suspended in 1 000 ml of 2 N sulfuric acid and kept at +95°C for 48 h with occasional shaking. Already after the first hours the fluid acquired a reddish-brown colour and at the end of the heating the fluid was rather dark. After filtration the fluid was neutralized with solid barium hydroxide. The precipitate adsorbed a part of the dark-brown colour but the filtrate was still rather brown, like concentrated urine.

The hydrolysis was continued at +95°C for an additional 48 h in 2 N sulfuric acid and more dark-brown colour was formed. The precipitation with barium hydroxide was repeated and the supernatant centrifuged clear. For removal of the dark colour additional barium sulfate was suspended and after 2 ½ h agitation the supernatant was collected by centrifugation. It resembled normal urine in colour. At a lower temperature (+37°C)

Table 1. The intensity of the yellow colour in some elastin preparations.

Method of preparation	Nitrogen mg/ml in solutions with $E^{1\,cm}_{330} = 1$
Oxalic acid-soluble elastin	0.82
Hydrolyzate with $Ba(OH)_2$	2.36
fraction obtained with Dowex-50, pH 3.42	0.57
Hydrolyzate (partial) with 4 N HCl,	
fraction obtained with Dowex-50, pH 3.42	0.42
» » » » pH 6.7	0.23
Hydrolyzate (partial) with 4 N H_2SO_4	0.85
outside the bag after dialysis	0.52
R-5	1.60
R-5/Al_2O_3 (adsorbed on Al_2O_3 and eluted with NH_3)	0.12
Hydrolyzate with papain	1.05
supernatant after precipitation with 10 % trichloroacetic acid	0.81
supernatant after precipitation with tungstic acid (final conc. 1.67 % sodium tungstate in 0.11 N H_2SO_4, supernatant neutralized to pH 5; the colour not quite elastin-like)	0.14
Humic acid (Light & Co., Ltd., in 0.1 N HCl)	0.093



Figs. 1—2. The absorption spectra of elastin in 0.1 N hydrochloric acid (solid) and in 0.1 N sodium hydroxide (dotted).

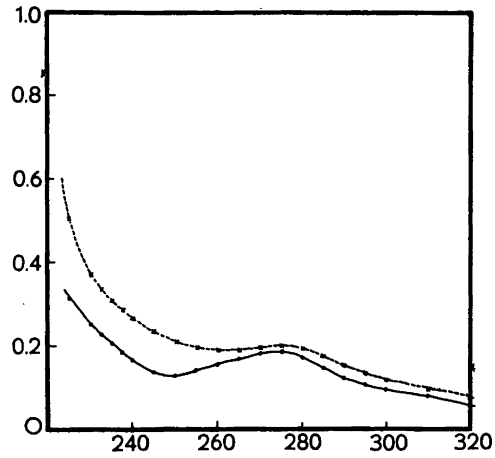


Fig. 3. The ultraviolet absorption spectrum of the preparation R-5/Al_2O_3 in 0.1 N hydrochloric acid (solid) and in 0.1 N sodium hydroxide (dotted).

less brown and red substances were formed, but hydrolysis lasted much longer and was more incomplete.

The hydrolysate was allowed to drain through a 2 cm layer of aluminium oxide (Merck, "nach Brockmann"). The yellow colour was retained in the surface of the aluminium oxide, which was washed with water until the washings were ninhydrin-negative. Only very little of the yellow colour was removed. The bulk of the yellow substance was eluted with 1 M ammonia, which was removed by evaporation in vacuum. The residue was brownish-yellow and the yield was 0.7 g.

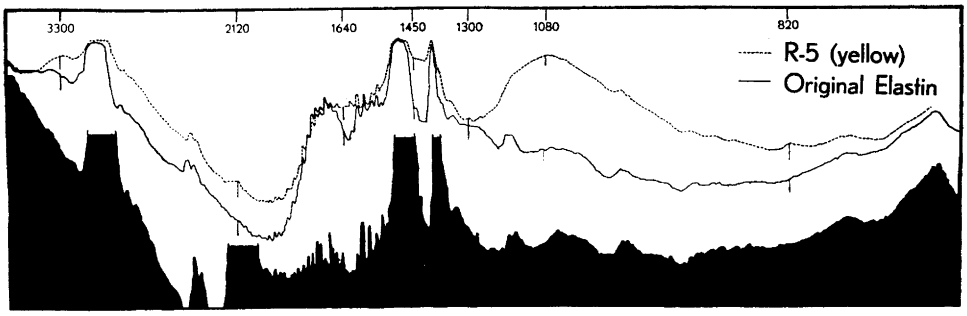

Fig. 4. The infra-red absorption spectra of oxalic acid-soluble elastin and of the enriched preparation R-5/Al_2O_3. (Perkin-Elmer single-beam instrument, sodium chloride cell of 0.05 mm, concn. 10 mg in 0.05 ml liquid paraffin, the borderline of the black area indicates the spectrum of the paraffine.) The differences in the spectra are pointed out with their wave numbers (cm^{-1}).

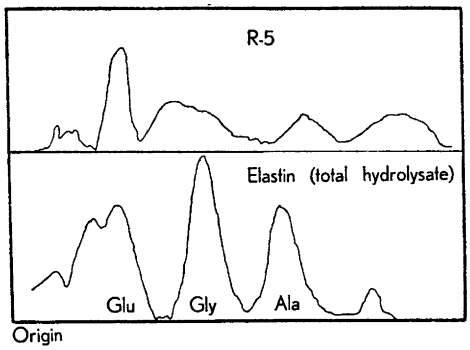

Fig. 5. Comparison of "total hydrolyzates" of elastin and of R-5/Al_2O_3 (densitograms from one-dimensional paper chromatograms run with phenol/NH_3). Note the absence of glycine in R-5.

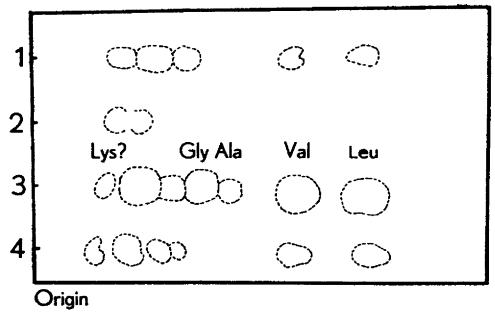

Fig. 6. Comparison of the butanol/acetic acid chromatograms of R-5 and original elastin. 1 = R-5/Al_2O_3, "total hydrolyzate"; 2 = Asp + Glu; 3 = elastin, "total hydrolyzate"; 4 = yellow "start" spot of No. 1 (the hydrolyzed R-5), rehydrolyzed.

Hydrolysis with papain was carried out at +37—38° C for 24 h. The digest contained 40 ml of 2.5 % elastin solution, 5 ml of 0.25 M citrate buffer (pH 5) and 5 ml of H_2S-activated papain (0.626 mg N/ml). The liberated amino nitrogen amounted to 18 % of the total.

Hydrolysis with saturated Ba (OH)$_2$ was performed in a solution containing 5 % elastin which was kept for 3—4 days at +37°C. The fluid remained "purely" yellow.

The *R-4-hydrolysate* was made at +37°C in 4 N sulfuric acid for 14 days and finally the mixture was boiled under a reflux condenser for 24 h.

The intensity of the yellow colour was expressed as the concentration of nitrogen per ml solution having the extinction coefficient $E^{1\,cm}_{330} = 1$.

Some data are presented in the Table 1. Specimens of the absorption spectra are given in Figs. 1—3. There was no evidence to support the hypothesis of bile pigment origin (attempts were made with chloroform extraction and oxidation with hydrogen peroxide.) The comparison with a "humic acid" sample remained inconclusive.

In the many fractionation experiments with Dowex-50 it was observed that after the change of any buffer a yellow fraction appeared. Two sources of error were recognized: (1) some yellow colour can be eluted from the resin itself and (2) other proteins, for example gelatin, form during the hydrolysis yellow artefacts which appear similarly. The significance of these yellow fractions remains unknown.

Analysis of the preparation R-5/Al_2O_3

Infra-red absorption (Fig. 4). Absorptions at 3 300 cm^{-1} and 1 640 cm^{-1} are due to amide groups, at 2 120 cm^{-1} to amino acids and at 1 450 cm^{-1} perhaps to carboxyl groups. Peaks at 1 300 cm^{-1} and 820 cm^{-1} are so small that no conclusions, for example concerning double bonds, seem warranted. The broad peak at 1 080 cm^{-1} may be interpreted in several different ways (C—O of ethers, alcohols, or anhydrides, molecular size).

Amino-acid composition. Although the yellow substance was of such lowmolecular weight that it was dialysable, it did not move in the chromatograms as a compact spot but the colour faded in these manipulations as also in column chromatography and in preparative electrophoresis. The comparison of the amino acids of R-5/Al_2O_3 and elastin is presented in Fig. 5.

It was found that on the origin of the chromatographed R-5-hydrolyzates there always remained a yellow ninhydrin-positive spot. When this "start" spot was rehydrolyzed, a pattern resembling original R-5 hydrolysate was obtained (Fig. 6). From this it is concluded that the yellow component is during acid hydrolysis gradually broken to non-coloured products and that the R-5/Al_2O_3 represents the smallest yellow unit for the present.

Acknowledgements. We are greatly indebted to Mr. Tapio Salo, M. A., from the Central Laboratories of Finnish State Alcohol Monopoly, for the infra-red spectrometry. This work was generously supported by *Finnish Medical Society "Duodecim"* and *Sigrid Jusélius Foundation.*

Short Communications

On the Amino Acid Sequence of Bovine Fibrinopeptides

BIRGER BLOMBÄCK and PER WALLÉN

Chemistry Department II, Karolinska Institutet, Stockholm,

JOHN SJÖQUIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Fibrinopeptides are split off from the fibrinogen of various species during its conversion to fibrin. Summaries of the results achieved in this field have recently been given by Scheraga and Laskowski [1] and by Blombäck [2]. From ox fibrinogen, at least two peptides, tentatively named A and B, are split off. These peptides have been isolated by different methods, and chemical studies on their amino acid and N-terminal composition have been performed in our laboratories, as well as in others [3-7]. These studies confirm that glutamic acid is N-terminal in peptide A, whereas peptide B seems to lack any N-terminal amino acid residue. With carboxypeptidase, however, arginine can be split off as C-terminal from both peptides A and B [8,9]. The sequence of the three first amino acid residues from the N-terminal end of peptide A has recently been described by Blombäck and Sjöquist [2]. Sequence studies of bovine peptides A and B have later been reported by Folk *et al.*[9]

Digestion of peptides A and B with a variety of proteolytic enzymes, *i. e.*, papain, chymotrypsin, subtilisin and trypsin, released several fragments which were separated either by high-voltage electrophoresis, or on ion-exchange columns of 2 % cross-linked Dowex-50 [5]. The N-terminal amino acids were determined with the phenylthiocarbamyl method of Edman, as applied by Sjöquist [10]. The amino acids were determined quantitatively according to the method of Sjöquist [7,11,12].

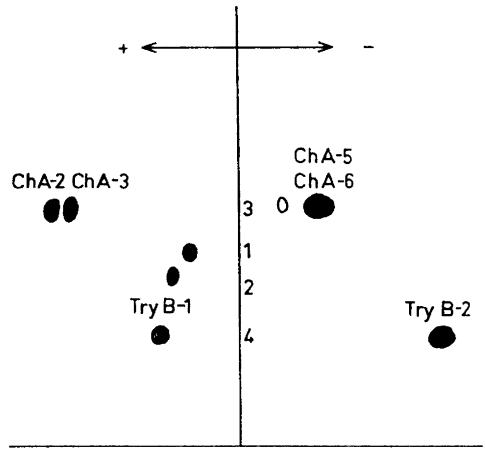

Fig. 1. Paper electrophoresis of peptides A and B after digestion with proteolytic enzymes. The experiments were carried out in 0.1 M pyridine adjusted to pH 4.1 with acetic acid. The potential gradient was approximately 20 V/cm. Each run lasted for about 3 hours.
1. Peptide B
2. Peptide A
3. Peptide A after digestion with chymotrypsin
4. Peptide B after digestion with trypsin

By means of chymotrypsin digestion, peptide A was split into four main fragments (Figs. 1 and 2). It can be seen from Table 1 that fragments ChA-2 and ChA-3 are similar in composition with respect to all amino acids except leucine (or *iso*leucine). Fragments ChA-5 and ChA-6 also differ only with regard to this particular amino acid. The latter peptides were not separated during electrophoresis at pH 4.1 in pyridine acetate buffer (Fig. 1). Separation could, however, be achieved by ion-exchange chromatography.

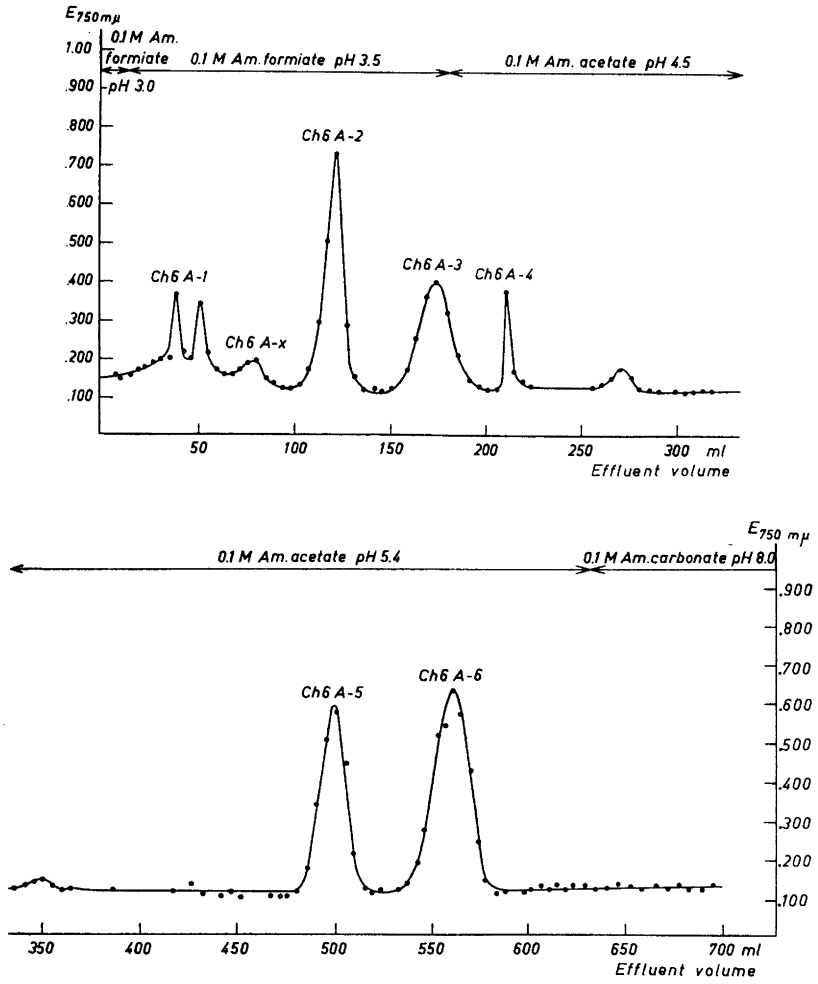

Fig. 2. Separation of peptides from a chymotryptic hydrolysate of peptide A by chromatography.

Assuming that peptide A consists of only one peptide chain, chymotrypsin had apparently split the chain on both sides of leucine (or *iso*leucine). The amino acid sequence determination of the fragments from the N-terminal end gave the following results: *ChA-2*: glu.asp.gly.ser.asp.asp., *ChA-3:* glu.asp.gly.ser.asp.asp., *ChA-5:* thr.glu.gly.gly.gly.val.arg., *ChA-6:* leu. (or ileu.) thr.glu.gly.gly.gly.val.arg. Since chymotrypsin has a specificity for peptide linkages near aromatic residues, the C-terminal residue in ChA-2 is most probably phenylalanine. An attempt was also made to investigate the C-terminal part of fragment ChA-2 and of the undigested A peptide, by means of the hydrazinolysis method of Akabori, as modified by Wallén and Sjöholm [14]. It was found that the C-terminal amino acid in fragment ChA-2 is phenylalanine, and that the residue next to the C-terminal amino acid is probably glycine. Furthermore, it was possible to confirm that the C-terminal sequence of the undigested A peptide is gly.val.arg. The amino acid

Table 1. Amino acid residues of peptide A and of peptides isolated from a chymotryptic digest of peptide A.

Amino acids	Number of residues						
	ChA-2	ChA-3	ChA-5	ChA-6	Peptide A	ChA-2+ ChA-6	ChA-3+ ChA-5
Arginine	0	0	1	1	1	1	1
Aspartic acid	3	3	0	0	3	3	3
Glycine	2	2	3	3	5	5	5
Glutamic acid	1	1	1	1	2	2	2
*Iso*leucine / Leucine	0	1	0	1	1	1	1
Phenylalanine	1	1	0	0	1	1	1
Proline	2	2	0	0	2	2	2
Serine	2	2	0	0	2	2	2

residues found in the fragments are in fairly good agreement with the residues found in the undigested peptide A (Table 1). From the N-terminal end, the following amino acid sequence was found in peptide A on direct determination: glu. asp.gly.ser.asp. However, when the sequence determination was performed on the undigested A peptide, an unidentified compound with the same R_F value as proline appeared in the second, third, fourth and fifth degradation steps. This compound is believed to be a side-reaction product formed during cyclization.

Digestion of peptide A with papain gave a fragment with the N-terminal sequence pro.pro.ser.gly. Thus, the studies so far seem to indicate that peptide A consists of a single peptide chain, with the following amino acid sequence: glu.asp.gly.ser.asp. asp.pro.pro.ser.gly.phe.leu.thr.glu.gly.gly. gly.val.arg.

Peptide B lacks an N-terminal residue which reacts with fluorodinitrobenzene, or which can form a phenylthiohydantoin derivative after coupling with phenyl*iso*thiocyanate. This indicates that at least this part of the molecule may be involved in a cyclic structure. Peptide B, however, has a C-terminal arginine residue as determined by means of carboxypeptidase or with the aforementioned hydrazinolysis method. This peptide has also been found to contain tyrosine-O-sulphate [5,13].

Peptide B could be split into two fragments by digestion with trypsin chymotrypsin or papain (Fig. 1). The different enzymes yielded different peptides, one of which was the main part of the original peptide, whereas the others contained fewer amino acid residues. The amino acid composition of the peptides (Try B-1 and Try B-2) obtained from a tryptic hydrolysate is shown in Table 2. The main fragment, Try B-1, containing tyrosine-O-sulphate, failed to give any N-

Table 2. Amino acid residues of peptide B and of peptides isolated from a tryptic hydrolysate of peptide B.

terminal residue. In the peptide Try B-2, valine is N-terminal. The amino acid sequence of this fragment is val.gly.leu. (or ileu.)gly.ala.arg. As is seen from Table 2, the residues found in the fragments are in fairly good conformity with the residues found in peptide B. In the preliminary report on the amino acid composition of peptide B (cf. Ref.[2]), threonine was stated to be absent. In subsequent analysis with a somewhat modified procedure [7], threonine was recovered from the hydrolysate of peptide B. This is in agreement with the original finding by Bettelheim [3].

For further elucidation of the structure of peptide B, digestion of this peptide by means of subtilisin has given promising results. After digestion with this enzyme, 6 or 7 small peptides were isolated by chromatography or by electrophoresis.

The complete paper on the amino acid sequence of bovine fibrinopeptides A and B will be published elsewhere.

The authors' thanks are due to Mr. Nils Gröndahl for the performance of the electrophoretic analysis.

A mass spectrometric study [1] of the methyl ester of mycocerosic acid isolated by Anderson and co-workers [2-4] from the lipids of tubercle bacilli, indicated a molecular weight of 494, corresponding to the methyl ester of a C_{32}-acid. The mass spectrum furthermore indicated the presence of methyl side chains at positions 2, 4, and 6. These methyl group positions were the same as deduced by Polgar [5] for the closely related or identical compound called mycoceranic acid [6,7]. The levo-rotation of mycoceranic acid and the optical rotations recorded by Polgar for the products obtained in the step-wise degradation suggested an all D optical configuration. For comparison we therefore synthesized (—)-methyl 2D,4D,6D-trimethylnonacosanoate. The synthesis was performed as follows.

n-Eicosylmalonic acid, m. p. 122.8—124.2°, was prepared in a yield of 90 % from ethyl *n*-docosanoate and ethyl oxalate [8]. The reaction of the acid chloride derived from (—)-6-methoxycarbonyl-3L, 5L-dimethylhexanoic acid [9] with the sodium derivative of di-(tetrahydropyranyl) *n*-eicosylmalonate [10] gave (+)-methyl 3D,5D-dimethyl-7-oxooctacosanoate, m. p. 42.8—43.6°, $[\alpha]_D^{25}$ +0.4° (c = 19.3) *,

* All optical rotations were measured in chloroform solution using a 1 dm tube.

A mass spectrometric study [1] of the methyl ester of mycocerosic acid isolated by Anderson and co-workers [2-4] from the lipids of tubercle bacilli, indicated a molecular weight of 494, corresponding to the methyl ester of a C_{32}-acid. The mass spectrum furthermore indicated the presence of methyl side chains at positions 2, 4, and 6. These methyl group positions were the same as deduced by Polgar [5] for the closely related or identical compound called mycoceranic acid [6,7]. The levo-rotation of mycoceranic acid and the optical rotations recorded by Polgar for the products obtained in the step-wise degradation suggested an all D optical configuration. For comparison we therefore synthesized (—)-methyl 2D,4D,6D-trimethylnonacosanoate. The synthesis was performed as follows.

n-Eicosylmalonic acid, m. p. 122.8—124.2°, was prepared in a yield of 90 % from ethyl *n*-docosanoate and ethyl oxalate [8]. The reaction of the acid chloride derived from (—)-6-methoxycarbonyl-3L, 5L-dimethylhexanoic acid [9] with the sodium derivative of di-(tetrahydropyranyl) *n*-eicosylmalonate [10] gave (+)-methyl 3D,5D-dimethyl-7-oxooctacosanoate, m. p. 42.8—43.6°, $[\alpha]_D^{25}$ +0.4° (c = 19.3) *,

* All optical rotations were measured in chloroform solution using a 1 dm tube.

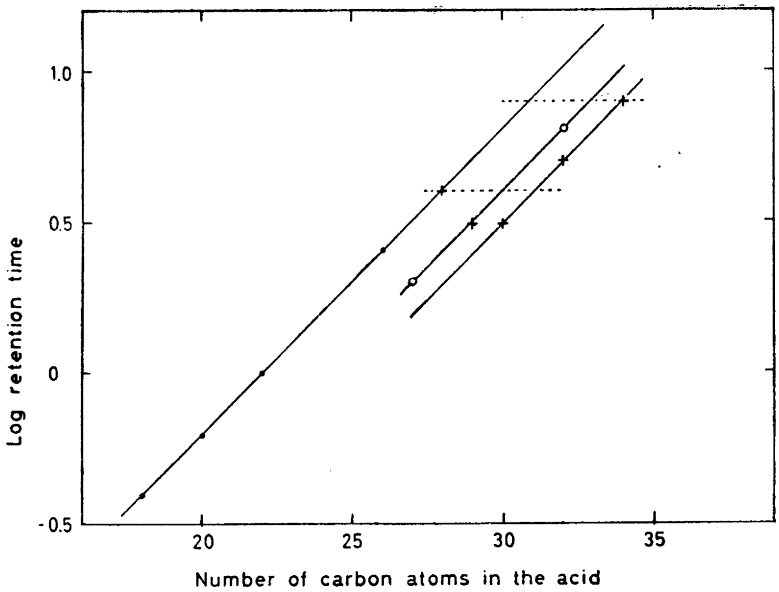

Fig. 1. The relations between the logarithm of the retention time and the number of carbon atoms in the acid in the gas chromatography of the methyl esters on silicone at 260°. ●, Methyl esters of normal chain acids; O, methyl esters of 2,4,6-trimethyl-substituted acids; +, fractions from methyl mycocerosate. Dotted horizontal lines are drawn through points corresponding to fractions of unknown molecular weight.

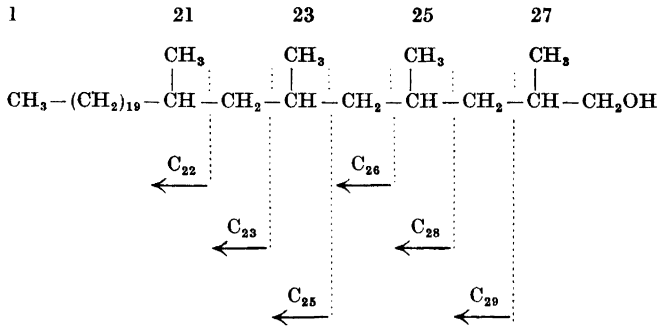
in a yield of 52 %. The reduction of the oxo-group was carried out by the desulphurization of the ethylene mercaptal [11]. (+)-Methyl 3D,5D-dimethyloctacosanoate, m. p. 41.2—42.0°, $[\alpha]_D^{25}$ +1.5° (c = 6.0), was obtained in a yield of 95 %. Saponification gave the free acid, m. p. 59.9—60.2°.

Hunsdiecker degradation [12] of the silver salt of this acid gave (—)-1-bromo-2D,4D-dimethyl-heptacosane, m. p. 40—41°, $[\alpha]_D^{21}$ —0.5° (c = 5.8), in a yield of 81 %. The bromide was converted into the iodide by means of sodium iodide in acetone. The reaction between the iodide and the sodium derivative of diethyl methylmalonate, followed by saponification and decarboxylation, gave a mixture of 2D, 4D,6D- and 2L,4D,6D-trimethylnonacosanoic acids in a yield of 72 %. The methyl esters were prepared by means of diazomethane, and the two stereo-isomers separated by means of chromatography on magnesium trisilicate. The separation was followed by measuring the optical rotation. Repeated chromatography finally yielded a levo-rotatory fraction, the rotation of which was unchanged on further chromatography. (—)-Methyl 2D,4D,6D-trimethylnonacosanoate thus obtained had m. p. 37.9—38.2°, $[\alpha]_D^{20}$ —7.2° (c = 5.5).

The melting point of the synthetic ester was about 17° higher than that of methyl mycocerosate (m.p. 20.8—21.2° [1]), and the mass spectra, although very similar, were not identical. It therefore became necessary to reinvestigate the natural product. Gas chromatography on silicone at a temperature of 260° showed the presence of two major and four minor components. The former (designated A and B in the following) had shorter retention times (10.2 and 16.9 min, respectively) than the methyl ester of the synthetic 2,4,6-trimethyl-substituted C_{32}-acid (21.3 min). The mass spectrometric examination of the isolated fractions A and B showed that A was a mixture of two compounds with molecular weights of 452 and 466, respectively. Fraction B (65 % of the total) appeared to consist of a single compound of molecular weight 494. In the diagram of Fig. 1



the point for the compound of molecular weight 452 falls on the same line as those for the methyl esters of the C_{27} and C_{32}-2,4,6-trimethyl-substituted acids. The positions of the compounds of molecular weights 466 and 494 in the diagram indicate that they possess still more branched structures. The mass spectrum of fraction B (M = 494) showed high peaks at m/e = 88 and 101, and very small peaks at m/e = 74, 115, and 157, which indicates methyl side chains at positions 2, 4, and 6. The mass spectrum of the ester suggested the presence of a methyl group also at position 8, but the relevant peaks were small. A comparison between the mass spectra given by the alcohol derived from synthetic methyl 2,4,6-trimethylnonacosanoate and that derived from fraction B provided conclusive evidence, however, that the main component (B) of methyl mycocerosate is the methyl ester of a 2,4,6,8-tetramethyloctacosanoic acid. The mass spectrum of 2,4,6-trimethylnonacosanol-1 shows a series of marked peaks due to hydrocarbon fragments formed by breaking the bonds to the tertiary carbon atoms. The C_{25}, C_{26}, C_{28}, and C_{29} groups of peaks are thus marked, whereas the C_{24}, C_{27}, and C_{30} peaks, which can only arise from fragments formed by simultaneous cleavage of two bonds, are of low height. In the alcohol derived from fraction B, the C_{22}, C_{23}, C_{25}, C_{26}, C_{28}, and C_{29} groups are marked, and the C_{21}, C_{24}, C_{27}, and C_{30} groups of peaks are low. The observed peak height distribution indicates the presence of methyl side chains at positions 21,23,25, and 27 from the hydrocarbon end of the molecule.

The alcohols were prepared on the milligram scale by reduction of the methyl esters by means of lithium aluminium hydride [13]. The alcohol (crude product) from fraction B had m.p. $\sim$ 35°, and alcohol derived from a partially separated mixture of the two stereo-isomeric methyl 2,4,6-trimethylnonacosanoates melted at 53°.

Components corresponding to fractions A and B are present also in the methyl esters derived from the *Test* and the *Canetti* strains of the tubercle bacilli. Our results indicate the occurrence of normal chain acids with 22, 24, 26, and 28 carbon atoms, 2,4,6-trimethyl-substituted acids with 25, 27, and 29 carbon atoms, and 2,4,6,8-tetramethyl-substituted acids with 30, 32, and 34 carbon atoms in the strains studied.

Full details of this work will be published later.

On the Accuracy of Moving-Bomb Calorimetry

III. The Accuracy of Heat of Combustion Data of Sulfur Compounds

STIG SUNNER

Thermochemistry Laboratory, University of Lund, Lund, Sweden*

The method of moving-bomb calorimetry has been shown to give highly reproducible results for sulfur compounds [1]. It has been more difficult, however, to assess the absolute accuracy of the bomb calorimetric data since there may be systematic errors present that defy detection. A reliable check can only be ascertained by a comparison of results obtained with the bomb calorimetric method with those determined in an independent way.

Hubbard and Waddington [2] compared the heat of formation value of propanethiol-2, obtained from heat of combustion experiments with that derived from equilibrium measurements. They found an excellent agreement, indicating the absence of systematic errors in the moving-bomb technique.

Sunner and Wadsö published a check based purely on thermochemical measurements [3]. They took advantage of the fact that thiolacetic acid can be quantitatively hydrolyzed to acetic acid. The heat of hydrolysis was determined as well as appropriate heats of solution and dilution of reactants and reaction products. Thus, the enthalpy change accompanying the idealized reaction

$$CH_3{\cdot}COSH(l) + H_2O(l) \rightarrow CH_3{\cdot}COOH(l) + H_2S(g)$$

was determined to -0.64 ± 0.07 kcal.mole^{-1}.

By combining this value with heat of formation data of water, acetic acid and hydrogen sulfide, a value for the heat of formation of thiolacetic acid could be derived and compared with that obtained from combustion experiments [4]. Unfortunately, the heat of formation of acetic acid was not unambiguously known at the time when Ref.[3] was published. A precise check of the moving-bomb technique by this method had therefore to await an accurate redetermination of the heat of combustion of acetic acid.

Recently, Evans and Skinner have determined the heat of combustion of acetic acid accurately [5]. They calculated therefrom the heat of formation of acetic acid to $\Delta Hf^\circ_{298.16} = -115.72 \pm 0.1$ kcal.mole^{-1}. Using this value, the well-known heat of formation data of water and hydrogen sulfide and the heat of hydrolysis value given above, the heat of formation of thiolacetic acid is found to be

$$\Delta Hf^\circ_{298.16} = -51.58 \pm 0.1 \text{ kcal.mole}^{-1}.$$

This datum has to be compared with the heat of formation of thiolacetic acid obtained from combustion calorimetry:

$$\Delta Hf^\circ_{298.16} = -51.5 \pm 0.2 \text{ * kcal.mole}^{-1}.$$

The close agreement between the two results is additional strong evidence to support the contention that the moving-bomb calorimetric method as used for sulfur compounds does not involve significant, systematic errors.

Oxidation by Partially Hydrolyzed Polysaccharides

KALE JUVA and EINO KULONEN

Department of Medical Chemistry, University of Turku, Finland

When certain polysaccharides are hydrolyzed partially with hydrochloric acid in sealed tubes compounds are formed which catalyze the oxidation of many aromatic substances (*e.g.* phenol, *p*-phenylenediamine), especially in the presence of hydrogen peroxide [1]. The chemical nature of the catalysts is unknown, but they are acidic and contain a carbonylic group [2]. Hydrogen peroxide degrades hyaluronic acid [3] in the presence of ascorbic acid but no catalyst is formed after this "oxidative depolymerization" (see below). The oxidizing ability may contribute in the production of humins and other artefacts in hydrolyzates. For example, an increased oxidation of methionine in acid hydrolysis in the presence of carbohydrates has been described [4].

For *testing* equal volumes of the solutions in question, 1.5 % hydrogen peroxide and ammoniacal water-saturated phenol or fresh aqueous 1 % *p*-phenylenediamine (Merck) were mixed in test tubes. Controls were run with water instead of hydrolyzate. The results were recorded after 1 h at room temperature, either visually or with a spectrophotometer at 500 mμ.

The *partial hydrolyzate* was made with 2 N HCl (0.33 % of polysaccharide) keeping the sealed tubes overnight at 100°C. The acid was removed by repeated evaporations on the water bath. The catalyzing agent was dialysable. The catalytic activity is dependent on the degree of polymerization.

Ascorbic acid did not influence the reaction in this system, even when added 2 h before the *p*-phenylenediamine.

The *hyaluronate* complex used in the present investigation was prepared from umbilical cords by 1 % NaCl extraction, precipitation with "Cetavlon", solution in 1.25 M sodium chloride and fractional precipitation by lowering the salt concentration below 0.3 M. Cetavlon was removed with Fuller's earth and the solution lyophilized [5]. Before the lyophilization the fluid contained dry matter 2.6 mg/ml, uronic acid (Dische) 1.07 mg/ml, glucosamine (Blix) 0.45 mg/ml, and protein 0.62 mg/ml.

The *depolymerization with ascorbic acid* was performed in 0.2 % solution of hyaluronate, buffered to pH 6.8 with 0.0067 M phosphate and containing 0.8 % NaCl. After addition of 0.020 % H_2O_2 no change occurred, but after further addition of 0.050 % ascorbic acid the relative viscosity fell in 20 min to a tenth ($\eta_{rel} = 1.5$). The fluid was dialyzed against tap water and lyophilized. The partial hydrolyzate from this degraded preparation had no catalytic activity.

Purification of the catalyst was carried out from 82.2 mg of HCl-treated material using a cellulose powder (Whatman) column (28 × 2 cm) and butanol (almost saturated with water):acetic acid (19:1) as the solvent [6]. Five ml fractions were collected and screened with spot tests. Fractions No. 20—30 and 170—185 were positive with aniline phthalate, but with ammoniacal phenol brown spots were obtained

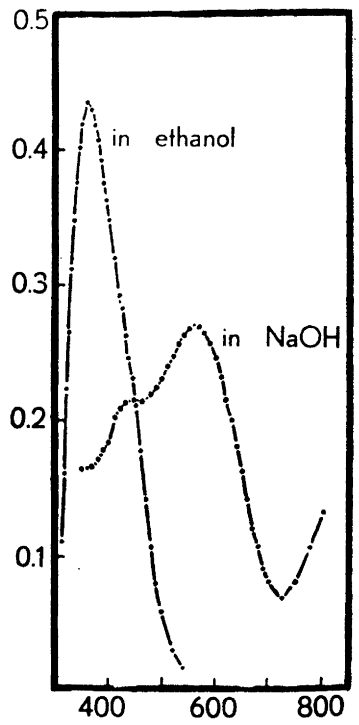

Fig. 1. The absorption spectra of the 2,4-dinitrophenylderivative of the isolated preparation. Abscissa: wavelength in mμ, ordinate: extinction.

only from fractions 30—50. They were combined and evaporated.

The residue weighed 5.6 mg and was hydrolyzed in 0.56 ml N sulfuric acid for 5 h at 100°C. The digest was neutralized with $Ba(OH)_2$ to pH 5.8. The supernatant was evaporated, the residue dissolved in 0.05 ml of water and chromatographed with butanol:pyridine:water (5:3:2). No distinct carbohydrate spots were obtained with aniline phthalate, but with ninhydrin several spots, one coinciding with that of glucosamine. The test with aniline for furfurol [7] was negative. 2,4-Dinitrophenylhydrazine (dissolved into 2 N H_2SO_4) gave a precipitate, which was collected and submitted to spectroscopic examination (Fig. 1). The sharp change to violet in alkali seems worthy of mention.

Studies on Ester Sulfates

1. Application of Two-Dimensional Paper Chromatography in Studies on the Biosynthesis of Ester Sulfates

ANDERS VESTERMARK and HARRY BOSTRÖM

Department of Metabolic Research, the Wenner-Gren Institute of Experimental Biology, Stockholm, Sweden

In several recent biochemical studies on ester sulfate compounds, great advantage has been taken of the selective incorporation of ^{35}S-sulfate in these compounds. Mainly on the grounds of their high sensitivity, different isotope methods, such as autoradiography of electropherograms on body fluids and tissue extracts, have been used successfully in this field.

A somewhat more detailed picture of the sulfatation of different compounds in various *in vitro* systems could be expected to result from the use of two-dimensional paper chromatography combined with autoradiography. For this reason, a screening study along these lines was undertaken. Some observations made during this work will be briefly reported in the following.

In one type of experiment, 2-mg slices of liver from albino rats were incubated in small test tubes in 100 µl of Krebs-Ringer bicarbonate solution and 10 µl of a solution of ^{35}S-labeled sulfate containing 10 mc/ml. A gas mixture consisting of 93.5 % of oxygen and 6.5 % of carbon dioxide was insufflated into each test tube during incubation.

In another type of experiment, 40 µl of a cell-free supernatant of liver homogenate prepared according to Roy [1] was mixed with 50 µl of a buffer solution, containing equal parts of 0.3 M KH_2PO_4/K_2HPO_4 buffer, pH 6.8, 0.03 M K_2SO_4 and 0.005 M $MgCl_2$. This mixture was combined with 10 µl of 0.04 M ATP and 10 µl of the ^{35}S-labeled sodium sulfate solution.

When these types of sulfatation system were used for studies on sulfatation of different substances, 10 µl of a 10 mM solution of the substance in alcohol or water was added to an empty test tube. The solvent was evaporated *in vacuo*. The slices or supernatant systems were added to this tube.

In each series of experiments, one tube with 10 µl of water and another with 10 µl of alcohol, to which the relevant sulfatation system was added, were run as controls.

In all experiments, 5 µl-samples of the medium were taken 45 and 120 min after starting incubation, for two-dimensional ascending chromatography according to Datta, Dent and Harris [2]. Solvent I: Phenol-water (400 g + 100 g). A beaker containing concentrated H_3N was placed in the chromatographic tank. Solvent II: Butanol — 2 N H_3N (250 ml + 250 ml).

After drying the papers in a stream of hot air from an electric hair-drying fan, the chromatograms were subjected to autoradiography on Gevaert Curix X-ray film, exposed for one week in a wooden screw press and then developed with Gevaert G 150.

Studies on Ester Sulfates

1. Application of Two-Dimensional Paper Chromatography in Studies on the Biosynthesis of Ester Sulfates

ANDERS VESTERMARK and HARRY BOSTRÖM

Department of Metabolic Research, the Wenner-Gren Institute of Experimental Biology, Stockholm, Sweden

In several recent biochemical studies on ester sulfate compounds, great advantage has been taken of the selective incorporation of ^{35}S-sulfate in these compounds. Mainly on the grounds of their high sensitivity, different isotope methods, such as autoradiography of electropherograms on body fluids and tissue extracts, have been used successfully in this field.

A somewhat more detailed picture of the sulfatation of different compounds in various *in vitro* systems could be expected to result from the use of two-dimensional paper chromatography combined with autoradiography. For this reason, a screening study along these lines was undertaken. Some observations made during this work will be briefly reported in the following.

In one type of experiment, 2-mg slices of liver from albino rats were incubated in small test tubes in 100 µl of Krebs-Ringer bicarbonate solution and 10 µl of a solution of ^{35}S-labeled sulfate containing 10 mc/ml. A gas mixture consisting of 93.5 % of oxygen and 6.5 % of carbon dioxide was insufflated into each test tube during incubation.

In another type of experiment, 40 µl of a cell-free supernatant of liver homogenate prepared according to Roy [1] was mixed with 50 µl of a buffer solution, containing equal parts of 0.3 M KH_2PO_4/K_2HPO_4 buffer, pH 6.8, 0.03 M K_2SO_4 and 0.005 M $MgCl_2$. This mixture was combined with 10 µl of 0.04 M ATP and 10 µl of the ^{35}S-labeled sodium sulfate solution.

When these types of sulfatation system were used for studies on sulfatation of different substances, 10 µl of a 10 mM solution of the substance in alcohol or water was added to an empty test tube. The solvent was evaporated *in vacuo*. The slices or supernatant systems were added to this tube.

In each series of experiments, one tube with 10 µl of water and another with 10 µl of alcohol, to which the relevant sulfatation system was added, were run as controls.

In all experiments, 5 µl-samples of the medium were taken 45 and 120 min after starting incubation, for two-dimensional ascending chromatography according to Datta, Dent and Harris [2]. Solvent I: Phenol-water (400 g + 100 g). A beaker containing concentrated H_3N was placed in the chromatographic tank. Solvent II: Butanol — 2 N H_3N (250 ml + 250 ml).

After drying the papers in a stream of hot air from an electric hair-drying fan, the chromatograms were subjected to autoradiography on Gevaert Curix X-ray film, exposed for one week in a wooden screw press and then developed with Gevaert G 150.

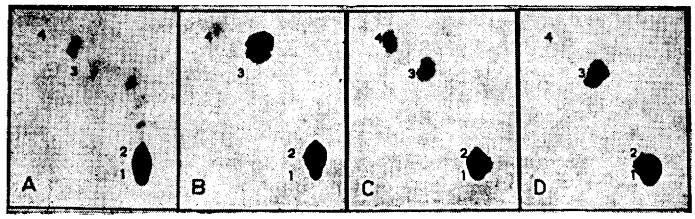

Fig. 1. Chromato-autoradiogram on 5-μl samples of the incubation mixtures after 2 h incubation. A. Slices system (see text) + 10 μl of water. B. Slices system + 10 μl of ethanol. C. Cell-free system + 10 μl of water. D. Cell-free system + 10 μl of ethanol.

Paper electrophoresis (0.075 M sodium acetate-acetic acid buffer, pH 5.5, 30 V/cm, 1 h) was also performed on 5-μl samples of the incubation medium.

In the control experiments with the slices system (Fig. 1, chromatograms A and B), the following basic pattern was obtained. In addition to a spot, No. 1, obtained where the sample was placed on the paper, and the inorganic sulfate spot, No. 2, two other spots, Nos. 3 and 4, were consistently present. The control with water (A) showed a weak No. 3 spot and a distinct No. 4. The control with ethanol (B) showed the reverse picture, a weak No. 4 and a very strong No. 3.

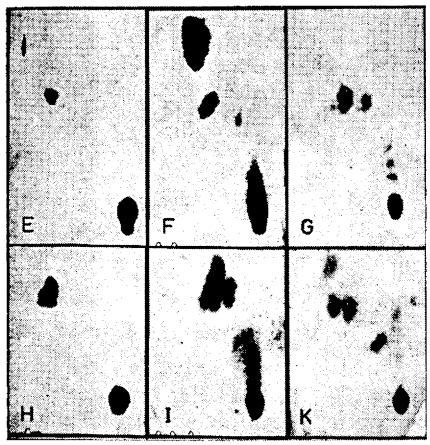

Fig. 2. Ester sulfate pattern of the incubation media after addition to the slices system of androsterone (E), α-naphthylamine (G) and β-naphthylamine (I) as compared to the corresponding pattern obtained with the same substances in the cell-free system (F, H, K), respectively.

In the supernatant system as well, the presence of small amounts of ethanol (D) resulted in increased strength of No. 3 and a decrease in concentration of No. 4, as compared to the water controls (C).

Addition of amines, steroids or phenols to either of the sulfatation systems used was generally followed by the appearance of one or several new spots in the chromatograms, as exemplified in Figs. 2 and 3 (chromatograms E—S).

Thus, both in the slices system (Fig. 2 E) and in the cell-free medium (F), one new distinct spot appeared when androsterone was added to the incubation mixtures. In similar studies, ester sulfates of several other steroids as well have been obtained [3].

Of the two isomeric amines tested, α-naphthylamine gave one new single spot in the cell-free medium (G), whereas at least two ester sulfates were formed in the presence of liver slices. More complex patterns were obtained in both systems with β-naphthylamine.

A series of new unidentified ester sulfates (Fig. 3) was also obtained when adrenaline (L) or noradrenaline (N) was added to the slices. Somewhat less complicated patterns were produced by these substances in the cell-free system (M and O).

A marked difference between the two systems was also observed in the presence of thymol, which gave two well-marked ester sulfates in the slices system (P), but only one in the cell-free medium (Q).

No evidence was obtained of the formation of tyrosine-O-sulfate, known to occur in human urine [4], in either of the sulfatation systems used (R and S).

When high voltage electrophoresis was applied to samples of all the incubation media mentioned above, separation of some of the

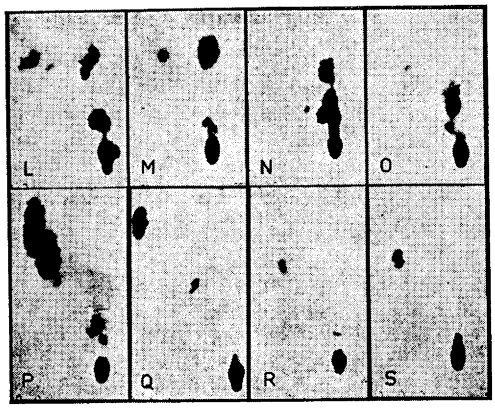

Fig. 3. Ester sulfate pattern found in the presence of adrenaline (L), noradrenaline (N), thymol (P) and tyrosine (R), in the slices system and the cell-free system (M, O, Q and S), respectively.

Fig. 4. Formation of different ^{35}S-labeled compounds *in vitro* in a cell-free or a slices system of rat liver, in the presence of various possible sulfate acceptors, as studied by high voltage electrophoresis and autoradiography. The black zone at the top of the picture corresponds to the position of inorganic sulfate. The various experiments are marked as in Figs. 1—3.

labeled compounds was also obtained. Thus, in the basic liver supernatant pattern, three distinct spots (C) were visualized, as compared to only two in the chromatographic system (Fig. 1 C). In the presence of ethanol (D), a shift occurred, consisting of a decrease in concentration of the slowest moving fraction, and an increase in the fastest moving compound. A similar phenomenon was observed in the slices system (A and B).

When adrenaline was present in the supernatant system (M), one radioactive spot, probably corresponding to a monosulfate of adrenaline, moved very slowly. Other compounds, which might have been derivatives of adrenaline containing two or three sulfate groups, moved faster. In the slices system (L), the slow moving spot was found, in addition to two other ^{35}S-labeled compounds.

With noradrenaline as well, a slow moving compound was synthesized in both systems (O:cell-free, N:slices). A few other labeled compounds were also recognized in these cases.

The results of this screening study on the ability of a system of liver slices, or of a cell-free supernatant of liver homogenates, to activate sulfate groups and transfer them to different types of acceptors are in good agreement with those reported by other authors on phenols [5-7], steroids [1,8,9] and amines [10].

Features of special interest in our study were the complicated ester sulfate pattern found in the presence of catechol amines, the failure of sulfatation of free tyrosine in either of the systems, and the interesting shift in the basic ester sulfate pattern in both systems in the presence of small amounts of ethanol (Fig. 1).

The particular value of the chromato-autoradiographic method used in the present study seems to be that a good overall picture of the occurrence of different types of transferring enzymes and sulfate acceptors in different sulfatation systems is obtained in small-scale experiments.

Mass Transfer by Forced Laminar Convection at Plane Plate Electrodes

GÖSTA WRANGLÉN

Division of Applied Electrochemistry, Royal Institute of Technology, Stockholm 70, Sweden

The investigation of the influence of liquid flow on electrode processes is of great interest for industrial electrolysis and for the theory of metallic corrosion in flowing liquids. Heat and mass transfer at a plane plate in longitudinal flow under laminar conditions have been treated by various authors [1-3] under the assumption of a uniform surface temperature and concentration, respectively. As far as electrolysis is concerned, this postulate probably applies only for limiting current conditions at the electrodes. In normal electrolysis with a uniform current density, the actual boundary condition is a uniform concentration gradient at the electrode surface. This case or the corresponding heat transfer problem does not seem to have been considered earlier.

The notation used in an earlier communication [4] is employed, except that x is taken to mean the distance in the flow direction from the leading edge of the electrodes and u denotes the flow velocity in the x-direction in the boundary layer. Furthermore, l is the length of the electrode in the flow direction and $\mathrm{Re}_x = \frac{u_b x}{\nu}$ is the local Reynolds number. The relevant boundary layer equations in integrated form are

labeled compounds was also obtained. Thus, in the basic liver supernatant pattern, three distinct spots (C) were visualized, as compared to only two in the chromatographic system (Fig. 1 C). In the presence of ethanol (D), a shift occurred, consisting of a decrease in concentration of the slowest moving fraction, and an increase in the fastest moving compound. A similar phenomenon was observed in the slices system (A and B).

When adrenaline was present in the supernatant system (M), one radioactive spot, probably corresponding to a monosulfate of adrenaline, moved very slowly. Other compounds, which might have been derivatives of adrenaline containing two or three sulfate groups, moved faster. In the slices system (L), the slow moving spot was found, in addition to two other ^{35}S-labeled compounds.

With noradrenaline as well, a slow moving compound was synthesized in both systems (O:cell-free, N:slices). A few other labeled compounds were also recognized in these cases.

The results of this screening study on the ability of a system of liver slices, or of a cell-free supernatant of liver homogenates, to activate sulfate groups and transfer them to different types of acceptors are in good agreement with those reported by other authors on phenols [5-7], steroids [1,8,9] and amines [10].

Features of special interest in our study were the complicated ester sulfate pattern found in the presence of catechol amines, the failure of sulfatation of free tyrosine in either of the systems, and the interesting shift in the basic ester sulfate pattern in both systems in the presence of small amounts of ethanol (Fig. 1).

The particular value of the chromato-autoradiographic method used in the present study seems to be that a good overall picture of the occurrence of different types of transferring enzymes and sulfate acceptors in different sulfatation systems is obtained in small-scale experiments.

Mass Transfer by Forced Laminar Convection at Plane Plate Electrodes

GÖSTA WRANGLÉN

Division of Applied Electrochemistry, Royal Institute of Technology, Stockholm 70, Sweden

The investigation of the influence of liquid flow on electrode processes is of great interest for industrial electrolysis and for the theory of metallic corrosion in flowing liquids. Heat and mass transfer at a plane plate in longitudinal flow under laminar conditions have been treated by various authors [1-3] under the assumption of a uniform surface temperature and concentration, respectively. As far as electrolysis is concerned, this postulate probably applies only for limiting current conditions at the electrodes. In normal electrolysis with a uniform current density, the actual boundary condition is a uniform concentration gradient at the electrode surface. This case or the corresponding heat transfer problem does not seem to have been considered earlier.

The notation used in an earlier communication [4] is employed, except that x is taken to mean the distance in the flow direction from the leading edge of the electrodes and u denotes the flow velocity in the x-direction in the boundary layer. Furthermore, l is the length of the electrode in the flow direction and $\mathrm{Re}_x = \frac{u_b x}{\nu}$ is the local Reynolds number. The relevant boundary layer equations in integrated form are

$$\frac{d}{dx}\int_0^{\delta_h} u(u_b-u)\mathrm{d}y = \nu\left(\frac{\mathrm{d}u}{\mathrm{d}y}\right)_{y=0} \quad (1)$$

$$\frac{\mathrm{d}}{\mathrm{d}x}\int_0^{\delta_d} u/c_b - c/\mathrm{d}y = j \quad (2)$$

with the boundary conditions

$$u = 0,\ \frac{dc}{\mathrm{d}y} = \frac{j}{D} \text{ for } y = 0$$

$$u = u_b \text{ for } y \geq \delta_h,\ c = c_b \text{ for } y \geq \delta_d$$

For the velocity profile we assume [1]

$$\frac{u}{u_b} = \frac{3}{2}\frac{y}{\delta_h} - \frac{1}{2}\frac{y^3}{\delta_h^3} \quad (3)$$

and obtain from (1)

$$\delta_h = \left(\frac{280\ \nu\ x}{13\ u_b}\right)^{\frac{1}{2}} \quad (4)$$

The concentration profile is approximated by the equation

$$/c_b - c/ = \frac{2}{3}\frac{j\delta_d}{D}\left[1 - \frac{3}{2}\frac{y}{\delta_d} + \frac{1}{2}\frac{y^3}{\delta_d^3}\right] \quad (5)$$

With $\frac{\delta_d}{\delta} = r$ and considering that $r < 1$ for high Schmidt numbers one obtains

$$\int_0^{\delta_d} u/c_b - c/\mathrm{d}y = \frac{u_b j}{10D}\, r^3\ \delta_h^2 \quad (6)$$

and hence

$$\frac{u_b}{10D}\frac{\mathrm{d}}{\mathrm{d}x}\,(r^3\,\delta_h^2) = 1 \quad (7)$$

Although δ_h and δ_d are functions of x, r may be considered to be independent of x. Hence, using eqn. (4)

$$r^3 = \frac{13}{28}\frac{D}{\nu} \quad (8)$$

Finally, we obtain for *uniform current density:*

$$= 0.774\ \mathrm{Sc}^{-1/3},\ \delta_d = 3.59\ D^{1/3}\,\nu^{1/6}\left(\frac{x}{u_b}\right)^{\frac{1}{2}},\ \delta_\mathrm{N} = \frac{2}{3}\,\delta_d$$

$$\Delta c_x = 2.39\ j\ D^{-2/3}\,\nu^{1/6}\left(\frac{x}{u_b}\right)^{\frac{1}{2}},\ \Delta c_\mathrm{av} = \frac{2}{3}\,\Delta c_l$$

$$\mathrm{Nu}_x = 0.417\ \mathrm{Re}_x^{\frac{1}{2}}\,\mathrm{Sc}^{1/3},\ \mathrm{Nu}_\mathrm{av} = 0.625\ \mathrm{Re}_l^{\frac{1}{2}}\,\mathrm{Sc}^{1/3}$$

An analogous treatment for *limiting current density* gives:

$$r = 0.976\ \mathrm{Sc}^{-1/3},\ \delta_d = 4.53\ D^{1/3}\,\nu^{1/6}\left(\frac{x}{u_b}\right)^{\frac{1}{2}},\ \delta_\mathrm{N} = \frac{2}{3}\,\delta_d$$

$$i_{\mathrm{lim},x} = 0.331\ \frac{zF}{1-t}\,\Delta c\ D^{2/3}\ \nu^{-1/6}\left(\frac{u_b}{x}\right)^{\frac{1}{2}},\ i_{\mathrm{lim,av}} = 2\,i_{\mathrm{lim},l} \quad (2)$$

$$\mathrm{Nu}_x = 0.331\ \mathrm{Re}_x^{\frac{1}{2}}\ \mathrm{Sc}^{1/3},\ \mathrm{Nu}_\mathrm{av} = 0.662\ \mathrm{Re}_l^{\frac{1}{2}}\ \mathrm{Sc}^{1/3}$$

According to an exact numerical solution [3], the coefficient for $i_{\mathrm{lim},x}$ and Nu_x is 0.332.

In both cases, one obtains for the concentration difference of an inert conducting electrolyte, such as sulphuric acid in copper refining,

$$/\Delta c^1/ = \frac{t^1}{1-t}\left(\frac{D}{D^1}\right)^{2/3} /\Delta c/ \quad (9)$$

where t^1 and D^1 are the transference number and diffusion coefficient of the inert electrolyte.

Forced laminar flow without disturbing free convection is probably best realized with bipolar horizontal electrodes, which act as anodes on the upper side and as cathodes on the under side. Vertical plate electrodes are, however, of greater practical interest in view of the attempts that are being made to develop processes for the electrodeposition of metals at high current densities in a flowing electrolyte [5]. In this latter case, free convection cannot be neglected, except at very high velocities for the forced flow.

A Surface-balance Study of the Structural Relationships between Cryptopimaric, Dextropimaric, and *Iso*dextropimaric Acids

HENRIK H. BRUUN

Institute of Wood Chemistry, Åbo Akademi, Åbo, Finland
and

EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, Uppsala, Sweden

In a surface-balance study of monomolecular layers of rosin acids carried out by one of us in 1953 [1], it was found that in a compressed monolayer a molecule of dextropimaric acid at 2.5° occupied an area approximately 1.6 Å^2 larger than that taken up by an *iso*dextropimaric acid molecule. Since, according to the opinion held at that time, these acids were believed to differ from each other only in the steric orientation of the vinyl and methyl groups at carbon-7 [2-4] *, the observed difference in molecular area was taken to justify certain conclusions about the configurations at this position in the two acids. The configuration that may be expected to occupy the larger area in the monolayer and which can be established by reference to molecular models was that in which the vinyl group is quasi-axially, and the methyl group quasi-equatorially, oriented. This configuration must thus be ascribed to dextropimaric acid and the opposite configuration to *iso*dextropimaric acid [1]. During recent years, however, convincing evidence has been collected which indicates that the acids also differ in configuration at carbon-13 [8-12]. The true C-7 epimer of dextropimaric acid seems to be cryptopimaric acid[11,12], an acid first described in 1937 [13]. These new developments, which are illustrated in Fig. 1, do not invalidate the conclusions drawn about the orientation of the groups at carbon-atom 7 in dextro- and *iso*dextropimaric acids, since the molecular areas taken up by the *iso*-dextropimaric-acid molecules with the old and new configurations cannot be expected to differ appreciably. Molecular models of the structures in Fig. 1 are shown in Fig. 2. In view of the importance of the structure of cryptopimaric acid when determining the structural relationships of the pimaric acids, it was considered desirable to supplement the previous monolayer data with similar data for cryptopimaric acid. Through the courtesy of Prof. H. Imamura of Tokyo in providing us with a sample of cryptopimaric acid, we have been able to measure the monolayer characteristics of the acid. At the same time we have repeated the measurements on the other two pimaric acids, using pure samples obtained from Dr. R. V. Lawrence, Olustee, Florida.

The surface-balance pressure-area curves of the three pimaric acids were recorded under identical conditions, and are reproduced in Fig. 3. The monolayers are seen to be similar in their mechanical properties (they are typical liquid condensed monolayers), and in all cases the monolayer collapses at approximately the same surface pressure, *viz.* 19—20 dyn/cm. The areas (Å^2) per molecule at the collapse point are:

	3°	20°
Dextropimaric acid	42.4	42.9
*Iso*dextropimaric acid	39.2	40.5
Cryptopimaric »	39.2	41.0

* See also Refs.[5-7]

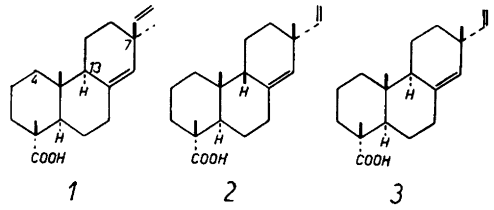

Fig. 1. Structures of *1* dextropimaric, *2 iso*dextropimaric and *3* cryptopimaric acids (see text).

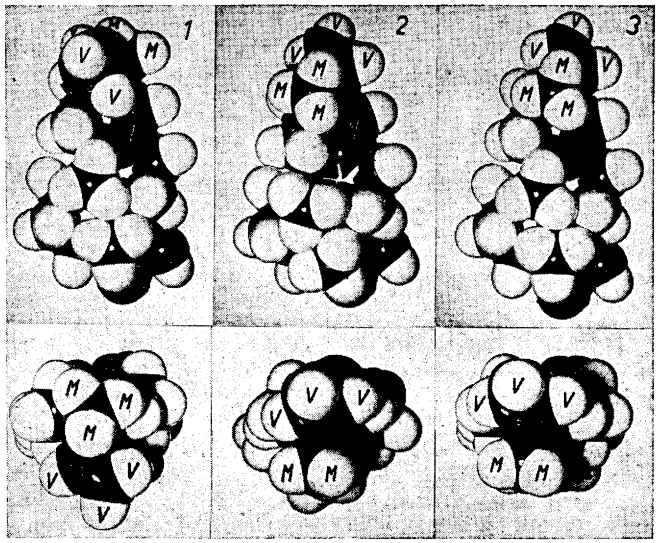

Fig. 2. Molecular models of *1* dextropimaric, *2* *iso*dextropimaric and *3* cryptopimaric acids based on the structures shown in Fig. 1. Upper row, viewed from the front. Lower row, viewed from above. The vinyl and methyl groups at C—7 are indicated by V and M, respectively.

The molecular areas taken up by crypto- and *iso*dextropimaric acid at 3° and 20° are not appreciably different, but they are 2—3 Å² smaller than the areas taken up by dextropimaric acid. These results confirm the previous findings that dextropimaric acid requires a distinctly greater area than *iso*dextropimaric acid in compressed monolayers [1].

The monolayer measurements suggest that cryptopimaric and *iso*dextropimaric acid both possess the same configuration at C-7, *i. e.* they have a quasi-equatorial vinyl group and a quasi-axial methyl group. This is in agreement with recent infra-red data [12], which have shown that the vinyl group has a different orientation in dextropimaric acid than in crypto- and *iso*dextropimaric acids.

Some of the area values found in the present study are slightly lower than those reported in the earlier study [1]. This is

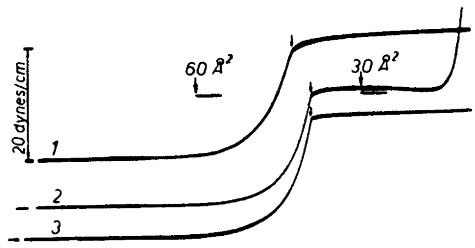

Fig. 3. Surface-balance (pressure-area) curves of *1* dextropimaric, *2* *iso*dextropimaric, and *3* cryptopimaric acids. Substrate, 3 M NaCl, pH 2 (HCl). Temperature, 3.0°C. The points from which the collapse areas were read are indicated by small arrows.

probably not due to the different type of surface balance used (for comparative data obtained with the Wilhelmy-Dervichian and the Mikrokator surface-balances, see Ref.[15]), but due to the fact that the samples of rosin acids used in the present study had been purified by chromatography and were exceptionally pure.

In contrast to the pressure-area curves for the other pimaric acids, the curve for *iso*dextropimaric acid exhibits an ascending part due to a relatively rapid solidification of the film under further compression after the collapse of the monolayer (Fig. 3). For further details relating to this interesting phenomenon, which is obviously related to some peculiarity in the structure of the *iso*dextropimaric acid molecule, see Ref.[16]

Experimental part. The pressure-area curves were obtained with the recording Mikrokator Balance [14]. The rate of compression was approximately 2 cm/min. The substrate was a solution of 3 M sodium chloride (Merck, pro analysi, ignited) brought to pH 2 by addition of hydrochloric acid. The importance of these conditions, which reduce the solubilities of the acid monolayers and the tendency of the monolayers to undergo collapse, has been demonstrated earlier [1]. The area values were reproducible within ± 0.2 Å^2. Spreading from benzene and from light petroleum (b.p. 60–80°) gave identical results.

For the physical properties of the rosin acids studied, the reader is referred to Ref.[11]

Isolation of Polynuclear Aromatic Hydrocarbons from the Roots of *Chrysanthemum vulgare* Bernh.

ERLING GUDDAL*

Institutt for organisk kjemi, Norges tekniske högskole, Trondheim, Norway

During the investigation of the roots of tansy (*Chrysanthemum vulgare* Bernh.) for the presence of acetylenic compounds [1], one sample collected in the vicinity of the local Gas Works gave a small hydrocarbon fraction with a characteristic ultraviolet spectrum and strong fluorescence, which turned out to be a complex mixture of polynuclear aromatic hydrocarbons.

15 kg of fresh roots were extracted with acetone, and the extracted lipids transferred to light petroleum. From the petroleum soluble material a mixture of sparingly soluble compounds were removed by crystallisation from ether at −10°C. The mother liquor was evaporated to dryness and the residue dissolved in a minimum of hot methanol. This was added to a hot saturated solution of trinitrotoluene in methanol. A yellow crystalline precipitate was formed immediately, and the crystallisation was completed by cooling to −10°C. The mixture of addition compounds was dissolved in benzene and filtered through a

* Present addres: Research Dept., Leo Pharmaceutical Products, Copenhagen, Denmark.

column of highly activated alumina. Evaporation of the benzene left 185 mg of a slightly yellow crystalline mixture of aromatic hydrocarbons. This mixture was dissolved in light petroleum and chromatographed on deactivated alumina.

The mixture showed strong fluorescence even when adsorbed, and the zones could readily be made visible by irradiating the column with an ultraviolet lamp. The fractions obtained were rechromatographed several times, and by this procedure it was possible to obtain spectroscopically pure fractions of anthracene, pyrene, and fluoranthene, the ultraviolet spectra of which were identical with those given in the literature [2]. 2.5 mg of anthracene was obtained as colourless plates with a strong violet fluorescence. It melted at 212–213°C in a sealed tube, not depressed on admixture with authentic anthracene. Further evidence of their identity was furnished by their infrared spectra.

To ensure that these compounds did not originate from adhering soil, a sample of 10 kg of the soil of the same location was extracted with acetone and treated as above. In this case, the splitting of the trinitrotoluene-complexes left 200 mg of a yellow oil, showing no tendency of crystallisation even after prolonged cooling to −10°C. Its ultraviolet spectrum, however, was very similar to that of the crude mixture of aromatic hydrocarbons isolated from the plant material. Since the contamination of the plant material with soil hardly exceeds a few per cent by weight, these findings indicate that some polynuclear aromatic hydrocarbons, although highly toxic to most higher organisms, are actually resorbed by the plant. By extraction of material from areas which are not polluted by the smoke from the Gas Works, it has been shown that these compounds are not normal metabolites of the plant.

Polynuclear aromatic hydrocarbons have previously been isolated from animal tissues in a few cases. Zechmeister and Koe [3] isolated a great number of these compounds from the barnacle *Tetraclita squarosa rubescens*, and Cahnmann and Kuratsune [4] reported similar results from oysters growing in polluted waters. Sula [5] isolated anthracene and benzpyrene from human lung tissue.

The occurrence of naphthalene in plant material has been reported in several cases. Soden and Rojahn [6] found "appreciable amounts" of naphthalene in oil of cloves and storax oil, and Schimmel & Co. isolated the same compound from iris oil [7], and from two samples of Indian costus root oil [8]. These findings have not been confirmed, and may have arisen as a result of a roasting of the roots before distillation [9]. Stoll and Scherrer isolated naphthalene from oakmoss from several localities, and noticed accompanying changes in the amount and composition of terpenes in the lichens [10]. Treibs [11] found naphthalene as a normal constituent of oil of leaf buds of *Betula lenta*, and Sebe [12] found it in rice embryo together with methyl substituted homologues. Regarding the two last findings, nothing can be said concerning the possibilities of smoke contamination, as nothing is said of the origin of the material. It appears that the isolation of higher aromatic hydrocarbons from plant material has not been reported previously.

The author is glad to thank Professor N. A. Sörensen for his interest in this work and for his constant encouragement. This work was carried out under the tenure of a Research Fellowship from *Norges tekniske högskole*.

Nucleotides Containing Amino Acids in Bacteria

J. JONSEN, S. LALAND and I. SMITH-KIELLAND

Department of Biochemistry, The University of Oslo, Blindern, Norway

The importance of nucleic acids in protein synthesis is well established [1,2]. In later years Hoagland *et al.*[3] and others [4-9] have presented evidence for the existence of amino acyl-adenylate compounds and amino acid — RNA complexes [10,11] as intermediates in the biosynthesis of proteins.

Since low molecular nucleotides containing amino acids may act as participants or carriers of amino acids to the active site of protein or peptide synthesis, our laboratory has for some time been actively engaged in the search for such substances in different bacteria, yeasts and mammalian cells under various conditions of growth.

The recent publications by Brown [12] on nucleotidebound peptides from *S.faecalis* and of similar reports [13-15] prompt us to describe some of our work.

As nucleotides containing amino acids might be labile and difficult to extract we have used different extraction procedures.

The present report concerns the isolation of nucleotides containing amino acids from *E. coli* and *B. subtilis* grown under aerobic condition and harvested in the logarithmic growth phase. In the case of *E.coli* the rapidly frozen cells were disrupted in a Hughes bacterial press and extracted with cold 0.6 M perchloric acid at 0°C. The perchloric acid was removed as the potassium salt. The cells of *B. subtilis* were extracted with 90 % phenol at room temperature. The extracted material was displaced into an aqueous solution by the addition of ether. Both extracts were adsorbed on a Dowex 1 column in the formate form and fractionated by gradient elution. Since the presence of weakly charged substances was anticipated, better resolution of these would be obtained by elution with weaker concentrations of formic acid than those usually employed. Details of the gradient chromatography are shown in Figs. 1 and 2.

Fraction III from *E. coli* (Fig. 1) was separated into 4 U.V. absorbing bands by paper chromatography in *iso*butyric acid-N ammonia-EDTA (100:60:1.6). The slowest band was DPN. The second slowest band (III_2) had the same R_F value as AMP-5′

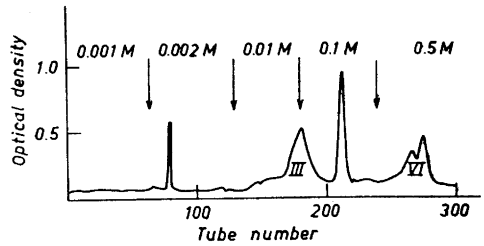

Fig. 1. Gradient elution of *E. coli* extract. Mixing volume 500 ml. Dowex 1 × 8 in the formate form (1.2 cm × 10 cm). Elution was started with 0.001 M formic acid followed by 0.002 M, 0.01 M, 0.1 M and 0.5 M as indicated by the arrows. Volume of individual fractions 5 ml. 2 190 optical units put on column.

in this solvent system and was further investigated. The substance had the same R_F value as AMP-5′ in *n*-butanol-conc. ammonia-water (30:5:15) and *n*-butanol-acetic acid-water (50:25:25). By paper electrophoresis in 0.2 M ammonium acetate buffer pH 5.8 and in borate buffer pH 10, the mobility was identical to that of AMP-5′. In 0.05 M phosphate buffer pH 7.5, AMP-5′ moved slightly ahead of the substance. By elution with 0.1 N HCl from a paper chromatogram in butanol-acetic acid-water the absorption maxima and minima were the same as for AMP-5′, whereas the ratios 280/260 and 290/260 were 0.44 (AMP-5′ 0.25) and 0.22 (AMP-5′ 0.09), respectively. The U. V. absorbing

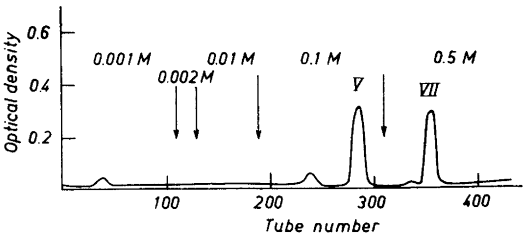

Fig. 2. Gradient elution of *B.subtilis* extract. Volume of mixing flask 500 ml. Dowex 1 × 4 in the formate form (20 cm × 1 cm). Elution was started with 0.001 M-formic acid in the reservoir flask followed by 0.002 M, 0.01 M, 0.1 M and 0.5 M as indicated by the arrows. Volume of individual fractions 5 ml. 216 optical units put on column.

substance gave a ninhydrine negative reaction. Chromatography in *n*-butanol-acetic acid-water (4:1:5) of material hydrolyzed with 6 N HCl for 18 h at 120°C gave four ninhydrine positive spots with the R_F values 0.43 (alanine 0.47), 0.35 (glutamic acid 0.36), 0.29 (glycine 0.29) and 0.15.

After hydrolysis with N HCl for one hour at 100°C adenine was identified and three ninhydrine spots (R_F 0.31, 0.26 and 0.14) were found by chromatography in *n*-butanol-acetic acid-water.

The elution diagram of *B. subtilis* is seen in Fig. 2. Each of the fractions V and VII were purified by successive chromatography in *iso*butyric acid-N ammonia-EDTA (100:60:1.6), ethanol-M ammonium acetate pH 7.5 (70:30), 0.1 M phosphate buffer pH 6.8-ammonium sulphate-*n*-propanol (Pabst) and gave only one U.V. absorbing spot with the same R_F value as AMP-5′ in these solvent systems.

After purification in the third solvent, the eluates were absorbed on charcoal and eluted with ethanol-ammonia. After freeze-drying, their spectra were determined in 0.1 N HCl and compared with AMP-5′ treated in the same way.

Fractions V, VII and AMP-5′ had the same absorption maxima (257 mμ) and minima (232 mμ), whereas the 280/260 ratios were: 0.33, 0.32, and 0.25, respectively. By paper electrophoresis in 0.2 M ammonium acetate buffer pH 5.8 fraction V had 33 % and fraction VII 85 % of the mobility of AMP-5′.

After hydrolysis with 6 N HCl for 20 h at 120°C 10 ninhydrine positive spots were found by chromatography in *n*-butanol-acetic acid-water (50:25:25).

The following amino acids were tentatively identified: lysine, aspartic acid, glycine, glutamic acid, alanine and valine.

Hydrolysate from substance VII gave four ninhydrine positive spots by chromatography in *n*-butanolformic acid-water (75:13:12). Three of these were tentatively identified as glycine, aspartic acid and alanine.

After hydrolysis in N HCl at 100°C for one hour adenin was identified.

Since the two substances from *E.coli* behave electrophoretically similar to AMP-5′ it is surprising that they are eluted more easily from the column than AMP-5′ (identified in fraction VI). The reason for this is not known for the present time, but the structure of the substances is being investigated.

The substances are possible intermediates in peptide or protein synthesis, but may also be formed by degradation of more complex substances containing nucleotides and amino acids.

A New Acidic Ultraviolet Absorbing Substance Containing Amino Acids in Bacteria, Yeasts and Spore Preparations

J. JONSEN, S. LALAND, I. SMITH-KIELLAND and R. SÖMME

Department of Biochemistry The University of Oslo, Blindern, Oslo, Norway

In recent years nucleotides containing amino acids have been isolated from extracts of mammalian tissues [1] and bacterial cells [2]. In a previous paper [3] we have described such substances from *E. coli* and *B. subtilis* harvested in the logarithmic growth phase. We now wish to report the occurrence and properties of an unidentified substance containing amino acids and with a characteristic ultraviolet absorption spectrum.

The substance has been isolated by gradient elution of cell extracts adsorbed on a Dowex 1 × 8 column in the formate form. Fig. 1 shows a typical elution of an extract from *B. cereus*. The unknown substance was eluted in fraction VII close to CMP-5′ when using 0.5 M formic acid in the reservoir. It was purified by successive paper chromatography and paper electrophoresis.

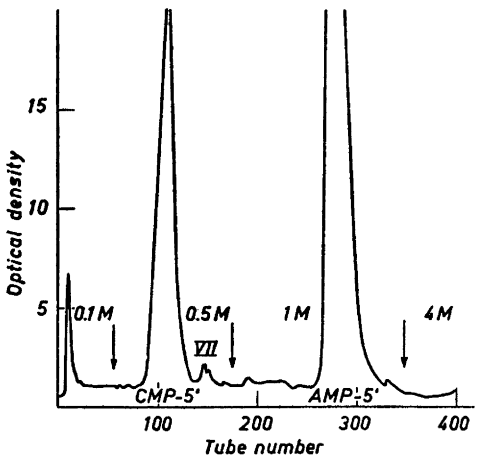

Fig. 1. Part of the gradient elution diagram of *B. cereus* extract. Volume of mixing flask 750 ml. Dowex 1 × 8 in the formate form (3 cm × 18 cm). Elution was started with 0.001 M formic acid in the reservoir flask followed by 0.002 M, 0.02 M, 0.1 M. The arrows indicate concentrations of 0.5 M, 1.0 M and 4 M formic acid. Volume of individual fractions. 29 600 optical units put on column.

The substance has been found in *E.coli*, *B. cereus* spores and vegetative cells and in *Candida tropicalis* var. *lambica*. It was present in acid-soluble extracts from cells disrupted in the Hughes bacterial press and was also released by boiling the cells in distilled water for 10 min. The substance could be adsorbed on activated charcoal and again eluted at 0°C with 50 % ethanol containing 2 % conc. ammonia. The amount varied from 0.3—0.6 % of the total U.V. absorption at 260 mμ fo the crude extracts.

The most conspicuous feature of the ultraviolet absorption spectrum of the highly purified material (Figs. 2 and 3) is the ratio 280/260 in 0.1 N HCl. This is on an average 0.1 and is therefore lower than that of known nucleotides. The ratio 250/260 is usually 0.60. While the point of maximum absorption has constantly been found at 261—262 mμ, the inflection points at about 258 mμ and 268 mμ (Fig. 2) have been more or less pronounced and may be almost missing as shown in Fig. 3. Figs. 2 and 3 represent the extremes of the variation in the absorption spectrum and the variation is not caused by U.V. absorbing impurities since it can be experienced in eluates from two identical chromatograms.

No significant change in the U.V. absorption was found after hydrolysis with formic acid at 175°C for 2 h or with 6 N HCl at 120°C for 18 h.

In paper electrophoresis the unidentified substance moved towards the anode at pH values above pH 4.0. In acetate buffer at pH 5.9 it had approximately the same mobility as orotic acid. In phosphate buffer of pH 7.4 the mobility was about 20 % greater than that of AMP-5′.

The R_F values in paper chromatography was greater than those of the usual nucleotides. For instance in *iso*butyric acid-N-ammonia-EDTA (100:60:1.6) it had R_F 0.78 whereas the R_F for AMP-5′ is 0.52. The mobility was unchanged after hydrolysis. The U.V. absorption of the substance and its hydrolysate could not be reduced by treatment with sodium amalgam [4].

No ribose was found by the orcinol test using 20 min of heating at 100°C. Tests on phosphorus on material hydrolyzed with 6 N HCl were negative.

The purified U.V. absorbing substance gave a negative ninhydrine test while

The substance has been isolated by gradient elution of cell extracts adsorbed on a Dowex 1 × 8 column in the formate form. Fig. 1 shows a typical elution of an extract from *B. cereus*. The unknown substance was eluted in fraction VII close to CMP-5′ when using 0.5 M formic acid in the reservoir. It was purified by successive paper chromatography and paper electrophoresis.

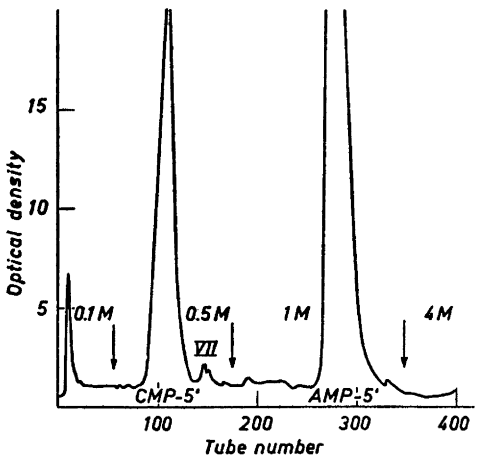

Fig. 1. Part of the gradient elution diagram of *B. cereus* extract. Volume of mixing flask 750 ml. Dowex 1 × 8 in the formate form (3 cm × 18 cm). Elution was started with 0.001 M formic acid in the reservoir flask followed by 0.002 M, 0.02 M, 0.1 M. The arrows indicate concentrations of 0.5 M, 1.0 M and 4 M formic acid. Volume of individual fractions. 29 600 optical units put on column.

The substance has been found in *E.coli*, *B. cereus* spores and vegetative cells and in *Candida tropicalis* var. *lambica*. It was present in acid-soluble extracts from cells disrupted in the Hughes bacterial press and was also released by boiling the cells in distilled water for 10 min. The substance could be adsorbed on activated charcoal and again eluted at 0°C with 50 % ethanol containing 2 % conc. ammonia. The amount varied from 0.3—0.6 % of the total U.V. absorption at 260 mμ fo the crude extracts.

The most conspicuous feature of the ultraviolet absorption spectrum of the highly purified material (Figs. 2 and 3) is the ratio 280/260 in 0.1 N HCl. This is on an average 0.1 and is therefore lower than that of known nucleotides. The ratio 250/260 is usually 0.60. While the point of maximum absorption has constantly been found at 261—262 mμ, the inflection points at about 258 mμ and 268 mμ (Fig. 2) have been more or less pronounced and may be almost missing as shown in Fig. 3. Figs. 2 and 3 represent the extremes of the variation in the absorption spectrum and the variation is not caused by U.V. absorbing impurities since it can be experienced in eluates from two identical chromatograms.

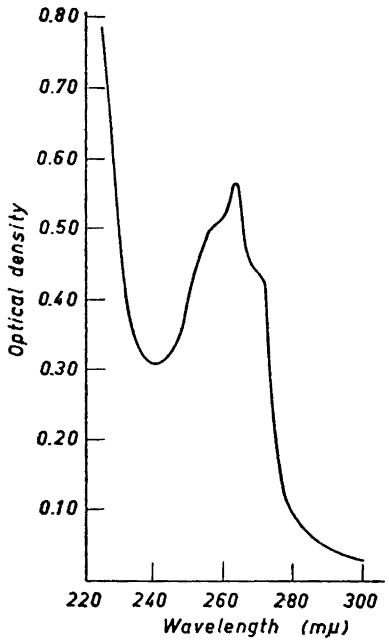
No significant change in the U.V. absorption was found after hydrolysis with formic acid at 175°C for 2 h or with 6 N HCl at 120°C for 18 h.

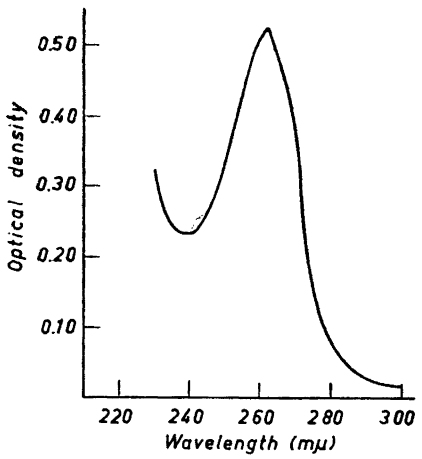
In paper electrophoresis the unidentified substance moved towards the anode at pH values above pH 4.0. In acetate buffer at pH 5.9 it had approximately the same mobility as orotic acid. In phosphate buffer of pH 7.4 the mobility was about 20 % greater than that of AMP-5′.

The R_F values in paper chromatography was greater than those of the usual nucleotides. For instance in *iso*butyric acid-N-ammonia-EDTA (100:60:1.6) it had R_F 0.78 whereas the R_F for AMP-5′ is 0.52. The mobility was unchanged after hydrolysis. The U.V. absorption of the substance and its hydrolysate could not be reduced by treatment with sodium amalgam [4].

No ribose was found by the orcinol test using 20 min of heating at 100°C. Tests on phosphorus on material hydrolyzed with 6 N HCl were negative.

The purified U.V. absorbing substance gave a negative ninhydrine test while





Figs. 2 and 3. Ultra violet absorption spectra in 0.1 N HCl of eluates of spots of the unknown substance from two identical chromatograms developed in ethanol-conc. ammonia-water (80:5:15)

several ninhydrine positive spots split off with varying rates when chromatographed. This seemed to occur particularly when using *n*-butanol-acetic acid-water (40:10:50) as a solvent. After hydrolysis for 18 h at 120°C in 6 N HCl, two dimensional chromatography in *n*-butanol-acetic acid-water (40:10:50) followed by phenol-*m*-cresol-borate buffer pH 8.3 [5] showed ninhydrine positive spots corresponding to the position of serine, glutamic acid, aspartic acid, glycine and alanine together with an unidentified spot.

The stability of the substance to hydrolysis makes the possibility of it being a purine unlikely and the failure of reducing it with sodium amalgam seems to exclude the possibility of a pyrimidine.

The unidentified substance is interesting for several reasons. So far it seems to be distributed widely in the microbial world. The fact that it seems to be a constituent of a bacterial spore may suggest an important function in essential processes of cell development.

The liberation of amino acids by paper chromatography in an acidic solvent suggests a very labile form of amino acid linkages not commonly found in peptides.

Large scale preparation of this substance, together with structural studies and its possible participation in the biosynthesis of proteins or cell wall substances are being carried out.

1,2-Dithiane-4-carboxylic Acid

GÖRAN CLAESON and
ARNE LANGSJOEN*

Chemical Institute, University of Uppsala, Uppsala, Sweden

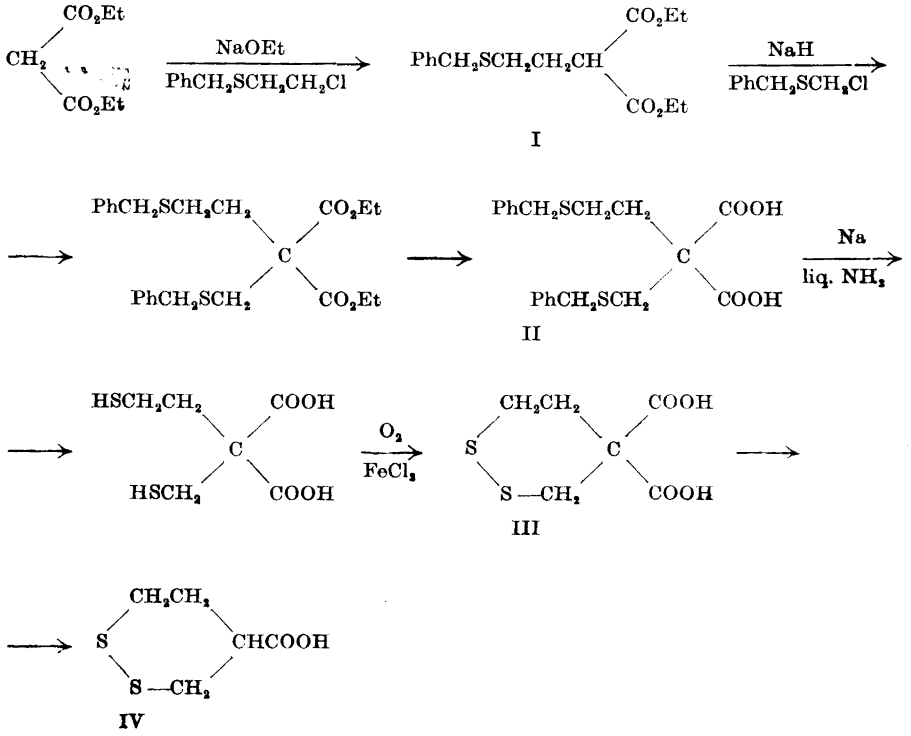
Studies of the stereochemistry of cyclic disulfides presently underway in these laboratories have dictated a need for the compound, 1,2-dithiane-4-carboxylic acid. We wish to report the unequivocal synthesis and preliminary resolution of this compound.

Using the reaction sequence illustrated below, pure 1,2-dithiane-4-carboxylic acid (IV) was obtained in 15 % overall yield from the readily prepared diethyl β-benzylthioethyl-malonate (I).

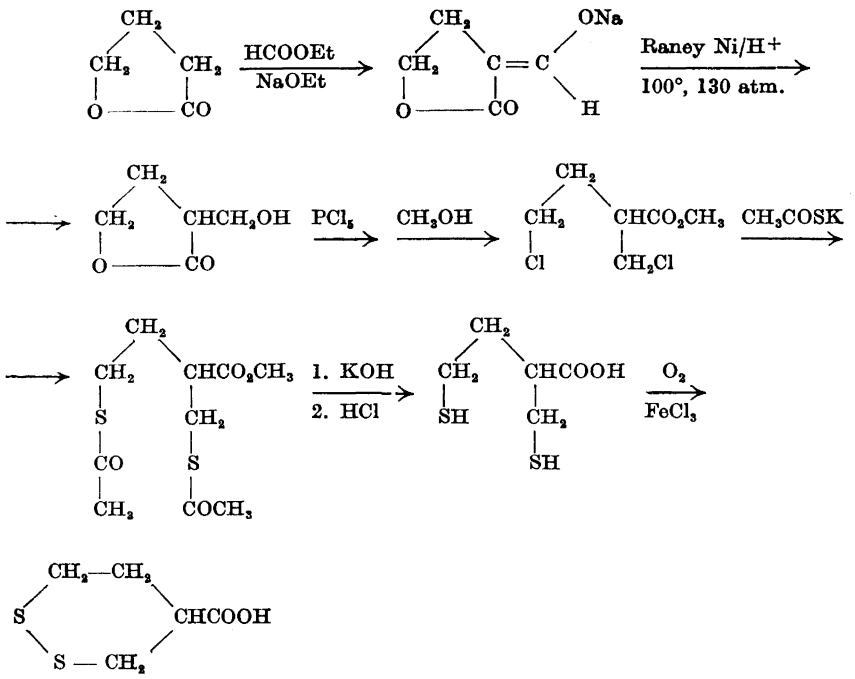
A small amount of IV was also isolated from among the products resulting when γ-butyrolactone was subjected to the following series of reactions (see p. 841). The presence of active hydrogen in β-position to sulphur, however, is known to favor disproportionation reactions under alkaline conditions [1], and these, together with thiolactone formation and polymerization reactions permitted very meager success with this synthesis.

A partial resolution of 1,2-dithiane-4-carboxylic acid has been accomplished.

Experimental. β-Benzylthioethyl-benzylthiomethylmalonic acid (II). β-Benzylthioethyl chloride and diethyl α-benzylthioethylmalonate (I) were prepared by the methods of du Vigneaud and Brown [2]. The pure monoalkyl ester (I), b.p. 176—178°/1 mm, was obtained in 56 % yield from diethyl malonate. (No physical constants were reported for compound I in Ref.[2]) Benzylthiomethyl chloride (b.p. 116.5—117.5°/8 mm) was obtained in 54 % yield using the method of Böhme, Fisher and Frank [3] at room temperature.



* Present address, Gustavus Adolphus College, St. Peter, Minnesota.



IV

A solution of 23.5 g (0.0755 mole) of diethyl β-benzylthioethylmalonate (I) in 20 ml of dry toluene was added dropwise and with stirring to 1.9 g (0.0793 mole) of sodium hydride suspended in 40 ml of dry toluene. The evolution of hydrogen had stopped after 5.5 h at 70°, and a solution of 13 g (0.0755 mole) of benzylthiomethyl chloride in 20 ml of toluene was added. The reaction mixture was stirred at 75° for 63 h (shorter reaction times proved to be insufficient). The toluene was removed under reduced pressure, and the crude ester saponified directly by refluxing for 4 h with a solution of 16 g (0.4 mole) of sodium hydroxide in 80 ml of water and 50 ml of ethanol. The alcohol was removed under reduced pressure, and the cooled, heterogeneous residue extracted with three 50 ml portions of ether. The water soluble remainder was acidified to pH 4 with 50 % ice-hydrochloric acid and the resulting yellow oil extracted with two 100 ml portions of benzene. The crude yield of (II) after removal of the benzene under reduced pressure at room temperature was 21 g (71 %). White radial clusters of needles were obtained after digestion in 85 % formic acid and repeated crystallization from petroleum ether-ether. M. p. 101.8–102.5° with evolution of CO_2 at 122°. Equiv. wt. calc. 195.3; found 201.0.

It is interesting to note that the ether extracts, upon evaporation and recrystallization from alcohol produced 2.8 g (28 % from benzylthiomethyl chloride) of dibenzylthiomethane, m. p. 47.5–48.2°. The structure was established through analyses, melting point and mixed melting point with an authentic specimen [4]. (Found: C 69.27; H 6.20; S 24.59. Calc for $C_{15}H_{16}S_2$ (260.41): C 69.18; H 6.19; S 24.62.)

1,2-Dithiane-4,4-dicarboxylic acid (III). A solution of 19 g (0.046 mole) of crude II in 30 ml of dry toluene was added dropwise over a period of one hour to 500 ml of liquid ammonia to which a small piece of sodium had been added. The blue colour was maintained by appropriate additions of sodium. After a total of 3 h, and the addition of 8.2 g (0.357 mole) of sodium, the reaction was complete. The excess sodium was neutralized with powdered ammonium chloride, the ammonia allowed to evaporate, and the remaining salts extracted with 1 500 ml of water. The pH was adjusted

to 7.5 with hydrochloric acid, 2 ml of 1 % ferric chloride added, and air was bubbled through *via* a sintered glass filter. After 27 h, the solution became clear yellow, and it was acidified to pH 3. An unidentified yellow oil was first removed by extraction with five 100 ml portions of benzene, and then the product (III) was isolated by extraction with three 100 ml portions of ether. The crude yield of 1,2-dithiane-4,4-dicarboxylic acid was 5 g (52 %). Recrystallization from alcohol-water produced white crystals which melted with decarboxylation at 152°. Equiv. wt. calc. 104.1; found 107.0.

1,2-Dithiane-4-carboxylic acid (IV). 4 g (0.0192 mole) of crude 1,2-dithiane-4,4-dicarboxylic acid (III) was heated at 150—170° for half an hour. Recrystallization from alcohol-water and subsequently from petroleum ether-benzene produced 1.85 g (59 %) of pure 1,2-dithiane-4-carboxylic acid melting at 115.2—116.2°. (Found: C 37.10; H 4.90; S 38.78; equiv. wt. 165.0. Calc. for $C_5H_8S_2O_2$ (164.2); C 36.81; H 4.91; S 39.05; equiv. wt. 164.2.)

Preliminary resolution of 1,2-dithiane-4-carboxylic acid. Quinine and cinchonidine salts were found to be suitable for the resolution of racemic IV. Brucine, α-phenyl-ethylthiuronium chloride and α-(2-naphthyl)-ethylamine proved to be ineffective as resolving agents. The impure dextro enantiomorph, $[\alpha]_D^{25} = +71.5°$ in ethanol solution; m. p. 109—113°, was obtained after four crystallizations of the cinchonidine salt from abs. ethanol. The impure levo antipode, $[\alpha]_D^{25} = -123.5°$; m. p. 106.5—108°, was obtained after four crystallizations of the quinine salt from abs. ethanol. The UV spectra of the two enantiomorphs were essentially identical, with absorption maxima at 211 and 298 mμ (in ethanol).

The authors are indebted to Professor Arne Fredga for constructive discussions and for the facilities placed at our disposal. The second author also gratefully acknowledges a Science Faculty fellowship from the *National Science Foundation, Washington, DC*, which has made his part of this work possible.

A Note on the Constitution of Rhodopin

SYNNÖVE LIAAEN JENSEN

Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

The carotenoid rhodopin was first isolated in 1936 by Karrer and Solmssen [1] from mixed cultures containing *Rhodovibrio* species and was also shown to be present in *Thiocystis* [2]. The elementary analysis was in good agreement with a molecular formula $C_{40}H_{56}O$, although Karrer *et al*[3]. did not exclude the possibility of $C_{40}H_{56}O$. The oxygen function was shown to be a hydroxyl group by quantitative determination of active hydrogen [2,3]. Because of its resistance to acetylation rhodopin was assumed to have a tertiary hydroxyl group [3]. Upon catalytic hydrogenation an uptake of 11.93 and 11.71 moles of hydrogen per mole rhodopin was recorded, and Karrer and Solmssen [3] assumed that twelve carbon-carbon double bonds were present in rhodopin. Rhodopin occurred in complex mixture with other carotenoids including a carotene which these workers named rhodopurpurin[1], and they suggested that rhodopin might be a derivative of rhodopurpurin [1]. They also pointed out the possible identity of lycopene and rhodopurpurin [3] *, but no structural formula for rhodopin was suggested.

More recently Goodwin *et al.*[4,5] have isolated from a number of photosynthetic bacteria *(Athiorhodaceae* and *Thiorhodaceae)* a carotenoid which has the lycopene chromophore and which according to partition tests and chromatographic behaviour was assumed to be a mono-OH-lycopene. Taking into account the source of isolation and the visible spectra and chromatographic behaviour Goodwin and Land concluded that this pigment was identical with rhodopin.

A mono hydroxy derivative of lycopene, lycoxanthin, had previously been isolated by Zechmeister and Cholnoky [6] from the berries of *Solanum dulcamara*. Lycoxan-

* This suggestion has since been verified by Goodwin and Land [5] by mixed chromatography and comparison of spectroscopic properties. It should, however, be kept in mind that lycopene from photosynthetic bacteria has so far not been isolated in crystalline state.

(I)

thin was easily acetylated, and Zechmeister and Cholnoky suggested the formula (I). The hydroxyl group was allocated to the 3-position in accordance with the normal, smooth formation of acetates from secondary alcohols, and the widespread occurrence of 3-OH-substituted carotenoids.

Goodwin and Land [5] reisolated lycoxanthin from *Solanum dulcamara*, and compared it with the rhodopin isolated from a photosynthetic sulphur-bacterium, *Chromatium spp.* It was concluded that rhodopin was identical with lycoxanthin on the basis of their similar chromatographic behaviour, and because of the fact that the two pigments exhibited the same visible absorption spectrum in different solvents before and after iodine isomerization. Whilst the similarity of the visible absorption spectra and chromatographic behaviour indicate that lycoxanthin and rhodopin have the same chromophore and the same number of hydroxyl groups, it is by no means certain that the positions of the latter are the same in the two compounds. Goodwin and Land did, however, exclude hydroxyl in the 4-position on the grounds of a negative $HCl-CHCl_3$ test. It is surprising that these authors made no comment on the different behaviour of rhodopin and lycoxanthin [3,6] towards acetylating agents. In later work the rhodopin of the photosynthetic bacteria has been referred to mainly as lycoxanthin in the literature [7], although Stanier *et al.*[8] preferred the designation OH-lycopene until this structural problem was satisfactorily settled.

It has been established by Stanier *et al.*[8] that OH-lycopene is an intermediate between lycopene and spirilloxanthin in the biosynthesis of carotenoids in *Rhodospirillum rubrum*. Since the structure of OH-lycopene is of importance in this connection, the properties of this carotenoid have been investigated in more detail.

OH-Lycopene was isolated from *Rhodospirillum rubrum* in the exponential growth phase and from *Rhodopseudomonas palustris*. According to van Niel [9] the genetic name *Rhodopseudomonas* is synonymous with *Rhodovibrio* and *Rhodobacillus*, from which Karrer and Solmssen isolated rhodopin.

As already reported by Goodwin and Land [5] no difference in structure for lycoxanthin and rhodopin can be predicted from comparison of visible spectra in different solvents, nor from partition tests and chromatographic behaviour. Also the melting points recorded are so close that they yield no useful information. The melting point reported for lycoxanthin is 168°C, whilst that for rhodopin varies from 159—160°C [1] to 171°C [3] with increasing purity. The OH-lycopene used in the present studies melted at 166—168°C.

The outstanding difference between lycoxanthin and rhodopin was in their behaviour towards acetylating agents, and this aspect was therefore studied first. Numerous attempts were made using different methods to acetylate OH-lycopene from *Rhodospirillum rubrum* and *Rhodopseudomonas palustris*. After standing with acetic anhydride in pyridine at room temperature for periods of up to two days the OH-lycopene could be completely recovered. A parallel experiment with lutein (3,3′-di-OH-α-carotene) resulted in the formation of lutein diacetate in quantitative yield. Treatment with freshly distilled acetyl chloride in pyridine at room temperature for periods up to four days gave a product with properties corresponding to an acetate. However, the yield did not exceed 8 % of the OH-lycopene used for the test. Upon saponification of this acetate with 15 % methanolic KOH about 30 % was converted to OH-lycopene. This behaviour of OH-lycopene towards acetylating agents is similar to that reported by Karrer *et al.*[3] for rhodopin, but not for lycoxanthin [6].

Further support for the tertiary character of the hydroxyl group in OH-lycopene from photosynthetic bacteria is obtained from the IR absorption data presented in Table 1.

Carotenoids with the hydroxyl groups in 3- or 4-positions show strong absorption in the 1 030 cm^{-1} region. Chloroxanthin and OH-lycopene, however, have no absorption band in this region. Chloroxanthin is a mono- or di-OH-neurosporene which was isolated by Nakayama [12] from a green mutant of *Rhodopseudomonas spheroides*. Less than 5 % of chloroxanthin is acetylated on treatment with acetic anhydride in pyridine, and this led Nakayama to the conclusion that the hydroxyl group(s) of chloroxanthin must be tertiary. Both chloroxanthin and OH-lycopene exhibit a band of somewhat weaker intensity around 1 140 cm^{-1} which might be due to tertiary hydroxyl groups [13]. It might be argued that this region is also typical for *iso*propyl groups (1 170—1 140 cm^{-1}) [13], but an IR-spectrum of lycopene isolated from tomatoes showed no band of similar intensity in this region. The

Table 1.

Carotenoid	IR-absorption connected with the hydroxyl group Frequency cm^{-1}
Cryptoxanthin (3-OH-β-carotene) $CHCl_3$[10]	*ca.* 1 035
Isozeaxanthin (4,4′-di-OH-β-carotene) CCl_4[11]	*ca.* 1 035
Zeaxanthin (3,3′-di-OH-β-carotene) KBr	1 038
Violaxanthin (3,3′-di-OH-β-carotene-5,6,5′,6′-di-epoxide) $CHCl_3$	1 025
Chloroxanthin KBr	1 145
OH-Lycopene KBr	1 140

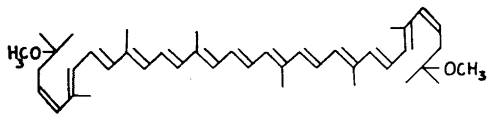
IR-spectrum of lycopene is in fact surprisingly simple, and corresponds closely to that of OH-lycopene apart from a band at 3 450 cm^{-1} (OH), a relatively weak band at 1 260 cm^{-1} and the band at 1 140 cm^{-1} already discussed.

Microdetermination of *iso*propylidene was carried out, using the method of Kuhn and Roth [14]. The result is presented in Table 2 together with the value obtained simultaneously for lycopene isolated from tomatoes.

Table 2.

Carotenoid	Found: Moles of acetone/mole	Number of *iso*-propylidene groups
Lycopene	1.70	2
OH-Lycopene	1.12	1

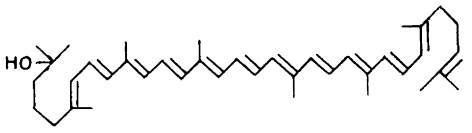
It is seen that the value obtained for OH-lycopene is much lower than that for lycopene. It has been shown that spirilloxanthin to which the formula (II) is now ascribed [15],



(II)

and which contains no *iso*propylidene groups, yields 0.42—0.73 [15,2] moles of acetone upon ozonolysis. The *iso*propylidene value obtained for OH-lycopene is therefore interpreted as being due to the presence of one *iso*propylidene end group together with a second end group which yields a small amount of acetone on ozonolysis.

Combining the chemical evidence obtained by Karrer *et al.*[1-3] for rhodopin, and the evidence presented here, the following structure (III) is suggested for the OH-lycopene from photosynthetic bacteria.



(III)

In accordance with the generally accepted nomenclature, this should now be referred to as rhodopin. The name lycoxanthin should be reserved for the hydroxy derivative of lycopene which was first isolated from *Solanum dulcamara* and for which the structure (I) has been suggested by Zechmeister and Cholnoky [6].

In view of the findings described above, it is clear that as far as the biosynthetic reactions leading from lycopene to spirilloxanthin are concerned, no definite conclusions should be drawn until the chemical structure of all the intermediates which can be isolated in reasonable amounts is firmly established.

The author wishes to express her gratitude to Professor C. B. van Niel for a generous gift of dried cells of *Rhodopseudomonas palustris*, to Dr. T. O. M. Nakayama for a sample of chloroxanthin, to Professor N. A. Sörensen for his inspiring interest and advice in this work and to *Norges Tekniske Högskole* for a maintenance grant.

The Mass Spectra of Methyl Oleate, Methyl Linoleate, and Methyl Linolenate

BO HALLGREN

EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, Uppsala, Sweden

In connexion with studies on the mass spectra of esters of long-chain fatty acids we have examined a number of unsaturated esters. In general, unsaturated esters give more complex spectra than esters of saturated, normal-chain acids [1,2]. In order to interpret the spectrum of methyl oleate we have examined the isomeric 2-, 6-, 8-, 10-, 13- and 17-octadecenoates, but it has proved desirable to study also the ester of an acid with the double bond at position 4:5 or 5:6. None of these acids has been described in the literature. Synthetic work will therefore have to be undertaken and may also be required for the interpretation of the spectra of the di- and triethenoid esters. In view of the common occurrence of oleic, linoleic, and linolenic acids, however, and the analytical possibilities afforded by the mass spectrometer [3], a brief description of the mass spectra of their esters will be made.

The mass spectrum of methyl oleate (Fig. 1a) shows that the introduction of a double bond in the hydrocarbon chain leads to a fragmentation pattern considerably different from that of saturated methyl esters. Compared with methyl stearate [2], the peaks in the low-mass range due to fragments containing an intact methoxycarbonyl group are much less prominent than those due to hydrocarbon fragments. The peak at $m/e = 55$ ($C_4H_7^+$) is of the same order of magnitude as the rearrangement peak at $m/e = 74$. In the sequence of the higher-methoxycarbonyl-type fragments, the peak at $m/e = 87$ is the most prominent one (45 % of the base peak). The higher members of this series of peaks do not show the marked rhythmic variation in height which is characteristic of methyl esters of normal-chain saturated acids. In the high-mass range, marked peaks are found at $m/e = 296$, 264, 222, and 180. The peak due to the molecule-ion at $m/e = 296$ is relatively small, and the base peak at $m/e = 264$ corresponds to a fragment formed with the loss of 32 mass units. A comparison with the ethyl ester shows that the molecule-ion loses a methoxyl group and one hydrogen atom (formally, this corresponds to the loss of one molecule of methanol). The peak at $m/e = 265$ is higher than expected for the isotope peak corresponding to the peak at $m/e = 264$, which shows that ions are also formed with the loss of the methoxyl group only. The peak at $m/e = 222$ ($= M-74$) is due to a fragment formed by the loss of methylene-methoxycarbonyl, $-CH_2COOCH_3$, of mass 73, together with one hydrogen atom. The appearance of fairly marked peaks at $m/e = 180$, 222, 264, and 265 in both the methyl and the ethyl esters shows that the corresponding ions do not contain the ester alkoxy group.

The mass spectrum of methyl elaidate is practically indistinguishable from that of methyl oleate. Methyl esters of *cis-* and *trans-*petroselinic acids were both found to be indistinguishable from that of methyl oleate. Even a shift of the double bond to the 17:18

The Mass Spectra of Methyl Oleate, Methyl Linoleate, and Methyl Linolenate

BO HALLGREN

Institute of Medical Biochemistry, Gothenburg, Sweden

RAGNAR RYHAGE

Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm, Sweden and

EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, Uppsala, Sweden

In connexion with studies on the mass spectra of esters of long-chain fatty acids we have examined a number of unsaturated esters. In general, unsaturated esters give more complex spectra than esters of saturated, normal-chain acids [1,2]. In order to interpret the spectrum of methyl oleate we have examined the isomeric 2-, 6-, 8-, 10-, 13- and 17-octadecenoates, but it has proved desirable to study also the ester of an acid with the double bond at position 4:5 or 5:6. None of these acids has been described in the literature. Synthetic work will therefore have to be undertaken and may also be required for the interpretation of the spectra of the di- and triethenoid esters. In view of the common occurrence of oleic, linoleic, and linolenic acids, however, and the analytical possibilities afforded by the mass spectrometer [3], a brief description of the mass spectra of their esters will be made.

The mass spectrum of methyl oleate (Fig. 1a) shows that the introduction of a double bond in the hydrocarbon chain leads to a fragmentation pattern considerably different from that of saturated methyl esters. Compared with methyl stearate [2], the peaks in the low-mass range due to fragments containing an intact methoxycarbonyl group are much less prominent than those due to hydrocarbon fragments. The peak at $m/e = 55$ ($C_4H_7^+$) is of the same order of magnitude as the rearrangement peak at $m/e = 74$. In the sequence of the higher-methoxycarbonyl-type fragments, the peak at $m/e = 87$ is the most prominent one (45 % of the base peak). The higher members of this series of peaks do not show the marked rhythmic variation in height which is characteristic of methyl esters of normal-chain saturated acids. In the high-mass range, marked peaks are found at $m/e = 296$, 264, 222, and 180. The peak due to the molecule-ion at $m/e = 296$ is relatively small, and the base peak at $m/e = 264$ corresponds to a fragment formed with the loss of 32 mass units. A comparison with the ethyl ester shows that the molecule-ion loses a methoxyl group and one hydrogen atom (formally, this corresponds to the loss of one molecule of methanol). The peak at $m/e = 265$ is higher than expected for the isotope peak corresponding to the peak at $m/e = 264$, which shows that ions are also formed with the loss of the methoxyl group only. The peak at $m/e = 222$ ($= M-74$) is due to a fragment formed by the loss of methylene-methoxycarbonyl, $-CH_2COOCH_3$, of mass 73, together with one hydrogen atom. The appearance of fairly marked peaks at $m/e = 180$, 222, 264, and 265 in both the methyl and the ethyl esters shows that the corresponding ions do not contain the ester alkoxy group.

The mass spectrum of methyl elaidate is practically indistinguishable from that of methyl oleate. Methyl esters of *cis-* and *trans-*petroselinic acids were both found to be indistinguishable from that of methyl oleate. Even a shift of the double bond to the 17:18

position has little effect upon the mass spectrum. On the other hand, the mass spectra of the *cis-* and *trans-* $\Delta^{2:3}$ isomers differ considerably from each other and from those of esters in which the double bond is at position 6:7 or beyond.

The results just described show that it is in general not possible to determine the position of the double bond in a monoethenoid acid by direct mass spectrometric analysis. The position of the double bond may be determined, however, after deuteration by means of hydrazine-d_4 [4] or after hydroxylation [5].

The spectrum of methyl linoleate (Fig. 1b) shows prominent peaks due to hydrocarbon fragments at $m/e = 67$ (base peak), 81, and 95. In general, the 'hydrocarbon' peaks are much stronger than those due to oxygen-containing fragments. The peak at $m/e = 294$ due to the molecule-ion is very prominent; the

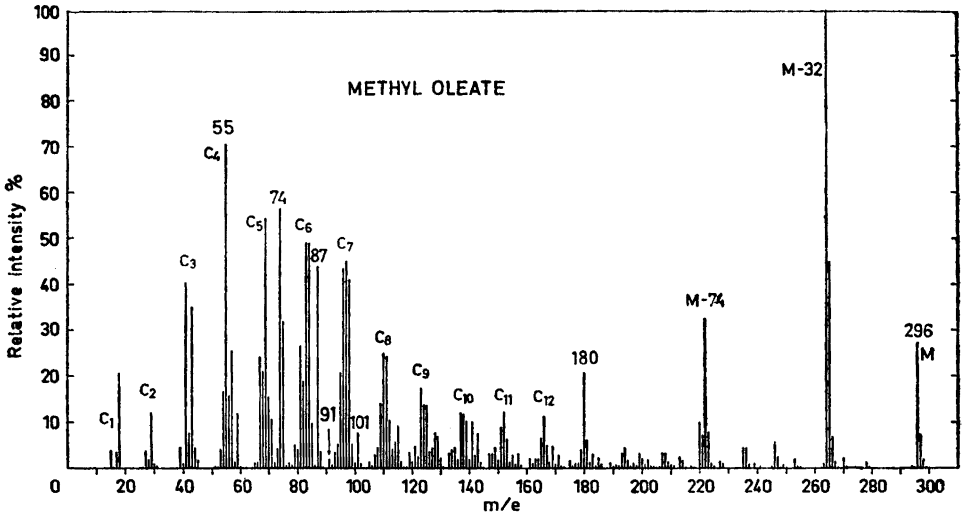

Fig. 1 a.

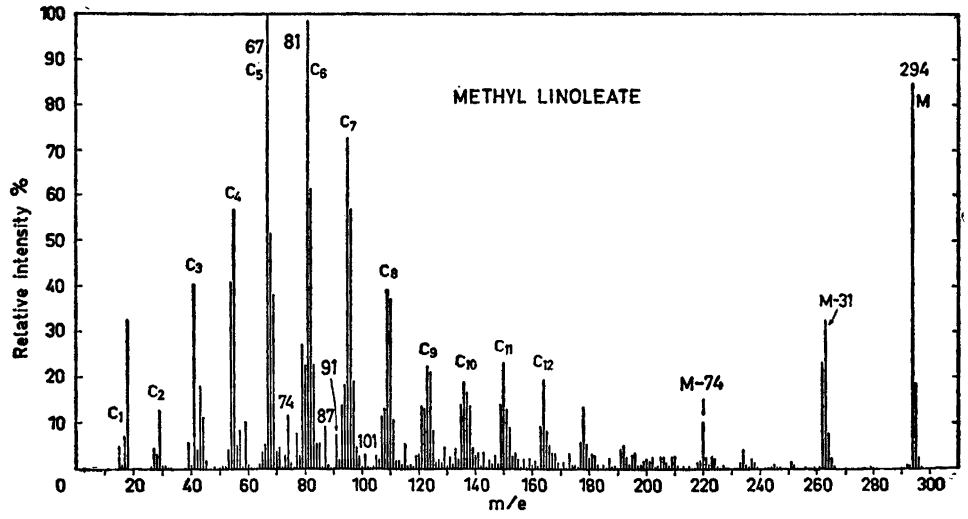

Fig. 1 b.

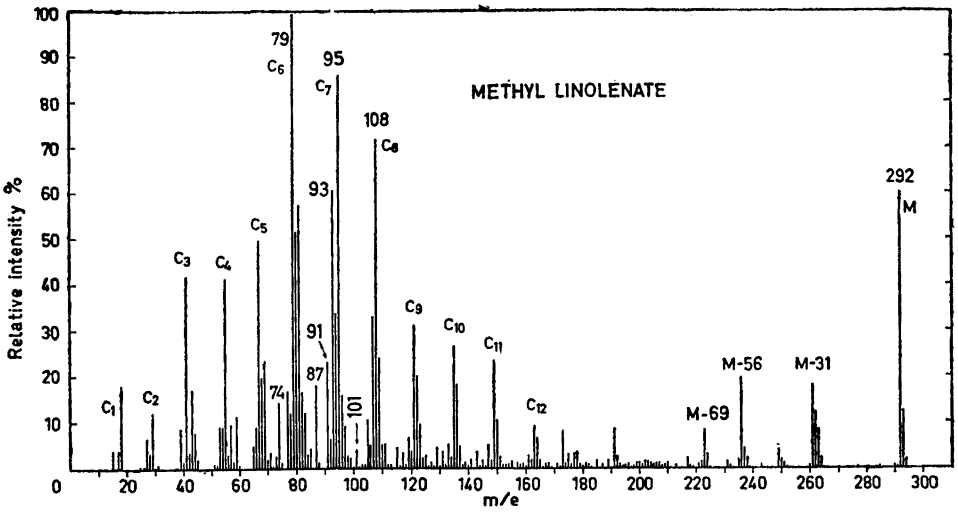

Fig. 1 c.

peak at $m/e = M-31$ is higher than that at $m/e = M-32$; and the peak at $m/e = 220$ (M−74) is obviously analogous to that at $m/e = 222$ in the spectrum of methyl oleate.

In the spectrum of methyl linolenate (Fig. 1c), the base peak is at $m/e = 79$ ($C_6H_7^+$). The 'methoxycarbonyl' peaks are relatively small. In the high-mass range, the molecule ion at $m/e = 292$ gives the most prominent peak, followed by the peaks at $m/e = M-56$ and $m/e = M-31$. The peak at $m/e = M-56$ is probably formed by cleavage between carbon atoms 14 and 15, with rearrangement of one hydrogen atom, leading to the formation of a neutral molecule of 1-butene and an ionized fragment of $m/e = 236$. In the spectrum of methyl linolenate there is a peak at $m/e = 91$ the height of which is about 20 % of that of the base peak. This peak, which may be due to tropylium ions [6] formed by cyclization and rearrangement, is very high in the spectra of methyl esters of unsaturated acids with many double bonds. It is the base peak in the case of a methyl docosahexaenoate which we have examined.

Experimental. The mass spectrometer and the general procedure have been described previously [7]. The intake system was kept at 200°, and the energy of the electrons was 70 eV.

The esters used in order to obtain the spectra shown in Fig. 1 were purchased from Mann Research Laboratories, New York. Their purity was checked by gas chromatography on a Reoplex 400 column with an efficiency approaching 5 000 plates. The oleate contained 1 % of palmitate, and the linoleate about 1 % of oleate. No significant amount of impurity was found in the linolenate. We are indebted to Dr. W. L. Courchene, The Procter & Gamble Company, Cincinnati, for samples of octadecenoic acids synthesized by Huber [8], to Dr. L. Crombie, University of London King's College, for the 2-octadecenoic acids, to Dr. R. T. Holman of the Hormel Institute of the University of Minnesota for the methyl docosahexaenoate, and to Mr. Ng. Dinh-Nguyen for the preparation of several esters. Grants from *Gustaf och Tyra Svenssons Stiftelse* and the *Swedish Medical, Natural Science,* and *Technical Research Councils* are gratefully acknowledged.

Preparation of Tritium Labelled Dioctyl Adipate

GUNNAR B. LINDSTRÖM

Division of Physical Chemistry, The Royal Institute of Technology, Stockholm, Sweden

The vapour pressure of a plasticizer, di(2-ethyl-hexyl) adipate (DOA), was to be studied at relatively low temperatures. The vapour pressures of plasticizers are very low and very difficult to determine. Several methods for the determination of low pressures have been used in the past but they are not very accurate. However, radioactive tracer methods possess certain advantages and are, moreover, relatively accurate. There are two suitable isotopes for the labelling of the molecules, *viz.* ^{14}C and T. Since a high sensitivity and thus high specific activities are needed and since also large amounts were required, ^{14}C would be too expensive. Besides it is more difficult to incorporate ^{14}C into the molecule.

Tritium can be introduced into a molecule in several ways but, in this case, only two were tried, *viz.* labelling by direct exposure to tritium gas according to Wilzbach [1] and catalytic hydrogenation.

The Wilzbach method is very simple. It consists merely in placing the substance to be labelled in contact with T-gas (usually of purity > 90 %). The substance then becomes labelled with tritium due to the catalytic influence of the radiation. The product has to be carefully purified since, of course, other substances are also formed.

In order to get high specific activities, the pressure of the tritium gas should be high (this means that the volume of the reaction vessel should be relatively small) and the surface area of the sample should be large. Thus, solid samples are usually powdered and liquid samples shaken vigorously so that the liquid forms a foam during the tritiation. The DOA is quite viscous and it was found to be impossible, when working with small volumes, to produce a foam from small amounts of DOA. It was found necessary to use a volume of 30–40 ml and more than 5 g DOA to obtain the conditions desired. This meant that the pressure of the gas was reduced considerably but it was thought that the low pressure should be more than compensated for by the large surface area obtained by the vigorous shaking. This was obviously not the case since the specific activity of the product (6.3 g) was only 2.2 μC/g. This is fairly low compared with those activities obtained by other authors [2] who had employed tritium pressures of about 1 atm. It therefore seems probable that a high pressure for the tritium gas is more important than a large surface area.

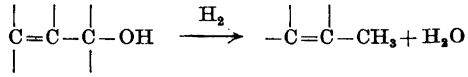
There is also another possible explanation for the poor result. Tables of G_T values seem to show that hydrogen atoms activated by polar groups in their neighbourhood are more readily exchanged by T-atoms than ordinary hydrogen atoms in saturated hydrocarbons. DOA contains some activated hydrogen atoms but most of them are not particularly activated and should thus exchange less readily.

The G_T value of this reaction is 0.0003.

Because the Wilzbach labelling failed, the conclusion was that the best way for getting high specific activities and sufficiently large amounts was to introduce the tritium gas by catalytic hydrogenation. A synthesis was required in which the tritium gas was introduced as late as possible in the synthesis run in order to avoid losses during the earlier stages. The following was considered a suitable way for doing this.

The starting material was 2-ethyl-3-propyl acrolein which is an intermediate product in the preparation of DOA. This was reduced to the corresponding alcohol which was then esterified with adipic acid. The unsaturated ester was then tritiated. However, when the product was subjected to a trial hydrogenation, it was found that 30–40 % more hydrogen was needed than the amount calculated. This was first thought to be due to the fact that the compound was not pure but, even after a very careful purification, more hydrogen was needed than expected. The following is a possible explanation.

It is known [3] that, in the catalytic hydrogenation of olefinic linkages, the following reaction occurs readily:



If the double bond is not so easily reduced, as in this case where one of the unsaturated carbon atoms is a tertiary one, then this serves to labilize the C–O linkage with the resultant reduction indicated above. Now, it is assumed that the catalyst contained some small amounts of acid impurities

which caused the hydrolysis of the ester to a certain extent. The unsaturated alcohol would then be reduced both at the double bond and the hydroxyl group. The free adipic acid, thus formed, would catalyze the further hydrolysis of other ester molecules and we would therefore get an accelerating hydrolysis of the ester, *i.e.* a chain reaction. In addition, it is possible that the double bond also activated the ester bonding, thus making the hydrolysis proceed faster.

Since neither of the two previous methods were successful, a third method for preparing this substance was chosen. Muconic acid was prepared from pyrocatecol. The muconic acid was then tritiated and esterified with 2-ethyl-hexanol. This method was successful.

Procedure. I. The tritium gas, obtained from AERE, England, was 96 % pure. It was introduced into a dispenser apparatus [4] and, from this, about 1 C was transferred to a tritium container. The transference of T-gas to the reaction vessel was somewhat more complicated since the reaction vessel must be cooled with liquid air in order to prevent evaporation during the evacuating. A simple, modified Toepler pump was designed for the transference of the T-gas to the reaction vessel (Fig. 1). The tritiating was carried out in a 50 ml bottle with 10 g of DOA of commercial grade. The flask was shaken vigorously for six days. The vessel was then connected with a U-tube (filled with activated carbon) and this was connected in turn to the Toepler pump. The vessel and the tube were cooled in liquid air. The tritium gas was then pumped back to the container. By this arrangement, the gases formed during the tritiating were either condensed in the bottle or adsorbed in the U-tube and thus the T-gas pumped back was quite clean. The DOA was then dissolved in 50 ml ether and washed three times with 10 ml saturated $NaHCO_3$-solution. After boiling off the ether, the DOA was distilled in a spinning band column at 206°C.

II. 2-Ethyl-3-propyl acrolein was distilled at 83°C, 10 mm Hg. The product was reduced with $LiAlH_4$ to the alcohol using a procedure given by Nystrom and Brown [5]. The product was distilled at 98—99°C, 23 mm Hg. The yield was 75 %. The ester was prepared by esterification with adipyl chloride. The crude ester was then distilled in a spinning band column at 206°—210°C, 6—7 mm Hg. The yield was 61 %. When the identity of the ester was investigated, it was found that 30—40 % more hydrogen was needed for the hydrogenation than the amount calculated. It was first thought that this was due to some decomposition during the distillation. The ester was molecularly distilled but there was still an over-consumption of hydrogen. This method was therefore abandoned.

III. The muconic acid [6] prepared, the identity of which was confirmed by catalytic hydrogenation (0.0596 mg muconic acid, 20.7 ml

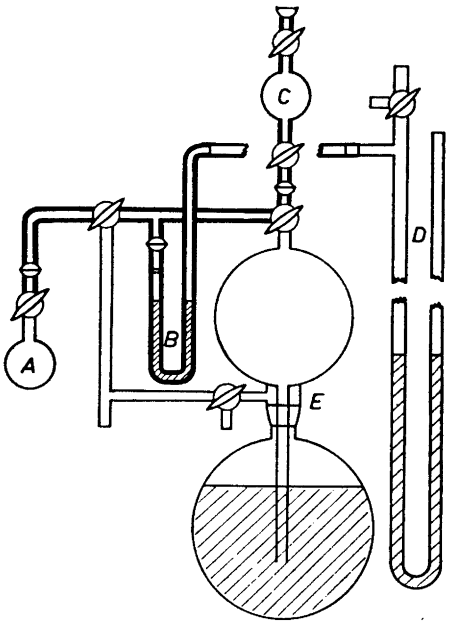


Fig. 1. Modified Toepler pump for the transference of tritium gas from the ampoule to the tritiating vessel and back again for Wilzbach labelling. Such an apparatus is particularly suitable for the labelling of liquids since the vessel can be cooled.

A) Reaction vessel, B) Zero-manometer,
C) T-container, D) Main Hg-manometer,
E) Toepler pump.

The "zero"manometer is used in order to keep the volumes between the reaction vessel and Toepler pump as small as possible. When reading the pressure, the "zero"manometer is set at zero by letting in air or pumping air out through the upper stopcock of the manometer. The pressure is read on the main manometer. The "zero" manometer is equipped with a glass filter under the ball joint in order to prevent mercury getting into the apparatus.

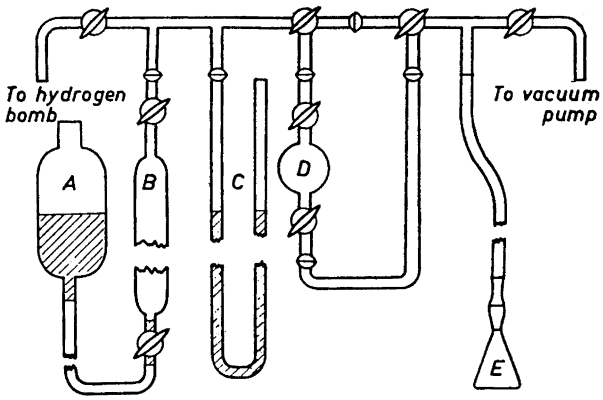

Fig. 2. Tritiating apparatus: A) mercury bottle, B) 50 ml gas burette, C) Hg manometer, D) tritium container, E) hydrogenation flask. Capillary glass tubes were used (D = 2 mm).

H_2, theor. 20.2 ml H_2) was tritiated in a modified tritiating apparatus (Fig. 2). Muconic acid (0.356 g) was dissolved in 10 ml *p*-dioxane (p.a.) in the hydrogenation flask and 25.5 mg Adams catalyst was added. The mixture was cooled with dry ice and the apparatus evacuated. The flask was the allowed to warm to room temperature and the reduction of the catalyst with hydrogen started. When ~ 8 ml H_2 had been consumed, the reduction was stopped by cooling once more with dry ice and the flask was then evacuated again. Hydrogen was introduced again into the apparatus but this time through the tritium gas container which, so to speak, forced the gas into the hydrogenation flask. The amount of tritium gas was ~ 200 mC. The total amount of hydrogen consumed was 58.7 ml, theor, calc. 57.3. Adipic acid (3 g) was then added as carrier and the combined acids were crystallized from the solution and recrystallized from dioxane. 1.00 g of the T-adipic acid and 4.85 g adipic acid were then esterified at 160°C with 13 g (theor. 10.43 g) of 2-ethylhexanol. The reaction was completed after 4 h. The crude product was dissolved in ether and washed three times with saturated $NaHCO_3$-solution. The ether-solution was dried, the ether boiled off and the residue distilled in a spinning band column at 206—208°C and 6 mm Hg. The yield was 11.85 g (78 %). The activity of the product was 0.65 mC/g. Taking into account the losses and dilution during the synthesis, this meant that the yield of tritium from the tritiating was ~ 65 %.

The author wishes to thank the head of the division, Professor Ole Lamm, for his support and encouragement. The author is also indebted to Dr. T. Westermark for putting at his disposal the facilities and the instruments of the »industrial group» and to Dr. G. Aniansson for valuable discussions and advice, to the *Swedish Atomic Committee* and the *State Technical Research Council* for financial assistance.

*iso*Thiocyanates XXXV.* Miscellaneous *iso*Thiocyanate Glucoside Acetates

ANDERS KJÆR

Organic Chemical Laboratory of The Royal Veterinary and Agricultural College, Copenhagen, Denmark

Most naturally occurring *iso*thiocyanate glucosides possess poor crystallization properties as apparent from the fact that so far only seven individual glucosides have been reported as crystalline substances (*cf.* Ref.[1]). In contrast herewith, crystalline glucoside O-acetates are frequently obtainable as useful derivatives for purification and characterization purposes. The acetylation procedure used in this laboratory [2] and independently applied to a broader range of glucosides by Schultz and Wagner [3] is similar to that customarily employed in carbohydrate chemistry. It is the purpose of the present note to describe a few *iso*thiocyanate glucoside acetates and, in addition, present some supplementary or corrective data for previously reported derivatives.

Glucoiberin, a crystalline glucoside isolated as a potassium salt from seeds of *Iberis amara* [4], affords a crystalline tetraacetate on acetylation. A non-analyzed specimen of the latter was characterized by its m. p.[3,5] (148–149° (decomp.)), optical rotation [5] $[\alpha]_D^{20}$ −12.2° (*c* 1.4, H_2O)) and infra-red spectrum [5]. A specimen of *potassium tetraacetylglucoiberate* prepared in this laboratory separated from 96 % ethanol as a *monohydrate* in tiny, colourless needles, m. p. 145–147° (decomp.) **, $[\alpha]_D^{28}$ −16.6° (*c* 2.0, H_2O). (Found: C 35.50; H 4.87; N 2.13; S 15.25. Calc. for $C_{12}H_{26}O_{14}NS_2K$, H_2O: C 35.23; H 4.67; N 2.16; S 14.85).

The rubidium salt of glucoiberin, desired for special purposes, was prepared from the corresponding potassium salt by percolating a solution of the latter through a column containing a cation exchange resin (Dowex 50) in its rubidium ion form. *Rubidium glucoiberate* separated as a *monohydrate* from 85 % ethanol, m. p. 130–132° (decomp.), $[\alpha]_D^{23}$ −51.9° (*c* 2.1, H_2O). (Found: C 24.95; H 4.24; N 2.66; Rb 16.62. Calc. for $C_{11}H_{20}O_{10}NS_2Rb,H_2O$: C 25.12; H 4.22; N 2.66; Rb 16.25).

In 1948 Schmid and Karrer [6] reported on the isolation and structure elucidation of the mustard oil sulphoraphene, an enzymic hydrolysis product of a glycosidic progenitor in radish seeds. From seeds of *Matthiola bicornis*, Schultz and Wagner [3] isolated a crystalline glycoside tetraacetate which was tacitly assumed to be identical with the tetraacetate of the radish seed glucoside for which the name glucoraphenin was introduced [5]. Because no rotation values were reported and analytical data were inconclusive with regard to the contents of water of crystallization [5], a sample of the tetraacetate of the glucosidic progenitor of sulphoraphene was isolated in this laboratory from radish seed.

A methanolic glucoside extract of crushed and defatted radish seed was purified, first by ion exchange on acid-washed alumina and then by removal of impurities with lead acetate [3]. The glassy residue was acetylated in the usual way in pyridine with acetic anhydride. After recrystallization from ethanol, in which the tetraacetate dissolved very slowly, an almost pure product was obtained in amounts corresponding to 3.6 g per 100 g of fresh radish seed. The analytical specimen was recrystallized thrice from ethanol, and separated as a *monohydrate* in colourless needles, m. p. 155–156° (decomp.) $[\alpha]_D^{27}$ −23.5° (*c* 1.5, H_2O). (Found: C 36.45; H 4.50; N 2.13; S 14.36; K 5.69; Calc. for $C_{20}H_{38}O_{14}NS_2K$, H_2O: C 36.41; H 4.58; N 2.12; S 14.58; K 5.93). The infra-red spectrum of our specimen proved identical with that reported elsewhere [5] *. Several attempts to prepare the genuine glucoside in crystalline form after deacetylation were unsuccessful.

From seeds of the wall-flower *(Cheiranthus cheiri)* Schneider and Schütz [7] isolated, many years ago, the *iso*thiocyanate glucoside glucocheirolin as a crystalline potassium salt, affording 3-methylsulphonylpropyl mustard oil upon enzymic hydrolysis. Failure to repeat the isolation of crystalline glucoside by the reported procedure prompted the development of the following modification which has afforded crystalline glucocheirolin monohydrate with

* Part XXXIV of this series: *Acta Chem. Scand.* 13 (1959) 144.

** All melting points reported are uncorrected and determined in capillary tubes in an electrically heated block. Microanalyses were performed by Mr. P. Hansen at the Chemical Laboratory of the University of Copenhagen.

* The author is grateful to Dr. W. Wagner for kindly placing the original spectrum at his disposal for comparison.

correct analysis and a rotation value in agreement with that reported *.

A methanolic extract of commercial wallflower seeds was concentrated, dissolved in water and filtered. Addition of potassium thiocyanate caused the precipitation of the quaternary base sinapine as the slightly soluble thiocyanate. The dried residue from the filtrate was subjected to acetylation in the usual way [3] and the crude tetraacetate, in turn, subjected to deacetylation with ammonia in methanol to give the oily glucoside. On recrystallization of this from 80 % ethanol, glucocheirolin monohydrate separated as colourless needles, purified for analysis by two additional recrystallizations.

The intermediate, anhydrous *potassium tetraacetylglucocheirolinate* was obtained from water as thin colourless needles, m. p. 193—194° (decomp.), $[\alpha]_D^{24}$ −18.0° (*c* 1.0, H_2O). (Found: C 35.32; H 4.26; N 2.04; S 14.78. Calc. for $C_{19}H_{28}O_{15}NS_2K$: C 35.33; H 4.37; N 2.17; S 14.89.)

Seeds of *Lunaria annua* L. (= *L. biennis Moench*) have formerly served in this laboratory as a source of *iso*propyl *iso*thiocyanate [8]. The hypothetical glucosidic progenitor of this mustard oil, *glucoputranjivin*, which was independently suggested by Puntambekar [9] as a constituent of the Indian plant *Putranjiva Roxburghii* Wall. *(Euphorbiaceae)*, has now been isolated in form of its crystalline tetraacetate. A crude specimen, isolated from *Lunaria* seeds and acetylated in the usual way, was repeatedly recrystallized from 96 % ethanol to give colourless needles of the anhydrous *potassium tetraacetylglucoputranjivate* with m.p. 180—190° (decomp.), highly dependent on the rate of heating; $[\alpha]_D^{23}$ −15.4° (*c* 1.2, H_2O). (Found: C 38.20; H 4.77; N 2.54. Calc. for $C_{18}H_{26}O_{13}NS_2K$: C 38.08; H 4.62; N 2.47.)

Valuable assistance of Dr. R. Gmelin, Mr. Bo W. Christensen and Mrs. Dorthe Hansen in the present work is gratefully acknowledged. The work is part of investigations supported by *The Danish State Research Foundation*, *The Carlsberg Foundation* and *Kai Hansen's Fond*.

* Present address: The Swedish Institute of Metal Research (Metallografiska Institutet), Stockholm 26.

in reflection from the surface of the bars revealed no changes during sintering.

Preliminary measurements indicated very low resistances for all samples, including PdS. Of this latter compound, only one test bar had been made, which was accidentally damaged before accurate measurements could be carried out. The preliminary experiments would put its conductivity in the same order of magnitude as that of the other palladium sulfides. For the other samples, measurements were made both with direct current and at different A. C. frequencies up to 10 kc/sec. They gave practically identical values, indicating that grain boundary resistance had no appreciable influence on the results.

The following values were recorded:

Compound	$\varrho_{20°C}$ * (Ωcm)	$d\varrho/dt$ (Ωcm/degree C)
Pd_4S	3.20×10^{-4}	$+1.05 \times 10^{-6}$
$Pd_{2.2}S$	10.00×10^{-4}	$+1.80 \times 10^{-6}$
Ag_2Pd_3S	1.93×10^{-4}	$+0.22 \times 10^{-6}$

The positive temperature coefficient as well as the low absolute values of the resistivities indicate that these compounds are metallic conductors. For the Pd sulfides, Grønvold and Røst had inferred, from magnetic susceptibility measurements, that they should be essentially nonionic, *i. e.* either metallic or covalent. The present measurements show that the former is the case. As for Ag_2Pd_3S, its high metal content suggested that this compound should be considered as an alloy phase.

I wish to thank Prof. G. Hägg for the facilities placed at my disposal. Thanks are due to Mr. S. Djurle for his assistence with the preparation of the samples, and to Telefon-AB L. M. Ericsson, Stockholm, for the loan of a conductivity bridge.

A New Crystalline Modification of Cellulose as Revealed by X-Ray Diffractograms of Hydrolyzed Cotton and Wood Pulp

Ø. ELLEFSEN

The Norwegian Pulp and Paper Research Institute, Oslo;

J. GJØNNES and N. NORMAN

Central Institute for Industrial Research, Oslo, Norway

In an attempt to obtain cellulose II with a high degree of crystallinity, it was discovered that surgical cotton as well as mercerized surgical cotton after 2—4 h treatment at 20°C with 40.3 % hydrochloric acid gave X-ray diffractograms which could not be explained exclusively by the hitherto known crystalline modifications of cellulose. A microphotometer curve of such an X-ray diffractogram obtained in an evacuated Guinier camera with Cu$K\alpha$-radiation is shown in Fig. 1a. Shorter or prolonged HCl treatments gave residues containing cellulose II only, as shown by the microphotometercurve in Fig. 1b. Diffractograms like the one in Fig. 1a could also be obtained from wood pulp and ground cotton at a lower acid concentration.

To investigate whether the strong reflections corresponding to the interplanar spacings 6.31 Å, 5.70 Å, 5.13 Å and 3.99 Å in Fig. 1a may be due to sodium cellulose formed during the neutralization, or to cellulose hydrates, oxycelluloses or hemicelluloses, tests were carried out leading to the following results: Flame photometry showed only negligible (0.4 %) amounts of sodium. Drying for 18 h at 105°C gave no observable change in the diffractograms. An infrared spectrogram indicated no bonds other than those characteristic of cellulose, and a chromatogram of the sample showed glucose to be the only monosaccharide present. It should also be mentioned that viscosity measurements for the sample led to a DP-value below 100.

It must, therefore, be concluded that the sample consists of pure cellulose. The few reflections in Fig. 1a are of course insufficient for solving the structure of the unknown phase or phases, but it is reasonable to assume a unit cell and an arrangement of the glucose rings not too different from

A New Crystalline Modification of Cellulose as Revealed by X-Ray Diffractograms of Hydrolyzed Cotton and Wood Pulp

Ø. ELLEFSEN

The Norwegian Pulp and Paper Research Institute, Oslo;

J. GJØNNES and N. NORMAN

Central Institute for Industrial Research, Oslo, Norway

In an attempt to obtain cellulose II with a high degree of crystallinity, it was discovered that surgical cotton as well as mercerized surgical cotton after 2—4 h treatment at 20°C with 40.3 % hydrochloric acid gave X-ray diffractograms which could not be explained exclusively by the hitherto known crystalline modifications of cellulose. A microphotometer curve of such an X-ray diffractogram obtained in an evacuated Guinier camera with Cu$K\alpha$-radiation is shown in Fig. 1a. Shorter or prolonged HCl treatments gave residues containing cellulose II only, as shown by the microphotometercurve in Fig. 1b. Diffractograms like the one in Fig. 1a could also be obtained from wood pulp and ground cotton at a lower acid concentration.

To investigate whether the strong reflections corresponding to the interplanar spacings 6.31 Å, 5.70 Å, 5.13 Å and 3.99 Å in Fig. 1a may be due to sodium cellulose formed during the neutralization, or to cellulose hydrates, oxycelluloses or hemicelluloses, tests were carried out leading to the following results: Flame photometry showed only negligible (0.4 %) amounts of sodium. Drying for 18 h at 105°C gave no observable change in the diffractograms. An infrared spectrogram indicated no bonds other than those characteristic of cellulose, and a chromatogram of the sample showed glucose to be the only monosaccharide present. It should also be mentioned that viscosity measurements for the sample led to a DP-value below 100.

It must, therefore, be concluded that the sample consists of pure cellulose. The few reflections in Fig. 1a are of course insufficient for solving the structure of the unknown phase or phases, but it is reasonable to assume a unit cell and an arrangement of the glucose rings not too different from

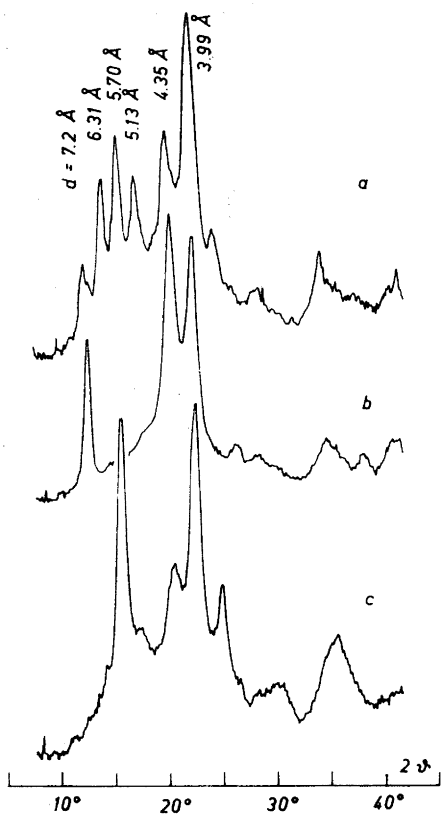

Fig. 1. Microphotometer curves: (a) surgical cotton after 3 hours treatment with HCl, (b) cellulose II, (c) cellulose IV.

cellulose I and II. Utilizing this for indexing the reflections, the three alternatives *A*, *B* and *C* in Table 1 may all be possible. In the three phase alternative *C*, the peak $d = 5.70$ Å and part of the peak $d = 3.99$ Å are ascribed to cellulose IV, a diffractogram of which is shown in Fig. 1c. Unit cell dimensions and density for this modification and for cellulose I and II based on the best crystalline samples prepared in our laboratories are also included in Table 1.

In our experiments the three lines $d = 6.31$ Å, 5.70 Å and 5.13 Å always appeared in the same reciprocal intensity ratio. This makes it likely that only one phase exists besides cellulose II. Of the two-phase alternatives *A* and *B*, the first one gives a rather long *a*-axis and a low density and must be considered the less probable one. Alternative *B* has the cell dimensions of cellulose IV and may look as an ordered form of this modification. Strong (011) and (020) reflections would require a very strict ordering of the cellulose chains with respect to each other along the chain axis in the crystalline lattice, but even then it is questionable whether reflections of the observed strength can be realized.

Further it should be mentioned that the indexing under *A* and *B* in Table 1 would make the relative intensities of the lines very sensitive to preferred orientation. No difference between transmission and reflection diffractograms could be observed, however, even after severe pressing of the samples into thin sheets. Alternative *C* thus seems to have a preference since all the strong reflections here would originate from planes containing the axis of the cellulose chain.

There are also other facts that favour the three phase alternative. Thus the proposed new monoclinic modification has a unit cell closely resembling those of cellulose I and cellulose IV, and has the same density. One would accordingly expect an arrangement of the glucose rings similar to

Table 1. Indices an dcell dimensions for possible cellulose modifications.

Modification	Indices				Cell dimensions				Density (g/cm³)
	d=6.31 Å	d=5.70 Å	d=5.13 Å	d=3.99 Å	a (Å)	b (Å)	c (Å)	(°)	
Alternative A	101	101	020	002	9.08	10.3	8.03	95.9	1.44
» B	011	101	020	002	8.12	10.3	7.99	90	1.61
» C	101		101	002	8.10	10.3	8.16	101.7	1.615
Cellulose IV		101		002	8.12	10.3	7.99	90	1.61
» I					8.20	10.3	7.90	96.7	1.625
» II					8.02	10.3	9.03	117.2	1.62

that in the lattice of cellulose I. For alternative *C* this seems to hold true since the relative intensities of the three predominant reflections (101), (10$\bar{1}$) and (002) are very near the same as for cellulose I.

Attempts have also been made to utilize the other less pronounced peaks in the X-ray diffractograms in order to discriminate between the different possibilities without this leading to any substantially new arguments. Further experimental and theoretical work are in progress. A more comprehensive description of the hydrolysis and the experimental technique will be given elsewhere.

This investigation is part of a research program on the structure of cellulose carried out at the Central Institute for Industrial Research and the Norwegian Pulp and Paper Research Institute. Financial support from the *Royal Norwegian Council for Scientific and Industrial Research* is gratefully acknowledged.

Luminescence of Aqueous Solutions of Substances Irradiated with Ionizing Radiation in the Solid State

G. AHNSTROM and G. v. EHRENSTEIN

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Sweden

If we place glucose crystals irradiated with X-rays, gamma rays or with fast neutrons over the window of a sensitive photomultiplier (EMI 9514S) we observe a luminescence. This luminescence is also exhibited by some other substances irradiated in the solid state, *e. g.* sorbitol, amylopectin, saccharose and glycine. Dry seeds of *Agrostis stolonifera* also show luminescence after irradiation with X-rays.

The luminescence disappeared completely in all substances investigated during the first hour after irradiation. However, by dissolving *e. g.* irradiated glucose in water, in air and at room temperature, a new luminescence appeared which, after the lapse of one minute from the start of the dissolution, reached a comparatively constant level. During storage for one day at room temperature the luminescence decays to half of the value observed after one minute. Non-irradiated glucose showed no luminescence when dissolved in water.

Glucose which had been irradiated and stored in air at room temperature for some months, still showed luminescence after dissolving in water. The following experiments have been carried out with glucose which was irradiated three months ago in a reactor with a fast neutron dose of 200 Mrad and a contaminating gamma dose of 200 Mrad.

The water solution of this sugar had a pH of 3, 0.2 mole of acid ($pK_a = 4.2$) had been formed from one mole of glucose. The intensity of luminescence — *i. e.* the number of pulses recorded by a scaler (Ecko N530) — was a function of the pH of the solution. After alkalinization with 0.1 N NaOH the intensity of luminescence increased twentyfold. The luminescence of a solution of non-irradiated glucose was negligible on alkalinization. The absorption spectrum of the acid (pH 3) and the alkaline (pH 12) solution of irradiated glucose showed an absorption peak at 265 mμ, probably due to the presence of dihydroxyacetone [1]. The alkaline solution exhibited a stronger light absorption, thus excluding the possibility of the increase of the luminescence intensity of the alkaline solution being due to a decrease of the light absorption.

The luminescence intensity in aqueous alkaline solutions is directly proportional to the amount of irradiated glucose dissolved and also directly proportional to the radiation dose. This experiment has been performed with ^{60}Co gamma irradiated glucose at different dose levels between 60 and 170 Mrad. It should be noted here that irradiation of crystalline glucose with fast neutrons produced five to seven times more luminescence after dissolving in alkaline solution than irradiation with the same dose of gamma rays from ^{60}Co.

The addition of hydrogen peroxide, benzoylperoxide or dioxan containing hydroperoxides to the alkaline aqueous solution of irradiated glucose increases the luminescence intensity about tenfold. The luminescence of non-irradiated glucose in this system was negligible. Burnt glucose, however, also exhibited a strong luminescence in this system. On addition of trace amounts of Fe^{++} or Cu^{++} to the peroxide-irradiated glucose system at pH 3, the

that in the lattice of cellulose I. For alternative *C* this seems to hold true since the relative intensities of the three predominant reflections (101), (10$\bar{1}$) and (002) are very near the same as for cellulose I.

Attempts have also been made to utilize the other less pronounced peaks in the X-ray diffractograms in order to discriminate between the different possibilities without this leading to any substantially new arguments. Further experimental and theoretical work are in progress. A more comprehensive description of the hydrolysis and the experimental technique will be given elsewhere.

This investigation is part of a research program on the structure of cellulose carried out at the Central Institute for Industrial Research and the Norwegian Pulp and Paper Research Institute. Financial support from the *Royal Norwegian Council for Scientific and Industrial Research* is gratefully acknowledged.

Luminescence of Aqueous Solutions of Substances Irradiated with Ionizing Radiation in the Solid State

G. AHNSTROM and G. v. EHRENSTEIN

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Sweden

If we place glucose crystals irradiated with X-rays, gamma rays or with fast neutrons over the window of a sensitive photomultiplier (EMI 9514S) we observe a luminescence. This luminescence is also exhibited by some other substances irradiated in the solid state, *e. g.* sorbitol, amylopectin, saccharose and glycine. Dry seeds of *Agrostis stolonifera* also show luminescence after irradiation with X-rays.

The luminescence disappeared completely in all substances investigated during the first hour after irradiation. However, by dissolving *e. g.* irradiated glucose in water, in air and at room temperature, a new luminescence appeared which, after the lapse of one minute from the start of the dissolution, reached a comparatively constant level. During storage for one day at room temperature the luminescence decays to half of the value observed after one minute. Non-irradiated glucose showed no luminescence when dissolved in water.

Glucose which had been irradiated and stored in air at room temperature for some months, still showed luminescence after dissolving in water. The following experiments have been carried out with glucose which was irradiated three months ago in a reactor with a fast neutron dose of 200 Mrad and a contaminating gamma dose of 200 Mrad.

The water solution of this sugar had a pH of 3, 0.2 mole of acid ($pK_a = 4.2$) had been formed from one mole of glucose. The intensity of luminescence — *i. e.* the number of pulses recorded by a scaler (Ecko N530) — was a function of the pH of the solution. After alkalinization with 0.1 N NaOH the intensity of luminescence increased twentyfold. The luminescence of a solution of non-irradiated glucose was negligible on alkalinization. The absorption spectrum of the acid (pH 3) and the alkaline (pH 12) solution of irradiated glucose showed an absorption peak at 265 mμ, probably due to the presence of dihydroxyacetone [1]. The alkaline solution exhibited a stronger light absorption, thus excluding the possibility of the increase of the luminescence intensity of the alkaline solution being due to a decrease of the light absorption.

The luminescence intensity in aqueous alkaline solutions is directly proportional to the amount of irradiated glucose dissolved and also directly proportional to the radiation dose. This experiment has been performed with ^{60}Co gamma irradiated glucose at different dose levels between 60 and 170 Mrad. It should be noted here that irradiation of crystalline glucose with fast neutrons produced five to seven times more luminescence after dissolving in alkaline solution than irradiation with the same dose of gamma rays from ^{60}Co.

The addition of hydrogen peroxide, benzoylperoxide or dioxan containing hydroperoxides to the alkaline aqueous solution of irradiated glucose increases the luminescence intensity about tenfold. The luminescence of non-irradiated glucose in this system was negligible. Burnt glucose, however, also exhibited a strong luminescence in this system. On addition of trace amounts of Fe^{++} or Cu^{++} to the peroxide-irradiated glucose system at pH 3, the

intensity of the chemiluminescence increases even more [2]. With our present photomultipier assembly it was not possible to obtain a time dependency curve of this reaction.

In order to elucidate this catalytic effect of irradiated glucose on the decomposition of hydrogen peroxide, and organic peroxides and hydroperoxides, we tested some compounds which possibly arise by the action of ionizing radiation on glucose [1]. The relative luminescence intensities of the non-irradiated substances investigated in the alkaline hydrogen peroxide system were: glucose 0, glyceraldehyde 100, dihydroxyacetone 7, arabinose 0, glucuronic acid 1. From these data it can be tentatively concluded that glyceraldehyde may possibly be one of the substances responsible for the luminescence of irradiated glucose. This hypothesis is strengthened by the fact that non-irradiated glyceraldehyde exhibits a strong luminescence in aqueous alkaline solution without added peroxide.

Infrared spectroscopy showed that the irradiation induced carboxyl groups already in the solid glucose, while carbonyl groups are not formed until the irradiated glucose reacts with water.

By means of electron spin resonance, it has been shown that long-lived free radicals are induced by X-rays in different substances and in living material [3-5 and quoted literature]. It has been strongly indicated — that at least part of the biological radiation effects are produced *via* free radicals. A portion of the radiation damage in dry plant seeds is latent and can be modified during storage by, *e. g.*, temperature and oxygen. However, when the water content of the seeds rises, *e. g.* during germination, the damage becomes manifest, (*cf.* discussion) [7].

The observations described in this communication may give a method by which we hope to be able to elucidate the role played by water and oxygen in radiobiological processes. The phenomena studied in this communication are also relevant in the discussion concerning the radiation preservation of foodstuffs and the possible mutagenicity of these. It is worthwhile in this connection to mention that mutations have been observed when biologic material — barley and wheat seeds — is treated with the aqueous solutions of irradiated substances, *e. g.* glucose, glycine [8], agar [9].

The investigations are being continued on a quantitative and qualitative basis, including emission spectroscopy during and after irradiation with ionizing radiation.

The authors' thanks are due to Dr. L. Ehrenberg for his promoting interest in this investigation.

Use of Butyl Acetate in Determination of Sialic Acid

T. MIETTINEN
and I. -T. TAKKI-LUUKKAINEN

Department of Medical Chemistry, University of Helsinki, Finland

Determination of sialic acid can be performed with several reactions: the Bial [1,2], direct Ehrlich [3], tryptophane-perchloric acid [4], diphenylamine [5,6] and sulphuric acid — acetic acid [7] reactions. Orcinol used in Bial's reaction has been replaced by resorcinol [8]. In all orcinol and resorcinol reactions presented in the literature the colour is extracted by amyl alcohol. This solvent extracts very effectively the developed pigments, but its disadvantages are the long procedure of purification, the necessity of centrifugation after extraction, and especially its ability to extract also the false pigments produced by other carbohydrates. Ion exchange resins and dichromatic readings are used to eliminate

intensity of the chemiluminescence increases even more [2]. With our present photomultipier assembly it was not possible to obtain a time dependency curve of this reaction.

In order to elucidate this catalytic effect of irradiated glucose on the decomposition of hydrogen peroxide, and organic peroxides and hydroperoxides, we tested some compounds which possibly arise by the action of ionizing radiation on glucose [1]. Use of Butyl Acetate in Determination of Sialic Acid

T. MIETTINEN
and I. -T. TAKKI-LUUKKAINEN

Department of Medical Chemistry, University of Helsinki, Finland

Determination of sialic acid can be performed with several reactions: the Bial [1,2], direct Ehrlich [3], tryptophane-perchloric acid [4], diphenylamine [5,6] and sulphuric acid — acetic acid [7] reactions. Orcinol used in Bial's reaction has been replaced by resorcinol [8]. In all orcinol and resorcinol reactions presented in the literature the colour is extracted by amyl alcohol. This solvent extracts very effectively the developed pigments, but its disadvantages are the long procedure of purification, the necessity of centrifugation after extraction, and especially its ability to extract also the false pigments produced by other carbohydrates. Ion exchange resins and dichromatic readings are used to eliminate

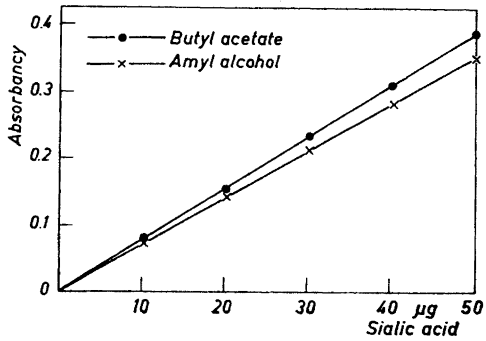

Fig. 1. Standard curves of N-acetylsialic acid read at 580 mμ against the blank. — ● — ● — Extracted with 4 ml of butyl acetate. × — × — × Extracted with 4 ml of amyl alcohol.

this last mentioned error [2,3,9]. The purpose of this work was to find an extracting solvent possessing as little of the mentioned disadvantages as possible.

The determination of sialic acid was performed by the resorcinol reaction [8], using as standard N-acetylsialic acid.* Of the many tested organic solvents, only butyl acetate, in addition to amyl alcohol, was found to be suitable. When used in 100 % concentration its ability to extract was negligible, but after addition of butyl alcohol this capacity was increased. For this reason *Butylium aceticum 85 percent normal ("Merck")* was chosen for use as such. Some minutes after extraction this solvent separates as crystal-clear layer without centrifugation also when proteins are present. The corresponding determinations were performed with both amyl alcohol and butyl acetate, using 4 ml of each solvent. The photoelectric readings were made with the Beckman Spectrophotometer model B in 10 mm cells.

It is seen from Fig. 1 that butyl acetate extracts increasing amounts of N-acetylsialic acid correctly. The two curves deviate because amyl alcohol dissolves more of the

* The N-acetylsialic acid was kindly presented to us by Dr. Lars Svennerholm, M. D., Gothenburg, Sweden.

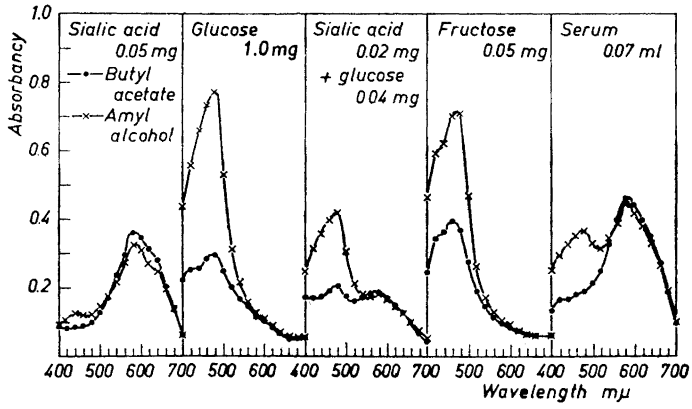

Fig 2. Absorption curves of N-acetylsialic acid, glucose, mixture of glucose and N-acetylsialic acid, fructose and serum without precipitation of proteins. Readings against reagent blank.

water layer, resulting in lower extinctions. It was observed that when the final volume in the reaction increased from 2 to 8 ml and the extraction was performed with 4 ml in each case, the absorbancy was somewhat smaller in greater volumes when butyl acetate was used. With amyl alcohol it remained constant. Thus butyl acetate seems to have a somewhat lower extracting capacity. This is, however, sufficient if the volume used in the reaction is 2—4 ml.

The shapes of the absorption curves in Fig. 2 are quite similar for both solvents, the maximum being at 580 mμ. At shorter wavelengths there is a slight difference, however. Examples of absorption spectra produced by carbohydrates (Fig. 2) are those of fructose and glucose. These substances have their maxima around 480 mμ. As is seen from the figure, butyl acetate has a remarkably lower peak at this point. Thus butyl acetate does not extract all the disturbing pigments, which is apparent already macroscopically from the strikingly yellow colour of the water layer after extraction if false pigments are present. Also at 580 mμ the absorbancy of glucose is smaller in the butyl acetate extraction. One mg of glucose corresponds to about 15 μg of sialic acid when butyl acetate is used, and to 21 μg with amyl alcohol.

From the absorption curves for a mixture of glucose and sialic acid and for serum rich in disturbing substances it is seen that butyl acetate leaves most of the disturbing pigments in the water layer.

ACTA CHEMICA SCANDINAVICA 13 (1959) 859–863

The Reaction between Ethylidenemalonic Ester and *o*-Methoxyphenylmagnesium Iodide

GUST.-AD. HOLMBERG

Institutet för organisk kemi, Åbo Akademi, Åbo, Finland

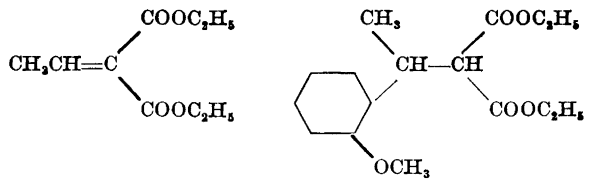
1-(*o*-Methoxyphenyl)ethylmalonic ester (II) and α-*o*-methoxybenzoyl-β-*o*-methoxyphenylbutyric ester (III) are formed in the reaction between ethylidenemalonic ester (I) and *o*-methoxyphenylmagnesium iodide. The latter reaction product has not been isolated as a pure compound, but its presence has been demonstrated by isolation of 1,3-di-*o*-methoxyphenyl-1-butanone (IV) (as its 2,4-dinitrophenylhydrazone) from the saponification products.

The identity of the isolated substances has been demonstrated by synthesis.

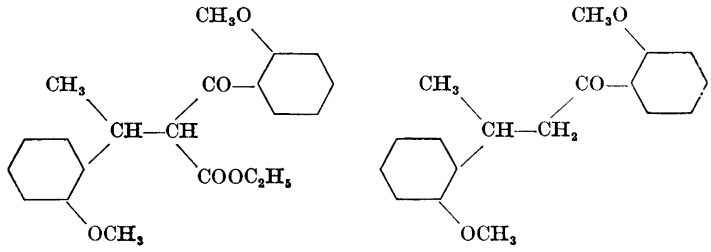
A preliminary examination of the reactions between ethylidenemalonic ester (I) and some aliphatic and aromatic Grignard reagents has shown that the main reaction seems to be 1,4-addition to the conjugated system [1].

When *o*-methoxyphenylmagnesium iodide was allowed to react with the unsaturated malonic ester, substances were found among the reaction products that could not have been formed by 1,4-addition only. The separation of the products was, however, difficult but some separation was attained by chromatography on alumina. The products were applied to the column in tetrachloromethane and the development and elution were performed successively with tetrachloromethane, ether, an ether-ethanol mixture and ethanol. The "normal" reaction product, 1-(*o*-methoxyphenyl)ethylmalonic ester (II), was eluted by tetrachloromethane. No pure product could be isolated from the ether fraction, but on saponification of the ether extract potassium carbonate and a neutral oil were obtained. The latter gave with 2,4-dinitrophenylhydrazine the 2,4-dinitrophenylhydrazone of 1,3-di-*o*-methoxyphenyl-1-butanone (IV).

This result indicates that the mixture of reaction products contains α-*o*-methoxybenzoyl-β-*o*-methoxyphenylbutyric ester (III), which is formed by 1,4-addition combined with a substitution of a methoxyphenyl group for an ethoxy group. Nothing can, of course, be concluded from the experimental results about the mechanisms leading to the above butyric ester.



I II



III IV

A similar double reaction between a Grignard reagent and an α,β-unsaturated ester has been reported by, *e.g.*, Kohler [2], who isolated α-benzhydrylpropiophenone as a by-product of the reaction between phenylmagnesium bromide and α-methylcinnamic ester.

When the ratio of the ethylidenemalonic ester to the Grignard reagent was 1:1.5, about 35 % of the ester had reacted to form 1-*o*-methoxyphenylethylmalonic ester. When the quantity of the Grignard reagent was increased so that the ratio was 1:2, about 50 % reacted in the same way. It was concluded from the quantity of potassium carbonate formed in the saponfication of the butyric ester derivative in the latter case that at least 19.6 % of the ethylidenemalonic ester had reacted twice with the Grignard reagent.

The identity of the reaction products was established by synthesis. 1-*o*-methoxyphenylethylmalonic ester was obtained in good yield by reacting methylmagnesium iodide with *o*-methoxybenzylidenemalonic ester. The same malonic and barbituric acids were obtained from this ester and the above ester. The malonic acid was decarboxylated to β-*o*-methoxyphenylbutyric acid, which was converted into the corresponding amide. This substance was dehydrated by a modification of a method of Stephens, Bianco, and Pilgrim [3] to form β-*o*-methoxyphenylbutyronitrile, which by a reaction with *o*-methoxyphenylmagnesium iodide gave 1,3-di-*o*-methoxyphenyl-1-butanone.

EXPERIMENTAL

o-*Methoxybenzylidenemalonic ester.* The yield of this substance [4] from the reaction between *o*-methoxybenzaldehyde and malonic ethyl ester in the presence of piperidine was improved and the reaction time shortened to 5 h by adding a small quantity of *o*-methoxybenzoic acid (1 g/100 g malonic ester) to the reaction mixture. The yield of material boiling at 207—209°/11 mm was 84 %. Before the ester was used in the following synthesis, it was twice recrystallized from ligroin.

1-(o-Methoxyphenyl) ethylmalonic ester. A solution of *o*-methoxybenzylidenemalonic ester (27.8 g) in dry ether (100 ml) was gradually added with cooling to a Grignard reagent prepared from magnesium (2.88 g) and methyl iodide (17.04 g) in dry ether (55 ml). During this addition two layers usually formed. Only when the cooling was less effective, the addition resulted in a homogeneous solution, which, however, separated into two layers on cooling. When the addition was complete, the reaction mixture was stirred for 20 minutes before it was poured into a mixture consisting of hydrochloric acid (70 ml), water (100 ml) and ice (about 100 g). After shaking, the organic phase was washed with water and a dilute potassium carbonate solution. The acid water solution was extracted once more with ether and this ether was also washed with water and potassium carbonate before it was combined with the main portion. After drying with sodium sulphate, the ether was evaporated and the residue distilled under reduced pressure. The yield of the ester, b.p. 183—183.5°/10 mm, was 89 % (26.19 g). (Found: C 65.10; H 7.57. Calc. for $C_{16}H_{22}O_5$: C 65.29; H 7.53.)

The same percentage yield was obtained from a larger batch (0.3 mole).

1-(o-Methoxyphenyl) ethylmalonic acid. 1-*o*-Methoxyphenylethylmalonic ester (37.66 g) was saponified with a solution of potassium hydroxide (38 g) in a mixture of water (40 ml) and ethanol (450 ml) during 5 h on a boiling water bath. The mixture was then kept in a refrigerator over night. The crystals (37.08 g) of potassium 1-*o*-methoxyphenylethylmalonate monohydrate were filtered off. (Found: H_2O 5.37. Calc. for $C_{12}H_{13}O_5K_2 \cdot H_2O$: 5.42.) This salt was dissolved in water (200 ml) and the solution acidified. The precipitated 1-*o*-methoxyphenylethylmalonic acid (25.04 g) melted at about 170° with evolution of gas. (Found: C 60.39; H 5.93. Calc. for $C_{12}H_{14}O_5$: C 60.50; H 5.92.)

The alkaline ethanolic filtrate was evaporated on a boiling water bath. The crystals that had formed on cooling were filtered and washed with ether. They were dissolved in water and the solution acidified. In this way a further quantity (3.56 g) of the malonic acid was obtained. The total yield of the acid was 93.8 %.

β-(o-Methoxyphenyl)butyric acid. 1-*o*-Methoxyphenylethylmalonic acid (28.5 g) was decarboxylated by heating in an oil bath at 170—180° for 15 min. The residue (23.0 g) was distilled under reduced pressure. In this way, pure *β-o*-methoxyphenylbutyric acid, b.p. 180—181°/15 mm, was obtained in a yield of 94.5 % (21.9 g). On standing and treatment with ligroin, the acid solidified and melted at 49—50°. The melting and boiling points correspond well with those reported by Lauer and Hansen [5], who prepared the acid by another method.

β-(o-Methoxyphenyl) butyramide. A mixture of *β-o*-methoxyphenylbutyric acid (22.8 g), thionyl chloride (20 ml) and benzene (40 ml) was heated on a boiling water bath for half an hour. The solvent and the excess of thionyl chloride were then distilled off (finally under reduced pressure). The residue, crude *β-o*-methoxyphenylbutyryl chloride, was dissolved in benzene (75 ml). This solution was gradually added to benzene (125 ml) through which dry ammonia was led at such a rate that an excess of ammonia was present during the whole addition. The flask was at the same time cooled with cold water. Next day the mixture was filtered and the solid material dissolved in boiling water. When the solution cooled, crystals of *β-o*-methoxyphenylbutyramide (16.45 g) separated. After recrystallization from water the substance melted at 127—128°. (Found: N 7.37. Calc. for $C_{11}H_{15}NO_2$: N 7.25.)

β-(o-Methoxyphenyl)butyronitrile. *β-o*-Methoxyphenylbutyramide (19.76 g) was dissolved in pyridine (90 ml), and benzenesulphonyl chloride (31.0 g) was added. After the exothermic reaction was over, the reaction flask was placed in warm water for 20 min. The mixture was then poured into water and the oil taken up in ether. The ether solution was shaken with dilute hydrochloric acid and potassium bicarbonate solution and finally dried with sodium sulphate. After evaporation of the ether, the residue was distilled under reduced pressure. The yield of *β-o*-methoxyphenylbutyronitrile, b. p. 148—149°/10.5 mm, was 81.5 % (14.60 g). (Found: N 8.03. Calc. for $C_{11}H_{13}NO$: N 7.99.)

2,4-Dinitrophenylhydrazone of 1,3-di-o-methoxyphenyl-1-butanone. A solution of *β-o*-methoxyphenylbutyronitrile (7.80 g) in dry ether (50 ml) was gradually added with cooling to a Grignard reagent prepared from magnesium (1.60 g) and *o*-iodoanisole (15.64 g) in dry ether (50 ml). During the addition, the reaction mixture separated into two layers. After all the nitrile had been added, the mixture was kept for one hour at room temperature. When it was then poured into an excess of dilute hydrochloric acid, a substance

(probably the ketimino hydrochloride) insoluble in both ether and water separated. Steam was led through the reaction mixture for one hour in order to hydrolyze the formed ketimine. The remaining oil was taken up into ether, in which it was readily soluble, and the ether solution washed with dilute sodium hydroxide. After drying with sodium sulphate, the ether was evaporated. An oil (11.06 g) remained in the flask.

A sample of this oil (1.36 g) was treated with 2,4-dinitrophenylhydrazine (0.53 g) in dilute ethanolic sulphuric acid. The quantity of hydrazine was intentionally chosen small in order to facilitate the later purification of the reaction product. On boiling yellow crystals (1.13 g) of 2,4-dinitrophenylhydrazone of 1,3-di-*o*-methoxyphenyl-1-butanone separated from the solution. After recrystallization from ethanol, the hydrazone melted at 158—159°. (Found: N 11.92. Calc. for $C_{24}H_{24}N_4O_6$: N 12.06.)

1,3-Di-*o*-methoxyphenyl-1-butanone was isolated from the above oily reaction product. It boiled at 219—221°/8.5 mm, but was not qute pure.

5-(1'-o-Methoxyphenylethyl)barbituric acid. Urea (1.44 g) and 1-*o*-methoxyphenylethylmalonic ester (5.88 g) were added to a sodium ethoxide solution prepared from sodium (0.55 g) and absolute ethanol (30 ml). The mixture was boiled for 8 h on a boiling water bath. The precipitate formed was filtered, washed with a small amount of absolute ethanol, and dissolved in water. The dihydrate of the barbituric acid (3.05 g) precipitated on adding hydrochloric acid. The ethanol was distilled off from the ethanolic filtrate, the residue treated with water and ether, and impure dihydrate of the barbituric acid (1.40 g) precipitated with acid from the aqueous phase. The crude products were repeatedly recrystallized from aqueous ethanol. The dihydrate melts at 92—94° on rapid heating and at 154—155° on slow heating. (Found: N 9.29; H_2O 12.24. Calc. for $C_{13}H_{14}N_2O_4 \cdot 2\,H_2O$: N 9.39; H_2O 12.08.) When the dihydrate is boiled with benzene or heated on a Kofler Heizbank at 70°, the anhydrous barbituric acid is formed. It melts sharply at 154—155°. (Found: N 10.60. Calc. for $C_{13}H_{14}N_2O_4$: N 10.68.) When the anhydrous barbituric acid is recrystallized from aqueous ethanol, the dihydrate is formed.

1-(o-Methoxyphenyl)ethylmalonic p-nitrobenzyl ester. 1-*o*-Methoxyphenylethylmalonic acid was characterized by preparing its *p*-nitrobenzyl ester, m. p. 144—145°, according to Reid [6]. (Found: N 5.58. Calc. for $C_{26}H_{24}N_2O_9$: N 5.51.)

Action of o-methoxyphenylmagnesium iodide on ethylidenemalonic ester. When 0.1 mole of ethylidenemalonic ester was allowed to react with 0.15 mole of *o*-methoxyphenylmagnesium iodide as previously described [1], no pure substance could be isolated by distillation under reduced pressure. Only impure 1-*o*-methoxyphenylethylmalonic ester was obtained in a yield of about 35 %. If the ratio of the ester to the Grignard reagent was changed to 1:2, a yield corresponding to about 50 % was obtained. The impurities seem to result from the pyrolysis of other reaction products than 1-*o*-methoxyphenylethylmalonic ester.

In order to obtain a sufficiently large quantity of the reaction product mixture, ethylidenemalonic ester (52.46 g) in dry ether (85 ml) was gradually added, with cooling, to a Grignard reagent prepared from magnesium (13.56 g) and *o*-iodoanisole (132 g) in dry ether (260 ml). The molar ratio of the ester to the Grignard reagent was thus 1:2. After the addition had been completed, the mixture was stirred for 20 min. The two layers formed were then poured into a mixture of hydrochloric acid, water and ice. After shaking, the organic phase was washed with water and potassium carbonate solution. After drying with sodium sulphate and evaporating the ether, an oil (105 g) was obtained.

After preliminary experiments the following separation method was considered most effective.

A sample of the oil (10.80 g) was dissolved in tetrachloromethane (50 ml). The solvent was then distilled off in order to remove any ether remaining in the oil. The residue was again dissolved in tetrachloromethane (50 ml) and this solution was transferred to a large chromatographic column consisting of standardized alumina (200 g; Riedel-de Haën A.G.) and tetrachloromethane. The chromatogram was developed with tetrachloromethane (650 ml) and the elution was performed first with ether (300 ml), then with ether and ethanol (1:1; 300 ml) and finally with ethanol (600 ml). After the solvents had been evaporated, it was found that the tetrachloromethane fraction contained 48.8 % (5.28 g) of the original oil, the ether fraction 35.4 % (3.83 g), the ether-ethanol fraction 6.6 % (0.71 g) and the ethanol fraction 1.7 % (0.18 g). The substance lost was 7.4 % (0.80 g).

When the combined tetrachloromethane fractions from two runs (22.03 g of the original oil in all) were worked up, a substance (8.61 g) boiling at 186—189°/12 mm was

obtained. The substance was in every respect identical with 1-*o*-methoxyphenylethylmalonic ester. The amount corresponds to a yield of about 49 % calculated on ethylidenemalonic ester. The forerun (1.36 g) in the distillation had a smell of anisole, but was not examined further.

Experiments conducted to separate the substances in the ether fraction chromatographically were not successful. A sample (17.81 g) of the combined residues was therefore examined in the following way. It was dissolved in ethanol (100 ml) and the solvent distilled off to drive away any remaining ether. The substance was then dissolved in ethanol (300 ml), a solution of potassium hydroxide (20 g) in water (20 ml) added, and the mixture heated on a boiling water bath. After 4 h it was cooled and kept for one night in a refrigerator. The mixture was filtered and the solid substance dissolved in water. By titrimetric analysis it was found that the substance was potassium carbonate (3.65 g in all). The ethanol was evaporated from the alkaline ethanolic filtrate and the residue treated with ether and water. After the evaporation of the solvent from the ether phase, an oil (8.51 g) was obtained. When this oil was treated with 2,4-dinitrophenylhydrazine, an impure hydrazone (8.00 g) was formed. After several recrystallizations from ethanol it melted at 158—159° and was identical with the above-mentioned 2,4-dinitrophenylhydrazone of 1,3-di-*o*-methoxyphenyl-1-butanone. On acidification of the aqueous phase, a resinous substance (5.70 g) was obtained. No pure substance has yet been isolated from it.

The ether-ethanol and the ethanol chromatographic fractions yielded no pure substance.

The Acid Hydrolysis of Alkoxymethyl Ureas

FRODE NORDHØY and JOHN UGELSTAD

Institute of Industrial Chemistry, Norges tekniske høgskole, Trondheim, Norway

The hydrolysis of alkoxymethyl ureas in acid solution has been investigated kinetically. The hydrolysis leads to the formation of methylol urea, which in turn will decompose to give formaldehyde and urea. The hydrolysis of the ether is a very fast reaction compared to the subsequent decomposition of the methylol compound. Values for the specific catalytic constant of H_3O^+ are given for some ethers with different ether-alkyl groups. Increased branching of the alkyl group increases the rate of hydrolysis. Ethers of methylol compounds of ordinary carboxylic acid amides are much more stable to acid hydrolysis than the ethers from methylolurea.

The alkyl ethers of methylolurea decompose in acid solution, leading to the liberation of free formaldehyde. From the kinetic experiments described below evidence is obtained that the reaction proceeds as follows:

$$NH_2CONHCH_2OR + H_2O \rightarrow NH_2CONHCH_2OH + ROH$$

$$NH_2CONHCH_2OH \rightarrow NH_2CONH_2 + CH_2O$$

In the first step the ether is hydrolysed giving methylolurea and alcohol. In the next step the methylolurea decomposes into urea and formaldehyde. The latter reaction is known to be acid catalysed [1]. In the above scheme the first step, the ether hydrolysis, is a much faster reaction than the second. Formerly published results on the rate of the acid catalysed decomposition of alkoxymethyl ureas [2], where the reaction has been followed by measurement of free formaldehyde formed, have, in fact, given the rate of the decomposition of methylolurea, the second step in the above scheme.

KINETIC INVESTIGATIONS

The kinetic investigations were performed in dilute water solutions (0.01—0.03 mole/l of ether). The pH was adjusted by use of acetic acid-acetate buffers or by addition of strong acid (HNO_3). In each experiment the ionic strength was adjusted to 0.2 by the addition of KNO_3. To obtain the rate of

hydrolysis of the ether, step 1 in the above scheme, it is necessary to analyse samples from the reaction mixture for the sum of free formaldehyde and formaldehyde bound as methylol urea (= ether converted). This was achieved by transferring the samples into a solution containing excess KCN and enough NaOH to bring the pH to 13. Under these conditions the methylol urea is rapidly decomposed into urea and formaldehyde, and the latter reacts practically spontaneously with KCN. After 30 minutes at 25°C the excess KCN is titrated with $Hg(NO_3)_2$ [3].

Use of higher alkalinity to speed up the rate of decomposition of the methylol urea is not advisable as the hydrolysis of the ethers themselves then becomes more pronounced [4]. Even at pH 13 the alkoxymethyl ureas will decompose to a small degree which has to be taken into consideration in calculating the rate constants as described later.

The hydrolysis of the ethers was followed up to about 75 % conversion. The rate of the reverse reaction of step 1 could be neglected under the experimental conditions.

The reaction was found to be of 1st order with regard to ether. Values for the specific catalytic constant of H_3O^+ for different ethers are given in Table 1.

The $[H_3O^+]$ values of the acetic acid-acetate solutions were calculated from the equation:

$$[H_3O^+_{(a)}] = K_a \cdot \frac{[HA]}{[A^-]} \Big/ \frac{f_{H^+} \cdot f_{A^-}}{f_{HA}}$$

where f are activity coefficients. The value of the term $f_{H^+} \cdot f_{A^-} / f_{HA}$ was taken to be 0.60 at the given ionic strength = 0.2 [5].

Table 1. Specific catalytic constants of H_3O^+ for the hydrolysis of some alkoxymethyl ureas and methoxymethyl benzamide.

	$k_{H_3O^+}$ (l · mole^{-1}sec^{-1})	Temp. °C
$NH_2CONHCH_2OCH_3$	2.8	25
»	12.2	40
$NH_2CONHCH_2OCH_2CH_3$	3.9	25
$NH_2CONHCH_2OCH_2CH_2CH_3$	3.9	25
$NH_2CONHCH_2OCH(CH_3)_2$	7.3	25
$C_6H_5CONHCH_2OCH_3$	7.3×10^{-3}	40

As seen from the table the rate of hydrolysis increases with increased branching of the alkyl groups.

The rate constant of an ether of a methylol compound of an ordinary carboxylic amide, *i. e.* methoxymethyl benzamide is also included in the table for comparison. The rate constant of the latter is about 1 650 times lower than for the corresponding urea ether. The difference is due to the difference in activation energy, which was found to be 18.1 and 23.0 kcal/mole for methoxymethyl urea and methoxymethyl benzamide, respectively.

Any contribution of HAc to the rate observed in the acetic acid-acetate buffers could be neglected under the given experimental conditions; some results confirming this are given in Table 2.

Table 2. $[Ac^-] / [HAc] = 1$.

[HAc]	$NH_2CONHCH_2OCH_3$ Temp. 25°C $k \times 10^5$ (sec^{-1})	$C_6H_5CONHCH_2OCH_3$ Temp. 40°C $k \times 10^7$ (sec^{-1})
0.2	8.2	2.1
0.06	8.1	2.1
0.02	8.1	2.1

Increasing the buffer concentration while keeping $[H_3O^+]$ constant does not influence the rate of hydrolysis. The rate constant observed in HAc—Ac buffers can therefore be taken as solely due to the effect of H_3O^+.

Evidence for the proposed reaction scheme, *i. e.* that the monomethylol compound is initially formed by the hydrolysis, was obtained from kinetic experiments where the samples were separately analysed also for free formaldehyde. Free formaldehyde could be determined separately by reaction with KCN at pH~8. At this pH the methylol compounds are fairly stable while the KCN-formaldehyde reaction is completed [6] within 5 min.

Results of these experiments with methoxymethyl urea and methoxymethyl benzamide are shown in Tables 3 and 4 where methylol compound + formaldehyde and free formaldehyde, as found experimentally, are given as % of initial amount of ether.

Table 3. Comparison between the amount of ether converted and free formaldehyde formed during the course of the reaction. HAc = 0.02 moles/l, B/A = 1. Temp. = 25°C.

Time (10^3 sec.)	Methoxymethyl urea % Ether converted (Methylol urea + CH_2O)	Free CH_2O %
1.8		1.2
3.9	27.1	2.0
7.2	44.8	3.2
14.4	69.3	4.0

Table 4. [HAc] = 0.02 mole/l, B/A = 0.25. Temp. = 40°C.

Time (10^4 sec.)	Methoxymethyl benzamide % Ether converted (Methylol benzamide + CH_2O)	Free CH_2O %
8.28		1.6
17.37	13.0	2.6
28.71	21.0	3.1
54.72	35.5	3.8

It will be seen from Tables 3 and 4 that, even after conversion of a large percent of the ether, only very little free formaldehyde is present in the reaction mixture. This excludes the possibility that the ether is initially broken at the dotted line in

$$R-CO-NH\vdots CH_2-O-CH_3$$

The hemiacetal thus formed would rapidly decompose to give free formaldehyde. Moreover, the methylol amide found could not have been formed from a recombination of free formaldehyde and urea. The equilibrium constant for this reaction is such that, with the dilute solutions used, most of the formaldehyde should exist in the free form. Furthermore, the rate constants for the reaction of amide and formaldehyde are much too low to allow any considerable recombination during the time of hydrolysis given in the tables.

REACTION MECHANISM

In spite of the fact that HAc showed no catalytic effect a mechanism which involves a general acid catalysis seems most probable. The effect of HAc may be difficult to detect because of the much greater effect of H_3O^+ in the pH range 4—5. Thus Dunn found a catalytic effect of piperidinium ion in the pH range 10.5—11.2 where a general acid effect should be more easily detected. The H_3O^+ catalysed reaction may therefore take place according to the following mechanism.

$$1.\ RCONHCH_2OR' + H_3O^+ \rightleftharpoons RCONHCH_2\overset{H^+}{O}R' + H_2O$$

$$2.\ RCONHCH_2\overset{H^+}{O}R' + H_2O \xrightarrow{k_2} RCON{=}CH_2 + R'OH + H_3O^+$$

$$3.\ RCON{=}CH_2 + H_2O \rightarrow RCONHCH_2OH$$

In step 2, which is rate determining, alcohol is split off with the formation of an unstable Schiff's base which in step 3 adds water to give the methylol compound. The rate of the reaction catalysed by H_3O^+ will be given by:

$$v = k_2K_1[RCONHCH_2\overset{H^+}{O}R'][H_3O^+][H_2O] \quad (K_1 = [RCONHCH_2\overset{H^+}{O}R']/[RCONHCH_2OR][H_3O^+])$$

The great difference between the rate of hydrolysis of the urea and the benzamide ether is most probably explained by the effect of the group R on the value of k_2. The formation of the double bound $N{=}CH_2$ with the simultaneous liberation of alcohol in step 2 involves an electron displacement from left to right. This displacement will most probably be hampered by the electron attracting C_6H_5 group and facilitated by the electron relasing NH_2 group.

An increased branching of the alkyl group will increase the basicity of the ether oxygen, and thus the value of K_1 in the rate equation. Apparently this effect more than outweighs the small counteracting effect which might be expected on the value of k_2.

DISCUSSION

Recently Dunn [2] has published results from the acid decomposition of the methoxymethyl urea. However, he has determined the rate by measuring free formaldehyde liberated during the experiment. What really is measured therefore is the rate of reaction 2, *i. e.* the decomposition of methylolurea, which decomposes with a much slower rate than the ether hydrolysis in step 1. Thus Dunn finds a rate constant,

$$k_{H_3O} = 1 \times 10^{-3} \text{ (l} \cdot \text{sec}^{-1} \cdot \text{mole}^{-1}\text{) at } 25°C$$

which is approximately the same as formerly given by de Jong and de Jonge for the decomposition of methylolurea. The value given in this paper is 2 800 times higher than the value given by Dunn.

The ethers were prepared according to procedures given by Kadowaki [7] and Ugelstad and de Jonge [4].

As mentioned above, the alkoxymethyl urea will also decompose to a small degree during the treatment with alkaline KCN solution used for determination of methylolurea and formaldehyde formed by the acid hydrolysis. This error is serious only with measurements taken at low conversions of the ether. It could be approximately corrected for as follows:

Let E_i = moles of ether in the sample taken from the reaction mixture at the start of the kinetic run ($t = 0$),
F' = formaldehyde liberated from E_i moles of ether during the analysis,
E_1 = the actual amount of undecomposed ether in the sample taken for analysis at a given time interval t_1,
UF_1, F_1 = the corresponding values for methylolurea and free formaldehyde in the same sample,
F = formaldehyde found by analysis of the sample taken at time t_1,
Then the latter is approximately given by:

$$F = UF_1 + F_1 + F' \cdot E_1/E_i \tag{6}$$

A material balance for the ether gives:

$$E_i = E_1 + UF_1 + F_1 \tag{7}$$

Combination of eqns (6) and (7) gives the degree of conversion of ether at time t_1:

$$\frac{E_i - E_1}{E_i} = \frac{F - F'}{E_i - F'}$$

Studies on Some Metal Complexes of Catechol-3,5-disulphonic Acid

REINO NÄSÄNEN

Institute of Chemistry, University of Helsinki, Finland

The investigation of the complex formation of catechol-3,5-disulphonic acid with divalent metals has been continued. The data obtained by the pH method on the lead complexes can be explained satisfactorily by postulating the formation of the complexes $PbHL^-$ and PbL^{2-} where L is the ligand. The formation of PbL_2^{6-} could not be established by the method used. The respective equilibrium constants were calculated. The formation of copper complexes was reinvestigated. In addition to the complexes CuL^{2-} and CuL_2^{6-} previously studied by the present author, the complex $CuHL^-$ is obviously also formed at low ionic strengths, but in 1 M sodium perchlorate solution no such ion could be detected. The respective equilibrium constants have been calculated. The complexes formed between catecholdisulphonic acid and six divalent metals hitherto studied by the present author are discussed.

The complex formation of catechol-3,5-disulphonic acid with divalent metals is generally considered to involve the reactions [1,5]:

$$M^{2+} + H_2L^{2-} \rightleftharpoons MHL^- + H^+ \quad (1)$$

$$M^{2+} + H_2L^{2-} \rightleftharpoons ML^{2-} + 2\ H^+ \quad (2)$$

$$M^{2+} + 2\ H_2L^{2-} \rightleftharpoons ML_2^{6-} + 4\ H^+ \quad (3)$$

The role of the first reaction has been found to be relatively slight in all cases studied hitherto. In 1 M sodium perchlorate solution the measurements relating to the copper complexes did not even show any formation of the complex MHL^-, as will be described below. The third equilibrium is important only in the cases of zinc and copper.

Reactions (1) and (2) overlap when $c_B < 2c_M$ and the equilibrium constants defined by

$$K_H = [MHL^-] / [ML^{3-}] [H^+] \quad (4)$$

and

$$K_I = [ML^{3-}] [H^+]^2 / [M^{2+}] [H_2L^{2-}] \quad (5)$$

can be calculated from the equation

$$1/K_I = (1 + K_H [H^+]) (c_M - c') / c' + K_{II} (2c_M - c') x^2 / c', \quad (6)$$

where c_M is the total metal concentration, $c' = c - [H_2L^{2-}] (1 + K_3 / [H^+])$ and $x = [H_2L^{2-}] / [H^+]^2$. The concentration of H_2L^{2-} is obtained from

$$[H_2L^{2-}] = (2c - c_B - [H^+] - [MHL^-]) / (2 + K_3 / [H^+]) \quad (7)$$

and

$$[MHL^-] = c' [H^+] K_H / (1 + K_H [H^+] + 2 K_{II} x), \quad (8)$$

where c and c_B are the total concentrations of Na_2H_2L and sodium hydroxide, respectively. The constant K_3 is defined by

$$K_3 = [H^+] [HL^{3-}] / [H_2L^{2-}] \quad (9)$$

The second term of eqn (6) is negligible when the ionic strength is low and $c_B < 2c_M$, but in 1 M $NaClO_4$ it must be taken into account since the equilibrium constant K_{II} of the reaction

$$ML^{3-} + H_2L^{2-} \rightleftharpoons ML_2^{6-} + 2\ H^+ \quad (10)$$

increases very greatly with ionic strength. The details of the calculation of the constants K_I and K_H have been described previously [1].

The constant K_{II}

defined by

$$K_{II} = [ML_2^{6-}] [H^+]^2 / [ML^{3-}] [H_2L^{2-}] \quad (11)$$

can also be calculated by means of eqn (6), which in this case is best used in the form

$$K_{II} = \frac{(1 + K_H [H^+]) (c' - c_M)}{x (2c_M - c')} + \frac{c'}{K_I x^2 (2 c_M - c')} \quad (12)$$

The calculation of K_{II} is, of course, possible only when $2 c_M < c_B < 4 c_M$ and $c_M \leqq 2 c$. The second term of eqn (12) is negligible at low ionic strengths, but must be taken into account in 1 M $NaClO_4$. The term $K_H [H^+]$ has been found to be negligible in the calculation of K_{II}.

EXPERIMENTAL

Beckman glass electrodes, types 4990—83 and E-2 were used. As reference electrode a calomel electrode was employed. When no neutral salt had been added to the solution studied, the electrode vessel and bridge were filled with a saturated solution of potassium chloride. When the solution to be measured was 1 M in sodium perchlorate, the electrode vessel and bridge were filled with a 1 M NaCl solution. In the former case a 0.05 M solution of potassium hydrogen phthalate, pH = 4.01, and in the latter case an acetate buffer

Table 1. Determination of hydrogen ion concentration of the acetate buffer at 25°C.

Solutions of hydrochloric acid, 1 M in $NaClO_4$		Acetate buffer, 0.005 M in acetic acid, 0.005 M in sodium acetate, 1 M in $NaClO_4$	
$-\log [H^+]$	E mV	E mV	$-\log [H^+]$
2.71	203.5	90.3	4.62
2.54	214.2	90.3	4.63
2.42	221.2	90.3	4.63
2.32	227.0	90.3	4.63

1 M in $NaClO_4$, served as standard buffer solutions. The acetate buffer was 0.005 M in acetic acid and in sodium acetate. Its hydrogen ion concentration was determined by means of a series of hydrochloric acid solutions, 1 M in $NaClO_4$, to be $10^{-4.63}$. The acid dissociation constant of acetic acid should thus be $10^{-4.63}$ in 1 M $NaClO_4$. The results are given in Table 1. For this constant Ellilä [2] has obtained the value $10^{-4.61}$. When a saturated calomel electrode was used, the pH values were converted to $-\log [H^+]$ values by using the apparent pf_{H^+} values [3].

The chemicals used were of analytical grade. In potentiometric measurements a Radiometer PHM 3 m potentiometer was used.

RESULTS AND DISCUSSION

The values obtained for the constants K_H and K_I in the cases of copper and lead without addition of a neutral salt are given in Table 2. The data previously obtained for cadmium, cobalt, nickel and zinc complexes have been included. The respective values at zero ionic strength are given in Table 3.

Table 2. Equilibrium constants relating to the complex formation by some metals with catecholdisulphonic acid at 25°C. Complexes MHL^- and ML^{2-}.

Ni	10.14	6.20	4.37	11.24
Zn	9.70	5.99	4.58	11.68
Pb	6.61	4.66	6.36	14.77
Cu	5.76	3.67	6.22	15.62

In extrapolating, the equation

$$pK_I = pK_I^\circ + \frac{1.018\sqrt{I}}{1+2.0\sqrt{I}} \quad (12)$$

obtained earlier for the respective copper complex was used [1]. The constant K_H was correspondingly extrapolated to zero ionic strength by means of the equation

$$\log K_H = \log K_H^\circ - \frac{2.04\sqrt{I}}{1+2\sqrt{I}} \quad (13)$$

Table 3 also contains the values of the stability constant

$$\beta_1^0 = (ML^{2-})/(M^{2+})\ (L^{4-}) \quad (14)$$

as calculated from

$$\beta_1^\circ = K_I^\circ/K_3^\circ\ K_4^\circ \quad (15)$$

For the acid dissociation constants K_3° and K_4° the values $10^{-8.31}$ and $10^{-13.07}$ (25°C), taken from a previous paper by the present author [4], were used. Further, the equilibrium constants of the reaction

$$M^{2+} + HL^{3-} \rightleftharpoons MHL^- \quad (16)$$

defined by

$$K_M^\circ = (MHL^-)/(M^{2+})\ (HL^{3-}) \quad (17)$$

are given in Table 3. This constant can be calculated from the expression

$$K_M^\circ = K_H^\circ K_I^\circ/K_3^\circ \quad (18)$$

Recently the values of β_1, K_M, K_3 and K_4 in 0.1 M KCl determined for some metals by Schwarzenbach and Willi have been published [5]. Since the value of K_4 determined by the present author differs considerably from that given by these authors, the comparison of the K_I and K_H values seemed to be more suitable than of the β_1 and K_M values. Therefore the values of K_I and K_H

Table 4. The constants K_3, K_4, K_H and K_I in 0.1 M KCl.

were calculated from the data of Schwarzenbach and Willi. The respective values of K_I and K_H at ionic strength 0.1 were calculated from the data of the present author by means of eqns (12) and (13). These results are given in Table 4. The pK_I values of the Co, Ni and Zn complexes are seen to agree so well that the small differences, 0.03, 0.04 and 0.05, might be attributed mainly to a temperature effect. In the case of copper, however, a greater difference exists. The log K_{II} values differ more; 0.09, 0.16 and 0.10 in the cases of Co, Ni and Zn, respectively. Here again, some of the difference may be due to the different temperatures used, but on the other hand the accuracy that can be achieved is not very high, as already mentioned above. The agreement is thus very good if one leaves out of account the constant K_4 and the constants for the copper complexes.

From the data of the second buffer range at which $2c_M < c_B < 4c_M$ the values of the constant K_{II} can be evaluated. As mentioned above, only in the case of zinc and copper [1] could a distinct formation of ML_2^{6-} be observed. The stability of CuL_2^{6-} has been reinvestigated. In Table 5 a titration is shown. The quantity K_{II} is seen to remain nearly constant, although the increase in the concentration of the CuL_2^{6-} ion during the titration causes a considerable change in ionic strength as defined by $I = \frac{1}{2}\Sigma z_i^2 c_i$. An equal change in ionic strength produced by addition of neutral salt has a considerable effect on the quantity K_{II}[1]. A similar state of affairs has previously been shown

to prevail in the cases of the zinc [1] and aluminium [6] complexes. Regarding the effect of added electrolytes, the sum of the concentrations of the positive ions, *i.e.* the quantity $\frac{1}{2}\Sigma|z_i|c_i$, seems to be the decisive factor and not $\frac{1}{2}\Sigma z_i^2 c_i$.

It is, of course, possible that in a medium containing sodium ions species such as $Na_\nu ML_2^{(6-\nu)-}$ are formed. If so, the quantity $[ML_2^{6-}]$ should in reality be a sum $\Sigma_\nu Na_\nu ML_2^{(6-\nu)-}$ and the quantity K_{II} a function of the sodium ion concentration of the form

$$K_{II} = K_{II}^{(0)} + K_{II}^{(1)}[Na+] + K_{II}^{(2)}[Na+]^2 + \ldots\ldots \quad (19)$$

Since the quantity $K_{II}^{(\nu)}$ defined by

$$K_{II}^{(\nu)} = \frac{[Na_\nu ML_2^{(6-\nu)-}]\,[H+]^2}{[ML^{2-}]\,[H_2L^{2-}]\,[Na+]^\nu} \quad (20)$$

is also obviously a function of ionic strength, the exact treatment of this contingency is not feasible. The experimental data seem to indicate, however, that at low ionic concentration the species ML_2^{6-} is the predominant one but that at a high concentration of sodium ions the species $Na_\nu ML_2^{(6-\nu)-}$ might also be formed.

Since the complex formation under investigation, especially the formation of ML_2^{6-}, is so highly dependent on the ionic medium it seemed advisable to investigate this system in a medium containing some neutral salt. Hitherto, only copper complexes have been investigated in this way. In Table 6 a titra-

tion for determination of the constant K_I for the copper complex in 1 M sodium perchlorate is given. In this case, the second term in eqn. (6) must also be considered, as already mentioned above. On the other hand, the formation of the complex $CuHL^-$ is so slight that it cannot be demonstrated. This is readily understandable in view of the fact that the equilibrium constant K_H decreases with increasing ionic strength and that the concentration of $CuHL^-$ is already small at low ionic strength. Titrations for the determination of K_I were carried out for four different Na_2H_2L-metal ratios. These results are given in Table 7 and it will be seen that the accuracy is even better than that reached in the measurements without addition of neutral salts. In Table 8 a titration for the determination of the constant K_{II} is given. The accuracy reached is seen to be very good in this case too. In eqn. (12) the second term must also be considered, because reactions (2) and (3) overlap somewhat. In Table 9 the results for K_{II} have been summarized.

For the constants K_I and K_{II} in the case of copper the present author obtained the values $pK_I = 6.08$ and $pK_{II} = 7.40$ in 1 M KCl. These values thus differ in an understandable way from the values $pK_I = 6.00$ and $pK_{II} = 7.79$ now obtained in 1 M $NaClO_4$.

The stability constants β_1 and β_2 for copper complexes are given in Table 10. The constant β_1 was calculated from eqn. (15) and the constant β_2, defined by

$$\beta_2 = [CuL_2^{6-}]/[Cu^{2+}]\ [L^{4-}]^2, \tag{21}$$

from the expression

$$\beta_2 = K_I K_{II}/K_3^2 K_4^2 \tag{22}$$

The values of the acid dissociation constants K_3 and K_4 in 1 M $NaClO_4$ were determined in the same way as before, but the electrode system used was the same as in the study of complexes in 1 M $NaClO_4$. Somewhat unexpectedly, the values obtained for K_3 and K_4 in 1 M $NaClO_4$ are almost identical with those obtained for these constants in 1 M KCl.

Table 10. Stability constants of catechol-3,5-disulphonic acid chelates of copper in 1 M $NaClO_4$ and at 25°C.

$pK_3 = 7.19$	;	$pK_I = 6.00$	;	$\log \beta_1 = 12.79$
$pK_4 = 11.6$	;	$pK_{II} = 7.79$	;	$\log \beta_2 = 23.79$

Analysis of Aromatic Solvents by Gas Chromatography

BENGT SMITH

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The utilization of stationary phases having a high degree of selectivity for different types of hydrocarbons has made possible the determination of saturated hydrocarbons in aromatic solvents over a wide range of boiling points. The application of various stationary phases to this analysis problem is discussed and examples are given of the separations obtained.

The determination of small amounts of saturated hydrocarbons in aromatic solvents such as "industrial pure benzol, toluol and xylol" has proved to be a difficult problem (*cf.* Ref.[1]). A satisfactory solution, however, can be achieved by means of gas liquid partition chromatography using stationary phases specially chosen to satisfy the specific demands put on them in this connection.

"Industrial pure benzol" and "benzene crystallizable". The separation of the benzene and saturated constituents in these solvents can be effected by means of various stationary phases. The choice of stationary phase depends on the information required. If the total amount of saturates is of major interest, then *p*-nitroaniline picrate is suitable. This stationary phase is namely rather nonselective for saturates, these compounds being eluated mainly as one peak (*cf.* Fig. 1). In order to determine the individual saturated hydrocarbons, a combination with other columns is necessary. A full analysis of "industrial pure benzol" or "benzene crystallisable" can be achieved in the following way. The saturates, eluted from the *p*-nitroaniline picrate column, are condensed and re-run on a 6 m tetra-*n*-amylsilane column. Nine major components and three trace components were identified in "industrial pure benzol" * (*cf.* Fig. 2). The same components were present in "benzene crystallizable" although in smaller amounts and other proportions. A 6 m squalane column can also be used. The chromatogram obtained with this column is very similar to the one shown in Fig. 2. The silane column was chosen here because of its better separation of the pair, *cyclo*hexane/3,3-dimethylpentane. In the actual sample, however, no 3,3-dimethylpentane was found. The pair, 2-methyl-

* The method used in the identification of the components will be described elsewhere.

hexane/2,3-dimethylpentane, cannot be separated on either of these columns. If their proportions are wanted, then the peak has to be condensed and re-run on a 6 m di-*n*-octyl phthalate column.

"*Industrial pure toluol*". In addition to toluene and saturates, this solvent contains small amounts of benzene, ethylbenzene and xylenes. It is necessary to choose a stationary phase which can separate these constituents. *p*-Nitroaniline picrate has proved to be a satisfactory stationary phase. Separate peaks

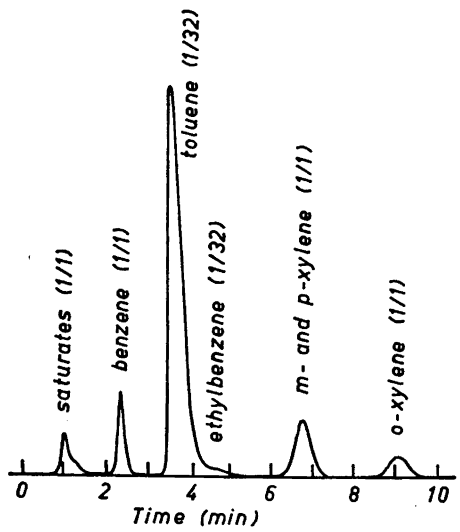

Fig. 3. "Industrial pure toluol." Column: *p*-nitroaniline picrate, 2 m. Temperature: 110°C. Flow of He: 50 ml/min. Recorder attenuation as denoted.

were obtained for saturates, benzene, toluene, ethylbenzene, *m*-plus *p*-xylene and *o*-xylene. (*cf.* Fig. 3). A full separation of *m*- and *p*-xylene by gas liquid partition chromatography has not been achieved so far *. However, if the

* Golay[2] has obtained a partial separation of *m*- and *p*-xylene using a 150 ft capillary column coated with didecyl phthalate. A partial separation has also been reported on some packed columns utilizing Apiezon[3], benzyldiphenyl[4] or tetrahalophthalates[5] as stationary phases.

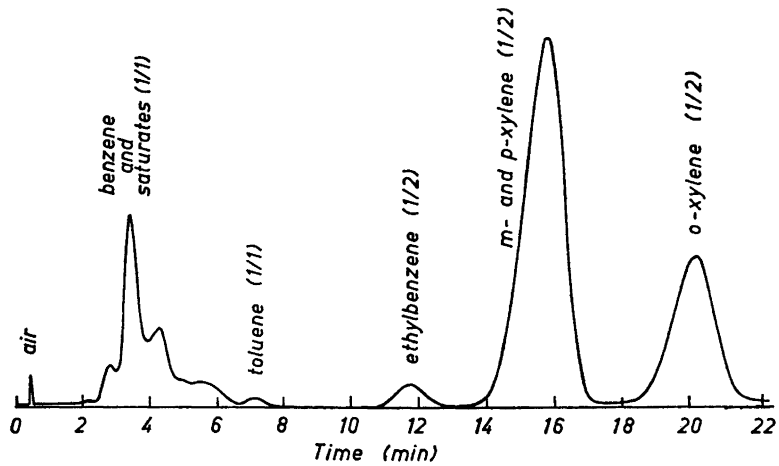

Fig. 4. "Industrial pure xylol." Column: fluorene picrate, 2 m. Temperature: 100°C. Flow of He: 80 ml/min. Recorder attenuation as denoted.

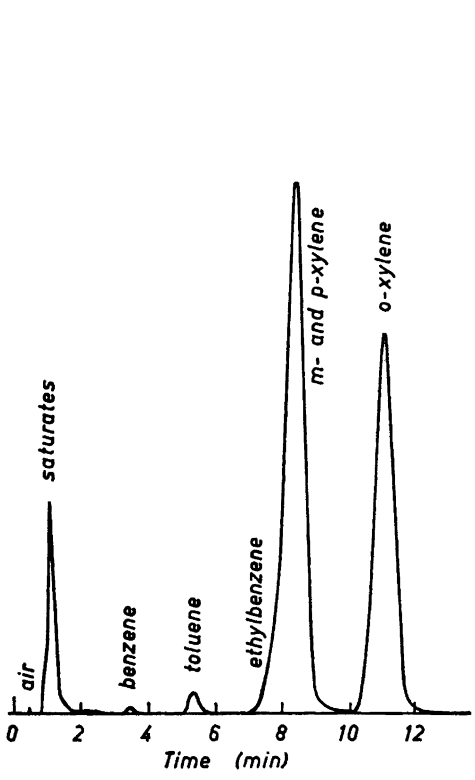

Fig. 5. "Industrial pure xylol." Column: β,β'-oxydipropionitrile, 2 m. Temperature: 100°C. Flow of He: 50 ml/min.

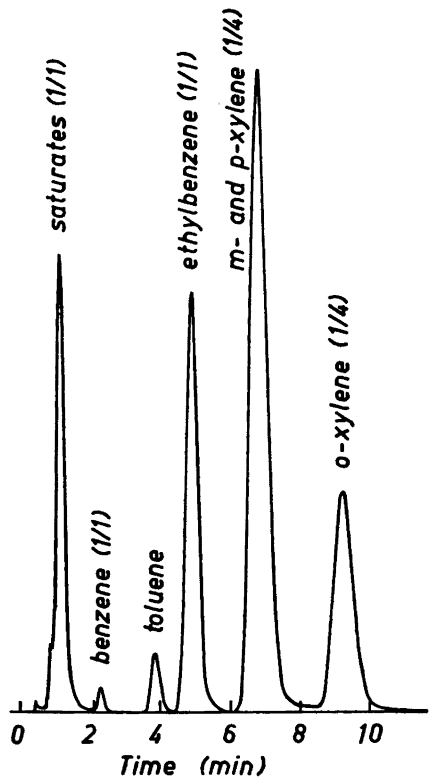

Fig. 6. "Industrial pure xylol." Column: *p*-nitroaniline picrate, 2 m. Temperature: 110°C. Flow of He: 50 ml/min. Recorder attenuation as denoted.

proportions of the two xylenes is wanted, it is possible to condense the mixture as it emerges from the column and analyze it using infrared spectrophotometry.

"Industrial pure xylol". The analysis of "industrial pure xylol" requires a stationary phase which is able to separate aromatic hydrocarbons and saturated hydrocarbons with an extremely high selectivity. To be useful it should release saturates boiling in the xylene range before releasing benzene. Fluorene picrate was reported by Keulemans, Kwantes and Zaal [6] to release *n*-octane (b.p. 125°C) and *iso*nonane (b.p. 143°C) before benzene. It is obvious, however, that a 2 meter fluorene picrate column is not selective enough to separate the saturated hydrocarbons in "industrial pure xylol" from benzene (*cf.* Fig. 4). The best selectivity is shown by β,β'-oxydipropionitrile but the separation of *m*- plus *p*-xylene from ethylbenzene is rather bad (*cf.* Fig. 5). *p*-Nitroaniline picrate leaves only *m*- and *p*-xylene unseparated and is therefore the stationary phase best suited for this analysis (*cf.* Fig. 6).

Table 1. Analysis values for "industrial pure benzol, toluol and xylol".

Sample	Saturated hydrocarbons (wt %)	Benzene (wt %)	Toluene (wt %)	Ethylbenzene (wt %)	*m*- plus *p*-Xylene (wt %)	*o*-Xylene (wt %)
Swedish "industrial pure benzol"	3.3	96.7	—	—	—	—
Swedish "industrial pure toluol"	3.4	0.3	96.2	trace	0.1	trace
Imported "industrial pure toluol"	0.2	0.3	98.7	trace	0.6	0.2
Swedish "industrial pure xylol"	11.0	0.1	0.3	4.0	57.7	26.9
Imported "industrial" pure xylol"	4.8	0.2	0.8	7.1	62.3	24.8

Quantitative analysis. Experiments with synthetic mixtures indicated that the internal normalization method, in which the percentage area is put equal to the weight per cent, was accurate enough for the purpose. The analyses obtained for some solvents are summarized in Table 1. It is seen that relatively large variations in the contents of various components exist in the case of the Swedish and imported qualities of toluol and xylol.

In order to analyze "industrial pure benzol" and "benzene crystallizable" for their individual saturated components, the method previously described

Table 2. Analysis values for "industrial pure benzol".

Compound	*wt* %
Benzene	96.7
*Cyclo*hexane	0.9
2,2,3-Trimethylbutane	0.8
Methyl*cyclo*pentane	0.3
2,3-Dimethylpentane	0.3
3-Methylhexane	0.2
2-Methylhexane	0.2
n-Hexane	0.2
n-Heptane	0.2
3-Ethylpentane	0.1
2,2-Dimethylpentane	0.02
2,4-Dimethylpentane	0.01
3-Methylpentane	0.01
Unknown compounds	0.05

was employed, *viz.* the saturated portion eluted from a *p*-nitroaniline picrate column was condensed and then analyzed on a 6 m tetra-*n*-amylsilane column or squalane column at 25°C. In both cases, the internal normalization method was used. More accurate values could be obtained by calibration using pure hydrocarbons but this was thought to be unnecessary in the present case. Typical values for "industrial pure benzol" are given in Table 2.

EXPERIMENTAL

The analyses were performed using a Perkin Elmer Vapour Fractometer Model 154.

Stationary phases

p-*Nitroaniline picrate* was prepared from *p*-nitroaniline and picric acid in chloroform solution according to Baril and Megrdichian [7]. *β,β'-Oxydipropionitrile* was prepared from acrylonitrile according to Bruson and Riener [8]. *Squalane* was obtained from May and Baker Ltd, Dagenham, England. *Tetra*-n-*amylsilane* was prepared from silicon tetrachloride and *n*-amylmagnesium bromide. Silicon tetrachloride (0.1 mole, 17.0 g) dissolved in abs. ether (25 ml) was added dropwise with stirring to a solution of *n*-amylmagnesium bromide prepared from *n*-amylbromide (1.0 mole, 151.0 g), magnesium (1.0 g.at., 24.3 g) and abs. ether (150 ml). After addition of the silicon tetrachloride, the reaction mixture was heated under reflux for 2 h and then most of the ether was distilled off. The residue was heated on a steam bath for another 2 h, cooled and hydrolyzed with dilute hydrochloric acid. The organic phase was taken up in ether, the ether solution washed with sodium carbonate solution and water and then dried. After distilling off the ether, the residue was fractionated in vacuum yielding 25.0 g (80 %) of crude tetra-*n*-amylsilane. The crude product was purified using conc. sulphuric acid and then heated over sodium and distilled. Final product: b.p. 208–210° (17 mm), $n_D^{20} = 1.4494$, $d_4^{20} = 0.8058$, $MR_D = 104.1$ (found); 104.5 (calc.[9]). % Si 8.91 (found); 8.98 (calc.).

Columns

The columns were made from glass or aluminum tubing of 4 mm internal diameter. The stationary phase was applied in solution on to the carrier, using a suitable low-boiling solvent. The solvent was evaporated and the dry powder then evenly packed in the column. Data for the columns used were:

p-*Nitroaniline picrate columns.* Two 1 m glass columns were used in series. The stationary phase (20 %) was applied on Silocel C 22 (42–60 mesh).

Fluorene picrate column. A 2 m Perkin-Elmer stainless steel column G was used. The stationary phase (about 20 %) was applied on Celite 545.

β,β'-Oxydipropionitrile column. A 2 m aluminum column was used. The stationary phase (20 %) was applied on Chromosorb (30–60 mesh).

Squalane and tetra-n-*amylsilane columns.* In both cases, two 3 m aluminum columns were used in series. The stationary phase (3 %) was applied on Chromosorb (30–60 mesh).

Di-n-*octyl phthalate columns.* Two 3 m aluminum columns were used in series. The stationary phase (10 %) was applied on Chromosorb (30–60 mesh).

Acknowledgement. The author wishes to thank the Town Council of Gothenburg for financial support to this work. The experimental assistance of Mr. M. Ervik is also gratefully acknowledged.

The Influence of Some Cations on the Kinetics of Ox Liver Arylsulphatase A

S. O. ANDERSEN*

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

The effects of some cations on the kinetics of sulphatase A are reported. It is shown that barium ions inactivate the enzyme if substrate is present, and a possible reaction mechanism is discussed. Strontium ions have no inhibitory effect on the enzyme, and it is therefore recommended to use strontium instead of barium ions to precipitate sulphate in investigations of this enzyme.

In a previous paper investigations of the kinetics of the enzymic hydrolysis of 2-hydroxy-5-nitrophenyl sulphate (nitrocatechol sulphate) were reported [1]. As sulphate ions inhibit the reaction, the sulphate ions liberated in the course of the reaction were precipitated as barium sulphate. It was found nescessary to add barium chloride in such a manner that there would never be excess of barium ions in the reaction mixture, as barium ions have some secondary effects on the reaction. In this paper some investigations of the influence of excess barium ions on the enzymic reaction are reported together with investigations of the influence of some other cations.

EXPERIMENTAL

The progress of the reaction was followed as described previously by continued automatic titration of the liberated acid in a recording pH-stat [1]. The base which was added from a syringe in small portions consisted of a solution of equivalent amounts of KOH, substrate and $BaCl_2$, so that both pH and the substrate concentration were kept constant during the reaction, and the sulphate was precipitated as $BaSO_4$.

The cations investigated have preferably been used as their chlorides, only for Zn++ this has not been the case as pure $ZnCl_2$ was not at hand. Instead $Zn(NO_3)_2$ was used as experiments conducted with KCl and KNO_3 did not show any difference in the reaction progress. When the effect of monovalent cations was investigated the concentrations of the salts were 0.10 M and when divalent cations were used the concentrations were 0.05 M, so the concentration of chloride ions was the same in all the experiments. Only $CuCl_2$ made an exception in this respect as it is not sufficiently soluble at pH 5. A saturated solution was therefore used.

* Present address: Universitetets zoofysiologiske laboratorium B, Copenhagen, Denmark.

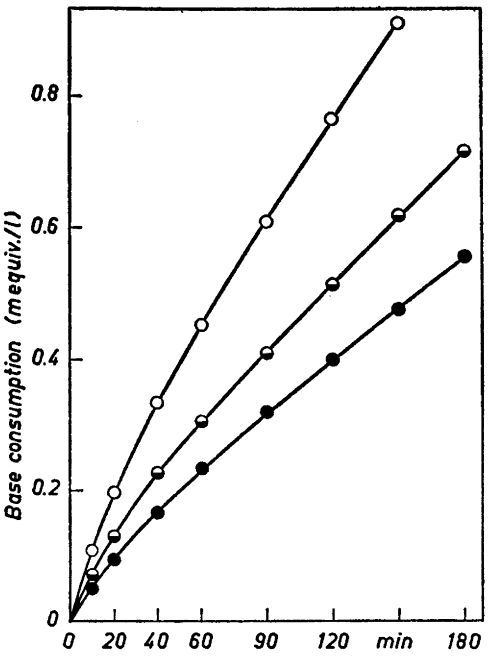

Fig. 1. Effect of cations on the activity of sulphatase A at 20°C and pH 5. The substrate concentration was 3 mM. O—O—O: 0.10 M KCl or NaCl, ◒—◒—◒: 0.05 M $CoCl_2$, ●—●—●: 0.05 M $CdCl_2$.

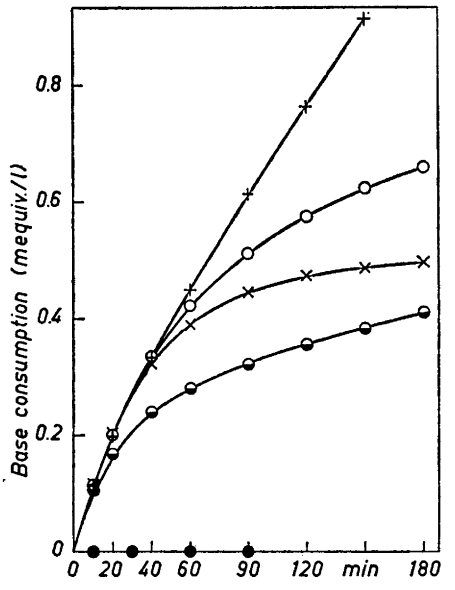

Fig. 2. Effect of cations on the activity of sulphatase A at 20°C and pH 5. The substrate concentration was 3 mM. +—+—+: 0.05 M $CaCl_2$, $MgCl_2$ or $SrCl_2$, O—O—O: 0.05 M $Zn(NO_3)_2$, ×—×—×: 0.05 M $BaCl_2$, ◒—◒—◒: 0.05 M $MnCl_2$, ●—●—●: 0.05 M $HgCl_2$ or saturated $CuCl_2$.

Mixtures of KCl and $BaCl_2$ were used in the experiments where the influence of different barium ion concentrations was investigated, so that the chloride concentration also in this experiment was kept at 0.10 M.

All the experiments were performed at pH 5.0 and 20.0°C, and the substrate concentration was 0.002 M. Enzyme and substrate were prepared as described previously[1].

RESULTS

The progress of the reaction in presence of different cations is demonstrated om Figs. 1 and 2. It is interesting to see that in the case of Ba^{++}, Zn^{++} and Mn^{++} the inhibition of the reaction first begins some time after the start of the reaction. When the enzyme is incubated for some hours together with these cations at pH 5 and the reaction is then started, then the same reaction progress is found. This indicates that the reaction between enzyme and metal ions is not simply a slow one, but that the substrate is involved in some way.

It is not surprising that Cu^{++} and Hg^{++} completely inhibit the reaction as it has been found that the enzyme contains sulfhydryl groups necessary for its activity [2].

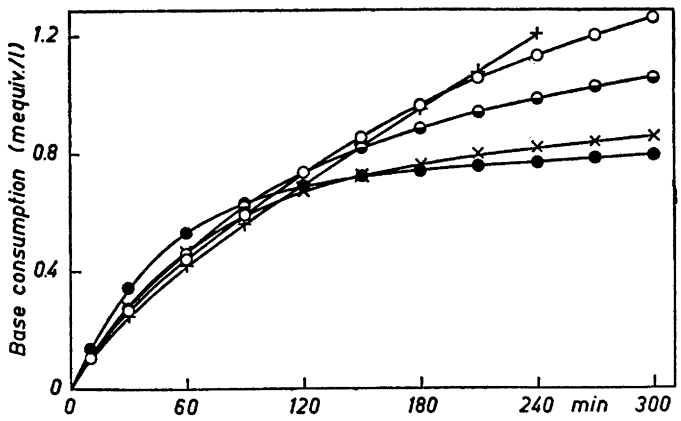

Fig. 3. Effect of $BaCl_2$ on the activity of sulphatase A at 20°C and pH 5. The substrate concentration was 3 mM. ●—●—●: 0.05 M $BaCl_2$, ×—×—×: 0.02 M $BaCl_2$, ◒—◒—◒: 0.01 M $BaCl_2$, O—O—O: 0.005 M $BaCl_2$, +—+—+: without addition of $BaCl_2$.

Co^{++} and Cd^{++} inhibit the reaction to some degree, and it is characteristic that there is a constant ratio between the activity when these ions are present and the activity of the noninhibited enzyme.

When K^+, Na^+, Mg^{++}, Ca^{++} or Sr^{++} are used no difference can be found between the progress of the reactions.

The influence of different concentrations of Ba^{++} on the reaction is shown in Fig. 3. The barium ions seem to have a double effect, first the enzyme is activated, later on inhibited. It was tried to reactivate the enzyme by removing the barium ions, but neither addition of K_2SO_4 nor dialyzing the reaction mixture against 0.1 M KCl for 24 h had any effect, so the inhibition is obviously irreversible. If the enzyme is incubated with $BaCl_2$ in the absence of substrate and the barium ions are removed by dialysis, then the enzyme shows the kinetics found in the absence of barium ions.

The reaction progress in the absence of heavy metal ions can be described by the expression:

$$\xi = At + B(1-e^{-\lambda t})$$

where ξ is the amount of substrate split at the time t, and A, B and λ depend on the enzyme and substrate concentrations[1]. The same expression with a very small value of A can describe the reaction progress in the experiment with the highest concentration of barium ions but not in the experiments with smaller concentrations.

DISCUSSION

This formal similarity between the reaction progress when no barium ions are added and when they are present in excess can be explained if it is supposed that the reaction scheme is essentially the same in both cases, but that in the presence of barium ions the enzyme is somehow modified so that the velocity constants are altered.

The scheme previously proposed for the reaction when no barium ions are present was:

$$\begin{aligned} A + X_1 &\rightleftharpoons X_2 \\ X_2 &\rightarrow X_1 + P \\ X_2 &\rightleftharpoons X_3 \end{aligned}$$

where X_1, X_2 and X_3 are different forms of the enzyme and A is the substrate and P is the reaction products. The transformation from X_2 to X_3 is assumed to be reversible and slow. If barium ions are present we should then have:

$$\begin{aligned} Ba^{++} + X_1 &\rightleftharpoons X_1' \\ A + X_1' &\rightleftharpoons X_2' \\ X_2' &\rightarrow X_1' + P \\ X_2' &\rightarrow X_3' \end{aligned}$$

X_i' represent one of the forms of the enzyme modified by barium ions. The larger initial velocity when barium ions are present can be explained if this barium modification of the enzyme is more active towards the substrate than the unmodified enzyme.

If the concentration of barium ions is so high that practically all the enzyme is in the form of the barium modification, it should be expected that the reaction progress could be described by the expression $\xi = B(1-e^{-\lambda t})$. As mentioned this is not the case, but the existence of the term At could be explained if the reaction X_2' to X_3' is not irreversible as written in the scheme, but reversible with the equilibrium far to the right. The final velocity in the experiment with 0.05 M $BaCl_2$ is about twenty times smaller than the initial velocity. In equilibrium 95 % of the enzyme must then be present as X_3', and the reaction from X_2' to X_3' must be about twenty times as fast as the opposite reaction. It should therefore be expected that a measurable reactivation could be demonstrated after 24 h dialysis. This is as mentioned not the case.

When the concentration of barium ions used is not so high that all the enzyme is in the form of the barium modification, we should expect a reaction scheme composed of both schemes here mentioned. This will give a complex reaction which cannot be simply expressed, which is in accordance with the experiments.

Barium chloride has been used to remove excess of sulphate ions in some investigations of the kinetics of sulphatases [1,3]. The results here presented show that it must be used with caution, and that it is better to use strontium chloride as this can be used in high concentrations without having any effects on the enzyme. It is peculiar that there is such a difference between the effects of barium and strontium ions. One is reminded of the fact that barium salts are toxic to the organism whereas strontium salts are not.

The Preparation of Some N-Methyl-1,2,3-Triazoles

CHRISTIAN PEDERSEN

Department of Organic Chemistry, University of Technology, Copenhagen, Denmark

The reaction between diazomethane and cyanogen bromide has been shown to give a mixture of the three N-methyl derivatives of 4-bromo-1,2,3-triazole. The structure of the three products is proved and their reaction with ammonia is studied.

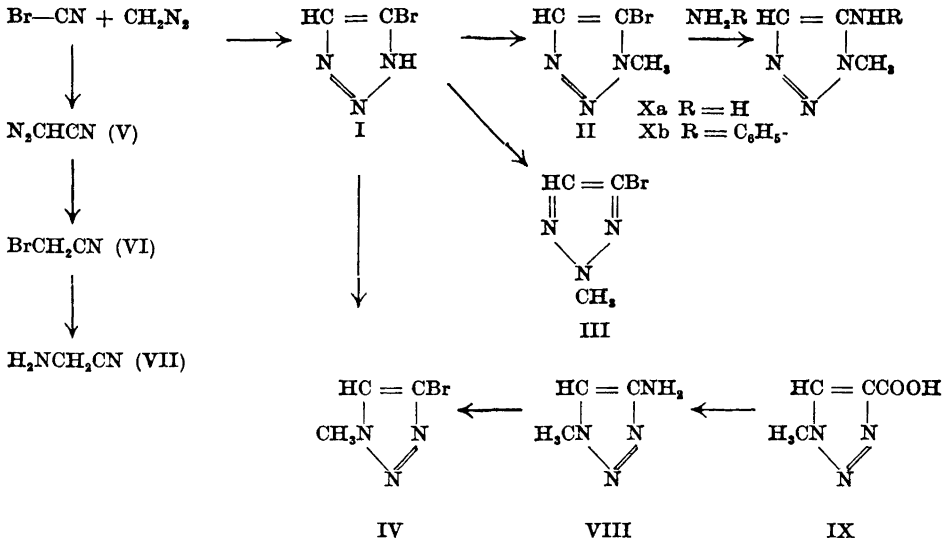
The reaction between cyanogen bromide and diazomethane has been studied by Tamburello and Milazzo [1]. According to these authors the first product of the reaction is 4-bromo-1,2,3-triazole (I) since this compound could be isolated when the reaction was carried out with excess cyanogen bromide. With excess diazomethane present in the reaction mixture I was further methylated and 2-methyl-4-bromo-1,2,3-triazole (III) was isolated.

The methylation of 1,2,3-triazole with dimethyl sulfate has been shown by Huttel and Welzel [2] to give a mixture of 1- and 2-methyl-1,2,3-triazole and in the present paper it is shown that the same two products are obtained when diazomethane is used as the methylating agent.

In view of this it would be expected that the methylation of I with diazomethane could give, besides III, two other products, namely 1-methyl-5-bromo-1,2,3-triazole (II) and 1-methyl-4-bromo-1,2,3-triazole (IV) and it was therefore decided to reinvestigate the reaction between diazomethane and cyanogen bromide.

The reaction product, on distillation, gave three fractions (1, 2 and 3, see experimental part) of which the largest and lowest boiling one (1) proved to be a mixture of α-bromoacetonitrile (VI) and 2-methyl-4-bromo-1,2,3-triazole (III). Treatment of fraction 1 with sodium hydroxide destroyed the bromoacetonitrile and gave pure III. When treated with ammonia the bromoacetonitrile of fraction 1 was converted into α-aminoacetonitrile (VII) which was isolated as the hydrochloride and identified by comparing its infrared spectrum with that of an authentic sample. Fraction 2 consisted mainly of 1-methyl-5-bromo-1,2,3-triazole (II) and fraction 3 of 1-methyl-4-bromo-1,2,3-triazole (IV).

The assignment of structure to the three isomeric methyl-bromo-triazoles is based on the following. III, in contrast to II and IV, does not form a hydrochloride when treated with hydrogen chloride in ether. A lower basic strength



of 2-substituted 1,2,3-triazoles as compared to the corresponding 1-substituted compounds seems to be a general rule. 2-Methyl-1,2,3-triazole does not form a hydrochloride whereas 1-methyl-1,2,3-triazole does [2]; the 1- and 2-methylbenzotriazoles behave in the same way [3] and so do 1- and 2-phenyl-1,2,3-triazole. This is probably analogous to the difference in basic strength between imidazoles and pyrazoles [4] since a 1-substituted 1,2,3-triazole is likely to be protonated in the 3-position giving an ion of structure XI which is analogous to a protonated imidazole, whereas a 2-substituted 1,2,3-triazole must take up the

proton in position 1- or 3- and give structure XII which is analogous to a protonated pyrazole.

IV has the same melting point as the 1-methyl-4-bromo-1,2,3-triazole described by Huttel and Welzel [2]. Besides, IV was prepared from 1-methyl-4-amino-1,2,3-triazole (VIII) by the Gattermann reaction. The synthesis of VIII is described later in this paper.

II on reaction with aniline gave 1-methyl-5-anilino-1,2,3-triazole (Xb), identical with the compound which Dimroth [5] obtained from 1-methyl-5-chloro-1,2,3-triazole.

The formation of α-bromoacetonitrile (VI) has probably taken place through diazoacetonitrile (V) which could be formed from diazomethane and cyanogen

bromide by a reaction similar to the formation of diazoketones from acyl halides and diazomethane. The conversion of V into VI by hydrogen bromide can only take place if the reaction mixture at some stage has been deficient in diazomethane since V will react much slower with hydrogen bromide than diazomethane.

The 1-methyl-5-bromo-1,2,3-triazole (II) is the most reactive of the three isomeric methyl-bromo-triazoles. With 10 % ethanolic ammonia at 100° it gives a low yield of 1-methyl-5-amino-1,2,3-triazole (Xa); III and IV do not react, under the same conditions. As shown in the present paper, II reacts with aniline and Dimroth [5] has shown that the corresponding chloro compound also reacts with aniline in contrast to 1-methyl-4-chloro-1,2,3-triazole [2].

1,2,3-Triazole was obtained by decarboxylation of 4-carboxy-1,2,3-triazole which was prepared in good yield by the reaction of propiolic acid with hydrazoic acid in boiling benzene. Since propiolic acid is easily obtained by oxidation of propargylic alcohol [6] this is probably the most convenient method for the preparation of 1,2,3-triazole. By the corresponding reaction of methyl azide with propiolic acid 1-methyl-4-carboxy-1,2,3-triazole (IX) was prepared. The isomeric 1-methyl-5-carboxy-1,2,3-triazole was not found in the reaction mixture. IX, *via* the chloride, gave the azide which on boiling in ethanol gave 1-methyl-4-carbethoxyamino-1,2,3-triazole. The latter on boiling with dilute sodium hydroxide yielded 1-methyl-4-amino-1,2,3-triazole (VIII).

EXPERIMENTAL

Melting points are uncorrected.

4-Carboxy-1,2,3-triazole. A solution of hydrazoic acid (1.5 mole) and propiolic acid (35 g, 0.5 mole) in benzene (1 200 ml) was refluxed on the steam-bath for 15 h with an effective, water-cooled condenser. Some hydrazoic acid escaped through the condenser during the heating. The product began to separate after a few hours. The mixture was cooled and the product filtered off. Recrystallization from water gave 40 g (71 %) of 4-carboxy-1,2,3-triazole as colourless crystals with m. p. 222—224° (reported [2,7]: 214—215° and 220°).

1-Methyl-4-carboxy-1,2,3-triazole. Methyl azide was generated from sodium azide (39 g, 0.6 mole) and dimethyl sulfate (37.5 ml) [8] and passed over anhydrous calcium chloride into a mixture of dry toluene (100 ml) and propiolic acid (14 g, 0.2 mole). The mixture was kept overnight at room temperature and was then heated for 2 h in a pressure-bottle in boiling water. After cooling in ice the crystalline precipitate was filtered off and dried. The product (18.4 g) was recrystallized from water giving 14.6 g (57 %) of 1-methyl-4-carboxy-1,2,3-triazole as colourless crystals with m. p. 218—219° (reported [2]: 224°).

1,2,3-Triazole. 4-Carboxy-1,2,3-triazole (40 g) was heated in an oil bath. At a bath-temperature of 220° a vigorous evolution of carbon dioxide took place. The reaction was over in a few minutes and the product was distilled giving 22.8 g (93 %) of 1,2,3-triazole with b. p. 205—206° (760 mm).

1- and *2-Methyl-1,2,3-triazole.* To an ice-cold solution of 1,2,3-triazole (10.0 g) in ether (100 ml) was added an excess of ethereal diazomethane. The mixture was kept overnight at 0°. Ether and excess diazomethane was distilled off and the residue was distilled through a column of the Podbielniak type giving 5.53 g (46 %) of 2-methyl-1,2,3-triazole with b. p. 102—103° (760 mm) and 5.02 g (42 %) of 1-methyl-1,2,3-triazol with b. p. 223—225° (760 mm).

Reaction of cyanogen bromide with diazomethane. To a solution of cyanogen bromide (31.8 g) in dry ether (100 ml) was added an ether solution of diazomethane in portions. At first there was a lively reaction and it was necessary to cool in ice now and then to prevent the solution from boiling. After *ca.* 50 % of the diazomethane had been added the reaction became slower. A total of 3 equiv. of diazomethane was added and the mix-

ture was left overnight at room temperature. Ether and excess diazomethane was distilled off and the residue was distilled through a Podbielniak type column at 16 mm pressure giving 3 fractions:

1. 28.9 g, yellow lachrymatory liquid, b. p. 45—48°.
2. 5.0 g, semi-solid mixture, b. p. 98—100°.
3. 3.9 g, yellow solid, b. p. 140°.

2-Methyl-4-bromo-1,2,3-triazole. Fraction 1 (28.9 g) was washed with four 25 ml portions of 2 N sodium hydroxide. The first portion of sodium hydroxide caused heat evolution and a decrease in the volume of the bromo compound. The compound was then dissolved in ether and washed with water and the ether solution was dried with magnesium sulfate and distilled. 2-Methyl-4-bromo-1,2,3-triazole (10.0 g, 21 % based on cyanogen bromide) was obtained as a slightly yellow solid; b. p. 161—162° (760 mm), m. p. 22°. (Found: C 22.35; H 2.46; N 26.14; Br 49.45. Calc. for $C_3H_4N_3Br$: C 22.24; H 2.49; N 25.94; Br 49.33.)

1-Methyl-5-bromo-1,2,3-triazole. Fraction 2 (5.0 g) was recrystallized from ether-light petroleum (b.p. 40—60°) giving 3.1 g (6.4 %) of colourless crystals with m. p. 37—40°. Two additional recrystallizations gave pure 1-methyl-5-bromo-1,2,3-triazole with m. p. 41—42°. (Found: C 21.95; H 2.55; N 26.23.)

1-Methyl-4-bromo-1,2,3-triazole. Fraction 3 (3.9 g) was recrystallized from benzene-light petroleum (b. p. 60—100°) to give 2.7 g (5.5 %) of colourless crystals with m. p. 95—97°. Two additional recrystallizations gave pure 1-methyl-4-bromo-1,2,3-triazole with m. p. 98—99° (reported [2]: 98.5—99°). (Found: C 22.10; H 2.68; N 25.90.)

β-Amino-acetonitrile hydrochloride. Fraction 1 (5.0 g) was dissolved in liquid ammonia (30 ml) and the mixture was kept in an open flask at room temperature until the ammonia had evaporated. The residue was treated with ether, the ammonium bromide was filtered off, and the ether solution was evaporated to remove excess of ammonia. The residue was again dissolved in ether and dry HCl was passed through the solution giving a white precipitate (1.1 g) which was recrystallized from abs. ethanol. The yield of β-amino-acetonitrile hydrochloride was 0.80 g, m. p. 165—167° (decomp.) (reported [9]: 165°). (Found: C 25.75; H 5.32; N 30.53. Calc. for $C_2H_5N_2Cl$: C 25.95; H 5.45; N 30.30.) The infrared spectrum * was identical with that of an authentic sample prepared according to Curtius [9].

The ether solution from which the amino-acetonitrile hydrochloride was precipitated gave, on evaporation, 2-methyl-4-bromo-1,2,3-triazole.

1-Methyl-4-carbethoxyamino-1,2,3-triazole. 1-Methyl-4-carboxy-1,2,3-triazole (10 g) and phosphorus pentachloride (16.5 g) were mixed and heated. The mixture melted and a vigorous reaction took place. After a few minutes the reaction was over and phosphorus oxychloride and excess phosphorus pentachloride was removed *in vacuo* at 100°. The crude chloride was dissolved in acetone (125 ml). The solution was cooled in ice and stirred and a solution of sodium azide (15 g) in water (75 ml) was added during a few minutes. The mixture was then stirred for 1 h. Water (500 ml) was added and the colourless precipitate was filtered off, washed with water and dried giving 11.2 g (93 %) of the azide of 1-methyl-4-carboxy-1,2,3-triazole. The azide decomposes at 152—154° with nitrogen evolution and forms a new, colourless compound which melts at 215—217°. This compound is probably the corresponding *iso*cyanate. The azide was not purified further.

The azide (11.2 g) in abs. ethanol (100 ml) was refluxed for 36 h. The solution was then concentrated to 30 ml and cooled yielding 9.1 g (74 %) of colourless crystals with m. p. 114—118°. Two recrystallizations from ethanol gave the pure 1-methyl-4-carbethoxyamino-1,2,3-triazole, m. p. 123—124°. (Found: C 42.60; H 5.98. Calc. for $C_6H_{10}N_4O$: C 42.35; H 5.92.)

1-Methyl-4-amino-1,2,3-triazole. The urethane (9.1 g, m. p. 114—118°) and sodium hydroxide (13.3 g, 6 equiv.) in 150 ml of water was boiled for 4 h. The solution was then acidified with conc. HCl and evaporated to dryness *in vacuo*. The residue was extracted with 3 × 50 ml of boiling ethanol, the ethanol solution was concentrated to 30 ml and cooled giving 6.35 g of crude material which was recrystallized from ethanol-ether. Yield 5.1 g (64 %), m. p. 181—184° (decomp.). Two additional recrystallizations from abs.

---

* Thanks are due to Mrs. Susanne Refn, M.Sc., for taking the IR-spectra and discussing the evidence thus obtained.

ethanol gave the pure hydrochloride of 1-methyl-4-amino-1,2,3-triazole as colourless crystals with m. p. 182—185°. (Found: C 26.50; H 5.10; N 41.35; Cl 26.45. Calc. for $C_3H_7N_4Cl$: C 26.80; H 5.24; N 41.65; Cl 26.35.)

The hydrochloride (1.0 g) was mixed with 5 ml of 40 % sodium hydroxide and extracted continuously with ether for 8 h. The ether was removed and the residue recrystallized from benzene-light petroleum. The yield of 1-methyl-4-amino-1,2,3-triazole was 0.65 g (90 %), colourless crystals, m. p. 88—90°. Recrystallized again, m. p. 88—89°. (Found: C 36.70; H 6.29; N 56.80. Calc. for $C_3H_6N_4$: C 36.72; H 6.16; N 57.11.)

1-Methyl-5-amino-1,2,3-triazole. 1-Methyl-5-bromo-1,2,3-triazole (1.0 g) was dissolved in 16 ml of 5 % ethanolic ammonia. The solution was heated to 100° in a sealed tube for 10 h. The mixture was then evaporated to dryness and the residue was extracted with ether. The ether solution was treated with dry HCl yielding 0.73 g of a colourless solid which after 2 crystallizations from abs. ethanol gave 0.18 g (22 %) of the hydrochloride of 1-methyl-5-amino-1,2,3-triazole as colourless crystals with m. p. 181—182°. (Found: C 26.90; H 5.27; N 41.90. Calc. for $C_3H_7N_4Cl$: C 26.80; H 5.24; N 41.65.)

The 1- and 2-methyl-4-bromo-1,2,3-triazoles did not react with ammonia under the same conditions as above.

1-Methyl-5-anilino-1,2,3-triazole. 1-Methyl-5-bromo-1,2,3-triazole (0.5 g) and 0.56 ml (2 equiv.) of aniline was heated on the steam bath for 6 h during which time the mixture solidified. Water was added and the crystalline product was filtered off, washed with water and dried. Yield 0.36 g. Two recrystallizations from benzene-light petroleum (b. p. 60—100°) gave 0.24 g (45 %) of colourless crystals with m. p. 169—171° (Dimroth [5] reports 172°).

1-Methyl-4-bromo-1,2,3-triazole from 1-methyl-4-amino-1,2,3-triazole. 1-Methyl-4-amino-1,2,3-triazole (0.5 g) was dissolved in 5 ml of constant boiling HBr, cooled in ice, and diazotized with 0.35 g of sodium nitrite. A small amount of copper-bronze was added causing a vigorous nitrogen evolution. After a few minutes the reaction was over and the mixture was heated to the boiling point and cooled again. The colourless crystals which separated were extracted with chloroform (3 × 10 ml). The chloroform solution was concentrated to 10 ml and 50 ml of light petroleum (b. p. 40—60°) was added. On cooling 0.34 g (41 %) of 1-methyl-4-bromo-1,2,3-triazole crystallized out; m. p. 97—99°.

Microanalyses were made by Mr. P. Hansen of The Chemical Laboratory of The University of Copenhagen.

Duodenal Glucuronide Synthesis

IV. Studies of Steroidglucuronide Conjugation by the Duodenal Mucosa in Rat

K. HARTIALA and ANITA LEHTINEN

Department of Physiology, University of Turku, Finland

Steroid hormones were incubated in the presence of rat duodena slices. Paper chromatographic analyses were then performed on the ethylacetate extracts of the incubation mixture. These extracts revealed no free steroids and also no spots indicating glucuronic acid. Treatment of the ethylacetate evaporate with β-glucuronidase resulted in the liberation of free steroids and glucuronic acid when estrone, estradiol, estriol, equiline and stilbestrol were tested. No such glucuronide conjugates were identified for progesterone, pregnandiol, androsterone or testosterone. A phenolic hydroxyl at 3 C is a common feature of the former steroid group. None of the unconjugated steroids had this characteristic.

In our previous qualitative and quantitative studies we have identified estradiol glucuronide as a conjugation product formed by rat duodenal mucosa [1,2]. In the present work a number of other steroids have been subjected to similar analyses.

MATERIAL AND METHODS

Albino rats (Wistar) were used also in these experiments.

Steroids. Estriol, estrone, equiline, stilbestrol, progesterone, pregnandiol, androsterone and testosterone propionate were used. These were dissolved in 2 ml propyleneglycol [5] in the following amounts: 5.0 mg, 4.8 mg, 4.7 mg, 4.9 mg, 5.6 mg, 4.7 mg, 5.2 mg, 6.2 mg.

Incubation. The incubation of free steroids in the Warburg apparatus was performed as in the earlier studies [3,4]. The Krebs Ringer incubation solution contained 100 mg glucose and 112 mg sodium lactate per 50 ml of the mixture. Into each Warburg flask were transferred 2.9 ml of this Ringer solution, 0.1 ml of the steroid propyleneglycol solution (0.9 μmole steroid) and after this the mucosal tissue specimens (dry weight 8–10 mg). The gas phase was 5 % carbon dioxide in oxygen.

Sampling. After incubation the contents of 2 Warburg flasks were combined to make one sample for further analyses (= 6 ml). The tissue slices were washed with 2 ml Ringer solution (6 ml + 2 ml) after being removed from the flasks.

Deproteinization. The incubation mixture was heated at 60°C for 3 min and centrifuged thereafter.

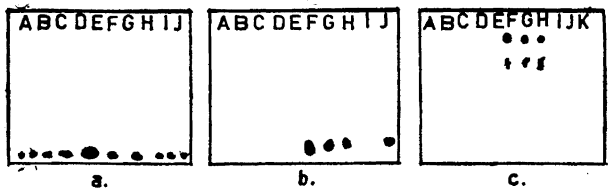

Fig. 1. Estrone. a. Unconjugated estrone. Positive spots (A, B, C, and D) for estrone present after the incubation of estrone with the tissue. The spots are, however, weaker than those obtained from the same incubation mixture without the tissue (G, H, I, and J). Control spots E (150 μg) and F (100 μg) pure estrone.

b. Estrone glucuronide acid and estrone liberated by hydrolysis. Unhydrolyzed samples show negative spots for free estrone (A, B, C, D, and E). Hydrolysis with β-glucuronidase results in liberation of free estrone (G, H, and J). Control, F, 150 μg estrone.

c. Estrone glucuronide and glucuronic acid liberated by hydrolysis. Unhydrolyzed samples give negative spots A, B, C, D, and E for free glucuronic acid. From the hydrolyzed samples (G, H, I, J, and K) G and H show positive spots for free glucuronic acid. F is obtained with pure glucuronic acid (150 μg). The spots which appear below the actual glucuronic acid spots are discussed in the text.

Extraction of free steroids with benzene, was carried out as in our earlier work [1,2].

Extraction of steroid glucuronides with ethylacetate from the acidified (2 N HCl) water phase was carried out as in the earlier work [1,2].

Hydrolysis of the conjugate was performed with β-glucuronidase (Worthington Biochem. Corp.) as in the previous papers [1,2]. Reextraction of the free steroids and glucuronic acid liberated by hydrolysis was also carried out as in the earlier work [1,2].

Paper chromatography. 1 ml of the solvent (ethylacetate/benzene) was added to each residue used for the chromatographic analyses. A mixture of butanol, glacial acetic acid and water was used as an irrigant; time 24 h, paper Whatman No. 1. Estriol, estrone, equiline, stilbestrol and pregnandiol spots were identified on the paper by a saturated aqueous solution of *p*-nitrobenzene-azodimethoxyaniline (Fast Black Salt, K. Heftman 1950 [6]). Stilbestrol gives a light brown spot on blue whereas the others give a blue red spot. Androsterone, testosterone and progesterone were identified with *m*-dinitrobenzene (1 vol. 2 % *m*-dinitrobenzene in alcohol + 1 vol. 2.5 N KOH in alcohol [7]). Glucuronic acid was identified with the $AgNO_3$-ammonia reagent (1 vol. 0.1 N $AgNO_3$, 1 vol. 5.0 N NH_3-solution + 1 vol. 2 N NaOH).

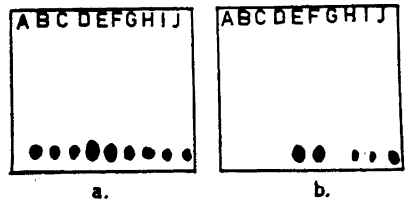

Fig. 2. Estriol. a. Unconjugated estriol. B, C, D, I, and J indicate free estriol present after incubation with the tissue slices. A is negative for some unknown reason. G and H, control runs made from the incubation mixture without the tissue. E and F pure estradiol (150 and 100 μg).

b. Estriol glucuronide acid and estriol liberated by hydrolysis. A, B, C, and D refer to the free estriol in the unhydrolyzed samples. H, I, and J, estriol liberated by hydrolysis. G is negative for some unknown reason. E and F, pure estriol (150 and 100 μg). From the hydrolyzed samples free glucuronic acid spots were never found. This is discussed in the text.

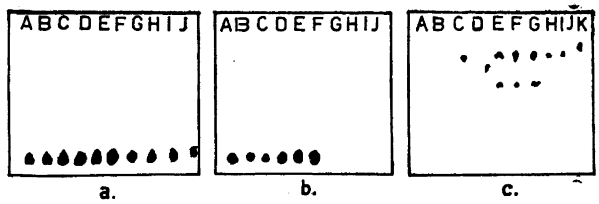

Fig. 3. Equiline. a. Unconjugated equiline. A, B, G, H, I, and J, free equiline present after incubation with the tissue slices. C and D, after incubation without the tissue. E and F, pure equiline (100 and 150 μg).

b. Unhydrolyzed equiline glucuronide and free equiline liberated by hydrolysis. G, H, I, and J refer to free equiline in the unhydrolyzed samples. A, B, C, and D free equiline after the hydrolysis. E and F pure equiline (100 and 150 μg).

c. Glucuronic acid liberated by hydrolysis. A, B, C, and E indicate the absence of free glucuronic acid before the hydrolysis. The positive spot D indicates that some liberation might take place without β-glucuronidase. H, I, J, and K, the same after enzymatic hydrolysis. F and G, pure glucuronic acid. Other spots seen in the pixture are discussed in the text.

RESULTS

In the following presentation the chromatograms of each of the steroids are given in a group. The first (left) picture of each group, a, indicates the spots due to steroids left unconjugated during the incubation. The second picture, b, indicates the results before and after hydrolysis of the conjugated steroids with β-glucuronidase. In this picture the absence of spots on the chromatograms of the unhydrolyzed steroid glucuronides or, in the cases in wich no glucuronide formation has occurred, the total absence of steroid spots is indicated. In the third picture, c, are indicated the glucuronic acid spots liberated during the hydrolysis. This picture, c, is not presented in Figs. 5—8, corresponding to experiments in which free glucuronic acid could never be demonstrated.

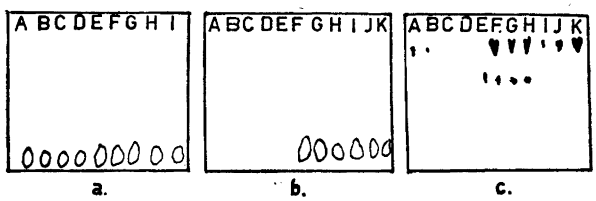

Fig. 4. Stilbestrol. a. Unconjugated stilbestrol. A, B, C, D, H, and I, free stilbestrol still present after incubation with the tissue slices. F and G, the same after incubation without the tissue. E, pure stilbestrol (150 μg).

b. Stilbestrol glucuronide and free stilbestrol liberated by hydrolysis. A, B, C, D, and E indicate negative spots for free stilbestrol before the hydrolysis. H, I, J, and K, free stilbestrol liberated by hydrolysis. F and G, pure stilbestrol (100 and 150 μg).

c. Glucuronic acid liberated by hydrolysis. A, B, C, D, and E, free glucuronic acid before the hydrolysis. Weak spots at A and B indicate some free glucuronic acid. G, H, I, J, and K the same after enzymatic hydrolysis. F, pure glucuronic acid (150 μg). The other spots present on the chromatogram are discussed in the text.

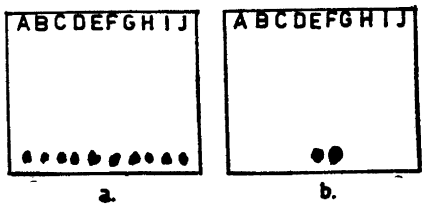

Fig. 5. Progesterone. a. Unconjugated progesterone. A, B, C, D, H, I, and J, free progesterone present after incubation with the tissue slices. E, control incubation without the tissue. F and G, pure progesterone (100 μg and 150 μg).

b. Absence of free progesterone in the unhydrolyzed and hydrolyzed samples. A, B, C, and D, before hydrolysis and G, H, I, and J, after hydrolysis with β-glucuronidase. E and F, pure progesterone (100 and 50 μg). The results indicate no glucuronide conjugation.

Positive results indicating glucuronide formation from the above listed estrogenic substances were obtained with

estrone	in	4	out	of	6	rats
estradiol	in	5	»	»	6	»
estriol	in	4	»	»	6	»
equiline	in	5	»	»	6	»
stilbestrol	in	6	»	»	6	»

Taking into consideration the size and color intensity of the different spots in the chromatogram stainings, it would appear that the degree of conjugation is not the same for the different estrogens. Using these indications as a rough estimate for the degree of conjugation, the following preliminary list can be given:

estrone	+
estradiol	+++ (reported in our previous paper [1,2])
estriol	+
equiline	++
stilbestrol	+++

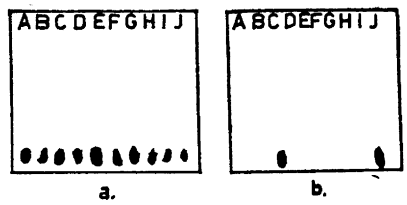

Fig. 6. Pregnandiol. a. Unconjugated pregnandiol. A, B, C, D, G, and H, free pregnandiol before incubation with the tissue slices. I and J, incubation without the tissue. E and F, pure pregnandiol (200 and 150 μg).

b. Absence of free pregnandiol in the hydrolyzed and unhydrolyzed specimens. A, B, C, before hydrolysis and E, F, G, H, and I, the hydrolyzed samples. D and J, pure pregnandiol (200 and 250 μg). The results indicate no glucuronide conjugation.

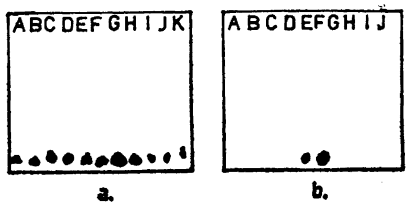

Fig. 7. Androsterone. a. Unconjugated androsterone. A, B, C, D, I, J, and K, free steroid present in the samples after incubation with the tissue slices. E and F, the same from the incubation mixture without the tissue. G and H, pure androsterone (150 and 100 μg).

b. Absence of free androsterone in the hydrolyzed and unhydrolyzed samples. A, B, C, and D, before hydrolysis and G, H, I, and J, after enzymatic hydrolysis. All spots are negative. E and F, pure androsterone (50 and 100 μg).

DISCUSSION

The chromatographic identification of the free and pure steroids used in these experiments has not met any difficulties. The presence of such spots on the chromatograms can also be taken as evidence of the reliability of the applied extraction procedures. On the other hand it occasionally appeared to be rather difficult to show free glucuronic acid on the chromatograms. In the case of estradiol, hydrolysis of the extract always resulted in the appearance of free glucuronic acid [1,2]. On the other hand glucuronic acid formation was detected only two or three times on 6 experiments with the other estrogens and never with estriol. The conjugate formation of the latter, as judged by the size and intensity of the free steroid spots of the conjugates in the different

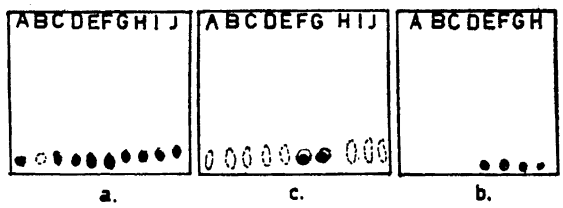

Fig. 8. Testosterone. a. Unconjugated testosterone. A, B, G, H, I, and J, free testosterone present after incubation with the tissue slices. C and D, samples incubated without the tissue. E and F, pure testosterone (150 and 100 μg). A positive spot was obtained for only one out of 6 animals.

b. Free testosterone in the hydrolyzed and unhydrolyzed specimens. A, B, C, and D negative spots for free testosterone in the unhydrolyzed samples. G and H, weak positive spots for free testosterone after hydrolysis. E and F, pure testosterone (150 and 100 μg).

c. In order to confirm the results obtained in the previous chromatograms the experiments were repeated three times with twice the amounts of solutions as used before. In the unhydrolyzed samples (A, B, C, D, and E) and in the hydrolyzed samples (H, I, and J) prolonged spots distinctly different from those given by pure testosterone (F and G, 150 and 100 μg) were found. These are discussed in the text. The results would indicate no glucuronide conjugation for the androgens.

chromatograms, is very small. It could be that the amount of glucuronic acid present is too small to give a positive spot on the paper. This possibility is enhanced by the fact that the experimental conditions do not eliminate the possibility of bacterial decomposition. This could reduce the amount of glucuronic acid present in the final steps of the analyses. This point was proved in our own experiments when it was found that free glucuronic acid added to the solutions under the same conditions as in the hydrolysis experiments disappeared completely in few days.

Extra spots are occasionally seen together with the glucuronic acid spots which arise from the apparent sensitivity of the $AgNO_3$ reagent towards various reducing substances. The small spots seen in several pictures beneath the glucuronic acid spots are identified as the lactone formed from the acid during the chromatographic procedure. These spots are also present when pure glucuronic acid alone is used.

The large, longish spots obtained with large amounts of the hydrolyzed and unhydrolyzed samples in connection with the repeated experiments with testosterone could not be more exactly identified due to lack of available pure testosterone conjugates. Since these spots stained with the same reagents as testosterone they might have an androgen molecular structure. The form of these spots would imply some kind of a salt compound. The possibility of a sulphate conjugate must also be considered. It may be pointed out that the tissue itself never interfered with the chromatographic analyses. Analyses of incubation mixture which contained tissue slices but not steroids never gave positive staining for spots which could erroneously be taken as steroid or glucuronic acid spots.

Finally, one interesting point can be stressed. If the interpretation of our results is correct, it would appear that glucuronide conjugation of substances possessing sexhormone activity is of a rather selective nature. Whereas the estrogens are conjugated, neither progesterone nor its metabolic product pregnandiol, nor the androgens are conjugated in this form. Examination of the molecular structure of these different substances reveals one interesting similarity of the glucuronide conjugated steroids which separates them from the others. They all have a phenolic hydroxyl group in the 3 C position. All of the compounds found to be unconjugated to a glucuronide lack this characteristic. It may be pointed out that in our previous studies indications of phenolphthalein and cinchophen glucuronide conjugation by the intestinal mucosa were found. The same molecular specificity also holds for these substances. The interpretation of this observation becomes however, rather complicated and difficult since recently a similar molecular characteristic, namely a phenolic hydroxyl at 3 C, has been found to belong to those steroids undergoing a sulphate conjugation[8].

Kinetics of the Hydrolysis of Phenylphosphate Catalyzed by Potato Phosphatase

O. B. JØRGENSEN

Department of Technical Biochemistry, Royal Danish Technical University. Copenhagen, Denmark

The hydrolysis of phenylphosphate catalyzed by potato phosphatase was investigated to a high degree of reaction, and the liberation of phenol was followed colorimetrically. The reaction was studied with different initial concentrations of enzyme and substrate and with and without phosphate added. It was found that the following chronometric integral can describe the reaction:

$$E \cdot t = [k_a + k_b\ (p + a)] \ln \frac{a}{a-x} - k_c \cdot x$$

where t is time, a initial substrate concentration, x phosphate concentration at the time t, p the concentration of phosphate added and k_a, k_b and k_c are constants. A reaction mechanism based on the chronometric integral found is suggested.

Potato phosphatase is a group-specific acid phosphatase present in potato juice. Pfankuch [1] found the optimum pH 5.8, and he showed that Mg^{++} had little or no inhibiting effect on the activity of the enzyme, whereas F^- was a strong inhibitor. The Michaelis constant of β-glycerophosphate was $K_s = 18$ mM, and strong inhibition was found on addition of phosphate. The dissociation constant, K_p, of the enzyme-phosphate complex was found to be 1.8 mM. Helferich and Stetter [2] found the optimum pH for the substrate phenylphosphate to be 5.2—5.3. At a low degree of reaction it was found that the reaction followed first-order kinetics. Sripathi *et al.*[3] found optimum pH 5.3 and $K_s = 10$ mM for β-glycerophosphate. For an enzyme preparation from sweet potato Kondo *et al.*[4,5] found optimum pH 5.3—6.0 and $K_s = 1.7$—2.0 mM for β-glycerophosphate, $K_s = 12$ mM for glucose-1-phosphate and $K_s = 0.6$ mM for phenylphosphate. Very active preparations of the potato phosphatase have also been prepared by Schramm and Flammersfeld [6].

The reaction is by all the investigations quoted above only examined to low degrees of reaction. In this investigation the reaction was studied to high degrees of hydrolysis of the substrate, and the influence of the inhibition of phosphate was examined. The reaction was followed by determining the phenol liberated during the hydrolysis.

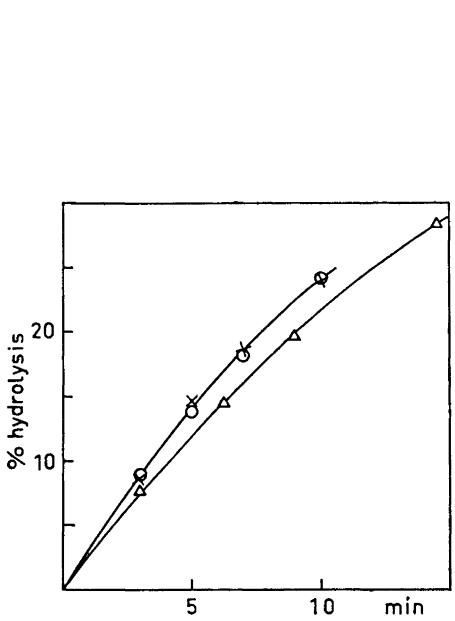

Fig. 1. Effect of Mg++ and phenol upon the rate of hydrolysis. ⊙——⊙ phenylphosphate concentration 4 mM, ×——× phenylphosphate concentration 4 mM and phenol concentration 6 mM, Δ——Δ phenylphosphate concentration 4 mM and concentration of Mg++ = 15 mM.

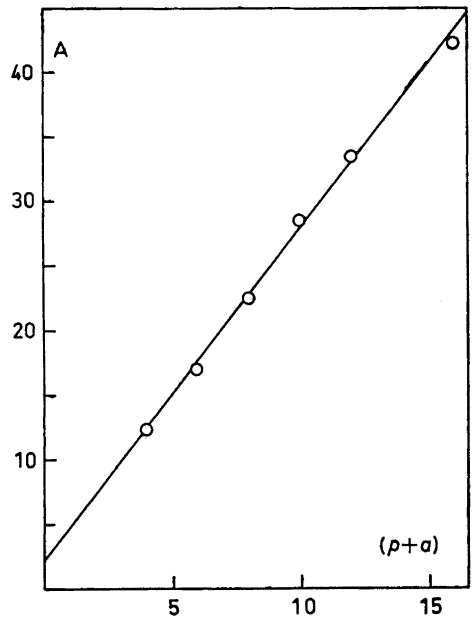

Fig. 2. Relation between the values of ($p_{\perp}$ + a) (abscissa) and the values of A (ordinate).

EXPERIMENTAL

Enzyme. Potato juice was fractionated by means of acetone and tannin as described by Helferich and Stetter [2]. Aqueous solutions of the most active fractions were used for the experiments. A slight activity of phenoloxydase in the enzyme solutions was completely inhibited by 0.5 p.p.m. sodiumsulfide. This reagent had no influence on the phosphatase activity. The enzyme solutions were stored at 0°C with some toluene added.

Substrate. The substrates were composed of 5 ml freshly prepared disodiumphenylphosphate solutions (Merck) and 4 ml 0.2 M citrate buffer (pH = 5.3). Investigating the phosphate inhibition the quantity of phosphate wanted was added to the phenylphosphate solution as KH_2PO_4.

Phenol determination. The phenol liberated during the reaction was determined colorimetrically with 4-aminoantipyrene as described by Hockenhull *et al.*[7]. The extinction was measured at 510 mμ in a Beckman spectrophotometer in 1 cm cells. A 0.1 mM solution of crystalline phenol (Merck) in 0.1 M HCl was used as a phenol standard. This solution was checked by iodometric determination. By neutralisation with 0.1 M NaOH and dilution of this stock solution different solutions with known contents of phenol were prepared. With a content of between 5×10^{-5} and 27×10^{-5} millimole phenol a linear relation between extinction and phenol concentration was found. The relative error of the phenol determination of the digest is 1.5 %.

Table 1. $a = 4$ mM, E = 1, A = 12.28 min, B = −0.95 min/mM.

52	0.056	48.67	−3.33	13.04

Procedure. The substrate (9 ml) and the enzyme solution (1 ml) were preheated in a water thermostat at 20.0°C. The reaction was started by adding 1 ml of enzyme solution. The moment of half emptied pipette was defined as time zero. At different times 0.5 ml of the digest was withdrawn with a constriction pipette and poured into 2 % K_2CO_3 (1.5—4.5 ml) by means of which the enzyme reaction was stopped. The moment of half emptied pipette was defined as the time of the withdrawal. The phenol determination was performed on samples of this solution either directly or after suitable dilution. In all the experiments the concentrations of phenylphosphate and of added phosphate are given as millimoles of the substance concerned per litre of digest.

RESULTS

Optimum pH. Different digests with phenylphosphate concentration $a = 4$ mM and the same amount of enzyme but with varying pH (4.75—5.60) were examined. After the same time of reaction ($\alpha < 5$ %) a sample of the digest was withdrawn, and the degree of reaction at this time was chosen as a measure of the enzyme activity. Optimum was found at pH 5.3.

Effects of Mg^{++} and phenol. Fig. 1 shows the results of an experiment with $a = 4$ mM and the concentration of $Mg^{++} = 15$ mM. It is seen that Mg^{++} inhibits the reaction slightly. Fig. 1 shows too that addition of phenol (6 mM) had no effect on the rate of hydrolysis. These results are in agreement with the examinations by Pfankuch [1] and Helferich and Stetter [2].

The influence of varying substrate, phosphate and enzyme concentrations

The influence of the substrate concentration on the rate of reaction. Tables 1—4 show the results of four experiments performed at different substrate concentrations, a, but with the same enzyme concentration. The reactions did not follow zero-order, first-order or second-order kinetics, but the experi-

The values of A and B were determined graphically by the method described by Schønheyder and Volqvartz [8]. The values of A and B at different substrate concentrations are shown in Table 9. The enzyme concentration in experiments 1—4 is arbitrarily fixed as 1. In Tables 1—4 corresponding values of experimental t values and t values calculated by eqn. (1) are shown.

By differentiation of eqn. (1) is found:

Table 5. a = 8 mM, p = 4 mM, E = 1, A = 33.50 min, B = −0.95 min/mM.

$\Delta t = (A/(a-x) + B) \cdot \Delta x$ where Δx is the deviation of x; this deviation varies during the reaction. The relative error of the phenol determination $\Delta x/x = 0.015$, which gives $\Delta t_{calc} = (|A|/|a-x| + |B|) \cdot 0.015 \cdot x$. Δt_{calc} of all the experimental times are calculated and shown together with $\Delta t_{expt} = (t_{calc} - t_{expt})$ in the tables. The deviation of t_{expt} is not taken into account as it is only of importance for small values of t.

The influence of phosphate concentration on the rate of reaction. Experiment 3 with phenylphosphate concentration a = 8 mM was repeated with phosphate of a concentration p = 4 mM and p = 8 mM added to the digest. Enzyme concentration as in experiment 3, E = 1. The results are shown in Tables 5 and 6. t_{calc} has been calculated by eqn. (1). The experiments show that phosphate has a strong inhibiting effect on the hydrolysis.

The influence of enzyme concentration on the rate of reaction. With constant substrate concentration, a = 8 mM, the enzyme concentration was varied. Tables 7 and 8 show the experimental results with E = 0.5 and E = 0.25. t_{calc} has been calculated by eqn. (1).

The variation of A and B with varying a, p and E. Table 9 shows that B is a constant, when a and p vary. Experiments 1—6 give an average value $B_{av} = -k_c = -0.96$ min/mM (E = 1). The A values change when a and p vary. In experiments 1—6 the values of A are found to fit a linear function of $(p + a)$, see Fig. 2. By the method of the least squares is found when E = 1:

Table 9.

Expt. No.	a mM	p mM	E	A min	B min/mM
1	4	0	1	12.28	−0.95
2	6	0	1	17.00	−0.90
3	8	0	1	22.55	−0.95
4	10	0	1	28.50	−0.90
5	8	4	1	33.50	−0.95
6	8	8	1	42.30	−1.10
7	8	0	0.5	47.50	−1.95
8	8	0	0.25	93.00	−3.95

$$A = 2.18 + 2.56\ (p + a) \tag{2}$$

Experiments 3, 7 and 8 show that A and B are inversely proportional to the enzyme concentration: $A = A'/E$ and $B = B'/E$. The empirical equation (1) then becomes:

$$E \cdot t = [k_a + k_b\ (p + a)] \cdot \ln \frac{a}{a - x} - k_c \cdot x \tag{3}$$

where $k_a = 2.18$, $k_b = 2.56$ and $k_c = 0.96$ when $E = 1$.

REACTION MECHANISM

The simplest reaction schemes that might describe the experimental results will be the following four where X_{1-4} are different enzyme forms, S phenylphosphate, P phosphate and F phenol:

1)

$$X_1 + S \rightleftharpoons X_2 \qquad (\pm 1)$$
$$X_2 \rightarrow X_1 + P + F \qquad (+ 2)$$
$$X_1 + P \rightleftharpoons X_3 \qquad (\pm 3)$$

2)

$$X_1 + S \rightleftharpoons X_2 + P \qquad (\pm 1)$$
$$X_2 \rightarrow X_1 + F \qquad (+ 2)$$

3)

$$X_1 + S \rightleftharpoons X_2 \qquad (\pm 1)$$
$$X_2 \rightarrow X_1 + P + F \qquad (+ 2)$$
$$X_2 + P \rightleftharpoons X_3 \qquad (\pm 3)$$

4)

$$X_1 + S \rightleftharpoons X_2 \qquad (\pm 1)$$
$$X_2 \rightarrow X_1 + P + F \qquad (+ 2)$$
$$X_2 + P \rightleftharpoons X_3 \qquad (\pm 3)$$
$$X_1 + P \rightleftharpoons X_4 \qquad (\pm 4)$$

The reaction with one molecule water, which is necessary in the hydrolysis, is omitted in the schemes, as it cannot be detected in the reaction kinetics, perhaps this reaction is involved in the step (+ 2). Scheme 1) represents competitive inhibition, scheme 3) uncompetitive and scheme 4) noncompetitive inhibition.

The reaction schemes were then treated mathematically using the steady state method as described by Christiansen [9,10]. Calling the steady state rate v and the reaction probabilities for the steps indicated w_i, we have from reaction scheme 1):

$$v = w_1 \cdot x_1 - w_{-1} \cdot x_2$$
$$v = w_2 \cdot x_2$$
$$w_3 \cdot x_1 = w_{-3} \cdot x_3$$

(x_{1-3} are the concentrations of the enzyme forms indicated). Solutions of the equations yield:

$$x_1 = v(w_2 + w_{-1})/w_1 \cdot w_2$$
$$x_2 = v/w_2$$
$$x_3 = v \cdot w_3(w_2 + w_{-1})/w_1 \cdot w_2 \cdot w_{-3}$$

The total enzyme concentration is $E = x_1 + x_2 + x_3$. Introducing the values of x_1, x_2, x_3 and $v = \frac{dx}{dt}$ and the values of w_i: $w_1 = k_1 \cdot (a—x)$, $w_{-1} = k_{-1}$, $w_2 = k_2$, $w_3 = k_3 \cdot (p + x)$ and $w_{-3} = k_{-3}$ where a is the initial substrate concentration, x the phosphate concentration at the time t and p the initial phosphate concentration, we find:

$$E \cdot dt/dx = (k_2 + k_{-1})/k_1 \cdot k_2 \cdot (a—x) + 1/k_2 + k_3 \cdot (k_2 + k_{-1})\,(p + x)/k_1 \cdot k_2 \cdot k_{-3} \cdot (a-x)$$

which by integration yields

1)

$$E \cdot t = \frac{k_2 + k_{-1}}{k_1 \cdot k_2} \cdot \left[1 + \frac{k_3}{k_{-3}}(p + a)\right] \cdot \ln \frac{a}{a—x} + \frac{k_2 + k_{-1}}{k_1 \cdot k_2}\left[\frac{k_1}{k_{-1} + k_2} - \frac{k_3}{k_{-3}}\right] \cdot x \quad (4)$$

which the has same form as the empirically found chronometric integral, eqn. (3).

When reaction scheme 2) is treated in the same manner, we find the following chronometric integral:

2)

$$E \cdot t = \frac{1}{k_1} \cdot \left[1 + \frac{k_{-1}}{k_2}(p + a)\right] \cdot \ln \frac{a}{a—x} + \frac{1}{k_2} \cdot \left[1— \frac{k_{-1}}{k_1}\right] \cdot x \quad (5)$$

which has also the same form as the empirically found chronometric integral, eqn. (3).

Scheme 3) gives the following chronometric integral:

3)

$$E \cdot t = \frac{k_2 + k_{-1}}{k_1 \cdot k_2} \ln \frac{a}{a—x} + \frac{1}{k_2}\left[1 + \frac{k_3}{k_{-3}} \cdot p\right] \cdot x + \frac{k_3}{2 \cdot k_2 \cdot k_{-3}} \cdot x^2$$

and 4) a similar integral. As both of these integrals are different from eqn. (3), the experimental facts cannot be satisfied by the schemes 3) and 4).

Comparing the chronometric integral of reaction scheme 2), eqn. (5), and the empirically found eqn. (3), it is found that:

$$k_{-1}/k_2 = k_b/k_a = 1.167$$

From this equation and reaction scheme 2) we then find, if the rate of reaction (— 1) is v_{-1} and the rate of reaction (+ 2) is v_2:

$$v_{-1}/v_2 = k_{-1} \cdot x/k_2 = 1.167 \cdot x \quad (6)$$

where x is the concentration of phosphate at the time considered. Eqn. (6) shows how many times X_2 will fall back after reaction (—1) compared with reaction (+ 2). By adding radioactive phosphate to the digest it should be

expected that the phosphate of the unhydrolyzed phenylphosphate and the radioactive phosphate were exchanged. Axelrod [11] has shown that citrus phosphatase cannot catalyze the transfer of inorganic phosphate to alcohols.

It was now investigated whether potato phosphatase would catalyze the exchange of phosphate. Radioactive phosphate, $NaH_2{}^{32}PO_4$, representing 10^9 counts per min per mM total phosphate, was added to 50 ml 20 mM phenylphosphate with buffer. Enzyme was added. The reaction was stopped, when 50 % of the substrate was hydrolyzed, and not hydrolyzed phenylphosphate was isolated from the digest by extraction with chloroform and several precipitations as described by Axelrod [11]. The isolated phenylphosphate showed 10^4 counts per min per mM phosphate. From eqn. (6) and the rate of hydrolysis is found that the isolated phenylphosphate should have shown about 10^8 counts per min per mM phosphate. This shows that reaction scheme 2) is not valid. Of the four reaction schemes proposed only scheme 1) can explain all the experimental results.

Introducing Michaelis constant, $K_s = \frac{k_2 + k_{-1}}{k_1}$, and the dissociation constant of the enzyme-phosphate complex, $K_p = k_{-3}/k_3$, in eqn. (4), it is found that:

$$E \cdot t = \frac{1}{k_2}\left[K_s + \frac{K_s}{K_p}(p + a)\right] \cdot \ln \frac{a}{a-x} + \frac{1}{k_2}\left[1 - \frac{K_s}{K_p}\right] \cdot x$$

Comparing this equation with the experimental eqn. (3), it is seen that with the enzyme and substrate here examined the values of K_s and K_p are found to be:

$$K_s = 1.36 \text{ mM and } K_p = 0.85 \text{ mM}.$$

Acknowledgements. I am much indebted to Professor Holger Jørgensen for excellent working conditions and for his interest in this work. I wish to thank Professor J. A. Christiansen for his helpful reading of the manuscript of this paper.

Crystal and Molecular Structure of Cytidylic Acid b

EYVIND ALVER and SVEN FURBERG

Chemical Institute, University of Bergen, Bergen, Norway

Cytidylic acid *b*, $C_9H_{14}N_3O_8P$, forms crystals of symmetry $P2_12_12$ with unit cell dimensions $a = 8.80$ Å, $b = 21.7$ Å, $c = 6.85$ Å. The structure was derived from electron density and difference syntheses along the *a* and *c* axes.

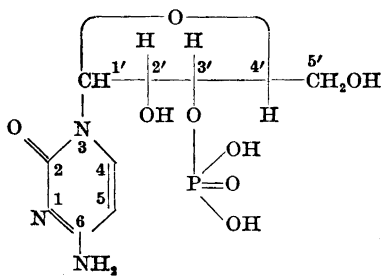
The molecule contains no unusual bond lengths, but some of the bond angles in the ribose ring differ significantly from "normal" values. The phosphate group is attached to the 3′-position of the sugar. The puckering of the ribose ring is different from what was found in crystals of cytidine, different ring atoms being out of the plane of the four other atoms in the two cases. The ribose and the phosphate group are arranged so as to make the molecule as extended as possible, the $P-O_3'$ bond having the same direction as the N_3-C_1' bond. This structure differs considerably from the structure hitherto assumed for nucleotides when building models of nucleic acids.

As constituents of the nucleic acids, the nucleosides and nucleotides are compounds of great biological interest, and it is important to have a detailed knowledge of their stereochemistry. The crystal structure of a nucleoside, cytidine, has been determined by one of us [1], and since then a number of heavy atom derivatives of nucleosides have been studied by X-ray methods [2,3]. As for the nucleotides, a note on the determination of a projection of adenylic acid has appeared in the literature [4]. Furthermore, a nucleotide-like component forms part of the molecule of vitamine B_{12}, the crystal structure of which has been determined by Hodgkin *et al*[5]. In the present paper the determination of the complete crystal structure of a nucleotide, cytidylic acid *b*, the 3′ phosphate ester of cytidine, is described. A preliminary note on this work has been published [6].

EXPERIMENTAL. CRYSTAL DATA

A specimen of cytidylic acid *b* was kindly supplied by Dr. Waldo E. Cohn, of the Oak Ridge National Laboratory, Tennessee. Large, well-developed crystals were obtained by evaporation of an aqueous solution, generally with (010) dominating and elongated along *c*. Forms {011}, {001}, {100} and {110} were also observed. (100) is a cleavage plane.

An examination by the polarising microscope showed the crystals to be biaxial positive, with (001) as the optic axial plane, and with $\alpha \| a$, $\gamma \| b$ and $\beta \| c$. The optic axial angle is great.



Structural formula, cytidylic acid b.

Oscillation and Weissenberg photographs were taken about the a and c axes, using filtered copper radiation (λ = 1.542 Å). The crystals are orthorhombic, with unit cell dimensions a = 8.80 Å, b = 21.7 Å and c = 6.85 Å (± 0.5 %). The only systematic absences occur in the $h00$ reflections for h odd and in the $0k0$ reflections for k odd, and the space group is therefore $P2_12_12$. Some of the odd-order $0k0$ reflections appear with low intensity on long-exposure photographs, but their form indicate that they are Renninger reflections. The density, measured by flotation, was found to be 1.66 g/cm³. There are four molecules $C_9H_{14}N_3O_8P$ in the unit cell, which gives a calculated density of 1.64 g/cm³.

For the structure determination, Weissenberg photographs of the zones $hk0-hk4$ and $0kl$-$5kl$ were taken, and about 1 300 independent reflections were recorded. The intensities were estimated visually and corrected for Lorentz-polarization effects [7] and for the variation of spot shape on equi-inclination photographs [8]. Small crystals were used and no correction for absorption was applied. The $hk0$ reflections were recorded from two different crystals and the mean value of the two sets of measurements was used. The calculations were carried out on desk machines and Beevers-Lipson strips were employed for the Fourier summations.

DETERMINATION OF THE STRUCTURE

Projections of the structure along the a- and c-axes were determined. The a-axis projection was first solved, as the strongest reflections are found in this zone. Approximate positions for most of the 21 atoms were derived by Patterson methods, inequalities and "trial and error", use being made of the Patterson function to determine phases. The refinement was carried out mainly by means of (F_o-F_c) syntheses.

Location of the phosphorus atom. Patterson projections along the a and c axes were first calculated (Fig. 1). The highest maxima were supposed to represent P—P vectors, and it can be seen from Fig. 1b that the phosphorus atom probably has the approximate coordinates $y_P = 0.25$, $z_P = 0.10$. The maxima in Fig. 1a are too diffuse to give reliable coordinates, but indicate that the phosphorus atom is situated near $x = 0$ or $x = 0.25$.

The Harker sections $(u, v, 0)$, $(1/2, v, w)$ and $(u, 1/2, w)$ were calcu'ated in the hope that they might give more reliable coordinates for the phosphorus atom. The section $u = 1/2$ has its highest maximum at (0, 0.23), corresponding to coordinates $y_P = 0.25$ and $z_P = 0.115$. This section was "sharpened" by dividing F^2 by $\hat{f}^2$. In the Harker section $w = 0$ the P—P vector $(2x, 2y)$ should then be found at $(2x, 0.5)$. However, two maxima of equal heights appeared at $v = 1/2$, leaving the two possibilities $x_P = 0.06$ and $x_P = 0.25$. This difficulty was overcome by an application of the "vector convergence"

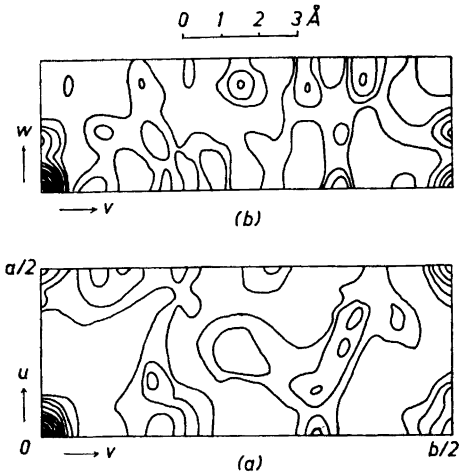


Fig. 1. Patterson projections on the (001) plane (a) and the (100) plane (b).

method [9]. The vector convergence map obtained by overlapping four transcriptions of the Patterson *c*-projection was derived for the two possible *x*-coordinates. In the case of $x = 0.25$, the map showed strong overlapping of peaks in the region near the axis of rotation, where no atoms can be situated. In fact, no atomic centre should be placed at a shorter distance from this axis than its van der Waals radius. The vector convergence map corresponding to $x = 0.06$ had a very low value in the "forbidden" region. Consequently, the phosphorus atom probably has the position (0.06, 0.25, 0.115). The agreement with the coordinates determined later on by Fourier methods is excellent. The "correct" vector convergence map also showed that the molecule probably should lie roughly diagonally in the *c*-projection.

Very little information on the positions of the lighter atoms could be derived from the Harker sections because of strong masking by non-Harker maxima.

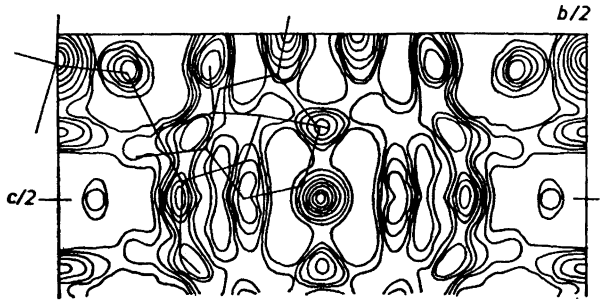

Fig. 2. The *a*-projection vector convergence map.

The a-projection. Attempts to solve the structure by the standard heavy atom technique were not successful. The phosphorus atom carries less than 10 % of the electrons in the molecule and is hardly heavy enough to determine the phases. Furthermore, its contribution to many structure factors is zero, as $y_P = 0.25$. Some information on the position of the lighter atoms was obtained from the Patterson functions in two ways. Firstly, a vector convergence map (Fig. 2) was derived by adding four transcriptions of the Patterson *a*-projection with their origins transferred to (0,0), (0.5, 0), (0, 0.23) and (0.5, 0.23). The map did not show sharp maxima which could be interpreted as individual atoms. Its symmetry is also too high. However, it indicated roughly the distribution of the atoms in the unit cell, and was used in conjunction with Bragg-Lipson charts to determine the probable signs of a number of structure factors. The second application of the Patterson function was based on the assumption that the lines $w = 0$ in the Patterson *a*-projection and $u = 1/2$ in the Patterson *c*-projection probably to a large extent represent vectors between equivalent atoms. By combining these two curves the vectors between non-equivalent atoms can be partly eliminated, and the curves may be expected to indicate the *y*-coordinates of the atoms. The probable signs of the four strongest $0k0$-reflections were derived in this way. The procedure may possibly be improved by sharpening the Patterson function.

The structure factors were put on an approximately absolute scale by Wilson's method [10]. The unitary structure factors (U) all had values below 0.30, except for $U_{0,14,1} = 0.40$ and $U_{005} = 0.34$. The signs of the strong reflections 005, 060, 080, 0,14,0, 0,16,0, 0,14,1 and 0,25,2 were derived from the vector convergence map and the distribution curve described above. As the unitary structure factors are small, the usual inequality $(U_H \pm U_K)^2 \leqslant (1 \pm U_{H+K})\ (1 \pm U_{H-K})$ could give no more signs. However, it was used to determine seven more probable signs after multiplying the U values by exp $(1.8 \sin^2\Theta/\lambda^2)$ [11]. The probable signs of eight additional reflections were indicated by the "multiplication rule" [12]. The F_o map calculated from these 22 important reflections was unclear, but indicated the positions of the oxygen atoms in the phosphate group. This was confirmed by calculating the three-dimensional Patterson function in this region and by the Harker sections. A number of other terms could now be included in the F_o synthesis, but in spite of this, the rest of the molecule had to be placed mainly by trial and error procedures. This was rather difficult, as freedom of rotation about a number of single bonds and the flexibility of the sugar ring make a great variety of molecular shapes possible. Extensive use was made of Bragg-Lipson charts and evidence from the Patterson, vector convergence, and F_o maps considered. The vector convergence map was particularly useful at this stage, as it seemed improbable that any atom should be lying in a strongly negative area. In effect, it represents the correct structure remarkably well, as will be seen from Fig. 2. An important clue is furthermore provided by the optical properties of the crystal, which indicate that the plane of the pyrimidine ring is roughly perpendicular to the *a*-axis. Reasonable qualitative agreement between observed and calculated structure factors for reflections of lower orders was finally obtained with a structure, in which the sugar and pyrimidine parts of different molecules overlapped very badly. By F_o refinement the reliability factor

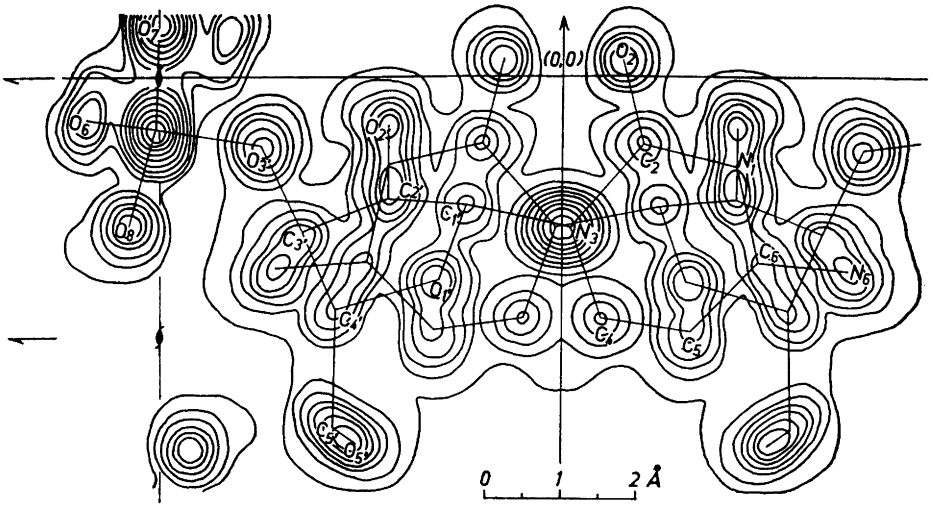

Fig. 3. Electron density projection in direction of *a* axis. Contours at 2, 4, 6, ... e . Å^{-2}.

$R = \Sigma\ (||F_o| - |F_c||)/\Sigma|F_o|$ was brought down to about 0.45 (ignoring reflections with sin Θ >0.75), but the lack of resolution made further improvement by this method difficult. The refinement was continued by successive (F_o—F_c) syntheses, about twenty of these being calculated. In the beginning only terms for which $|F_c|$ was considerably greater than $|F_o|$ were included. The refinement process did not seem to be automatic at the earliest stages and a certain election amongst the shifts indicated by the difference maps had to be made. The positions of most of the fourteen hydrogen atoms were indicated by the final maps. The others were placed by stereochemical considerations. Their inclusion did not improve the agreement significantly. Furthermore, the eight strongest reflections were corrected for extinction effects, following the procedure described by Lipson et *al.*[19] The final value for R for all $0kl$ reflections observable by copper radiation is 0.11. In calculating R the non-observed reflections are only taken into account when F_c exceeds the observable limit of intensity. In the temperature factor $\exp(-B\sin^2\Theta/\lambda^2)$ the value of B is 2.2—0.5$\sin^2\varphi$ for the phosphorus atom and 2.7—0.5$\sin^2\varphi$ for all the other atoms, φ being the angle between the *c*-axis and the normal to the reflecting plane. The atomic scattering curves of McWeeny [13] (for C, N, O and H) and Viervoll and Øgrim [14] (for P) were used. The final electron density map is reproduced in Fig. 3.

The c-projection. Approximate x-coordinates were derived by means of the *a*-projection and approximately known interatomic distances, assuming that x_P was correctly determined from the Harker section and that there were hydrogen bonds between the NH_2-group and the neighbouring PO_4-group. The postulated structure gave a factor R of 0.50, which was brought down to 0.11 by about ten successive (F_o—F_c) refinements. Some very radical shifts in the

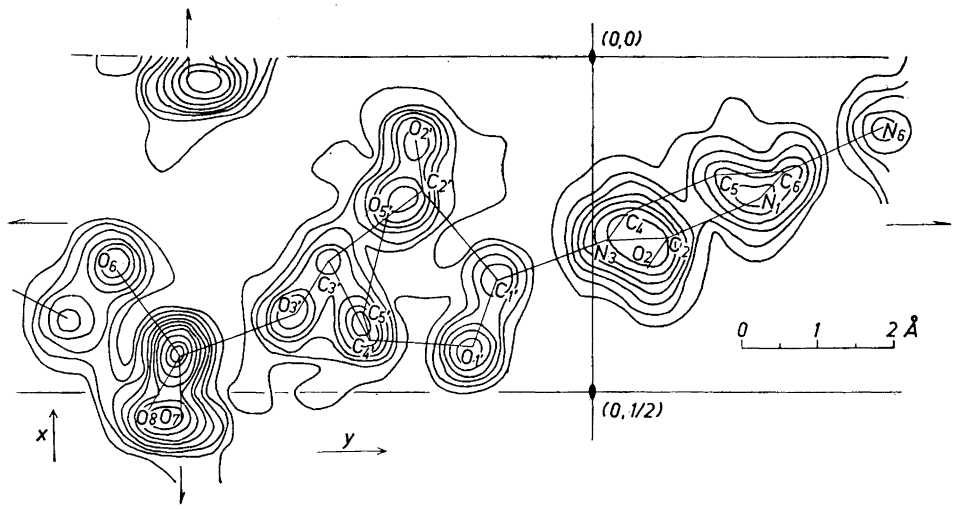

Fig. 4. Electron density projection in direction of c axis. Contours at 2, 4, 6, ... e . Å^{-2}.

rotation about single bonds were clearly indicated by the difference maps in the course of this process. The hydrogen atoms were located in the same way as in the *a*-projection and their inclusion made *R* drop to 0.10. Correction for extinction led to a final value of 0.09 for *R*. The final value chosen for *B* was 1.7 for all the atoms, but a comparison of F_o and F_c indicated that the vibrations of the phosphorus atom and the keto oxygen atom were anisotropic. This was taken into account by applying a factor *B* of 1.7—0.5 $\sin^2 \varphi$ to the phosphorus atom and of 1.7 + 1.0 $\cos^2\varphi$ to the keto oxygen atom, φ being the angle between the *a*-axis and the normal to the reflecting plane. Further refinements of the thermal parameters were not carried out. The final electron density map is given in Fig. 4. In Table 4 observed and calculated structure factors are compared for the *hk*0 reflections. A corresponding list for the 0*kl* reflections can be supplied by the authors on request.

In Table 1 the atomic coordinates derived from the final difference maps in the two projections are given. The two sets of *y*-coordinates were in good agreement and the mean value was taken. In Table 2 the coordinates employed in the calculation of the contribution from the hydrogen atoms are given.

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

The bond lengths and bond angles calculated from the coordinates in Table 1 are given in Table 3 and Fig. 5. A rough estimate of the accuracy of the structure was obtained by comparing the two sets of independently determined *y*-coordinates. For several atoms, inclusive the phosphorus atom, the two values are identical. The greatest deviation, 0.04 Å, occur for the atom C_6, and the

N_6	0.388	0.679	0.387

standard deviation of the y-coordinates from their means, all atoms taken together, is 0.012 Å. It is assumed that the accuracy of the x- and z-coordinates is about the same as that of the y-coordinates from one projection only, corresponding to a standard deviation of about 0.017 Å. This gives a standard deviation of 0.015—0.025 Å in the bond lengths and of 1—2° in the bond angles. The errors within the phosphate group probably correspond to the lower limit, whereas somewhat greater errors may occur where the atoms overlap most badly.

The molecular structure. It is seen from the projections of the structure that the N-glycosidic linkage is of the β-type and that the phosphate group is bound to ribose in the 3'-position. Cytidylic acid *b* is consequently the 3'-phosphate ester of cytidine, in agreement with the conclusions drawn from more indirect physical studies [15].

The dimensions of the phosphate group agree well with those found in dibenzylphosphate[17] and in crystalline phosphoric acid [16]. Values between 1.48 Å and 1.60 Å are derived for the P—O bond lengths and all of them evidently have a large amount of double bond character. Correspondingly the angle $P—O_{3'}—C_{3'}$ is 121°, close to the value usually found for angles between double and single bonds. The longest P—O bond (1.60 Å) is the $P—O_{3'}$ ester bond. It runs roughly in the direction of the *y*-axis and should thus be expected to be more accurately determined than the other bonds. The lengthening of this bond relative to $P—O_6$ and $P—O_7$ is therefore probably significant. No such effect was, however, observed in the case of dibenzylphosphate. The shortest P—O distance ($P—O_8$) is 1.48 Å, indicating that O_8 is the "lone" oxygen atom. Correspondingly, all the angles involving $P—O_8$ are somewhat greater than the tetrahedral angle and the angles between other P—O bonds somewhat smaller, the mean values being 112° and 106°, respectively, as was also found in phosphoric acid.

Four of the atoms of the ribose ring lie nearly in one plane, namely $C_{1'}$, $O_{1'}$, $C_{3'}$ and $C_{4'}$, but the fifth member of the ring, $C_{2'}$, is out of this plane by about 0.5 Å in such a direction that its oxygen atom $O_{2'}$ is brought close to the plane. In cytidine a different atom, $C_{3'}$, was displaced from the plane of the other atoms by about 0.5 Å. The bond lengths are normal within the limits

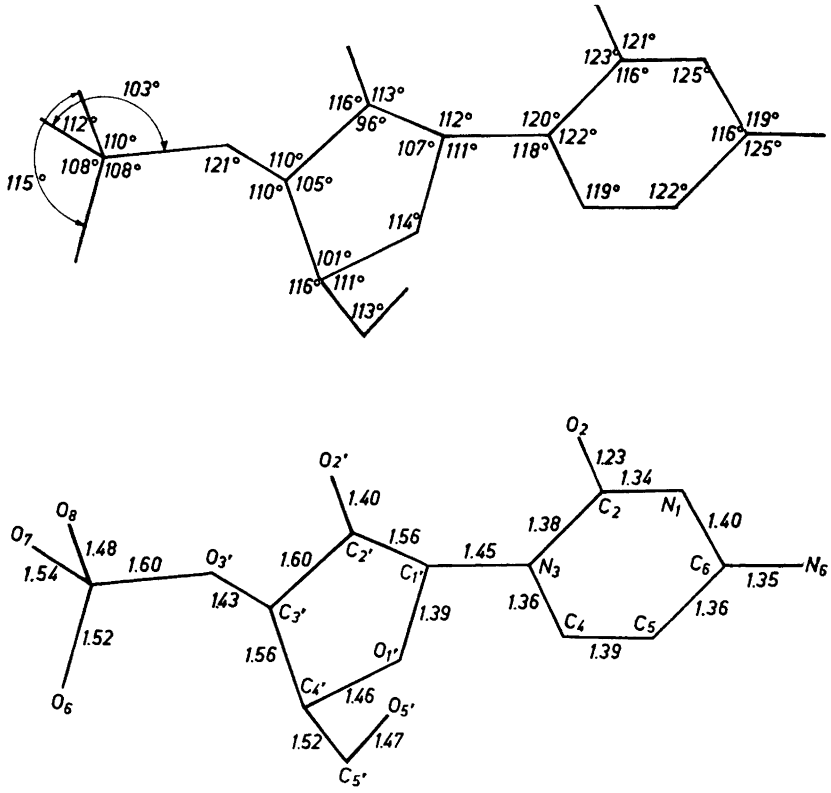

Fig. 5. Bond lengths and bond angles in cytidylic acid *b*.

of error, but some of the bond angles differ significantly from the expected values. Thus the ring angles at $C_{4'}$ and $C_{2'}$ are found as small as 101° and 96°, respectively. By a deformation of the furanose ring from a hypothetical planar structure the sum of the ring angles must become smaller. If it is deformed so as to bring base and phosphate into the relative orientation found in this work, it is seen by means of models that the most reasonable way of obtaining this is to make the angles at $C_{2'}$ and $C_{4'}$ smaller. Unfortunately the coordinates of $C_{2'}$ are very difficult to determine by two-dimensional methods because of overlapping with other atoms in both projections. The hydrogen and oxygen atoms attached to the ring are in a nearly staggered position with respect to the C—C ring bonds, corresponding to a stable conformation of the sugar.

The bond N_3—$C_{1'}$ is found to be 1.45 Å and is thus essentially a single bond. It lies in the plane of the pyrimidine ring and forms angles of 111° and 112° with the adjacent ring bonds in the ribose. The bond angles and bond lengths in the pyrimidine part of the molecule are all normal, being in close agreement with those derived by Parry for uracil [18]. Thus the ring angles at the nitrogen

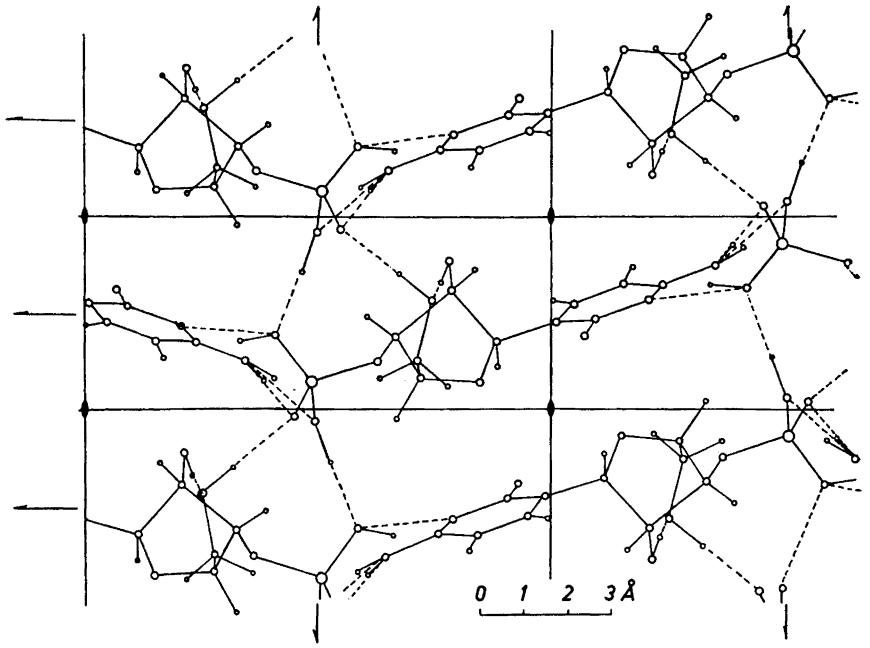

Fig. 6. The *c*-projection of the structure. Broken lines indicate hydrogen bonds. The hydrogen atoms are shown as small circles.

atoms are greater than 120°, the values 124° and 125° being found in uracil and 122° and 125° in the present structure. The C=O distance of 1.23 Å agrees with the values found for keto groups in similar compounds. All the ring atoms and substituents lie in the same plane within the limits of error. The C_6—N_6 distance of 1.35 Å indicates a considerable amount of double bond character. The peaks corresponding to the two hydrogen atoms of the amino group are well defined in both projections, and show that the three bonds from N_6 form a flattened pyramid, as in other amines. This is also in agreement with the directions of the two hydrogen bonds from N_6.

The mutual orientation of the pyrimidine and ribose rings is very nearly as in crystals of cytidine, the two ring "planes" being roughly perpendicular to each other. The midpoints of the bonds $C_{3'}$—$C_{4'}$ and $C_{5'}$—$O_{5'}$ lie nearly in the pyrimidine plane. The distance C_4—$O_{5'}$ is 3.53 Å, corresponding to normal van der Waals separation between H_4 and $O_{5'}$. In cytidine this distance was found to be as short as 3.24 Å*.

Intermolecular forces. The chemical formula of the compound shows that six of the hydrogen atoms in the molecule would be expected to engage in the

* *Note added in proof.* In a recent paper [22] Spencer has discussed most of the available information on the structure of nucleic acid components and related compounds. The present work seems to support his views regarding the conformations of the ribose ring.

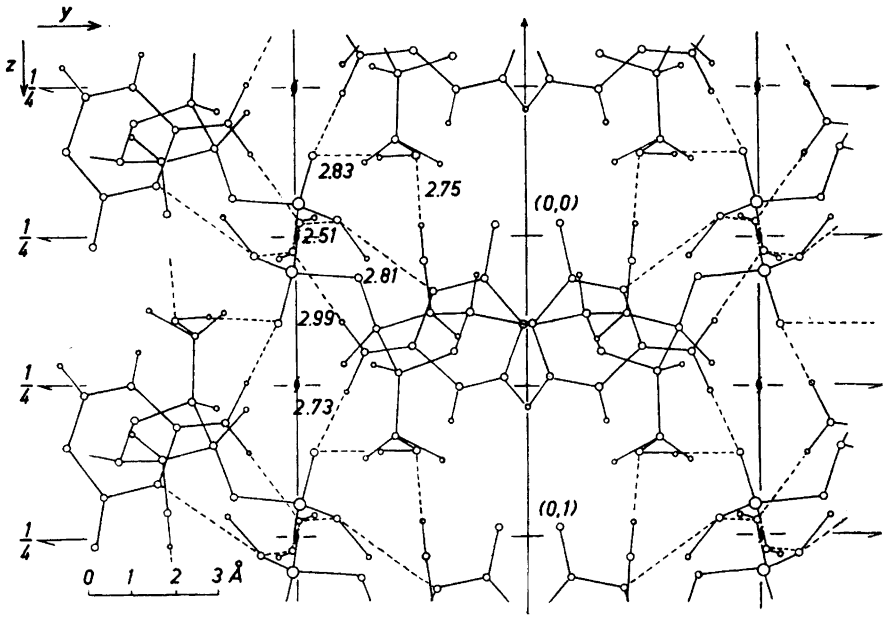

Fig. 7. The *a*-projection of the structure. The lengths of the hydrogen bonds are indicated (Ångström units).

formation of hydrogen bonds as there are two P—OH groups, one NH_2 group and two sugar hydroxyl groups in the molecule. Correspondingly only six intermolecular distances are found to be shorter than 3.1 Å and it appears therefore reasonable to interpret these interactions as hydrogen bonds.

Two hydrogen bonds of lengths 2.73 Å and 2.99 Å form linkages from the amino group to O_8 and O_7 in different phosphate groups. They are situated symmetrically with respect to C_6—N_6 and lie in a plane which forms an angle of about 30° with the plane of the pyrimidine ring.

The oxygen atom O_6 of the phosphate group is linked by a hydrogen bond (length 2.81 Å) to the nearest ring nitrogen atom. This bond lies nearly in the ring plane. Furthermore, the atom O_6 is engaged in a very short hydrogen bond (length 2.51 Å) to O_7 in a neighbouring phosphate group. The two hydroxyl groups in the ribose, $(OH)_{2'}$ and $(OH)_{5'}$, are connected by an O—H...O bond of length 2.75 Å running approximately in the *z* direction and $(OH)_{5'}$ takes also part in a similar bond (2.83 Å) to O_8.

The amino derivatives of purines and pyrimidines are known to occur in crystals in the amino form. Thus there are two hydrogen atoms at N_6 and none at N_1. Taking this into account, a consideration of the hydrogen bonding scheme shows that there are hydrogen atoms attached to O_6 and O_7, but not to O_8. Consequently O_8 is the "lone" oxygen atom of the phosphate group, as was also deduced above. The hydrogen bonds conform remarkably well to

the general stereochemistry of the molecule, and the angles between the hydrogen bonds and the adjacent intramolecular bonds do not deviate much from normal valency angles.

Neither the C=O group nor the ring oxygen atom of the ribose take part in hydrogen bonds. The number of "active" hydrogen atoms is not sufficient for hydrogen bond formation between all the electronegative atoms in the molecule.

None of the other intermolecular distances are shorter than normal van der Waals separations. There are "holes" in the structure around the twofold rotation axes. Every alternate one of these axes is surrounded by pairs of equivalent oxygen atoms at distances 3.4 Å ($O_{1'}$—$O_{1'}$) and 3.6 Å (O_2—O_2) whereas the packing around the others is even less close, the shortest distance across the axis being 3.9 Å (H_4—H_4).

The general arrangement of the molecules and the hydrogen bonds are shown in Figs. 6 and 7.

Because of the great amount of overlap in both projections the structure can hardly be determined very accurately by two-dimensional methods, and probably not much more accurately than in this work. It is planned to carry out further refinements in three dimensions.

Relation to nucleic acid structure. The structure of nucleotides and its relation to nucleic acid structure has been discussed by one of us on the basis of the crystal structure analysis of cytidine [21]. It was concluded that base and sugar were likely to be nearly perpendicular to one another and that in the most probable orientation of the 3′ phosphate group the bond P—$O_{3'}$ was roughly perpendicular to the plane of the base. The distance from this plane to the phosphorus atom was about 3.4 Å, and it was shown how nucleotides of this structure could be combined to macromolecules of helical and other shapes. Roughly the same nucleotide structure has been maintained in later models of nucleic acids, such as the Crick-Watson double helix model for DNA [20], and it would therefore appear to be of interest to compare it with the structure derived for cytidylic acid in the present work.

Firstly, some of the main features of the nucleotide model used are confirmed. Thus the relative orientation of pyrimidine and ribose is almost exactly as in crystals of cytidine, the two "planes" being roughly perpendicular to one another. Furthermore, the length of the glycosidic linkage N_3—$C_{1'}$, as well as the angles between this bond and the adjacent bonds in the ribose are also the same in the two cases within the limits of error. At present there would appear to be no reason to revise the nucleotide model in this respect.

As both base and phosphate are linked directly to the sugar, the structure of the latter is very important for the shape of the whole molecule. In the models hithertho constructed for nucleic acids the sugar ring is supposed to be puckered in the same way as in crystals of cytidine. As shown above, the ring has a different shape in crystals of cytidylic acid. In both conformations there is a nearly staggered arrangement of the substituent hydrogen and oxygen atoms. They would appear to be about equally favourable and should therefore both be considered when building models of nucleic acids.

As for the position of the phosphate group relative to the rest of the molecule, two directions of $C_{3'}$—$O_{3'}$ differing by about 60° should be considered,

corresponding to the two conformations of the sugar. Furthermore, the angle $C_{3'}$—$O_{3'}$—P is 121°, in agreement with the results of the structure analysis of dibenzylphosphate [17], whereas the tetrahedral angle has been assumed in the nucleic acid models. The bond $O_{3'}$—P is in a *trans* position with respect to the ribose ring and is almost parallel to the N_3—$C_{1'}$ bond at a distance of about 0.6 Å, whereas these bonds are nearly perpendicular to one another in current nucleic acid models. In fact, the puckering of the ribose ring and the large angle at $O_{3'}$ make the molecule a very extended one.

The question then arises if nucleotides with the sugar conformation found in the present work can be combined to form macromolecules by 3′—5′ diester phosphate linkages, making the assumption that the bases are perpendicular to the molecular axis and separated by a distance of 3.4 Å corresponding to the dominating X-ray reflection. We have tried to study this problem by means of models.

In the helical structures proposed for DNA, such as our model I [21] and the Crick-Watson model [20], the phosphate groups of the external sugar-phosphate spiral lie roughly in the plane of the bases, which form a central column. In order to build these structures using the sugar conformation found in the present work, we have found it necessary to place the phosphate group roughly midway between successive bases, a position which may possibly not be consistent with the strength of the 3.4 Å reflection. Even with this position of the phosphate group, some of the van der Waals separations are too short. This is also the case in the existing helical models, but on the whole it appears more promising to maintain the ribose conformation found in crystals of cytidine

as a basis for helical models. The possibility that different ribose residues within the same macromolecule may have different conformations should also be borne in mind.

Turning now to other possible structures for the macromolecules, such as the zig-zag model II described by one of us [21], no difficulties are encountered when combining nucleotides of the shape found in the present work to models of this type. Evidently the two sugar conformations may both be used in this case to construct models which contain no unfavourably short van der Waals separations. However, there is considerable evidence that DNA has a double helix structure and other types of structures may therefore serve as models only for RNA. Very little is known about the space structure of this macromolecule, and so it does not seem worth while to discuss the models for it in more detail at the present stage.

We wish to express our thanks to *Norges Almenvitenskapelige Forskningsråd*, whose financial support made this work possible. We should also like to thank Dr. Waldo E. Cohn for providing us with a sample of cytidylic acid *b*, and the Medical Research Council Unit for Molecular Biology, Cavendish Laboratory, Cambridge, in particular Mrs. L. Barnett, for checking our calculations of bond lengths and bond angles.

The Crystal Structure of $TlOHSO_4(H_2O)_{2.5}$

GEORG JOHANSSON

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The structure of $TlOHSO_4(H_2O)_{2.5}$ has been determined by means of X-ray crystallographic methods. Each thallium atom is octahedrally surrounded by six oxygen atoms at an average distance of 2.22 Å. The thallium atoms form chains in the structure with the shortest distance between two thallium atoms equal to 4.01 Å. The positions of the light atoms have been determined from reflections to which the thallium atoms give no contribution.

In the course of a study of the structures of basic salts of some trivalent metals a basic thallium(III) sulfate has also been prepared. It has been described in the literature by Meyer and Wilk [1], who found that it crystallized from solutions of Tl_2O_3 in sulfuric acid containing between about 10 and 40 % H_2SO_4. They ascribed to it the formula $TlOHSO_4(H_2O)_2$.

PREPARATION AND ANALYSIS

Dilute sulfuric acid containing about 20 % H_2SO_4 was saturated with Tl_2O_3 and the solution was placed in a vacuum desiccator. After a couple of days, colourless, rod-shaped crystals of the basic sulfate had formed and were large enough for single crystal measurements. They were filtered off on a glass filter plate and drained by being pressed between filter papers. They could not be washed with water as this immediately resulted in a hydrolysis to Tl_2O_3.

Thallium was determined by precipitation with ammonia and weighing as Tl_2O_3. The sulfate was determined gravimetrically as $BaSO_4$. The water was determined by Hartwig-Bendig's [2] modification of Brush and Penfield's method as described by Kolthoff and Sandell [3].

The density of the crystals was obtained from the apparent loss of weight in benzene.

	Found	Calculated for $TlOHSO_4(H_2O)_2$	Calculated for $TlOHSO_4(H_2O)_{2.5}$
% Tl_2O_3	63.2	64.61	63.00
% SO_3	22.4	22.65	22.09
% H_2O	15.1	12.74	14.91
Density	3.94	3.85	3.94

The analysis data show a better agreement with the formula $TlOHSO_4(H_2O)_{2.5}$ than with $TlOHSO_4(H_2O)_2$ which was assumed by Meyer and Wilk [1]. As will be shown later, only the first formula is consistent with the results of the X-ray analysis.

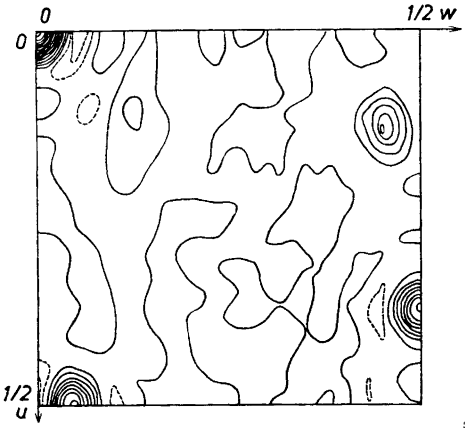

Fig. 1. Patterson projection $P(upw)$ calculated from the intensities of the $h0l$-reflections.

UNIT CELL AND SPACE GROUP

The crystals have orthorhombic symmetry which was shown by rotation and Weissenberg photographs taken with CuK-radiation for two of the axes ($0kl$—$4kl$ and $h0l$—$h4l$). The dimensions of the unit cell were calculated to be $a = 12.5$ Å $b = 8.0$ Å and $c = 12.1$ Å. From powder photographs in a Guinier focusing camera (Table 1) the following more accurate values for the cell dimensions were obtained (Cu$K\alpha$ radiation. $\lambda_{CuK\alpha_1} = 1.54050$ Å)

$$a = 12.453 \pm 0.005 \text{ Å}$$
$$b = 8.019 \pm 0.005 \text{ Å}$$
$$c = 12.224 \pm 0.005 \text{ Å}$$
$$V = 1220.7 \text{ Å}^3$$

According to the observed density, the unit cell must contain 8 formula units of $TlOHSO_4(H_2O)_{2.5}$.

The reflections systematically absent were such that

$0kl$ was observed only for $k + l = 2n$
$hk0$ was observed only for $h = 2n$

This is characteristic for the space groups No 62: $Pnma$ and No 33: $Pn2_1a$.

Intensities were estimated visually and were corrected for Lorentz and polarization factors. No absorption corrections were applied but only very small crystals were used (about 0.1 mm in length).

POSITIONS OF THE THALLIUM ATOMS

On the rotation photograph around the b-axis the odd layer lines were very weak, and the intensities did not seem to increase for the higher layer lines. Therefore the positions of the Tl-atoms may be described by a unit cell with a b-axis of only half that of the structure as a whole.

For the determination of the x and z coordinates the $h0l$-intensities were used to calculate the Patterson projection $P(upw)$. $P(upw)$ shows three sharp maxima which can be ascribed to the Tl-atoms (Fig. 1). For the space group *Pnma* this can be explained by the point position 8(d) which gives the vectors:

$(2x,\ 2z)$	weight 1
$(2x\text{-}\frac{1}{2},\ \frac{1}{2})$	» 2
$(\frac{1}{2},\ 2z\text{-}\frac{1}{2})$	» 2

By comparison with the maxima in $P(upw)$ the following coordinates were obtained:

$$x = 0.064 \qquad z = 0.226$$

All other coordinate possibilities can be transferred to these by shifting the coordinate system half a unit along one of the axes.

As it was possible to place the Tl-atoms in *Pnma* it was first tried to solve the structure by means of this space group.

The Tl-atoms give no or at least only a very small contribution to the reflections $h1l$, $h3l$, . . . and the y-coordinates must therefore be very close to $y = 0$ and $y = \frac{1}{2}$.

POSITIONS OF THE SULFATE GROUPS

The unit cell of the space group *Pnma* has mirror planes in $y = \pm\ ¼$. As the distance between them is only 4.01 Å the SO_4-groups cannot be situated between the planes, which would have required an interplanar distance not less than about 4.3 Å. The SO_4-groups must then be in the mirror planes and the S-atoms and two of the four O-atoms of the SO_4-group must be in point positions 4(c). The other two O-atoms must be outside the mirror planes and therefore have the same x and z parameters. In an electron density projection on this plane they should therefore give a maximum about 0.85 Å from the peak of the sulfur atom and of approximately the same height.

From the structure factors for the Tl-atoms, calculated with the above coordinates, all the signs of the intensities of the $h0l$-reflections were determined and the projection of the electron density on the xz-plane, with the contribution from the Tl-atoms subtracted, was calculated.

$$\varrho'(xpz) = \sum_h \sum_l [F_{obs}(h0l) - F_{Tl}(h0l)] \cos 2\pi(hx + lz)$$

F_{Tl} are the calculated structure factors for the Tl-atoms multiplied by the factor $\Sigma F_{obs}/\Sigma|f_{Tl}A_{Tl}|$. (The temperature factor obtained by means of the expression $F_{obs} = c\,.\,F_{calc} \exp(-B \sin^2 \Theta/\lambda^2)$ was negligible. Probably the temperature factor is cancelled by the absorption effects).

Fig. 2 shows $\varrho'(xpz)$. There are two double maxima in the projection:

A	$x = 0.236$, $z = 0.343$	$x = 0.162$, $z = 0.367$	(Distance 0.97 Å)
B	$x = 0.374$, $z = 0.382$	$x = 0.440$, $z = 0.397$	(Distance 0.84 Å)

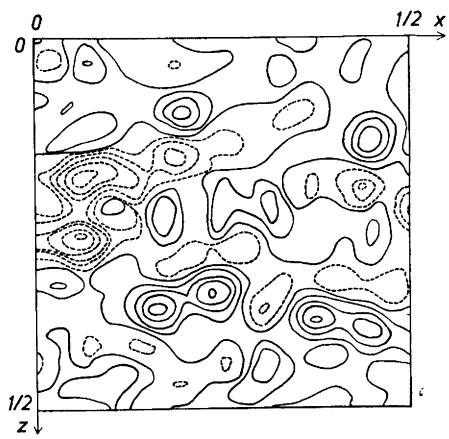

Fig. 2. The electron density projection $\varrho'(xpz)$ calculated from the structure factors of the $h0l$-reflections with the contribution from the thallium atoms subtracted. Dashed lines indicate negative regions.

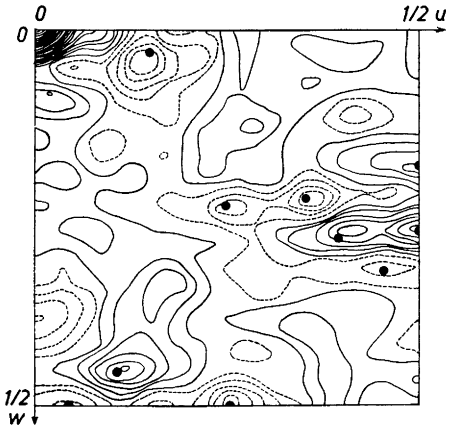

Fig. 3. The generalized Patterson projection $P_1(uw)$ calculated from the intensities of the $h1l$-reflections. The dots indicate the positions of S—S-vectors.

The heights of the maxima are approximately the same and are also the same as might be expected for one sulfur or two oxygen atoms.

From purely geometrical reasons it is difficult to decide which of the maxima comes from the sulfur atom and which from the oxygen atoms, particularly as the coordinates obtained could be expected to be only approximate because of the influence of the heavy thallium atoms. It should, however, be possible to reduce the contribution from the two oxygen atoms relative to the sulfur atom by calculating a generalized Patterson projection [4] $P_1(uw)$ from the intensities of the $h1l$-reflections to which the Tl-atoms do not contribute:

$$P_1(uw) = \frac{1}{A} \sum_h \sum_l |F(h1l)|^2 \cos 2\pi(hu + lw)$$

The vectors in $P_1(uw)$ are equal to the vectors in the $(h0l)$-projection multiplied by the factor $\cos 2\pi(y_1 - y_2)$. For vectors between atoms in the planes $y = \pm \frac{1}{4}$, *i.e.* the sulfur atoms, this will not reduce the size of the maxima but the signs for vectors between atoms in different planes will be negative. The maxima from vectors between atoms in the planes $y = \pm \frac{1}{4}$ and those oxygen atoms from the SO_4-groups which are in the position $8(d)$ will be reduced to about half the magnitude they would have had in the $h0l$-projection. Atoms in the planes $y = 0$ and $y = \frac{1}{2}$ will not contribute at all.

The vectors between the sulfur atoms must therefore have the largest relative contribution to $P_1(uw)$ and the correspinding maxima should be easily recognized.

Within the point position $4(c)$ the following two vectors occur with only one variable:

$u = 2x - \frac{1}{2}$, $w = \frac{1}{2}$ (with negative sign)
$u = \frac{1}{2}$, $w = 2z - \frac{1}{2}$ (with positive sign)

From Fig. 3 it can be seen that for both $u = \frac{1}{2}$ and $w = \frac{1}{2}$ there are two maxima which probably come from the S-atoms and from which the following parameters can be calculated:

$x = 0.377$ $\quad z = 0.383$
$x = 0.228$ $\quad z = 0.340$

A comparison with the coordinates obtained from $\varrho'(xpz)$ shows that the parameters of the sulfur atoms must be:

A $x = 0.228$, $z = 0.340$ $\quad$ B $x = 0.377$, $z = 0.383$

By means of these values the other vectors between the sulfur atoms were calculated and Fig. 3 shows that they also occur in the projection with their correct signs. Because of the great number of vectors in the projection it cannot be used for determining the coordinates of other atomic positions.

The positions of the sulfate groups are now approximately determined as having the following parameters (the coordinates for the O-atoms in 4(c) have been obtained by assuming the dimensions of the SO_4-group to be O—O = 2.4 Å and S—O = 1.5 Å):

SO_4 (A)	4 S in 4(c)	$x = 0.228$	$y = 1/4$	$z = 0.340$
	8 O in 8(d)	$x = 0.162$	$y = 0.10$	$z = 0.367$
	4 O in 4(c)	$x = 0.26$	$y = 1/4$	$z = 0.22$
	4 O in 4(c)	$x = 0.33$	$y = 1/4$	$z = 0.41$
SO_4 (B)	4 S in 4(c)	$x = 0.377$	$y = 3/4$	$z = 0.383$
	8 O in 8(d)	$x = 0.440$	$y = 0.60$	$z = 0.397$
	4 O in 4(c)	$x = 0.33$	$y = 3/4$	$z = 0.27$
	4 O in 4(c)	$x = 0.29$	$y = 3/4$	$z = 0.47$

ELECTRON DENSITY PROJECTIONS OF THE LIGHT ATOMS

From the coordinates of the SO_4-groups the signs of most of the $h1l$-reflections were determined and the generalized electron density projection, $\varrho_1(xz)$, was calculated:

$$\varrho_1(xz) = -\int_0^1 \varrho(xyz) \sin 2\pi y dy = \sum_h \sum_l F(h1l) \sin 2\pi(hx + lz)$$

In this projection the electron density at each point has been multiplied by $-\sin 2\pi y$ which means that the atoms in the planes $y = \pm 1/4$ will give the same contribution as in a $h0l$-projection, with the exception of the signs, but atoms outside these planes will give smaller contributions and atoms in the planes $y = 0$ and $y = \frac{1}{2}$ will not be seen at all.

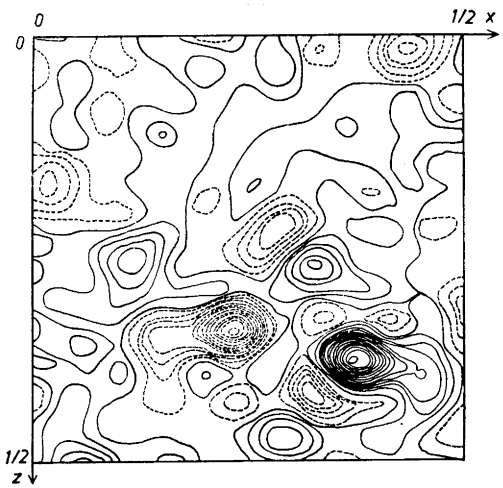

Fig. 4. The generalized electron density projection $\varrho_1(xz)$. The two large peaks come from the sulfur atoms; the negative peak (dashed lines) from S_A and the positive peak from S_B.

Fig. 4 shows the final result with all intensities from the $h1l$-level included. The two largest maxima can be ascribed to the sulfur atoms and give the coordinates:

A: $x = 0.232$ $z = 0.347$ $(y = 1/4)$
B: $x = 0.377$ $z = 0.382$ $(y = 3/4)$

Among the other maxima that can be seen in Fig. 4, the six maxima from the oxygen atoms of the sulfate groups can be identified in positions with coordinates which are in fair agreement with those calculated above.

A new projection $\varrho_1'(xz)$ with the S-atoms substracted was now calculated:

$$\varrho_1'(xz) = \sum_h \sum_l [F_{obs}(h1l) - F_S(h1l)] \cdot \sin 2\pi(hx+lz)$$

This projection, which is shown in Fig. 5, was used for the final determination of the parameters of the oxygen atoms in the SO_4-group:

SO_4 (A): 8 O_1 in 8(d) : $x = 0.167$ $y = 0.10$ $z = 0.353$
4 O_2 in 4(c) : $x = 0.324$ $y = 1/4$ $z = 0.424$
4 O_3 in 4(c) : $x = 0.278$ $y = 1/4$ $z = 0.232$

SO_4 (B): 8 O_4 in 8(d) : $x = 0.439$ $y = 0.60$ $z = 0.390$
4 O_5 in 4(c) : $x = 0.331$ $y = 3/4$ $z = 0.272$
4 O_6 in 4(c) : $x = 0.299$ $y = 3/4$ $z = 0.473$

The y-coordinates of O_1 and O_4 have been calculated from the dimensions assumed for a sulfate group. An approximate value can, however, be obtained from the electron density projection by a comparison between the heights of

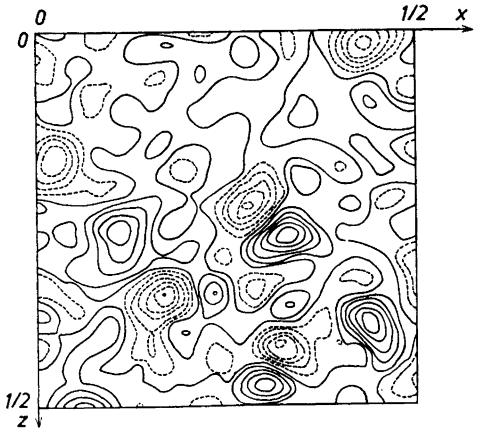

Fig. 5. The generalized electron density projection $\varrho'_1(xz)$ calculated from the structure factors of the $h1l$-reflections with the contribution from the sulfur atoms substracted.

the peaks of O_1 and O_4 and the heights of the peaks of the oxygen atoms in the planes $y = \pm 1/4$, which gives the following values for the y-coordinates of O_1 and O_4:

$$y = 0.09_8 \text{ for } O_1$$
$$y = 0.59_8 \text{ for } O_4$$

This leads to a distance between these oxygen atoms of 2.4_4 Å for both SO_4(A) and SO_4(B), which is the expected distance between the O-atoms of a sulfate group. This method of determination, however, is rather approximate. Some information about the accuracy can be obtained from the scatter of the heights of the 4-fold O-positions around the calculated mean. This gives a standard deviation of 0.013 in the y-coordinates of O_1 and O_4.

In the electron density projection in Fig. 5 there are three further peaks of about the same height as for an oxygen atom in one of the planes $y = \pm 1/4$. The two maxima with the coordinates

$$x = 0.024,\ z = 0.170 \quad \text{and} \quad x = 0.109,\ z = 0.267$$

cannot be ascribed to oxygen atoms outside the mirror planes as this would lead to a Tl—O distance less than about 1.2 Å. Their y-coordinates must therefore be 1/4 and 3/4, respectively, which leads to the Tl—O distances 2.17 and 2.14 Å. Each of these two oxygens (O_7 and O_8) is therefore in contact with two thallium atoms.

Of the thallium atoms no trace can be seen in Fig. 5 and their y-parameters must therefore be exactly or very nearly $y = 0$ and $y = \frac{1}{2}$.

The result of the analysis shows that, in addition to the 40 oxygen atoms that have already been found, there are at least 16 and probably 20 more

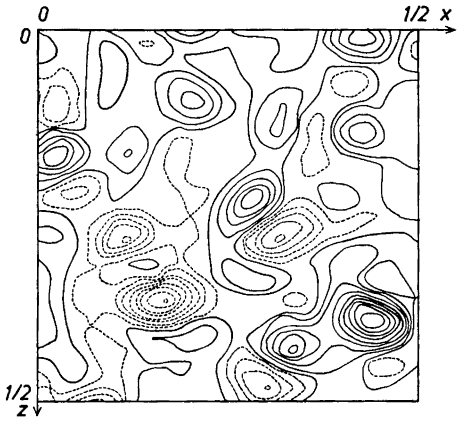

Fig. 6. The generalized electron density projection $\varrho_3'(xz)$ calculated from the structure factors of the $h3l$-reflections with the contribution from the sulfur atoms substracted.

oxygen atoms in the unit cell. In the electron density projection in Fig. 2 there are, besides the maxima from the sulfate groups, two other maxima of about the same height. These might therefore correspond to two sets of oxygens (O_9 and O_{10}) in position 8(d).

Their coordinates are:

$$x = 0.198 \text{ and } x = 0.447$$
$$z = 0.099 \quad » \quad z = 0.142$$

In the electron density projection from the $h1l$-reflections, Fig. 5, there are, however, no marked maxima corresponding to these positions, and the y-coordinates must therefore be close to $y = 0$ and $y = \frac{1}{2}$. This would give a Tl—O distance of about 2.25 Å for O_9 and the rather short distance of 2.05 Å for O_{10}.

In order to obtain a more accurate value for the y-parameters the following electron density projection was calculated:

$$\varrho_3'(xz) = \sum_h \sum_l [F_{obs}(h3l) - F_S(h3l)] \sin 2\pi(hx + lz)$$

This will give the same result as the corresponding projection from the $h1l$-reflections with the exception that the electron density is now multiplied by $-\sin 6\pi y$ instead of $-\sin 2\pi y$. This will change only the signs of the maxima of the atoms in the planes $y = \pm 1/4$, but will greatly increase the maxima from atoms near — but not in — the planes $y = 0$ and $y = \frac{1}{2}$. The result is shown in Fig. 6. The projection is in the main the same as $\varrho_1'(xz)$ in Fig. 5, but the maxima from the 8(d) atoms of the sulfate groups have increased by about the same factor as could be calculated from the relationship $\sin 6\pi y / \sin 2\pi y \approx 1.6$, and in the assumed positions for O_9 and O_{10} there are now marked maxima. From the heights of these maxima in relation to the heights of the maxima of the other oxygen atoms the following y-parameters can be calculated:

$$O_9 : y = -0.020 \qquad O_{10} : y = -0.022$$

(An estimation of the accuracy of these parameter values, analogous to that for O_1 and O_4, gives an approximate value for the standard deviation of about 0.003). The positions of the maxima in the xz-plane are:

O_9: $x = 0.203$ $z = 0.097$ (From the $h3l$-projection)
$x = 0.198$ $z = 0.099$ (From the $h0l$-projection)

O_{10}: $x = 0.425$ $z = 0.137$ (From the $h3l$-projection)
$x = 0.447$ $z = 0.142$ (From the $h0l$-projection)

In both the $h1l$- and $h3l$-projections (Figs. 5 and 6) there is also another maximum with the coordinates:

$x = 0.433$ $z = 0.017$ (From the $h1l$-projection)
$x = 0.427$ $z = 0.012$ (From the $h3l$-projection)

This can be explained by assuming four oxygen atoms in the position 4(c). From space considerations this also seems very probable.

FINAL PARAMETERS

As the structure seems to be satisfactorily explained by means of the space group *Pnma* no further investigation has been made with the space group $Pn2_1a$, which would also have been in accordance with the systematically absent reflections.

The positional parameters of the light atoms were refined by the method of least squares from the 82 observed $h1l$-reflections, and independently from the 78 $h3l$-reflections. The average values of the differences between the final parameters as calculated from the $h1l$- and the $h3l$-reflections, respectively, was 0.002 for the x-parameters and 0.001 for the z-parameters. The standard deviations in atomic coordinates calculated from the least squares residuals are 0.002 for S, 0.004 for O in 4(c), 0.003 for O_1 and O_4, 0.007 for O_9, and 0.005 for O_{10}. For the y-parameters of O_9 and O_{10} the standard deviation is 0.004 which is close to the estimation made above by comparing the heights of the maxima in the Fourier-projections. These values lead to standard deviations of about 0.06 Å for S—O and 0.07 Å for O—O distances except those involving O_9 and O_{10} for which the values are somewhat higher.

Assuming the SO_4-group to be a regular tetrahedron a standard deviation of 0.04 Å in the S—O-distances can be calculated from the scatter around the average value of the S_A—O_2, S_A—O_3, S_B—O_5, and S_B—O_6 distances, which is close to the value calculated above. This would indicate that the estimation of the standard deviations from the least squares residuals is essentially correct in spite of the high absorption from the heavy Tl-atoms. However, the presence of these heavy atoms may introduce systematic errors that are not included in the calculations of the standard deviations and the accuracy may therefore be lower than the values indicate.

The final parameters are shown in Table 2. For the light atoms the average value of the parameters obtained from the *h*1*l*- and the *h*3*l*-reflections has been used. The *y*-parameters of O_1 and O_4 have been calculated assuming the O_1—O_1 and O_4—O_4 distances to be the same as the average value of the O_2—O_3 and O_5—O_6 distances.

Table 2. Final parameters.

From these parameters the structure factors which are listed in Table 4 were calculated assuming the temperature factor $B = 0$ for thallium and $B = 0.1$ Å^2 for the light atoms. For the calculation of the reliability index

$$R = \frac{\Sigma||F_o| - |F_c||}{\Sigma|F_o|}$$

shown below for different classes of reflections, only observed reflections have been included:

*h*0*l* : $R = 0.16$
*h*1*l* : $R = 0.13$ (no contribution from the Tl-atoms)
*h*3*l* : $R = 0.11$ (» » » » »
0*kl* : $R = 0.20$
1*kl* : $R = 0.12$

DESCRIPTION OF THE STRUCTURE

In the structure proposed each thallium atom is octahedrally surrounded by six oxygen atoms. There seems to be no significant difference between the six Tl-O distances (Table 3). The average value is 2.22 Å which is close to the value 2.26 Å found by Zachariasen [5] for the Tl—O distances in Tl_2O_3. Of the oxygen atoms in the TlO_6-octahedron O_1 and O_4 also belong to a sulfate group and each of them is in contact with only one thallium atom. O_7 and O_8 are both in contact with two thallium atoms (Fig. 7) and Pauling's rule for

Table 3. Interatomic distances.

Within a TlO_6-group:			
$Tl-O_1$ = 2.21 Å	O_1-O_7 = 3.18 Å	O_4-O_9 = 3.21 Å	
O_4 = 2.26	O_1-O_8 = 3.08	O_4-O_{10} = 3.10	
O_7 = 2.19	O_1-O_9 = 3.39	O_7-O_9 = 3.17	
O_8 = 2.16	O_1-O_{10} = 3.00	O_7-O_{10} = 3.33	
O_9 = 2.26	O_4-O_7 = 3.07	O_8-O_9 = 3.01	
O_{10} = 2.22	O_4-O_8 = 3.17	O_8-O_{10} = 2.97	
Within the SO_4-groups:			
SO_4(A):	S_A-O_1 = 1.51 Å	O_1-O_2 = 2.46 Å	
	$-O_2$ = 1.49	O_1-O_3 = 2.50	
	$-O_3$ = 1.53	O_2-O_3 = 2.44	
		(O_1-O_1 = 2.43)	
SO_4(B):	S_B-O_4 = 1.46 Å	O_4-O_5 = 2.37 Å	
	$-O_5$ = 1.46	O_4-O_6 = 2.34	
	$-O_6$ = 1.43	O_5-O_6 = 2.42	
		(O_4-O_4 = 2.43)	
Short O—O distances:			
	O_7-O_2 = 2.74 Å	O_8-O_5 = 2.69 Å	
	O_9-O_2 = 2.78 Å	$O_{10}-O_5$ = 2.77	
	O_9-O_6 = 2.65 Å	$O_{10}-O_{11}$ = 2.70	
Other O—O distances less than 3.5 Å:			
	O_1-O_9 = 3.44 Å	O_4-O_9 = 3.13 Å	
	O_2-O_4 = 3.19	O_5-O_9 = 3.31	
	O_3-O_6 = 3.40	O_6-O_7 = 3.33	
	O_3-O_7 = 3.39, 3.16	O_6-O_8 = 3.35	
	O_3-O_9 = 2.95	O_6-O_{11} = 2.94	
	O_3-O_{10} = 3.13	O_8-O_{11} = 3.07	
	O_3-O_{11} = 3.19	O_9-O_{10} = 3.14	
	O_4-O_4 = 3.39	$O_{10}-O_{11}$ = 3.11	

the sum of the bond strengths [6] therefore suggests that one hydrogen atom is probably bound to each of O_7 and O_8. The remaining two oxygen atoms in the TlO_6-group, O_9 and O_{10}, are in contact with only one thallium atom and it seems reasonable to assume that each of O_9 and O_{10} is associated with two hydrogen atoms. The oxygen atom, O_{11}, which is not in contact with any of the thallium atoms, must be a water of crystallization. These results of the structure determination show that the formula should probably be written $Tl_2(OH)_2(H_2O)_4(SO_4)_2 \cdot H_2O$

Chains of TlO_6-octahedra running parallel to the *b*-axis can be distinguished in the structure; the thallium atoms within such a chain being joined together by means of O_7, O_8 and the oxygens of the sulfate groups, O_1 and O_4 (Fig. 7). The shortest distance between two thallium atoms linked together in this way is 4.01 Å. The different chains have no oxygens or sulfate groups in common. The packing of the atoms is shown in Fig. 8, which is a projection of half the unit cell on the *xz*-plane.

Water molecules in contact with cations with a high charge usually tend to form hydrogen bonds to surrounding oxygen atoms and it therefore seems reasonable to assume that in this structure the forces that hold the different

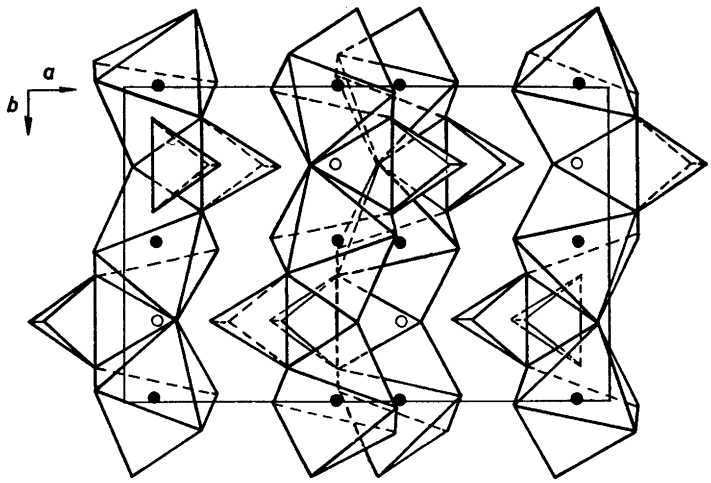

Fig. 7. Projection of the structure along the *c*-axis showing the chains of TlO_6-octahedra running parallel to the *b*-axes. Filled circles indicate Tl-atoms; open circles indicate O_{11}-atoms.

chains together are hydroxyl bonds from the water molecules with O_9 and O_{10} and perhaps also from the oxygen atoms O_7 and O_8. Among the interatomic distances listed in Table 3 there are also some short O—O-distances of about the length expected for a hydroxyl bond. The accuracy of the parameter values is probably not high enough definitely to distinguish these as being significantly shorter than a normal O—O-distance. However, each of O_7 and O_8 is involved in one and each of O_9 and O_{10} in two such short bonds, which is the same as

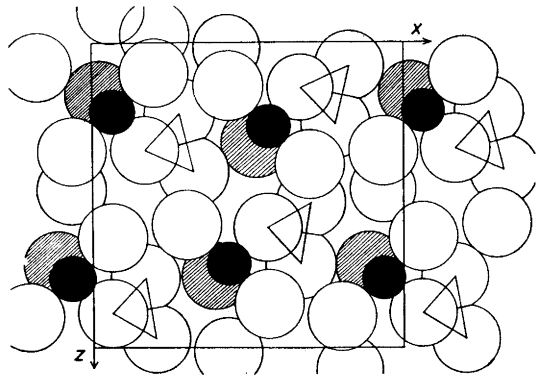

Fig. 8. Projection of half the unit cell on the *xz*-plane. Small circles represent thallium atoms and large circles oxygen atoms. Large shaded circles represent O_7 or O_8.

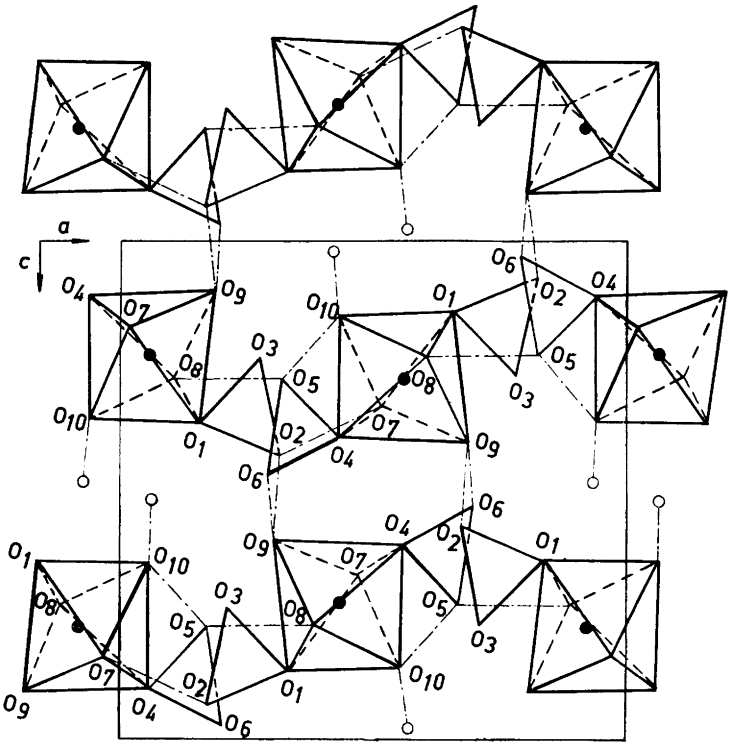

Fig. 9. Projection of the unit cell along the *b*-axis. The projection shows how the sulfate groups (represented as triangles) and the TlO_6-octahedra are linked together. Lines marked —.—.—, between oxygen atoms represent short O—O distances which may indicate the presence of hydrogen bonds. Filled circles indicate Tl-atoms; open circles indicate O_{11}-atoms.

the number of hydrogen atoms that can be assumed to be associated with these oxygens. If hydroxyl bonds were present the arrangement around these oxygen atoms could be expected to be approximately tetrahedral. Except for O_{10} the deviations from an approximate tetrahedral arrangement do not seem so large as to make the assumption of hydrogen bonds unlikely and even if small parameter changes are assumed no other way of forming the hydrogen bonds seems to give a more plausible arrangement. The water molecule O_{11} is in contact with two O_{10} atoms at a distance of 2.70 Å. The angle O_{11}—O_{10}—O_{11} is 110°, which is close to the tetrahedral angle 109° and therefore supports the assumption of a hydrogen bond between O_{10} and O_{11}. The other short distance in which O_{10} is involved is O_5—O_{10} but the angle O_{11}—O_{10}—O_5 is as large as 147°.

With the possible exception of O_5—O_{10} it therefore seems reasonable to assume that the short O—O distances listed in Table 3 and shown in the projection in Fig. 9

Table 4. Observed and calculated structure factors. The F_c and F_o-values are listed in groups in the following order: *h0l*, *0kl*, *1kl*, *h1l*, *h3l*. Structure factors belonging to more than one group are listed only once.

Studies on the Heat Inactivation of Intestinal Invertase, Maltase and Trehalase

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The heat inactivation of the invertase, maltase, and trehalase activities in a solubilized glycosidase preparation from swine intestinal mucosa has been studied.

The trehalase activity was completely separated from the invertase and maltase activities, which is in accordance with earlier findings.

Two different maltase activities were recognized, one *heat-labile* (inactivated at 50°C) and one more *heat-stable* (stable at 70°C when heated for 1 h at pH 6.0). These activities were chromatographically separable, and must therefore be caused by different enzymes.

The invertase activity was inactivated parallel with the heat-labile maltase activity. These two activities are, however, not quite identical, since a heat-labile maltase with low invertase activity was isolated chromatographically. The heat-labile maltase activity is possibly caused by two different enzymes, one of which is combined with the invertase activity, while the other one is not.

Particle-bound glycosidases in microsomes show the same behaviour as the solubilized enzymes when exposed to heat, which demonstrates that all the activities observed have their origin in the intestinal mucosa and that the properties of the enzymes are not altered during solubilization by trypsin digestion.

The hydrolysis of different α-D-glucopyranosides, including sucrose, by intestinal mucosa has been proposed to be caused by one single α-D-glucopyranosidase [1,2]. Recently has, however, been found that intestinal trehalase activity in preparations from swine intestine could be separated from the invertase and maltase activities by anion exchange chromatography [3]. The invertase and maltase activities formed one common peak, but this peak was not homogeneous, since the maltase/invertase activity quotient was lower in the beginning of the peak than in its end. It was therefore apparent, that the intestinal mucosa contains several different enzymes capable of hydrolyzing α-D-glucopyranosides, but for further studies a more complete separation is necessary.

Different enzymes show great variations in their sensitivity to heat inactivation during standardized conditions. This fact may be used for distinguishing

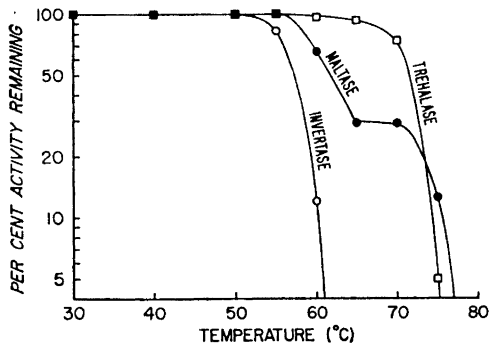

Fig. 1. Heat inactivation of intestinal glycosidases at continuously increasing temperature (gradient 1°C per min). The enzyme solution used was purified by ethanol fractionation and contained 90 U of invertase, 180 U of maltase, 20 U of trehalase and 6.1 mg of protein per ml in 0.01 M phosphate buffer pH 6.0.

different enzymes in mixture. This method has been used for the demonstration of two different bromo-naphthyl-β-D-galactopyranosidase activities in calf intestinal mucosa, only one of which was combined with lactase activity [4]. Invertase from human jejunum is known to be more sensitive to heat than yeast invertase [5], but a comparison between the heat sensitivities of the different α-D-glucopyranosidase activities of intestinal mucosa seems never to have been performed.

In the present paper is described a study of the heat inactivation of the invertase, maltase, and trehalase activities of a solubilized glycosidase preparation from swine intestinal mucosa. The heat inactivation of different fractions from an anionic exchange chromatogram of this preparation also was studied. In addition the heat inactivation of these activities in their non-soluble form in a preparation of microsomes from swine intestinal mucosa was studied.

RESULTS AND DISCUSSION

A. Heat inactivation of solubilized glycosidases

The enzyme preparation used was a solubilized preparation of glycosidases from swine intestinal mucosa, purified by ethyl alcohol fractionation [3]. It contained 90 U of invertase, 180 U of maltase, 20 U of trehalase, and 6.1 mg of protein per ml. Before use the solution was dialyzed against 0.01 M phosphate buffer pH 6.0.

Inactivation at increasing temperature. In a preliminary experiment, 5 ml of the enzyme solution was heated in a waterbath at increasing temperature (increasing 1°C per min.). At intervals 0.5 ml samples were taken, and immediately blown down into test-tubes chilled with crushed ice, in which they were stored until analysed.

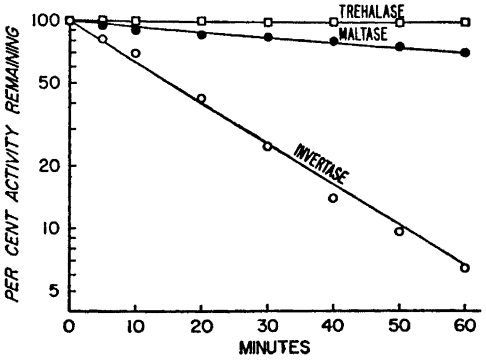

Fig. 2. Heat inactivation of intestinal glycosidases at 50°C. Enzyme solution the same as in Fig. 1.

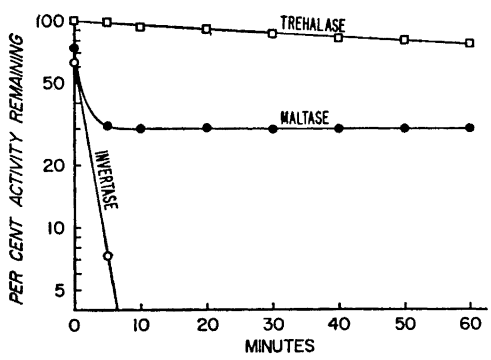

Fig. 3. Heat inactivation of intestinal glycosidases at 60°C. Enzyme solution the same as in Fig. 1.

The different activities investigated were found to differ widely in their sensitivity to heat. The invertase actvity was abolished between 50 and 60°C while the trehalase activity was not influenced below 65°C (Fig. 1). These activities must therefore be caused by two different enzymes, which has also been revealed by ion exchange chromatography [3]. The maltase was inactivated in two steps. 70 % of the maltase activity disappeared in the same temperature interval as the invertase activity, while the remaining 30 % of the total maltase activity were inactivated first when the temperature exceeded 70°C.

Inactivation at constant temperature. At constant temperature the heat inactivation of enzymes usually follows the kinetics of a first order reaction, *i.e.* if the logarithm of the remaining enzymatic activity is plotted against time, a straight line is obtained [6].

To reach the desired temperature within reasonable time, it was necessary to heat the enzyme solution, in a thin-walled test tube, in a preheating bath which has a temperature 8°C higher than the desired inactivation temperature. When the desired temperature was reached (within 45 sec.) the tube was immediately transferred to the inactivation bath, and in the same moment a zero-time sample was taken and a stop-watch was started. At time intervals samples were taken as described above. The glycosidase activities in the samples are expressed as per cent of the original activity (before exposure to heat).

At 50°C (Fig. 2) the invertase activity diminished to 50 % of its original value in 18 min. The maltase was inactivated more slowly, and the trehalase activity was not affected at all.

At 60°C (Fig. 3) 99 % of the invertase activity was destroyed in about 10 min. The maltase activity rapidly diminished to 30 % of its original value, but even after heating for 1 hour at 60°C the maltase activity was not further affected. The trehalase activity decreased only very slightly.

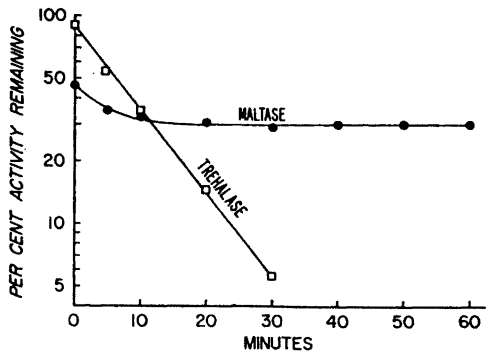

Fig. 4. Heat inactivation of intestinal glycosidases at 70°C. Enzyme solution the same as in Fig. 1.

At 70°C (Fig. 4) the invertase activity was practically immediately destroyed, and the trehalase activity was rapidly diminishing, following first order kinetics. The maltase activity decreased immediately to 30 % of its original value, but was then not measurably affected. At higher temperature also the maltase activity was completely destroyed.

The maltase activity apparently consists of two components, one more *heat-labile*, constituting 70 % of the total activity, and one more *heat-stable*, constituting 30 % of the total maltase activity. The maltase activity must therefore be caused either by two different enzymes or by one enzyme which in inactivated in two steps. As will be seen below, the heat-labile and the heat-stable maltase activities are chromatographically separable, and must therefore be caused by two different enzymes.

From the inactivation experiment at 70°C (Fig. 4) it is clearly seen that the trehalase activity is independent of both the invertase and heat-labile maltase activities (which are practically immediately destroyed) and the heat-stable maltase activity (which is not affected at all). This is in accordence with the earlier reported isolation of a trehalase fraction from intestinal mucosa which had no maltase or invertase action.

The relations between the heat-stable and heat-labile maltase activities and the invertase activity were further investigated by analysis of fractions obtained by chromatography of these activities upon DEAE-cellulose.

B. Heat inactivation of fractions from DEAE-cellulose chromatography

In chromatography upon DEAE-cellulose [3] the invertase and maltase activities form one common peak, which, however, is inhomogeneous. The maltase/invertase activity quotient is 0.6 in the beginning of the peak, while it rises to over 4 in its end.

Chromatography on DEAE-cellulose. A solubilized glycosidase preparation, containing 24 000 U of invertase, 48 000 U of maltase, and 400 mg of protein in 0.05 M phosphate buffer pH 6.0 was applied to a column containing 10 g (dry weight) of DEAE-cellulose. The column was first eluted with 2 liters of 0.05 M phosphate buffer pH 6.0. This fraction contained no maltase or invertase activity and was discarded. The column was then eluted with phosphate buffer of the same pH with step-wise increasing molarity (Table 1).

Table 1. Chromatography of intestinal maltase and invertase on DEAE-cellulose with step-wise elution.

Fraction No.	Molarity of buffer	Volume	Mg of protein	U of invertase	U of maltase
I	0.065	300 ml	24	3 300	2 000
II	0.150	300 »	229	20 000	42 000
III	0.200	200 »	7.6	400	1 700

Concentration of the fractions. After dilution of the fractions with distilled water to give a final concentration of 0.05 M buffer, the fractions were applied to small DEAE-cellulose columns (dry weight of DEAE-cellulose 1 g for fraction I and III and 5 g for fraction II) and thereafter eluted with 50 ml of 0.2 M phosphate buffer pH 6.0. Before heat inactivation the solutions were dialyzed against 0.01 M phosphate buffer pH 6.0.

Heat inactivation of the fractions obtained. Fraction I contained after concentration 80 U of invertase, 50 U of maltase, and 0.6 mg of protein per ml. This means that the maltase/invertase activity quotient is 0.6. When heated at 48°C both the invertase and the maltase activity diminished, following first order kinetics, and closely following each other (Fig. 5). The maltase activity in this fraction is apparently all heat-labile. The question arises if the maltase

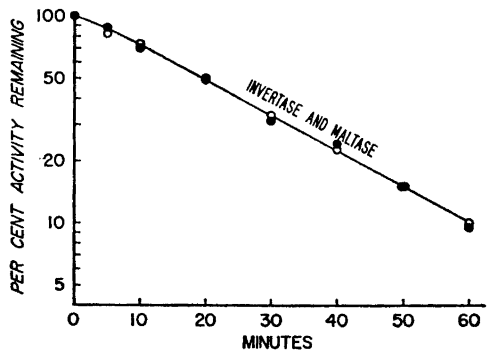

Fig. 5. Heat inactivation at 48°C of fraction I from DEAE-cellulose chromatography. The solution contained 80 U of invertase, 50 U of maltase, and 0.6 mg of protein per ml in 0.01 M phosphate buffer pH 6.0. The maltase activity is all heat-labile, and invertase and maltase are inactivated parallel.

and invertase activities in this preparation are caused by the same enzyme. When a sample of this fraction was rechromatographed on DEAE-cellulose, using gradient elution, the invertase and maltase activities appeared as one peak, which was quite homogeneous. Heat inactivation was performed in buffers of varying pH in order to find any differences in behaviour of the maltase and the invertase activities, but no difference was found (Table 2).

Table 2. Heat inactivation of fraction I at 45°C in varying buffers. Maltase/invertase activity quoient 0.6.

Buffer	Half-time for the invertase activity, min	Half-time for the maltase activity min
0.01 M acetate pH 5.2	10	10
0.01 M phosphate pH 6.0	90	90
0.01 M phosphate pH 7.0	80	80
0.01 M veronal pH 8.0	3	3

Fraction III contained after concentration 10 U of invertase, 41 U of maltase, and 0.2 mg of protein per ml. When the solution was heated at 60°C, the invertase activity rapidly disappeared together with 20 % of the maltase activity (Fig. 6). The remaining 80 % of the maltase activity were however not affected even after heating for 1 h. This part therefore consists of heat-stable maltase. That the heat-labile and the heat-stable maltase activities are chromatographically separable, demonstrates that they are caused by two different enzymes.

It is apparent, that the heat-stable maltase has no invertase action. On the other side the invertase fraction obtained (fraction I) had (heat-labile) maltase activity, with a maltase/invertase activity quotient of 0.6. This maltase activity could not be separated from the invertase activity, and there

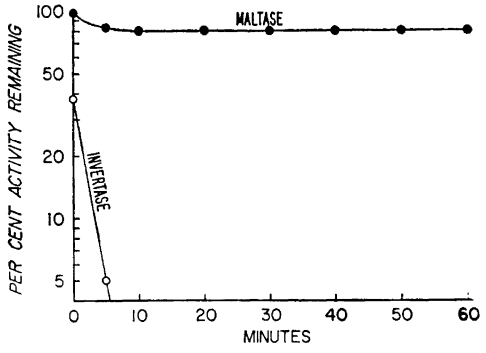

Fig. 6. Heat inactivation at 60°C of fraction III from DEAE-cellulose chromatography. The solution contained 10 U of invertase, 41 U of maltase, and 0.3 mg of protein per ml in 0.01 M phosphate buffer pH 6.0. The maltase activity is mainly heat-stable.

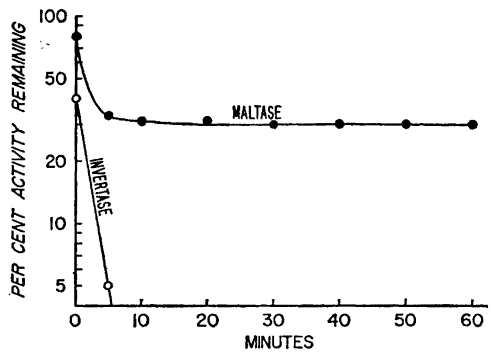

Fig. 7. Heat inactivation at 60°C of a preparation obtained by repeated rechromatography of the middle fraction from DEAE-cellulose chromatography. The solution contained 3.9 U of invertase, and 67.5 U of maltase per ml. In spite of the low invertase activity, the major part of the maltase activity is heat-labile.

are reasons to believe that these two activities are caused by the same enzyme. The original enzyme preparation had, however, a maltase/invertase activity quotient of 2.0. Since the heat-labile maltase activity amounted to 70 % of the total maltase activty, this preparation had a heat-labile maltase/invertase activity quotient of 1.4. It stands therefore clear, that even if the invertase has maltase activity, it cannot cause more than 50 % of the heat-labile maltase activity in the original preparation.

When fraction II, which contained the main part of the original enzyme activity, was rechromatographed on DEAE-cellulose, again a first fraction with a maltase/invertase activity quotient of 0.6, and a last fraction mainly consisting of heat-stable maltase were obtained. By repeated collection and rechromatography of the middle fraction, a preparation was obtained which contained all three activities, but in which the heat-labile maltase/invertase quotient was gradually increased. After four times repeated chromatography, this fraction had a heat-labile maltase/invertase quotient of 12.1 (Fig. 7). There exists therefore one heat-labile maltase activty which has no (or very low) invertase action. On DEAE-cellulose it is only possible to purify this activity partially, wherefore more suitable separation methods are under investigation. The relation between this invertase-free heat-labile maltase activity and the maltase activity which accompanies the invertase activity will be further studied.

If it is supposed that there exist *two* different *heat-labile* maltases, the following intestinal maltases will be recognized:

Maltase I: heat-labile maltase activity accompanying the invertase activity and amounting to 30 % of the total maltase activity.

Maltase II: heat-labile maltase activity without invertase action, amounting to 40 % of the total maltase activity.

Maltase III: heat-stable maltase activity, amounting to 30 % of the total maltase activity.

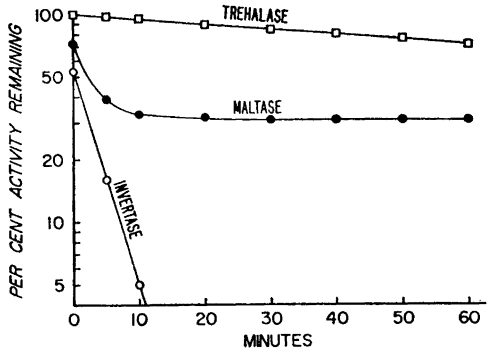

Fig. 8. Heat inactivation at 60°C of particle-bound intestinal glycosidases. The sample contained 35 U of invertase, 70 U of maltase, 10 U of trehalase and 7 mg of protein per ml in 0.01 M phosphate buffer pH 6.0.

C. Heat inactivation of particulate glycosidases

In the method used for preparation of soluble glycosidases, the intestinal contents are not removed from the mucosa [3]. This offers the possibility for contamination with enzymes secreted from other organs or bacterial enzymes. It has, however, been found that the invertase obtained in this way has the same properties as the invertase in washed microsomes from the intestinal mucosa, and that the relation of the maltase and trehalase activities to the invertase activity is unaltered [3]. It must also be considered, that the solubilization by trypsine digestion may alter the properties of the enzymes. This seems, however, not probable, because the enzymatic activity is unaltered [3].

The behaviour of particle-bound intestinal glycosidases during heat inactivation was studied on a desoxycholate-extract from washed intestinal microsomes [3]. This extract is known to contain only particle-bound glycosidases, which can be sedimented in a centrifuge if the desoxycholate is removed [3]. It contained 35 U of invertase, 70 U of maltase, 10 U of trehalase, and 7 mg of protein per ml. The extract was dialyzed against 0.01 M phosphate buffer pH 6.0 before use.

At 60°C (Fig. 8) the invertase activity disappeared within 10 min together with 68 % of the total maltase activity. The remaining 32 % of the maltase activity was not further affected. The trehalase activity was only very slowly diminishing. This behaviour is quite identical with that which was found with solubilized glycosidases (Fig. 3). This shows that all the activities observed have their origin in the microsomes of the intestinal mucosa, and that the properties of the enzymes are not altered during their solubilization by trypsin digestion.

MATERIALS AND METHODS

Enzymes. Solubilized glycosidases were prepared from swine intestinal mucosa by trypsin digestion and ethyl alcohol fractionation as described earlier [3]. *Particle-bound glycosidases* were prepared from washed microsomes from swine intestinal mucosa by extraction with sodium desoxycholate as described earlier [3].

Substrates. Sucrose was obtained from J. T. Baker Co., maltose (monohydrate) from Merck A. G. (Germany), and trehalose (dihydrate) from Pfanstiehl Chemical Co.

Determination of glycosidase activity was performed at 37°C. The reaction mixture had 0.1388 M substrate concentration and contained 0.05 M maleate buffer of pH 6.5 for invertase and maltase and 6.0 for trehalase. The degree of hydrolysis was determined with the 3,5-dinitrosalicylic acid reagent of Sumner [7] for sucrose and trehalose, and with the acid copper reagent of Tauber and Kleiner [8] for maltose. The degree of hydrolysis was not allowed to exceed 10 % in one hour. During these conditions the amount of monosaccharides produced was proportional to the glycosidase activity (zero order reaction). One U of glycosidase activity means the activity producing 1 mg of monosaccharides in one hour during the above conditions.

Protein determination was made with the method of Lowry *et al.*[9] A standard curve was made with human serum albumin (kindly supplied by A. B. Kabi). *Spectrophotometric readings* were made with a Beckman B spectrophotometer.

Diethyl-aminoethyl-cellulose (DEAE-cellulose) was prepared by the method of Peterson and Sober [10]. It contained 0.78 mequiv. titrable hydroxyl groups per g dry weight.

Studies on Molybdenum Oxides *

LARS KIHLBORG

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The MoO_2–MoO_3 region of the molybdenum-oxygen system has been investigated within the temperature range 500°–870°C, by means of X-ray diffraction techniques. Temperature regions are given for the formation of the seven intermediate phases found, among which are two previously undescribed oxides designated ϑ- and $\varkappa$-oxides.

Unit cell dimensions and X-ray diffraction data are given and formulae are suggested for the ζ-oxide (Mo_9O_{26}, triclinic), the $\varkappa$-oxide ($Mo_{17}O_{47}$, orthorhombic) and the η-oxide (Mo_4O_{11}, monoclinic). The unit cell dimensions have also been determined for the ϑ-oxide ($MoO_{\sim 2.80}$, tetragonal), which is probably metastable.

The electrical resistivity at room temperature has been determined for the various intermediate phases excluding the ϑ-phase.

The oxidation of the oxides in air at 230°–350°C has been studied. An intermediate stage, called λ-oxide, has been observed in the oxidation of the two Mo_4O_{11} phases to MoO_3.

The first phase analysis by means of X-ray methods on the molybdenum-oxygen system was published in 1944 by Hägg and Magnéli [1]. They reported the existence of four oxides with compositions between MoO_2 and MoO_3, called β-, β'-, γ- and ε-oxide. By determination of the crystal structures Magnéli was later able to establish the exact formula Mo_8O_{23} (monoclinic) for the β-oxide [2], Mo_9O_{26} (monoclinic) for the β'-oxide [2] and Mo_4O_{11} (orthorhombic) for the γ-oxide [3]. These and other structural studies are reviewed and further discussed in Ref.[4].

In 1950 Glemser and Lutz published a paper on molybdenum oxides studied by X-ray powder methods, electrical resistivity measurements and chemical and microscopical techniques [5]. Their phase analysis in general confirmed the results of Hägg and Magnéli, but as has already been pointed out [6], the notations of the phases used in the two articles are inconsistent (*v. infra*).

In connection with studies of the thermal decomposition of MoO_3 *in vacuo*, two other oxide phases were observed, which were provisionally called ζ- and

* A survey of part of the work reported in this article was presented to the XVIth International Congress for Pure and Applied Chemistry, Paris 1957, and has been published in *Mémoire présenté à la Section de Chimie Minérale*, Sedes, Paris 1958, p. 59–61.

η-oxide [7]. There were indications that the composition of ζ-oxide is near $MoO_{2.88}$, but at that time nothing could be said about the composition of the η-oxide.

A review of the structural investigations of oxygen compounds of molybdenum and tungsten carried out at this Institute up to 1954 is given in Ref.[8]

As the investigations by Hägg and Magnéli were limited mainly to a restricted region of temperature around 650—750°C, it was thought desirable to extend the phase analysis studies to a wider range of temperature and to try to establish the formulae of the new oxides.

The results obtained to date are presented in this article. Crystal structure determinations of several of the new oxides are in progress.

EXPERIMENTAL

The starting materials for the preparations were molybdenum trioxide ("Baker's Analyzed", 99.9 % dried at 200°C), and molybdenum dioxide prepared by reducing the trioxide in a stream of dry hydrogen gas at 500°C, the degree of reduction being controlled by weighing. In a few cases molybdenum powder ("Kahlbaum", heated *in vacuo* at about 400°C) was used instead of the dioxide.

The samples, prepared by thoroughly mixing weighed amounts of MoO_2 (or Mo) and MoO_3, were heated in evacuated, sealed silica tubes, which had been cleaned and preheated in air at about 800°C. As had been observed previously by Hägg and Magnéli, MoO_3 attacks the silica to some extent, especially above 700°C, giving a white, crystalline coating inside the tubes. This coating showed the powder lines of low-cristobalite, often together with those of MoO_3. To avoid contamination, those samples which did not contain molybdenum metal were often packed into platinum foil when heated at the higher temperatures.

The high volatility of MoO_3 made it necessary to minimize any temperature gradient within the tubes which were therefore kept in appropriate borings in heavy steel cylinders placed in vertical electrical furnaces [6]. In spite of these precautions a slight escape of MoO_3 from the main sample could not be avoided, especially during the heat treatments above 700°C. This gave rise to a small drift of the composition towards lower oxygen content ($\Delta x < 0.02$ in MoO_x) which had to be taken into account.

A calibrated platinum-platinum rhodium thermocouple was used, inserted into a boring of the steel cylinder. The cold junction was kept at 0°C. The temperature was measured with a potentiometer bridge at the beginning and the end of each heat treatment, and was kept constant by a Wheelco regulator which controlled only about 5 % of the stabilized voltage of the furnace [6]. In this way the short-time variations of the temperature were reduced to within ± 2°C, but a long-time drift of the temperature level was sometimes observed. The total variations were, however, always within ± 4°C.

The studies have been concerned with the temperature interval 500° — 870°C, the lower limit being set by the rapidly decreasing reaction rate. At the lower temperatures heating times of several weeks and repeated powdering of the samples were necessary in order to obtain equilibrium. At the higher temperatures heating for some days was usually sufficient.

The silica tubes were quenched in water from the reaction temperatures. No chemical analysis of the products was considered necessary.

The samples were examined microscopically and X-ray powder photographs were taken in Guinier focusing cameras of 80 mm diameter using monochromatized Cu$K\alpha$ or Cr$K\alpha$ radiation. These cameras, covering the angular region $1.5° < \Theta < 45°$, give a high resolution and very low background which greatly facilitated the identification of the patterns and the detection of phases present in small amounts. The powder patterns were evaluated according to the method given by Hägg, which introduces an automatic correction for film shrinkage [9]. Potassium chloride (Analar, BDH, ground and recrystallized) was added to the powder specimens as an internal standard, and its lattice parameter was taken to be $a = 6.29215$ Å (21°C) according to Hambling [10]. The use of Guinier

cameras for accurate determination of lattice dimensions has recently been demonstrated in this journal [11]. The powder patterns of several of the molybdenum oxide phases are given in Table 1.

Single crystal photographs were taken in Weissenberg and precession cameras using Cu*K* and Mo*K* radiation.

The electrical resistivity of the oxides was determined in a simple cell, permitting the measurements to be carried out on a powder specimen under considerable pressure, applied by means of a screw press. The data thus obtained are given in Table 2.

RESULTS OF THE PHASE ANALYSIS

The results of the phase analysis within the 500°—800°C region are summarized in Fig. 1, where the formation temperatures *versus* composition are indicated for the intermediate phases found. As far as can be determined from the powder photographs, none of the phases has an extended homogeneity range. It must be emphasized that the temperature ranges indicated do not necessarily represent the true stability regions. These may be very difficult to establish because of an observed disposition of several phases to remain for a long time in a metastable state.

Preparations — the starting mixtures as well as the pure oxides prepared — heated above 800°C and quenched in water always contained at least three phases, *viz.* MoO_2, MoO_3 and orthorhombic Mo_4O_{11} (γ-oxide), and thus did not represent a state of equilibrium. When the cooling rate was slower, the lines of MoO_2 generally disappeared. This seems to indicate that MoO_2 and MoO_3 are the only phases stable above 800°C, but that orthorhombic Mo_4O_{11}

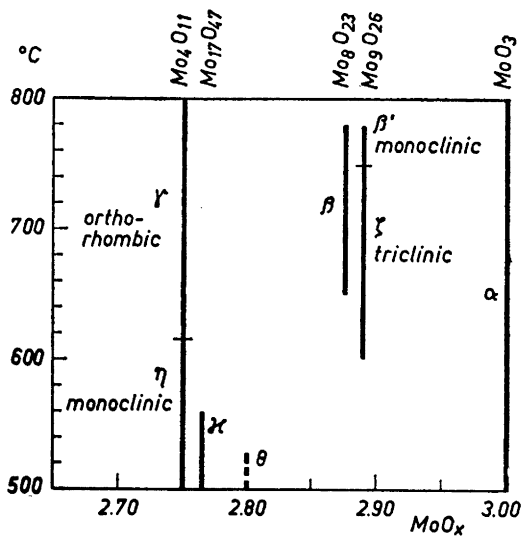

Fig. 1. Formation temperature *v.* composition diagram for molybdenum oxides.

forms fairly rapidly when the temperature is lowered. The triclinic Mo_9O_{26} (ζ-oxide) likewise was sometimes found in samples slowly cooled from above 800°C. According to Fig. 1, the formation of this phase should occur below 750°C.

Hägg and Magnéli reported that the β'-oxide (monoclinic Mo_9O_{26}) and the γ-oxide (orthorhombic Mo_4O_{11}) decompose when heated to 850°C, giving MoO_2, MoO_3 and a new phase which they designated ε-oxide[1]. Upon reexamination of samples prepared by these authors and reported to contain ε-oxide, it became evident that this phase was identical with the ζ-oxide (triclinic Mo_9O_{26}). The cooling rate was, however, not very high in these early experiments and may explain the occurrence of this phase.

Description of the phases observed

Triclinic Mo_9O_{26} (ζ-oxide). The ζ-phase has been obtained between 600° and 750°C *, and is the purest in samples of compositions close to $MoO_{2.89}$. It is transformed into monoclinic Mo_9O_{26} (β'-oxide) when heated at 760°—780°C (within 2 h at 780°C), and is slowly decomposed into MoO_3 and monoclinic Mo_4O_{11} (η-oxide) at 550°C. It forms almost-black, irregular, but rather flaky crystals, readily distinguishable from the other molybdenum oxides. With the aid of single crystal data, its powder pattern (see Table 1a) has been indexed and the following triclinic unit cell has been derived by least squares refinement

* The accuracy of the formation temperature limits given in the following are, in general, about ± 10°C.

$a = 8.145$ Å	$b = 11.89$ Å	$c = 19.66$ Å	$V = 1779.5$ Å^3
$\alpha = 95.47°$	$\beta = 90.39°$	$\gamma = 109.97°$	

As is the case with all the oxides below MoO_3 the electrical conductivity makes impossible the use of piezo-electrical methods for detection of any non-centrosymmetry.

The density was found to be 4.74, which corresponds to 35.7 $MoO_{2.89}$ per unit cell and suggests a cell content of 4 formula units Mo_9O_{26}.

Mo_8O_{23} (β-oxide) and monoclinic Mo_9O_{26} (β'-oxide). These two phases, first described by Hägg and Magnéli [1], have been obtained within the temperature ranges 650°—780°C for Mo_8O_{23} (by decomposition of $Mo_{17}O_{47}$ even at 630°C; see below) and 750°—780° for monoclinic Mo_9O_{26}. Both decompose into MoO_3 and orthorhombic Mo_4O_{11} when heated at 785° and 800°C. At temperatures below their formation regions they are, however, markedly stable; no change was actually observed after tempering Mo_8O_{23} for three days at 643°C or three weeks at 550°C and monoclinic Mo_9O_{26} three days at 700°C or one week at 648°C.

The structures of the two oxides have been determined by Magnéli [2]. They constitute the first two members of a series of structurally interrelated oxides of the general formula Me_nO_{3n-1} [12]. By substituting tungsten for part of the molybdenum, higher homologues in this series have been prepared, *e.g.* $(Mo, W)_{10}O_{29}$ and $(Mo, W)_{12}O_{35}$ [6]. The introduction of a small proportion of tungsten has furthermore been found to extend the formation range for the β'-phase down to 650°C [6].

The *d*-values of the powder patterns of Mo_8O_{23} and monoclinic Mo_9O_{26} are listed in Ref.[13], and the unit cell dimensions are given in Table 2 of Ref.[6]

It has been pointed out earlier [6] that, in view of its chemical properties, the "β-molybdenum oxide" of Glemser and Lutz [5] is probably identical with the triclinic Mo_9O_{26} (ζ-oxide), while their "β'-oxide" is Mo_8O_{23}, monoclinic Mo_9O_{26} or a mixture of these two phases. The resistivity measurements made (*cf.* Table 2) strongly support this view: the triclinic Mo_9O_{26} is seen to have by far the highest resistivity of all the intermediate phases, as has the "β-oxide" according to Glemser and Lutz.

$Mo_{17}O_{47}$ ($\varkappa$-oxide). In samples heated below about 560°C, a new phase appeared with a composition close to $MoO_{2.78}$. It decomposes into orthorhombic Mo_4O_{11} (γ-oxide) and Mo_8O_{23} (β-oxide) at 630°C, but does not change when kept at 590°C for one week.

Table 2. Specific electrical resistivity of molybdenum oxides (at room temperature).

Phase	Resistivity ohm . cm
Mo_9O_{26} triclinic	~ 250
Mo_9O_{26} monoclinic	~ 3.7
Mo_8O_{23}	~ 1.2
$Mo_{17}O_{47}$	< 0.05
Mo_4O_{11} orthorhombic	~ 0.25
Mo_4O_{11} monoclinic	~ 0.2

The $\varkappa$-oxide forms long, flat, extremely thin, black needles and looks dark grey when powdered. Its powder pattern, given in Table 1b has revealed an orthorhombic unit cell with the dimensions

$$a = 21.61_5 \text{ Å} \qquad b = 19.63_2 \text{ Å}, \qquad c = 3.951_5 \text{ Å}.$$

The reflection absences found in the single crystal photographs are in accordance with the space groups No. 32, *Pba*2 and No. 55, *Pbam*.

The density was measured to be 4.72, which corresponds to 34.0 $MoO_{2.78}$ units per cell and suggests the formula $Mo_{17}O_{47}$, with 2 formula units per cell.

The low electrical resistivity of this phase is noteworthy (see Table 2).

ϑ-Oxide. A second phase not previously reported has been observed in preparations heated for a relatively short time below 530°C. The composition of this phase, called ϑ-oxide, seems to be in the neighbourhood of $MoO_{2.80}$, but it has not been possible to obtain it in a very pure state. With prolonged heating, it slowly decomposes into $Mo_{17}O_{47}$ ($\varkappa$-oxide) and MoO_3. It seems, therefore, probable that the ϑ-oxide is not stable within the temperature region investigated, but is formed in a metastable state.

Its powder pattern is given in Table 1c. The unit cell is tetragonal with the dimensions

$$a = 45.99 \text{ Å}, \qquad c = 3.937 \text{ Å}.$$

The reflections *hkl* with h or k odd are absent for $l = 0$; they are revealed in the layer line $l = 1$ as very weak, diffuse spots growing stronger in the higher layer lines. This phenomenon evidently indicates the presence of a subcell of the dimensions

$$a' = \tfrac{1}{2}a = 23.00 \text{ Å}, \qquad c' = c = 3.937 \text{ Å}.$$

The most probable space-group of the large cell is No. 129, *P*4/*nmm*.

As it has not been possible to prepare the oxide in an amount sufficient for density determinations, no proposal of its formula can be given at present.

Orthorhombic Mo_4O_{11} (γ-oxide). The orthorhombic Mo_4O_{11} (γ-oxide) forms between 615° and 800°C approximately. As was mentioned above, it is often found also in samples heated above this upper limit and furthermore sometimes in preparations treated at about 500°C. In these cases equilibrium had, however, never been reached. It is transformed into the monoclinic form, η-oxide (see below), by heating for three weeks at 550° but remains unchanged after one week at 590°C.

The crystal structure has been determined by Magnéli [3] and the X-ray powder pattern is listed in Ref.[13]. The unit cell dimensions are *

$$a = 24.49 \text{ Å}, \qquad b = 5.457 \text{ Å}, \qquad c = 6.752 \text{ Å}, \qquad V = 902.3 \text{ Å}^3.$$

Monoclinic Mo_4O_{11} (η-oxide). Below about 615°C another phase of composition $MoO_{2.75}$ is formed. This phase, η-oxide, has previously been observed

* The present values are somewhat more exact than those previously given [13].

as a product of thermal decomposition of MoO_3 *in vacuo* at 549° and 608°C [7]. It is probably identical with the phase designated γ' by Glemser and Lutz which was rarely obtained at 600°C [5]. It remains unchanged after heating for two days at 634°, but is transformed into the orthorhombic, high-temperature form (γ-oxide) within two weeks at 655°C.

This phase forms wine-red, rather irregular crystals, which are similar to those of the orthorhombic form (γ-oxide). The powder pattern given in Table 1d has been evaluated with the aid of single crystal photographs, and the following unit cell has been derived

$a = 24.54$ Å, $b = 5.439$ Å, $c = 6.701$ Å, $\beta = 94.28°$ $V = 891.8$ Å^3.

The observed density is 4.17, which is in good agreement with the value 4.168 calculated for Mo_4O_{11} with 4 formula units in the unit cell. The space group in probably No. 14, $P2_1/a$.

The close similarity of the unit cell dimensions of the two Mo_4O_{11}-modifications is striking; the slight monoclinic deformation of the η-oxide is the main difference. In addition there are many common features in the intensity distribution of the diffraction pattern indicating that the structures of the two oxides are probably interrelated. In view of this the sluggishness of the transformation between the two forms is remarkable.

By means of differential thermal analysis no polymorphic transformation has been observed[14], which is not surprising in the light of the sluggishness of the transformation.

OXIDATION IN AIR OF MOLYBDENUM OXIDES

A few experiments have been carried out on the oxidation of molybdenum oxides in air at elevated temperatures. Finely ground specimens of the various oxides (except the ϑ-oxide) were heated in a muffle furnace at a few temperatures within the region 230°—350°C.

It was found that MoO_2 and triclinic Mo_9O_{26} (ζ-oxide) were the phases most resistant to oxidation (hardly affected by heating for two days at about 270°C), while orthorhombic Mo_4O_{11} (γ-oxide) was the most sensitive phase (completely transformed to MoO_3 within 18 h at about 300°C). The high-temperature forms of Mo_4O_{11} and Mo_9O_{26}, in a metastable state at the oxidation temperature, were much more rapidly oxidized than the low-temperature forms.

Indications from the powder photographs of intermediate stages in the course of oxidation were found only in the cases of monoclinic and orthorhombic Mo_4O_{11} heated at about 230° and 270°C, at which temperatures a quite new, somewhat diffuse pattern appeared in the photographs of partially oxidized products. In the samples treated at about 300° and 350°C, this intermediate stage, here designated λ-oxide, was not observed. When a mixture of λ-oxide and MoO_3 (the mixture obtained by oxidizing orthorhombic Mo_4O_{11} for 13 days at about 230°C) was heated *in vacuo* at 390° for 20 h, the lines of the λ-oxide disappeared: the sample consisted of MoO_3 and monoclinic Mo_4O_{11}. It is thus evident that the λ-oxide is unstable, at least at higher temperatures, and that it has a composition lying somewhere within the range

$MoO_{2.75} \leq MoO_x < MoO_3$, but is probably not very close to the latter limit. The main lines of its powder pattern are listed in Table 1e.

Acknowledgements. I wish to express my sincere gratitude to Professor G. Hägg and Dr. A. Magnéli for their encouraging interest in this investigation and for putting their early preparations as well as many facilities at my disposal. I am also indebted to Mr. A. Rönnquist for valuable assistance in part of the experimental work.

A scholarship from "Th. Nordströms testamentsfond" of the *Royal Swedish Academy of Sciences* is gratefully acknowledged.

The research reported in this article has been sponsored in part by the *Swedish Natural Science Research Council* and in part by the *Office, Chief of Research and Development, U.S. Department of Army*, through its *European Office*.

On the Reaction of *tert*-Butyl Chloride with Ethylene

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

The reaction between *tert*-butyl chloride and ethylene has been studied. The following four chlorides have been isolated.
1-chloro-3,3-dimethylbutane
1-chloro-3,3-dimethylpentane
1-chloro-3,3,4-trimethylpentane
1-chloro-3,3,6,6-tetramethylheptane
A mechanism which explains these products is given for the reaction.

The condensation of some saturated halides with ethylene has been studied by Schmerling [1]. With *tert*-butyl chloride the main reaction is

$$(CH_3)_3C{-}Cl + CH_2{=}CH_2 \xrightarrow{AlCl_3} (CH_3)_3C{-}CH_2{-}CH_2{-}Cl$$

This reaction has now been studied in greater detail. The byproducts obtained in the reaction have been examined and the structure has been proved for three of them.

The reaction was carried out by bubbling pure ethylene at —15° to —20° into pure *tert*-butyl chloride containing about 1.5 % by weight of $AlCl_3$ [2]. By careful fractionation of the crude chloride mixture obtained in the reaction, the following chlorides have been isolated from the reaction of 132 kg of *tert*-butyl chloride and 47.5 kg of ethylene:

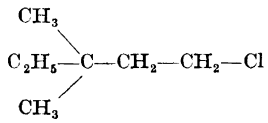
3.6 kg (2.7 %) of *tert*-butyl chloride
146.9 kg (85.4 %) of the main product $C_6H_{13}Cl$, b.p. 115—122°
1.35 kg (0.7 %) of a chloride $C_7H_{15}Cl$, b.p. 145—150°
12.00 kg (5.7 %) of a chloride $C_8H_{17}Cl$, b.p. 45—50°/8 mm Hg and
1.65 kg (1.2 %) of a chloride $C_{11}H_{23}Cl$, b.p. 82—84°/8 mm Hg

The yield of the chloride $C_{11}H_{23}Cl$ was calculated on the assumption that two moles of *tert*-butyl chloride is consumed to produce one mole of the chloride $C_{11}H_{23}Cl$.

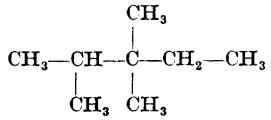
The chlorides mentioned above correspond to 95.7 % of the *tert*-butyl chloride. There were also obtained a residue boiling above 85°/8 mm weighing 5 kg and several small intermediate fractions having a total weight of 1.5 kg. Gas chromatographic analysis of these intermediate fractions showed that they

consisted of mixtures of the chlorides mentioned above together with a small quantity of a fraction boiling at 72—74°/8 mm Hg, probably a chloride $C_{10}H_{21}Cl$, which could not be obtained in a pure state. The weight of this chloride is about 0.1 % of the total weight of the chlorides.

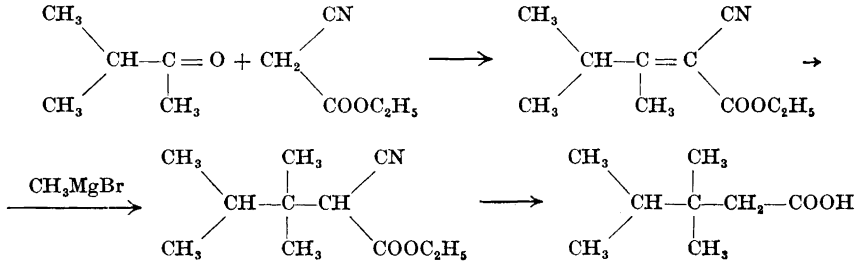
The main product $C_6H_{13}Cl$ has the formula $(CH_3)_3C—CH_2—CH_2—Cl$ [1] and the chloride $C_7H_{15}Cl$ is identical with the main product obtained from *tert*-amyl chloride and ethylene [1] and has the structure



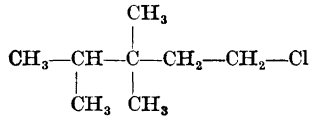
The chloride $C_8H_{17}Cl$ reacts with magnesium to form a Grignard reagent which on treatment with water gives the hydrocarbon



The chloride $C_8H_{17}Cl$ can further be converted to an alcohol $C_8H_{17}OH$ which can be oxidized to an acid $C_7H_{15}COOH$ [3]. This acid is identical with that obtained by the reactions



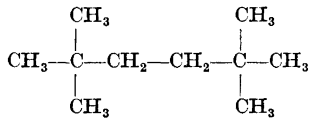
The chloride $C_8H_{17}Cl$ has thus the following structure



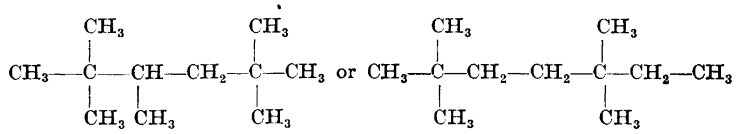
The chloride $C_{11}H_{23}Cl$ reacts with magnesium to form a Grignard reagent which on treatment with water gives a hydrocarbon $C_{11}H_{24}$ which seems not to have been described before. The chloride can be converted to a hydrocarbon $C_{10}H_{22}$ by the following reactions.

$$C_{11}H_{23}Cl \rightarrow C_{11}H_{23}OH \rightarrow C_{10}H_{21}COOH \rightarrow C_{10}H_{21}COOAg \rightarrow C_{10}H_{21}Br \rightarrow C_{10}H_{22}$$

This hydrocarbon has the same infrared absorption and boiling point as

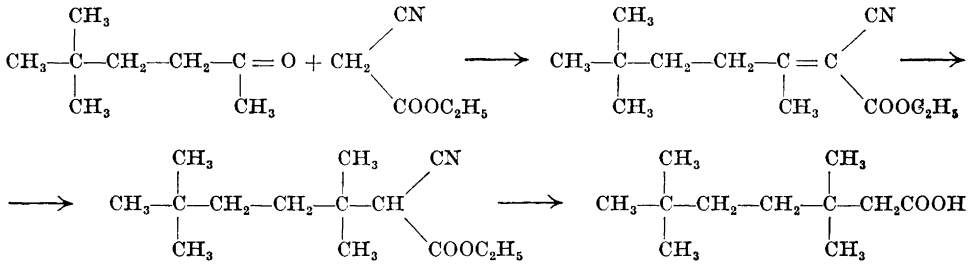


The hydrocarbon $C_{11}H_{24}$ must then be

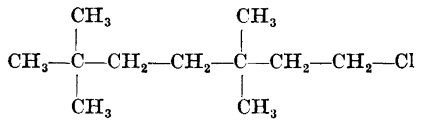


The left hand of these has been described by Moersch and Whitmore [3] and has a boiling point, a refractive index and a density which is different from that of the hydrocarbon $C_{11}H_{24}$ obtained from the chloride $C_{11}H_{23}Cl$. This hydrocarbon must therefore have the right hand of the two structures given.

The acid $C_{10}H_{21}COOH$ obtained from the chloride $C_{11}H_{23}Cl$ is identical with the acid obtained by the reactions:



The chloride $C_{11}H_{23}Cl$ has thus the following structure



The fact that the yield of the main product is high, together with the limited number of byproducts obtained in the reaction suggests that a very simple reaction mechanism is most probable. Such a mechanism which explains all the byproducts obtained can in fact be conceived. It is based on the following considerations:

The reaction conditions are such that a carbonium ion mechanism is probable. The reaction has further a definite period of initiation during which it is very slow, followed by a rapid increase in velocity so that the absorption of ethylene becomes as rapid as the rate of addition and the capacity of the cooling bath permits. This indicates that a chain reaction is operating. This chain is probably

$$(CH_3)_3C{-}Cl + AlCl_3 \xrightarrow{\text{slow}} (CH_3)_3\overset{+}{C} + (AlCl_4)^- \qquad \text{I}$$

$$(CH_3)_3\overset{+}{C} + CH_2 = CH_2 \xrightarrow{\text{rapid}} (CH_3)_3C{-}CH_2{-}\overset{+}{C}H_2 \qquad \text{II}$$

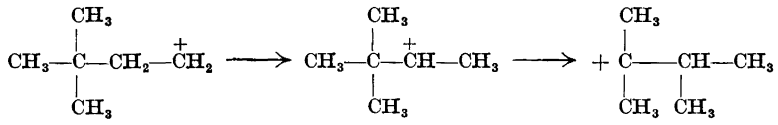
$$(CH_3)_3C{-}CH_2{-}\overset{+}{C}H_2 + Cl{-}C(CH_3)_3 \xrightarrow{\text{rapid}} (CH_3)_3C{-}CH_2{-}CH_2{-}Cl + \overset{+}{C}(CH_3)_3 \qquad \text{III}$$

In step I, which is a slow heterogeneous reaction, the reactive component, a carbonium ion, is formed. This is rapidly used up in step II, and regenerated in step III. The mechanism up to this point is just a slight modification of that generally accepted [4], which however, does not explain the period of initiation.

The very important point in the mechanism given above is the existence of the carbonium ion $(CH_3)_3C\text{-}CH_2\text{-}\overset{+}{C}H_2$. This is a primary carbonium ion which will undergo rearrangements or other reactions unless the step III is extremely rapid.

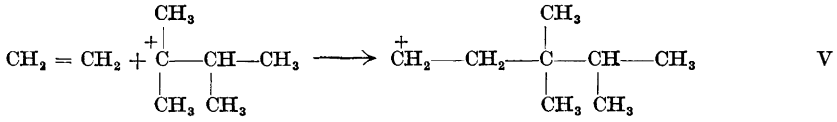
The fact that $(CH_3)_3C\text{-}CH_2\text{-}CH_2\text{-}Cl$ is obtained in a 85.4 % yield indicates that step III is in fact extremely rapid. All byproducts obtained can, however, be explained as results of subsequent reactions of the ion $(CH_3)_3C\text{-}CH_2\text{-}\overset{+}{C}H_2$.

The ion $(CH_3)_3C\text{-}CH_2\text{-}\overset{+}{C}H_2$ may undergo a succession of 1,2-shifts to give a more stable carbonium ion. The most likely succession is:

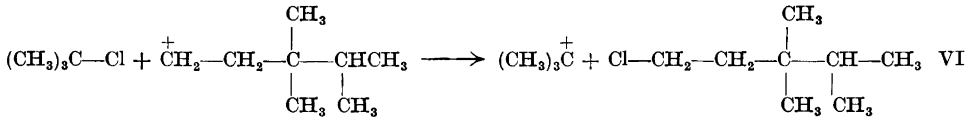


IV

The carbonium ion thus formed can then undergo reactions similar to steps II and III.



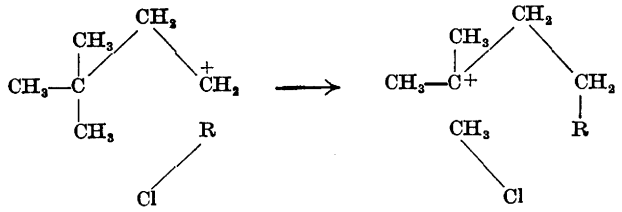
V



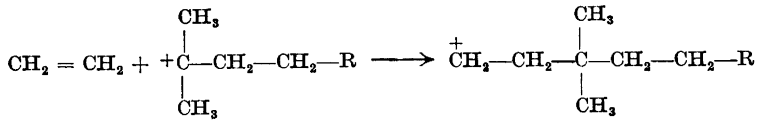
VI

By the reactions IV, V and VI the formation of the main byproduct, the chloride $C_8H_{17}Cl$ is explained.

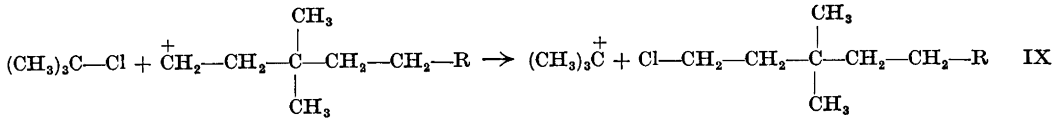
The formation of the chlorides $C_7H_{15}Cl$ and $C_{11}H_{23}Cl$ means that an uneven amount of carbon atoms are added or lost. Only two chlorides containing an uneven number of carbon atoms could be isolated from the reaction mixture. The reaction is further probably ionic and the chlorides $C_7H_{11}Cl$ and $C_{11}H_{23}Cl$ differ by 4 carbon atoms. All this suggests that a methyl group is lost in the $(CH_3)_3C\text{-}CH_2\text{-}CH_2$ ion and replaced by an hydrogen atom or a *tert*-butyl group. Such a mechanism may be



VII



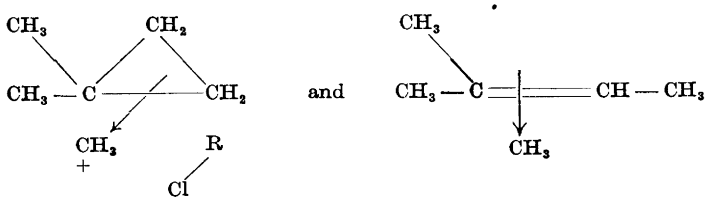
VIII



IX

When R represents H the chloride $C_7H_{15}Cl$ is formed and when it represents $(CH_3)_3C$- the chloride $C_{11}H_{23}Cl$ is formed.

The weakness in the scheme of step VII is that the wrong end of the R-Cl molecule appears to attack the positive charge of the carbonium ion. The point of attack is the significant difference between step III and step VII. The charge distribution in the carbonium ion $(CH_3)_3C\text{-}CH_2\text{-}\overset{+}{C}H_2$ is, however, not so absolutely certain as that given by the conventional formula. Dewar [5] has *e.g.*, explained the tendency of carbonium ion to rearrange itself by the formation of a π-complex between the migrating group and the rest of the molecule. Whether Dewar's explanation of the carbonium ion rearrangement is correct or not, it indicates the presence of a positive charge on the methyl group and some similarity between this type of reaction and reaction VII, which can be seen from the following formulas:



These represent the hypothetical structures in the steps VII and IV, respectively.

A still closer similarity exists between the mechanism given in step VII and the mechanism for a 1,3-rearrangement [6]. Step VII is in fact an exact intermolecular analogue to the intramolecular 1,3-shift, and can be expressed as a 1,3-substitution.

The halides R-Cl which can be expected to be reactive in step VII and which are present in the reaction mixture are HCl and $(CH_3)_3C$-Cl, which exactly correspond to the two halides $C_7H_{15}Cl$ and $C_{11}H_{23}Cl$ which have been found. Whether the chloride $C_6H_{13}Cl$ which is obtained as the main product in the reaction is capable of functioning as R-Cl in step VII is impossible to say. If it can, a chloride $C_{13}H_{27}Cl$ should be present in the high boiling residue. The residue was, however, not examined for this product.

From the formulations given for step VII it follows that CH_3Cl can be expected as a byproduct. No attempts have been made to isolate it from the reaction mixture due to experimental difficulties and the fact that the presence of CH_3Cl can have many explanations and its absence can be explained by subsequent reactions.

EXPERIMENTAL

The reaction between *tert*-butyl chloride and ethylene was performed as described by Brändström [7] but on a larger scale using 12 kg of *tert*-butyl chloride in each run. 11 such runs were collected and distilled through a 2 m packed column.

The conversion of the chloride obtained into the acid with the same number of carbon atoms has been described by Brändström [2].

Preparation of 3,3,4-trimethylpentanoic acid. 115 g of ethyl cyanoacetate, 96.5 g of 3-methylbutanon-2, 15.6 g of ammonium acetate, 50 g of glacial acetic acid, and 170 ml of benzene are mixed and refluxed in a 1-litre flask fitted with a water separator. When no more water is obtained, the mixture is cooled and treated in the usual way [8]. The yield is 134 g or ethyl 2-cyano-3,4-dimethylpent-2-enoate, b. p. 115–120°/8 mm Hg.

A Grignard reagent is prepared from 0.3 moles of magnesium, 0.3 moles of methyl iodide and 120 ml of ether. This reagent is added to a mixture of 50 ml of ether, 0.25 moles of ethyl 2-cyano-3,4-dimethylpent-2-enoate, and 0.5 g of Cu_2Cl_2 during 30 min. The temperature is kept below +5° during this operation by cooling. The reaction mixture is then treated in the usual way [9]. The yield is 84 % of ethyl 2-cyano-3,3,4-trimethylpentanoate, b. p. 118–122°/8 mm.

This ester is saponified by refluxing for 1 h with a solution of 21 g of potassium hydroxide in 60 ml of water. The resulting solution is acidified and extracted with benzene. The benzene extract is distilled at ordinary pressure during which operation decarboxylation occurs. The resulting distillate is fractionated under reduced pressure giving a 67 % yield of 1-cyano-2,2,3-trimethylbutane, b. p. 64–65°/10 mm Hg.

A portion of this cyanide is saponified [9] by refluxing with a solution of potassium hydroxide in ethylene glycol. When the resulting solution is worked up in the usual way, 3,3,4-trimethyl-pentanoic acid, b. p. 112–113°/8 mm Hg is obtained. This acid is in all respects identical with the acid obtained from the chloride $C_8H_{17}Cl$.

Preparation of 3,3,6,6-tetramethylheptanoic acid. 5,5-Dimethylhexanone-2 is prepared from 4,4-dimethylpentanoyl chloride by acylating diethyl malonate and hydrolysing the resulting diethyl acylmalonate [10].

The diethyl 4,4-dimethylpentanoylmalonate, b. p. 145–155°/10 mm Hg, is obtained in a yield of 89 % and the treatment of this ester with propionic acid and sulphuric acid gives 5,5-dimethylhexanone-2, b. p. 145–157°, in a yield of 76 %.

5,5-Dimethylhexanone-2 is condensed with ethyl cyanoacetate by the method given above [8], giving the ethyl 2-cyano-3,6,6-trimethylhept-2-enoate, b. p. 145–160°/10 mm Hg, in a yield of 68 %.

This ester is treated with an ether solution of methylmagnesium bromide by the method given above [9] giving ethyl 2-cyano-3,3,6,6-tetramethylheptanoate, b. p. 145–155°/10 mm Hg, in a yield of 70 %.

This ester is hydrolysed and decarboxylated by the method given above [9], giving 1-cyano-2,2,5,5-tetramethyl hexane, b. p. 205–215°, in a yield of 64 %.

A portion of this cyanide is hydrolysed by the method given above [9], giving 3,3,6,6-tetramethylheptanoic acid. This acid is in all respects identical with the acid obtained from the chloride $C_{11}H_{23}Cl$.

Preparation of 2,3,3-trimethylpentane from the chloride $C_8H_{17}Cl$. A Grignard reagent is prepared from 1 mole of the chloride $C_8H_{17}Cl$, 1 mole of magnesium and 200 ml of ether. This reagent is decomposed by cautious addition of water and hydrochloric acid. The layers are separated and distilled giving a 80 % yield of 2,3,3-trimethylpentane, b. p. 112–115°. The structure was established by a comparison of the infrared spectra of the product with that given for 2,3,3-trimethylpentane.

Preparation of 2,2,5,5-tetramethyl hexane. 50.2 g of the dry powdered silver salt of 3,3,6,6-tetramethylheptanoic acid are placed in a dry 250 ml three-necked flask fitted with a stirrer, a reflux condenser and a dropping funnel. The flask is cooled in ice-water and a solution of 9.0 ml of bromine in 40 ml of dry carbon tetrachloride is added during 20 min. The flask is then heated on a water-bath for 3 h.

The reaction mixture is cooled and filtered. The solid is washed with some ether. The combined filtrates are washed with a sodium bisulphite solution and then with a sodium carbonate solution. The ether and carbon tetrachloride are distilled off and the residue fractionated under reduced pressure.

The yield of 1-bromo-2,2,5,5-tetramethylhexane, b. p. 76–78/10 mm Hg, is 60 %.

A Grignard reagent is prepared from 10 g of the bromide above and magnesium which is then treated with hydrochloric acid giving 2,2,5,5-tetramethylhexane, b. p. 134–138°. The structure of this hydrocarbon was established by comparing the infrared spectra with that given for 2,2,5,5-tetramethylhexane.

Preparation of 2,2,5,5-tetramethylheptane from the chloride $C_{11}H_{23}Cl$. A Grignard reagent, prepared from the chloride $C_{11}H_{23}Cl$ and magnesium, is treated with hydrochloric acid giving a 50 % yield of 2,2,5,5-tetramethylheptane, b. p. 161.5–162.5°, $d_4^{20} = 0.7452$, $n_D^{20} = 1.4186$.

The author is indebted to Lennart Storgärds and Ingvar Eriksson for the large scale preparation of the chlorides, to Wolfgang Kirsten and Mats Carlsson for the gas chromatographic analyses, to Bengt Nygård for the infrared analyses and to Ragnar Lindblom for good help with the manual work.

On the Metabolism of Ursodeoxycholic Acid in the Rat

Bile Acids and Steroids 84

BENGT SAMUELSSON

Department of Physiological Chemistry, University of Lund, Lund and the Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

The metabolism of intraperitoneally administered tritium labelled ursodeoxycholic acid has been studied in bile fistula rats. This acid is partly converted into 3α,6β,7β-trihydroxycholanic acid (Acid I), chenodeoxycholic acid and one unidentified metabolite.

Ursodeoxycholic acid (3α,7β-dihydroxycholanic acid) has been isolated from certain bear species, the coypu [1] and recently also from the rat [2] and man [3]. In the two last-mentioned species it occurs in very small amounts. Studies of the metabolism of chenodeoxycholic acid in the rat have shown that together with the two principal metabolites [4,5], 3α,6β,7β-(Acid I) and 3α,6β,7α- (Acid II) trihydroxycholanic acid, small amounts of 7-ketolithocholic acid [6] and ursodeoxycholic acid [2,6] are formed. Furthermore it has been shown that 7-ketolithocholic acid is mainly transformed into ursodeoxycholic acid and Acid I in the rat liver [2,7]. In order to get more information about the course of the metabolism of chenodeoxycholic acid, tritium labelled ursodeoxycholic acid has been injected intraperitoneally into bile fistula rats, and the labelled products excreted in the bile have been separated by chromatography.

EXPERIMENTAL

Tritium labelled ursodeoxycholic acid. Ursodeoxycholic acid was prepared by the procedure of Samuelsson [6], (M. p. 201–202°). 10 mg of this acid was exposed to tritium gas (2C, 200 mm Hg, 95.5 % pure) for 6 days at room temperature according to the method of Wilzbach [8]. The tritium labelled product was diluted with 25 mg of inactive ursodeoxycholic acid and chromatographed with phase system F[9]. The titration and activity peaks coincided.

Crystallization from ethylacetate/light petroleum yielded 24 mg of ursodeoxycholic acid (M. p. 201–202°), specific activity; 40 × 10^6 c.p.m/mg when counted in a Tracerlab flow counter or approximately 70 μC/mg. A sample of this acid was diluted with inactive ursodeoxycholic acid and recrystallized from aqueous acetic acid, ethylacetate/light petroleum and aqueous methanol. The specific activity remained constant.

3α,6β,7β-Trihydroxycholanic acid (Acid I) was prepared according to the method of Doisy *et al.*[5] (M. p. 226–227°).

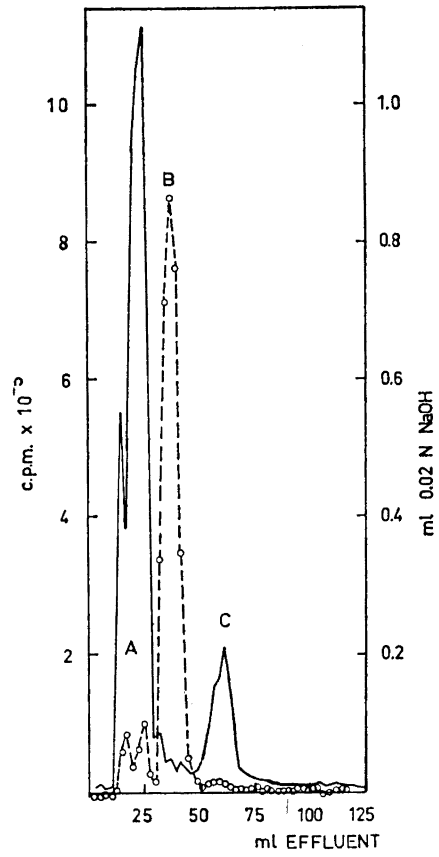

Fig. 1. Chromatographic separation of acids from hydrolyzed bile, excreted during 24 h following intraperitoneal administration of 0.3 mg of tritium labelled ursodeoxycholic acid. Column: 4.5 g hydrophobic Supercel. Phase system: Type F, see page 971. Solid line: Titration values. Broken line: Radioactivity.

Animal experiments. Bile fistulas were made on white male rats of the institute stock weighing about 200 g. The rats had free access to white bread and oats and 0.9 % sodium chloride solution. The bile was collected in ethanol. 0.3 mg of the tritium labelled ursodeoxycholic acid was neutralized with sodium hydroxide and injected intraperitoneally in 0.9 % sodium chloride solution into each of three rats 12 h after the bile fistula had been made. The bile was collected for 24 h. The conjugated bile acids were hydrolyzed in 1.5 N NaOH for 6 h at 120° in a sealed tube. The free bile acids were extracted with ether after acidification with hydrochloric acid.

Chromatographic separations. The free bile acids were chromatographed on hydrophobic Supercel as described by Bergström, Sjövall and Norman [9,10]. The following solvent systems were used.

System	Moving phase	ml	Stationary phase	ml
F[9]	Methanol-water	165:35	Chloroform-heptane	45:5
C[10]	Methanol-water	150:150	Chloroform-*iso*octanol	15:15

4 ml of the stationary phase was supported on 4.5 g of hydrophobic Supercel. Each fraction from the chromatography was titrated with 0.02 N NaOH and an aliquot plated in an "infinitely thin" layer on an aluminium planchet which was counted in a Tracerlab flow counter.

Table 1. Recrystallizations of radioactive bands isolated by chromatography from the bile after administration of tritium labelled ursodeoxycholic acid to bile fistula rats.

RESULTS

Tritium labelled ursodeoxycholic acid was administered intraperitoneally into three bile fistula rats. 70—82 % of the administered ^3H was recovered in the bile collected during 24 h following the injection. The saponified bile from each animal was chromatographed with phase system F. With this system ursodeoxycholic acid (peak at 40 ml effluent) chenodeoxycholic acid (60 ml) and more hydrophobic bile acids separate from cholic acid and other more polar bile acids which appear with the front. In Fig. 1 is shown a chromatogram of the hydrolyzed bile from one rat (R I). Most of the activity is eluted at the place of ursodeoxycholic acid (B), but about 10 % of the activity appears almost with the front as an incompletely separated double peak (A). A small but significant amount of the activity was found to coincide with the titration peak, caused by chenodeoxycholic acid present in the bile (C). Less than one per cent of the activity remained in the stationary phase. The material in the first band (A) was rechromatographed with phase system C, suitable for the separation of trihydroxycholanic acids (Fig. 2). The activity then appears as two separate peaks, one at 40—50 ml and one at the place of Acid I (120—160 ml), immediately after the titration peak of inactive cholic acid.

Identification of the labelled products separated by chromatography. Unchanged ursodeoxycholic acid (Fig. 1, peak B) was identified by recrystallizations from four different solvent systems after rechromatography with unlabelled ursodeoxycholic acid with phase system F. The labelled material eluted at the place of chenodeoxycholic acid was rechromatographed with phase system F and identified by isotope dilution (Table 1). The radioactive material eluted immediately after cholic acid (Fig. 2) was diluted with inactive Acid I and identified by isotope dilution after chromatography with phase system C.

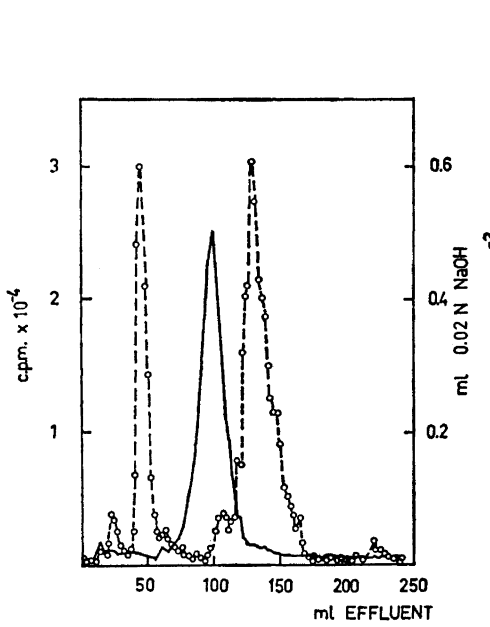

Fig. 2. Chromatographic separation of peak A in the chromatogram shown in Fig. 1. Column: 4.5 g hydrophobic Supercel. Phase system: Type C, see page 971. Solid line: Titration values. Broken line: Radioactivity.

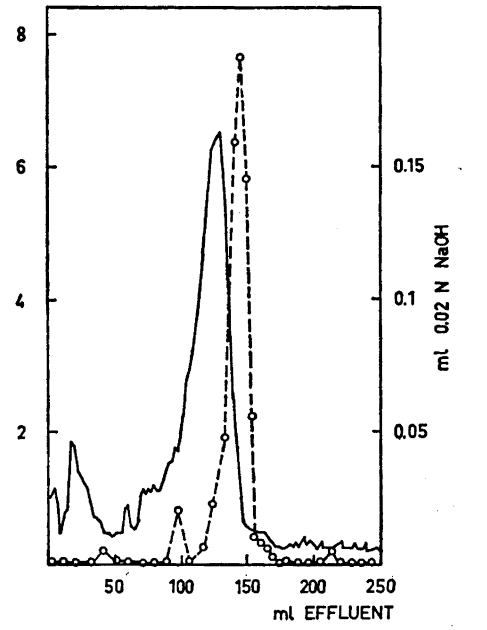

Fig. 3. Chromatographic separation of the reaction product after chromic acid oxidation of Metabolite III and 25 mg of inactive cholic acid. Column: 4.5 g hydrophobic Supercel. Phase system: Type C, see page 971. Solid line: Titration values. Broken line: Radioactivity.

The appearence of the radioactive band at about 50 ml (metabolite III) with phase system C (Fig. 2) is characteristic of a trihydroxycholanic acid or a dihydroxymonoketocholanic acid. As it was chromatographically identical with another 7β-hydroxylated bile acid (3α,7β,12α-trihydroxycholanic acid) with this phase system [6], it was, together with inactive cholic acid, oxidized with chromic acid under conditions [11] known to give dehydrocholic acid from 3,7,12-trihydroxycholanic acids. The chromatography of the reaction product with phase system C is shown in Fig. 3. The radioactivity is eluted immediately after the titration peak of inactive dehydrocholic acid. This result also excludes that metabolite III is a 3,6,7-trihydroxycholanic acid as chromic acid oxidation of these acids under the conditions used results in the formation of the more hydrophilic 3-keto-6,7-secocholanic acid-6,7-dioic acid [12,13], which appears with the front with phase system C. No further attempts were made to identify metabolite III. The percentage composition of the labelled products excreted in the bile is given in Table 2.

Table 2. Percentage composition of the labelled products excreted in the bile during 24 h following intraperitoneal injection of tritium labelled ursodeoxycholic acid into three rats with bile fistulas.

Compound	Per cent		
	R I	R II	R III
3*α*, 6*β*, 7*β*-Trihydroxycholanic acid	7.4	3.9	6.1
Chenodeoxycholic acid	1.5	0.6	1.4
Metabolite III	2.7	1.9	3.1
Ursodeoxycholic acid	79.7	91.5	85.3
Total	91.3	97.9	95.9

DISCUSSION

The results show that ursodeoxycholic acid is only slightly transformed in the rat liver. Its principal metabolite consists of 3*α*,6*β*,7*β*-trihydroxycholanic acid (Acid I), *i.e.* a 6*β*-hydroxyl group is introduced.

However, ursodeoxycholic acid seems only to be a minor intermediate in the formation of Acid I from chenodeoxycholic acid, as it is formed in very small amounts from chenodeoxycholic acid [2,6]. The demonstration of the direct transformation of Acid II into Acid I also points in this direction [6]. Another more polar bile acid was also isolated, but the structure of this metabolite has not been determined. A metabolite with the same elution rate as this acid was also found [7] in the bile after intraperitoneal administration of 7-ketolithocholic acid-24-^{14}C[7].

A small amount (0.6—1.5 %) of the recovered avtivity was identified as chenodeoxycholic acid. This acid is probably formed by dehydrogenation of ursodeoxycholic acid to 7-ketolithocholic acid which is then reduced to chenodeoxycholic acid.

Ursodeoxycholic acid present in normal rat bile may probably be formed by two routes. The direct formation of ursodeoxycholic acid from chenodeoxycholic acid in the liver has been demonstrated [2,6], and furthermore *in vitro* experiments have shown that chenodeoxycholic acid is dehydrogenated by different strains of *E. coli* to 7-ketolithocholic acid [14], which is readily reduced in the liver to ursodeoxycholic acid.

The technical assistence of Miss H. Rytz is gratefully acknowledged. This work is part of an investigation supported by the *Medical Faculty of the University of Lund* and by a research grant (H 2842) to Prof. S. Bergström from the *National Institutes of Health, United States Public Health Service*, Bethesda, Maryland.

On the Metabolism of Chenodeoxycholic Acid in the Rat

Bile Acids and Steroids 85

BENGT SAMUELSSON

Department of Physiological Chemistry, University of Lund, Lund and the Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

Chenodeoxycholic acid-7β-^{3}H and randomly tritium labelled 3α, 6β, 7α-(Acid II) and 3α, 6β, 7β- (Acid I) trihydroxycholanic acids have been prepared. Acid II is converted into Acid I when injected into a bile fistula rat, whereas the reverse reaction does not occur. The inversion of the 7α-hydroxyl group has been studied with 7β-tritio, 24-^{14}C labelled chenodeoxycholic acid. The tritium label is completely lost in this reaction. The mechanism for the inversion and the course of the metabolism of chenodeoxycholic acid are discussed.

Chenodeoxycholic acid constitutes a minor component of the bile acids normally present in rat bile[1,2]. In 1954 Bergström and Sjövall showed that chenodeoxycholic acid is transformed in the rat liver into two more polar acids which are not identical with cholic acid [2]. The same metabolites had been observed earlier by Bergström and Norman after administration of cholesterol-4-^{14}C to bile fistula rats [3]. These metabolites have recently been identified by Doisy *et al.* as 3α,6β-7β- (Acid I) and 3α,6β,7α-trihydroxycholanic acid (Acid II) [4,5].

The aim of the present investigation was to study the mechanism of the conversion of chenodeoxycholic acid into Acid I and II with chenodeoxycholic acid 7β-^{3}H, 24-^{14}C and randomly tritium labelled Acid I and Acid II.

EXPERIMENTAL

Syntheses

Chenodeoxycholic acid-7-^{3}H. 60 mg of 7-ketolithocholic acid (M. p. 200–202°) prepared through oxidation of methyl 3α-cathyloxy-7α-hydroxycholanate with sodium dichromate,[6] were dissolved in 10 ml of "diglyme" (Diethyleneglycoldimethylether, Fluka A. G., Buchs/S.G., Switzerland, refluxed over calciumhydride and distilled from lithium-aluminium hydride) and 40 mg of sodium borohydride were added. The latter compound had been labelled through exposure to an athmosphere of tritiumgas [7] (2C, 95 % pure, 200 mm Hg) for ten days at room temperature. After 12 h at room temperature the reaction mixture was diluted with water, acidified with 2 N hydrochloric acid and extrac-

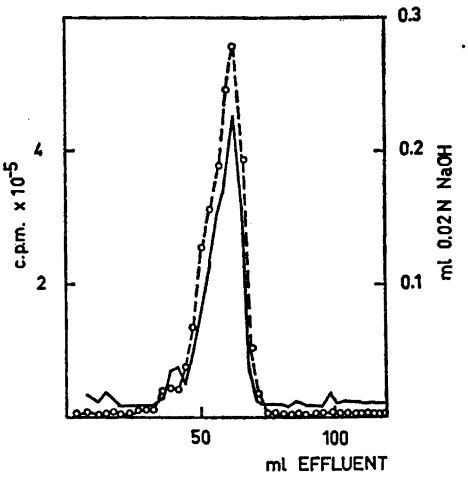

Fig. 1. Chromatographic separation of the reaction product after NaB^3H_4 reduction of 7-ketolithocholic acid. Column: 4.5 mg hydrophobic Supercel. Phase system: Type F. Solid lines: Titration values. Broken line: Radioactivity.

ted with ether. After evaporation *in vacuo* the residue was chromatographed with phase system F[10]. The single peak (Fig. 1) appeared at the place of chenodeoxycholic acid, which with this system separates clearly from the 7β-isomer, ursodeoxycholic acid. The radioactive material was crystallized from ethylacetate/light petroleum yielding 47 mg of chenodeoxycholic acid-7β-^{3}H, m. p. 141—143°. Mixed melting point with authentic chenodeoxycholic acid showed no depression. Specific activity: ~0.5 μC/mg (1 μC ^{3}H is equivalent to approximately 6×10^5 c.p.m. when counted in an infinetely thin layer in a Tracerlab gas flow counter). Dilution of a sample of this acid with inactive chenodeoxycholic acid and extensive recrystallizations gave no depression of the specific activity. 25 mg of this diluted acid was oxidized with chromic acid in aqueous acetic acid to 3,7-diketocholanic acid (m. p. 152—154°). The diketoacid contained 2.5 % of the amount of tritium label present in the acid before the oxidation.

A stock solution of chenodeoxycholic acid-7β-^{3}H, 24-^{14}C was made by dissolving 10 mg of chenodeoxycholic acid-7β-^{3}H (0.5 μC/mg) and 0.25 mg of chenodeoxycholic acid-24-^{14}C (10 μC/mg) in 10 ml of acetone.

Acid I and Acid II were prepared by the methods of Doisy *et al.*[4,5] They were labelled with tritium by exposing 5 mg of the acid to tritium gas (2 C, 200 mm Hg, 95 % pure) for 6 days at room temperature [7]. The tritium labelled products were diluted with 20 mg of the corresponding inactive acid and chromatographed with phase system C[3]. Acid I was crystallized from ethylacetate yielding 17 mg, m. p. 226—227°. Specific activity ~50 μC/mg.

Acid II was crystallized from acetone/light petroleum. Yield 13 mg, m. p. 201—202°. Specific activity: ~35 μC/mg.

Ursodeoxycholic acid was prepared according to Samuelsson [8]. M. p. 201—202°.

Chenodeoxycholic acid-24-^{14}C was prepared according to the method of Bergström *et al.*[9] Specific activity: 10 μC/mg.

Animal experiments

The labelled bile acids were injected intraperitoneally as the sodium salt in 0.9 % sodium chloride solution into 200—250 g white male rats of the institute stock. The bile duct was cannulated 12 h before the administration. The rats had free access to white bread and oats and 0.9 % sodium chloride during the experimental period. The bile was collected daily in ethanol and hydrolyzed with 1.5 N NaOH in a sealed tube for 6 h at 120°. The free acids were extracted from the acidified solution with ether.

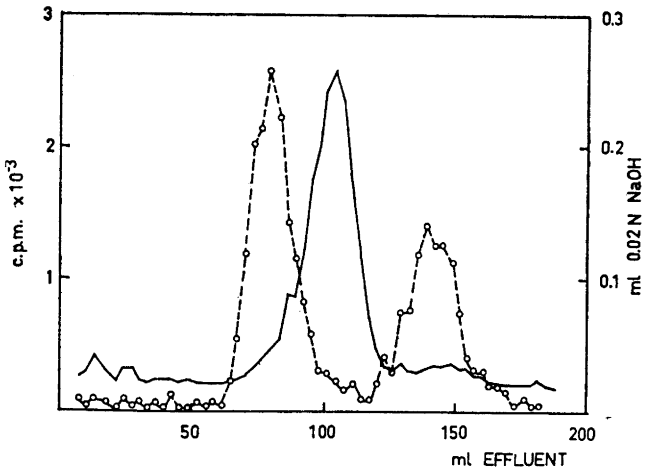

Fig. 2. Chromatographic separation of acids from hydrolyzed bile, excreted during 24 hours following intraperitoneal administration of 2 mg of chenodeoxycholic acid-7β-^{3}H, 24-^{14}C. Column: 4.5 g hydrophobic Supercel. Phase system: Type C. Solid line: Titration. Broken line: Radioactivity.

Chromatographic separations

The free acids were chromatographed on hydrophobic Supercel as described by Bergström, Norman and Sjövall[3,10]. The following solvent systems were used.

System	Moving phase	ml	Stationary phase	ml
F[10]	Methanol: water	165:135	Chloroform: heptane	45:5
C[3]	Methanol: water	150:150	Chloroform: isooctanol	15:15

4 ml of the stationary phase were used per 4.5 g of hydrophobic Supercel. All the chromatograms were run at a constant temperature of +23°.

Isotope determinations

Suitable aliquots of the titrated fractions of the chromatographies were plated on aluminium planchets and counted in a Tracerlab gas flow counter, when tritium labelled compounds were chromatographed.

The radioactivity of the products obtained after injection of chenodeoxycholic acid-7β-^{3}H,24-^{14}C was determined in a Tracerlab end window counter, in which only the ^{14}C activity is recorded. In this way it was possible to get a quantitative picture in spite of the fact that some of the metabolites had lost their tritium label. The ^{3}H and ^{14}C activity in the administered and isolated acids were determined by gas phase counting after combustion to $^{14}CO_2$ and ^3H_2O and conversion of the latter to tritio butane by the methods of Glascock [11].

RESULTS

Metabolism of chenodeoxycholic acid-7β-^{3}H, 24-^{14}C. 2 mg of chenodeoxycholic acid-7β-^{3}H, 24-^{14}C was injected into each of two bile fistula rats. The bile excreted during the first 24 h following the injection was hydrolyzed

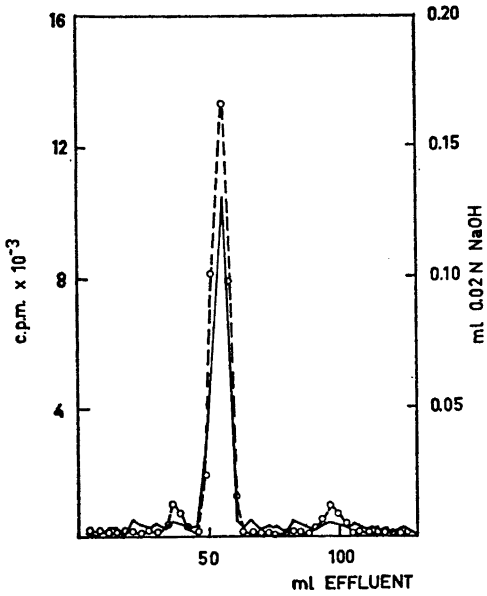

Fig. 3. Chromatographic separation of acids remaining in the stationary phase of the chromatogram shown in Figure 2. Column: 4.5 g hydrophobic Supercel. Phase system Type F. Solid line: Titration values. Broken line: Radioactivity.

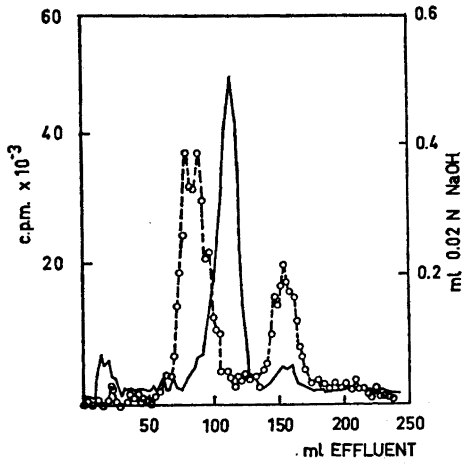

Fig. 4. Chromatographic separation of acids from hydrolyzed bile, excreted during 24 hours following intraperitoneal administration of 0.2 mg of Acid II. Column: 4.5 g hydrophobic Supercel. Phase system: Type C. Solid line: Titration values. Broken line: Radioactivity.

and chromatographed with phase system C (Fig. 2). The material remaining in the stationary phase was separated by chromatography with phase system F. The chromatogram is shown in Fig. 3.

As found earlier [2] the two main metabolites are eluted with phase system C (Fig. 2). One of them (Acid II) appears before the inactive cholic acid (100 ml) and the other (Acid I) after this acid. Acid I and II were diluted, with the corresponding inactive acid to suitable specific activity for the $^{3}H/^{14}C$ determinations and crystallized from ethylacetate and acetone/light petroleum respectively.

In the chromatogram shown in Fig. 3, most of the activity is eluted at the place of chenodeoxycholic acid, but two small radioactive bands also occur, one before (ursodeoxycholic acid) and one after (7-ketolithocholic acid) chenodeoxycholic acid. The radioactive material in these two peaks were rechromatographed with the corresponding inactive acid and were finally identified by isotope dilution.

The percentage composition of the recovered ^{14}C is shown in Table 1. The ^{3}H and ^{14}C content was determined in the administered doubly labelled chenodeoxycholic acid and in the isolated metabolites (Table 2).

Table 1. Percentage composition of the ^{14}C recovered in the bile during 24 h following intraperitoneal injection of chenodeoxycholic acid-7β-^{3}H, 24-^{14}C.

Compound	Per cent	
	Rat I	Rat II
Chenodeoxycholic acid	48.3	53.1
7-Ketolithocholic acid	5.3	4.9
Ursodeoxycholic acid	4.0	3.7
Acid II (3α, 6β, 7α)	17.3	15.5
Acid I (3α, 6β, 7β)	24.0	21.0
Total	98.9	98.2

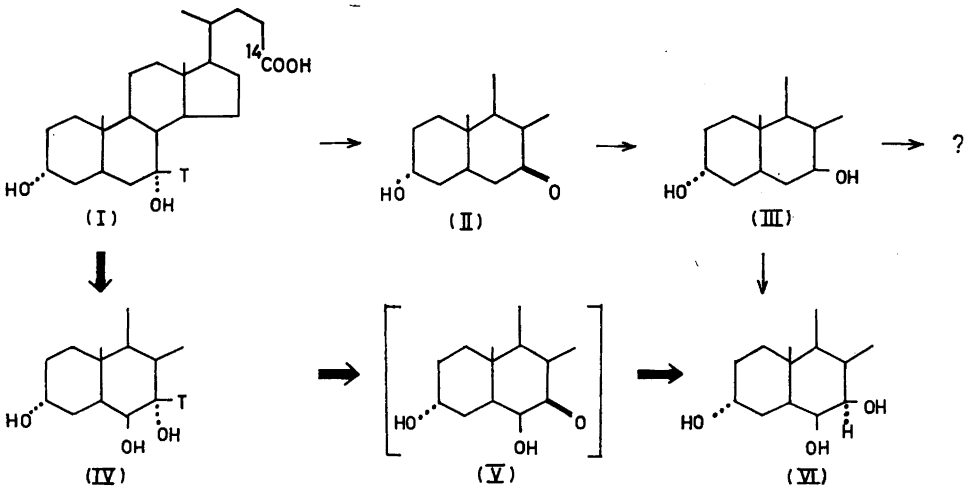
7-Ketolithocholic acid, ursodeoxycholic acid and Acid I only contained traces of ^{3}H whereas this isotope was retained in Acid II.

Metabolism of ^{3}H-labelled Acid II. 0.2 mg of randomly tritium labelled Acid II was injected intraperitoneally into a bile fistula rat and the bile excreted during 24 h following the injection was chromatographed with phase system C after hydrolysis. (Fig. 4). About 35 % of the chromatographed activity was eluted as Acid I, which was identified by isotope dilution.

Metabolism of ^{3}H labelled Acid I. Chromatography of the hydrolyzed bile excreted during 24 h following administration of 0.2 mg of tritium labelled Acid I to a bile fistula rat showed only unchanged Acid I.

Table 2.

Compound	^{3}H c.p.m./mg	^{14}C c.p.m./mg	$^{3}H/^{14}C$	Per cent ^{3}H retained
Administered chenodeoxycholic acid-7β-^{3}H, 24-^{14}C	253	356	0.71	
7-Ketolithocholic acid Rat I and II	3	319	0.01	1
Ursodeoxycholic acid Rat I and II	8	382	0.02	3
Acid II (3α, 6β, 7α)				
Rat I	154	237	0.65	92
Rat II	202	298	0.68	96
Acid I (3α, 6β, 7β)				
Rat I	3	244	0.01	2
Rat II	4	242	0.02	2
Acid I (after administration of acid II-7β-^{3}H, 24-^{14}C)	5	209	0.02	3



Metabolism of biosynthetically formed doubly labelled Acid II. Acid II, which had been isolated from the bile after administration of chenodeoxycholic acid-7β-^{3}H, 24-^{14}C was injected into a bile fistula rat and the excreted bile separated with phase system C after hydrolysis. About 8 % of the injected Acid II had been transformed into Acid I. Determination of ^{3}H and ^{14}C in Acid I showed that the tritium label is completely lost during this transformation (Table 2).

DISCUSSION

Based on results obtained in this and previous investigations [2,4,5,12] the course of the metabolism of chenodeoxycholic acid in the rat liver may be formulated as in scheme 1. The main pathway leads from chenodeoxycholic acid to Acid I (VI) *via* Acid II (IV). Acid II is formed from chenodeoxycholic acid in good yield through direct 6β-hydroxylation, and as was shown with tritium labelled Acid II this acid is readily transformed into Acid I when a tracerdose is injected. The proportion between Acid II and Acid I after injection of chenodeoxycholic acid is about 1:0.7 and after injection of Acid II 1:0.6.

The experiments with 7β-tritiochenodeoxycholic acid showed that Acid I is formed with loss of the tritium label and it was further established with biosynthetic 7β-tritio Acid II, that the tritium loss occurs in the reaction Acid II $\rightarrow$ Acid I, *i.e.* the inversion of the hydroxyl at C7 from α to β position.

Concerning the mechanism of the inversion it is most likely that the 7α-ol is dehydrogenated to a ketone, which is reduced stereospecifically to the equatorial 7β-ol in Acid I. The steroid alcohol dehydrogenases show a very high degree of stereospecificity for the substrate [13], and there are presumably two separate enzymes which carry out the inversion. The following equilibrium might then be obtained:

$$7\alpha\text{-ol} \rightleftharpoons \text{7-ketone} \rightleftharpoons 7\beta\text{-ol}$$

The presence of both 7α- and 7β-hydroxydehydrogenases active in the bile acid series has been demonstrated in the rat liver through metabolic studies of 7-ketohydroxycholanic acids. As mentioned above 7-ketolithocholic acid is formed in small amounts from chenodeoxycholic acid and the former acid is mainly reduced to ursodeoxycholic acid in the liver [12,14]. About equal parts of cholic acid (7α-ol) and 3α,7β,12α-trihydroxycholanic acid are obtained when 7-ketodeoxycholic acid is administered [15]. A mechanism consisting of the formation of a double bond through dehydration of the 7α-ol and a rehydration to the opposite steric position can be excluded by the isotope experiments. The above-mentioned oxidation-reduction reactions which were suggested for the inversion are usually linked to DPN or TPN[13]. The requirement of DPN for the lactate racemase described by Kaufman *et al.*[16] has recently also been found for the β-hydroxybuturyl CoA racemase by Wakil[17]. The latter author also shows that the racemization is effected by two different dehydrogenases (D(—) and L(+) β-hydroxy buturyl-CoA-dehydrogenase) with acetoacetyl CoA as an intermediate. A problem similar to the transformation of Acid II into Acid I is the epimerization of the hydroxyl at C4 in the conversion of uridinediphosphogalactose to uridinediphosphoglucose. The mechanism of this reaction has been studied extensively with ^3H_2O and $H_2{}^{18}O$ in the medium and also with tritium labelled DPN or DPNH [18]. Of the originally proposed mechanisms essentially only one involving a dehydrogenation remains. This reaction, however, is considered to be carried out by one enzyme bearing two specific groups, the epimerization consisting of a shift of a hemiacetal between the 4-carbonyl group and these groups under the influence of a certain catalyst [18].

A minor pathway (I→II→III→VI) for the metabolism of chenodeoxycholic acid consists of the formation of 7-ketolithocholic acid, reduction of the 7-carbonyl group to ursodeoxycholic acid and a 6β-hydroxylation of this acid to Acid I.[19] Another metabolite of ursodeoxycholic acid was also isolated but the structure of this acid has not been determined.[19] It is probable that a direct 6β-hydroxylation of 7-ketolithocholic acid also can take place, as the proportion between ursodeoxycholic acid, Acid I and the unidentified metabolite after administration of essentially the same amount of a tracerdose of 7-ketolithocholic acid and ursodeoxycholic acid, respectively, are 1:0.75:0.05 and 1:0.07:0.03 [12].

The technical assistence of Miss I. Lindell, Miss H. Rytz and Mr. S. Jönsson is gratefully acknowledged. This work is part of an investigation supported by *Karolinska Institutets Reservationsanslag* and by a research grant (H 2842) to Prof. S. Bergström from the *National Institutes of Health, United States Public Health Service*, Bethesda, Maryland.

ACTA CHEMICA SCANDINAVICA 13 (1959) 984–988

The Thermal Expansion of the Crystalline B- and C-Forms of Stearic Acid

GUNNAR DEGERMAN and ERIK von SYDOW

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The changes with temperature of the cell dimensions and the density of the B- and C-forms of stearic acid have been determined. The influence on the c-axis is very slight. The effect on the subcell axes is similar to the disturbing effect of branching groups, *i. e.* the a_s-axis, ~ 4.95 Å, is almost unchanged but the b_s-axis, ~ 7.40 Å, is appreciably increased.

In connection with studies on polymorphism of normal fatty acids and transitions between the different polymorphs [1-3] it was found necessary to determine the variation of the cell dimensions of two polymorphs of an acid for temperatures between 0°C and the transition and melting points, respectively. The B- and C-forms of stearic acid were chosen. The structure of the B-form of stearic acid has been described by von Sydow [4]. The C-form of stearic acid has a structure analogous with the C-form of lauric acid, which has been described by Vand *et al.*[5] The cell dimensions of the C-forms of the whole homologous series have been determined by Abrahamsson and von Sydow [6] at one temperature (+ 23°C). Some of these data are given in Table 1.

Table 1. Dimensions of the B- and C-form of stearic acid and the orthorhombic subcell (O ⊥) at room temperature (+23°C) [3,4,6].

	a Å	b Å	β	Space group	a_s, $a \sin \beta$ and b, respectively	b_s, b and $a \sin \beta$, respectively
O ⊥	4.95	7.40	90°	$P\ b\ n\ m$	4.95	7.40
B-form	5.59	7.40	117°22′	$P2_1/a$	4.96	7.40
C-form	9.36	4.96	128°14′	$P2_1/a$	4.96	7.35

These crystal forms have both the same chain packing: the common orthorhombic type [3] with every second chain plane perpendicular to the others ($O_{\perp}$). The main difference between the structures is that in the case of the B-form the structure is tilted over the long subcell axis (7.40 Å) giving an increase in the short axis (4.95 Å to 5.59 Å) while in the case of the C-form the structure is tilted over the short subcell axis (4.95 Å) increasing the long axis from 7.40 Å to 9.36 Å (Table 1). These tilts are necessary to give space for the carboxylic groups, which are held together two and two by hydrogen bonds.

The B-form, which is obtained by crystallization from various solvents [2], is the stable form at room temperature but it is irreversibly transformed into the C-form by raising the temperature above + 46°C[1]. The C-form is stable up to the melting point + 69°.7C [1]. Solid phase in equilibrium with melt is always of the C-form.

By X-ray diffraction spectrometry the variations with temperature of the cell-dimensions and the densities of the B- and C-forms of stearic acid have been determined by measuring the variations with temperature of the diffraction angles of four reflexions of each crystal form.

TECHNIQUE

The X-ray spectrometer equipped with a scintillation counter and the heating arrangement used are constructed by Prof. G. Hägg. A shallow teflon beaker was used as specimen holder for the finely chopped crystal specimens.

The determination of the diffraction angle for a reflexion at a particular temperature was carried out in the following manner. After stabilising the specimen at the correct temperature for half an hour, the diffraction peak was located within ± 5′. The peak was scanned back and forth 4 times and exactly for each ½′ an artificial extra pulse was given to the rate meter. In this way the peak could be located within 0.1′, the standard deviation for the eight measurements generally being 0.07—0.09′. During these manipulations the temperature was recorded five times. The mean temperature is correct within ± 0.4°C.

Owing to serious orientation effects and comparatively low intensities, the best position of the specimen holder for registration of one particular reflexion

Table 2. The cell dimensions and the calculated density of the B-form of stearic acid at temperatures between 0°C and its transition point.

Temp. °C	a Å	b Å	c Å	β	ϱ_{calc} gcm $^{-3}$
0	5.591	7.368	49.439	117° 15′.2	1.0444
10	5.592	7.381	49.412	117° 18′.8	1.0432
20	5.594	7.400	49.388	117° 21′.9	1.0414
30	5.595	7.420	49.365	117° 24′.5	1.0391
40	5.595	7.443	49.343	117° 25′.3	1.0365
45	5.595	7.457	49.337	117° 26′.4	1.0349

was found empirically. This, of course, implies that no absolutely correct diffraction angles were obtained, but the changes with temperature were very accurately determined. The curves Θ *vs.* temperature for every reflexion were therefore put on an absolute scale by comparison with the data from the previous structure investigations [4,6], which were of course, also used for indexing.

The following reflexions were used:

B-form (005), (020), (201) and (2, 1, $\bar{1}9$)
C-form (005), (110), (200) and (2, 1, $\bar{2}0$)

The cell dimensions and the density were calculated for each 10°C in both cases.

It was not possible to measure (2, 1, $\bar{2}0$) at temperatures over 50°C with any accuracy, owing to the lowering of intensity and broadening of the peak. Thus some of the data above this temperature are obtained by extrapolation.

RESULTS AND DISCUSSION

The cell dimensions and densities of the crystalline B- and C-forms of stearic acid at different temperatures are given in Tables 2 and 3. The accuracy is the same as in the earlier papers [4,6], but as regards changes in dimensions and densities, which are given in Figs. 1 and 2, the accuracy is much higher (< 0.001 Å for a- and b-axes, < 0.005 Å for c-axes, < 0.1 for β and < 0.0002 gcm^{-3} for ϱ_{calc}).

As can be seen the changes in the c-dimensions are comparatively very small. As the molecules are very nearly parallel to the c-axis [3-5], this means that the length of the molecule of stearic acid is almost independent of temperature in the interval investigated. Of the other axes, the shortest in both cases are hardly at all influenced by temperature changes, but the medium ones are very sensitive. As the changes in β are very small, these conclusions are directly transferable to the subcell-dimensions, *i.e.* the shortest subcell

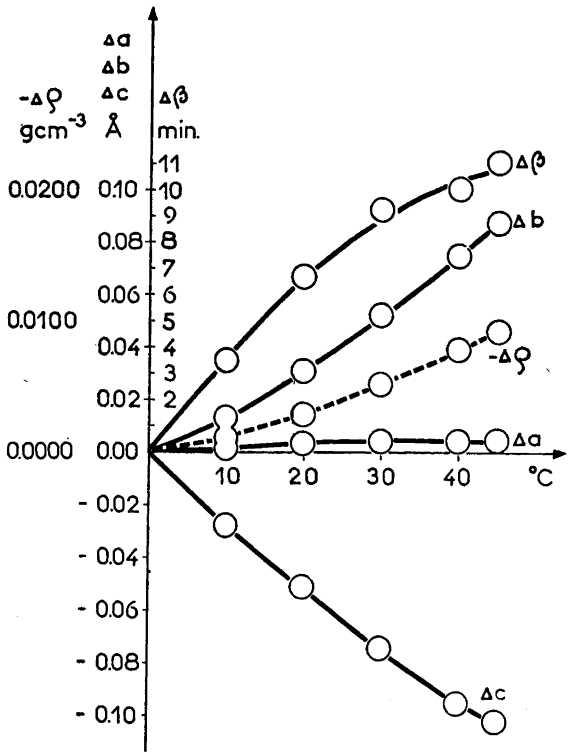

Fig. 1. The changes of the cell dimensions and the calculated density of the B-form of stearic acid.

dimension (~ 4.95 Å) is almost unchanged but the largest one (~ 7.40 Å) If very variable with temperature. This is also observed for *n*-hydrocarbons [7]. is the packing of the hydrocarbon chains is disturbed in other ways, *e.g.* by branching groups, the effect on the subcell dimensions is the same. In the case of 14-heptacosanol [8] the dimensions are 4.95 and 7.8 Å, respectively, and for *trans*-DL-9,10-methyleneoctadecanoic acid [9] they are 4.98 and 8.12 Å. As that of branching [9] the effect of temperature is certainly a trend to achieve a hexagonal closepacking of cylindrical rods (*e.g.* rotating hydrocarbon chains) which happens when the b_s-axis is increased from 7.40 Å to 8.6 Å.

The decrease in the density of the C-form is larger than for the B-form, which indicates that the C-structure is more flexible than the B-structure. It might have been expected that the density curve of the B-form would intersect the curve of the C-form at the transition temperature (B → C, 46°C) but this is not the case (Tables 2 and 3). This calls for caution in discussing molecular interactions and its connection with density. It is obvious from this investigation that not only chain packing and end group packing [3], but also the arrangement of the carboxylic groups are important factors in this connection.

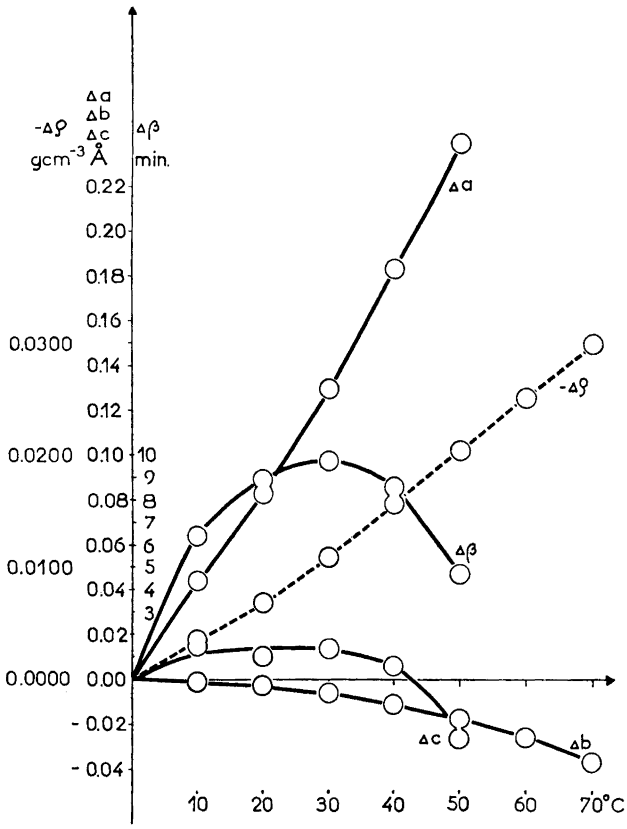

Fig. 2. The changes of the cell dimensions and the calculated density of the C-form of stearic acid.

We are indebted to Professors G. Hägg and E. Stenhagen for the facilities put at our disposal and to Dr. S. Abrahamsson for interesting discussions. The expenses involved have been defrayed by grants from the *Swedish Natural Science Research Council.*

A Homologous Series of Mixed Titanium Chromium Oxides $Ti_{n-2}Cr_2O_{2n-1}$ Isomorphous with the Series Ti_nO_{2n-1} and V_nO_{2n-1}

STEN ANDERSSON, ANITA SUNDHOLM and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

By heating mixtures of titanium(IV)oxide and chromium(III)oxide at 1 300°—1 400°C in an inert atmosphere, mixed oxides $Ti_{n-2}Cr_2O_{2n-1}$ (n = 6, 7, 8, and 9) are obtained. These phases are isomorphous with the members of the homologous series Ti_nO_{2n-1} and V_nO_{2n-1}. Some structural data are given for the mixed oxide homologues. When heated at still higher temperatures, the structures seem to undergo a partial disordering.

From a consideration of an X-ray phase analysis of the vanadium-oxygen system carried out by Georg Andersson, it was suggested by one of the present authors (A.M.) that the phases occurring in the composition region $VO_{1.75-1.87}$ form a "homologous series" based structurally on the rutile-type structure [1]. The evidence constituting the grounds for this suggestion was the following:

1) The compositions of the phases, none of which shows an extended range of homogeneity, are all in good agreement with the general formula V_nO_{2n-1}, n being an integer. The phases prepared by Andersson correspond to values of n equal to 4, 5, 6, 7 and 8.

2) The powder photographs of the various phases are of a closely related appearance and are similar to the pattern of a structure of rutile type. Thus, all the strong reflexions of the former occur as doublets or triplets close to the positions of the rutile type lines. With increasing n, the distribution of the reflexions converges towards that of the rutile-type pattern.

Recent studies on the titanium-oxygen system have revealed the existence of an analogous family of oxides with the general formula Ti_nO_{2n-1} [2-4]. The members of this series ($4 \leq n \leq 10$) should, as indicated by the analogous appearance of the powder diagrams, in every case be isomorphous with the corresponding vanadium oxides.

An alternative formulation of a series M_nO_{2n-1} is $(n—2)MO_2 \cdot M_2O_3$. The latter formula suggests the possibility of preparing an oxide series from appropriate mixtures of oxides of tetravalent and trivalent metals. This article will give results obtained in this way using titanium(IV) and chromium(III) oxides.

The TiO_2-Cr_2O_3 system has previously been studied by Hamelin [5] who found a wide region of solid solubility in preparations rich in titanium. A phase transition was observed for this region at temperatures rising from about 1 440° to 1 500°C with increasing contents of chromium. It was pointed out that the X-ray powder patterns of the low temperature form were very similar to those given by products obtained by reducing rutile. The existence of a phase with the stoichiometric composition $2TiO_2 \cdot Cr_2O_3$ was also stated.

A different picture resulted from the studies on this system by Dietzel and Flörke [6,7] who found that the rutile-type structure broke down when the chromium content was raised above 3—5 %, giving rise to a series of new phases structurally related to the rutile type.

EXPERIMENTAL

The starting materials for preparing the mixed titanium chromium oxides were titanium dioxide (Baker analyzed, anatase modification, about 99.97 % pure) and dichromium trioxide (Matheson Coleman and Bell, reagent grade). Intimate mixtures of weighed amounts of the oxides were pressed into tablets and then heated at temperatures between 1 200° and 1 450°C for periods of time ranging from a few hours to ten days. In several cases, the samples had to be refired after grinding. The heating was performed in a glow-bar furnace provided with a horizontal heating tube made of pythagoras mass. The tablets were always placed on a thin sheet of platinum which prevented the sample from reacting with the corundum boat carrying the specimen. The heating was performed in air or a stream of oxygen or argon. After completion of the period of heating, the boat was quickly moved out of the hot zone in order to ensure a fairly rapid cooling of the sample. In a few instances, the mixed oxide tablets were melted in an electric arc furnace under argon atmosphere.

X-Ray powder photographs were taken of all the samples using a Guinier set-up with monochromatized $CuK\alpha_1$ radiation. An aluminium foil (35 μ) covering the film served to reduce the back-ground fogging caused by the fluorescent radiation from the samples. Potassium chloride (a = 6.2919 Å at 20°C [8]) was always added to the specimens as an internal standard. Details about the techniques employed in the X-ray work have been given in a previous article [9].

Table 1 gives a survey of several of the experiments performed during this investigation. The colour of the samples listed was always graphite grey after the heat-treatment but, upon grinding, it turned to a dark brown. Density data for several preparations are given in Table 5.

PHASE ANALYSIS

Most of the synthesis experiments were carried out in an argon atomsphere. It is obvious from Table 1 that the attainment of a state of equilibrium requires a more intense heat-treatment of the reaction mixture at low titanium contents than at higher ones. Fig. 1 gives a schematic representation of the powder patterns of several equilibrium samples.

The non-existence of a compound $TiO_2 \cdot Cr_2O_3$ and the existence of the phase $2TiO_2 \cdot Cr_2O_3$ ($Ti_2Cr_2O_7$) reported by Hamelin [5] are clearly demonstrated by our results. For higher contents of titanium dioxide, the powder patterns

are of a mutually related appearance and the whole of this region could easily be mistaken for being one sigle phase of a composition varying within wide limits. A careful study, however, reveals the existence, at least up to the composition $7TiO_2 \cdot Cr_2O_3$, of a regular alternation of one-phase and two-phase regions. The compositions of the former are underlined in Fig. 1. The ranges of homogeneity should be very narrow since the positions of the X-ray reflexions of the various phases do not change appreciably with the composition of the samples. The discontinuous character thus demonstrated for this region of the titanium chromium oxide system is in agreement with the opinion put forward independently by Dietzel and Flörke [6,7] but conflicts with the results reported by Hamelin [5].

For titanium dioxide contents exceeding $7TiO_2 \cdot Cr_2O_3$, the powder patterns still maintained the same general appearance. It was not, however, possible to observe the existence of any two-phase regions or to demonstrate a discontinuous character in this range of composition. This may indicate either that there is actually a continuos series of solid solutions or that the series of discrete oxide phases observed at lower titanium dioxide contents is continued up into this range of composition. In the latter case, the failure to demonstrate the existence of two-phase regions would be due to an inadequate resolving power of the powder camera. The upper limit of this range of composition is at about $15TiO_2 \cdot Cr_2O_3$, where the first indications of another two-phase region show up, rutile being the additional phase.

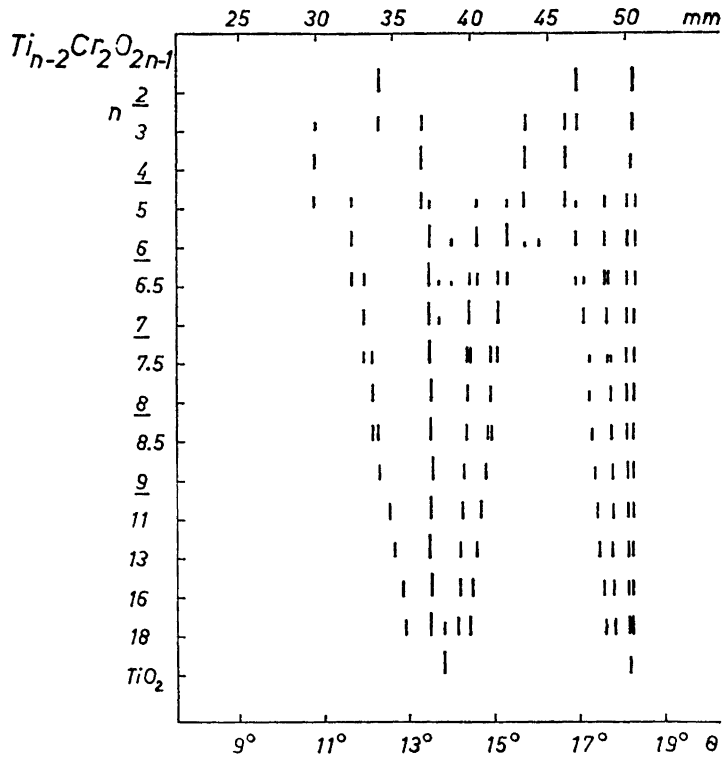

Fig. 1. Powder patterns of samples $Ti_{n-2}Cr_2O_{2n-1}$.

The phase analysis evidently demonstrates the existence of at least four discrete, related phases of compositions $xTiO_2 \cdot Cr_2O_3$, x having values close to the integers 4, 5, 6, and 7. An alternative way of expressing these compositions is $Ti_{n-2}Cr_2O_{2n-1}$, where n stands for $x + 2$. The powder patterns of the four phases show pronounced similarities and approach that of a rutile-type pattern with increasing values of n. The results obtained for the series of mixed titanium chromium oxides thus suggest that a far-reaching analogy exists with the homologous series Ti_nO_{2n-1} and V_nO_{2n-1}. Actually, a comparison of the powder photographs of all these phases reveals that the pattern of a member of the mixed oxide series may generally be described as something intermediate between the patterns of the titanium and vanadium oxide phases with the same value for n. The isomorphism of the three series has been further elucidated by the detailed interpretation of the powder photographs (*v. infra*).

The identification of the phases of the series $Ti_{n-2}Cr_2O_{2n-1}$ made possible the phase analysis of preparations obtained by heating the mixed oxide samples in air or in oxygen (*cf.* Table 1). Preparations heat-treated in this way give X-ray powder patterns showing phases of higher n values than those corresponding to the compositions of the starting mixtures. These starting mixtures

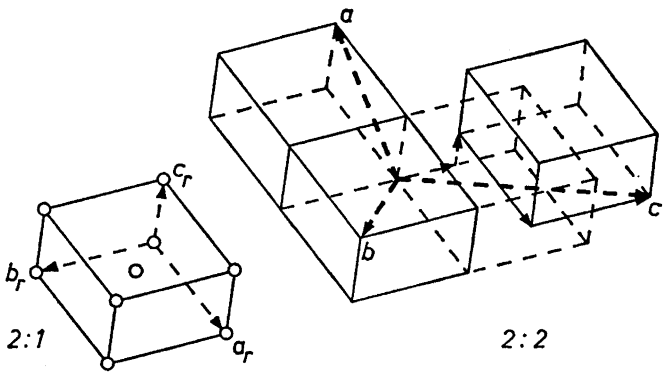

Fig. 2. 1) Unit cell of rutile with positions of metal atoms indicated. 2) Interrelation of basic rutile-type structure of adjacent slabs of Ti_5O_9. Unit cell axes of the latter indicated by dashed heavily-drawn arrows.

have therefore evidently been partly oxidized during the firing. This process is accompanied by a slight loss of weight of the sample. This phenomenon has so far not been further investigated. An oxidation of chromium(III)oxide when it was heated together with titanium(IV)oxide in air at 700°C was observed by Dietzel and Flörke. They also found that chromium(III)oxide when heated in air at 1 000°C is slightly volatile, forming a higher oxide [6,7].

Upon heating members of the series $Ti_{n-2}Cr_2O_{2n-1}$ at sufficiently high temperatures (*cf.* Table 1), preparations are obtained which give powder patterns that differ in a characteristic way from those shown in Fig. 1. Thus, while part of the reflexions are unchanged, several appear diffuse and with reduced intensities while others are not even visible after the high-temperature firing. This phenomenon, which is probably associated with the phase-transition reported by Hamelin [5], may indicate a partial disordering of the structures of the homologues. Further studies on this matter are in progress.

STRUCTURAL DATA OF THE SERIES $Ti_{n-2}Cr_2O_{2n-1}$

Crystals of the members of the homologous titanium chromium oxide series grow only very slowly and this of course made X-ray studies of these compounds with single-crystal methods impracticable. The deduction of detailed structural data of the homologues under such circumstances had to be based on information now available for the Ti_nO_{2n-1} series and especially for its second member, *i.e.* Ti_5O_9.

The crystal structure of Ti_5O_9 has recently been determined by one of the present authors (S.A.)[10] and is now being refined. (A detailed account of this investigation will, in due time, appear elsewhere.) The structure may be described as being built up of slabs of a rutile-structure type, *i.e.* TiO_6 octahedra joined by edges and corners as in the rutile structure. The slabs are of infinite extension in two dimensions and have a characteristic finite width correspond-

ing to five TiO_6 octahedra in a third direction. The mutual connection of the slabs takes place by means of TiO_6 octahedra sharing faces. If the axes of the rutile-type subunit cell ($\boldsymbol{a}_r$, $\boldsymbol{b}_r$ ($\boldsymbol{b}_r = \boldsymbol{a}_r$) and $\boldsymbol{c}_r$) are used to define the coordinate system, then the axes of the "ideal" Ti_5O_9 unit cell will be $\boldsymbol{a} = \boldsymbol{c}_r - \boldsymbol{a}_r$, $\boldsymbol{b} = \boldsymbol{a}_r + \boldsymbol{b}_r + \boldsymbol{c}_r$ and $\boldsymbol{c} = \boldsymbol{a}_r - \frac{3}{2}\boldsymbol{b}_r + \frac{1}{2}\boldsymbol{c}_r$. (The term, "ideal" cell, is used here to imply that no deformation of the geometry of the rutile subunit takes place.) The infinite extension of the slabs is parallel to the *ab* plane. The rutile arrangements of adjacent slabs are out of step by $\frac{1}{2}(\boldsymbol{b}_r + \boldsymbol{c}_r)$ (*cf.* Fig. 2).

Assuming the structural principles found for Ti_5O_9 to be valid also for the other members of the series, general expressions may be derived for the characteristics of the "ideal" structures of all the homologues. This is done in a way similar to that applied when deducing general structural data for the homologous series of molybdenum wolfram oxides M_nO_{3n-1} [11]. A detailed account of this investigation will be presented elsewhere. For the present discussion, the following vectorial expressions for the unit cell parameters will suffice.

$$\boldsymbol{a} = \boldsymbol{c}_r - \boldsymbol{a}_r$$

$$\boldsymbol{b} = \boldsymbol{a}_r + \boldsymbol{b}_r + \boldsymbol{c}_r$$

$$\boldsymbol{c} = \frac{n-3}{2}\boldsymbol{a}_r - \frac{n-2}{2}\boldsymbol{b}_r - \frac{n-6}{2}\boldsymbol{c}_r$$

The fundamental role of the rutile-type subcell in the structures of the various homologues shows itself in the character of the X-ray patterns. Thus, the latter only show strong reflexions when the reciprocal lattice points are situated close to those of the strong rutile reflexions. The indices of the strong reflexions of a homologue M_nO_{2n-1} may thus be found by means of the following matrix giving the relations between the homologue and rutile.

	→ rutile		
M_nO_{2n-1}	$\bar{1}$	0	1
	1	1	1
	$\frac{n-3}{2}$	$\frac{2-n}{2}$	$\frac{6-n}{2}$

Thus the reciprocal point of the strong rutile reflexion 110 corresponds, for all the homologues, to the point $1\bar{2}\frac{1}{2}$, which implies that the reflexions of the adjacent points $1\bar{2}0$ and $1\bar{2}1$ should always be strong. On the other hand, the rutile point $1\bar{1}0$ corresponds, for the various homologues, to $1\ 0\ \frac{5-2n}{2}$. The reflexions generated by the strong $1\bar{1}0$ reflexion of rutile should thus be $10\bar{3}$ and $10\bar{4}$ for M_6O_{11}, $10\bar{4}$ and $10\bar{5}$ for M_7O_{13} *etc.*

Such considerations should in principle make it possible to index the powder pattern of any member of a homologous series M_nO_{2n-1} possessing the structural characteristics given above. Actually all well resolved patterns of members

of the series Ti_nO_{2n-1}, V_nO_{2n-1} and $Ti_{n-2}Cr_2O_{2n-1}$, have been indexed in this way *. Parts of the powder diagrams of the latter homologues are given in Table 2. The good agreement between the calculated and the observed diffraction data may be taken as a confirmation of the structural character discussed above for these phases.

* According to a private communication Mr. Jørgen Villadsen of F:a Haldor Topsøe, Hillerup, Denmark, has indexed the powder patterns of Ti_4O_7 and V_4O_7 by applying a procedure according to De Wolff [12] and has found parameter values in perfect agreement with those derived in this investigation.

Table 3. Observed and calculated unit cell parameters and densities of the members of the $Ti_{n-2}Cr_2O_{2n-1}$ series.

Phase	Unit cell parameters						Density
	a_{obs} a_{calc}	b_{obs} b_{calc}	c_{obs} c_{calc}	α_{obs} α_{calc}	β_{obs} β_{calc}	γ_{obs} γ_{calc}	obs calc
$Ti_4Cr_2O_{11}$	5.50 Å	7.07 Å	11.89 Å	98.6°	120.6°	107.4°	4.42

	5.46	7.14	14.78	98.1°	125.2°	108.5°	4.42
$Ti_6Cr_2O_{15}$	5.49	7.08	18.64	99.5°	128.2°	108.1°	4.33
	5.46	7.14	18.18	98.6°	128.3°	108.5°	4.40
$Ti_7Cr_2O_{17}$	5.49	7.09	22.13	99.5°	130.3°	107.3°	4.24
	5.46	7.14	21.40	98.9°	130.8°	108.5°	4.38

Table 3 gives a comparison between the unit cell parameters of the members of the $Ti_{n-2}Cr_2O_{2n-1}$ series derived from the experimentally obtained X-ray data and parameter values calculated from the expressions given above. For simplicity, the parameters a_r and c_r are taken here to be equal to those of rutile, *viz.* 4.59 and 2.96 Å, respectively. The agreement between the observed and calculated data is satisfactory when considering the simplifying assumptions involved in the derivation of the latter. Thus, for the a and b axes, which should be constant for all the homologues, the deviation does not exceed 1 %. The observed length of the c axis, which increases with increasing n, is throughout larger than the calculated value by about 4 %. This difference is, however, easily accounted for by the repulsion between the metal atoms of octahedra sharing faces. The resulting expansion of the structure, which was not considered when deriving the ideal lattice parameters, has its largest component in the c direction. The agreement is satisfactory also for the angle parameters.

Further developments of the expressions giving the structural characteristics of »ideal» and eventually also real members of a series M_nO_{2n-1} should make it possible to calculate rather accurate positions for the metal and oxygen atoms of the various phases. The distribution of the titanium and chromium atoms on the metal atom sites might possibly be derived from comparisons of detailed structural data, including interatomic distances, obtained from single-crystal studies of titanium chromium and titanium oxides.

This investigation has been sponsored in part by the *Office, Chief of Research and Development, U.S. Department of Army* through its *European Research Office* and in part by the *Swedish Natural Science Research Council.*

On the Complex Chemistry of the Tervalent Rare-Earth Ions

III. The Glycolate Systems

ARTUR SONESSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The complexity constants of the glycolate systems of ten rare earths have been determined by potentiometric measurements similar to those used previously in the investigation of the acetate systems [1,2]. The results are given in Tables 5 and 6 and Fig. 5.

The glycolate systems show a considerably higher complexity than the corresponding acetate systems. This is probably due to the formation of chelates in the glycolate systems. The value of the first complexity constant, $\beta_1 = [MA] \cdot [M]^{-1} \cdot [A]^{-1}$, increases from La to Sm. For the Gd-system a somewhat lower value of β_1 is found than for the Sm-system. From Gd to Yb, however, β_1 increases again, contrary to the variation of β_1 for the corresponding acetate systems.

The potentiometric measurements show that the formation of anionic glycolate complexes must be assumed.

The neodymium glycolate system has also been investigated extinctiometrically. The complexity constants obtained in this way are in good agreement with those obtained potentiometrically.

The glycolate ion, $HO \cdot CH_2 \cdot COO^-$, contains a hydroxide group but has in other respects the same constitution as the acetate ion, $CH_3 \cdot COO^-$. On account of the OH-group the glycolate ion has a more or less pronounced tendency to form chelates. A five-membered ring can be formed. In those cases where chelates are not formed, the glycolate solutions ought to show a lower degree of complexity than the corresponding acetate solutions, in as much as glycolic acid is stronger than acetic acid (*cf.* Sundén [3] and Ahrland [4]). If on the other hand chelates are formed, we would expect the first complexity constants (the very first one at least) to be greater than the constants of the corresponding acetate complexes.

Investigations indicating that the glycolate systems of the rare earths probably contain chelates are to be found in the literature (Jantsch and Grünkraut [5]), but no attempts to compute the complexity onstants have been made. In order to make possible a comparison between the complexity of the

corresponding acetate and glycolate systems, the investigation of the glycolate systems described in this paper has been performed in the same way as the investigation of the acetate systems reported in papers I [1] and II [2]. Thus all measurements have been made at 20°C and with an ionic strength of 2.0 M. The main method of investigation has been the potentiometric determination of the hydrogen-ion concentration in solutions with known total concentrations of rare-earth ions, glycolate ions and glycolic acid. As a check on the potentiometric investigations the neodymium glycolate system has been examined extinctiometrically in the way described in II for the erbium acetate system.

Concerning the symbols and the formulae used in the calculations, the reader is referred to I and II.

CHEMICALS USED

Glycolic acid ((Fluca puriss. and Kahlbaum puriss.) was dried *in vacuo* over concentrated H_2SO_4. Both preparations gave after drying the equivalent weight 76.1 (calc. 76.0).

A stock solution of glycolic acid * HAcOH and sodium glycolate NaAcOH in the proportion 2 M HAcOH: 2 M NaAcOH was prepared by partial neutralization of calculated amounts of dried acid by carbonate-free sodium hydroxide. Afterwards the concentrations of HAcOH and NaAcOH were checked.

Buffer solutions with δ = 1.0, 2.5 and 4.0 were prepared from calculated amounts of the stock solution and dried glycolic acid. Sodium perchlorate from a stock solution was added to make I = 2.0 M. Besides, a buffer solution with the composition 0.387 M HAcOH, 1.107 M NaAcOH and $NaClO_4$ to make I = 2.0 M was used.

A. POTENTIOMETRIC MEASUREMENTS

The cells in which the electromotive forces were measured were of the following composition (Me^{3+} = the rare earth ion):

Au	Quinhydrone 10.2 mM $HClO_4$ $NaClO_4$ to I = 2.0 M	2.0 M $NaClO_4$	Quinhydrone C_M mM $Me(ClO_4)_3$ $C_H = \nu \cdot C_M$ mM $HClO_4$ C'_A mM NaAcOH $C'_{HA} = \delta \cdot C'_A$ mM HAcOH $NaClO_4$ to I = 2.0 M	Au	(1)

The solution of the right cell was prepared from a known volume of the rare-earth perchlorate solution S_1 and increasing volumes of the buffer solution S_2:

	S_1	S_2		
$Me(ClO_4)_3$	C°_M	0	mM	
$HClO_4$	$C^\circ_H = \nu \cdot C^\circ_M$	0	mM	
NaAcOH	0	C°_A	mM	(2)
HAcOH	0	$C^\circ_{HA} = \delta \cdot C^\circ_A$	mM	
$NaClO_4$	$2\,000 - 6\,C^\circ_M - C^\circ_H$	$2\,000 - C^\circ_A$	mM	

The relation between C_M and C'_A is given by

$$C_M = C^\circ_M(1 - C'_A \times 10^{-3}) \text{ mM} \qquad (3)$$

except in the case where C°_A = 1 107 mM.

* $AcOH^-$ = the glycolate ion.

The emf of the element in (1) is denoted by E when $C_M \neq 0$, and by E' when $C_M = 0$, that is, when the right cell contains only the buffer solution. During the experiments the solutions were kept in a thermostat in which the temperature was 20.0° ± 0.1°C.

Every titration series was repeated at least once. With the exception of the cases where the rare-earth glycolate was precipitated, the potential was steady and could with few exceptions be reproduced within 0.2 mV.

The variation of the stoichiometric acid constant K_c with C'_A and C'_{HA} is shown in Table 1. It is evident that the addition of glycolic acid and the exchange of perchlorate ions for glycolate ions have a marked influence on the ionic medium. The variation of E' may to some degree depend on the salt error of the quinhydrone electrode. As only $E_A = E'—E$ is used for the computation of [A] (except for the determination of some correction terms), the salt error caused by the addition of the buffer solution is reduced to a minimum.

However, the medium changes probably also influence the activity factors of other ion species in the complex solution. Then it is possible that the complexity constants β_n vary with C'_A and C'_{HA}. As the variation of E' is especially significant at high values of δ, some difference might be expected between the $\bar{n}$/[A]-values obtained with buffer solutions having great differences in δ. Therefore buffer solutions with $\delta = 0.350$ and $\delta = 4.0$ were used in investigating the complexity systems. The results of the measurements on the gadolinium glycolate system are shown in Tables 2a and 2b and Fig. 1. The agreement between the $\bar{n}$/[A]-values obtained with the two buffers is rather good. The differences fall generally within the limits of the random errors. Thus it appears that a high concentration of glycolic acid does not have any great influence on the complexity constants.

As the glycolic acid has a OH-group, it is possible that the unprotolyzed acid molecules form complexes with the rare-earth ions. We have therefore examined the question as to whether the addition of glycolic acid to an acidified solution of a rare-earth perchlorate has any effect on the extinction curve of the rare earth. It was found that the extinction of the holmium ions within the wave length range 320—700 mμ was unchanged, except for the peak at 450 mμ, when C_{HA} was increased from 0 mM to 750 mM ($C_M = 50$ mM, $[H^+] = 125$ mM, $NaClO_4$ to $I = 2.0$ M). The molar extinction coefficient of the peak at 450 mμ increased from 4.0 to 4.8. This increase, however, can be attributed to a complex formation between holmium ions and glycolate ions, as $[A] \approx 1.1$ mM in a solution having $C_{HA} = 750$ mM ($K_c = 1.8 \times 10^{-4}$) and $[H^+] = 125$ mM. This assumption was confirmed by an examination of the extinction of holmium perchlorate solutions ($C_H^o \approx 0.5$ mM), to which different amounts of glycolate buffer ($\delta = 1$) were added. It was found that the molar extinction coefficient of the peak at 450 mμ was about 4.8 when $[HA] \approx 18$ mM and $[A] \approx 1.0$ mM ($\bar{n} \approx 0.3$ according to the potentiometric measurements) *. Thus, complex formation between unprotolyzed glycolic

* The formation of holmium glycolate complexes is accompanied by a rather strong increase of the extinction band at 450 mμ, whereas the increase of the band at 360 mμ is considerably lower. The band at 450 mμ has two peaks at a distance of about 1 mμ. It is the peak with the shorter wave length that increases when glycolate complexes are formed.

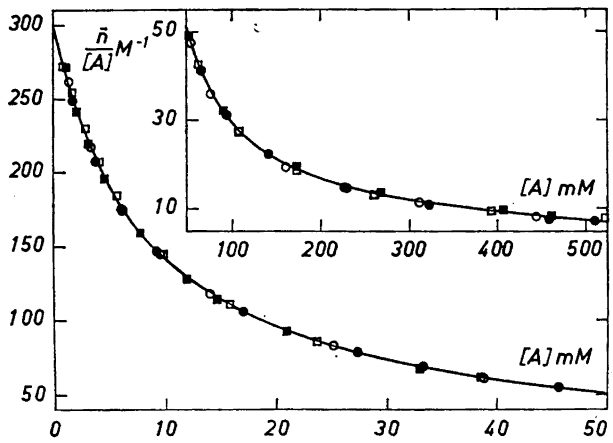

Fig. 1. The relation between $\bar{n}/[A]$ and [A] for the gadolinium glycolate system according to the titration series in Tables 2a and 2b.

acid and holmium ions (and other rare-earth ions) may probably be excluded.

Any significant signs of polynuclear complexes have not been found, as the $\bar{n}$/[A]-functions of series with different C_M coincide at low [A] within the limits of the random errors.

The rare-earth glycolates are rather slightly soluble. The solubilities of the glycolates of the lighter rare earths have been determined by Jantsch and Grünkraut [5]. They found that the solubility at 18°C increases from 9.1 mmole/l at La to 12.5 mmole/l at Nd and 17.0 mmole/l at Sm. These glycolates have the composition $Me(AcOH)_3$ when dried in air at room temperature. The gadolinium glycolate showed a considerably higher solubility, 33.8 mmole/l, and contained 2 H_2O after drying.

The solubilities of the higher rare-earth glycolates seem to decrease from Gd to Yb. No determinations of the solubilities have been performed, but Jantsch and Grünkraut found that if a solution containing a mixture of rare-earth nitrates was partially precipitated with sodium glycolate, the higher rare earths were concentrated in the precipitate. It was also found by the present author in the investigation of the complexity of the glycolate systems that in order to avoid precipitation solutions with considerably lower rare-earth concentrations must be used for the higher rare earths than for gadolinium. The precipitate obtained in the Ho^{3+}—$AcOH^-$-system was analyzed after drying in air at room temperature. Its composition was $Ho(AcOH)_3 \cdot 2H_2O$ (Found: Ho 38.3; H_2O 8.4. Calc. Ho 38.7; H_2O 8.45).

The precipitates of the rare-earth glycolates were formed rather slowly, except at $\bar{n} \approx 3$. Therefore it was also possible to investigate the glycolate systems at high ligand concentrations and relatively high rare-earth concentrations.

According to the potentiometric measurements anionic glycolate complexes are formed. Then it was expected that the precipitate of the rare-earth glycolate should dissolve at least partially when the concentration of glycolate ions was increased. However, such a dissolution could not be proved directly.

As the complex solutions have pH < 4, the degree of hydrolysis of the rare-earth ions must be so slight that it can be neglected (*cf.* I[p. 171] and II[p. 1940]).

As the ionic strength of the complex solutions decreases by the complex formation, the E_A-values must be corrected. By using the method indicated in Paper I the relation between the correction term, ΔE_A, and the depression of the ionic strength, ΔI, has been determined. The correction term should be subtracted from E_A to give the true E_A at $I = 2.0$ M. For the glycolate systems the following function was obtained:

$$\Delta E_A = 2.3 \cdot \Delta I \tag{4}$$

Thus the E_A-values of the glycolate systems are not so sensitive to changes of the ionic strength as the E_A-values of the acetate systems.

For the calculation of ΔI the following formula was used:

$$\Delta I = 0.5 \cdot C_M \cdot \bar{n}(7-\bar{n}) \tag{5}$$

where $\bar{n}$ was obtained by means of the uncorrected E_A-values (*cf.* I[p. 171]).

Table 3 gives $\bar{n}/[A]$ for various values of [A] for all the rare-earth glycolate systems examined. [A] and $\bar{n}/[A]$ have been calculated according to eqns. II(2), II(3) and II(4). Fig. 2 shows the complex formation curve $\bar{n} = f(\log[A])$ for the glycolate systems of La^{3+}, Sm^{3+}, Dy^{3+}, and Yb^{3+}.

The complexity constants $\beta_n = [MA_n]\cdot[M]^{-1}\cdot[A]^{-n}$ have been computed according to eqns. II(5), II(7) and II(8) after a graphical integration of the function $\bar{n}/[A] = f([A]))$. The complexity constants are given in Table 5.

B. THE EXTINCTIOMETRIC INVESTIGATION

The neodymium glycolate system was examined extinctiometrically in the same way as the erbium acetate system described in II[p. 1947]. As the potentiometric investigation showed that polynuclear complexes can be formed only to a very limited extent, the terms depending on polynuclear complexes are neglected in the extinctiometric equations.

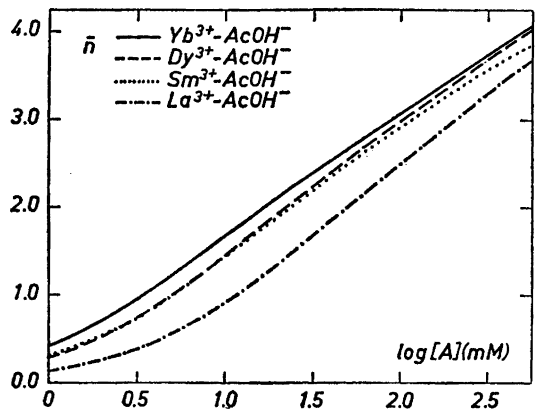

Fig. 2. The complex formation curves $\bar{n} = f(\log[A])$ for four rare-earth glycolate systems.

The measurements were performed at 20°C by means of a Hilger Uvispek with tungsten lamp and glass prism. As seen in Fig. 3 the complex formation has the greatest effect on the absorption band at 580 mμ. The band is shifted towards longer wave length, and the extinctiometric measurements were therefore performed at 586 mμ. At this wave length the slope of the absorption band has approximately the same value for all the solutions measured, and therefore the errors caused by the imperfect monochromaticity of the light are reduced (*cf.* Fronæus [6], p. 98). The effective band width was about 5 Å.

In order to reduce the error caused by the partial reflection of the light at the end plates of the absorption cells (*cf.* Fronæus [6], p. 98), solutions with the same value of ε should

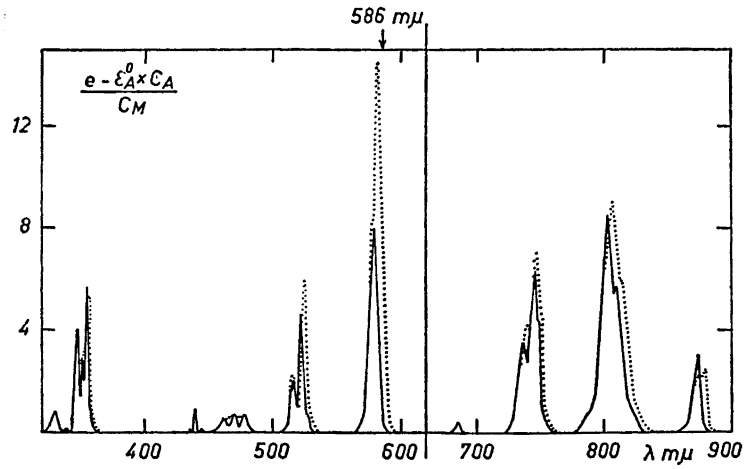

Fig. 3. The extinction curves for a neodymium perchlorate solution (the fulldrawn curve) and a complex solution with $C_{Nd^{3+}} = 50$ mM and $C_A = 500$ mM (the dotted curve). The ionic strength of both solutions was 2.0 M.

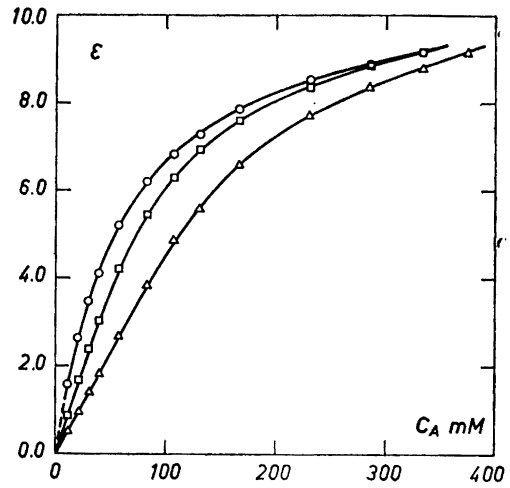

Fig. 4. ε for the neodymium glycolate system as a function of the glycolate concentration at different values of d. O : d = 4 cm, □ : d = 2 cm, △ : d = 1 cm. The relation between C_M, C'_A and d is given by eqn. (6). By correcting C'_A according to the formula $C_A = C'_A + [H^+] - C_H$ the true total concentration C_A of glycolate ions is obtained.

have the same total extinction (E). This condition has been fulfilled approximately by holding the following relation between the rare-earth concentration (C_M mM), the glycolate concentration (C'_A mM) and the length of the absorption cell (d in cm):

$$C_M = \frac{50}{d}\,(1 - C'_A \times 10^{-3}); \qquad (C_M \text{ and } C'_A \text{ in mM}) \tag{6}$$

The solutions to be measured have been prepared by mixing different volumes of two solutions:

$$S_1 : \frac{50}{d} \text{ mM } Nd(ClO_4)_3 + \left(2\,000 - 6 \cdot \frac{50}{d}\right) \text{ mM } NaClO_4$$

$$S_2 : 1\,000 \text{ mM } HAcOH + 1\,000 \text{ mM } NaAcOH + 1\,000 \text{ mM } NaClO_4$$

In the calculation of the true total concentration of glycolate ions ($C_A = C'_A + [H^+] - C_H$) the potentiometrically obtained values of the correction terms $[H^+]$ and C_H have been used. C_H depends on the presence of free perchloric acid in the rare-earth perchlorate solution ($C_H = 1.34 \times 10^{-3} \times C_M$ mM).

The relation between the lengths of the absorption cells was found to be 4.00:2.00:0.998 by means of extinction measurements performed with an alkaline solution of sodium picrate.

The validity of Beer's law was checked for neodymium perchlorate solutions with $C_M \leq 50$ mM.

The relation between

$$\varepsilon = \frac{e - \varepsilon_M^\circ \cdot C_M - \varepsilon_A^\circ \cdot C_A}{C_M}$$

and the glycolate concentration C_A has been determined experimentally for three values of d in eqn. (6). The three functions $\varepsilon = f(C_A)$ are shown in Fig. 4. By means of the three curves and eqn. (6) the pairs of values $(C_M, C_A)_\varepsilon$ — that is, the corresponding values of C_M and C_A at a given value of ε — have been calculated for the three values of d (Table 4).

According to eqn. II(13) the following equation is valid if only mononuclear complexes are formed:

$$\varepsilon = \frac{\xi}{X} = \frac{1}{X} \cdot \sum_{n=1}^{N} (\varepsilon_n - \varepsilon_M^\circ - n \cdot \varepsilon_A^\circ)\beta_n \cdot [A]^n \qquad (7)$$

Therefore solutions with the same value of ε must have the same concentration [A] of free glycolate ions. Thus if $\bar{n}_\varepsilon$ is the ligand number, the relation between $(C_A)_\varepsilon$ and $(C_M)_\varepsilon$ is given by the straight line

$$(C_A)_\varepsilon = \bar{n}_\varepsilon \cdot (C_M)_\varepsilon + [A] \qquad (8)$$

The pairs of values $(C_M, C_A)_\varepsilon$ given in Table 4 for $2.0 \leq \varepsilon \leq 6.5$ represent approximately a straight line. Therefore it is possible to calculate $\bar{n}_\varepsilon$ and [A] according to eqn. (8). The determinations of $\bar{n}_\varepsilon$ and [A] have been performed graphically. The accordance between $\bar{n}_\varepsilon$/[A] and $\bar{n}$/[A] obtained potentiometrically is relatively good. On account of the method of extrapolation, the determination of $\bar{n}_\varepsilon$/[A] begins to be very uncertain for [A] < 4 mM.

Table 4. Determination of the corresponding values of [A] and $\bar{n}_\varepsilon$ for the neodymium glycolate system and a comparison between $\bar{n}_\varepsilon$/[A] and the potentiometrically obtained values of $\bar{n}$/[A].

B. Extinctiometric investigation					
60 Nd	350 ± 50	25 ± 5	~ 20		

As the function $\bar{n}/[A] = f([A])$ is very steep for low values of [A] for the rare-earth glycolate systems, it is not possible to extrapolate $\bar{n}_\varepsilon/[A]$ to [A] = 0 from [A] = 4×10^{-3} M, the lowest value at which $\bar{n}_\varepsilon/[A]$ could be determined. In the computation of the X-function (*cf.* eqn. II(7)), [A] = 0.004 M has been chosen as the inferior limit of the integration

$$\ln \frac{X([A])}{X(0.004)} = \int_{0.004}^{[A]} \frac{\bar{n}_\varepsilon}{[A]} \, d([A]) \qquad (9)$$

In this way $X([A])/X(0.004)$ has been computed. The value of $X(0.004)$ was obtained by extrapolation of the function $X([A])/X(0.004) = f([A])$ to [A] = 0. As $X(0) = 1$ according to eqn. II(5), we have $X(0)/X(0.004) = 1/X(0.004)$. The extrapolation gave $1/X(0.004) = 0.35 \pm 0.03$. After the calculation of the X-function the complexity constants have been computed in the same way as before (Table 5).

The complexity constants have also been computed directly by means of eqn. II(4a) from the values of $\bar{n}_\varepsilon$ obtained for [A] = 4, 6, 15, and 30 mM ($\bar{n}_\varepsilon$ = 0.82, 1.02, 1.37, and 1.82, respectively). Assuming that only three complexes are formed at these low concentrations of the free ligand, we get $\beta_1 = 350$, $\beta_2 = 28 \times 10^3$, and $\beta_3 \approx 2 \times 10^5$, in good accordance with the constants in Table 5.

RESULTS

The complexity constants of the rare-earth glycolate systems are found in Table 5. The stability constants and the ratios for consecutive stability constants are shown in Table 6.

Table 6. The stability constants ($b_1 = \beta_1$, $b_n = \beta_n/\beta_{n-1}$ for $n \geq 2$) and the ratio b_n/b_{n+1} between the consecutive stability constants of the rare-earth glycolate systems.

Yb	520	127	32	2.9	4.1	4.0	11

A comparison between the complexity constants of the glycolate and the acetate systems (Tables II:13 and II:14) shows that the glycolate systems, especially those of the heavier rare earths, are complex to a much higher degree than the corresponding acetate systems.

The complexity constants β_1, β_2 and β_3 of the higher rare-earth glycolates vary with the atomic number of the rare earth in another way than the constants of the corresponding acetates, as shown in Fig. 5. β_1, β_2 and β_3 of the glycolate systems increases from Gd to Yb, contrary to the corresponding constants of the acetate systems.

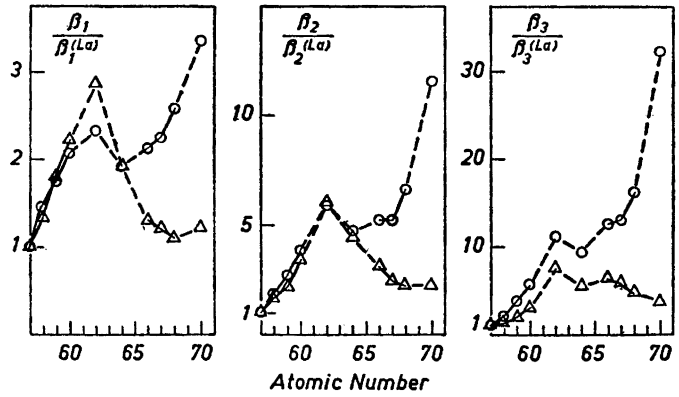

Fig. 5. The variation of β_1, β_2 and β_3 for the acetate and the glycolate systems with the atomic number of the rare earth. In order to facilitate a comparison between the variations of the complexity constants of the two systems, the quotients $\beta_n/\beta_n^{(La)}$ have been chosen as ordinates, $\beta_n^{(La)}$ denotes the complexity constant of the lanthanum system in question. ---- O: the glycolate systems; △: the acetate systems. The symbols have been linked together with a broken line if the complexity system has not been examined for a rare earth lying between them.

Statistical calculations indicate, according to Bjerrum [7], that we ought to have the following relation between the stability constants for systems with simply bound ligands

$$b_1 : b_2 : b_3 : b_4 : b_5 : b_6 = 6 : \frac{5}{2} : \frac{4}{3} : \frac{3}{4} : \frac{2}{5} : \frac{1}{6}$$

It is expected from purely statistical reasons that the quotients b_n/b_{n+1} should have greater values in systems with chelating ligands than in systems with only simply bound ligands, as the chelating ligand leaves fewer sites vacant for coordination, where the next ligand can be bound, than does the simply bound ligand. If the central ion has six octahedrically-arranged coordination sites and if the ligand occupies two adjacent coordination sites, we ought to have, according to Bjerrum [7]

$$b_1 : b_2 : b_3 = 12 : 2 : 1/3$$

The values of b_n/b_{n+1} of the glycolate systems are not so high as six, and moreover they do not differ much from the quotients b_n/b_{n+1} of the corresponding acetate systems. It may, however, be noticed that b_1/b_2 and b_2/b_3 for the glycolate systems of Dy, Ho, Er, and Yb are somewhat higher than the corresponding values for the acetate systems.

Because of the high values of β_n for the glycolate systems relative to β_n for the corresponding acetate systems, although glycolic acid is stronger than acetic acid, it is probable that the glycolate ion acts as a chelating ligand, even if the quotients b_n/b_{n+1} do not have the expected values.

I wish to express my thanks to Professor Sven Bodforss and to Professor Sture Fronæus for their kind interest in this work.

This investigation has been supported by a grant from the *Swedish Natural Science Research Council*, which is gratefully acknowledged.

High Molecular Weight Enzyme Inhibitors

IV. Polymeric Phosphates of Synthetic Estrogens

E. DICZFALUSY, O. FERNÖ, H. FEX, B. HÖGBERG and P. KNEIP

Research Department, AB Leo, Hälsingborg and Hormone Laboratory, Department of Women's Diseases, Karolinska Sjukhuset, Stockholm, Sweden

The preparation and some of the biochemical and pharmacological properties of polydiethylstilbestrol phosphate and of some other polymeric phosphates of closely related synthetic estrogens are described. These compounds are very potent inhibitors of certain enzymes, such as acid and alkaline phosphatases, hyaluronidase and β-glucuronidase.

When injected systemically to spayed mice, the polymeric phosphates studied, especially polydiethylstilbestrol phosphate, exhibited a prolonged duration of estrogenic activity. When administered by the oral route, their estrogenic effect was negligible.

In the third paper of these series, the synthesis and properties of polyestradiol phosphate (P.E.P.) were described [1]. The greatly prolonged estrogenic activity of this compound [2] suggested a study of similar polymers prepared from synthetic estrogens. The synthesis of one of these polymers has previously been reported from our laboratories [3].

In the present paper the polymeric phosphates of diethylstilbestrol [3,4-bis(*p*-hydroxyphenyl)-3-hexene], dienestrol [3,4-bis(*p*-hydroxyphenyl)-2,4-hexadiene], hexestrol [3,4-bis(*p*-hydroxyphenyl)-hexane] and benzestrol [3-ethyl-2,4-bis(*p*-hydroxyphenyl)-hexane] are described. These polymers were prepared practically in the same way as P.E.P. Some of the properties of these compounds are shown in Table 1. In Table 2 the antienzymic activity and the duration of estrogenic action of these compounds are compared with that of P.E.P.

It appears that among the polymers of synthetic estrogens, polydiethylstilbestrol phosphate has by far the most prolonged duration of activity. Therefore the present investigation will mainly deal with this compound. The polydiethylstilbestrol phosphate preparation obtained following phosphorylation with 1.1 mole phosphoryl chloride for 70 h will hereafter be denoted as P.S.P.

a) Calculated on samples free from moisture, pyridine and chlorine.
b) According to B. Baggett *et al.*[14] Calculated as % of 'estrogen oxygens'.
c) Hydrolysis at 100° for 27 h at pH 5.0 (0.1 M acetate buffer).
d) From titration experiments. Results corrected for pyridine and chlorine.

The molecular weight of P.S.P. was found to be about 14 000 (ultracentrifuge) indicating that the polymer contains approximately 40 diethylstilbentrol moieties. The viscometric behavior of P.S.P. was found to be the same as that of P.E.P.[1], that is typical for linear polyelectrolytes.

Hydrolysis experiments with P.S.P. performed in the same way as previously described for P.E.P.[1] seem to indicate that also in this case the liberated inorganic phosphorus is formed from primary phosphoric acid esters only.

Titration experiments indicated that a certain degree of branching occurs (Table 1).

EXPERIMENTAL

A. Preparation of polymers

1. Preparation of polydiethylstilbestrol phosphates. This was carried out practically in the same way as previously described for the preparation of P.E.P. Standard[1]. In the

preparation of different batches the molar ratio $POCl_3$/diethylstilbestrol was varied between 0.8 and 1.2. Dialysis was carried out against dist. water containing 1 % NaCl, and the polydiethylstilbestrol phosphate preparations were precipitated by HCl without any addition of ethanol. Using molar ratios of $POCl_3$/diethylstilbestrol between 0.8 and 1.0 it was found that the mixture had changed into a jelly after 10 to 20 h reaction time. After hydrolysis of these jellies with ice it was necessary to heat on a steam bath for 1—2 h with stirring in order to obtain a clear solution (no inorganic phosphorus was liberated during heating). No jelly formation took place when the molar ratio of $POCl_3$/diethylstilbestrol was higher than 1.0. With a reaction time of 70 h the yields from 5 g diethylstilbestrol varied between 5.5 and 5.7 g of crude polymer. The various polydiethylstilbestrol phosphates were analyzed for moisture, *(in vacuo* 100°; found 1—2 %), pyridine (determined spectrophotometrically after alkalization and distillation; found 1—3 %), chlorine (found 0—0.5 %) and phosphorus (Table 1).

The polydiethylstilbestrol phosphate obtained with 1.1 mole $POCl_3$ and with a reaction time of 70 h (P.S.P.) has a melting range of 195—205°.

Analysis of P.S.P.: Moisture: 1.7 %; pyridine: 2.9 %; chlorine: 0.3 %; P, C and H (calculated on sample free from moisture, pyridine and chlorine): 9.8; 63.1 and 5.8 %, respectively. P.S.P. (free from moisture, pyridine and chlorine) should thus contain 78.3 % diethylstilbestrol. Molar ratio P/diethylstilbestrol: 1.08.

P.S.P. is very soluble in aqueous pyridine, soluble in aqueous alkali, slightly soluble in dry pyridine, ethanol and ethanol-water (1:1) and very slightly soluble in water, dioxane, acetone and chloroform.

2. Polydienestrol phosphate, polyhexestrol phosphate and polybenzestrol phosphate. All these polymers were prepared in the same manner as described for P.S.P. (1.1 mole $POCl_3$, 70 h at room temperature). No jelly was formed.

3. Diethylstilbestrol diphosphate. This was prepared by the method of Miescher *et al.*[4] It was purified over the sodium salt. M.p. 213—215°. [Found: P 14.7 %; equiv. wt 108 (as a dibasic acid) and 105 (as a tetrabasic acid). Calc. for $C_{18}H_{22}O_8P_2$: P 14.5 %; equiv. wt 107.]

Hydrolysis experiments. These were run at 100° between pH 3 and 10 (0.1 M buffer solution) and in 0.2 N sodium hydroxide solution. The rate of hydrolysis was followed by determining the amount of inorganic phosphorus (P_o) liberated. The formation of P_o was most rapid at pH values between 3 and 6, practically all P_o being liberated within 10 h. Practically no P_o was liberated on hydrolysis in 0.2 N NaOH solution.

At pH 5.0 (acetate buffer) the hydrolysis of diethylstilbestrol diphosphate was found to follow a first order reaction with $k = 0.87$ h^{-1}. Under the same conditions when calculated on hydrolyzable phosphorus only (Table 1), the rate of hydrolysis for various polydiethylstilbestrol phosphate preparations was found to be virtually the same. Polydienestrol phosphate, polyhexestrol phosphate and polybenzestrol phosphate were found to have k-values of 0.94, 0.71 and 0.71 h^{-1}, respectively.

Molecular weight, viscosity measurements and potentiometric titration. All these measurements have been carried out in the same manner as previously described for P.E.P. Standard [1]. For P.S.P. the following values were found. In 0.2 M phosphate buffer solution at pH 7.1, $S^\circ_{20} = 1.4 \times 10^{-13}$; $D_{20} = 7.8 \times 10^{-7}$; $V_{20} = 0.69$ *. The molecular weight was calculated to be approximately 14 000. The intrinsic viscosity of the sodium salt was found to be $[\eta] = 0.04$ in 0.25 M NaCl solution at pH 7.3. The amount of primary phosphoric acid esters found in titration experiments corresponded well to the values obtained in hydrolysis experiments (Table 1).

B. Antienzymic properties

The enzymes studied were acid phosphatase, alkaline phosphatase, hyaluronidase and β-glucuronidase. With the exception of the last mentioned enzyme, the experimental conditions and the preparations used have been described in detail in a previous communication [1].

* The estimation of the sedimentation constant has been carried out in the Carlsberg Laboratories, Copenhagen, through the courtesy of Professor K. Linderstrøm-Lang.

Table 2. Some of the biochemical and pharmacological properties of the compounds studied.

No.	Rel. amount (P.E.P. = 1.0) of inhibitor necessary for 50 % inhibition				Duration of estrogenic effect a)

a) Potency is expressed as a percentage of the effect of P.E.P. Standard (Preparation No. 1).
b) Practically unchanged after hydrolysis (27 h, pH 5.0, 100°).
c) When assayed against P.S.P. these compounds show a significant deviation from parallelism. Thus these assays are statistically not valid, and the potency estimates are only approximate values calculated from the results obtained at the same dose levels (5 and 10 μg, respectively). These data are included only to demonstrate that the potency of these compounds is much less than that of P.S.P.

β-Glucuronidase. For the measurement of enzyme activity the liberation of phenolphtalein from 0.0005 M phenolphtalein glucuronide in 0.05 M acetate buffer was estimated by a modification [5] of the method of Talalay, Fishman and Huggins [6]. The volume of the incubation mixture was 1.5 ml and after 30 min at 37° the reaction was stopped and the colour developed by the addition of 5 ml of 0.2 M glycine buffer (pH 10.4).

Enzyme. Bacterial β-glucuronidase was a purified commercial product from Sigma Chemical Co., St. Louis, U.S.A. Another enzyme prepared from the common limpet *(Patella vulgata)* according to the method of Levvy, Hay and Marsh [7] was also used in some of the experiments.

Results. The relative amounts of inhibitors necessary for 50 % inhibition of the enzymes studied are shown in Table 2. In all cases the enzyme inhibition by P.S.P. could be reversed by basic proteins, *e. g.* protamine sulphate. The type of inhibition was studied by preparing classical Lineweaver plots [8]. The results are summarized in Table 3.

Table 3. Type of inhibition of different enzymes studied.

Estradiol-3,17-diphosphate	»	»	»

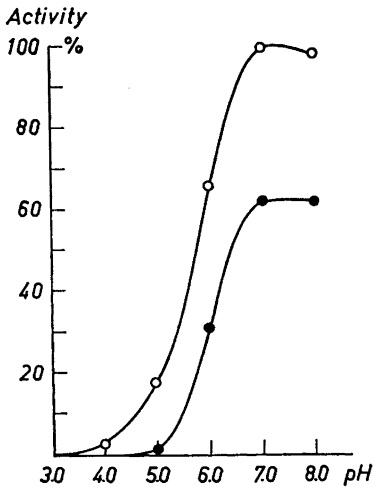

Fig. 1. Hydrolysis of 0.0005 M phenolphtalein glucuronide by bacterial β-glucuronidase (1.15 mg) at various pH values in 0.05 M acetate buffer in the absence (○) and presence (●) of polydiethylstilbestrol phosphate (100 μg P.S.P./1.5 ml).

1. Acid phosphatase. The inhibition of acid phosphatase was studied at pH 4.5 using disodium *p*-nitrophenyl phosphate as a substrate.

It appears from the data of Table 2 that the inhibitory potency of the different polymeric phosphates of synthetic estrogens is of the same order as that of P.E.P. On the other hand, diethylstilbestrol diphosphate is a very poor inhibitor of the enzyme, a fact which is in close agreement with previously reported data on estradiol diphosphate [1]. It is of interest, however, that a commercial diethylstilbestrol diphosphate preparation (Honvan®, Asta-Werke A-G.) exhibited a considerably stronger inhibition than the product synthetized by us.

The inhibition of acid phosphatase by P.S.P. is non-competitive. This is in agreement with previous data on the type of inhibition by P.E.P. On the other hand, diethylstilbestrol diphosphate, and also estradiol-3,17-diphosphate [1] inhibit the enzyme in a substrate-competitive manner.

2. Alkaline phosphatase. The enzyme used was a highly purified commercial product of Sigma Chemical Co., St. Louis, U.S.A., prepared from calf intestinal mucosa. It appears from Table 2 that the polymeric phosphates of synthetic estrogens are much weaker inhibitors of alkaline phosphatase than of acid phosphatase, when compared to P.E.P. It is of interest to note that in contrast to the results obtained with acid phosphatase the inhibition of alkaline phosphatase by diethylstilbestrol diphosphate is of the same order as that by P.S.P. It is also of interest that the use of smaller amounts of $POCl_3$ in the phosphorylation of diethylstilbestrol seems to result in compounds exhibiting a decreased antienzymic activity with regard to alkaline phosphatase, but not to acid phosphatase. The inhibition of alkaline phosphatase by P.S.P. as well as by diethylstilbestrol diphosphate and also by polyhexestrol phosphate is substrate-competitive.

3. Hyaluronidase. It is of interest to note the close correlation between the inhibitory activity of the different compounds on hyaluronidase on the one hand, and on acid phosphatase on the other hand.

4. β-Glucuronidase. The inhibition of bacterial β-glucuronidase by P.S.P. at different pH-values is illustrated in Fig. 1. The same type of curve was obtained when P.E.P. was used as an inhibitor. The schematic curves showing per cent inhibition at pH 7.0 as a function of inhibitor concentration are presented in Fig. 2. Finally Fig. 3 shows the variation in enzymic activity of the limpet β-glucuronidase at different pH-values and the inhibitory effect of P.S.P. and P.E.P. thereupon.

As far as the type of enzyme inhibition is concerned, it was found that all the compounds studied (P.S.P., P.E.P., polyhexestrol phosphate, diethylstilbestrol diphosphate) inhibited the bacterial β-glucuronidase (at pH 7.0) in a competitive manner.

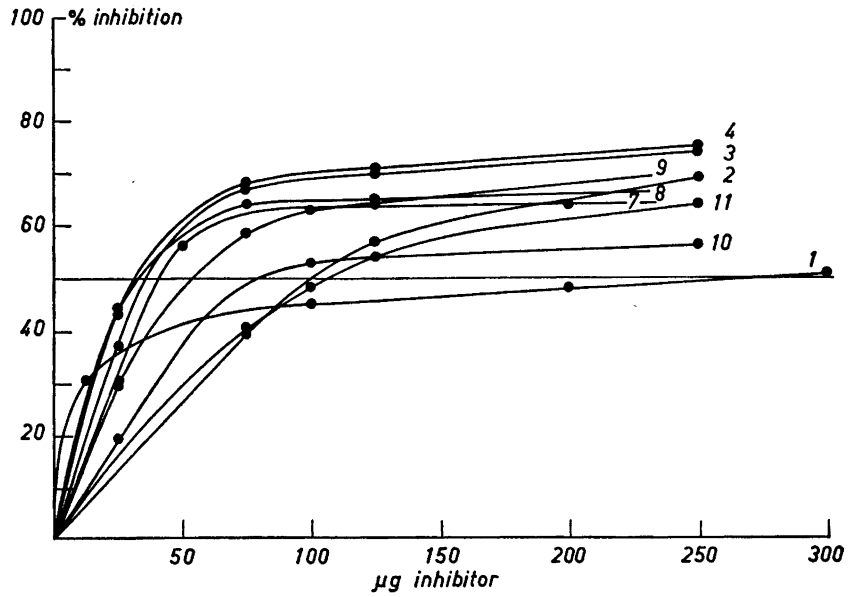

Fig. 2. Per cent inhibition of bacterial β-glucuronidase (1.5 mg) by the substances listed in Table 1. 0.05 M acetate buffer pH 7.0. Substrate 0.0005 M phenolphtalein glucuronide. Incubation time 30 min at 37°.

C. Pharmacological properties

Toxicity. The acute toxicity of P.S.P. was estimated in spayed female mice 48 h following a single intravenous injection. LD 50 was found to be 252 mg/kg, with 95 % fiducial limits of error at 232 and 273 mg/kg, respectively.

When male albino rats were injected intramuscularly with doses up to 10 mg/kg of P.S.P., and sacrificed 10 weeks after the injection, no gross pathological changes could be seen either at autopsy or on microscopical examination, except those attributable to the typical action of an efficient and prolonged estrogen such as decrease in the weight of accessory reproductive organs and gynaecomastia in the highest dosages administered. Thus, the toxicity of P.S.P. seems to be of the same order as that of P.E.P.[1] The low toxicity of P.S.P. suggests that it can probably be administered also to human beings without any major harmful effects.

Biological activity. The duration of action of the various polymeric phosphates was estimated by the use of a previously described method based on the duration of vaginal cornification in spayed mice [9]. The relative potencies of the different compounds when compared to the activity of P.E.P. are summarized in Table 2. It appears from the data of Table 2 that polymeric phosphates prepared from dienestrol, hexestrol or benzestrol exhibit a much shorter duration of estrogenic activity than similar compounds prepared from diethylstilbestrol. It also appears that the commercial preparation of diethylstilbestrol diphosphate (Honvan ®) is virtually devoid of prolonged estrogenic activity. When P.S.P. was hydrolyzed at 100° for 27 h at pH 7.6 (21.2 % P_o liberated), its biological potency remained unchanged. It is also of interest that the polymeric phosphates prepared from dienestrol, hexestrol or benzestrol are much weaker long-acting estrogens than P.S.P. These compounds also exhibit a greatly reduced *anti*-alkaline-phosphatase activity, and a somewhat reduced *anti*-β-glucuronidase activity when compared to P.S.P. However, their effect on hyaluronidase and acid phosphatase appears to be of the same order. It also appears from Table 2 that polyestradiol phosphate and polydiethylstilbestrol phosphate are equipotent long-acting estrogens.

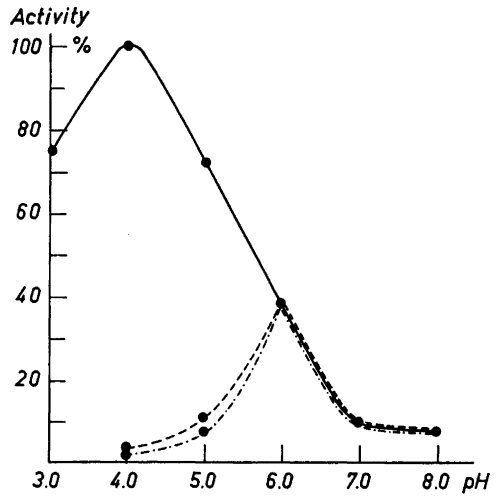

Fig. 3. Hydrolysis of 0.0005 M phenolphtalein glucuronide by limpet β-glucuronidase (112 Fishman units) at various pH values in 0.05 M acetate buffer in the absence and presence of inhibitors; ●——● no inhibitor; ● - - - ● P.E.P. Standard 100 μg/1.5 ml, ● — . — ● P.S.P. 100 μg/1.5 ml. Incubation time 30 min.

Attempts have also been made to estimate the ED 50 of P.S.P. when given orally. The ED 50 of P.S.P. by the oral route was found to be 3.9 mg/kg, that of diethylstilbestrol diphosphate 0.36 mg/kg, whereas that of diethylstilbestrol was 0.1 mg/kg. When P.S.P. was submitted to hydrolysis at 100° for 74 h at pH 6.7 (24.3 % P_o liberated), its ED 50 by the oral route was still 3.6 mg/kg, indicating that previous hydrolysis has very little, if any, effect on the absorption of the P.S.P. molecule.

In other experiments P.S.P. was administered to spayed mice by the oral route in dosages of 5 mg/kg and 10 mg/kg, respectively. Vaginal smears taken from these animals either could not reveal any estrogenic activity, or showed just a very short, transient estrogenic reaction with a mean duration of 0.8 and 1.1 days, respectively. It seems therefore safe to conclude that orally administered P.S.P. is not absorbed to any appreciable extent. These results have also been confirmed in rats using tritium-labelled P.S.P.[10]

DISCUSSION

In a previous communication[1] where the preparation of P.E.P. was described the molar ratio between $POCl_3$ and estradl-1-io7β was kept constant at 1.1. Under those conditions it was found necessary to employ a reaction time of 20 h or more, in order to obtain compounds exhibiting maximally prolonged estrogenic activity. It appears from the data of the present study that a reaction time of 5 h is already sufficient to obtain polydiethylstilbestrol phosphate preparations of maximal activity. It was also found that preparations with maximally prolonged activity could be obtained in all experiments, where the $POCl_3$/diethylstilbestrol ratio was kept between 0.9 and 1.2. Ratios below 0.9 resulted in compounds with diminished activity. On the other hand, highly active non-dialyzable preparations could be obtained even by the use of $POCl_3$/diethylstilbestrol ratios much higher than 1.2.

As to P.E.P. we have already suggested[1] the possibility that the molecular weight of the compound might be considerably lower than indicated by the

results of ultracentrifugation. A similar analysis of the present data seems to speak very much in favour of the possibility that also P.S.P. might occur in form of an association of smaller molecules.

A comparison between polydiethylstilbestrol phosphate and polyestradiol phosphate reveals marked differences as far as the antienzymatic properties are concerned. Whereas the antihyaluronidase or *anti*-acid-phosphatase activities appear to be approximately equal, polydiethylstilbestrol phosphate is a much weaker inhibitor of alkaline phosphatase than polyestradiol phosphate. As far as the inhibition of β-glucuronidase is concerned, the opposite relationship can be observed, polydiethylstilbestrol phosphate being a much stronger inhibitor than polyestradiol phosphate.

The inhibition of acid phosphatase by P.S.P. was found to be non-competitive. It is of interest that Hummel *et al.* found that the inhibition of this enzyme by polyxenyl phosphate is also of the non-competitive type [11].

As to the type of enzyme inhibition by the various compounds the inhibition of alkaline phosphatase by all compounds studied is competitive. This seems to be at variance with previously reported data from our laboratories [12], where the inhibition of kidney alkaline phosphatase by estradiol diphosphate was described as non-competitive. It should be noted. however, that neither the source of enzyme, nor the experimental conditions were identical in the present investigation with those published by Aldman *et al.*[12]

It also appears from the data of the present investigation that the majority of compounds studied are very potent inhibitors of β-glucuronidase. The inhibition is of the substrate-competitive type. This inhibition seems to be of interest in view of the fact that higher amounts of β-glucuronidase have been found in human cancer tissue than in normal tissues [13].

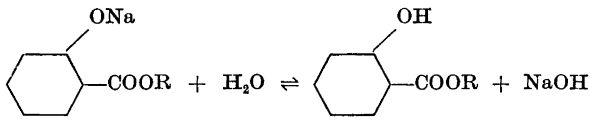
The Hydrolysis of Alkyl Salicylates in Alkaline Solutions

LAURI PEKKARINEN and EERO TOMMILA

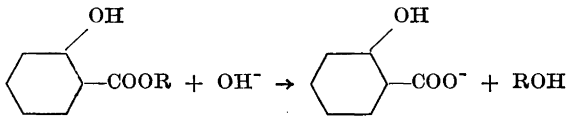
Institute of Chemistry, University of Helsinki, Helsinki, Finland

The alkaline hydrolysis of methyl, ethyl and *iso*propyl salicylates has been investigated in pure water and in various methanol-water, ethanol-water, *iso*propanol-water and acetone-water mixtures at different temperatures. All facts sustain the proposition suggested by Goldschmidt and Scholtz in 1907 that in solutions the reacting substance is the free ester, which is in equilibrium with its ionized form. Beside this reaction, a simple bimolecular process between the ester ion and hydroxyl ion has a subordinate importance. The alkaline hydrolysis of *p*- and *m*-hydroxybenzoates takes place practically solely as a reaction between the ester ion and hydroxyl ion.

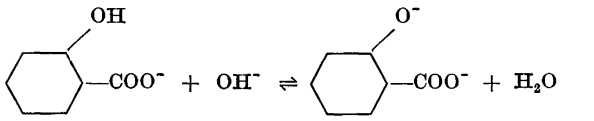
In 1907, Goldschmidt and Scholtz [1] observed that methyl salicylate in alkaline solution undergoes hydrolysis by first-order kinetics. On the basis of Goldschmidt's earlier investigations on the hydrolysis of sodio-acetoacetate [2], they concluded that the reacting substance is not the sodium compound but the free ester with which the former is in equilibrium:



I



II



III

They showed mathematically that this mechanism leads to first-order kinetics. Suppose that a is the initial total concentration of the ester and b that of the alkali hydroxide, ξ the concentration of the free ester and η that of the disodi-

um salt at any instant, and x the decrease in the concentration of the ester after a lapse of time t. Then according to the law of mass action, since the concentration of water can be taken as constant, we have

$$\frac{[\text{Free ester}] \times [OH^-]}{[\text{Ester ion}] \times [H_2O]} = \frac{\xi\ (b+\xi-\eta)}{(a-x-\xi)} = K \qquad (1)$$

The velocity equation is then given by

$$\frac{dx}{dt} = k\xi[OH^-_{\text{A}}] = kK(a-x-\xi) \qquad (2)$$

Taking into account that $\xi \ll (a-x)$, and writing $kK = k_1$, we obtain

$$\frac{dx}{dt} = k_1(a-x) \qquad (3)$$

i.e. an equation of the first order.

There is a considerable body of evidence in support of Goldschmidt's hypothesis. To-day, however, the well-known ability of salicylic acid and its esters to form chelate rings must be taken into account. The purpose of the present investigation is to study this reaction from different points of view and so gain insight into its mechanism. The reaction was investigated with different salicylic esters and under various conditions, and some kinetic measurements were also carried out with ethyl *m*- and *p*-hydroxybenzoates.

EXPERIMENTAL

Esters. The esters were prepared from the corresponding acid and alcohol by the usual method. The salicylic esters were purified by repeated distillation at reduced pressure. Their refractive indices were identical with the best values reported in the literature. The *m*- and *p*-hydroxybenzoates were crystallized from ethanol. Their melting points (72° and 115.2°) agreed with those given in the literature.

The alkali hydroxides were of a high degree of purity. The alkali solutions used were as carbonate-free as possible.

Solvents. The water used in the kinetic experiments was freshly distilled and freed from carbon dioxide by brief boiling. The methanol and ethanol were purified by the method of Walden [3]. The *iso*propanol was treated with solid sodium hydroxide and distilled. Merck's acetone "pro analysi" was used as received.

Method. The reaction vessels and method used in most of the kinetic experiments have been previously described [4]. In general, equal volumes of an a M ester solution and an $(a + b)$ M alkali hydroxide solution were used, so that after mixing the concentration of the ester salt was $a/2$ and that of the hydroxyl ions $b/2$. The reaction was stopped with an excess of 0.02 N HCl and the mixture titrated back with 0.02 N baryta solution, cresol red being used as indicator. For ethyl *m*- and *p*-hydroxybenzoates, however, methyl red was used as indicator, and the titration carried to a standard tint. The experiments at the greatest dilution were conducted in large flasks from which the samples were withdrawn with a pipette. The experiments in methanol-water and ethanol-water at 50° were carried out in sealed ampoules of Pyrex glass and filled with nitrogen. The reaction mixtures were carefully protected from atmospheric carbon dioxide.

The electrically controlled thermostats were constant to within ±0.01°. The thermometers were checked against a thermometer calibrated at the National Bureau of Standards (U.S.A.).

RESULTS AND DISCUSSION

1. The order of the reaction. Goldschmidt's observation concerning the order of the reaction was confirmed. The first-order formula gave a good constancy for k, as is exemplified by the following run (solvent: water; [sodium salt of the ester] = [NaOH] = 0.04 mole/l; temperature 25°):

Time, min.	50	82	100	120	144 ½	195	272	346
Change, %	19.0	29.5	34.5	38.5	45.5	55.5	68.5	76.5
10^7 k, s^{-1}	725	710	705	680	700	690	700	697

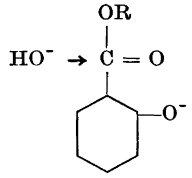
Moreover, within the limits of experimental error, in dilute solutions, the time of half completion of the reaction is independent of the initial concentrations, as the following figures show (water, 25°):

$[C_6H_4(ONa)COOEt]$ = [NaOH], mole/l	0.001	0.0025	0.005	0.01	0.02	0.04
t, min.	175	174	171	165	168	165

For the alkaline hydrolysis of ethyl *p*-hydroxybenzoate ion and ethyl *m*-hydroxybenzoate ion, the second order formula always gave a good constancy for k.

The results obtained with the ester salts are summarised in Tables 1—3.

2. The mechanism of the reaction. As already mentioned, many facts are in conformity with the reaction mechanism proposed by Goldschmidt according to which the reaction occurs between the free ester and hydroxyl ion. As is easily seen, a reaction between the ester ion (or chelate) and hydroxyl ion would exhibit second-order kinetics. The experimental results, however, as we have seen, reveal that the reaction follows a first-order rate law. In fact, the free charge on the oxygen atom of the ionized phenol group in the *ortho*-position generates a large negative charge on the carbonyl carbon in the ester ion, and this causes a very powerful repulsion between this carbon atom and the attacking hydroxyl ion:



This results in a high activation energy and small reaction velocity. A similar case occurs in the alkaline hydrolysis of ethyl *p*-hydroxybenzoate [5]. In the case of the ethyl *m*-hydroxybenzoate, the negative charge on the carbonyl carbon is less, because only the inductive effect is operative, and the effect on the activation energy is correspondingly weaker. The values in pure water [6] and in 56 % aqueous acetone [5] are seen from the following figures:

	Water			*56 % acetone*		
	10^4k_{25}	E cal	log A	10^4k_{25}	E cal	log A

In the case of the *ortho*-compound, owing to the close proximity between the charged oxygen atom and the carbonyl carbon, the repulsion of the hydroxyl ion must be still greater than in the case of the *para*-compound. Further, the electromeric displacement $C{=}\overset{\curvearrowright}{O}$ will be somewhat hindered by the direct field effect of the charged oxygen atom. Thus the bimolecular reaction between the salicylate ion and hydroxyl ion must be very slow. This is clearly seen from the following argument. If we assume that part of the salicylic ester is hydrolysed by the Goldschmidt mechanism and part changed by a bimolecular reaction between the ester ion and hydroxyl ion, the total rate equation is, instead of (3)

$$dx/dt = k_1'(a-x) + k_2[OH^-](a-x) \quad (4)$$

or

$$dx/dt = (k_1' + k_2[OH^-])(a-x) \quad (5)$$

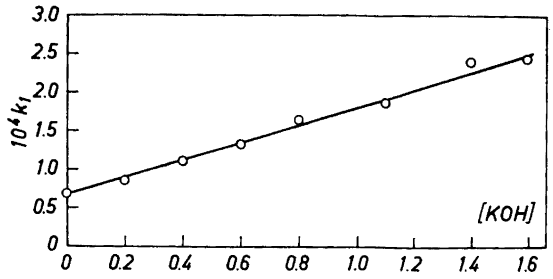

Fig. 1. Plot of k_1 *vs.* KOH in water at 25°.

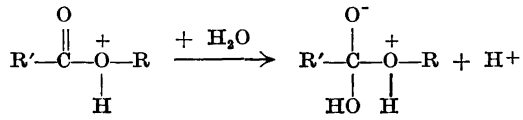
If the alkali is used in sufficient excess, the hydroxyl ion concentration remains practically constant during the reaction and the experimental rate constant, k_1, is

$$k_1 = k_1' + k_2[OH^-] \quad (6)$$

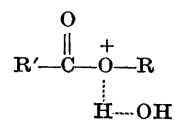
Accordingly, k_1 as a function of the hydroxyl ion concentration should yield a straight line. Fig. 1 shows that this is indeed the case. From the slope of this straight line we obtain for the bimolecular reaction in pure water at 25° $k_2 = 1.1 \times 10^{-4}$ litre mole^{-1} s^{-1}. The corresponding value for ethyl *p*-hydroxybenzoic ester ion is 2.63×10^{-4} litre mole^{-1} s^{-1}. The result shows that, beside the hydrolysis of the free ester, the bimolecular reaction between the salicylic ester ion and hydroxyl ion also takes place, although its velocity is low. The result is further interesting in that it shows that the velocity of this reaction is of the same order of magnitude as that of the *para*-compound and also that the relation of the rate constants is in the direction to be expected. The experiments were carried out with potassium hydroxide, since in this case the salt effect is at a minimum (Section 3).

Any possible role played by chelate formation is treated in Section 3.

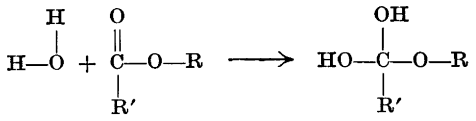
Apart from Goldschmidt's mechanism, a "water hydrolysis" would also display first-order kinetics. It is now generally accepted that the acid-catalyzed hydrolysis begins with primary addition of a proton to the ethereal oxygen, and this step is followed by addition of hydroxyl from the water to the carbonyl carbon, which is now less negative,



In the case of "water hydrolysis", the first step could correspondingly be assumed to be the transfer of a proton from the water to the ethereal oxygen,

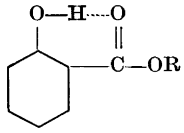


after which the reaction would proceed as in the acid-catalyzed hydrolysis. This mechanism, however, and likewise one with primary addition of water to the carbonyl group *cf.* [7],



is excluded by the fact that the acid-catalyzed hydrolysis of ethyl salicylate is extremely slow [8].

The bimolecular rate constant for the reaction $C_6H_4(OH)\cdot COOEt + OH^-$ in water at 25°, calculated from the measured first-order rate constant ($k_1 = 69.2 \times 10^{-6}$ s^{-1}) and the ionization constant of ethyl salicylate (log $K = -10.5$)[9], is $k_2 = 0.23$ l mole^{-1} s^{-1}. The corresponding value for methyl salicylate ($k_1 = 78.1 \times 10^{-6}$ s^{-1}, log $K = -10.19$) is $k_2 = 0.51$ l mole^{-1} s^{-1}. For ethyl benzoate in water at 25°, $k_2 = 0.0293$ [6]. As a comparison, it may be mentioned that the bimolecular rate constants for ethyl *o*-, *m*- and *p*-nitrobenzoates [5] in water at 25°, estimated from the measurements in 56 % acetone and supposing that the effect of the change of solvent is about the same as for ethyl benzoate [6], are $k_2 = 0.12$, 1.5 and 2.5, respectively. In the same manner, for ethyl *p*-chlorobenzoate and ethyl *p*-bromobenzoate we obtain $k_2 = 0.13$ and $k_2 = 0.15$, respectively. In 50 % ethanol the values at 25° are: ethyl salicylate ($k_1 = 22.2 \times 10^{-6}$ s^{-1}, log $K = -11.6$)[9] $k_2 = 0.0089$, ethyl benzoate $k_2 = 0.0017$ l mole^{-1} s^{-1}. We see that the unionized phenyl group acts as a rather powerful electron-attracting substituent. No doubt also the internal hydrogen bond formation [11]



which makes the carbonyl carbon more positive, plays an important role here. However, it is noteworthy that ethyl lactate, in which internal hydrogen bond formation is very weak [11], is hydrolysed much faster [12] than ethyl propionate [13] or ethyl acetate [14].

The ionization constants of the ethyl esters of *m*- and *p*-hydroxybenzoic acids are appreciably larger (log $K = -9.1$ and -8.3, respectively [9]) than that of ethyl salicylate (log $K = -10.5$). This implies that the concentration of the free ester in their alkali salt solutions is much less than that in the salicylate solutions. Further, as mentioned above, the reaction of the free salicylic ester is favoured by internal hydrogen bond formation. We have also seen that the reaction between the ions of *m*- and *p*-hydroxybenzoic esters and hydroxyl ion is less hindered than in the case of salicylate. The result is that the esters of the *m*- and *p*-isomerides undergo alkaline hydrolysis mainly by a simple bimolecular process between the ester ion and hydroxyl ion.

In one experiment with water as solvent equal equivalents of the ester and sodium hydroxide were mixed, [ester] = [NaOH] = 0.02 mole/l, 25°. The result was as follows:

Time, min.	52.5	82	118	160	260	287	320	361	420
Change, %	18.5	27.0	35.5	44.5	61.5	65.0	68.5	72.5	77.5
$10^5 k_1$, s^{-1}	6.50	6.40	6.20	6.11	6.11	6.10	6.01	5.94	5.93

As is seen, first-order kinetics are approximately obeyed in this case also. Since the ester is a very weak acid, the solution now contains a considerable concentration of the free ester and hydroxyl ions:

$$C_6H_4(O^-)COOR + H_2O \rightleftharpoons C_6H_4(OH)COOR + OH^-$$

Consequently, ξ in eqn. (2) cannot now be ignored; the neglect of ξ in the calculations has caused a small continuous decrease in the rate constant and also made its value somewhat less than the value obtained in the presence of excess of alkali ($k_1 = 6.92 \times 10^{-5}$ s^{-1}, Table 1). Thus this result of Goldschmidt and Scholtz has likewise been confirmed.

The experimental activation energies and frequency factors, as given in Tables 1—3, are strikingly high. Their values, as is shown by the data given on p. 1021, are remarkably higher than the corresponding values for the reaction between hydroxyl ion and ethyl *p*-hydroxybenzoate ion or ethyl *m*-hydroxybenzoate ion. However, we must bear in mind that the activation energies, E_a given in Tables 1—3 are only apparent, as the rate constants from which they are obtained include the change of the equilibrium constant K of eqn. (1) with change in temperature. We have

$$\frac{\mathrm{d}\ \ln\ k}{\mathrm{dT}} = \frac{E}{RT^2} \quad \text{and} \quad \frac{\mathrm{d}\ \ln\ K}{\mathrm{d}T} = \frac{\Delta H}{RT^2}$$

Thus, if E and ΔH are independent of temperature,

$$\ln k_{\mathrm{exp.}} = -E_a/RT + \ln A \text{ and } \ln K = -\Delta H/RT + \ln B$$

where k_{exp} is the experimental rate constant and E_a the (apparent) activation energy calculated from its dependence on temperature; ln A and ln B are integration constants. From (p. 1020) follows that

$$k_{\mathrm{exp.}} = k_1 = kK,\ \ln\ k = \ln\ k_1 - \ln\ K = -(E_a - \Delta H)/RT + \ln\ (A/B)$$

or

$$k = (A/B)e^{-(E_a - \Delta H)RT} \tag{7}$$

We see that the true activation energy for the bimolecular reaction between the free ester and hydroxyl ion is

$$E' = E_a - \Delta H \tag{8}$$

The values of ΔH for the reaction I are not known, but it is, perhaps, legitimate to assume that they do not differ essentially from those for phenol. For phenol (log K = —9.92), *e.g.* in ethanol-water mixtures, the values of ΔH are seen from the following table [15]:

wt. % of EtOH	0	20	50	80	95
ΔH, kcal	7.20	8.15	5.40	4.42	3.20
E', ethyl salic., kcal	11.3	10.5	14.8	16.3	17.4
E, ethyl benz., kcal	12.7	11.5	15.7	17.2	19.1

If the values of ΔH are substracted from E_a given in Table 1, the figures in the third line are obtained for ethyl salicylate. These values are of the same order of magnitude as those found for the alkaline hydrolysis of ethyl benzoate [6]. Furthermore, in accordance with the fact that the unionized phenol hydroxyl acts as an electron-attracting substituent, the activation energy for ethyl salicylate is somewhat smaller than that for ethyl benzoate in the same solvent. Corresponding results are obtained in other cases:

Methyl salicylate in methanol-water

wt. % of MeOH	0	20	50	95
ΔH for phenol, kcal	7.20	6.57	3.60	1.40
E', kcal	11.7	12.7	16.5	19.7

Iso*propyl salicylate in* iso*propanol-water*

wt. % of *i*-PrOH	0	20	50	80
ΔH for phenol, kcal	7.20	9.25	6.70	5.17
E', kcal	11.1	8.8	14.5	15.6

From the values of k_2 calculated on p. 1025 log A can also be estimated for reactions in pure water and in 50 % ethanol. The values obtained are 7.65 and 8.80, respectively. The values of log A for the alkaline hydrolysis of ethyl benzoate in the same solvents are 7.76 and 8.70, respectively. The result is very striking, for it is known that in the alkaline hydrolysis of ethyl benzoates the substituents exert their main influence on the rate of the reaction through changes in the activation energy, whereas the frequency factor often remains almost constant if the reactions are carried out in exactly the same solvent. All this is in excellent agreement with earlier experiences concerning esterhydrolysis. However, it must be reiterated that the results are based on the assumption that ΔH for salicylates is equal to that for phenol in the same solvent.

The reaction mechanism propounded obtains additional support from the fact that if the values of E' are plotted against the composition of the solvent, the graphs have the form usual for alkaline ester hydrolysis; for instance, they pass through a minimum, except in the case of methanol-water [13,14,16] (Fig. 2). On the other hand, if E_a is plotted against the composition of the solvent, the curves have a decidedly different shape.

3. Salt effects. The dependence of the rate constants of the alkaline hydrolysis of ethyl *m*- and *p*-hydroxybenzoates on the initial concentration of the reactants in water at 25° is seen from the following experimental data obtained in reaction mixtures prepared by mixing equal volumes of a $2a$ molar ester solution and a $4a$ molar sodium hydroxide solution:

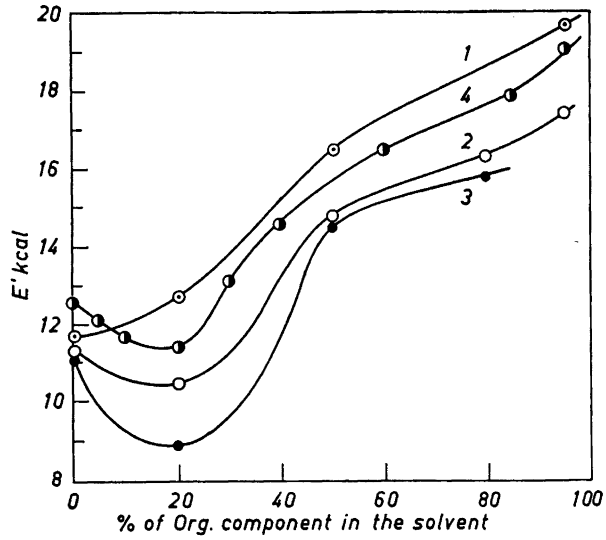


Fig. 2. Variation of the activation energy E' with the composition of the solvent.
1. Methyl salicylate in methanol-water
2. Ethyl salicylate in ethanol-water
3. *Iso*propyl salicylate in *iso*propanol-water
4. Ethyl benzoate in ethanol-water.

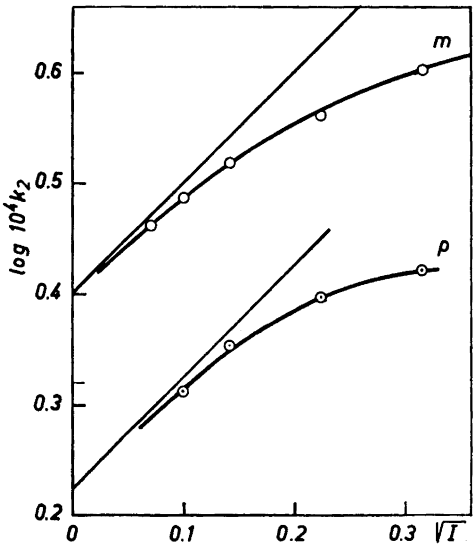

Fig. 3. Influence of the ionic strength I on the rate of the alkaline hydrolysis of ethyl *m*- and *p*-hydroxybenzoates.

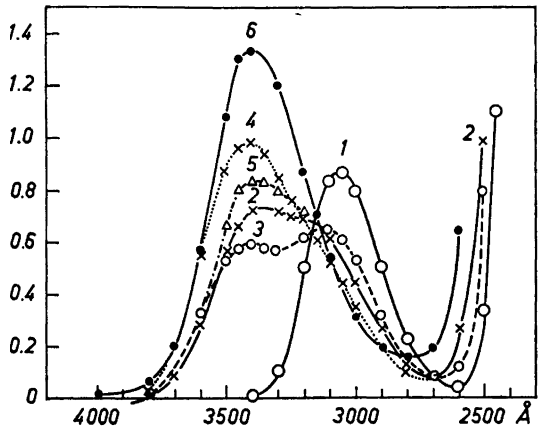

Fig. 4. Absorption curves, 95 wt. % ethanol, 1 cm cell. *1.* $c_{est.} = 0.0002$; *2.* $c_{est.} = 0.0002$, $c_{KOH} = 0.002$; *3.* $c_{est.} = 0.0002$, $c_{LiOH} = 0.0004$; *4.* $c_{est.} = 0.0002$, $c_{LiOH} = 0.0004$, $c_{LiCl} = 0.0023$; *5.* $c_{est.} = 0.0002$, $c_{NaOH} = 0.0016$, $c_{NaI} = 0.0013$; *6.* $c_{est.} = 0.0002$, $c_{NaOH} = 0.15$, $c_{NaI} = 0.09$.

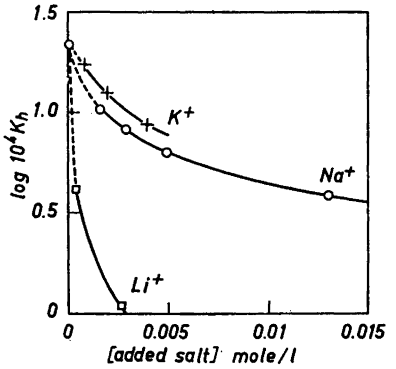

Fig. 5. The relative hydrolysis constants of the ester as a function of salt concentration.

a	0.0025	0.005	0.01	0.025	0.05
$\sqrt{I}$	0.071	0.1	0.142	0.224	0.316
m-, 10^5 k, 1 mole^{-1} s^{-1}	290	307	331	365	402
p-, 10^5 k, 1 mole^{-1} s^{-1}		20.5	22.6	25.0	26.3

Fig. 3 shows that these values approximate to the equation

$$\log k = \log k_0 + 1.02\, z_A z_B \sqrt{I}$$

in a manner which shows that we have here a reaction between two univalent ions of the same sign. Thus this result also shows that the reaction takes place between the ester ion and the hydroxyl ion.

In the hydrolysis of alkyl salicylates the rate constants are only very slightly dependent on the initial concentration of the reactants, as is seen from Tables 1—3. (The effect of excess alkali concentration has been treated in Section 2). An increase in salt concentration always decreases the reaction velocity (Table 1). In water the salt effect is very weak, except in the case of lithium salts. In 95 % ethanol, for the initial concentration 0.02 mole/l of the ester and alkali, the rate constant at 50° is 30.2×10^{-6} s^{-1} when KOH is used and 15.4×10^{-6} s^{-1} when NaOH is used. The lithium ion reduces the reaction rate still more than the sodium ion. A very interesting point is that in aqueous alcohol even at a relatively low lithium ion concentration the reaction becomes sensitive to hydroxyl ions, and as the lithium salt concentration increases the reaction finally approaches one of second-order rate.

In general, addition of alkali metal ions shifts the equilibrium (I) towards the left, which causes a decrease in the reaction velocity. This shift of the equilibrium was spectrometrically verified with a Beckman spectrophotometer. Some typical absorption curves are presented in Fig. 4. The relative hydrolysis constants, K_h, of the ester as a function of salt concentration are graphically represented in Fig. 5. As is seen, the effect of lithium ion is much greater than that of potassium or sodium ions. This corresponds to the greater effect of the lithium ion on the reaction velocity *.

One possible explanation of the powerful effect of the lithium ion is that owing to its small size this ion can be fitted between the charged oxygen and the oxygen of the carbonyl group in the salicylic ester, thus forming a chelate. Chelate formation should render the carbonyl carbon more positive and also facilitate the electrometric displacement $C=\overset{\frown}{O}$ and thus facilitate the bimolecular reaction between the ester ion and hydroxyl ion. Thus chelate formation on the one hand reduces the part of the ester changed by the Goldschmidt mechanism, and on the other hand increases the amount changed by the reaction between the ester ion and hydroxyl ion.

* The maximum for the salt form is shifted towards longer wave lengths in the order K, Na, Li, and furthermore, the extinction is greatest for the Li compound and weakest for the K compound. This was taken into account in estimating the concentration of the salt form.

Short Communications

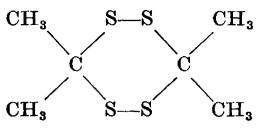
Reactions between Ketones and Ammonium Polysulphide

BENGT MAGNUSSON

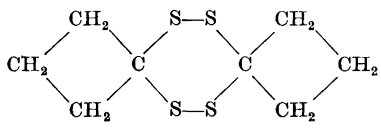
Chemical Institute, University of Uppsala, Sweden

Duplodithioacetone (I) and related compounds have been prepared by the reaction of a ketone and excess of aqueous ammonium polysulphide [1,2]. Asinger obtained 5- and 6-membered rings by allowing the carbonyl compound to react with elementary sulphur and an amine, saturated with hydrogen sulphide [3,4]. The author found that duplodithioacetone was obtained without disturbing byproducts by running the reaction in alcohol-water solution at about +4°C for one to two days. As this is a way to avoid resinous material, attempts were made with other ketones under the same conditions.

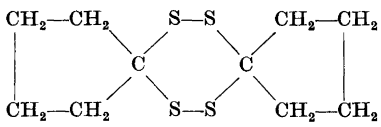
With *cyclo*hexanone white crystals were obtained, which were recrystallized from a mixture of chloroform and ethanol. However, the purified product was not the expected duplodithio*cyclo*hexanone (IV) obtained by Fredga [2] but a compound with the composition of (V), bis-4,4,7,7-pentamethylene-1,2,3,5,6-pentathiepane. Such a pentathiepane (VI) was first obtained by Fredga from *cyclo*heptanone and ammoniumpolysulphide [2].



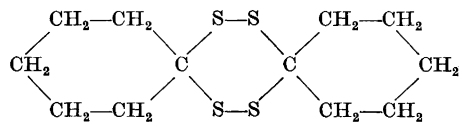
I



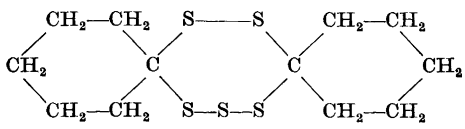
II



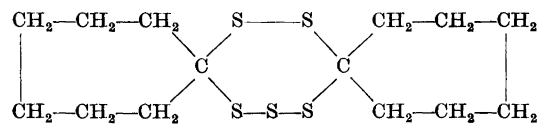
III



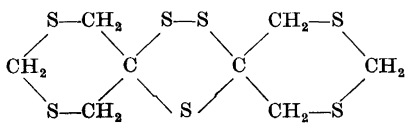
IV



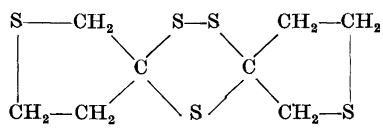
V



VI



VII



VIII

*Cyclo*pentanone gives (III) after reaction in alcoholic or aqueous solution.

*Cyclo*butanone gives the compound (II) in aqueous solution [5].

1,3-Dithian-5-on and 3-ketothiophane give five-membered rings (VII, VIII) of the type obtained by Asinger [3,4] in aqueous and alcohol-water solutions, respectively.

From the results it is apparent that the ring size is greatly dependent on the reaction conditions and the starting materials. More experiments to obtain 6-membered and larger rings are planned; results will be reported at a later date.

Experimental. Duplodithioacetone (3,3,6,6-tetramethyl-1,2,4,5-tetrathiane) (I). In a 300 ml Erlenmeyerflask 45 ml of acetone was mixed with 100 ml of ethanol and cooled to +4°C. A cooled solution of ammonium polysulphide (prepared by dissolving 20 g of ammoniumchloride in 77 ml of 2.5 M Na_2S_2) was added. The flask was closed, shaken for a minute and left in a refrigerator at about 0°C for 3 days. The crystals were then separated, washed with water to dissolve inorganic salts, dried and recrystallized 3 times from ethanol. In the first recrystallisation some Norit was added to remove colloidal sulphur. 6.57 g of duplodithioacetone with a m.p. of 94°—95° was found. On dilution of the motherliquor with water roughly 0.6 g of inpure tetrathiane was obtained.

Bis-,4,4,7,7-pentamethylene-1,2,3,5,6-pentathiepane (V). In a 200 ml Erlenmeyer flask 4 g of *cyclo*hexanone was dissolved in 100 ml of ethanol and was allowed to react with ammonium disulphide as described above. The crude material (4.74 g) was recrystallised several times from chloroform and ethanol. Colourless flakes with m.p. 85°—87°C were obtained. The product is readily soluble in chloroform, carbontetrachloride and benzene. (Found: C 44.05, 44.29, 44.80; H 5.90, 6.53, 6.24; S 49.17, 49.20; Mol. wt: 316, 316. Calc.for $C_{12}H_{20}S_5$: C 44.40; H 6.21; S 49.39; Mol. wt: 324.6).

The author is greatly indebted to Professor Arne Fredga for suggesting the present work, for stimulating discussions and for some starting materials. Thanks are further due to Dr. Göran Bergson and to Dr. Sven-Olov Lawesson for valuable advice during the preparation of this manuscript.

Mass Spectrometric Demonstration of Extensive Replacement of Hydrogen by Deuterium During Catalytic Deuteration of Methyl Oleate, Methyl 9,10-Dibromostearate, and Methyl 12-Chlorostearate

NGUYEN DINH-NGUYEN

Department of Medical Biochemistry, University of Gothenburg,

and RAGNAR RYHAGE

Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm, Sweden

In connection with work on the determination of the position of double bonds in unsaturated fatty esters by mass spectrometric analysis [1], methyl stearate obtained by catalytic deuteration of methyl oleate over Adams' platinum catalyst at room temperature was submitted to analysis. The high-mass end of the mass spectrum reproduced in Fig. 1 shows clearly that deuterium has entered the chain not only in position 9,10. Instead of a single molecule-ion peak at $m/e = 300$ and its isotope-peak, corresponding to the entrance of two deuterium atoms, we have a whole series of molecule-ion peaks, the intensities of which decrease in a regular manner with increasing mass number. It is evident from Fig. 1 that molecules of mass 330 have been present. In these molecules all hydrogen atoms except six have been replaced by deuterium. This extensive replacement is probably closely related to the double bond shifts which are known [2] to occur during catalytic hydrogenation of olefins. Exchange reactions with the saturated hydrocarbon chain seems excluded, as no deuterium could be detected in methyl stearate which had been submitted to the same treatment as methyl oleate above.

Attempted replacement of bromine by deuterium in methyl 9,10-dibromostearate, using Adams' platinum catalyst, failed until sodium carbonate was added, and then gave a debrominated ester with mass spectrum practically identical with that of the ester obtained by catalytic deuteration of methyl oleate. A reaction similar to the debromination of vicinal dibromides by zink to give olefins [3,4] is probably involved.

*Cyclo*pentanone gives (III) after reaction in alcoholic or aqueous solution.

*Cyclo*butanone gives the compound (II) in aqueous solution [5].

Mass Spectrometric Demonstration of Extensive Replacement of Hydrogen by Deuterium During Catalytic Deuteration of Methyl Oleate, Methyl 9,10-Dibromostearate, and Methyl 12-Chlorostearate

NGUYEN DINH-NGUYEN

Department of Medical Biochemistry, University of Gothenburg,

and RAGNAR RYHAGE

Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm, Sweden

In connection with work on the determination of the position of double bonds in unsaturated fatty esters by mass spectrometric analysis [1], methyl stearate obtained by catalytic deuteration of methyl oleate over Adams' platinum catalyst at room temperature was submitted to analysis. The high-mass end of the mass spectrum reproduced in Fig. 1 shows clearly that deuterium has entered the chain not only in position 9,10. Instead of a single molecule-ion peak at $m/e = 300$ and its isotope-peak, corresponding to the entrance of two deuterium atoms, we have a whole series of molecule-ion peaks, the intensities of which decrease in a regular manner with increasing mass number. It is evident from Fig. 1 that molecules of mass 330 have been present. In these molecules all hydrogen atoms except six have been replaced by deuterium. This extensive replacement is probably closely related to the double bond shifts which are known [2] to occur during catalytic hydrogenation of olefins. Exchange reactions with the saturated hydrocarbon chain seems excluded, as no deuterium could be detected in methyl stearate which had been submitted to the same treatment as methyl oleate above.

Attempted replacement of bromine by deuterium in methyl 9,10-dibromostearate, using Adams' platinum catalyst, failed until sodium carbonate was added, and then gave a debrominated ester with mass spectrum practically identical with that of the ester obtained by catalytic deuteration of methyl oleate. A reaction similar to the debromination of vicinal dibromides by zink to give olefins [3,4] is probably involved.

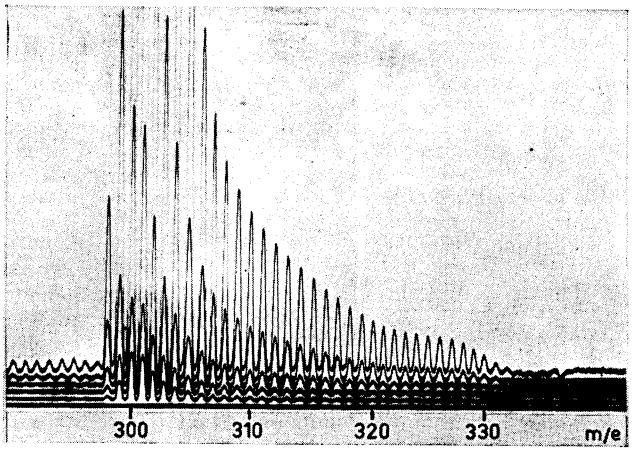

Fig. 1. High-mass end of mass spectrum of catalytically deuterated methyl oleate.

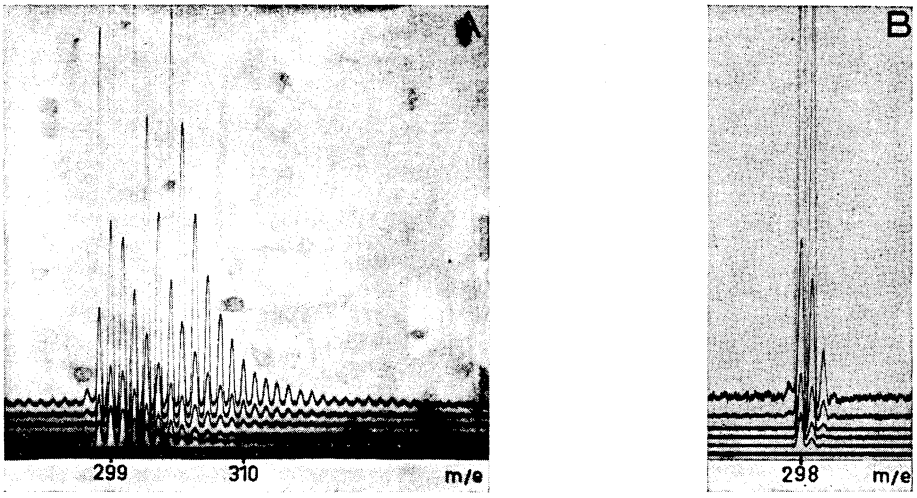

Fig. 2. A) High-mass end of mass spectrum of catalytically deuterated methyl 12-chlorostearate; B) High-mass end of mass spectrum of methyl stearate.

Deuteration of methyl 12-chlorostearate over Adams' platinum catalyst gave a dehalogenated ester without the use of sodium carbonate. The high-mass end of the mass spectrum of the ester is reproduced in Fig. 2A and shows that the molecule-ion peak at $m/e = 299$, corresponding to the replacement of chlorine by deuterium, is followed by about sixteen molecule-ion peaks of decreasing intensity. Molecules where deuterium have replaced nearly half the number of hydrogen atoms in the hydrocarbon chain have therefore been present.

Full details will be published later.

The Deswelling Action of Hydrazine on Nitrile Rubber

SVEN SÖNNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

In a previous paper [1] an outline was given of the primary and side reactions taking place when hydrazine or hydrazine hydrate reacts with linear homopolymers of acrylonitrile. Favourable conditions were found in homogeneous systems, as indicated by gel formation and disappearance of the strong infrared band at 2 260 cm^{-1}, measuring the amount of nitrile groups in the sample. The primary polymer particle does not show this high degree of accessibility, but insolubilization occurs in both cases due to formation of interlinking units between macromolecules. The interlinking structural unit is 4-N-amino-1,2,4-triazole.

Such a reactivity is not found in copolymers of acrylonitrile and butadiene. Still more, *solubility* is limited already by the formation of microgel in the growing polymer particle at increasing degree of conversion during polymerization. Standard nitrile rubber latex with an acrylonitrile content of 37—40 % dissolves in acetone, *cyclo*hexanone or dioxane, yet with difficulty. The last mentioned solvent, however, shows a low solvent power, why phase separation instantly takes place when hydrazine is added (three phases!). Acetone and *cyclo*hexanone are obviously unsuitable due to their reactivity.

A convenient way to study the action of an aqueous solution of hydrazine hydrate on the polymer is simply to add said reagent into a nitrile rubber latex with a low particle size. Commercial grades of butadiene-acrylonitrile latices are available for this purpose, *e. g.* Hycar Latex 1561, showing a medium particle size of 500 Å. The change of solubility characteristics can be observed at arbitrary intervals by casting a rubber film, preferably at reduced pressure or in a stream of dry nitrogen, followed by thorough washing in distilled water, soaking in acetone (if possible) and drying at 80°C in an inert atmosphere before use.

The weight swelling ratios of such a rubber film in a selected series of swelling agents is shown in Table 1. The degree of swelling is — rather arbitrarily — measured after an immersion time of 24 h in a large excess of liquid.

Table 1. Weight swelling ratios of nitrile rubber films, prepared at room temperature from a latex showing a solid content of 0.25 $g.ml^{-1}$. Conc. of hydrazine hydrate: 0.85 $g.ml^{-1}$. All samples preextracted in acetone at room temperature and dried at 80°C one hour before use. Time of reaction in the rubber latex: 24 h. Grade of nitrile rubber: High acrylonitrile content (37—40 %), density in pure state 1.00, medium particle size 500 Å.

The Deswelling Action of Hydrazine on Nitrile Rubber

SVEN SÖNNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

In a previous paper [1] an outline was given of the primary and side reactions taking place when hydrazine or hydrazine hydrate reacts with linear homopolymers of acrylonitrile. Favourable conditions were found in homogeneous systems, as indicated by gel formation and disappearance of the strong infrared band at 2 260 cm^{-1}, measuring the amount of nitrile groups in the sample. The primary polymer particle does not show this high degree of accessibility, but insolubilization occurs in both cases due to formation of interlinking units between macromolecules. The interlinking structural unit is 4-N-amino-1,2,4-triazole.

Such a reactivity is not found in copolymers of acrylonitrile and butadiene. Still more, *solubility* is limited already by the formation of microgel in the growing polymer particle at increasing degree of conversion during polymerization. Standard nitrile rubber latex with an acrylonitrile content of 37—40 % dissolves in acetone, *cyclo*hexanone or dioxane, yet with difficulty. The last mentioned solvent, however, shows a low solvent power, why phase separation instantly takes place when hydrazine is added (three phases!). Acetone and *cyclo*hexanone are obviously unsuitable due to their reactivity.

A convenient way to study the action of an aqueous solution of hydrazine hydrate on the polymer is simply to add said reagent into a nitrile rubber latex with a low particle size. Commercial grades of butadiene-acrylonitrile latices are available for this purpose, *e. g.* Hycar Latex 1561, showing a medium particle size of 500 Å. The change of solubility characteristics can be observed at arbitrary intervals by casting a rubber film, preferably at reduced pressure or in a stream of dry nitrogen, followed by thorough washing in distilled water, soaking in acetone (if possible) and drying at 80°C in an inert atmosphere before use.

The weight swelling ratios of such a rubber film in a selected series of swelling agents is shown in Table 1. The degree of swelling is — rather arbitrarily — measured after an immersion time of 24 h in a large excess of liquid.

Table 1. Weight swelling ratios of nitrile rubber films, prepared at room temperature from a latex showing a solid content of 0.25 $g.ml^{-1}$. Conc. of hydrazine hydrate: 0.85 $g.ml^{-1}$. All samples preextracted in acetone at room temperature and dried at 80°C one hour before use. Time of reaction in the rubber latex: 24 h. Grade of nitrile rubber: High acrylonitrile content (37—40 %), density in pure state 1.00, medium particle size 500 Å.

Dimethylsulfoxide	4.73

A glance at the figures in Table 1 makes evident that the degree of swelling is qualitatively related to the molar volume of the solvent and its specific interaction coefficient with parent polymer. Such a

relation is strictly valid for isotropic swelling of nonionic networks, why an obvious conclusion would be to anticipate the existence of some kind of crosslinking, at least partly responsible for swelling behaviour. As a pure thermal curing reaction at the carbon-carbon double bonds must be excluded at the low temperature in question, only two cases can be considered, *viz.*

a. Reaction between hydrazine hydrate and nitrile groups at the polymer-water interface.
b. Formation of a highly active redox system between hydrazine hydrate and activator residues, capable of initiating a continued polymerization (crosslinking) to a low extent.

Said types of reaction are mutually independent but cooperate in reducing the degree of swelling of the copolymer. As the parent polymer itself shows only a moderate affinity to solvents cited above, a very slight degree of crosslinking or reduction of the number of solvogenic groups would be sufficient to produce a gel fraction. In fact the infrared spectrum of cured rubber films gives no definite information of chemical changes but a new band at 3 250 cm^{-2}, possibly due to formation of amide groupings.

An increase of reaction temperature to 80°C, as well as a prolonged time of curing, does not principally change the swelling behaviour. This remarkable insensitivity would be unintelligible if the curing effect were solely caused by a propagating chain reaction within the polymer particles, initiated by free radicals at the polymer-water interface. It is easily demonstrated that addition of a reactivating system, such as potassium persulphate-sodium pyrosulphite to a rubber latex, buffered with sodium carbonate-sodium bicarbonate, causes a gradual deswelling of the polymer due to crosslinking at the carbon-carbon double bonds. The rate is dependent of temperature and concentration of initiator. Analogous experiments on emulsions of butadiene-styrene copolymer have been reported [2].

Scope of reaction in anhydrous systems. A carefully purified and dried rubber film reacts with anhydrous hydrazine at elevated temperature. A gradual deswelling takes place at 80°C, as seen from Table 2. The rate of deswelling rapidly decreases after 24 h. The reaction is too slow at room temperature to be practically applicable.

Table 2. Weight swelling ratios of nitrile rubber films, prepared at room temperature, purified in water, dried in a current of carbon dioxide, cured in a large excess of anhydrous hydrazine at 80°C. Swelling agent: dioxane. Temperature of swelling: 20.0°C.

Time of curing, h	Weight swelling ratio, g/g
12	4.32
24	3.74
48	3.45
72	3.24
120	3.18
144	3.00
168	2.94

The cured films were not preextracted in acetone before use, because a preliminary test revealed no significant amount of soluble polymer. Remaining hydrazine in the samples was removed by soaking in methanol, followed by drying *in vacuo* for 48 h. During this drying operation a distinct pink color is gradually developed in the specimens. The intensity is related to the time of curing. This color formation is wellknown from the reaction between hydrazine and homopolymers of acrylonitrile [1].

Deswelling of a rubber film merely by heating in air at the actual temperature gives a limiting swelling ratio of 10.27 after 168 h (preextracted sample). A blank, heated in dry carbon dioxide gas in the same way, is too readily redispersed in the swelling agent to be used for quantitative measurements. Even an immersion of a film in 0.1 M potassium persulphate solution for an identical period gives a moderate decrease of swelling (weight swelling ratio = 7.92, preextracted sample). It is apparent that contributions from chemical reactions between polymer and hydrazine are of primary importance in reducing swellability. Work is continued to find more favourable working conditions, as infrared spectra also in this case give but scanty information on the extent of conceivable reactions.

Syntheses of Some Thiolacetic Acid Derivatives [1]

II. Phenyl- and 1-Naphthylthiolacetic Acids

BERTIL SJÖBERG

Högre Tekniska Läroverket, Malmö, Sweden

Phenylacetic acid has earlier been prepared by Johnson [2] from phenylacetyl chloride and a water solution of potassium hydrosulfide. Johnson describes the acid as an oil but gives no physical data. Sakurada [3] reports the synthesis of phenylthiolacetic acid from the O-ethyl ester of the phenylthiolacetic acid through hydrolysis with an alcoholic solution of potassium hydroxide. Sakurada, however, describes the acid as yellow crystals, which definitely must be wrong (see below). 1-Naphthylthiolacetic acid does not seem to have been prepared before.

In our investigation of the plant growth activity of some thiolacetic acids [4,5] these two acids seemed to be of interest and therefore were prepared. Phenyl- and 1-naphthylacetic acids were transformed to the corresponding acetyl chlorides by phosphorus pentachloride in carbon tetrachloride solution. The acid chlorides were thoroughly purified by vacuum distillation and then reacted with sodium hydrosulfide in water solution. Both thiolacetic acids were purified by vacuum distillation and the 1-naphthylthiolacetic acid was recrystallized as well. The physical data for the acetyl chlorides and the thiolacetic acids are given in Table 1.

The infra-red spectra of the phenylthiolacetic acid in a solution of carbon disulfide (Fig. 1) and of the 1-naphthylthiolacetic acid in KBr (Fig. 2) have been recorded.

Experimental results. Preparation of phenylacetyl chloride 45 g phenylacetic acid dissolved in 180 ml carbon tetrachloride was mixed with 70 g phosphorus pentachloride (equiv.amount) at 60°C. After completed reaction the carbon tetrachloride was distilled off. By vacuum distillation we obtained at 92–98°C and 7 mm Hg 40 g phenylacetyl chloride (yield 78 %). The product was redistilled at 90–92°C and 7 mm Hg. (Found: Cl 22.5. Calc. for C_8H_7OCl: Cl 22.9.)

Preparation of phenylthiolacetic acid. 31 g phenylacetyl chloride was slowly added to a sodium hydrosulfide solution (20 g sodium hydroxide dissolved in 150 ml water and saturated with hydrogen sulfide) at 70°C. After about an hour the reaction solution was cooled to room temperature and filtered. After acidifying with hydrochloric acid the precipitated oil was extracted with ether. The ether was dried with anhydrous sodium sulfate and distilled. At 90–93°C and 2 mm Hg we obtained 22 g phenylthiolacetic acid (59 %). The acid was further purified by distillation at 92°C and 2 mm Hg. (Found: S 20.9; equiv.wt. 151.0. Calc. for C_8H_8OS: S 21.06; equiv.wt. 152.22.)

Preparation of 1-naphthylacetyl chloride. 30 g 1-naphthylacetic acid (from PAL. Ltd, London, M. P. 132.3–132.7°C) dissolved in 110 ml carbon tetrachloride was reacted with 37 g phosphorus pentachloride as described above. At 152°C and 4 mm Hg 26 g 1-naphthylacetyl chloride was obtained (yield 79 %). (Found: Cl 18.1. Calc. for $C_{12}H_9OCl$: Cl 17.3.)

Preparation of 1-naphthylthiolacetic acid. 25 g 1-naphthylacetyl chloride was reacted with sodium hydrosulfide in the same way as phenylacetyl chloride. By acidifying after completed reaction a yellow oil was obtained, which was washed with water. By drying in vacuum the oil crystallized. The yield of crude 1-naphthylthiolacetic acid was 23 g (94 %). The acid was distilled in vacuum at 170–173°C and 1 mm Hg. Recrystallization from chloroform-petroleum ether gave light yellow crystals with m. p. 59.6–60.2°C. (Found: S 15.5; equiv.wt. 204.7. Calc. for $C_{12}H_{10}OS$: S 15.85; equiv.wt. 202.28.)

Ternary Complex Formation of Fatty Acids and Fatty Acid Amides with Horse Liver Alcohol Dehydrogenase-Coenzyme Complexes

ALFRED D. WINER* and HUGO THEORELL

Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

In 1955 Theorell *et al.*[1] concluded from reaction velocity constant measurements that formate reacts with the ADH—DPN ** complex but not with ADH—DPNH and suggested that it enters into the binding site for ethanol in ADH—DPN. More recent studies by Theorell and Winer [2] have shown that while formate has a small effect on D_{red}, it exerts a very strong effect on D_{ox} and suggested that the effect of formate depends on the formation of a ternary ADH—DPN-formate complex.

Since the fluorometric method appeared to offer a very rapid procedure for scanning the effects of potential inhibitors on both D_{ox} and D_{red} it was decided to investigate the effects of other saturated fatty acids. All fatty acids studied (C_1—C_{20}) form ternary complexes with ADH—DPN and compete with the ethanol binding site. It is possible to calculate the dissociation constants describing the effects of ADH-fatty acid, $K_{E,I}$, ADH—DPN-fatty acid, $K_{EO,I}$, and ADH-fatty acid-DPN, $K_{EI,O}$. The formation of fluorescent ternary complexes of ADH—DPNH-amides is also reported and it is suggested that these complexes, just as the fluorescent lactic dehydrogenase-DPNH-anion complexes recently described by Winer and Schwert [3], are similar in structure to the activated complex involved in the conversion of ADH—DPNH-aldehyde to ADH—DPN-alcohol.

Experimental. Fluorometric measurements of emission spectra and the calculation of dissociation constants have been previously described [2,4] and were made at 23.5°C in 0.1 ionic strength phosphate buffer, pH 7.03. Pure crystalline ADH was prepared as described earlier [3]. DPN and DPNH were commercial products from the Sigma Chemical Company. Fatty acids, C_1—C_8, were reagent grade chemicals further purified by distillation under suitable pressures; C_{10}—C_{20} acids were gifts of Professor E. Stenhagen and solubilized after lyophilization of the potassium salts. Amides were Eastman Kodak products.

Discussion and results. Long chain saturated fatty acids exhibit very strong ternary complex formation with ADH—DPN. The dissociation constant for the ternary complex, ADH—DPN-fatty acid, $K_{EO,I}$, decreases from 2 800 μM for formate to 0.7 μM for C_{15} fatty acid. While the dissociation constant for fatty acid and ADH, $K_{E,I}$, decreases from 40 000 μM for formate to 6 μM for C_{15} acid, the dissociation constant reflecting the effect of DPN on the ADH-fatty acid complex, $K_{EI,O}$, is rather constant at about 5 μM to C_{11} acid and then increases to 2—7 times this value from C_{11}—C_{15}. The ability of the fatty acids to form complexes of the type EI and EIO disappears abruptly from C_{16} and upwards but the dissociation constant reflecting the formation of ternary complex, $K_{EO,I}$, remains constant at about 25 μM from C_{16}—C_{20}. The formation of ADH—DPN-fatty acid results in a further quenching of the ADH—DPN emission spectra measured at 350 mμ when activated at 289 mμ. The acids show no effect on the ADH—DPNH emission spectra when measured and activated at the same wave lengths. From initial velocity measurements of the enzymatic reaction obtained kinetically, the acids compete with ethanol for the same binding site.

The corresponding fatty acid amides form fluorescent ternary complexes with ADH—DPNH but not with ADH—DPN. A representative emission spectrum with acetamide in shown in Fig. 1. The curve labelled ADH—DPNH-acetamide was obtained when acetamide at a final concentration of 0.2 M was added to ADH and DPNH present at the concentrations used for the other curves. While the wave length of maximum emission for ADH—DPNH is shifted to 450 mμ, the wave length for the ternary complex, ADH—DPNH-acetamide, is shifted to 440 mμ.

---

* U.S. Public Health Service Research Fellow of the National Institute of Neurological Diseases and Blindness, 1958—60.

** Abbreviations. ADH—DPN and ADH—DPNH, ½ molecule of horse liver alcohol dehydrogenase (E) and oxidized (O) or reduced (R) diphosphopyridine nucleotide, respectively; D_{ox}, the dissociation constant of ADH—DPN; D_{red}, the dissociation constant of ADH—DPNH; I, fatty acid or fatty acid amide.

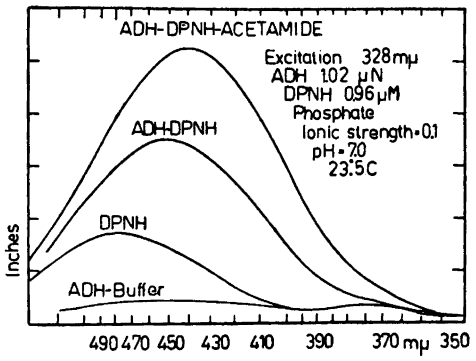

Fig. 1.

Similar wave length shifts have been observed with the lactic dehydrogenase-DPNH-carboxylic acid ternary complexes [3]. The lower amides, through *iso*butyramide, fluoresce more intensely than the ADH—DPNH complex, but higher molecular weight amides, though actually quenching, to varying extents, the fluorescence of ADH—DPNH, still exhibit the wave length shift. By analogy with kinetic experiments with formate [1], it is presumed that the very strong ternary complex formation observed with the longer chain amides has its effect on the "off" velocity of the ternary complex. The dissociation constants of the ternary complex, ADH—DPNH-amide, $K_{ER,I}$, and the ADH-amide complex, $K_{E,I}$, vary from 5 000 μM and 50 000 μM, respectively, for acetamide to 11 μM and 160 μM, respectively, for *n*-hexamide. $K_{EI,R}$ varies from 0.05 μM for acetamide to 0.02 μM for *n*-hexamide. From emission spectral data at 350 mμ the amides show a further quenching of the ADH—DPNH fluorescence when the ternary complex is formed. No effect, however, is seen with the ADH—DPN complex. As indicated by initial velocity measurements, the amides compete for the aldehyde binding site.

Ternary complex formation with the longer chain amides and acids is a logical consequence of the substrate specificity studies on liver ADH with different aldehydes and alcohols recently reported by one of us (A.D.W.) [6]. If it is considered that aldehydes and amides, and alcohols and acids, in this system, function as structural analogs, there is strong suggestion that the ADH—DPNH-amide and ADH—DPN-fatty acid complexes, in which no net reaction can occur, represent abortive complexes formed between ADH, DPNH, aldehyde and ADH, DPN, alcohol.

The complete data will be given in a forthcoming paper in this journal.

Isolation of Palustric Acid from the Oleoresins of North-European Pine and Spruce by Partition Chromatography

HENRIK H. BRUUN, STEIN GÅSLAND and GUNNAR LUNDQVIST

Institute of Wood Chemistry, Åbo Akademi, Åbo, Finland

Partition-chromatographic analyses of the resins of North-European (Scotch) pine, *Pinus silvestris*, and (Norway) spruce, *Picea abies*, have shown that these contain palustric acid. Palustric acid was discovered in 1954 by Loeblich, Baldwin and Lawrence in the gum and wood rosins of two American pine species, *Pinus palustris* and *Pinus caribaea* [1]. The acid has subsequently been isolated from the rosin of a further American pine, *Pinus elliotti*, and from gum rosin, wood rosin and tall oil rosin isolated from this species [2]. The acid has also been found as a component in tall oil rosin from North-European pine (Bruun and Gåsland [3,4]), but has not yet been isolated from the natural rosins of North-European tree species or other non-Ameri-

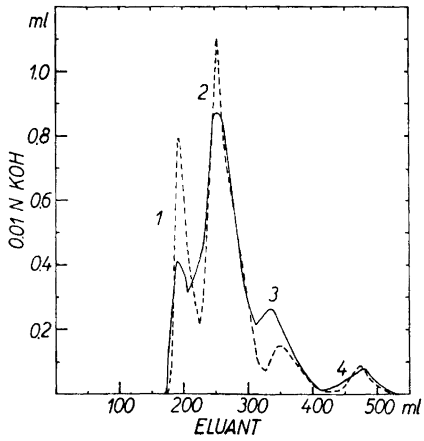

Fig. 1. Chromatogram of the rosin acids in the oleoresins of North-European pine (———) and spruce (— — —). Ordinate gives consumption of 0.010 N alcoholic potassium hydroxide in the titration of 5-ml eluent volumes employing phenolphthalein as indicator. Peak 1 contains palustric acid. For the compositions of the other peaks, see text.

can species. Similarly as other abietic acids, palustric acid may be transformed by isomerization into other rosin acids and may also be formed by similar molecular rearrangements from other rosin acids, for instance, from levopimaric acid by heat treatment [1,5].

Experimental. The analyzed samples consisted of rosin that had recently oozed from the trunks of 60-year-old living trees of pine and spruce from which the bark had been removed to increase the oleoresinous exudation. The acid value of the pine rosin was 125 mg and that of the spruce rosin 110 mg of potassium hydroxide per g, which figures indicate that the samples contained 67 and 59 % rosin acids (based on an assumed mean equivalent weight of 302). The respective saponification values were 137 and 124 mg of potassium hydroxide per g.

In order to obtain correct analytical data on the rosin acid contents of the natural, unchanged rosins, the samples were chromatographed without prior separation of the rosin acids from other components, primarily terpenes, present in the samples. These latter components were not found to cause any difficulties in the chromatographic analyses.

The chromatographic analyses were performed according to Ref.[1] with aminopyridine and furfuryl alcohol as the immobile phase on silicic acid and *iso*octane as the eluent. For details, see Ref.[3]

Results. The chromatograms of the pine and spruce resins are reproduced in Fig. 1. Each chromatogram exhibits four peaks. The peak volumes and peak areas are given in Table 1.

According to our earlier studies [3] peak 1 consists of palustric acid, peak 2 may include pimaric acids, *l*-abietic acid and levopimaric acid, peak 3 contains *neo*abietic acid and peak 4 dehydrogenated rosin acids.

In order to confirm the identity of the acid in peak 1, the respective eluant fractions were combined, the *iso*octane removed by reduced pressure, and the resulting acid dissolved in acetone and reprecipitated with *cyclo*hexylamine [6]. A sample of palustric acid was also precipitated as its *cyclo*hexylamine salt under the same conditions. The *cyclo*hexylamine salts, which were isolated in a yield of 85—90 %, were dissolved in optically pure alsolute ethanol and the ultraviolet absorption spectra of the solutions recorded. The recorded ultraviolet spectra (Fig. 2) showed that the *cyclo*hexylamine salts of the acids in peak 1 of pine and spruce were identical with the spectrum for the *cyclo*hexylamine salt of the sample of palustric acid. The specific extinction coefficient (a) for the latter salt at 265—266 mμ is 25.0, while the value

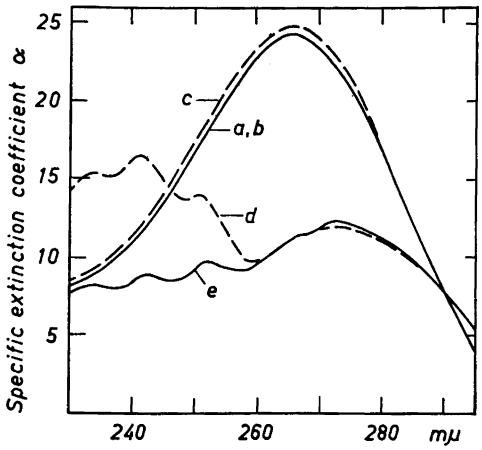

Fig. 2. Ultraviolet absorption spectra of palustric acid (in form of its *cyclo*hexylamine salt) isolated by partition chromatography from oleoresins of North-European pine (*a*) and spruce (*b*) and the spectrum of the *cyclo*hexylamine salt of a palustric acid sample (*c*). Curves *d* and *e* gives the absorption spectra of the *cyclo*hexylamine salts of the acids in peak 2 (in Fig. 1) from pine and spruce respectively. The specific extinction coefficients α were calculated to refer to the acids rather than to the salts.

of very pure palustric acid reported by Loeblich, Baldwin and Lawrence [1] is 30.1. This implies that the palustric acid sample we have employed as reference compound contained 83 % palustric acid. (The ultraviolet spectrum of the latter acid in absolute ethanol gave the same value for the specific extinction coefficient.) The palustric acid content of the pine resin was thus 15 % and that of the spruce rosin 21 % of the total rosin acids in the sample. Palustric acid hence represents a major component in the rosin of North-European pine and spruce. The palustric acid content is higher in the spruce rosin than in any pine species, where its content has been found to vary between 7 and 12 % (see Ref.[2]).

We have also isolated by *cyclo*hexylamine precipitation the acids in peak 2 and determined the ultraviolet absorption of the precipitate in absolute ethanol. The recorded spectrum for the acids in peak 2 for pine rosin (Fig. 2d) exhibits a maximum absorption, $\alpha = 16.6$, at 241 mμ and another, $\alpha = 12.0$, at 272 mμ. These maxima are characteristic for *l*-abietic and levopimaric acids, respectively; the absorption values indicate that the *l*-abietic acid content in peak 2 for the pine is about 18 % or 11 % of the total rosin acid fraction and the levopimaric acid content in the same peak is 63 % or 37 % of the total rosin acid fraction (in these calculations the contribution of levopimaric acid to the α-value of *l*-abietic acid has been taken into account). The corresponding values of α for spruce (Fig. 2 e) are 9.0 and 12.4, which imply that the abietic acid content is 7.5 %, or 4.5 % of the total rosin acids, and the levopimaric acid content 65 %, or 39 % of the total rosin acids. In American pine species [2] the abietic acid content is near 10 % and the levopimaric acid content between 24 and 31 %. The distribution of rosin acids in the oleoresin of the North-European spruce thus differs essentially, particularly with respect to palustric acid, but also with respect to abietic acid, from that in the pine species.

The authors are indebted to Dr. E. L. Patton, Naval Stores Research Station, Olustee, U.S., for the sample of palustric acid. One of us (H.B.) has received a grant from the *State Commission for Natural Sciences of Finland* and one (S.G.) a grant from the *Royal Norwegian Council for Scientific and Industrial Research.* This aid is gratefully acknowledged.

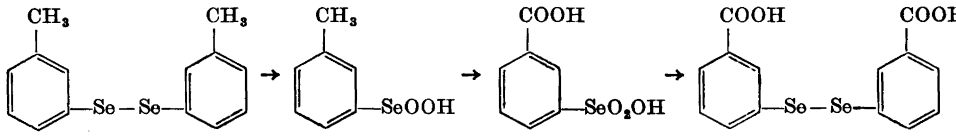
Diphenyldiselenide-3,3'-dicarboxylic Acid

ARNE FREDGA and
CHRISTINA EVERTSDOTTER

Chemical Institute, University of Uppsala, Uppsala, Sweden

The diphenyldiselenide-2,2'-dicarboxylic acid is easily obtained from diazotised anthranilic acid and alkali diselenide [1]. The 4,4'-isomer has been prepared in the same way [2] and also *via* the 4-selenocyanobenzoic acid [3], but all attempts to obtain the 3,3'-compound (IV) from diazotised 3-aminobenzoic acid have failed [2,4]. It is known that the corresponding sulphur compounds behave in the same manner, but here the 3,3'-isomer is easily obtained from 3-chlorosulphonyl-benzoic acid [5].

As the isomeric diphenyldiselenide-dicarboxylic acids and their methyl esters were needed for spectrochemical studies, we have tried to prepare the 3,3'-isomer by the following route:



(I) (II) (III) (IV)

The difficulty is to oxidise the methyl group without loss of selenium and destruction of the molecule. It was found that careful oxidation with permanganate on a small scale and subsequent reduction with tin and hydrochloric acid gave the desired acid (IV) in very good yield. It was not necessary to isolate the intermediate III.

The methyl ester was easily obtained from the acid and diazomethane.

Experimental: The *3,3'-ditolyldiselenide (I)* was prepared from 3-tolylmagnesium bromide and elementary selenium. The procedure of Foster [6] was followed with some minor modifications. The compound was obtained as an orange-coloured oil, which did not crystallise even after standing at −15°C for 8 months.

3-Tolylseleninic acid (II) was obtained by oxidation of the diselenide with perhydrol in ethereal solution according to Mc Cullough and Gould [7].

Diphenyldiselenide-3,3'-dicarboxylic acid (IV). In a 250 ml three-necked flask, fitted with a stirrer, a reflux condenser and a dropping funnel, was placed a solution of 2.03 g 3-tolylseleninic acid and 0.85 g sodium hydrogen carbonate in 30 ml of water. A solution of 2.99 g potassium permanganate in 45 ml of water was added dropwise with stirring, after which the solution was heated gently for 15 min. 5.08 g of solid potassium permanganate were then added, and the stirring and gentle heating continued for 1 h. The excess permanganate was then destroyed by adding 20 ml of ethanol. The manganese oxides were filtered off and washed with water. The combined filtrates were then concentrated to 100 ml and heated with 10 g tin and 100 ml concentrated hydrochloric acid. A current of air was passed through the solution to oxidise any selenol groups which might have been formed. The acid separated as a yellow microcrystalline powder which was filtered off, dissolved in sodium hydrogen carbonate solution, and reprecipitated with hydrochloric acid. The yield was nearly quantitative. M. p. 238° (decomp.). (Found: Se 39.4. Calc. for $C_{14}H_{10}O_4Se_2$: Se 39.47.)

Dimethyl diphenyldiselenide-3,3'-dicarboxylate. 1.0 g acid was dissolved in 50 ml of ether, and an ethereal solution of diazomethane was added drop by drop until nitrogen was no longer evolved. The ether was evaporated and the residue recrystallised from methanol. The ester was obtained as small yellow needles. M. p. 74—75°. (Found: Se 36.8. Calc. for $C_{16}H_{14}O_4Se_2$: 36.88.)

On the Transfer of L-5-Vinyl-2-thiooxazolidone from the Rumen to the Milk

ARTTURI I. VIRTANEN, MATTI KREULA and MARTTI KIESVAARA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

When the method for microdetermination of goitrogenous L-5-vinyl-2-thiooxazolidone (VTO) was further developed in this laboratory, it was found that this compound disappears from the milk even at low temperatures*. This disappearance takes place in different milk samples with varying speed. If the milk is heated immediately after milking, no disappearance occurs even within several days at low temperature. Also at room temperature retention is then fairly good for one day. Kreula and Kiesvaara will present the analytical method for determination of VTO both in cruciferous plants and in milk in this journal.

Taking the above observations on the retention of VTO in milk into consideration, we have made numerous feeding experiments with cows fed with green turnip rape, green rape, and marrow kale. The results showed that VTO is transferred to the milk in very small amounts [1]. When a cow was fed with 15 kg of marrow kale twice a day, 5 μg of VTO per litre was found in the milk (daily milk production 6 l). Altogether 0.05 % of the total amount of VTO formed in marrow kale (2.2 mg of VTO per kg fresh plants) was transferred to the milk. In another experiment in which 10 kg of green rape (28 mg of VTO per kg fresh plants) was once fed per cow to a group of four cows (milk production 12 h after the feeding was 5 l per cow), 27 μg of VTO per litre was found in the milk. Also in this case 0.05 % of the total VTO in fodder was transferred to the milk.

When 500 mg of crystalline VTO was fed to a cow, and the cow was milked 2, 6.5, 10.5, 24, and 48 h after feeding, the following amounts of VTO were found in the milk (Table 1).

The experiment showed that VTO is very rapidly transferred from the rumen to the milk. In milk samples taken 24 h after feeding, VTO could not be found with certainty in the milk. Of the 500 mg crystalline VTO fed, about 0.05 % was found in the milk. It is remarkable that the same percentage of VTO is transferred to the milk, on the one hand when the cow is fed with green plants which contain the glycoside from which VTO is formed in the rumen, and on the other hand when feeding crystalline VTO.

In another feeding experiment 1.6 g of the precursor (glycoside of 2-hydroxy-3-butenyl*iso*thiocyanate compound isolated from rape seeds) of VTO was fed to a cow. Only traces of VTO could be found in the milk. The results show that the glycoside is not appreciably hydrolyzed in the rumen without the enzyme present in cruciferous plants. The quantitative, or almost quantitative, enzymatic hydrolysis of the glycoside in the rumen by the influence of the enzyme present in

* Later it has been noticed that the VTO reappears in the milk on treatment with H_2S.

Table 1. Transfer of VTO from rumen to milk when the cow is fed with 500 mg of crystalline VTO. The feeding took place immediately after morning milking, and the cow was then milked after the hours given in the table.

	Before VTO feeding	After 2 h	6.5 h	10.5 h	24 h	48 h
VTO content of milk μg/l	0	190	35	17	possibly traces	0
VTO transferred to milk, % of total fed	—	0.035	0.013	0.006		
			0.054			

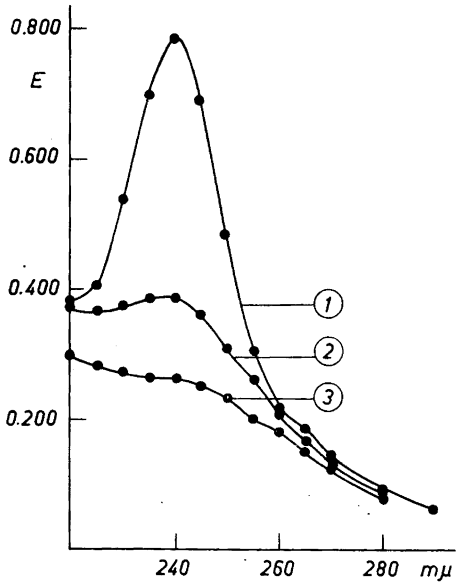

Fig. 1. UV-spectra of VTO in cow's milk after feeding of 500 mg of crystal VTO. The curves show the relative values after 2 h (1), 6.5 h (2), and 48 h (3).

the plants in question is supported by these results.

The earlier performed feeding experiment with 0.5 kg of crushed moistened rape seeds, whereby so large an amount of VTO as 4.5 g could be formed in the seeds, gave a negative result as to the transfer of VTO to the milk [2]. The result probably partly depended on that the milk came to stand unheated for several hours before the analysis. Another cause may, however, be the physiologically abnormally large amount of VTO which could be formed in the rape seeds fed. This unfavourable effect was shown by the fact that the cow lost her appetite for some days after the feeding. A new experiment with 100 g of crushed moistened rape seeds in which 900 mg of VTO could be formed, showed that 12 h after feeding the milk sample contained 100 μg of VTO per litre. 0.07 % of the total amount of VTO formed in the crushed seeds was thus transferred to the milk.

On the basis of the experiments performed, it can be said that about 0.05 % of the VTO present in the fodder, or formed in it during chewing and in the rumen, regularly seems to be transferred to the milk. When feeding cows on farms with green cruciferous plants, the amount of VTO can hardly exceed 100 μg of VTO per litre of milk. It is therefore not very likely that the cruciferous plants in the feeding of cows could increase the VTO content of the milk to such a degree that the milk could cause disturbances in the functioning of the thyroid gland of man. The problem requires a thorough elucidation, however. Investigations on the presence of substances which possibly disturb the functioning of the thyroid gland, in plants used by man and animals, as well as on their mode of action, are in progress in this laboratory.

New Syntheses of 3-Bromothiophene and 3,4-Dibromothiophene

SALO GRONOWITZ

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

3-Bromothiophene is a key intermediate in the preparation of 3-substituted thiophenes [1]. It has been obtained from 2,3,5-tribromothiophene by removal of the α-bromines through the Grignard, entrainment method [2] with ethyl bromide as the auxiliary halide or through halogen metal interconversion with *n*-butyllithium [3]. In both cases the metal-organic compounds were hydrolyzed with water. It has also been obtained from 4,5-dibromo-2-thiophenecarboxylic acid through simultaneous debromination and decarboxylation with copper powder in quinoline [4].

Zinc-dust in acid media is a classical reagent for the removal of halogen and has been used for the preparation of alkanes from alkyl halides [5]. It appears however, that this reagent has been considered rather unspecific and therefore has not been used for selective dehalogenation of polyhalogen compounds. The effectiveness of this reagent is evident from the results of Bak *et al.*[6] They reduced 3-iodo- and 3,4-diiodothiophene to the corresponding deuterated thiophenes in 75 min at 100°C using Zn-dust in CH_3COOD and D_2O.

For other investigations 2,3- and 2,4-dideuterothiophene were needed [7]. It was, however, found that when the corresponding bromine compounds were subjected to dehalogenation with Zn-dust in acetic acid under conditions similar to Bak's only small yields of the desired dideuterated compounds were obtained [7]. The main products (70—80 %) were the corresponding deuterated 3-bromothiophenes. With ordinary acetic acid 3-bromothiophene free from the 2-isomer was obtained.

This prompted the present author to investigate the possibility of obtaining isomer-free 3-bromothiophene from 2,3,5-tribromothiophene and 3,4-dibromothiophene from tetrabromothiophene. It was also found that refluxing 2,3,5-tribromothiophene with Zn-dust in acetic acid gave an 80 % yield of 3-bromothiophene free from the 2-isomer (< 0.5 %). This fact was established by the absence in the product's IR-spectrum of the very strong 2-bromothiophene absorption band [2] at 10.25 μ.

It is interesting to note that in the dehalogenation of tetrabromothiophene under similar conditions a 65 % yield of 3-bromothiophene and only 10 % of 3,4-dibromothiophene was obtained. The IR-analysis proved the absence of other isomeric bromothiophenes. These results indicate that one β-bromine facilitates the removal of another. By changing the experimental conditions it was, however, possible to obtain 3,4-dibromothiophene in 68 % yield.

This preparation of 3-bromothiophene is more convenient and gives better yield than earlier methods.

Experimental. 3-Bromothiophene. To a mixture of 55 g of 2,3,5-tribromothiophene, 32 ml of acetic acid and 100 ml water, 65 g of Zn-dust was added. The mixture which grew hot was frequently shaken during the first half hour and then refluxed for 16 h. Thiophene 3-bromothiophene and water were directly distilled off until the temperature of the vapour had risen to 103°. The organic layer was separated, dried with anhydrous sodium carbonate and fractionated. After a small forerun consisting of mainly thiophene (1.2 g), 22.4 g of 3-bromothiophene, b.p. 159—161° $n_D^{20} = 1.5919$, was obtained, which had the same IR-spectrum as authentic 3-bromothiophene [2].

3,4-Dibromothiophene. In a two-necked flask fitted with a refluxcondenser and a dropping-funnel was placed 65 g of tetrabromothiophene 65 ml of acetic acid 200 ml of water and 65 g of Zn-dust. The mixture was heated until a vigorous reaction started. The heating mantle was removed and when the reaction had somewhat subsided the flask was arranged for distillation. The reaction mixture was rapidly distilled. After each 50 ml of distillate the heavier organic layer was separated and the aqueous layer returned to the reaction mixture through the dropping-funnel. After 3 h 35 g of organic phase had been obtained and no more distilled with the water. The organic phase was dried with sodium carbonate and fractionated *in vacuo*. After a forerun of 3.2 g, b.p. 45—94°/12 mm Hg, consisting of 3-bromo- and 3,4-dibromothiophene, 26,5 g (68 %) of pure 3,4-dibromothiophene, b.p. 94—95°/12 mm Hg, $n_D^{20} = 1.6380$ was obtained. The IR-spectrum was identical to that of the authentic 3,4-dibromothiophene [8] and the strong characteristic lines of 2,3-, 2,4- and 2,5-dibromothiophene in the 10.0—10.3 μ region were absent in its spectrum.

The Identification of Drugs

VI. Nitration of Acetarsol *

K. ILVER, J. BERGER and Aa. JACKEROTT

Laboratory of the Pharmacopoeia Commission, and The Royal Danish School of Pharmacy, Chemical Laboratory B, Copenhagen, Denmark

In order to obtain a suitable derivative of acetarsol (3-acetamido-4-hydroxyphenylarsonic acid) as an identity test in the Scandinavian Pharmacopoeia nitration was tried. Burschkies and Rothermundt [1] state that acetarsol treated with a mixture of concentrated nitric acid and concentrated sulphuric acid at a temperature below 0°C yields 5-nitroacetarsol (m.p. 218–220°C).

In the present work 2 M nitric acid was added to acetarsol and the solution was boiled for 15 sec and then cooled. A yellow derivative immediately crystallised and it did not contain arsenic.

We have now proved that the derivative is identical with 2-acetamido-4,6-dinitrophenol which means that besides the expected introduction of a nitro group *ortho* to the hydroxyl group another nitro group has replaced the arsonic group to give a dinitro derivative. The identity was confirmed by quantitative titration with titanous chloride and mixed melting point determination with an authentic sample prepared by nitration of 2-acetamidophenol. Furthermore, the free phenol group of the derivative was acetylated and the resulting product was found to be identical with O,N-diacetylpicramic acid. This compound was prepared by acetylation of picramic acid.

The proposed derivative is specific for acetarsol as none of the other arsenicals used as drugs will give this derivative.

Experimental. 2-Acetamido-4,6-dinitrophenol from acetarsol. 0.1 g acetarsol is added 5 ml of 2 M nitric acid and the solution is boiled about 15 sec. and then immediately cooled with tap-water. The yellow precipitate is recrystallised from 10 ml of water. M.p. (corr.) 206–207°C (lit.[2] 205–206°C). Titanometric equiv. weight, found: 20.2, 20.1. Calc. for $C_8H_7O_6N_3$: 20.1. If the mixture is boiled for 5 min no precipitate is formed, probably due to an oxidation.

Acetylation of picramic acid and 2-acetamido-4,6-dinitrophenol. The substance is refluxed for 30 min with acetic anhydride and a few drops of pyridine. After cooling water is added and the precipitate is recrystallised from glacial acetic acid. Nearly colourless crystals, m.p. (corr.) 191°C (lit.[2] 190–191°C).

Isolation of ^{32}P-labeled Phosphorylserine from a Purified Preparation of Alkaline Bone Phosphatase Incubated with Radioactive Inorganic Phosphate

GUNNAR ÅGREN, ÖRJAN ZETTERQVIST and MAIE OJAMAE

Department of Medical Chemistry, University of Uppsala, Sweden

In a previous paper from this laboratory it was reported that ^{32}P-labeled phosphorylserine could be isolated from an acid hydrolysate of a commercial preparation of intestinal alkaline phosphatase [1]. This seemed to indicate that an intermediate enzyme-phosphate was formed in the enzyme reaction, as we had earlier suggested for the hexokinase reaction [2]. The results with intestinal alkaline phosphatase have recently been confirmed with a highly purified preparation of the enzyme [3]. Meanwhile similar results have also been obtained with preparations of alkaline bone phosphatase. Bone tissue is a poor source of phosphatase when compared with intestinal tissue [4].

The enzyme was first prepared from calf foreleg bones as described by Volkin [5] and for subsequent purification the method of Portmann [6] was followed. The fraction corresponding to step 14 was further purified by chromatography on a diethylaminoethyl cellulose column [3]. The buffer used was Tris-hydrochloric acid buffer pH 7.8. The column was loaded with 1 mg of protein per ml of column volume. The elution was performed with a stepwise increase of magnesium acetate concentration. The enzyme appeared in a protein peak at a magnesium acetate concentration of 0.04 M as determined by its ultraviolet absorbancy at 2 800 Å. The specific activity of the most active enzyme preparation, calculated according to Portmann, was 70 000 PU (Portmann units). In this way the enzyme was purified about 300 times as compared with the five-fold increase in purity obtained by Martland and Robison[7].

6 300 PU with the specific activity of 70 000 PU/mg N in Tris-buffer pH 7.0 was incubated with 0.75 mC of ^{32}P in the presence of 0.03 M magnesium acetate. After 5 min the enzyme was precipitated by adding 50 % trichloroacetic acid to a final concentration of 10 % and acetone was added to complete precipitation. The enzyme was hydrolyzed with 2 N HCl and radioactive phosphorylserine isolated as previously described [2] and identified by scanning of paper strips of electropherograms.

In a series of experiments 600 mg samples of enzyme with a specific activity of 420 PU/mg N and 5 mC ^{32}P were incubated at different pH for 5 min at room temperature. The total radioactivity of the isolated phosphorylserine fractions measured in L.K.B. Robot Scaler was the following:

pH 5 839 000 cpm	pH 8 629 000 cpm
(counts per min)	
pH 6 885 000 cpm	pH 9 126 000 cpm

In a second series of experiments similar samples of enzyme were incubated for 3, 6 12, 24, and 48 sec. with 5 mC ^{32}P. The total activities of the isolated phosphorylserine fractions were the same in all cases. The results indicate that inorganic phosphate is rapidly incorporated into the bone phosphatase molecule by covalent linkage. Calculations showed that the affinity of radioactive inorganic phosphate to bone alkaline phosphatase was of the same size as that of intestinal alkaline phosphatase. The incorporation of phosphate into the bone enzyme also increased within the same pH range as previously found with the intestinal enzyme [1]. The rapid incorporation and the high affinity of phosphate to the bone enzyme may be of interest with regard to its possible rôle as a transphosphorylating agent in bone tissue.

The Phosphotransferase Activity of Alkaline Phosphatases. Studies with Dephosphorylated Phosphopeptone as Phosphate Acceptor

GUNNAR ÅGREN

Department of Medical Chemistry, University of Uppsala, Sweden

In a recent paper it was reported that alkaline bone phosphatase catalysed the synthesis of phosphorylated amino acids and amines when labeled glycerophosphate was used as phosphate donor [1]. The present report describes similar experiments with dephosphorylated phosphopeptone as phosphate acceptor.

Radioactive glycerophosphate was obtained by use of AT^{32}P and glycerokinase prepared according to Bublitz and Kennedy [2]. Dephosphorylated phosphopeptone was obtained from a caseinphosphopeptone preparation made according to Mellander [3] and further separated in a four cell electrodialysing apparatus [4]. Material from cell 2 with a phosphorus content of 5.5 % was dephosphorylated with phosphoprotein-phosphatase purified in this institute [5] and at pH 5.8 in the presence of thioglycolic acid [6]. Dephosphorylated phosphopeptone was separated from phosphopeptone on a Dowex 1 formate column. Dephosphorylated phosphopeptone eluted from the column with water appeared in two fractions, one containing considerable amounts of sodium phosphate and a second rather saltfree fraction. This second fraction, II, was used in the following. It was not homogeneous. Electropherograms carried out at pH 3 showed the presence of at least 6 fractions.

A comparison was made between the transphosphorylating activity of alkaline phosphatases from milk [7] and bone [8]. 16 mg of milk phosphatase with a total activity of 1 120 Portmann units (PU)[9], and 23 mg of bone phosphatase with a total activity of 1 960 PU were each incubated with 25 mg of dephosphorylated phosphopeptone in bicarbonate buffer of pH 9.5 for 10 min at room temperature and in a total volume of 2 ml. To each solution 25 mg of glycerophosphate labeled with 1 mC of radioactivity had also been added. The heat-inactivated solutions were separated by gradient elution with 0 → 1 M formic acid on small Dowex 1 formate columns. Only in the experiment with milk phosphatase was it possible to isolate phosphopeptides where radioactivity moved parallel with ninhydrin colour on electropherograms. One of the 4 fractions gave sufficient amount of material for amino acid analysis and the one-dimensional chromatogram gave spots corresponding to aspartic acid, serine, glycine, glutamic acid, alanine and valine.

While the detailed sequence has not been established, it is to be noted that the composition of the peptide is in agreement with the composition of phosphopeptides obtained from the phosphate-catching "active sites" in chymotrypsin and phosphoglucomutase, respectively [10]. In a further attempt to elucidate Koshland's hypothesis [10] 90 mg of dephosphopeptone II were incubated in the presence of 0.01 M magnesium acetate with 5 mC of ^{32}P at pH 6 for 10 min [8]. The hydrolysed portion was separated on a Dowex 50 column. After inorganic phosphate three small radioactive peaks were obtained. The last one ran parallel with unlabeled phosphorylserine on electropherograms. The first fraction after a second hydrolysis with 2 N HCl for 20 h at 120°C showed an identical pattern of amino acids when run parallel on the chromatogram with the hydrolysate of the phosphopeptide isolated from the enzymatic transphosphorylation. The result supports Koshland's hypothesis [10] of a more common sequence of amino acids around serine making the otherwise inert CH_3OH side chain reactive to the phosphoryl group and a second amino acid sequence responsible for the enzyme specificity.

On the Crystal Structure of β-ZnOHCl

H.-E. FORSBERG and W. NOWACKI*

Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden; Institut für anorganische, analytische und physikalische Chemie, Institut für Mineralogie und Petographie, Universität, Berne, Switzerland

Recently single crystals of β-ZnOHCl have been prepared from ZnO and $ZnCl_2$ by Feitknecht and Oswald [1], who kindly supplied us with specimens suitable for X-ray investigations. From rotation and Weissenberg photographs taken around the *a*- and *b*-axes with Cu*K* radiation, it was concluded that the crystals are orthorhombic with the following cell dimensions.

$a \approx 5.86$ Å $b \approx 6.58$ Å $c \approx 11.33$ Å $V \approx 436.9$ Å^3

The unit cell contains eight formula units.

The extinctions *h0l* for *h* odd, *hk*0 for *k* odd and 0*kl* for *l* odd are in agreement with the centrosymmetric space group *Pcab* (No. 61 in the *International Tables for X-ray Crystallography* [2]) which also has been confirmed by the structure determination.

The following preliminary parameters of the atoms were determined mainly from Patterson and Fourier projections of *h0l* and 0*kl*:

8 Zn in 8(*c*) with $x = 0.250$ $y = 0.131$ $z = 0$

8 O in 8(*c*) with $x = 0.594$ $y = 0.126$ $z = 0.071$

8 Cl in 8(*c*) with $x = 0.583$ $y = 0.107$ $z = 0.357$

8(*c*) $\pm$ (x,y,z), $\pm$ $(\frac{1}{2}-x, \frac{1}{2}+y, \bar{z})$,
$\pm$ $(\frac{1}{2}+x, \bar{y}, \frac{1}{2}-z)$, $\pm$ $(\bar{x}, \frac{1}{2}-y, \frac{1}{2}+z)$.

Figs. 1 and 2 show the structure of β-ZnOHCl. The zinc atoms are surrounded by three oxygen and three chlorine atoms, so that a coordination Zn-6X in the shape of an octahedron is obtained. The structure can also be described as pseudohexagonal zinc layers separated by an ordered layer of oxygen and chlorine atoms.

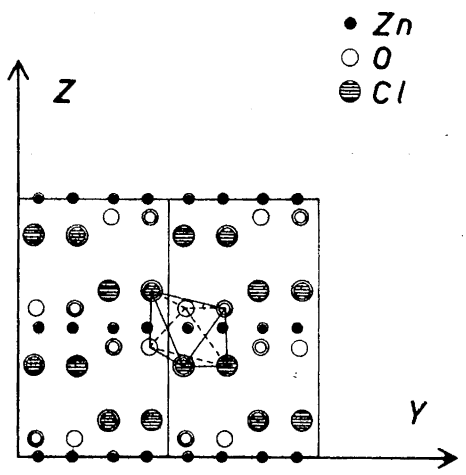

Fig. 1. The structure of β-ZnOHCl, viewed along [100]. (The range for the *x* parameter is $-0.406 \leq x \leq 0.594$.)

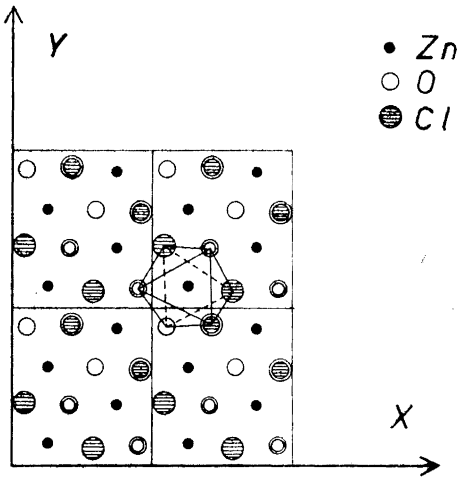

Fig. 2. The figure shows the pseudohexagonal zinc layer at $z = \frac{1}{2}$.

The following ranges of interatomic distances were found.

Zn – Zn	3.29 – 3.40 Å
Zn – O	2.01 – 2.17 Å
Zn – Cl	2.46 – 2.56 Å
O – O	2.56 – 3.36 Å
O – Cl	3.08 – 3.51 Å
Cl – Cl	3.48 – 4.08 Å

Unit Cell and Space Group of VS_4

BJØRN PEDERSEN

Kjemisk institutt, Universitetet i Oslo, Blindern, Norway

In an X-ray and magnetic study of the system V/S by Klemm and Hoschek [1] a polysulphide of vanadium was discovered. By means of vapour pressure measurements the composition of this compound was decisively determined as VS_4 by Biltz and Køcher [2]. A polysulphide of vanadium is also found in nature as patronite first described by Hewett [3]. On the basis of analytical data given by Hillebrand [4], Biltz and Køcher [2] concluded that patronite is VS_4. A sample of this mineral was kindly placed at our disposal by the Curator of Harvard Museum, Dr. C. Frondel. Powder photographs showed that the major phase present was the same as synthetic VS_4. — No crystallographic data on VS_4 seems to have been reported.

In a recent investigation of the vanadium sulphides [5], single crystals of VS_4 were obtained by heating a mixture of $VS_{1.5}$ and sulphur, corresponding to the formula VS_4, in an evacuated and sealed silica tube for four months at 400°C and slowly cooled to 100°C over another four months. The reaction was not complete, however, as some sulphur was still present in the tube. The crystals had grown as clustres of long, black needles with metallic lustre. Most of them were unsuitable for X-ray work, but after some search a crystal with very good properties was found. Its dimensions were: $0.33 \times 0.06 \times 0.07$ mm^3.

Oscillation and Weissenberg photographs taken with CuK-radiation ($\lambda_{\alpha_1} = 1.5405$ Å) around the needle axis (the c-axis) showed the crystal to be monoclinic. This was confirmed by precession photographs taken with MoK-radiation of the $h0l$-plane. From Guinier powder photographs the cell dimensions were found to be:

$a = 12.67$ Å $b = 10.41$ Å $c = 12.11$ Å
$\beta = 148.37°$

Missing reflexions were: hkl when $h+k = 2n+1$, $h0l$ when $l = 2n+1$ and $(h = 2n+1)$ and $0k0$ when $(k = 2n+1)$. This is characteristic of the space groups No. 9, Cc and No. 15, $C2/c$. The density was determined by flotation to be 2.80 g/cm^3, which indicates the presence of eight VS_4 groups in the unit cell ($d_{calc} = 2.835$ g/cm^3).

As the basis for a structure determination, the intensities of the $hk0$- and $h0l$-reflexions were estimated visually. The intensities were corrected for Lorentz and polarisation effects, but not for absorption and extinction.

This intensity material was used to decide between the two characteristic space groups by means of the Wilson ratio for detection of centers of symmetry, $\varrho = \langle|F_0|\rangle^2/\langle|F_0|^2\rangle^6$. For the 48 $hk0$- and 38 $h0l$- reflexions ϱ was calculated as 0.77 and 0.71, respectively. The predicted value for ϱ is 0.635 for centrosymmetric crystals and 0.785 for noncentrosymmetric crystals. Thus the Wilson ratio indicates that the crystal is noncentrosymmetric and the space group accordingly No. 9, Cc.

Some crystals were kindly tested for piezoelectricity by Dr. W. G. Perdok of the University of Groningen, but with negative results. This might perhaps be due to the smallness of the crystals (< 0.06 mm) in the direction of the polar axis.

ACTA CHEMICA SCANDINAVICA 13 (1959) 1051–1063

Transition Point Depression and its Structural Interpretation in the Binary System Sodium Sulfate-Potassium Sulfate

T. FÖRLAND

N.T.N.F.'s Institutt for Silikatforskning, N.T.H., Trondheim, Norway,

and J. KROGH-MOE

Svenska Silikatforskningsinstitutet, Göteborg, Sweden

The heat content curves of K_2SO_4 and of $NaKSO_4$ have been determined in the temperature range from 25°C to 850°C. The depression of the transition point of sodium sulfate by the addition of potassium sulfate has been determined experimentally. The equilibrium lines of transitions in the phase-diagram of the binary system, sodium sulfate-potassium sulfate have been calculated from the heats of transition of these two compounds together with the heat of transition found for $NaKSO_4$.

A consistent treatment of the system is shown to require that in the high temperature solid solution of sodium sulfate with potassium sulfate there is a cation disorder. The second order transition in $NaKSO_4$ is established as an order-disorder transition.

For regions of solid solution high in potassium sulfate the data available indicate that the sodium ions occur in groups, probably consisting of two ions occupying neighbouring cation positions.

The system sodium sulfate-potassium sulfate exhibits a continuous series of solid solutions in a limited temperature range below the liquidus curve. This is shown in the phase diagram in Fig. 1 taken from the work of Nacken [1]. For compositions from 50 to 75 mole-% potassium sulfate, the hexagonal (high temperature) structure is preserved below the transition temperature [2]. Several authors observed a thermal effect in this composition range [1-5]. Bredig states that the thermal effect is due to a second order transition, since he found only a change in the axial ratio of the hexagonal crystals on passing the transition point [2]. He further suggests that this transition is due to the excitation of at least one rotational degree of freedom of the sulfate ion in the high temperature range. The possibility of an order-disorder reaction is

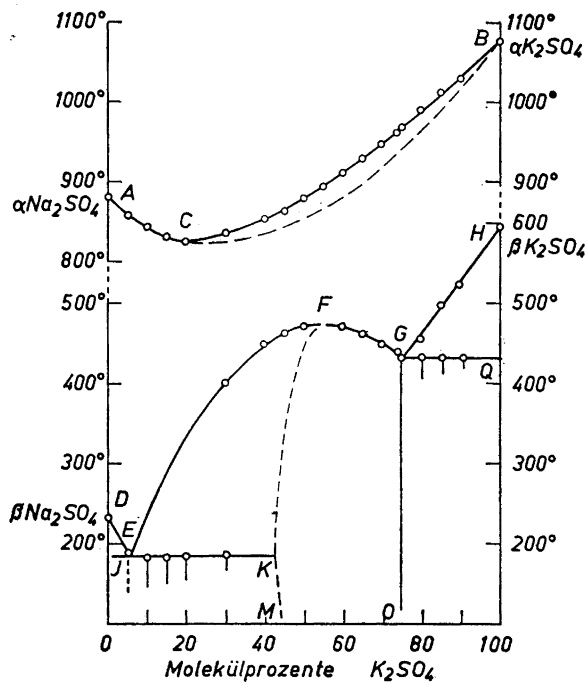

Fig. 1. Phase diagram of the system sodium sulfate-potassium sulfate according to Nacken.

also considered, but is believed to be less likely because of the speed of the transition. An order-disorder reaction is not ruled out by this argument, however. The average diffusion distance necessary to establish the ordered state and the activation energy of diffusion are probably small in this case, so that the reaction should be expected to proceed rapidly. In the following it will be shown that the phase diagram of the system sodium sulfate-potassium sulfate, observed by Nacken [1,3], can be interpreted on the basis of an order-disorder transition.

In the high temperature solid solution it is reasonable to assume that the sodium and potassium ions can replace each other on any one of the cation positions, since the solid solution extends across the whole diagram. Just below the transition point the solid solution extends only from about 50 to 75 mole-% potassium sulfate. This indicates that only in one fourth of the cation positions can sodium and potassium ions replace each other. Thus in the low temperature solid solution one-half of the cation positions have become permanent potassium ion positions and one-fourth of the positions are permanently filled with sodium ions. Hence an ordering has taken place.

The crystal structures of $NaK_3(SO_4)_2$ and $Na_2K_2(SO_4)_2$ determined at room temperature give additional evidence for this particular ordering. In these structures the cations are distributed over three different kinds of positions.

One kind of cation position takes potassium ions, another takes sodium ions and, finally, the last cation position takes either a sodium or a potassium ion [6-8]. There are twice as many of the former cation positions as of either of the two others.

Hilmy [8] investigated the composition of crystals formed from a water solution of sodium and potassium sulfate, and he found that below 35°C the solid solubility range is very narrow and close to the composition $NaK_3(SO_4)_2$.

The lines in the phase diagram corresponding to the transition are analogous to the liquidus lines in a binary system with limited solid solution, and the depression of the transition temperature can be treated in the same way as the depression of a freezing point.

On the basis of the structural model outlined above, the change in configurational entropy with the sodium potassium ratio may be calculated in the high temperature and low temperature modifications. With an additional knowledge about the change in heat content by the transition from high to low temperature modification, the equilibrium lines of the phase diagram may be calculated. In the following, equilibrium lines of the phase diagram calculated on the basis of the structural model and calorimetric measurements of heat of transitions, will be compared with experimental points on the equilibrium lines.

DEPRESSION OF THE TRANSITION POINT OF SODIUM SULFATE

The depression of the transition point of sodium sulfate by addition of potassium sulfate can, according to classical thermodynamics, be derived briefly as follows:

At the transition point of a solid solution of potassium sulfate in sodium sulfate the partial free energy of sodium sulfate in the high temperature state ($\overline{F}_{Na_2SO_4}$) is equal to the free energy of pure sodium sulfate in the low temperature state ($F_{Na_2SO_4(low)}$):

$$\overline{F}_{Na_2SO_4} = F_{Na_2SO_4(low)}$$

Here an eventual small solubility of potassium sulfate in the low temperature phase is disregarded.

We will now choose pure sodium sulfate in the high temperature state as standard state. Referring to this state the above equation can be written:

$$\overline{F}_{Na_2SO_4} - F_{Na_2SO_4(high)} = \Delta\overline{F}_{Na_2SO_4}$$
$$= F_{Na_2SO_4(low)} - F_{Na_2SO_4(high)} = -\Delta F_{tr}$$

where $F_{Na_2SO_4(high)}$ is the free energy of sodium sulfate in the standard state and ΔF_{tr} is the free energy of transition. Neglecting a minor correction term due to the difference in specific heat of sodium sulfate in the two states, we can introduce

$$\Delta F_{tr} = \Delta H_{tr} - T\Delta S_{tr} = \Delta H_{tr}\left(1 - \frac{T}{T_{tr}}\right) = -\Delta\overline{F}_{Na_2SO_4}$$

where ΔH_{tr} is the heat of transition, T is the temperature of the equilibrium and T_{tr} is the transition temperature of pure sodium sulfate. If further $\Delta\bar{F}_{Na_2SO_4}$ is expressed by the partial entropy $\Delta\bar{S}_{Na_2SO_4}$ and the partial heat content $\Delta\bar{H}_{Na_2SO_4}$, we finally obtain

$$\Delta\bar{S}_{Na_2SO_4} = \Delta H_{tr}\left(1 - \frac{T}{T_{tr}}\right) + \frac{\Delta\bar{H}_{Na_2SO_4}}{T} \quad (1)$$

Introducing the assumption of complete sodium-potassium disorder in the solid solution, the entropy of mixing due to this disorder can be expressed as

$$\Delta S = -R(n_{Na}\ln N_{Na} + n_K \ln N_K) \quad (2)$$

where n_{Na} and n_K are the molar amounts of sodium and potassium ions in the mixture and N_{Na} is defined by

$$N_{Na} = \frac{n_{Na}}{n_{Na} + n_K}$$

and N_K is defined correspondingly.

Differentiating with respect to n_{Na}, one obtains

$$\frac{\partial \Delta S}{\partial n_{Na}} = \Delta\bar{S}_{Na} = -R\ln N_{Na}$$

and as

$$\frac{\partial \Delta S}{\partial n_{Na_2SO_4}} = 2\,\frac{\partial \Delta S}{\partial n_{Na}}$$

one obtains the partial entropy of sodium sulfate

$$\Delta\bar{S}_{Na_2SO_4} = -2\ R\ln N_{Na} \quad (3)$$

Introducing this into eqn. (1) one obtains

$$-2\ R\ln N_{Na} = \Delta H_{tr}\left(\frac{1}{T} - \frac{1}{T_{tr}}\right) + \frac{\Delta\bar{H}_{Na_2SO_4}}{T} \quad (4)$$

For mixtures of this kind the partial heat content of a component will generally be proportional to the square of the fraction of the second component. If N_{Na} is close to unity, N_K^2 will be small, and $\Delta\bar{H}_{Na_2SO_4}/T$ will be small compared to $-2\ R\ln N_{Na}$. The change in partial heat content of sodium sulfate may, therefore, be expected to be insignificant for systems with a high sodium sulfate content.

Calorimetric measurements of the heat content of sodium sulfate by Coughlin [9] give 1.68 kcal for the heat of transition. The transition temperature is 234°C according to Nacken. The same value was found in the present investigation. Using these data, the transition temperature T of the solid solution

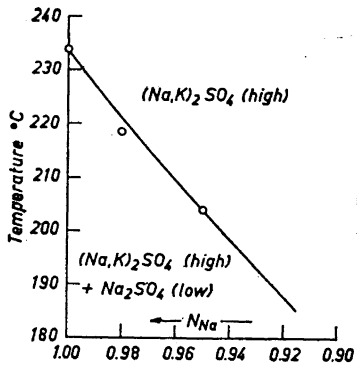

Fig. 2. Transition point depression of sodium sulfate by potassium sulfate. Circles represent observed points. Solid line is calculated.

may be calculated as a function of the composition N_{Na} and a comparison with the experimental data can be done.

No good previous determination of the depression of the transition point of sodium sulfate by addition of potassium sulfate was found in the literature. (One point on the depression curve indicated by Nacken [7] is more likely to be the eutectic point). Therefore, measurements of the transition point depression were carried out by the present authors.

Experimental

The transition point was determined by ordinary thermal analysis. A sample of approximately 200 g with a Pt-PtRh thermo-couple in the center was cooled at a speed of about 0.1° C/min, and the break in the temperature-time curve was observed. The accuracy of the temperature measurement was of the order ± 1°C. The results are given in Table 1.

Table 1.

Mole % Na_2SO_4 in the solid solution in the high temperature phase	Temperature at which transition starts
100	234°C
98	218°C
95	204°C

On Fig. 2 is shown a plot of the transition temperature, T, as a function of N_{Na} as given by eqn. (4) omitting the term $\Delta\bar{H}_{Na_2SO_4}/T$. The circles represent the observed transition temperature for different compositions. As is seen from the figure, the agreement between calculated and observed values is good. One may conclude that the K^+ ions introduced into the high temperature modification of sodium sulfate are randomly distributed over all positions which are available for the K^+ ions. Further, one may conclude that the partial heat of mixing of sodium sulfate is small in this composition range.

It should be emphasized that the above results do not give information about whether the K^+ ions are randomly distributed over all cation positions

or a fraction of them. Assuming, *e.g.*, that in this concentration range only half of the cation positions can be occupied by K^+ ions, one will have a system where $1/2\ (n_K + n_{Na}) - n_K$ moles of Na^+ ions and n_K moles of K^+ ions are distributed over $1/2\ (n_K + n_{Na})$ moles of cation positions. If this distribution is random, the entropy of mixing due to this disorder can be expressed by the equation

$$\Delta S = -R\left[1/2\ (n_{Na} - n_K)\ln \frac{1/2\ (n_{Na} - n_K)}{1/2\ (n_{Na} + n_K)} + n_K \ln \frac{n_K}{1/2\ (n_{Na} + n_K)}\right] \quad (5)$$

$$\Delta\bar{S}_{Na_2SO_4} = -R\ln(1 - 2N_K) \quad (6)$$

Comparing eqns. (3) and (6) one can see that in both cases will the calculated partial entropy of sodium sulfate be approximately equal to $2\ RN_K$ when N_K is small. Thus, in the concentration range in question it is not possible to determine whether the entropy of the system corresponds to eqn. (3) or to eqn. (6) when only $\Delta\bar{S}_{Na_2SO_4}$ is known.

THE DEPRESSION OF THE TRANSITION POINT OF POTASSIUM SULFATE

Analogous to the above treatment, the depression of the transition point of potassium sulfate by additions of sodium sulfate can be expressed by the equation

$$\Delta\bar{S}_{K_2SO_4} = \Delta H_{tr}\left(\frac{1}{T} - \frac{1}{T_{tr}}\right) + \frac{\Delta\bar{H}_{K_2SO_4}}{T} \quad (7)$$

where $\Delta\bar{S}_{K_2SO_4}$ and $\Delta\bar{H}_{K_2SO_4}$ are partial entropy and heat content of potassium sulfate in the high temperature modification, and T_{tr} and ΔH_{tr} are the transition temperature and heat of transition of pure potassium sulfate. As for the region high in sodium sulfate, one may assume that also in this concentration region the cations are randomly distributed over all cation positions giving an entropy of mixing

$$\Delta S = -R(n_{Na}\ln N_{Na} + n_K \ln N_K)$$

and

$$\Delta\bar{S}_{K_2SO_4} = -2\ R\ln N_K \quad (8)$$

Introducing this into eqn. (7), one obtains

$$-2\ R\ln N_K = \Delta H_{tr}\left(\frac{1}{T} - \frac{1}{T_{tr}}\right) + \frac{\Delta\bar{H}_{K_2SO_4}}{T} \quad (9)$$

The transition temperature is according to Nacken [1] 595°C, and calorimetric measurements by Shomate and Naylor [10] give 1.94 kcal for the heat of transition of pure potassium sulfate. Assuming that the term $\Delta\bar{H}_{K_2SO_4}/T$ is of minor importance, at least for mixtures high in potassium sulfate, one can thus calculate the transition temperature as a function of composition.

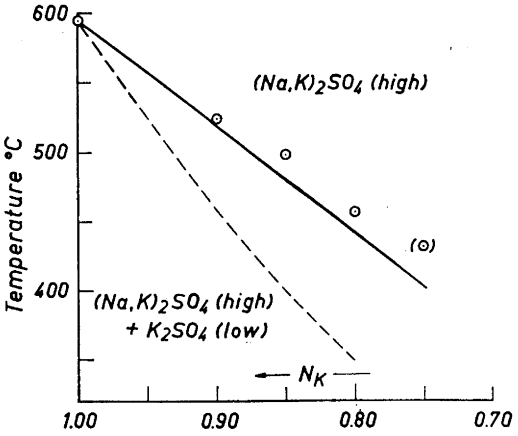

Fig. 3. Transition point depression of potassium sulfate by sodium sulfate. Circles represent points observed by Nacken. Dotted line is calculated assuming independent sodium ions and solid line is calculated assuming sodium pairs.

This is shown on Fig. 3 where the transition temperature is plotted as a function of N_K, giving the dotted line. This calculated line may be compared with the transition temperatures observed by Nacken and given as small circles in the figure. As is seen from the figure, there is a large discrepancy between observed and calculated values.

One will notice that the deviations are very closely proportional to N_{Na}. This indicates that the discrepancy is not due to a change in the partial heat content of potassium sulfate, as this term generally would give a deviation proportional to N_{Na}^2. The partial entropy of potassium sulfate, on the other hand, would vary approximately proportionally to N_{Na} as $-\ln N_K \approx N_{Na}$ in the concentration range in question. Actually the observed change in transition temperature by addition of sodium sulfate is only one-half of the calculated. This corresponds to a partial entropy of potassium sulfate, only one-half of that expressed by eqn. (8).

The only reasonable interpretation of this is that the Na^+ ions occur in groups probably consisting of two ions. The entropy of mixing for a mixture of K^+ and Na^+ ions where the Na^+ ions occur in groups of two ions occupying neighboring positions can be expressed by the equation (compare Flory [11]):

$$\Delta S = -R(n_K \ln \frac{n_K}{n_{Na} + n_K} + \frac{n_{Na}}{2} \ln \frac{n_{Na}}{n_{Na} + n_K}) \quad (10)$$

From this the partial entropy of potassium sulfate is:

$$\Delta \bar{S}_{K_2SO_4} = -2\ R \ln N_K - R(1 - N_K) \quad (11)$$

Introducing this into eqn. (7), the equation for the transition temperature, T, as a function of composition N_K, will be:

$$-2\,R\ln N_K - R(1-N_K) = \Delta H_{tr}\left(\frac{1}{T} - \frac{1}{T_{tr}}\right) + \frac{\Delta\bar{H}_{K_2SO_4}}{T} \qquad (12)$$

A plot of this function (omitting the term $\Delta\bar{H}_{K_2SO_4}/T$) is shown on Fig. 3 as the solid curve. As can be seen, the agreement between this calculated curve and the observed transition temperatures is good. One may conclude from this that for solid solutions with a high content of potassium sulfate the Na^+ ions occur in groups of two, and these groups are randomly distributed over the positions available for them.

One could also assume that the cation positions themselves occur in groups of two which either can be occupied by two Na^+ ions or two K^+ ions. The entropy of mixing for such a mixture is given by

$$\Delta S = -R(1/2\,n_K \ln \frac{1/2\,n_K}{1/2\,n_K+1/2\,n_{Na}} + 1/2\,n_{Na}\ln \frac{1/2\,n_{Na}}{1/2\,n_K+1/2\,n_{Na}}) \qquad (13)$$

Differentiation gives for the partial entropy of potassium sulfate

$$\Delta\bar{S}_{K_2SO_4} = -R\ln N_K \qquad (14)$$

It can be easily shown that this expression for mixtures high in potassium sulfate is almost identical with the previous entropy expression (eqn 11), so that a distinction between the two types of disorder is not possible on the basis of the above data.

The inversion point depression could also be explained by the assumption of groups consisting of 3 Na^+ ions. This model would, however, give a larger difference between observed and calculated inversion point at the lowest content of sodium sulfate. As one should expect the agreement to be better in this region, groups of 3 Na^+ may be considered less probable.

The formation of pairs of Na^+ ions on neighbouring sites in the sodium-potassium sulfate mixture was certainly not expected. The conclusion depends on the applied value of the heat of transition of potassium sulfate (besides on the phase diagram measurements), and thus it could possibly be due to an error in this quantity. For this reason the heat of transition was redetermined.

Experimental

The heat content of potassium sulfate as a function of temperature was obtained with a calorimeter fairly similar to that first used by Oelsen, Rieskamp and Oelsen [12] and later modified by Tashiro [13]. This apparatus is designed to allow a simultaneous recording of the sample temperature and the water temperature of the calorimeter. For details of the experimental technique employed, Tashiro's paper should be consulted. Our calorimeter differed from his mainly in having two more radiation shields around the sample container to decrease the rate of cooling of the sample.

A sample of 65.8 g K_2SO_4 was fused in the sample container, and then kept at a temperature of about 1 000°C before being placed in the calorimeter. During the cooling in

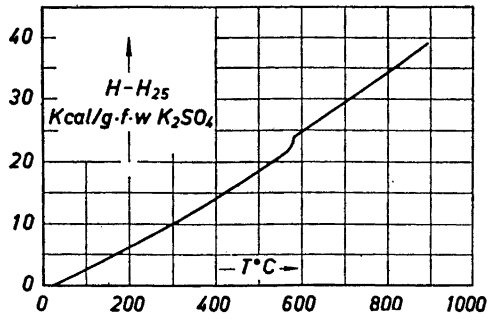

Fig. 4. Experimental heat content curve for K_2SO_4.

the calorimeter the temperature of the sample was recorded at intervals of about 15°C. The observed heat content as a function of temperature is shown in Fig. 4. The heat of transition was found to be

$$H_{tr} = 1\,920 \text{ cal/g.f.w. } K_2SO_4$$

Average specific heat for the following temperature regions are:

25 to 595°C: $\bar{c}_p = 39.2$ cal/deg.g.f.w.
595 to 850°C: $\bar{c}_p = 48.4$ cal/deg.g.f.w.

As is seen from the figure, the specific heat of the low temperature modification increases considerably with increasing temperature.

The value for the heat of transition (1.92 kcal) agrees very well with the previous value (1.94 kcal) obtained by Shomate and Naylor, and thus it confirms our conclusion that groups of Na^+ ions are formed in the high temperature modification of potassium sulfate.

DEPRESSION OF THE TRANSITION POINT OF $NaKSO_4$ BY ADDITIONS OF SODIUM SULFATE

Analogous to the two preceding calculations the depression of the transition point of $NaKSO_4$ by additions of sodium sulfate can be expressed by the equation

$$\Delta\bar{S}_{NaKSO_4} = \Delta H_{tr}\left(\frac{1}{T} - \frac{1}{T_{tr}}\right) + \frac{\Delta\bar{H}_{NaKSO_4}}{T} \qquad (15)$$

where $\Delta\bar{S}_{NaKSO_4}$ and $\Delta\bar{H}_{NaKSO_4}$ are the partial entropy and the partial heat of mixing of $NaKSO_4$ in a mixture in the high temperature modification, the standard state being pure $NaKSO_4$ in the same modification. T_{tr} and ΔH_{tr} are the transition temperature and the heat of transition of $NaKSO_4$, respectively. The equation is based on the assumption that there is no sodium-

potassium disorder in the low temperature modification of $NaKSO_4$. (The phase diagram by Nacken indicates that $NaKSO_4$ in the low temperature modification can only have a very small amount of excess sodium. It should be noted, as indicated by the dotted curves for this region of the phase diagram shown in Fig. 6, that $NaKSO_4$ does not have a sharp transition point, but rather a transition region. However, the major change appears (*e.g.*, from the heat content curve) to take place over a fairly short temperature interval so that the expression $\Delta S_{tr} = \Delta H_{tr}/T_{tr}$ may be considered to be a good approximation.)

Assuming a complete sodium potassium disorder in the high temperature modification, the entropy due to this disorder is equal to

$$S = -R(n_{Na}\ln N_{Na} + n_K \ln N_K)$$

Differentiation with respect to n_{Na} and n_K gives:

$$\frac{\partial S}{\partial n_{NaKSO_4}} = \frac{\partial S}{\partial n_{Na}} + \frac{\partial S}{\partial n_K} = -R(\ln N_{Na} + \ln N_K)$$

As we have chosen pure $NaKSO_4$ in the high temperature modification as the standard state, the partial entropy of $NaKSO_4$ in the mixture referring to this standard state will be:

$$\Delta\bar{S}_{NaKSO_4} = -R\ln(N_{Na}N_K) + R\ln\ 1/4) \qquad (16)$$

Introducing (16) into (15) one obtains

$$-R\ln N_{Na}N_K + R\ln\ 1/4 = \Delta H_{tr}\left(\frac{1}{T} - \frac{1}{T_{tr}}\right) + \frac{\Delta\bar{H}_{NaKSO_4}}{T} \qquad (17)$$

Neglecting a change in the heat of mixing in the concentration range in question, one may thus calculate the transition temperature as a function of composition if the transition temperature and heat of transition of pure $NaKSO_4$ is known.

From Nacken's measurements the transition temperature is equal to 470°C. No data were available for the heat of transition, however, and a calorimetric determination was, therefore, carried out.

Experimental

The heat content of $NaKSO_4$ as a function of temperature was determined by the method described in the previous part of this paper. A sample of 63 g $NaKSO_4$ was made by fusing together equal molar amounts of *pro analysi* potassium and sodium sulfate. The observed heat content curve is given in Fig. 5. The heat of transition was found to be:

$$\Delta H_{tr} = 1\,750 \text{ cal/g.f.w. } NaKSO_4$$

at 470°C. The heat of fusion was found to be

$$\Delta H_f = 4\,650 \text{ cal/g.f.w.}$$

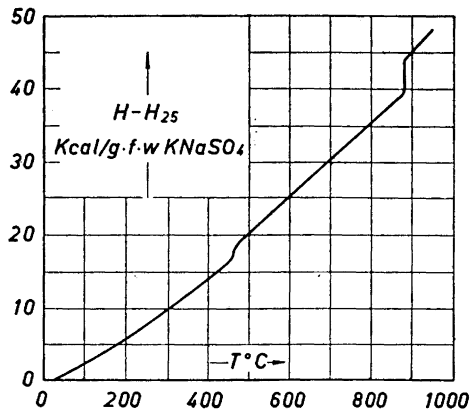

Fig. 5. Experimental heat content curve for $NaKSO_4$.

with a fusion point of 884°C. Average specific heats for the following two regions are:

25 to 450°C $\bar{c}_p$ = 37.4 cal/deg.g.f.w.
500 to 850°C $\bar{c}_p$ = 50.3 cal/deg.g.f.w.

The specific heat in the low temperature region increases considerably with the temperature, so that the specific heat just below the transition is not very different from the specific heat above the transition. This speaks against the view that the transition releases new degrees of freedom.

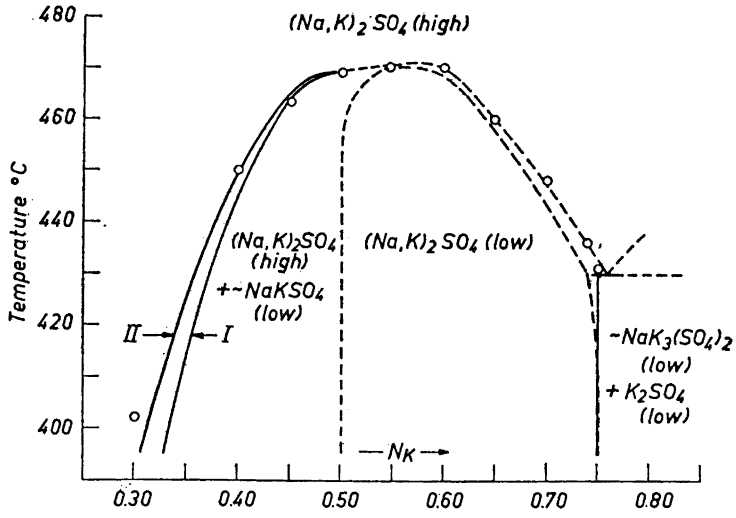

Fig. 6. Part of the phase diagram of the sodium potassium sulfate system in the composition range around the compound $NaKSO_4$. Circles represent points observed by Nacken. The solid lines are calculated on the basis of certain models for the structure of the solid solution.

Knowing the heat of transition of $NaKSO_4$ it is now possible to calculate the transition temperature of mixtures having an excess of Na_2SO_4, according to eqn (17).

A plot of such a calculation is shown on Fig. 6, curve I. The circles represent the transition temperature observed by Nacken. As can be seen from the figure, the agreement between calculated and observed transition temperature is good. Before concluding that this structural model is therefore the most likely, one should however calculate the partial entropy of $NaKSO_4$ based on other postulates about the cation disorder in the solid solution.

Previously it was shown that in solid solutions with a high sodium sulfate content the K^+ ions were randomly distributed over certain cation positions. But on the basis of measurements one could not say whether this applied to all cation positions or only a fraction (*e.g.*, 1/2) of them. Assuming that only half of the positions can be occupied by K^+ ions, the entropy of the solid solution is given by eqn (5). Differentiation gives the following expression for the partial entropy of $NaKSO_4$:

$$\Delta\bar{S}_{NaKSO_4} = -R\ln N_K - R\ln 2$$

This calculated entropy is in distinct disagreement with the experimental results.

The formation of pairs of Na^+ ions may possibly persist for $N_{Na} > 1/2$. It is, therefore, of interest to calculate the depression of the transition point of $NaKSO_4$ on this basis. The entropy of mixing for such a system is given by eqn (10). Differentiation gives the following expression for the partial entropy of $NaKSO_4$:

$$\Delta\bar{S}_{NaKSO_4} = -R\ln\left(N_K\sqrt{N_{Na}}\right) - \frac{R}{2}(N_{Na} - N_K) + R\ln\tfrac{1}{2}\sqrt{\tfrac{1}{2}}$$

Substituting this entropy expression into eqn (15) the change in transition temperature for $NaKSO_4$ as a function of composition can be calculated (omitting the term $\Delta\bar{H}_{NaKSO_4}/T$). A plot of this function is shown on Fig. 6, curve II. As is seen from the figure, the agreement between the calculated and observed transition temperature is even better than for the previous calculation based on complete $Na^+ - K^+$ disorder. However, without more accurate information on the thermodynamic properties of the solid solution, a distinction between the two kinds of disorder cannot be made. However, the possibility that the cation positions as well as the cations occur as pairs may be excluded in this concentration range. According to eqn (13) we have:

$$\Delta S = -1/2\ R(n_K\ln N_K + n_{Na}\ln N_{Na})$$

Differentiation with respect to the $NaKSO_4$ content gives

$$\Delta\bar{S}_{NaKSO_4} = -1/2\ R\ln N_K N_{Na} + 1/2\ R\ln\ 1/4 \qquad (18)$$

which gives a transition point depression only half of that experimentally found.

In region $1/2 < N_K < 3/4$ a solid solution exists both in the high and the low temperature state of the mixture. A calculation of the change in transition temperature with composition could be based on an assumption about the disorder in the high temperature state as discussed in the preceding paragraphs combined with a limited disorder over one-quarter of the positions in the low temperature state. Such a calculation would give curves of the type as indicated by the dotted lines on Fig. 6. However, without more experimental data than available now, such calculations would not be of much value. One would have to know the compositions of both the high and low temperature phase in equilibrium. Further, more thermal data should be available, particularly the heat of transition of $K_3Na(SO_4)_2$. Without these data the calculations would contain at least one freely chosen parameter and, thus, an agreement between experiment and calculation could always be obtained.

CONCLUSION

The preceding discussion has shown that consistent values for the structural entropies can be obtained by assuming a random distribution of K^+ ions and a random distribution of pairs of Na^+ ions over all cation positions in the high temperature solid solution. This proves that the second order transition of $NaKSO_4$ is an order-disorder transition.

Evidence of the Different Nature of Human Plasminogen and Proactivator

MOGENS LASSEN

From the Biological Institute of the Carlsberg Foundation, and the University Institute of Physical Chemistry, Copenhagen, Denmark

Human plasminogen and proactivator were found to have different thermal stabilities at 50° and pH 10.6. This observation supports the assumption that these components are chemically different.

The fibrinolytic activity induced in human blood by streptokinase, an extracellular streptococcal product, is due the conversion of plasminogen into the proteolytic enzyme, plasmin. Studies by Christensen [1] and Christensen and MacLeod [2] indicated a direct catalytic effect of streptokinase on plasminogen. Müllertz and Lassen [3] suggested that streptokinase does not react directly with human plasminogen, but that an activator of plasminogen is formed through a reaction between streptokinase and a substance, termed proactivator, which is present in large amounts in human plasma. Troll and Sherry [4] and Müllertz [5] independently suggested the reaction between streptokinase and proactivator to be a stoicheiometric and reversible reaction, while the effect of the activator on plasminogen was catalytic:

$$\text{Streptokinase} + \text{proactivator} \rightleftharpoons \text{activator}$$

$$\text{Plasminogen} \xrightarrow{\text{activator}} \text{plasmin}$$

This concept was rejected again by Sherry. He now assumes identity between plasminogen and proactivator and supposes the activator to be a complex of streptokinase with plasminogen or plasmin (Sherry and Alkjaersig [6,7]), and his concept has been accepted by several investigators. The present work gives evidence for the original suggestion that proactivator and plasminogen are two different factors.

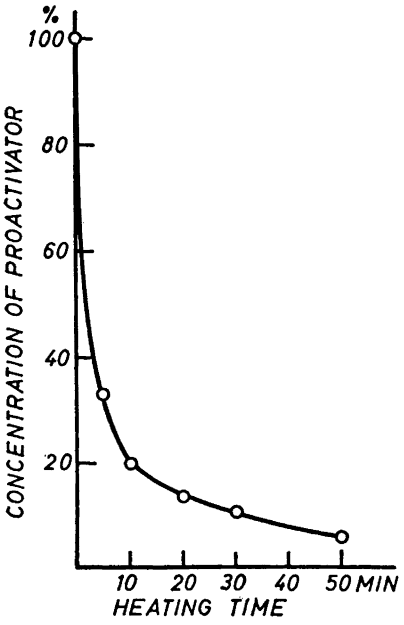

Fig. 1. Inactivation of proactivator at 50° and pH 10.6. Abscissa: heating time. Ordinate: residual concentration of proactivator in per cent of the concentration in the unheated solution.

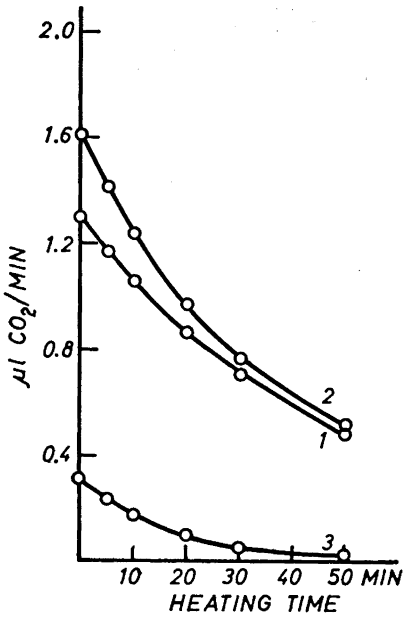

Fig. 2. Inactivation of plasminogen at 50° and pH 10.6. Abscissa: heating time. Ordinate: residual concentration of spontaneously occurring plasmin (curve 1), of plasminogen + plasmin (curve 2), and of plasminogen (curve 3). The last curve was obtained by subtracting curve 1 from curve 2. The activation of plasminogen with urine activator is described in the text. The estimations were performed by the manometric method using 0.25 M $NaHCO_3$ in the liquid phase and 50 % carbon dioxide in the gas phase, giving the pH 7.34. In the side arms: 25 mg BAEe. In the main compartment of flasks: Curve 1; 40 µl of the heated solution + 1 960 µl 0.25 M $NaHCO_3$. Curve 2; 40 µl of the heated solution + 20 µl of the urine activator solution + 1 940 µl 0.25 M $NaHCO_3$.

MATERIALS AND METHODS

Streptokinase. "Varidase" was kindly supplied by the Lederle Laboratories Division, American Cyanamid Company. The units are those stated on the packages as determined according to Christensen [8].

Urine activator. A preparation of human urokinase (Ploug and Kjeldgaard [9]) was kindly supplied by Løvens kemiske Fabrik, Copenhagen. By means of the lysis time method (Lassen [10]) the activating power of this preparation was compared with that of streptokinase activated human plasma. 1 mg urine activator preparation was found to

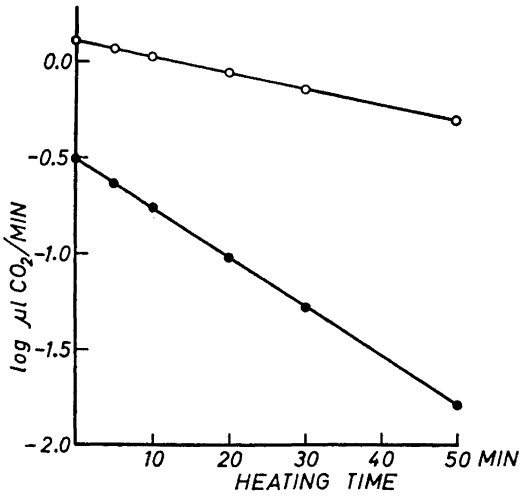

Fig. 3. Denaturation of plasminogen (○) and plasmin (●) at 50° and pH 10.6. First order rate constants: plasminogen, 0.0198 min^{-1}; plasmin 0.059 min^{-1}. $t_{\frac{1}{2}}$: plasminogen, 36 min; plasmin 12.5 min.

correspond in activity to approximately 1 500 units of streptokinase mixed with 1 ml of human plasma (excess).

Plasminogen and proactivator. 100 ml freshly prepared human serum was diluted with 1 900 ml icecold distilled water and adjusted to pH 5.5 with acetic acid. After standing for 30 min at 0° the precipitate was collected by centrifuging and dissolved in 0.9 % NaCl to a final volume of 16 ml. This solution was adjusted to pH 2.0 with 1 M HCl and heated at 70° for 30 min. The heated solution was then mixed with 4 ml veronal-gelatin buffer (Lassen [10]), adjusted to pH 7.7, and clarified by centrifuging. The procedure caused some loss in plasminogen and proactivator, but it removed the bulk of inhibitory substances.

Manometric determination of plasmin. Plasmin was measured by the method previously reported (Lassen [11]), using benzoyl-L-arginine ethylester (BAEe) as substrate.

Determination of proactivator. Proactivator was measured by the lysis time method as described by Lassen [10].

RESULTS

Advantage was taken of the difference between the stabilities of the components at alkaline reaction. The heat inactivation was performed as follows:

10 ml of the plasminogen and proactivator solution was mixed with 0.5 ml 0.1 M NaOH. The resulting pH was 10.6. 1 ml aliquots were then heated at 50° for different periods of time, whereafter they were cooled, neutralized by adding 50 µl 0.1 M HCl, and cleared by centrifuging. The final determinations of proactivator and plasminogen were performed as follows:

Proactivator was estimated as described using the unheated solution for the standard curve (Fig. 1). Plasminogen was converted into plasmin (see below) and estimated by the manometric method. Because of the low content of proactivator in the heated solutions, streptokinase was considered unsuitable for the activation of plasminogen. Instead 200 µl of the samples

were activated for 30 min at room temperature with 100 μl of a solution containing 4 mg urine activator per ml. The unheated solutions of proactivator and plasminogen contained small amounts of plasmin. The activity of this spontaneously occurring plasmin was determined separately, and subtracted from the activities obtained after activation with urine activator (Fig. 2).

The figures show that by heating at pH 10.6 proactivator disappears more rapidly than plasminogen, indicating that we are concerned with two different compounds. The denaturations of plasminogen and of the spontaneously occurring plasmin are first order reactions (Fig. 3), while the denaturation of proactivator seems to be more complicated. The relative decreases of plasmin and proactivator during heating for 30 min are in accordance with the results obtained by Müllertz [5,12].

DISCUSSION

The experimental results indicate the presence of at least two fibrinolytic precursors in human plasma. One of these is plasminogen. About the other can only be said that it is essential for the formation of the activator by streptokinase. On the basis of our present knowledge it seems most natural to identify this factor with the proactivator presented in the introductory scheme.

Experimental evidence of different heat stabilities of human plasminogen and proactivator has been presented by Troll, Sherry and Wachman [13] and by Troll and Sherry [4]. The first authors found proactivator to be labile in plasma at pH 7.0 and a temperature of 50°, while plasminogen was found to be stable. The present author has tried to reproduce this experiment, but found both precursors to be stable at the above conditions. A less marked, although obviously still significant difference between the heat stabilities of the two precursors were found at 100° and pH 2 and at 50° and pH 9 by Troll and Sherry [4]. The results of the last experiment resemble the results presented in this paper (50° and pH 10.6). However, Sherry later abandoned the two component-theory, which means that he questions the results of these experiments (Sherry and Alkjaersig [6,7]). Ablondi and Hagan [14] who used a more purified preparation of human plasminogen found identical heat stabilities of plasminogen and proactivator at 50° and pH 6.4. However, they filtered the heated aliquots before the assays. In a similar experiment at 50° and pH 7.0 where filtration was omitted, a greater stability of plasminogen than of proactivator was apparent from their results. The authors ascribe this deviation to a different solubility of the heated proteins in different assay methods, and suggest that this phenomenon might be interfering in similar experiments made by other investigators. In the present investigation the neutralized aliquots were cleared by centrifuging, and no precipitation occurred during the assays.

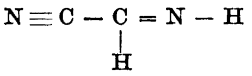
Studies on a Polymerization Product of Hydrogen Cyanide

TOMMY WADSTEN and STEN ANDERSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

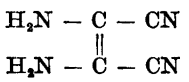
The crystalline compound formed by the polymerization of hydrogen cyanide has been studied by X-ray diffraction methods and infrared absorption measurements. The compound has been found to be a dimer of HCN and not a tetramer as suggested by previous authors. The following structure of the molecule is proposed:



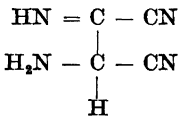
Strong intermolecular hydrogen bonds should be present in the structure.

It has long been well-known that pure hydrogen cyanide or hydrogen cyanide to which a small amount of an alkaline substance has been added polymerizes more or less rapidly depending on the concentration of the alkaline compound and on the temperature. The polymerization of pure hydrogen cyanide is very slow. The product is a dark, almost black, coal-like solid which cannot be reconverted to monomeric hydrogen cyanide. In the dark solid obtained, reddish brown, rodshaped crystals can be found. These crystals can be extracted by means of their solubility in ether. The dark residue, which is X-ray amorphous, is thought to consist of a mixture of several phases.

The structure of the crystalline polymerization compound has been discussed by several authors. From ebullioscopic measurements in methanol, Bedel [1] concluded the compound to be a tetramer of hydrogen cyanide. He suggested the structural formula $CN{\cdot}CH(CN){\cdot}NH_2{\cdot}HCN$. Gryszkiewicz-Trochimowski [2] considered it to have the following structure



while Hinkel and co-workers [3] thought this structure to be wrong and proposed instead the tautomeric structure:



Webb and co-workers [4] studied the compound by means of its ultraviolet absorption spectra, dipole moment measurements and infrared absorption spectra. They considered their data to support the structure proposed by Gryszkiewicz-Trochimowski.

By means of single crystal X-ray data, Sass and Donohue [5] found the unit cell dimensions of the polymer to be

$$a = 6.47 \text{ Å}, \quad b = 18.20 \text{ Å}, \quad c = 5.23 \text{ Å}, \quad \beta = 123°.$$

They did not, however, determine the structure.

EXPERIMENTAL

The polymerization products were obtained from a HCN gas bomb that had been kept for several years. The polymerization in the bomb was complete. From the dark solid, a lot of rod-shaped, reddish brown crystals could be picked out by hand. The crystals were almost colourless when recrystallized from ether. The X-ray patterns obtained from the crystals before and after the purification were identical.

The polymerization product was also prepared according to Linstead and co-workers [6]. The specimen obtained in this way was identical with the above mentioned one.

The purified crystals gave the following analysis:

	C	N (by residue)	H
weight % obs.	44.6	51.6	3.8
weight % calc.	44.4	51.9	3.7

The "melting point" (decomposition temperature) was found to be 180—181°C in good agreement with earlier observations.

The X-ray powder pattern was obtained using a Guinier camera with strictly monocromatized CuKα_1 radiation. The single crystal data were registered by the Weissenberg techniques with CuK radiation.

The infrared absorption spectrum was obtained on a Perkin-Elmer Spectrometer, Model 21. The sample was prepared for the measurements by the potassium bromide technique.

Table 1. The Guinier powder pattern of HCN dimer. Dimensions of the monoclinic unit cell:

$a = 6.511$ Å, $b = 18.31$ Å, $c = 5.208$ Å, $\beta = 121.9°$

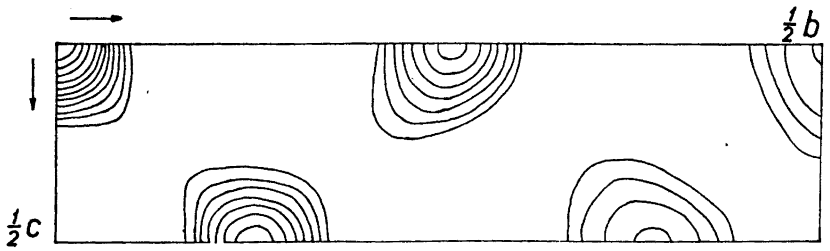

Fig. 1. HCN dimer: Patterson function. Projection along [100].

X-RAY STUDIES

A crystal was picked out from the dark solid and rotated around the rod-axis in the Weissenberg-camera. The identity period in this direction was found to be about 6.5 Å. Complete single crystal data were collected with this crystal setting. The crystal was monoclinic. Using the single crystal data, the powder pattern could be indexed as shown in Table 1. The following unit cell dimensions were thus derived:

$$a = 6.511 \text{ Å}, \quad b = 18.31 \text{ Å}, \quad c = 5.208 \text{ Å} \quad \beta = 121.9°.$$

The volume, 527.3 Å^3, gives a calculated density of 1.36 for 16 formula units HCN in the cell in fair agreement with the observed value of 1.31. The density was determined with the flotation method. The deviation from the value 1.41 determined by Sass and Donohue [5] is remarkable.

The reflexions which were systematically absent were $0k0$ with k odd and $h0l$ with l odd. This is in agreement with the space group $P2_1/c$, but the reflexion material may be insufficient (because of the high termal motion of the atoms) to draw definite conclusions.

The Patterson projection $P(vw)$ was calculated (*cf.* Fig. 1). It shows only eight strong, sharp and well resolved maxima. The spacing between the maxima in the projection is never less than 3.1 Å, which greatly exceeds the intramolecular distances of a compound of this kind. The structure must thus contain chain molecules running parallel to the a axis and distributed in the bc plane just like the maxima of Fig. 1. The length of the molecules must therefore correspond to the dimer (HCN_2). Adjacent molecules are probably connected by hydrogen bonds — this may also be inferred from the somewhat distorted appearance of the maxima in $P(vw)$.

Further studies on the crystal structure, which also include low-temperature investigations, are in progress.

DISCUSSION OF THE MOLECULAR STRUCTURE

In addition to the available X-ray data, some physical data concerning this substance are of particular interest. According to Webb and co-workers [4], the compound is a strong dipole and hence the molecule must be asymmetric.

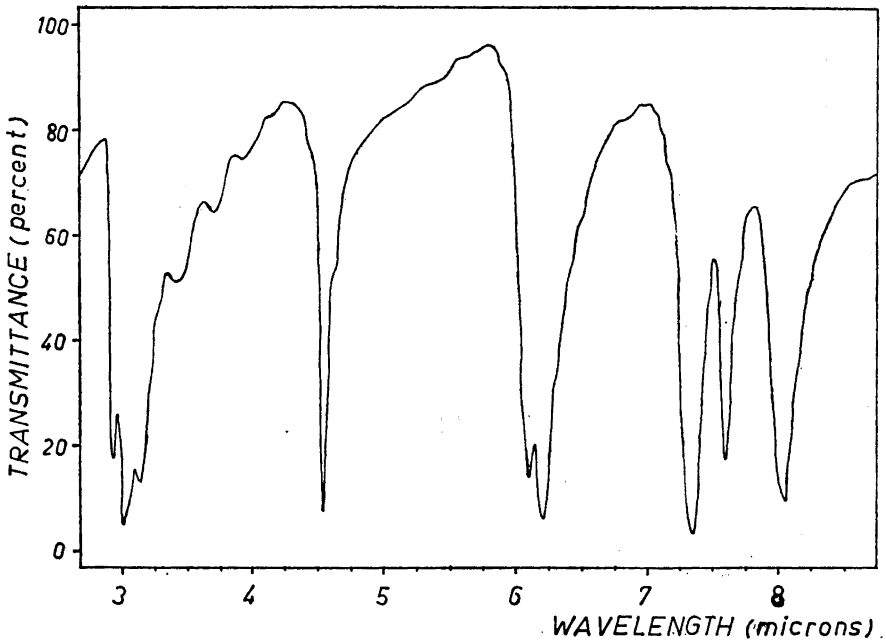

Fig. 2. Infrared spectra of HCN dimer.

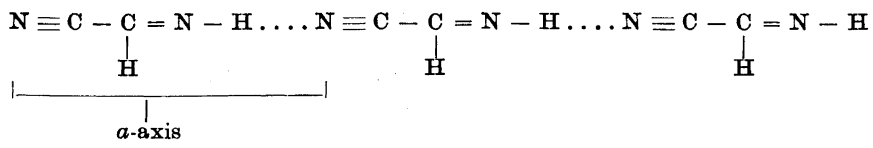
Like Webb and co-workers, we have also studied the infrared absorption spectrum of the compound. However, our interpretation of the spectrum is not in agreement with theirs. As is seen in Fig. 2, the diffuse, weak absorption maxima at 3.42 μ (2 924 cm^{-1}), 3.70 μ (2 703 cm^{-1}) and 3.92 μ (2 551 cm^{-1}) clearly demonstrate the presence of strong hydrogen bonds. Furthermore, there is a characteristic maximum at 4.54 μ (2 203 cm^{-1}) corresponding to a carbon-nitrogen triple bond. The maxima at 6.08 μ (1 645 cm^{-1}) may correspond to a carbon-nitrogen double bond. The maxima at 2.93 μ (3 413 cm^{-1}), 3.01 μ (3 322 cm^{-1}) and 6.20 μ (1 613 cm^{-1}) correspond to nitrogen-hydrogen bonds. The maxima at 3.15 μ (3 175 cm^{-1}) and 7.35 μ (1 361 cm^{-1}) and possibly also at 7.60 μ (1 316 cm^{-1}) can probably be assigned to carbon-hydrogen bonds. The cause of the maxima at 8.05 μ (1 242 cm^{-1}) is uncertain.

A molecule satisfying the above mentioned physical data can thus be written:

$$N \equiv C - \underset{\displaystyle H}{\overset{\displaystyle |}{C}} = N - H$$

A suitable name for the compund seems to be iminoacetonitrile. The sum of the three bond lengths N $\equiv$ C, C—C and C = N is about 3.8 Å, if conventional bond distances are used. The chains are arranged along the *a*-axis as follows:



The bond distance N—H....N will thus be quite short, indicating strong hydrogen bonds in agreement with the infrared data. (The result obtained by Bedel in his molecular weight determination may be due to these hydrogen bonds.)

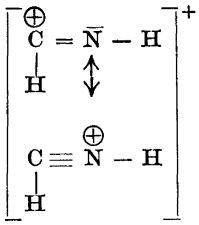
The high "melting" point, 181°C, for such a small molecule supports this suggestion concerning the presence of strong hydrogen bonds.

PROPOSED MECHANISM FOR THE POLYMERIZATION

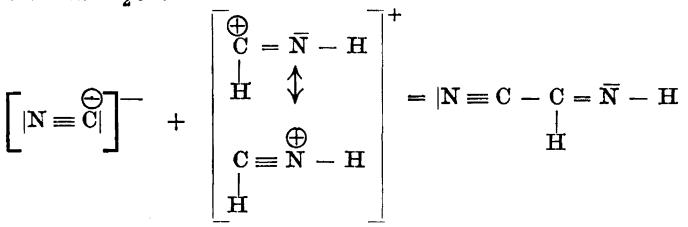
Pure hydrogen cyanide exhibits autoprotolyse according to the scheme

$$HCN + HCN = H_2CN^+ + CN^-$$

The ion H_2CN^+ can be written in two resonance forms:



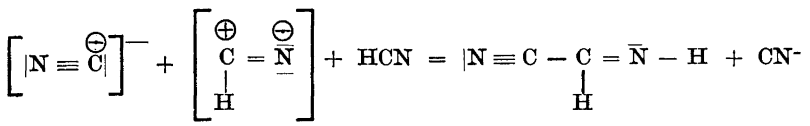
The dimer may thus be formed by the combination of the CN^--ion and the upper resonance form of H_2CN^+



In the presence of hydroxyl ions, the protolysis of hydrogen cyanide follows the scheme

$$HCN + OH^- = CN^- + H_2O$$

The cyanide ion may react with another molecule of hydrogen cyanide according to



The process evidently regenerates the cyanide ion and the polymerisation may thus be caused by a very small quantity of an alkaline substance.

It is interesting to note that no real melting occurs when the dimer is heated at temperatures above its "melting point". Some decomposition occurs and a black, X-ray amorphous residue is left which is stable up to several hundred degrees. The black residue resembles the dark solid formed originally during the polymerization of hydrogen cyanide. Further studies on this subject are in progress.

Acknowledgements. The authors wish to thank Dr. Arne Magnéli for his never failing support and many valuable discussions. Thanks are also due to Dr. Lennart Larsson for his help with the interpretation of the infrared absorption spectrum and to Miss Kerstin Stenberger for valuable discussions in the field of organic chemistry.

Determination of Starch Solubilized by Means of Irradiation

JANUSZ TRZEBIŃSKI* and LARS EHRENBERG

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

Solubilization of starch by irradiation can be utilized for analytical purposes. Water, chlorophyll, sugars, and other alcohol-soluble compounds must be removed before irradiation by means of extraction of the material with hot ethanol. After irradiation, starch is extracted with water and may be determined colorimetrically as the iodine complex or as glucose after hydrolysis. Since the method involves only simple and well-defined procedures, it seems well suited for rapid analysis of great numbers of samples. For application of the method a suitable radiation source is required, *e. g.* a (50—) 100—1 000 curie ^{60}Co gamma-source or a van de Graaff accelerator.

In routine investigations of plants and plant materials, the analysis of starch has always been an intriguing problem. The quantitative determination of this inexactly defined compound is laborious and time-consuming, especially owing to difficulties in extracting and solubilizing the compound in a reproducible manner. It has previously been found that irradiation makes starch more easily soluble in water, chiefly due to the induction of carboxyl groups [1]. This investigation is primarily concerned with the question, whether irradiation can facilitate a rapid and reproducible quantitative determination of starch.

The methods in use for the determination of starch involve the extraction and dissolution by means of HCl, $HClO_4$, $CaCl_2$, or alkalis. These chemicals are either so reactive that the structure of starch is changed, or, as in the case of $CaCl_2$, their dissolving capacity is rather small. Since the chemicals often also dissolve contaminating compounds, great difficulties arise which hinder subsequent procedure.

For the determination of starch several methods have been used. Determination of glucose after acid hydrolysis gives correct values only if the starch has first been isolated. The determination of glucose after hydrolysis by means of enzymes is also circumstantial, depending on, *i.a.*, variations in the amylose/

* Present address: Instytut Hodowli Roslin, Bydgoszcz, Poland.

amylopectin ratio. Between starches of different origin, differences in the proportions of these starch components also prevent the general use of a colorimetric determination of the starch-iodine complex. Since amylose and amylopectin exhibit different spectra with iodine, and perhaps also for other less well-defined reasons, the iodine complexes of starches of different origin exhibit different spectra and intensities of extinction [2,3]. Similarly, as in the case of enzyme hydrolysis, such factors may be corrected for, if the method is standardized by means of starch from the plant material under investigation [4]. Apart from the genetically controlled variation of the composition of starch, there is also a variation within the plant during its vegetative development [5]. The latter variation is rather small ($\pm$ 2 %) and has but an insignificant influence on the colorimetric determination of the iodine complex.

Polarometric methods [6] give reliable values only when fairly large amounts of starch are determined.

In summarizing this short review of methods for the determination of starch, it can be stated that the quantitative extraction and purification followed by acid hydrolysis permits the most exact determination [7]. This method is laborious, however, and not suited to routine determinations.

PROCEDURES

From the studies by Ehrenberg, Jaarma, and Zimmer [1] on the effects of roentgen- and gamma-radiations on starches it can be concluded that different physico-chemical changes are induced in the material leading to a greater solubility in water of the latter. This effect seems partly to be due to a disintegration of the molecules but especially to the introduction of acidic -COOH groups, which can be titrated and which, in neutral milieu, occur as the negatively charged base groups, $-COO^-$. (Such changes are already obtained when monosaccharides are irradiated [8]; the true nature of the groups in the case of polysaccharides has not yet been determined.)

Two criteria must be fulfilled to permit the use of these radiation-induced changes for analytical purposes:

(1) Irradiation should not interfere with opportunities for determining starch colorimetrically (or, in tests aiming at a calibration, as glucose after hydrolysis);

(2) Irradiation of the plant material should permit the extraction and dissolution of starch.

Chemical changes which might be of importance to the first criterion were studied by irradiating starches of different origin (potato, rice, arrow root, maize) with doses 10^5—10^7 rad of γ-radiation from a 60 curie ^{60}Co-source. Before irradiation, the starches were desiccated with aceton to a water content of 5 %.

Throughout the investigation, 0.1 % solutions of starch were prepared by dissolving 250 mg in 150 ml boiling water, and, after another 15 min of boiling and cooling, diluting to the mark of a 250 ml volumetric flask. For the colorimetric investigation of the iodine complex, 2 ml of the 0.1 % solution (*i. e.*, 2 mg starch) were introduced in a 100 ml volumetric flask, followed by 18 ml water, 2 ml 2 N acetic acid, 1 ml 10 % KI solution, and,

Table 1. Influence of gamma radiation on the properties of potato starch; *cf.* text.

Radiation dose Mrad	Extinction at λ = 590 mμ	Reducing sugar, % of starch	Specific viscosity	pH of 0.1 % solution
0	0.295	< 1	0.520	6.92
0.12	0.295	< 1	0.220	6.90
0.19	0.295	< 1	0.220	6.90
0.50	0.295	< 1	0.166	6.72
0.86	0.295	< 1	0.154	6.70
1.6	0.295	< 1	0.135	6.60
10	0.281	10	0.070	5.60

finally, 10 ml 0.01 N KIO_3. Water was then added to the mark. The extinction of the greenish solution was determined in a Beckman spectrophotometer at wave-lengths 500—650 mμ.

The radiation effects on the starch were also characterized by determinations of reducing sugars (5 ml samples of the 0.1 % solution were determined according to the method of Somogyi [9]), specific viscosities, and pH of the solutions.

The data demonstrate that up to doses of 1—2 × 10^6 rad, no changes occur which could be suspected to appreciably affect the analytical properties of the starches. In Table 1 this is demonstrated for potato starch; the other starches behaved identically in all respects. Higher doses, around 10 × 10^6 rad, are required to change the extinction. At the same time great amounts of reducing groups are introduced, and the viscosity indicates a considerable breakdown of the molecules [1]. The decreased extinction has to be ascribed, to a great extent, to a displacement towards red of the colour of the iodine complex (Fig. 1 and earlier publication [1]).

For the elucidation of factors pertinent for the second criterion it was important to include materials widely different in composition in general and in their starch content. Tissues storaging starch (potato tubers and barley seeds), as well as vegetative parts of plants with a low starch content (leaves of potato and maple, *Acer platanoides*) were investigated. In the following, the pilot experiments with potato tubers and maple leaves will be described.

Roughly disintegrated parts of the material were dehydrated in boiling ethanol. This treatment extracts chlorophyll and other alcohol-soluble substances (simple sugars, glycosides, alkaloids, fats, and waxes). The enzymes become inactivated, which is of extreme importance in the determination of starch in green, vegetative parts of plants,

where the (low) starch content undergoes rapid changes. Two extractions were performed at a final alcohol concentration of 75 %, and a third one at 80 % alcohol.

The dry material was ground in a Wiley mill (sieve 60). Parts of the samples were then very finely ground in a ball mill and sifted through silk-fabric.

The ball mills were prepared from thick-walled 100 ml cream bottles, each with 80—100 ball bearings 0.4—0.6 cm in diameter. In each bottle 0.5—0.8 g plant material was ground by placing the rubber-stoppered bottles in a shaking-machine. Gentle shaking (about 50 times per min) for 4—5 h was sufficient to disintegrate the material beyond a limit where no cells could be identified in the microscope.

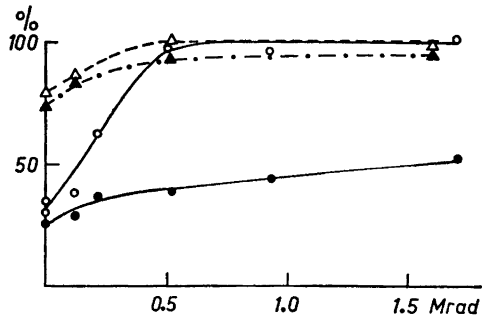

Fig. 2. Colorimetrically determined starch as a function of radiation dose. 100 % = starch content determined according to Pucher *et al.* ● Maple leaves: Wiley mill; ○ Maple leaves: ball mill; ▲ Potato tubers: Wiley mill; △ Potato tubers: ball mill.

200—500 mg material, depending on the starch content, is weighed, suspended in 25 ml water and then poured quantitatively into 150 ml of boiling water. The boiling is continued under reflux for 30 min. The addition of a few drops of *n*-octanol prevents foaming. After cooling, the solution is diluted to 250 ml, and after clearing by centrifugation, the iodine compound is determined colorimetrically at 590 mμ and in accordance with the method given above. The starch concentration is calculated from a calibration curve, which is prepared utilizing isolated starch of the type to be determined [10]. (Since in some cases, *e. g.*, maple leaves, absolutely pure starch could not be easily prepared, the calibration curve was based on the amount of glucose determined after hydrolysis.)

In order to compare the data from irradiated materials with exact values for their starch contents, the latter were determined according to Pucher *et al.*[7]. In addition, a generally applied laboratory method was used, involving determination of total reducing sugars after 2.5 h hydrolysis in 0.7 N HCl, followed by subtraction of pentosanes, determined according to Tollens and Kröber [11]. The difference, multiplied by 0.9, was regarded as starch.

When the starch content had to be related to total dry or fresh weight, the loss of original material by the alcohol extraction was determined in a special sample. (1 g of material was weighed into a Soxhlet extraction thimble, extracted with alcohol as described above, dried and weighed again.)

In Tables 2—3 data are presented for three materials which were subjected to thorough study, *viz.* maple leaves I (harvested about June 1st), maple leaves II (harvested a month later), and potato tubers. In principle the other materials behaved identically. Table 2 gives the weight of the material after extraction with alcohol, as per cent of original fresh weight (column 1), as well as the starch values, as percentages of the extraction residue, determined as the difference between total reducing sugars and pentosanes, or according to Pucher. These two methods give acceptably agreeing values for the starch contents.

For the same materials, the results of the colorimetric analyses after irradiation are presented in Table 3. The influences of the radiation dose and of the grinding method are clearly demonstrated, as illustrated by the summarizing graph, Fig. 2. The following conclusions can be drawn from the data:

(1) that with both methods of grinding, irradiation increases the possibility of extracting starch with water;
(2) that effective extraction is reached, however, only in the finely ground samples (ball mill), *i.e.*, where all cells were destroyed;
(3) that the dose required to make the starch fully soluble and extractable, amounts to about 500 000 rad. At this and higher doses good agreement was obtained with the data given in Table 1.
(4) It was further demonstrated that irradiation of thermally dried samples, which had not been extracted by means of alcohol, did not lead to corresponding solubilization of the starch, not even at higher doses ($> 10^6$ rad).

The stay of J. Trzebiński at the University of Stockholm was financed by a fellowship granted by the *Rockefeller Foundation*. The investigation was further supported by the *Swedish Agricultural Research Council*.

Electrophoresis Studies on Blood Plasma Esterases

II. Avian, Reptilian, Amphibian and Piscine Plasmata

KLAS-BERTIL AUGUSTINSSON

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

The esterase activity of the plasmata from birds, reptiles, amphibians and fish was investigated using as substrates a series of aliphatic, aromatic, heterocyclic and choline esters. The distribution of esterase activity and total protein after electrophoresis on cellulose columns are reported for the plasmata of cock, duck, turtle, two frogs *(Rana, Xenopus)*, and five teleostian fishes (pike, cod, eel, wrasse, frogfish). The electrophoretic patterns for the plasma proteins of one Elasmobranch *(Squalus)* and one Cyclostome *(Myxine)* are also demonstrated.

Of the three types of esterases present in most mammalian plasmata, only the aliesterases (B-esterases) and cholinesterases (C-esterases) were present in the plasmata of lower vertebrates, with the single exception of the plasma from female frogs which also contained an arylesterase (A-esterase) in addition to a propionylcholinesterase. Cock and chicken plasmata were characterized by a propionylcholinesterase which was the only esterase present and differed from other cholinesterases in many respects. Duck plasma contained a propionyl-B-esterase in addition to a propionylcholinesterase. One esterase only was present in turtle plasma; it had the characteristics of both a B- and C-esterase and was highly sensitive to physostigmine although non-choline esters were hydrolysed more rapidly than choline esters. More than one B-type esterase were probably present in the plasma of *Xenopus laevis*, which also contained a butyrylcholinesterase in low concentration.

In all the teleostian plasmata, an acetylcholinesterase was present in low concentration. The main esterases present in these plasmata were acetyl- or propionyl-B-esterases. Eel plasma contained such an esterase in very high concentration. The plasma of spiny dogfish had low B- and C-esterase activities, and the esterase activity of hagfish plasma with most substrates was negligible.

The esterase patterns of mammalian plasmata were discussed in the first paper of this series [1]. This paper considers the plasmata from lower vertebrates from a comparative point of view.

MATERIAL AND METHODS

Plasmata were prepared from heparinized blood, obtained by heart puncture or by cutting the ventral aorta (fish).

Substrates and inhibitors were the same as in the first report of this series. The following abbreviations are employed: acetyl, Ac; propionyl, Pr; butyryl, Bu; benzoyl, Bz; succinyl, Su; *iso*amyl, Am; triglycerides, *e. g.*, TBu; phenyl, Ph; choline, Ch; acetyl-β-methylcholine, MeCh; polyoxyethylene sorbitan monolaurate, Tween 20; tetra-*iso*propylphosphoramide, *iso*-OMPA; bis-mono*iso*propylamine fluorophosphine oxide, mipafox; 10-(1-diethylaminopropionyl) phenothiazine hydrochloride, Astra 1397; 1,5-*bis* (4-trimethylammoniumphenyl) pentane-3-one diiodide, 62C47; *bis*- (piperidinomethyl coumaranyl-5)ketone, 3318CT.

Electrophoresis was carried out on cellulose columns (3 cm × 40 cm) in veronal buffer solution (pH 8.4, $I = 0.1$) at 5—15°C, using 5 ml of buffered plasma [1]. The protein concentration of each eluted fraction (2.8 ml) was estimated by a modified Folin procedure [2].

Esterase activity was determined by the Warburg technique and expressed in b_{30} values [3]. The efficiency of esterase inhibition by various compounds was expressed in pI_{50} values, extrapolated from curves of inhibition (%) — inhibitor concentration (pI) where sufficient inhibitor was used at the higher pI levels to establish the point of complete inhibition.

RESULTS

The hydrolysis rates of various substrates by original plasma samples are summarized in Table 1. Activity values (b_{30} per 0.1 ml plasma) obtained with additional substrates are given in the text. The electrophoretic patterns presented in Figs. 1—11 show the rate of elution of the esterases in relation to various protein constituents. In the legends to these figures, relative substrate specificity and sensitivity to certain inhibitors of each esterase component are summarized in tabular form. The peaks of esterase activity are designated B and C, corresponding to aliesterase and cholinesterase activities, respectively. Arylesterases (A) were not present in the plasmata studied, except for a sample from frog (*Rana*).

Cock and chicken (Fig. 1). The esterase pattern of cock plasma was characterized by the comparatively high hydrolysis rate of propionylcholine which was the highest value observed among the esters used as substrates. This plasma was unique among those examined in being devoid of both A- and B-esterases. The B-type esterase described by Aldridge [4] was actually identical with the propionylcholinesterase present, hydrolysing acetyl-β-methylcholine at a comparatively high rate. This enzyme was a typical physostigmine-sensitive propionylesterase hydrolysing both tripropionin and phenyl propionate at a higher rate than their other acyl homologues. No other esterases were detected on electrophoresis in the separated plasma. The hydrolysis rates of four different substrates were all found to be influenced at the same degree by the eight inhibitors tested (Table 2), providing additional evidence that the same single esterase hydrolysed these substrates. This esterase was found to be extremely sensitive to mipafox.

The propionylcholinesterase of the cock differed from both the acetylcholinesterases present in most animal erythrocytes and from the butyrylcholinesterases present in several mammalian plasmata. This difference included the unusual substrate specificity, *i.e.*, high rate of hydrolysis of acetyl-β-methylcholine (also observed previously [5,6]) and various types of non-choline esters,

Table 1. Enzymic hydrolysis of various esters by avian, reptilian, amphibian and piscine plasmata. Samples from at least three animals of each species were analysed. The activity values (b_{30}) refer to initial hydrolysis rates with a representative sample and are expressed in μl CO_2 per 0.10 ml of plasma per 30 min, corrections made for nonenzymic hydrolysis. Where values are indicated in brackets, initial hydrolysis rate was determined by extrapolation. A question mark indicates that such extrapolation could not be done because of a too rapid decrease of the hydrolysis rate. An asterisk denotes that the activity varies greatly from individual to individual. Code names are explained in the text.

and a unique pattern of susceptibility to various esterase inhibitors since those being selective inhibitors of acetylcholinesterase (62C47 and 3318CT) had very little effect in this case (Table 2). The low inhibiting effect of such compounds on the chicken serum cholinesterase was observed previously [7,8]. Rat plasma contains a propionylcholinesterase based on substrate specificity, but the propionylcholinesterase of cock plasma differs from that of the rat in showing no inhibition by excess substrate (AcCh or PrCh), as was demonstrated also in previous papers [5,9]. The cock (chicken) plasma cholinesterase, therefore, has to be regarded as a special type of physostigmine-sensitive esterase, differing from the cholinesterases of other vertebrate plasmata in many respects. It is another example of the view [1] that no clear-cut distinction between various groups of cholinesterases can be made.

Chicken plasma gave the same results both regarding the properties of the propionylcholinesterase present and the lack of other types of esterases. The sex difference in plasma cholinesterase activity observed by Caridroit *et al.*[10] was not further investigated.

Table 2. Susceptibility of cock-plasma esterase to various inhibitors. Values refer to negative logarithm of molar inhibitor concentration producing 50 % esterase inhibition. The enzyme preparation (whole plasma and separated esterase fractions, respectively) was incubated for 50 min with the inhibitor prior to addition of substrate.

Duck (Fig. 2). The plasma from duck hydrolysed the phenyl esters and the triglycerides at a much higher rate than did cock plasma. With these substrates and with choline esters, the propionates were hydrolysed more rapidly than the corresponding acetates and butyrates. The hydrolysis rate with

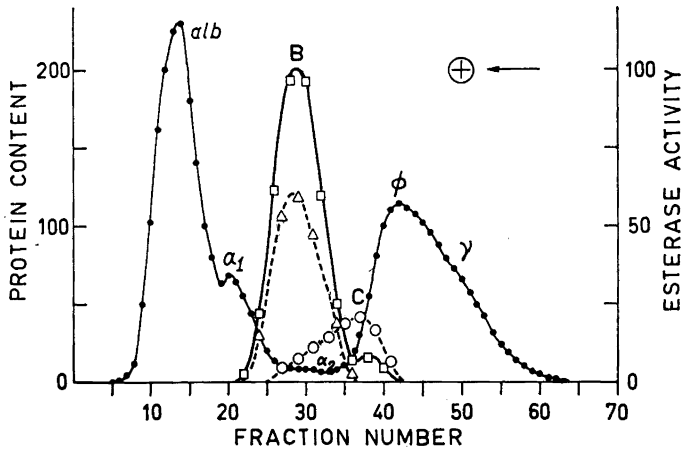

Fig. 2. Duck plasma. Conditions as for Fig. 1. □———□, PhBu (0.20) and PhPr (0.10); △– – –△, TPr (0.20); O– – –O, PrCh (0.40).

C	1	5	4	<1	5	4	8.5	8.8	5.5	5.7

acetyl-β-methylcholine was relatively high, but lower than that for cock plasma. On the other hand, the carbon analogue of acetylcholine (3,3-dimethylbutyl acetate) was hydrolysed at a comparatively high rate (b_{30} 20). The hydrolysis rates with the *iso*amyl esters dropped off very rapidly with time although the initial rates were as high as with the triglycerides.

In contrast to cock plasma, the duck plasma gave two esterase peaks on electrophoresis. The main peak was due to a B-estrase which was sensitive to *iso*-OMPA (Fig. 2) and mipafox (pI_{50} 8.5). This esterase differed from the B-type esterases of the mammalian plasmata in being sensitive to 10^{-5} M physostigmine as is also characteristic of certain B-esterases of lower vertebrates (turtle, frog, pike). This propionyl-B-esterase was similar to a cholinesterase in regard to the susceptibility to inhibitors. However, a propionylcholinesterase (C) was found in a second slower-moving peak. Some of the esterase activity was also found in the B-esterase peak as determined by comparing the hydrolysis of propionylcholine and phenyl propionate by these fractions. Except for differences in sensitivity to physostigmine, the B- and C-esterases were best differentiated by using Astra 1397 (or atoxyl) which selectively inhibited the C-esterase in a concentration of 10^{-5} M.

Indoxyl acetate was hydrolysed by the B-esterase only.

Turtle, Testudo graeca (Fig. 3). The propionyl esters of all series of substrates were hydrolysed at the highest rate. Particularly high rates were observed with tripropionin and phenyl propionate. This plasma hydrolysed heroin

(b_{30} 220) and the carbon analogue of acetylcholine (b_{30} 160) more rapidly than the choline esters.

Turtle plasma was almost free of albumin-like proteins, confirming a recent observation made by Cohen and Stickler [11]. Only one esterase peak was obtained on electrophoresis and this had about the same electrophoretic mobility as was found for most B-esterases of vertebrate plasmata. Most results obtained were consistent with the view that only one esterase was present in this plasma. Summation experiments with tripropionin, heroin and propionylcholine showed that all three substrates were probably split by the same esterase. This was also indicated by the inhibitory experiments, although the 50 % inhibition values (Table 3) obtained with the original plasma showed some discrepancies for the compounds *iso*OMPA and 3318CT.

The properties of this esterase were unique in many respects. It hydrolysed the propionates in the following order of decreasing rates: TPr > PhPr > AmPr > Heroin > PrCh. This esterase was sensitive to both physostigmine and the organophosphorus compounds used (Table 3). Therefore, it had the characteristics of both a B-and C-esterase (*cf.* Ref.[1]), and is the first example of a physostigmine-sensitive esterase hydrolysing non-choline esters more rapidly than choline esters. This esterase, therefore, may represent an intermediate stage in the phylogenetic evolution of plasma esterases (see further the third paper of this series [12]).

Frog, Rana temporaria (Fig. 4). The hydrolysis rate with phenyl esters varied considerably from animal to animal. The plasma from female frogs generally had much greater activity than that from male frogs against these esters. Phenyl acetate, for instance, was hydrolysed at about a 40 times higher rate by female plasma compared with male plasma. This sex difference was due to the presence of a propionyl- (or acetyl-) arylesterase (A-esterase; see Fig. 4, inserted graph) which was absent in the male frog plasmata investigated in this study. Heroin was hydrolysed at a higher rate by frog plasma (both sexes, b_{30} 25) than by most mammalian plasmata.

On electrophoresis the B- and C-esterases migrated close together, the latter having a somewhat lower mobility than the former, in contrast to most other plasma esterases of these types. A fast-migrating esterase was probably identical with the B-esterase of the main esterase peak as was demonstrated by substrate specificity and inhibitor experiments. This esterase was a propionylesterase which was more sensitive to physostigmine (pI_{50} 4.5) than the B-esterases of mammalian plasmata.

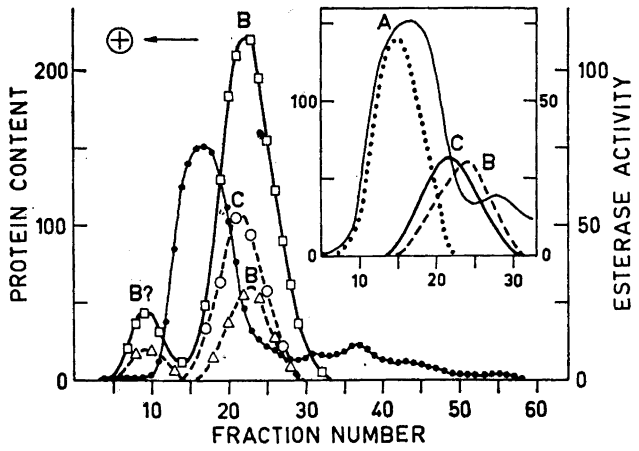

Fig. 4. Frog (male) plasma. Conditions as for Fig. 1. □———□, PhBu (0.40); △– – –△, TPr (0.40); O– – –O, PrCh (0.40).

The insert (of the same scale as the main graph) is the electrophoretic pattern of the plasma from a female frog with high activity against phenyl esters (PhAc, $b_{30} > 5\,000$). ———, protein; ....., PhAc (0.02); – – – –, TPr (0.20); ———, BuCh (0.20).

The C-esterase of frog plasma was a propionylcholinesterase which hydrolysed butyrylcholine at a relatively high rate and was less sensitive to mipafox (pI_{50} 5.2) but more sensitive to atoxyl (pI_{50} 5.1) and quinine (pI_{50} 4.2) than are most other plasma cholinesterases. Atoxyl was a useful selective inhibitor of cholinesterase of this plasma, because both B- and A-esterases (when present) were resistant to this agent. Plasma cholinesterase of male frogs was responsible for about 30 % of the total hydrolysis of the phenyl esters.

The propionylcholinesterase was inhibited by high concentrations of propionylcholine and butyrylcholine with a substrate optimum of 7×10^{-3} M. In this respect this esterase resembles the group of acetylcolinesterases present in the erythrocytes of various animals.

South African clawed frog, Xenopus laevis (Fig. 5). The esterases present in the plasma sample analysed, collected from five females, differed greatly from those of the plasma of *Rana*. An arylesterase was absent because the

C	?	?	?	?	?	<1	7	7

hydrolysis of phenyl esters was completely inhibited by low concentrations of both mipafox and *iso*-OMPA. There were probably more than one B-type esterase with different substrate specificities. The complexity of the esterase peak obtained on electrophoresis was in conformity with this hypothesis. The peaks B1 and B2 could possibly be due to the same enzyme, but the esterase of peak B3 was characterized by relatively higher rate of Tween-20 hydrolysis and greater sensitivity to physostigmine than the B1- and B2-esterase fractions. The B-esterases were all of the butyryl- or propionyl-esterase type and hydrolysed heroin at high rates (b_{30} per 0.1 ml plasma, 110).

The C-esterase, present in too low concentration to be detected after electrophoresis, was a butyrylcholinesterase which was highly sensitive to Astra 1397 ($pI_{50} \approx 5$) as are most of the plasma butyrylcholinesterases.

This plasma contained in high concentration a protein which migrated faster on electrophoresis than most albumin-like proteins of other plasmata.

Pike, Esox lucius (Fig. 6). Plasma from this fish hydrolysed triglycerides more rapidly than phenyl esters, tripropionin being split at the highest rate. The main esterase present was a B-esterase being highly sensitive to mipafox ($pI_{50} \approx 9$) and less so to physostigmine (pI_{50} 4.8) when tested with tripropionin,

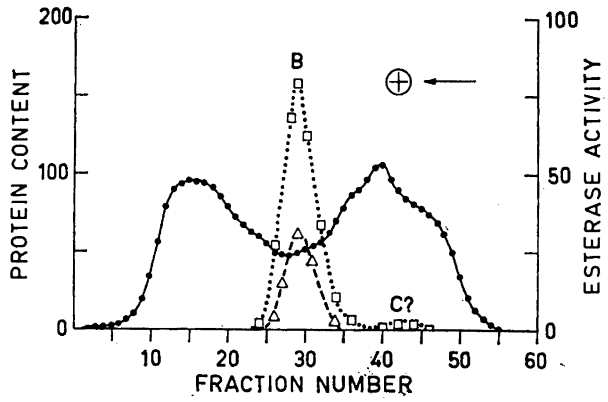

Fig. 6. Pike plasma. Conditions as for Fig. 1. □·····□, PhAc (0.10); △———△, AmBu (0.10).

						Phys	Mipafox
B	80	75	30	100	0	4.8	≈9
C	?	0	0	0	<1	6.5	≈4

phenyl acetate and phenyl butyrate respectively as substrates. This enzyme hydrolysed heroin at a low rate (b_{30} 7) in contrast to the B-esterases of cod and eel plasmata, and the carbon analogue of acetylcholine at a relatively high rate (b_{30} 34).

The C-esterase present in low concentration was an acetylcholinesterase which was much less sensitive to mipafox than the B-esterase. In this respect the pike cholinesterase was similar to an acetylcholinesterase of higher animals.

Cod, Gadus callarias (Fig. 7). An acetyl-B-esterase was characteristic of this plasma. Heroin was hydrolysed at a high rate (b_{30} 220), and mipafox was an inhibitor but not *iso*-OMPA. The esterase appeared as a uniform peak on electrophoresis.

An acetylcholinesterase was present but in too low concentration to be detected in the fractions after electrophoresis.

Eel, Anguilla anguilla (Fig. 8). This plasma was characterized by its unusually high activity in hydrolysing aromatic esters and triglycerides, especially those of butyric acid. This material seems to be the richest animal source of "lipase" activity ever described. It is 100 times more active than human plasma in hydrolysing these esters. Heroin was hydrolysed at a high rate (b_{30} 210) and so also was Tween 20 (b_{30} 60). The high "lipase" activity tested with tributyrin has been reported previously [13].

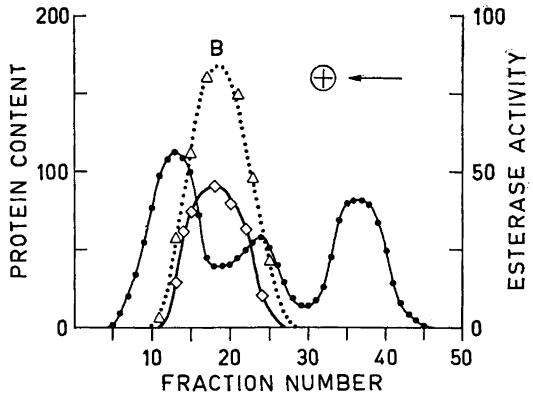

Fig. 7. Cod plasma. Conditions as for Fig. 1. △·····△, TAc (0.20); □———□, heroin (0.20).

						Phys	Mipafox
B	60	40	42	23	0	≈3.5	5.3
C	?	?	?	?	<1	≈6	—

The main esterase present was a butyryl- or propionylesterase (B1), which hydrolysed the aromatic esters at a higher rate than the triglycerides. This enzyme was highly sensitive to mipafox and *iso*-OMPA (see legends to Fig. 8), and as many esterases of this type present in the plasmata of lower vertebrates it was relatively sensitive to physostigmine. A minor esterase peak with a lower electrophoretic mobility was also observed. It was due to an esterase which differed from the main esterase in hydrolysing the acetates more rapidly than the butyrates, in being much less sensitive to mipafox and *iso*-OMPA and highly resistant to physostigmine. This enzyme has to be regarded as a B-esterase, although the aliphatic esters were hydrolysed at a lower rate than the aromatic ones.

As with most fish plasmata, eel plasma contained a C-esterase, the specificity and sensitivity to inhibitors of which were characteristic of an acetylcholinesterase. High concentration of acetylcholine inhibited the activity.

Wrasse, Labrus berggylta (Fig. 9). The plasma from females contained a B-esterase which hydrolysed butyrates and propionates at a higher rate than acetates. It was similar to the B2-esterase of eel plasma in being sensitive to mipafox but not to *iso*-OMPA. Tween 20 was hydrolysed at a relatively high rate by this enzyme (b_{30} 100). Choline esters were hydrolysed at very low rates, due probably to an enzyme similar to an acetylcholinesterase.

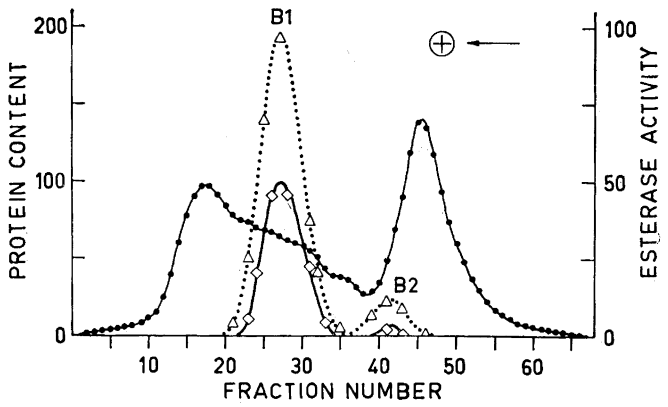

Fig. 8. Eel plasma. Conditions as for Fig. 1. △·····△, TAc (0.05); ◇———◇, heroin (0.1).

The plasmata of Labrides are characterized by the presence of a blue-coloured dye [14,15]. On electrophoresis, this dye of protein nature was easily separated from the other three main protein constituents by its comparatively low mobility. The coloured protein was probably a chromoprotein which gave absorption maxima at 390, 600 and 645 mμ. Part of the dye with the same absorption maxima was found also in two other protein fractions (see Fig. 9).

The four protein peaks obtained on electrophoresis were recently observed also by Fine and Drilhon [16] on electrophoresis on paper and gelatine.

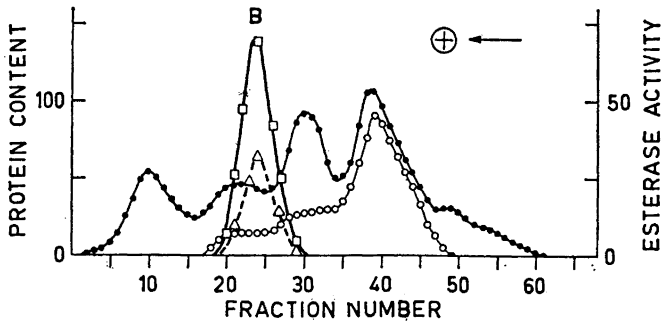

Fig. 9. Wrasse plasma. Conditions as for Fig. 1. □———□, PhBu (0.05); △ – – – △, TPr (0.1); ○———○, blue colour measured spectrophotometrically at 645 mμ.

C	0	0	0	<1	≈ 6	≈ 6	—	—

Frogfish, Lophius piscatorius (Fig. 10). A B-esterase was present in high concentration and had the properties of an acetylesterase. This esterase hydrolysed heroin at a higher rate (b_{30} 535) than any other plasmata studied in this series. In contrast to most other esterases of this type, *para*-substitution in phenyl acetate with a nitro group increased the enzymic hydrolysis. Mipafox was an inhibitor but not *iso*-OMPA. Like the B-esterase of *Labrus* plasma, the frog-fish esterase was sensitive to physostigmine and 3318CT in 10^{-4} M or higher concentrations. An acetylcholinesterase was probably present in low concentration.

This plasma was characterized by the very low content of albumin-like proteins.

Other teleostians. Blood plasma samples from sea-scorpion (*Cottus scorpius*) and mackerel (*Scomber scomber*) were also analysed. Both plasmata contained a B-esterase in low concentration which was of a butyryl- or propionylesterase type. Choline esters were hydrolysed at very low rates, due to the presence of an acetylcholinesterase. The low content of such an esterase in teleostian plasmata was reported previously [5,17].

The electrophoretic patterns showed three or four protein peaks, the mackerel plasma having higher concentration of fast-running proteins than most other fish plasmata studied. The green dye characteristic of the Cottied plasmata was probably a chromoprotein which migrated electrophoretically more rapidly than the other main plasma proteins. The electrophoretic patterns of these two plasmata will be published in a following paper [12].

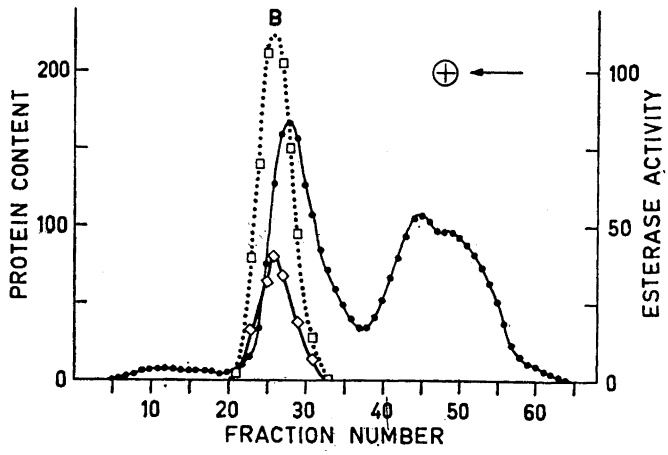

Fig. 10. Frogfish plasma. Conditions as for Fig. 1. □·····□, PhAc (0.05); ◇————◇, heroin (0.025).

C	?	?	?	≈ 7	—	—	—

Spiny dogfish shark, Squalus acanthias. The plasma sample obtained from this Elasmobranch had very low esterase activity, too low to be detected after electrophoresis. The activity was due to a propionyl-B-esterase and an acetylcholinesterase. The low content of the latter enzyme was previously reported [5,17]. The protein curve obtained on electrophoresis is shown in Fig. 11.

Hagfish, Myxine glutinosa. The sample collected from several animals had negligible esterase activity when tested with most substrates. Aromatic esters were hydrolysed at very low rates and this reaction was probably due to an acetyl- or propionyl-B-esterase. A cholinesterase was probably not present. Fig. 11 shows the electrophoretic pattern of the protein components which were present in low concentrations (3.5 mg of total protein per 100 μl plasma).

The low lipase activity of the plasma from another Cyclostome (*Petromyzon marinus*) was noticed previously [13].

A discussion of the results reported above in relation to those of the first report of this series will be presented in a concluding paper [12].

This investigation was supported by a grant from the *Swedish Natural Science Research Council*. A grant from *Stiftelsen Lars Hiertas Minne* made it possible to work during the summer 1957 at the *Kristineberg Zoological Station*, Sweden, on fresh material from

Electrophoresis Studies on Blood Plasma Esterases

III. Conclusions

KLAS-BERTIL AUGUSTINSSON

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

A discussion is given of the results obtained in a comparative study of the esterases present in the plasmata from 27 various vertebrates. Each species has its own esterase pattern, and within each of the three groups of esterases, arylesterases (A-esterases), aliesterases (B-esterases) and cholinesterases (C-esterases), there are variations in the properties of individual enzymes. Arylesterase is the predominant esterase in mammalian plasmata, and is absent in the plasmata of birds, reptiles, amphibians and fish. Aliesterase (lipase) is the main esterase of lower vertebrate plasmata, and is not present in human, monkey, dog, ruminant, cock, or turtle plasmata. A propionyl-aliesterase is considered to be the most primitive type of esterase present in vertebrate plasmata, and other esterases including the various types of aryl- and cholinesterases are suggested to be phylogenetically evolved from such an esterase. The esterase present in turtle plasma is of an intermediate stage. The physiological function and origin of the plasma esterases are briefly discussed.

The plasma protein patterns of little piked whale, sea-scorpion and mackerel are illustrated.

A number of investigations have demonstrated that there are appreciable and characteristic variations in plasma (serum) protein patterns with animal species. Significant differences in the electrophoretic patterns for various species have been observed in respect of mobilities, number and relative proportion of protein components, and presence or absence of components [1–5]. Such electrophoresis studies were performed either with the Tiselius apparatus or with the paper electrophoresis technique. Only rarely were the biochemical properties of individual proteins investigated in these comparative studies. In the present investigation, the results of which were reported in the first two papers of this series [6] and in a preliminary paper [7], preparative electrophoresis on cellulose columns was used to separate esterase-active components for studies of the properties of individual enzymes with respect to specificity and sensitivity to various selective esterase inhibitors. Such investigations were regarded to be of importance because previous differentiation of these enzymes

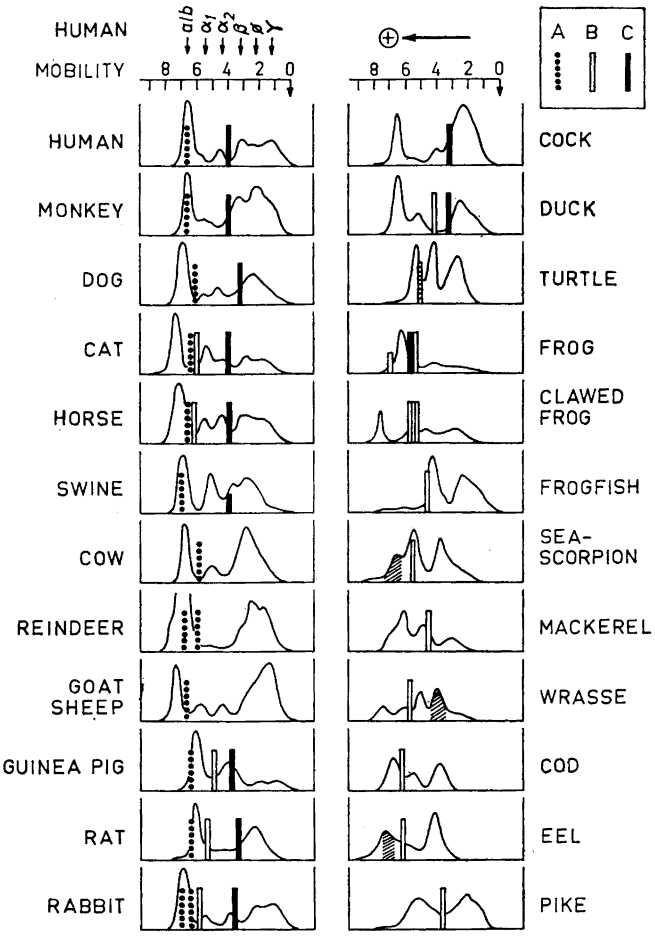

Fig. 1. Comparison of the electrophoretic mobilities of proteins and esterases of vertebrate plasmata relative to those of human plasma proteins (marked at the top of the graph). Experimental conditions: 5 ml plasma fractionated on cellulose columns (3 cm × 40 cm) for 30 h in veronal buffer (pH 8.4, $I = 0.1$) at an applied voltage of 260 V and 60 mA. The mobilities of human plasma proteins expressed in $cm^2V^{-1}s^{-1} \times 10^{-5}$ are those obtained with the Tiselius apparatus in the same buffer solution[8]. ————, protein; A, arylesterase; B, aliesterase and/or lipase; C, cholinesterase. The unique properties of the esterase of turtle plasma is specifically marked. Shaded areas refer to coloured proteins: blue for wrasse, green for sea-scorpion and eel.

was based mainly on work with original plasma (serum) or crude enzyme preparations. These previous studies have led to much difference of opinion as to the classification of plasma esterases.

Protein patterns. The absolute electrophoretic mobilities of various protein components were difficult to evaluate with the technique used. However, all

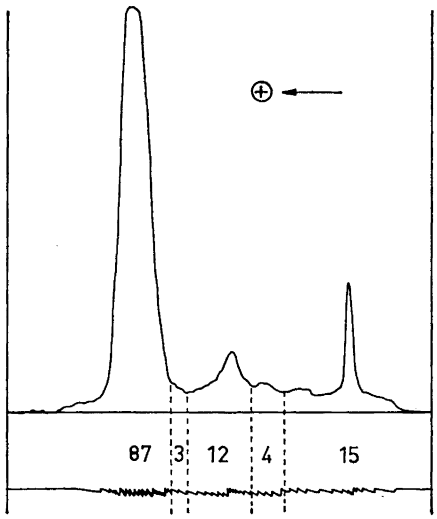

Fig. 2. Electrophoretic pattern of a plasma sample from *Balaenoptera acutorostrata* (little piked whale). Integrated curve from a paper electropherogram; veronal buffer (pH 8.6, $I = 0.1$), 150 V, 5 mA, 8 h. Numbers refer to relative protein concentrations.

electrophoresis runs and elutions were carried out under identical conditions, and therefore the relative mobilities of the components of various plasmata could be compared relative to those of human plasma proteins. Such a comparison of the results obtained with most of the plasmata studied is shown in Fig. 1. The results presented for individual species are based on a relatively low number of animals, but the patterns obtained are reproducible enough to demonstrate the species variation of protein patterns of the plasmata investigated. It will be remembered in this connection that individual variations in these patterns have been observed [1] in certain species. In the experience of the present author, such variations are particulary frequent for the esterase patterns of rabbit and swine plasmata. In addition, sex differences for certain vertebrate plasmata, *e. g.*, fowl plasma [2], have been reported, and alterations in anatomy and ecology during metamorphosis and growth has been shown to be accompanied by radical biochemical changes, also in the blood plasma proteins [9,10]. These individual variations, however, were not further investigated in the present investigation, since the electrophoretic plasma patterns of each species were generally reproducible with a few exceptions.

The electrophoretic patterns of all mammalian plasmata studied were characterized by a sharp albumin peak, the mobility of which varied relatively little from animal to animal. Albumin was also the predominant protein in a plasma sample from a whale, *Balaenoptera acutorostrata*, the electrophoretic pattern of which is shown in Fig. 2; the esterase activity of this sample was too low to be detected after electrophoresis. Proteins with similar mobilities to those of mammalian albumins were present in avian and amphibian plasmata, but not in the plasma of turtle. The absence of albumin-like serum proteins

in turtles was reported previously [11,12]. The influence of genetic and physiologic factors on plasma protein composition are obvious for amphibian and reptilian plasmata [13], and is particularly striking for teleostian plasmata [14,15]. Considerable differences were thus observed in the present investigation for two *Rana* species, the clawed frog *(Xenopus laevis)* which is a member of the peculiar family Aglossa, and seven teleostian fishes. Frogfish plasma was characterized by a sharp protein peak with a mobility similar to that of human plasma α_2-globulin. Other teleostian plasmata contained albumin-like proteins in varying amounts. It is of possible significance that the phylogenetically lowest teleostian studied, pike, had a very low amount of albumin-like protein, which was absent in the plasmata of both the spiny dogfish shark (an Elasmobranch), confirming a previous observation [16], and the hagfish (a Cyclostome). The electrophoretic pattern of pike plasma was also in other main characteristics similar to that of the elasmobranch plasma.

In certain species (cat, reindeer, rat, cock, duck, frog, eel) a small amount of protein, migrating somewhat faster than albumin, was present. These components had no relation to the esterases studied, and their relation to other plasma proteins is unknown. A fast-moving protein was present in a relatively high amount in the plasma of clawed frog.

Among all plasmata studied much variation was observed in the globulins, both those migrating between albumins and fibrinogen and the γ-globulins with lower mobility relative to that of fibrinogen. No distinct separation of β- and γ-globulins and fibrinogen was obtained in most cases. The α-globulins of several plasmata were more complex than those of human plasma. Turbidity, probably associated with lipoid, appeared to be caused in most cases by these components, especially the fast-migrating α-globulins. The amount of γ-globulins in mammalian plasmata varied considerably with species, and a component comparable to this protein was absent, or present in low amount, in most teleostian plasmata. Great variation in fibrinogen concentration was also observed. The amount of this component was particularly low in animals belonging to lower phylogenetic orders. In the whale plasma sample analysed, fibrinogen was apparently absent (Fig. 2).

Esterase patterns. Electrophoretic separation of plasma esterases has been reported only in a few cases. Human plasma *cholinesterase*, which precipitates together with albumin on ammonium sulphate fractionation [17,18], migrates on electrophoresis between the α_2- and β-globulin components [19–21]. Horse plasma cholinesterase behaved similarly on paper electrophoresis [22,23]. It was demonstrated in the present series of investigations that there was very little variation from animal to animal in the electrophoretic mobility of this type of esterase, when present. Frog plasma cholinesterase was an exception in this respect, with an unusually high electrophoretic mobility. Although the biochemical properties of these esterases varied considerably with species, the cholinesterases present in mammalian and avian plasmata behaved similarly on electrophoresis, with mobilities close to those of α_2 and/or β-globulins of human plasma. The low cholinesterase activity of ruminant and fish plasmata could not be detected after electrophoresis, but by indirect methods it was found that the cholinesterase present had an electrophoretic mobility close to those of other plasma cholinesterases. The unique single esterase of turtle

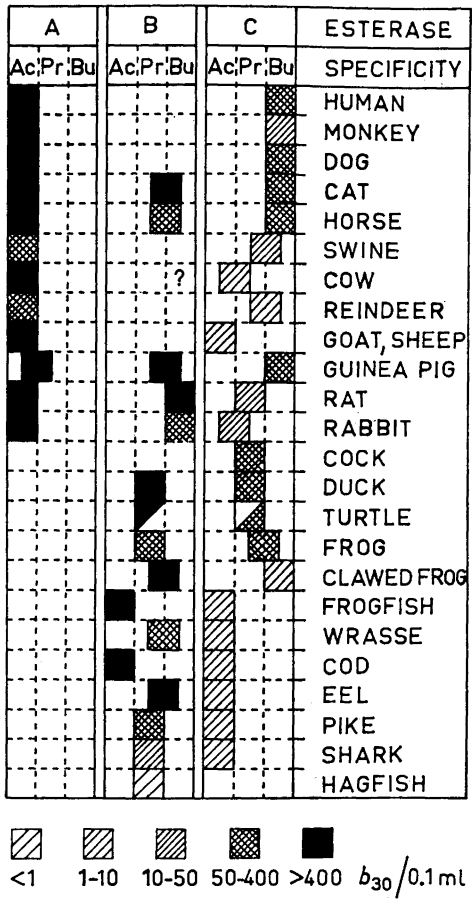

Fig. 3. Plasma-esterase patterns of vertebrates. Groups of esterases: A, arylesterase; B, aliesterase, lipase; C, cholinesterase. Relative esterase specificity based on the acyl radical of the substrate, selectively hydrolysed by the enzyme in each group: Ac, acetyl; Pr, propionyl; Bu, butyryl. Activity values in b_{30} per 0.1 ml plasma (μl CO_2 evolved from a bicarbonate — CO_2 buffer in 30 min at 25°C corrections made for the spontaneous substrate hydrolysis) refer to the hydrolysis rates observed with the substrate which is hydrolysed at the highest rate by each esterase. Monkey plasma is a sample from a macaque monkey. The properties of the esterase of turtle plasma are those of a propionyl-B- *and* propionyl-C-esterase. This histogram includes revisions in addition to that previously reported [7].

plasma moved at a higher rate than other plasma cholinesterases, but more slowly than the aliesterases of mammalian plasmata. The electrophoretic behaviour, as well as other properties of turtle-plasma esterase, are intermediate between the C- and B-esterases.

Great variation in the properties of cholinesterases present in various vertebrate plasmata was observed (Fig. 3). The cholinesterases of human, monkey,

dog, cat, horse and guinea-pig plasmata had the specificity of butyrylcholinesterases. A similar esterase was also present in low amounts in clawed-frog plasma. The ruminant plasmata had low cholinesterase activity, and the specificity of these esterases varied considerably from animal to animal, but in no case was a butyrylcholinesterase detected. Swine plasma cholinesterase had unique properties, and was present in high concentration in sow's colostum and milk [24,25]. An acetylcholinesterase was present in low concentration in the plasmata of goat and sheep and in those of all teleostians studied. Rat and rabbit plasmata were characterized by propionylcholinesterases, the properties of which were different with respect to sensitivity to quaternary ammonium compounds and organophosphorus compounds, respectively [6]. The plasmata of cock and duck also contained propionylcholinesterase, differing from both the rat and rabbit cholinesterases, *e. g.*, in the activity-substrate concentration relationship for choline esters. The esterase in turtle plasma had the properties of a cholinesterase in being highly sensitive to physostigmine, but differed from all other esterases of this type by hydrolysing choline esters at a lower rate than non-choline esters. It is suggested that this esterase is of a phylogenetically intermediate stage between the B-esterases present in high concentration in the plasmata of lower vertebrates, and the C-esterases of vertebrates belonging to higher orders. It is also of probable significance that the plasma esterase of turtle is a propionylesterase, since such an esterase type may be the most primitive one from a phylogenetic point of wiew. During the biochemical evolution, the propionyl- and butyrylcholinesterases might have originated from the B-esterases, the former being more specialized forms of the latter. The acetylcholinesterases of goat, sheep and fish plasmata and the propionylcholinesterase of rabbit plasma, the properties of which differed from those of most propionylcholinesterases of other vertebrates, might have a different source of origin. The similarity of these esterases to the acetylcholinesterases present in nervous and muscle tissues and in erythrocytes is suggestive evidence for this hypothesis.

Plasma cholinesterases therefore are regarded as a group of esterases with much divergent properties, with regard to specificity against various choline and non-choline esters, sensitivity to inhibitors, and activity-substrate concentration relationships. No clearly cut classification can be made, and it is advisable to state the enzyme source in any work with these esterases. It is not possible to apply results obtained with the plasma of one species to any other species. Intermediate types between "specific" cholinesterases, as butyryl-, propionyl- and acetylcholinesterases, also exist, and in most vertebrate plasmata the cholinesterase present is characteristic of the species.

Aliesterase seems to be the main esterase of lower vertebrate plasmata. It was absent in human and monkey plasmata, and its presence in ruminant plasmata is questionable. This esterase was not detected in cock (and chicken) plasma, but was present in high concentration in fish plasmata, and was the only detectable esterase in cyclostome plasma. The electrophoretic mobility of aliesterase varied considerably with species, but the enzyme migrated in most cases together with α-globulins, at a higher rate than cholinesterases but more slowly than arylesterases. The electrophoretic separation of the A- and B-esterases of rabbit and guinea-pig plasmata was reported previously [26].

The aliesterases of vertebrate plasmata are represented by various types as far as the specificity is concerned. Acetyl-, propionyl-and butyryl-aliesterases as well as intermediate types were found in the present investigation. Although "aliesterase" is not always an adequate term for these esterases, since phenyl esters are also hydrolysed, in some cases at a higher rate than aliphatic esters, this nomenclature is still recommended. Aliesterases are in most cases the predominant esterases for the hydrolysis of aliphatic esters, including triglycerides. When these esterases are absent, the cholinesterases are the only esterases able to hydrolyse these substrates. In no case were the arylesterases found to split aliphatic esters. Most aliesterases are highly sensitive to organophosphorus compounds and, when aromatic esters are used as substrates for these esterases, certain organophosphorus compounds are the best reagents for differentiating them from plasma arylesterases, all of which are resistant to these agents. However, animal tissues contain other esterases differing from those discussed in the present series of papers [27,28]. Aliesterases differ from the cholinesterases in being unable to hydrolyse choline esters, and being in most cases resistant to 10^{-5} M physostigmine. The latter agent, however, is not an absolute selective inhibitor of cholinesterase, because the aliesterases of duck, frog, clawed frog, frogfish and pike are sensitive to physostigmine in comparatively low concentrations (pI_{50} 5.5—4.5), although they do not hydrolyse choline esters. This is indicative of a close relation between the B- and C-esterases mentioned above. The turtle-plasma esterase displays the characteristics of both a B- and C-esterase including high sensitivity to physostigmine (pI_{50} 6.3). The plasma aliesterases of the lowest vertebrates studied in this series were propionylesterases and this type of esterase is therefore suggested to represent a more primitive stage in the phylogenetic evolution of plasma esterases, of which both cholinesterases and arylesterases may be regarded as specialized forms.

Arylesterases are typical for mammalian plasmata and are absent in all other vertebrate plasmata studied. They have the highest electrophoretic mobility, in most cases migrating close to the albumins. In certain cases (human, swine, rabbit) it was not possible to separate the albumin and arylesterase peaks by the technique used. For swine plasma, the biosyntheses of albumin and arylesterase during the suckling period for piglets were found to parallel each other [25]. This does not mean, however, that the two proteins have the same origin (*e. g.*, the liver; see further below). In addition, albumin itself may have esterase activity, which was actually shown for the reaction between certain α-naphthyl esters (*e. g.*, acetate, N-methyl carbamate) and the albumin of various plasmata [29].

Arylesterases are, with few exceptions, acetylesterases. In all cases aromatic butyrates (phenyl and naphthyl) were found to be hydrolysed at a much lower rate than the corresponding acetates. These esterases are probably also responsible for the hydrolysis of aromatic phosphates, e.g., *p*-nitrophenyl phosphate and its diethyl derivative. In addition, the hydrolysis by blood plasma of other organophosphorus compounds, e. g., di*iso*propoxy-phosphoryl fluoride (DFP), dimethylamido-ethoxy-phosphoryl cyanide (tabun) and tetraethyl pyrophosphate [26,30,31] is in some cases at least partly due to arylesterase. The hydrolysis of dimethylcarbamoyl fluoride was also found to parallel the

hydrolysis of DFP [32] and tabun in separated rabbit plasma (unpublished results from this laboratory), and arylesterase may therefore be one of the esterases responsible for this reaction.

Arylesterases differed from the aliesterases and cholinesterases in their resistance to all enzyme inhibitors tested in this investigation. Introductory experiments demonstrated that *p*-hydroxymercuribenzoate (and *p*-chloromercuribenzoate) and certain metallic ions (*e. g.*, Ag^+, Hg^{2+}, Cu^{2+}) are powerful inhibitors of arylesterases. These agents are useful selective inhibitors of these esterases, because both B- and C-esterases were resistant to those concentrations of the SH-reagents, which gave at least 50 % inhibition of the arylesterase activity. It was found that the reaction between the active SH-group(s) of those enzymes and the SH-reagents (including the metallic ions) was time-dependent, and that the inhibited esterase could be reversed by cystein. A full account of these studies will be reported elsewhere.

Physiological function and origin of plasma esterases. As long as the natural substrates of the plasma esterases are unknown, the physiological function of these enzymes are not easily understood. They may be of importance in the metabolism of various types of compounds containing ester linkages. Such compounds may be natural metabolites or administered medical products. Aryl- and aliesterases are present in high amounts in liver, kidney and pancreas. Preliminary *in-vivo* experiments with swine (performed in collaboration with B. Olsson) have shown that acetylsalicylic acid is hydrolysed to salicylic and acetic acids more readily in an animal with high plasma arylesterase activity compared with one with low activity. Aliesterase (lipase) may be the predominant enzyme for the hydrolysis of triglycerides, including fats, and the high aliesterase of eel plasma may be related to the toxic properties of this plasma [33]. Plasma cholinesterase may be of importance in hydrolysing acetylcholine or other naturally occurring choline esters (*e.g.*, propionylcholine) which come out into the blood stream. Finally, it is the opinion of the author that the great variation in the properties of plasma esterases with species reflects random species-differentiation of specific properties, rather than being the result of enzyme adaptation in relation to specific natural substrates.

The distributation of plasma esterases in animal tissues and the origin of these enzymes have not been investigated in the present study, a knowledge of which should be helpful in approaching the problem with regard to the physiological function of these enzymes. It is known that various tissues, *e. g.*, liver, kidney, pancreas and intestinal mucosa, contain esterases which sometimes are identical with those present in blood plasma, sometimes have fundamentally different properties compared with the plasma esterases. The latter types of esterases may occur in the plasma under pathological conditions. Human plasma cholinesterase is produced in the liver, according to a number of previous investigations. However, the origin of plasma cholinesterases of other vertebrates may not be the same. For instance, it has been demonstrated recently in this laboratory that swine plasma cholinesterase is not produced in the liver, but in the pancreas. The arylesterase of the same species, being closely related to albumin, is probably produced in the kidney. Any of these organs (liver, kidney, pancreas) may be the site of biosynthesis of plasma

esterases. The acetylcholinesterase present in the plasmata of lower vertebrates originate probably from still other sources.

Grateful acknowledgements are due to Prof. W. N. Aldridge, of the Medical Research Council, Toxicology Research Unit, Carlshalton, England, and to Prof. Alf G. Johnels, of the Swedish Museum of Natural History, Stockholm, Sweden, for valuable comments on the presentation of this paper.

On the Photo-Transformation of Ergot Alkaloids

III. Two New Lumi-Ergot Alkaloids

HANS HELLBERG

Chemical Department, State Pharmaceutical Laboratory, Stockholm, Sweden

The preparation and properties of lumiergometrine II and lumiergocristine II have been described.

In work performed by Stoll and Schlientz [1] and by the present author [2] there has been reported the preparation of all the four lumialkaloids of the ergotamine series and three of the four possible lumialkaloids in each of the ergometrine and ergocristine series. However, the two missing alkaloids had been seen on chromatograms by this author [2] and now they have been prepared in a crystalline form.

The lumialkaloids in question are obtained in very minute yields on irradiation of the corresponding genuine alkaloids, and the methods of preparation therefore had to be refined. The new procedures are given under "Experimental". The main improvement in the case of ergometrine is the partition chromatographic procedure for the separation, taken from our work on lumilysergic acids [3]. In the case of ergocristine the new method for removing coloured material from the alkaloids has turned out to be of general value in the peptide alkaloid group. Another improvement is here the decrease in ethanol content of the first elutrient in the chromatography. In that way the peak of lumiergocristine II is more completely separated from an impurity, making the substance more readily crystallizable.

EXPERIMENTAL

Lumiergometrine II (and I) from ergometrine

In a quartz flask under N_2 atmosphere a solution of 1 g of ergometrine maleate in 40 ml of M/5 HCl was irradiated by a mercury lamp (Hanovia S4) until the transformation ceased (c. 3 h) as judged from the quotient between the extinctions at 283 and 315 mμ. The blue solution was treated with 0.2 g of sodium phosphate and 10 g of sodium chloride

and the pH adjusted to 8—9 with sodium hydroxide. The alkaloids *etc.* were extracted with 5 × 50 ml of a mixture of ethanol and ether (1 + 2), the extract dried for several hours over desiccated sodium sulphate and finally evaporated to dryness in a vacuum (N_2 atmosphere). The residue was submitted to partition chromatography on celite. Column: 50 × 2.5 cm. Solvent: butanol, benzene and acetic acid 20 % (1 + 1 + 2). The water phase was used as a stationary phase and the organic phase as elutrient. The course of the elution was followed by the colour reaction with *p*-dimethylaminobenzaldehyde, performed as in paper chromatography [2,3] on spots of the eluate, which were applied to a sheet of filter paper. After a small fraction, containing, *i. a.*, untransformed ergometrine, two lumialkaloid fractions were obtained, the first one strongly dominating and containing lumiergometrine I, the second one containing lumiergometrine II. The two fractions were separately evaporated to dryness (vacuum, N_2 atmosphere), dissolved in a mixture of ethanol and chloroform (1 + 3) and filtered through a column of alumina, subsequently washed with the same solvent until no alkaloid appeared in the eluate. The solutions were evaporated to dryness again. The residue of lumiergometrine I was dissolved in 2 ml of methanol and treated with 12 ml of ether, when the substance crystallized. The lumiergometrine II was dissolved in 0.5 ml of methanol by heating. On cooling the material crystallized, and the crystallization was made more complete by adding 1 or 2 ml of ether.

The yield of lumiergometrine I was c. 65 % and of lumiergometrine II c. 1 %.

Lumiergometrine II, α-lumiergometrine of Ref[2], crystallized from methanol in thin needles. In accordance with the loss on drying (100°C, high vacuum) and acidimetric equivalent weight the crystals contained one mole of methanol of crystallization. They melted on the Kofler block very diffusely between 128—138°C under decomposition. The pK_a-value in 20 % ethanol obtained as in Ref[2] was 7.20. The following constants are given on a dry basis. *Light absorption:* E (1 %, 1 cm) = 189 at 285 mμ (max) in M/10 HCl. *Optical activity:* $[\alpha]_D^{20°} = -19°$ (±5°) in pyridine, $c = 0.4$*. Sufficient material for elementary analysis was not available.

Lumiergocristine II (and I) from ergocristine

A solution of 1 g of ergocristine in 10 ml of concentrated acetic acid and 90 ml of water was illuminated as described for ergometrine in the previous paragraph. To the green solution was added 30 ml of 5 M sodium hydroxide and then 5 M ammonia to pH 9. The mixture was extracted with 3 × 15 ml of chloroform and the filtered solution evaporated to dryness (vacuum, N_2 atmosphere). The strongly discoloured residue was purified from most of the coloured material by the following procedure. It was weakly heated with 3 × 15 ml of 5 % tartaric acid solution. The liquid was centrifuged or filtered until clear and put into a separator together with 250 ml of ether. 10 ml of 5 M ammonia were added in one portion and the separator immediately rotated until the precipitate had mainly dissolved and only a small residue lay in the interphase. The remaining precipitate and the water solution in the separator were washed with a further 50 ml of ether, and then not only the ether but also as much as possible of the water phase was poured out. The rest was redissolved in 5 % tartaric acid solution and the treatment with ammonia and ether repeated on a smaller scale. The collected ether solutions were dried over desiccated sodium sulphate for several hours, and evaporated to dryness (vacuum, N_2 atmosphere). The residue, now only faintly coloured, was dissolved in 20 ml of methanol by gentle heating, and from this solution pure lumiergocristine I crystallized. The mother liquor was evaporated to dryness, dissolved in absolute chloroform and chromatographed on alumina (60 × 1 cm Al_2O_3). With 0.8 % ethanol in absolute chloroform as elutrient a small fraction of unchanged ergocristine came out first and then two small fractions of transformation products were obtained, the second one containing lumiergocristine II. On changing the elutrient to 5 % ethanol in chloroform another quantity of lumiergocristine I was obtained. The lumiergocristine II was crystallized from methanol.

---

* Based on one single determination.

The yield of lumiergocristine I was c. 70 % of lumiergocristine II c. 1 %.

Lumiergocristine II, α-lumiergocristine of Ref [2], crystallized from methanol in short pillars. In accordance with the small loss on drying (1—2 % at 130°C, high vacuum) the crystals did not contain any solvent of crystallization. On the Kofler block they underwent some sort of transformation at about 70°C and melted at 171—174°C under decomposition. The following constants are calculated on a dry basis. *Light absorption:* E (1 %, 1 cm) = 104 at 285 mμ (max) in M/10 HCl. *Optical rotation:* $[\alpha]_D^{20°} = 0°$ (±3°) in pyridine, $c = 0.6$. *Elementary analysis:* Found: C 66.16; H 7.06; O 15.29; N 11.05. Calc. for $C_{35}H_{41}O_6N_5$ (627,7): C 66.96; H 6.58; O 15.29; N 11.16.

Acknowledgements. The work has been financially supported by *Statens Medicinska Forskningsråd*. The elementary analysis was performed by Dr. Alfred Bernhardt, Max-Planck-Institut für Kohlenforschung, Mühlheim (Ruhr). The English was revised by Mrs. M. Spilsbury. To all these I am very grateful.

The Action of Bacterial Trypsin on Tyrosine-Ethyl-Ester

S. O. ANDERSEN and JOHN GRAAE

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

The splitting of tyrosine-ethyl-ester by a bacterial enzyme was studied. The reaction follows strictly the first order form to more than 99 % hydrolysis. pH optimum is found to 7.4 at 20°C and to 6.8 at 40°C. This variation can be explained by assuming that the enzyme attacks only the positively charged substrate molecules. The variation of activity with temperature is determined.

Bacterial trypsin is an enzyme isolated from *Bacillus subtilis*, closely related to, or identical with subtilisin. Subtilisin is mostly known for its proteolytic activity [1] but it has been shown that it is able to split methyl-esters of the lower fatty acids too [2,3]. In this work the hydrochloride of tyrosine-ethyl-ester is used as substrate, because it is a welldefined, reasonably soluble compound.

Crystalline bacterial trypsin was kindly placed at our disposal by *Novo Terapeutisk Laboratorium*, Copenhagen, Denmark.

The substrate was a commercial product (from Nutritional Biochemical Corporation) which was once recrystallized from ethyl-acetoacetate. Titration of the recrystallized product gave a molecular weight of 247.9 (Theoretical: 245.7).

The experiments were carried out in 50 ml N/10 KCl in which the desired amount of substrate was dissolved. Substrate concentrations varied from 8 mmoles/l to 20 mmoles/l. The enzyme was added and the hydrolysis followed by continuous automatic titration in a selfregistering pH-stat. If nothing else is stated temperature is 20°C and pH 7.0.

It was seen that the reaction strictly follows the first order form under all conditions examined. In Fig. 1 is plotted $\log_{10}(1-\alpha)$ *versus* t for an experiment followed to 99.7 % hydrolysis. For the routine determinations of the velocity constants a plot of log $(c_{t+\tau}-c_t)$ *versus* t was used, as suggested by Guggenheim [4]. $c_{t+\tau}$ is the amount hydrolysed at time $t+\tau$ and c_t is the amount hydrolysed at time t. The straight line obtained by this plot indicates that the reaction can be described by a first order form, with a velocity constant that is the slope of the line. It is experimentally proved that this constant, k', can be written as $k \cdot E$, where E is the enzyme concentration (see below).

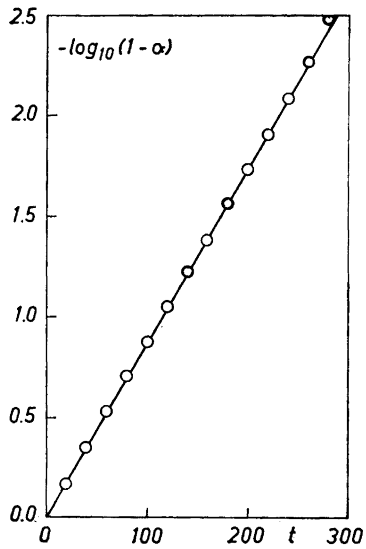

Fig. 1. As abscissa time in min and as ordinate $-\log_{10}(1-\alpha)$ for a typical experiment. Note that the degree of reaction at 260 and 280 min are 0.995 and 0.997, respectively. Temp. 20°C. pH = 7.0. Initial concentration of substrate = 17 mM. E = 8.75×10^{-4} mM. From the graph k is determined to 9 850 $min^{-1} M^{-1}$. At this experiment precipitation of tyrosine started at about 50 min. (α = 0.62.)

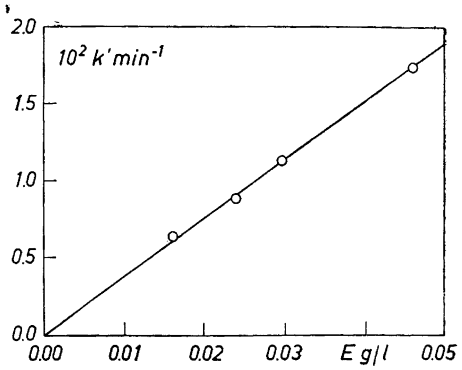

Fig. 2. As abscissa concentration of enzyme in g/l and as ordinate velocity constant k'. Temp. 20°C. pH = 7.0.

Where the constant is given per mole of enzyme it is based on a molecular weight of the enzyme of 27 500 [5]. The constant determined in this way is used for all further comparisons of experiments performed under different contions.

During the experiments it was noticed that after a period of supersaturation, tyrosine suddenly precipitated. As this precipitation in no way changed the fact that the reaction follows the first order form very strictly (*cf.* Fig. 1) it seems reasonable to conclude that the concentration of tyrosine has no influence at the reaction.

Table 1. The table gives the velocity constants determined with enzyme kept in solution in a refrigerator for the period indicated in the first column. pH = 7.0. Temp. = 20°C. Calculations based on $\log_{10}$.

Time, h	k min^{-1} l g^{-1}
0	0.396
4	0.374
23.6	0.392
26.2	0.398
47.4	0.382

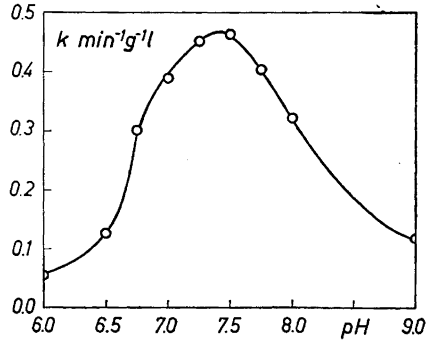

Fig. 3. Dependence of velocity constant on pH. Temp. 20°C.

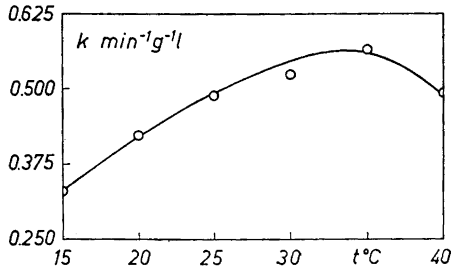

Fig. 4. Dependence of velocity constant on temperature. pH = 7.4.

As subtilisin is known to undergo selfdigestion when left alone, experiments were carried out in order to find out whether it was necessary to take special precautions to prevent selfdigestion. An enzyme sample was dissolved in water (1 g/l) and placed in a refrigerator. At suitable intervals an experiment was performed and the velocity constant determined. The results are given in Table 1. It is seen that there is no decrease in activity within 48 h.

The variation of the velocity constant with the enzyme concentration was studied. Experiments were performed at different enzyme concentrations and the constant determined in each case. From Fig. 2 it is seen that the constant is proportional to the enzyme concentration, as could be expected.

The variation of activity with pH was investigated. A pH optimum is found at 7.4 (Fig. 3). This is somewhat lower than that found when determined with other substrates [1-3].

The dependence of activity on temperature is shown in Fig. 4, where the experiments are performed at pH 7.4 at all temperatures. The pH was determined with a Sørensen phosphate buffer (80 ml M/15 Na_2HPO_4 and 20 ml M/15 KH_2PO_4) which is supposed to have pH 7.4 at all temperatures in the investigated interval. The somewhat strange decrease in activity at higher temperatures cannot be due to an irreversible denaturation of the enzyme, as the reaction still follows the first order scheme, and that indeed would not be expected if the enzyme were destroyed during the reaction. An investigation of the activity-pH curve has shown a shift in the pH-optimum with increasing temperature so that pH optimum at 40°C is lowered to pH = 6.9 (Table 2). It is most likely that this fact is the explanation of the peculiar form of the temperature-activity curve.

It is known that the pK values at 20°C of the amino group in amino acid esters is about 7—8 [6], and titration shows that the amino group in our sub-

Table 2. Variation of velocity constant with pH at 40°C.

pH	7.40	7.20	7.00	6.80	6.50
k min^{-1} l g^{-1}	0.495	0.571	0.665	0.659	0.576

strate has a pK value of 7.4 at 20°C and 6.95 at 40°C. This gives ΔH about 9 500 cal/mole in good agreement with findings for analogous compounds [6]. It therefore seems reansonable to conclude that the enzyme attacks only the positively charged substrate molecules, as this theory, combined with the found values for pK_{20} and pK_{40}, explains the finding of a pH optimum lower than that found ordinarily as well as the changing in pH optimum with temperature.

The pH optimum is usually found at about 8 [1-3] and it seems reasonable to assume that about this pH we have the highest concentration of the active form of the enzyme. But if the enzyme attacks only the positively charged tyrosine-ethyl-ester molecules this will give a lower pH optimum as the concentration of the positively charged molecules is very low at pH over and about 8. The effect of the temperature is understood in the same way as the pK for the substrate is lowered from 7.40 to 6.95 when the temperature is increased from 20°C to 40°C and therefore the concentration of the active — positively charged — form of the substrate is lowered at pH 7.4 (pH optimum at 20°C) and hence pH optimum is lowered.

Eine quantitative Untersuchung über die Protolysenverhältnisse zweier sulfonierten basischen Triphenylmethanfarbstoffe

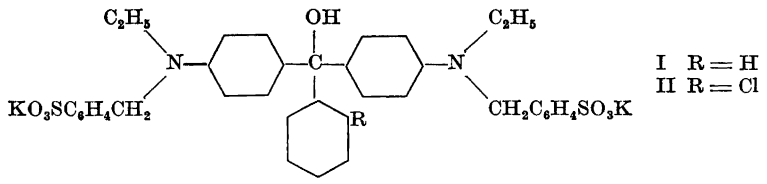
RUNE CIGÉN

Abteilung für anorganische und physikalische Chemie des Chemischen Instituts der Universität Lund, Schweden

Die Protolysenreaktionen zweier sulfonierten basischen Triphenylmethanfabstoffe wurden bei 20°C in Wasserlösungen mit konstanter Ionenstärke = 0,5 M quantitativ untersucht. Sie bilden eine Reihe gefärbter und eine Reihe farbloser Formen, die in Protonen- und Hydratationsgleichgewichten miteinander stehen. Die Reaktionen verlaufen nach demselben Protolysenschema, das früher für Malachitgrün und einige Derivate von Malachitgrün aufgestellt wurde. Die Dissoziations-, Hydratations- und Geschwindigkeitskonstanten in dem Protolysenschema wurden bestimmt. Die Messungen wurden spektrophotometrisch durchgeführt.

In einer Schrift 1954 von Bodforss, Ahrland und Cigén [1] wurden die Protolysenreaktionen von Malachitgrün untersucht. Später publizierten Bodforss und Cigén [2] eine Untersuchung über u.a. einen sulfonierten basischen Triphenylmethanfarbstoff, Lichtgrün SF. Diese beiden Untersuchungen waren indessen unvollständig, und Cigén [3] publizierte 1956 eine Dissertation, in der zehn Farbstoffe, Malachitgrün und Derivate von Malachitgrün, genau untersucht waren. In der letztgenannten Schrift wurde ein Protolysenschema aufgestellt, das nun ein einer eingehenderen Untersuchung über zwei sulfonierte malachitgrünähnliche Farbstoffe, Lichtgrün SF und Brillantsäuregrün 6 B geprüft wird. Es hat sich gezeigt, dass das Protolysenschema im Prinzip auch für solche Farbstoffe wie Kristallviolett anwendber ist (Cigén [4]).

Den Analysen von Bodforss [5] gemäss hat das Lichtgrün SF, (LG), zwei Sulfonsäuregruppen und die Konstitution I. Das Brillantsäuregrün 6 B (BG), hat die Konstitution II

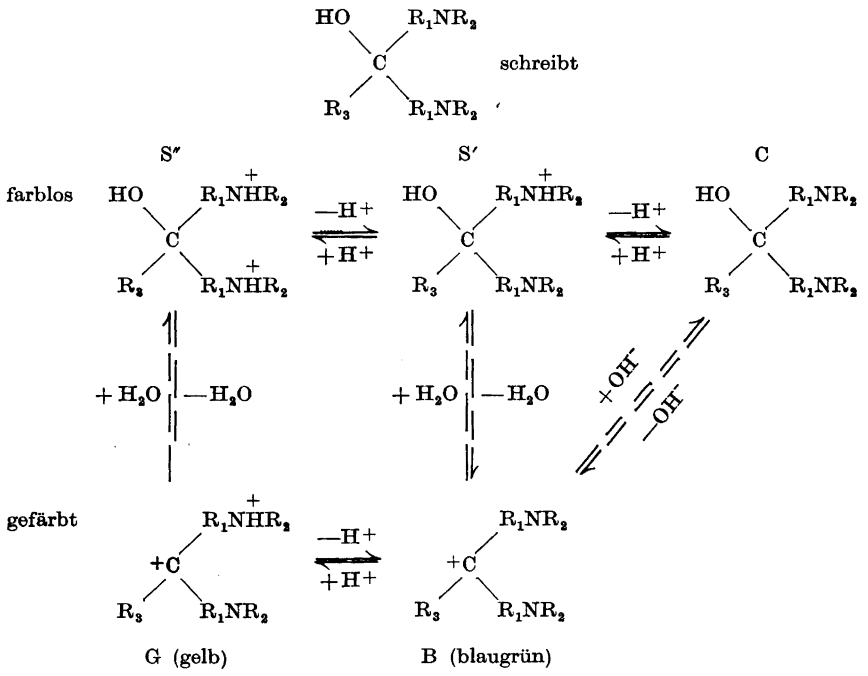


I R = H
II R = Cl

An diesen Farbstoffen durchgeführte Untersuchungen zeigten, dass ihre Protolysenreaktionen qualitativ mit denen der früher untersuchten nicht sulfonierten basischen Triphenylmethanfarbstoffe übereinstimmen. Man kann darum ein Protolysenschema derselben Art für LG und BG aufstellen wie das früher für Malachitgrün und Kristallviolett geschah.

Eine neutrale Wasserlösung von BG oder LG ist blaugrün. Bei Zusatz von Alkali wird die Lösung mit einer Geschwindigkeit entfärbt, die dem [OH^-] proportional ist. Fügt man eine starke Säure hinzu wird die Lösung augenblicklich gelb und verblasst dann wegen der Hydratation der gelben Form. Die Reaktionen sind reversibel. Die Reaktionen, die zu den Farbänderungen Veranlassung geben, finden bei den beiden Aminogruppen und bei dem zentralen Kohlenstoffatom statt. Da die Reaktionen, wenn man die Lösung sauer macht, so nahe mit den entsprechenden Reaktionen von Malachitgrün übereinstimmen, scheinen die Dissoziationen bei den Sulfonsäuregruppen die Protolysenverläufe betreffs Farbänderungen nicht zu beeinflussen.

Die Reaktionen, die stattfinden, wenn man das pH der Lösung verändert, können folgenderweise geschrieben werden, falls man BG und LG



Ausgezogene Pfeile bedeuten, dass die Reaktionen sehr rasch, "momentan", verlaufen, während gestrichelte Pfeile bedeuten, dass die Reaktionen mit messbarer Geschwindigkeit verlaufen.

Folgende Konstanten werden definiert:

$$K_1 = \frac{[G]}{[B][H^+]} \; ; \; K_3 = \frac{[S'][H^+]}{[S'']} \; ; \; K_4 = \frac{[C][H^+]}{[S']} \; ; \; K_2 = \frac{[S'']_\infty}{[G]_\infty} \; ;$$

$$K_6 = \frac{[B]_\infty}{[S']_\infty}$$

k_1 = die Geschw.keitskonst. der Reaktion $G + H_2O \rightarrow S''$
k_2 = » » » » $S'' \rightarrow G + H_2O$
k_3 = » » » » $B + H_2O \rightarrow S'$
k_4 = » » » » $S' \rightarrow B + H_2O$
k_5 = » » » » $B + OH^- \rightarrow C$
k_6 = » » » » $C \rightarrow B + OH^-$

Die Untersuchungen wurden mit einem Spektrophotometer durchgeführt, weshalb spezifische Extinktionen benutzt wurden, um die Konzentrationen der verschiedenen Farbstoffkomponenten auszudrücken. Hierbei bedeuten
ε_B, ε_G die molekularen Extinktionskoeffizienten für B und G
e_o, e_t, e_∞ die spezifische Extinktion einer Lösung bei der Zeit 0 und t und bei Gleichgewicht (die Schichtdicke $d = 1$ cm)
E_o, E_t, E_∞ die abgelesenen Extinktionen, wenn $d \neq 1$
e_B, e_G die spezifische Extinktion einer Lösung die nur B oder G enthält.
Man kan folgende Beziehungen ableiten (vgl. Ref.[3,4])

$$K_1 = \frac{e_B - e_o}{(e_o - e_G)[H^+]} \tag{1}$$

(1) kann folgenderweise umgeschrieben werden

$$\frac{[H^+]}{e_B - e_o} = [H^+] \frac{1}{e_B - e_G} + \frac{1}{K_1(e_B - e_G)} \tag{2}$$

In einem Diagramm trägt man $[H^+]/(e_B - e_o)$ als Funktion von $[H^+]$ auf und bekommt so eine Gerade, deren Abschnitt auf der Orinatenachse, y, und deren Winkelkoeffizient, l, die Gleichungen $y = 1/K_1(e_B - e_G)$ und $l = 1/(e_B - e_G)$ ergeben.

Bei Gleichgewicht wird die Extinktion

$$e_\infty = \frac{e_B + K_1[H^+] \cdot e_G}{1 + 1/K_6 + K_4/K_6[H^+] + K_1[H^+](1 + K_2)} \tag{3}$$

In sauren Lösungen, pH $\sim$ 1, gibt (3)

$$K_2 = \frac{e_G}{e_\infty} + \frac{e_B - e_\infty(1 + K_1[H^+] + 1/K_6)}{e_\infty \cdot K_1[H^+]} \tag{4}$$

und in schwach alkalischen Lösungen kann (3) folgendermassen approximiert und umgeschrieben werden

$$\frac{[H^+]}{e_\infty} = [H^+] \cdot \frac{1 + K_6}{K_6 \cdot e_B} + \frac{K_4}{K_6 \cdot e_B} \tag{5}$$

Aus (5) kann man, wenn man $[H^+]/e_\infty$ als Funktion von $[H^+]$ aufträgt, K_4/K_6 und unter gewissen Umständen K_6 erhalten.

Man kann folgende zusammenfassende Gleichung für die Kinetikreaktionen ableiten, wenn man annimmt, dass die individuellen Geschwindigkeitskonstanten $k_1 ... k_4$ bei den Hydratationen und Dehydratationen im Reaktionschema unabhängig von dem pH sind, was für früher untersuchte Farbstoffe gilt. Da die Totalkonzentration des Farbstoffes, C_M, bei den Messungen im Vergleich mit den Konzentrationen der benutzten Pufferlösungen sehr gering ist, verlaufen die Zeitreaktionen pseudomonomolekular.

$$k = \frac{1}{t} \ln \frac{e_o - e_\infty}{e_t - e_\infty} = \frac{k_2[H^+]^2 + k_4 K_3[H^+] + k_6 K_3 K_4}{[H^+]^2 + K_3[H^+] + K_3 K_4}$$

$$+ \frac{k_1 K_1[H^+] + k_3 + k_5[OH^-]}{K_1[H^+] + 1} \tag{6}$$

(6) kann in saurer Lösung, pH $\leq$ 1, folgendermassen approximiert werden

$$k = \frac{1}{t} \ln \frac{e_o - e_\infty}{e_t - e_\infty} = k_1 \cdot \frac{K_1[H^+]}{1 + K_1[H^+]} + k_2 \tag{7}$$

und in stark alkalischer Lösung, pH > 10,

$$k = k_6 + k_3 + k_5[OH^-] \tag{8}$$

Zwischen diesen beiden Extremen kann man für pH 4—8 eine kleinere Approximation von (6) vornehmen

$$k = \frac{k_4 K_3[H^+]}{[H^+]^2 + K_3[H^+] + K_3 K_4} + k_3 \tag{9}$$

Wenn man für eine grosse Anzahl von Lösungen, die man durch Mischung einer Farbstoffstammlösung mit geeigneten Puffern erhält, die Anfangs- und die Gleichgewischtsextinktionen bestimmt und ausserdem die Geschwindigkeit der Farbänderungen misst, kann man aus den oben gegebenen Gleichungen die Konstanten im Protolysenschema bestimmen.

Je nach den Grössenverhältnissen zwischen den verschiedenen Konstanten sind die vorgenommenen Approximationen mehr oder weniger gut, und schrittweise Approximationen können erforderlich werden.

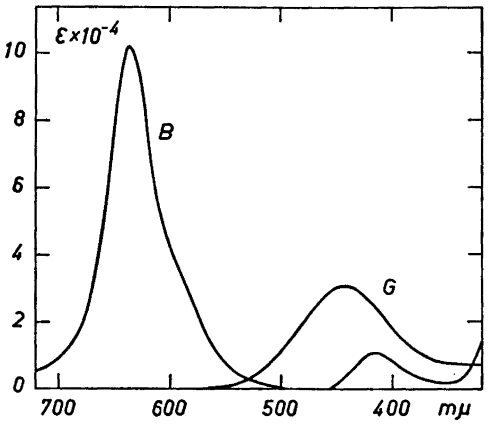


Fig. 1. Absorptionskurven von Brillantsäuregrün 6 B in Wasserlösungen. Kurve B entspricht dem blauen Farbion, B, (in 0,5 M KCl) und Kurve G dem gelben, G, (in 2 M HCl).

EXPERIMENTELLES

Chemikalien und Lösungen. Brillantsäuregrün 6 B (Farbenfabrik Bayer) und *Lichtgrün SF* (Ciba). Die Präparate wurden in Methanol fraktionsweise mit Kaliumacetat gefällt. Die besten Fraktionen wurden aus Methanol umkristallisiert und über P_2O_5 getrocknet. Man erhält die Farbstoffe als grüne Pulver, die etwas hygroskopisch sind. Von den Farbstoffen wurden Stammlösungen durch Abwägung und Auflösung in Wasser bereitet.

Zu Pufferlösungen wurden *Salzsäure, Natriumacetat, Dinatriumhydrogenphosphat, Kaliumdihydrogenphosphat, Borsäure* und *Natriumhydroxyd*, die sämtliche von pro Analysi Qualität waren, verwendet.

Man kann thermodynamische Konstanten in einem so komplizierten Reaktionsschema wie das von diesen Farbstoffe kaum bestimmen. Darum wurde die Methode gewählt, Konzentrationskonstanten zu bestimmen, die bei der Ionenstärke 0,5 M gelten, mit *Kaliumchlorid* p.a. als Neutralsalz.

Die Apparatur war dieselbe, die für die Untersuchungen über Kristallviolett benutzt wurde (Ref.[4]).

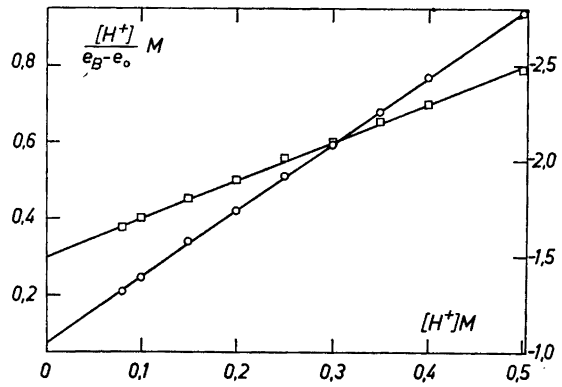

Fig. 2. $[H^+]/(e_B - e_o)$ als Funktion von $[H^+]$ für die Bestimmung von K_1 und ε_G. □ λ = 636 mμ. ○ λ = 450 mμ.

MESSUNGEN UND ERGEBNISSE

Brillantsäuregrün 6 B. Zuerst wurden Absorptionskurven für BG in 0,5 M KCl und in 2 M HCl aufgenommen; Fig. 1 Kurve B und G. Kurve B zeigt, dass die blaue Form ein Absorptionsmaximum für $\lambda = 636$ mμ, $\varepsilon_{max} = 1{,}02 \times 10^5$ und eines für $\lambda = 416$ mμ, $\varepsilon_{max} = 1{,}05 \times 10^4$, hat. Die gelbe Form G hat ein Absorptionsmaximum für $\lambda = 440$ mμ, und ε_{max} wurde später zu $3{,}0 \times 10^4$ bestimmt. In 2 M HCl liegt der Farbstoff teilweise als ein farbloses Salz, S″, vor, weshalb man aus der Absorptionskurve die molekulare Extinktion von G nicht direkt erhalten kann.

Die Bestimmung von K_1. Zwischen pH 1 und pH 0 schlägt die Farbe von BG von blau in gelbgrün um, wegen der Reaktion $B + H^+ \rightleftharpoons G$. Eine Reihe von Messlösungen wurde dadruch bereitet, dass die Farbstammlösung schnell mit verschiedenen Pufferlösungen von HCl + KCl in Y-geformten Röhren gemischt wurde. Das Gleichgewicht $B + H^+ \rightleftharpoons G$ stellt sich augenblicklich ein, aber die Lösungen verblassen danach. Deshalb wurden die Extinktionen zur Zeit $t = 0$ extrapoliert. Für die Messlösungen war $C_M = 1 \times 10^{-5}$ M, $[H^+] = 0{,}080$—$0{,}500$ M, $d = 1$ cm, $\lambda = 636$ und 450 mμ, $T = 20{,}0$°C. In Fig. 2 ist $[H^+]/(e_B - e_0)$ als Funktion von $[H^+]$ der Gleichung (2) gemäss aufgetragen. Man erhält für $\lambda = 636$ mμ: $y = 0{,}300$ M und $l = 0{,}99$ und für $\lambda = 450$ mμ: $y = -1{,}05$ und $l = -3{,}45$. Dies ergibt bei 636 mμ: $K_1 = \mathbf{3{,}30 \pm 0{,}05\ M^{-1}}$, $e_G = 0{,}010$, $\varepsilon_G = 1{,}0 \times 10^3$ und bei 450 mμ: $K_1 = \mathbf{3{,}29 \pm 0{,}05\ M^{-1}}$, $e_G = 0{,}301$, $\varepsilon_G = 3{,}0 \times 10^4$.

Die Bestimmung von K_2. Die Gleichgewichtsextinktionen wurden für eine Reihe von Lösungen abgelesen. $C_M = 2 \times 10^{-5}$ M, $[H^+] = 0{,}150$—$0{,}500$ M, $d = 5$ cm, $\lambda = 636$ mμ, $T = 20$°C. In Tab. 1 sind die aus (4) berechneten K_2-Werte. Der Mittelwert wird $\mathbf{10{,}0 \pm 0{,}2}$.

Die Bestimmung von k_1 und k_2. Die Bleichung der gelbgrünen Lösung, die man erhält, wenn man eine blaue Farbstoffstammlösung mit verschiedenen Pufferlösungen aus HCl + KCl mischt, wurde kinetisch verfolgt. In Tab. 1 finden sich die Geschwindigkeitskonstanten k und k_1, die man bekommt,

Tabelle 1. Berechnung von K_2 und k_1. Brillantsäuregrün 6 B. $\lambda = 636$ mμ, $T = 20{,}0$°C, $C_M = 2 \times 10^{-5}$ M, $d = 5$ cm.

[H+] M	e_∞	K_2	k min^{-1}	k_1 min^{-1}

Mittelwert		10,0		0,188

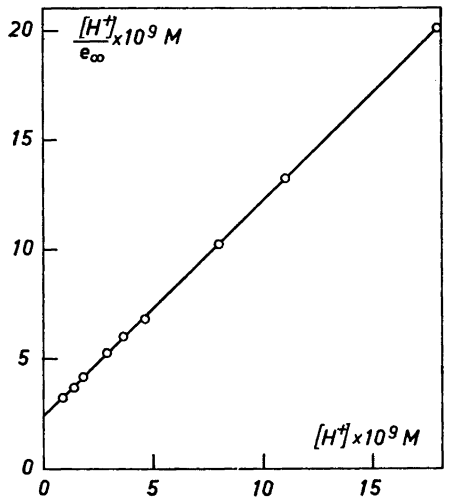

Fig. 3. $[H+]/e_\infty$ als Funktion von $[H+]$ für die Bestimmung von K_4/K_6. λ = 636 mμ.

wenn man die Gleichung (7) verwendet. Da $k_1[G]_\infty = k_2[S'']_\infty$ und $[S'']_\infty/[G]_\infty = K_2$, kann man k_1 und k_2 aus (7) berechnen, wenn man K_1 und K_2 kennt. Ganz wie für die früher untersuchten basischen Triphenylmethanfarbstoffe sind auch hier k_1 und k_2 vom pH unabhängig. Man bekommt die Mittelwerte k_1 = **0,188 ± 0,003 min^{-1}** und k_2 = **0,0188 ± 0,0006 min^{-1}.**

Die Bestimmung von K_4/K_6. In schwach alkalischen Lösungen verblasst BG langsam unter Bildung von dem farblosen Salz, S', und dem farblosen Carbinol, C. In einer Reihe von Lösungen wurde die Farbstoffstammlösung mit verschiedenen Boratpuffern gemischt. Die Gleichgewichtsextinktionen, e_∞, wurden nach drei Tagen abgelesen. $C_M = 1 \times 10^{-5}$ M, d = 1 cm, λ = 636

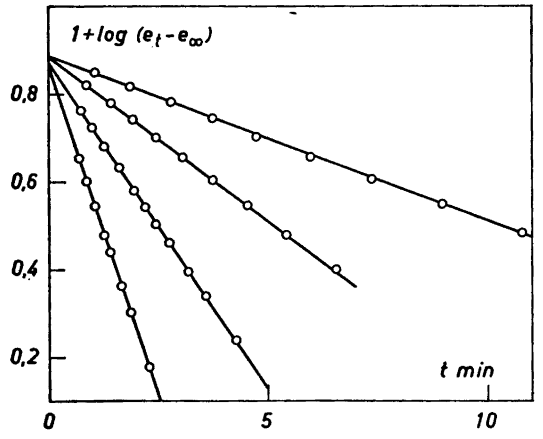

Fig. 4. Kinetikmessungen in NaOH + KCl, λ = 636 mμ, T = 20.0°C. $[OH^-]$ ist von oben nach unten 0.0316, 0.0632, 0.1264 und 0.2528 M.

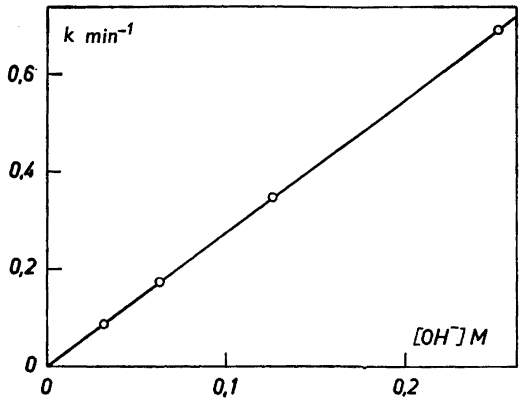

Fig. 5. Die Geschwindigkeitskonstante k als Funktion von $[OH^-]$ für die Bestimmung von k_5. $[OH^-] = 0.0316-0.2528$ M.

mμ. In Fig. 3 ist $[H^+]/e_\infty$ gemäss Gleichung (5) als Funktion von $[H^+]$ aufgetragen. Man erhält $y = 2{,}43 \times 10^{-9}$ M, $l = 0{,}98$ und $K_4/K_6 = \mathbf{(2{,}48 \pm 0{,}05) \times 10^{-9}\ M}$.

Die Bestimmung von k_5 und k_6. Die Verbleichung in stark alkalischen Lösungen wurde auch untersucht. In Fig. 4 sind Kinetikmessungen bei vier verschiedenen $[OH^-]$ graphisch dargestellt, und in Fig. 5 sind die aus Fig. 4 erhaltenen Geschwindigkeitskonstanten, k, als Funktion von $[OH^-]$ aufgetragen. Man ersieht aus Fig. 5, dass k dem $[OH^-]$ direkt proportional ist. Von der Gleichung (8) erwartet man ja auch, dass k eine lineare Funktion von $[OH^-]$ sein soll. Man kann aber $k_6 + k_3$ nicht aus Fig. 5 bestimmen, da die Gerade durch die Origo läuft. Man bekommt $k_5 = \mathbf{2{,}73 \pm 0{,}03\ min^{-1}\ M^{-1}}$ und k_6 kann dann folgenderweise bestimmt werden. Bei Gleichgewicht gilt

$$k_5[OH^-][B]_\infty = k_6[C]_\infty \tag{10}$$

Aber $[H^+][C]_\infty = K_4[S']_\infty$ und $K_6[S']_\infty = [B]_\infty$, weshalb $k_6 = k_5 K_w K_6/K_4$. Früher wurde K_4/K_6 zu $2{,}48 \times 10^{-9}$ bestimmt, und da wird $k_6 = \mathbf{(1{,}36 \pm 0{,}05) \times 10^{-5}\ min^{-1}}$, da einer anderen Untersuchung gemäss $K_w = 1{,}24 \times 10^{-14}$.

Die Bestimmung von K_3, K_4, K_6, k_3 und k_4. k_3 wurde durch Kinetikmessungen in einem Boratpuffer pH = 8,74 bestimmt; Fig. 6. In diesem pH-Gebiet kann man die Gleichung (6) folgendermassen approximieren

$$k = k_3([H^+]K_6/K_4 + 1) + k_6 + k_5[OH^-] \tag{11}$$

Da k_5, k_6 und K_6/K_4 bekannt sind, kann man k_3 bestimmen. Man erhält $k_3 = \mathbf{(4{,}79 \pm 0{,}05) \times 10^{-4}\ min^{-1}}$.

Die restlichen Konstanten wurden folgenderweise bestimmt. Eine partiell entfärbte Farbstammlösung von BG in 0,02 M HCl wurde mit verschiedenen Acetatpuffern gemischt, deren Zusammensetzung so war, dass man pH 3,92 — 6,14 bekam. Hierbei bildete sich B wieder, mit einer Geschwindigkeit, die k in der Gleichung (6) ergibt. In diesem pH-Gebiet kann man (6) zu

$$k = \frac{k_4 K_3[H^+]}{[H^+]^2 + K_3[H^+] + K_3K_4} + k_3 \tag{12}$$

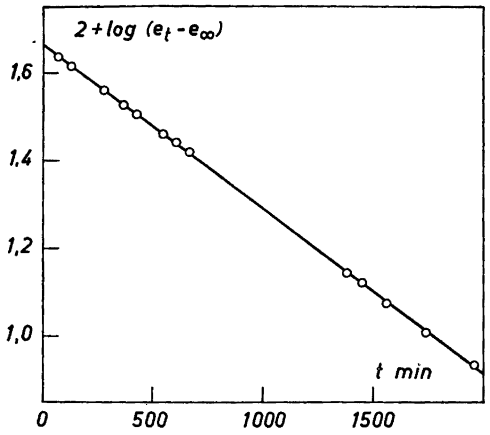

Fig. 6. Eine Kinetikreihe in Boratpuffer pH = 8.74 für die Bestimmung von k_3. λ = 636 mμ.

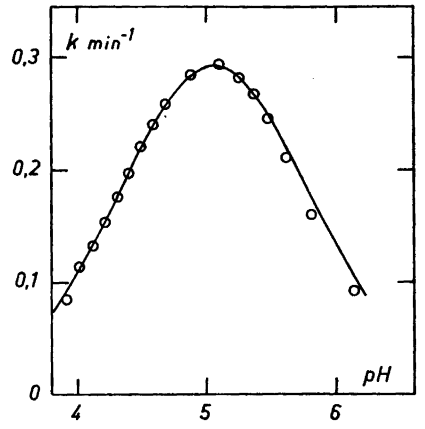

Fig. 7. Kinetikmessungen in Acetatpuffern. $C_M = 8 \times 10^{-6}$ M, λ = 636 mμ, T = 20,0°C. Die Geschwindigkeitskonstante als Funktion von pH. Die ausgezogene Kurve wurde aus der Gleichung (12) berechnet.

approximieren. Deriviert man (12) hinsichtlich $[H^+]$ erhält man

$$[H^+]_{k\,max} = \sqrt{K_3K_4} \tag{13}$$

und

$$k_{max} = \frac{k_4K_3}{K_3 + 2\sqrt{K_3K_4}} + k_3 \tag{14}$$

(14) kann wie folgt geschrieben werden

$$k_{max} = \left(\frac{K_6}{K_4} \cdot \frac{K_3K_4}{K_3 + 2\sqrt{K_3K_4}} + 1\right) \cdot k_3 \tag{15}$$

In (15) sind K_6/K_4 und k_3 früher bestimmt, und aus (13) erhält man K_3K_4. Man kann daher K_3 aus (15) bestimmen und danach K_4, K_6 und k_4 berechnen. In Fig 7 ist k gegen pH für eine Reihe von Kinetikmessungen in Acetatpuffern aufgetragen. Man bekommt $k_{max} = 0{,}297$ min^{-1} für pH = 5,06, und $[H^+] = 8{,}71 \times 10^{-6}$ ergibt $K_3K_4 = 7{,}59 \times 10^{-11}$. Dies ergibt $K_3 = \mathbf{(3{,}27 \pm 0{,}06) \times 10^{-5}}$ **M,** $K_4 = \mathbf{(2{,}32 \pm 0{,}05) \times 10^{-6}}$ **M,** $K_6 = \mathbf{(9{,}4 \pm 0{,}3) \times 10^2}$ und $k_4 = \mathbf{(0{,}45 \times 0{,}02)\ min^{-1}}$.

Hiermit sind sämtliche Konstanten im Protolysenschema bestimmt. Die ausgezogene Kurve in Fig. 7 ist aus (12) berechnet, wobei die oben gegebenen Konstantwerte benutzt wurden. Die Übereinstimmung zwischen den experimentell gefundenen k-Werten (Kreise) und den aus (12) berechneten ist gut.

Dem Protolysenschema gemäss soll $K_1K_2K_3K_6 = 1$ sein. Das experimentell gefundenen Konstantprodukt wird 1.01.

Lichtgrün SF. In Ref.[2] wurden einige Konstanten in dem Protolysenschema des Lichtgrün SF bestimmt, nämlich $K_1 = \mathbf{2{,}5 \pm 0{,}1}$ **M**$^{-1}$, $K_2 = \mathbf{113 \pm 2}$, $k_1 = \mathbf{(1{,}30 \pm 0{,}04)}$ **min**$^{-1}$, $k_2 = \mathbf{(0{,}0115 \pm 0{,}0005)}$ **min**$^{-1}$ und $K_4/K_6 = 1/K_5 = \mathbf{(1{,}92 \pm 0{,}06) \times 10^{-8}}$ **M.** Die restlichen Konstanten wurden dort wegen experimenteller Schwierigkeiten nicht bestimmt. Die Untersuchungen sind jedoch wiederaufgenommen und glücklich zu Ende geführt worden. Die grössten Schwierigkeiten lagen darin, dass der Farbstoff sich sehr schwer reinigen liess, und dass die grossen Reaktionsgeschwindigkeiten im pH-Gebiete 4—5 die Kinetikmessungen unsicher machten. Die Reaktionen verlaufen bei pH 5 bis 50 % in nur 16 sek.

Die Messungen und Bestimmungen der Konstanten wurden in derselben Weise wie für Brillantsäuregrün 6 B durchgeführt. Die Genauigkeit der Konstantwerte sind jedoch nicht ebenso gut.

Kinetikmessungen in NaOH + KCl ergaben $k_5 = \mathbf{(59 \pm 1)}$ **min**$^{-1}$ **M**$^{-1}$, $k_6 = \mathbf{(3{,}8 \pm 0{,}2) \times 10^{-5}}$ **min**$^{-1}$ und in Boratpuffer, pH = 8,72, $k_3 = \mathbf{(0{,}0233 \pm 0{,}0005)}$ **min**$^{-1}$ Die Kinetikmessungen in Acetatpuffern ergaben pH = 5,07 für k_{max}, $k_{max} = 1{,}05$ min^{-1}, und man erhält daraus $K_3 = \mathbf{(1{,}95 \pm 0{,}10) \times 10^{-5}}$, $K_4 = \mathbf{(3{,}7 \pm 0{,}2) \times 10^{-6}}$, $K_6 = \mathbf{193 \pm 10}$, $k_4 = \mathbf{(4{,}5 \pm 0{,}3)}$ **min**$^{-1}$. Das experimentell gefundene Konstantprodukt $K_1K_2K_3K_6$ wird 1.06.

Die erhaltenen Ergebnisse zeigen, dass die beiden nun untersuchten Farbstoffe sich ähnlich verhalten wie die früher untersuchten basischen Triphenylmethanfarbstoffe. Auffallend ist die Einwirkung eines Substituenten in *orto*-Stellung zum zentralen Kohlenstoffatom. Vergleicht man die Konstanten für Malachitgrün und dessen *p*-Chlor und *o*-Chlor Derivate und ferner Lichtgrün SF und dessen *o*-Chlor Derivat, Brillantsäuregrün 6 B, ersieht man aus Tabelle 2, dass ein Chlor in *para*-Stellung verhältnismässig wenig auf die Konstantwerte einwirkt. Dasselbe gilt von den Dissoziationskonstanten K_1, K_3 und K_4 für ein Chlor in *orto*-Stellung. Dagegen wirkt ein *o*-Chlor stark auf die Gleichgewichte zwischen den gefärbten und den farblosen Formen sowie auf die Geschwindigkeitskonstanten ein. Die Reaktionen gehen wesentlich langsamer, und die Gleichgewichte werden gegen die gefärbten Formen stärker verschoben, wahrscheinlich, weil das *o*-Chloratom durch sterische Hinderung

die Anlagerung von Wassermolekeln am zentralen Kohlenstoffatom erschwert. Entsprechend sind die Verhältnisse bei den früher untersuchten Farbstoffen *p*- und *o*-Nitro-Malachitgrün. Der sterische Einfluss einer *o*-Nitrogruppe ist noch stärker als der eines *o*-Chloratoms. Die Untersuchung von ein paar anderen *orto*-Derivaten von Malachitgrün wird geplant.

Statens Naturvetenskapliga Forskningsråd (Schwedischer naturwissenschaftlicher Forschungsrat) hat einen Teil dieser Arbeit finanziell unterstützt. Herrn Mag.phil. Ingmar Grenthe danke ich für seine wertvolle Mitwirkung bei zeitraubenden Kinetikmessungen.

The Identity of Thujopsene and Widdrene and of Hinokiic and Widdrenic Acids

H. ERDTMAN and T. NORIN

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Widdrene is identical with the main constituent of thujopsene. Widdrenic acid is identical with hinokiic acid. The structure of this acid requires modification. Tentative structures are suggested for thujopsene and hinokiic acid.

The wood oil of the Hiba tree, *Thujopsis dolabrata* (L.f.) Sieb. et Zucc. has been studied by Japanese chemists over a long period. Both Yano [1] and Uchida [2] concluded from their early investigations that the main neutral constituent of the oil was a tricyclic sesquiterpene $C_{15}H_{24}$. This was given the name thujopsene by Kawamura [3] who investigated it in some detail and suggested two alternative structures. Obata and Fukushi [4] reported that they had been unable to isolate thujopsene from Hiba oil but Fujita [5] definitely confirmed its presence. These investigations and especially the important contribution of Kawamura, published in Japanese, have remained largely unknown in the West.

The chemistry of thujopsene has recently attracted considerable interest in Japan and several groups are now studying its structure. A careful description of this compound was published (in English) a short time ago by Akiyoshi and Nagahama [6] in a paper which is a repetition and extension of Kawamura's work and from which most of the above details have been taken. Their paper records the UV and IR absorption of thujopsene and some results of permanganate oxidation including the isolation, together with other degradation products, of a C_{15}-ketocarboxylic acid. This on oxidation with hypobromite furnished a C_{14}-dicarboxylic acid from which an anhydride and a dimethyl ester were prepared.

During studies in this laboratory on the constituents of heartwood extracts from trees of the South African genus *Widdringtonia* [7] a tricyclic sesquiterpene $C_{15}H_{24}$ was obtained, which was called widdrene and according to its IR absorption and gas chromatographic behaviour was undoubtedly a pure compound. Further studies have demonstrated the presence of the same compound in several other conifers of the family *Cupressaceae* (*Chamaecyparis*

thyoides [8], *Biota orientalis* [9] and some species of *Juniperus* [10]) and it appears that it is a common constituent of woods that have the characteristic sweet fragrance of "pencil wood".

On ozonisation widdrene gave a C_{15}-ketocarboxylic acid that was oxidised by hypobromite to a C_{14}-dicarboxylic acid.

Table 1 shows the constants for thujopsene and widdrene and some of their degradation products.

Table 1.

Thujopsene $C_{15}H_{24}$	*Widdrene* $C_{15}H_{24}$
B. p. 121–122°/12 mm $n_D^{25} = 1.5015$, $[\alpha]_D^{20} = -79.7°$	B. p. 118–120°/10 mm $n_D^{25} = 1.5033$, $[\alpha]_D^{20} = -109°$
Ketocarboxylic acid $C_{15}H_{24}O_3$	*Ketocarboxylic acid* $C_{15}H_{24}O_3$
M. p. 164–165° Semicarbazone, m. p. 219° (decomp.) 2,4-Dinitrophenylhydrazone, m. p. 187–189°	M. p. 166–168°, $[\alpha]_D^{20} = -129°$ Semicarbazone, m. p. 220° (decomp.) 2,4-Dinitrophenylhydrazone, m. p. 153–154°
Dicarboxylic acid $C_{14}H_{22}O_4$	*Dicarboxylic acid* $C_{14}H_{22}O_4$
M. p. 209.5–210.5° Anhydride, m. p. 109–110° Dimethyl ester, m. p. 71–73°	M. p. 215°, $[\alpha]_D^{20} = -57°$ Anhydride, m. p. 113°, $[\alpha]_D^{20} = -39°$ Dimethyl ester, m.p. 71–73°, $[\alpha]_D^{20} = -59°$

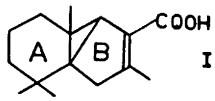
From the close similarity of these constants (apart from those of the ketocarboxylic acid 2,4-dinitrophenylhydrazones) and since widdrene is of widespread occurrence it seemed very probable that thujopsene and widdrene were identical but that the former was not a pure compound. This was confirmed by comparison of the IR spectrum of thujopsene with that of pure widdrene.

Through the courtesy of Dr. S. Katsura, Takasago Perfumery Co, Tokyo, it has been possible to investigate a large sample of Japanese hiba oil. The neutral fraction gave pure widdrene, only the small fractions at the beginning and end showing boiling point and rotation changes. The IR absorption curves of both *Thujopsis* and *Widdringtonia* widdrenes were superimposable and the crystalline oxidation products were identical. Pure widdrene shows a single sharp carbon-carbon double bond stretching vibration band at 1 682 cm^{-1}. Impure samples of widdrene from *Widdringtonia* and thujopsene from *Thujopsis* gave an additional band at 1 647 cm^{-1} together with other minor differences.

Hirose and Nakatsuka [19] arrived at the same conclusion as regards the identity of thujopsene and widdrene. Oxidation of their "thujopsene" ($[\alpha]_D$ −92°) with selenium dioxide gave an aldehyde identical with that obtained by similar oxidation of "widdrene" from *Biota orientalis*.

Since the name thujopsene has considerable priority we suggest that it should be retained but reserved for the fraction of thujopsene that corresponds to widdrene.

In the investigation of thujopsene from *Widdringtonia* it was oxidised with selenium dioxide to give a characteristic aldehyde "widdrenal" (thujopsenal) which was oxidised further with silver oxide to a monocarboxylic acid, "widdrenic acid", $C_{15}H_{22}O_2$. This acid was also isolated directly from the *Widdringtonia* heartwood extracts and has recently been found in several other woods containing thujopsene including *Chamaecyparis thyoides* [8] and several *Juniperus* species [10]. Uchida [11] long ago isolated an acid, which he called hinokiic acid, from the steam volatile oil obtained from the leaves of the Japanese hinoki tree, *Chamaecyparis obtusa* Endl. Hinokiic acid has also been shown to occur in small amounts in the leaves of *Chamaecyparis taiwanensis* Masamune et Suzuki [12] and has recently been obtained by Masamura [13] from a garden variety of hinoki, "chyabohiba". Uchida thought that the composition was $C_{15}H_{24}O_2$ but Moroe and Hara [14] have shown that the correct composition of hinokiic acid is $C_{15}H_{22}O_2$. Okuda [15a-f] has made an extensive investigation of hinokiic acid and has proposed the structure (I).



I

It was noticed that there were considerable similarities between the physical constants of hinokiic acid and widdrenic acid but there were also certain discrepancies. According to Okuda, permanganate oxidation of hinokiic acid gave a dicarboxylic acid containing only thirteen carbon atoms. However the melting point of this acid agreed with that of our C_{14}-widdrenedicarboxylic acid which has also been obtained by permanganate oxidation of widdrenic acid. The optical rotation of Okuda's dicarboxylic acid [15f] was reported to be almost exactly 100° lower than that of the widdrene dicarboxylic acid (misprint?). The analytical data recorded for the "C_{13}-dicarboxylic acid" were not very satisfactory and it seemed probable that it was not a pure compound. Okuda also obtained the dicarboxylic acid by ozonisation of hinokiic acid followed by further oxidative degradation. From the neutral fractions of the ozonisation products he isolated an oily ketone, $C_{13}H_{20}O$.

Okuda's papers are all in Japanese and we are grateful to Dr. Y. L. Chow for translating them.

Ozonisation of widdrenic acid followed by oxidation with hypobromite also gave acid and neutral products. From the former there was isolated widdrene dicarboxylic acid and from the latter a dibromoketone, m.p. 99—100°. (Found: C 44.6; H 5.2; Br 46.0. $C_{13}H_{18}OBr_2$, requires C 44.6; H 5.2; Br 45.7) which on treatment with zinc and acetic acid gave a crystalline ketone, m.p. 49.5—50.5°. (Found: C 81.3; H 10.4. $C_{13}H_{20}O$ requires C 81.3; H 10.4.)

Some constants for hinokiic acid and widdrenic acid and some of their degradation and transformation products are shown in Table 2.

From the close similarity of these constants (apart from those of the dicarboxylic acid) it seemed very probable that hinokiic acid and widdrenic acid were identical. Dr. Okuda very kindly supplied a generous sample of crude hinokiic acid from which the pure acid was obtained and direct comparison

Table 2.

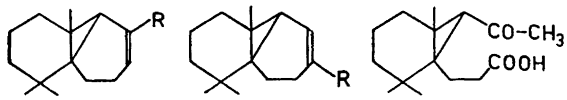
Oily ketone $C_{13}H_{20}O$ Semicarbazone, m. p. 224—225°	*Ketone* $C_{13}H_{20}O$, m. p. 49.5—50.5° Semicarbazone, m. p. 225—226°

of this acid and widdrenic acid (mixed m.p., IR) showed that they were identical. The name widdrenic acid is thus redundant and should be abandoned *.

The structure (I) proposed for hinokiic acid cannot, however, be entirely correct. In ring B there can be no C=C—CH_3 grouping since the dicarboxylic acid, m.p. 215° (thujopsene dicarboxylic acid) and hinokiic acid on oxidation according to Kuhn-Roth gave almost the same yield of acetic acid (0.62 and 0.57 moles; thujopsene 1.49 mole). The oxidation of thujopsene to hinokiic acid and further to the C_{14}-dicarboxylic acid shows that there is only one substituent, the carboxyl group on the double bond.

Further investigation here has now shown that the ketone, m.p. 49.5—50.5°, from the ozonolysis products obtained from hinokiic acid is identical with a ketone formed by a Dieckmann condensation from the dimethyl ester of thujopsene dicarboxylic acid. According to the IR and UV absorption this ketone contains a bi*cyclo*[3.1.0]hexane system with a carbonyl group in conjugation with the *cyclo*propane ring ($\nu_{max}^{CCl_4}$ 1 723 cm^{-1}; λ_{max}^{EtOH} 210.5 mμ, ε 4 900). Dihydroumbellulone [16] which has a similar structure shows the same absorption ($\nu_{max}^{CCl_4}$ 1 722 cm^{-1}; λ_{max}^{EtOH} 210 mμ. ε 2 470). Dihydrolumiprednisone acetate [17] and dihydrolumisantonin [18] are also similar. The presence of both the *cyclo*propane ring and the double bond is also indicated by the results of the hydrogenation experiments of thujopsene and hinokiic acid (*cf.* Table 2). There is at present no reason to doubt Okuda's conclusions on the nature of ring A. The structure of thujopsene and hinokiic acid are therefore presumably either IIa or IIb (with R = CH_3 and COOH, respectively):

* It may in the future be found advantageous to rationalise the nomenclature of these compounds by abandoning the name hinokiic acid altogether in favour of names based on thujopsane.



IIa IIb III

The UV spectra of the ketocarboxylic acid obtained by ozonolysis of thujopsene (λ_{max}^{EtOH} 210.5 mμ, ε 4 700), of the C_{14}-dicarboxylic acid (no maximum above 205 mμ in EtOH, $\varepsilon_{205\ m\mu}$ *ca.* 800), and of a lactone, m.p. 126—128°, obtained by potassium borohydride reduction of the ketoacid (no maximum above 205 mμ in EtOH, $\varepsilon_{205\ m\mu}$ *ca.* 150) indicate that the ketogroup of the ketocarboxylic acid is conjugated with the *cyclo*propane ring (structure III). Structure IIa (R = CH_3) is therefore preferred for thujopsene and IIa (R = COOH) for hinokiic acid.

The Structure of the Oxazolidine-2-thione Derivatives Synthesized from Some Reducing Sugars

ALF WICKSTRÖM and JENS KRISTIAN WOLD

Universitetets farmasøytiske institutt, Blindern-Oslo, Norway

The structure of the previously described cyclic thione-carbamates of some reducing sugars has been examined by means of their oxidation by periodate and their absorption spectra in infrared and ultraviolet. Results were obtained which contribute to the determination of the structure of the compounds prepared from D-xylose, L-arabinose, and D-fructose.

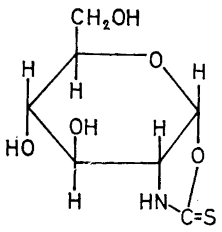
It appeared that they all contain an oxazolidine-2-thione ring fused with the pentoses (through C_1 and C_2) in their furanose form or with D-fructose (through C_2 and C_3) in its pyranose form.

These oxazolidine-2-thione derivatives crystallize in the thione form. In aqueous solution they exhibit uniform acid strength.

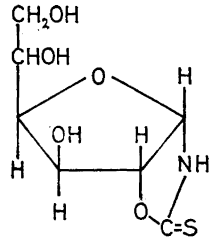
Some reducing sugars, D-glucose [1], D-fructose [2], D-galactose, D-xylose, and L-arabinose [3], have been reported to give with thiocyanic acid crystalline condensation products which presumably all contain an oxazolidine-2-thione ring. Since this cyclic thione-carbamate group in simpler compounds is known to exhibit antithyroid activity [4] and since the structure of these sugar derivatives still presents some unresolved problems, it seemed of interest to examine their structure as far as new methods of approach would allow.

In the present work infrared and ultraviolet absorption spectra as well as a periodate oxidation technique eliminating the disturbing effect of the thione group, have been used to elucidate the structure of the cyclic thione-carbamates of the following sugars: D-xylose, L-arabinose, and D-fructose. Oxazolidine-2-thione, tetrahydrogen-1,3-oxazine-2-thione, and D-gluco-oxazolidine-2-thione have served as reference compounds. All the above-mentioned substances were synthesized according to previously described methods. The D-fructose derivative, not obtainable as a completely homogeneous product by recrystallizations [2], required a chromatographic purification.

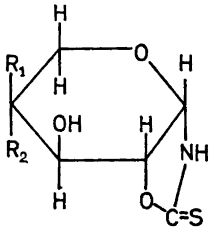
The condensation product between thiocyanic acid and D-glucose, D-gluco-oxazolidine-2-thione, was used as a reference substance because its structure is that most completely examined in this series of sugar derivatives. The formula (II) now accepted differs from the originally suggested structure [1]



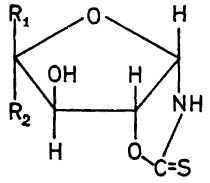
I



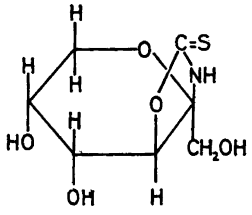
II



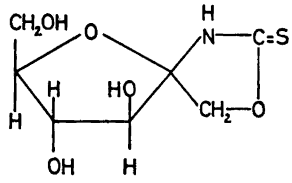
III: $R_1 = H$, $R_2 = OH$
IV: $R_1 = OH$, $R_2 = H$



V : $R_1 = CH_2OH$, $R_2 = H$
VI: $R_1 = H$, $R_2 = CH_2OH$



VII



VIII

(I) by having a furanose ring instead of a pyranose ring and by the mode of attachment of the thione-carbamate group to the sugar chain.

Schwarz [5], studying the oxidation of the D-glucose and the D-galactose derivative by periodate, found that they both yielded one molecule of formaldehyde, a result which is consistent with the furanose form only. Further, the D-glucose compound readily formed an *ortho*formate [5], proving that the thione-carbamate group is incorporated in a five-membered and not in a six-membered ring. Only the hydroxyl group on C_3 and not that on C_2 of the sugar ring is so located as to render the formation of an *ortho*formate sterically possible.

After hydrolytic cleavage of the oxazolidine ring of the D-glucose compound the presence of 2-amino-2-deoxy-D-glucose could not be demonstrated [3]. Edward and Martlew [6] found by paper chromatography of the acid hydrolysate no spots of the very acid-resistant 2-amino-2-deoxy-D-glucose, but 1-aminoglucose and diglucosylamine could be detected. They concluded that the nitrogen of the thione-carbamate group is attached to C_1 as in formula (II) and not to C_2 as previously [1] suggested (I).

All formulas discussed in the present paper are written in agreement with this conclusion, the nitrogen being attached to the anomeric carbon. Primarily, it is difficult to conceive of a reaction between a reducing sugar and thiocyanic acid resulting in the replacement of a hydroxyl group by nitrogen on any carbon other than the anomeric, whereas a similar replacement on the anomeric carbon might result from a hypothetic sequence of possible reactions already mentioned by Bromund and Herbst [3]: intermediate formation of glycosyl-*iso*thiocyanate undergoing intramolecular urethane formation to a cyclic thione-carbamate with one of the alcohol groups of the sugar moiety, *e. g.* with the adjacent hydroxyl group to an oxazolidine-2-thione ring. Further, the sugar derivatives are found to be of uniform acid strength ($pK_A^{20°} = 9.33$—9.48) and considerably stronger acids than the unsubstituted ring system, oxazolidine-2-thione ($pK_A^{20°} = 11.05$), which according to the present investigation is incorporated in all the sugar derivatives studied. This shows that the interaction of the sugar moiety on the presumably acid NH-group is of similar magnitude throughout the series, indicating that the nitrogen is probably located in an analogous position in all the derivatives, *e. g.* on the anomeric carbon.

According to Schwarz [5] the reaction of D-gluco-oxazolidine-2-thione and of D-galacto-oxazolidine-2-thione with unbuffered sodium periodate is complica-

Table 1. Oxidations by means of periodate of the condensation products between thiocyanic acid and reducing sugars.

Parent sugar	Reaction time at 20° (h)	0.5	1	2	6	22	44
D-Glucose	I [a]	5.02	5.01			5.18	
	II [b]	2.02	2.03			2.05	
D-Fructose	I [a]		3.90	4.32	4.65	5.00	5.03
	II [b]		0.38	0.45	0.83	1.50	1.50
D-Xylose	I [a]	4.05	4.05	4.17	4.32	4.32	
	II [b]	0.19	0.19	0.13	0.18	0.19	
L-Arabinose	I [a]	4.04	4.07	4.15	4.10	4.30	
	II [b]	0.18	0.27	0.27	0.26	0.25	

[a] molecules of periodate reduced.

[b] molecules of potassium cyanide reacting with the oxidation product. The figures are mean values of at least two determinations and are referred to one molecule of the sugar derivative.

ted by the oxidation of the thione group. Iodine was liberated, indicating that periodate was reduced beyond the iodate step, and in most cases the reaction mixture also became cloudy (possibly sulphur), indicating that the sulphur of the thione group was not completely oxidized to sulphate. The authors have overcome this difficulty by carrying out the oxidation with a large excess of periodate in a solution acidified by acetic acid. The organic sulphur is then completely oxidized to sulphate by periodate and no reduction of the resulting iodate occurs. This modification affords the possibility of studying the periodate oxidation of these sulphur compounds by classical analytical methods such as the arsenite titration of excess periodate followed by the cyanide titration of carbonyl groups in the oxidation product (Table 1).

Thus, D-gluco-oxazolidine-2-thione (II) consumes five molecules of periodic acid — four molecules to oxidize the sulphur to sulphate (Found: 0.97 mole) and one molecule to transform a glycol group to two aldehyde groups, one of which is formaldehyde [5].

The two pentose compounds reduce four molecules of periodate, corresponding to the oxidation of sulphur to sulphate (Found: 0.94 mole). The insignificant consumption of potassium cyanide, being apparently independent of the reaction time and the reduction of the oxidant, does not indicate a glycol-splitting reaction.

The fructose compound reduces the four molecules of periodate required to oxidize the thione group to sulphate (Found: 0.99 mole) and one additional molecule of periodate which is consumed in the cleavage of a glycol group liberating two (Found: 1.5) titratable aldehyde functions. Only two possible bicyclic formulas, (VII) and (VIII), are consistent with this result, and formula (VII) has been chosen because it agrees with other experimental evidence.

The cyclic thione-carbamates of D-xylose and L-arabinose were believed to possess a pyranose structure [3] (formulas (III) and (IV), respectively) in complete analogy with the previously suggested structure of D-gluco-oxazolidine-2-thione (formula (I)). The two pentose compounds, however, have no glycol group able to reduce periodate. Formula (IV) of the L-arabinose compound includes a *cis* glycol group, and the actual resistance of the ring system towards periodate, therefore, contradicts this structure. The two vicinal hydroxyl groups in formula (III) of the D-xylose compound are held in a *trans* position which presumably renders this glycol group relatively more resistant to glycol-splitting reagents. Complete resistance of *trans* glycol groups towards periodate has so far been observed only in extremely rigid systems, such as 1-6-anhydro-D-glucofuranose [7]. In case, however, the argument against formula (III) based upon the stability of the sugar ring when exposed to periodate might be considered less decisive, it should be mentioned that a supporting argument favouring the modified formula (V) emerged from the infrared spectrum of the D-xylose compound.

The infrared spectra of all substances enumerated in Table 2 have been studied by the potassium bromide plate technique. The main purpose of this examination was to obtain information about the size of the N-heterocyclic ring in the various sugar derivatives.

The infrared absorption of different series of oxazolidine-2-thione derivatives has been investigated by Ettlinger [8] (samples in chloroform) and Skulski *et al.*[9] (samples in Nujol).

The strong absorption band of the five-membered cyclic thione-carbamate in oxazolidine-2-thione (1 525 cm^{-1}) and in D-gluco-oxazolidine-2-thione (1 510 cm^{-1}), tentatively attributed to a NH bending vibration [9], is found in the same region of the spectra of all the sugar derivatives studied, whereas this band of the six-membered cyclic thione-carbamate, tetrahydrogen-1,3-oxazine-2-thione, is displaced to a higher frequency (1 575 cm^{-1}). This is a strong indication of the presence of a five-membered ring (oxazolidine-2-thione) not only in the D-glucose compound but in all the sugar derivatives examined.

It also emerged from the infrared spectra of the sugar derivatives that, in analogy with the unsubstituted oxazolidine-2-thione and some of its substitution derivatives [9], they crystallize in the thione form (and not in the tautomeric thiol form). Absorption due to SH stretching or to C=N bonds did not occur (Table 2).

Further, on comparing the infrared spectra of the oxazolidine-2-thiones of the two homomorphous [10] sugars D-glucose and D-xylose, it was noticed that the absorption curves exhibited a striking parallelism between 4 000 cm^{-1} and 900 cm^{-1}. This may be taken as an indication of the presence of the same fused ring system in both sugar derivatives, formula (II) and (V).

The ultraviolet absorption of the unsubstituted N-heterocyclic rings and the sugar derivatives was also recorded. Results tabulated in Table 3 support the above conclusion that the cyclic thione-carbamates of various sugars examined all contain this group in a five-membered ring.

In order to choose between the two D-fructo-oxazolidine-2-thione formulas (VII) and (VIII) the reducing product of the periodate oxidation was examined by methods which have proved to be reliable in the study of oligo-saccharides, *e. g.* by Courtois and Wickstrøm [11]: paper chromatographic analysis of carboxylic acids formed by bromine oxidation of the aldehyde groups and subsequent acid hydrolysis. D-Fructo-oxazolidine-2-thione yielded glycolic acid in about 50 % of the theoretical amount. The glycolic acid is considered to contain C_6 and C_5 of the fructose moiety of formula (VII), whereas a substance of the formula (VIII) by the same sequence of reactions should yield D-glyceric acid (from C_6, C_5, and C_4). Only one acid spot was observed, probably as a result of destruction of the N-heterocyclic moiety during hydrolysis.

All experimental results agree with the formulas (V) and (VI) for the D-xylose and the L-arabinose derivative, respectively, and with formula (VII) for the D-fructose derivative. According to these formulas the two pentose compounds have a structure analogous to that of the D-gluco-oxazolidine-2-thione (II) and not to the erroneous formula of this compound (I). The size of the rings in formula (VII) of the D-fructose compound is in agreement with the structure attributed to this substance by Zemplén *et al.*[2]

Table 2. Infrared absorption from 1 500 to 4 000 cm^{-1}.

Assignment	NH or OH stretching vibration (bonded) cm^{-1}	NH bending [a] cm^{-1}
Substance		
Oxazolidine-2-thione	3 220	1 525
Tetrahydrogen-1,3-oxazine-2-thione	3 210	1 575
D-Gluco-oxazolidine-2-thione	3 410 3 200	1 510
D-Fructo-oxazolidine-2-thione	3 370 3 180	1 505
D-Xylo-oxazolidine-2-thione	3 420 3 170	1 525
L-Arabo-oxazolidine-2-thione	3 380 3 270	1 485

Table 3. Ultraviolet absorption.

Substance	Aqueous solution		Solution in 0.1 N NaOH [b]	
	λ_{max} (mμ)	$\varepsilon \times 10^{-3}$	λ_{max} (mμ)	$\varepsilon \times 10^{-3}$
Oxazolidine-2-thione [a]	239	16.0	228	12.3
Tetrahydrogen-1,3-oxazine-2-thione	244	14.9	242	11.8
D-Gluco-oxazolidine-2-thione	241	19.7	233	14.5
D-Fructo-oxazolidine-2-thione	241	21.5	233	16.8
D-Xylo-oxazolidine-2-thione	241	20.3	233	14.6
L-Arabo-oxazolidine-2-thione	241	19.6	233	14.3

[a] the ultraviolet absorption found is in agreement with previously published curves for this compound [4].

[b] the absorption in alkaline solution is due to the ionized heterocyclics because of the occurrence of an isosbestic point between the curve in 0.1 N NaOH and curves recorded at several lower pH values.

EXPERIMENTAL

All melting points are micro melting points (Kofler's hot-stage microscope).

1. Preparations

(a) *Cyclic thione-carbamates* were prepared from the various reducing sugars (D-glucose, D-xylose, L-arabinose, D-fructose) according to methods previously described [1-3]. The products obtained from the aldoses were found to be identical with the compounds described in the literature by determination of their melting points, their optical rotation in water, and their reduction of hypoiodite [12] (8 equiv.): D-glucose compound, m. p. 170°, $[\alpha]_D^{20°} = +33.9°$ ($c = 2$), 99.7 %; D-xylose compound, m. p. 131°, $[\alpha]_D^{28°} = +13.2°$ ($c = 2$), 99.5 %; L-arabinose compound, m. p. 136°, $[\alpha]_D^{20°} = +11.8°$ ($c = 2$), 98.7 %.

The heterocyclic product obtained from D-fructose and thiocyanic acid (Zemplén's "Fructose Rhodanverbindung 2") is contaminated with variable amounts of Zemplén's

"Fructose Rhodanverbindung 1", presumably an open chain addition product, m. p. 217°, which is extremely difficult to remove completely by recrystallizations [2]. The two products may be separated on paper chromatograms with the solvent system acetone, *n*-propanol, water (45:45:10 v/v) and the spots ($R_F^{20°}$ = 0.53 (1) and 0.66 (2)) revealed by silver nitrate and ethanolic sodium hydroxide [13]. From columns packed with Whatman standard grade cellulose powder (4.6 × 37 cm) and developed with the above-mentioned solvent system, a poor yield of chromatographically pure "Fructose Rhodanverbindung 2" was obtained, *e. g.* from 0.5 g of the crude mixture (m. p. 172—76°, containing about 10 % of the "Fructose Rhodanverbindung 1") 0.05 g of chromatographically pure "Fructose Rhodanverbindung 2" was obtained. It was further purified by recrystallization from methanol, m. p. 185° (decomp.), $[\alpha]_D^{20} = -50.7°$ (c = 1, water), iodometric titration [2], 97.8 %.

(b) *Oxazolidine-2-thione*, m. p. 97.5°, was prepared from ethanolamine according to Rosen [14], and tetrahydrogen-1,3-oxazine-2-thione was synthesized by a similar procedure starting with 3-amino-propanol; the method described by Rosen [14] for the preparation of 4,4,6-trimethyl-tetrahydrogen-1,3-oxazine-2-thione from 4-amino-4-methyl-pentanol-2 was followed without any essential modification. Repeated crystallization from *n*-butanol gave long, colourless needles (only 3 % yield), m. p. 127°, titration with hypoiodite [12] 99.7 %. (Found: C 41.01; H 5.95; N 11.98; S 28.17. Calc. for C_4H_7ONS: C 41.02; H 6.03; N 11.95; S. 27.36.)

2. Oxidations with periodate

(a) *Titration of periodate uptake and liberated aldehydes.* A 0.05 M periodate reagent (A) of pH about 4 was prepared by dissolving sodium *para*-periodate (Hopkin and Williams Ltd) (7.5 g) in N acetic acid (200 ml) and water (about 200 ml), filtering the solution after some days through sintered glass and adding water to 500 ml. The samples (10 ml of 0.005 M solutions) were oxidized with this reagent (20 ml) at room temperature in the dark. Iodic acid, not iodine or hydroiodic acid, was formed by reduction of the periodic acid. After neutralization with sodium bicarbonate the periodate uptake was determined by the classical arsenite method [15] and titratable carbonyl groups were estimated according to the previously described technique [11]. For oxidation of the fructose compound 0.01 M periodate was used. Results are shown in Table 1.

(b) *Determination of sulphuric acid liberated by periodate oxidation.* The samples (5×10^{-5} molecule in 10 ml of water) were oxidized by the periodate reagent (A) (20 ml). The oxidation was stopped by adding 2 N hydrochloric acid (1.5—2 ml) and then hydrazine hydrate (50 % w/w) dropwise, stirring constantly until the colour of the reaction mixture changed from violet to yellow (0.5—1 ml). The solution was heated on a water bath till the colour (iodine) disappeared completely. Barium sulphate was precipitated from the boiling solution by adding barium chloride in slight excess. The following molecular yields of sulphuric acid per molecule of oxidized sugar derivative were found as mean values of repeated gravimetric determinations (reaction time with periodate in brackets): D-gluco-oxazolidine-2-thione, 0.97 (30 min), D-xylo-oxazolidine-2-thione, 0.94 (60 min), L-arabo-oxazolidine-2-thione, 0.94 (60 min), D-fructo-oxazolidine-2-thione, 0.99 (20 h).

(c) *Examination of the reducing product formed by periodate oxidation of the* D-*fructo-oxazolidine-2-thione.* The sample (25 mg) was oxidized with free periodic acid (500 mg) in aqueous solution at room temperature for 20 h. The solution was neutralized with strontium hydroxide to pH 5—6 and filtered. The filtrate was treated with a weak excess of bromine at room temperature until an aliquot failed to reduce the Nessler reagent (6—8 days). Bromine was then removed by aeration and the solution evaporated to dryness (reduced pressure). The residue was taken up in 2 N sulphuric acid (1.50 ml) and heated in a boiling water bath for one hour. Sulphuric acid was removed by treatment with strontium carbonate and the hydrolysate examined by paper chromatography in the following solvent systems: I, ethyl acetate-formic acid-water (10:2:5 v/v), and II, *n*-butanol-formic acid-water (10:1:5 v/v), which clearly separated authentic samples of glycolic acid ($R_F^{20°}$ = 0.52 (I) and 0.67 (II)) and D-glyceric acid ($R_F^{20°}$ = 0.35 (I) and 0.55

(II)). In repeated experiments only spots corresponding to glycolic acid were observed (bromophenol blue spray). By comparison with a series of standard solutions of glycolic acid (0.1 to 0.5 %) the amount of glycolic acid recovered from the fructose compound was evaluated to about 50 % of the theoretical, indicating its formation by a main reaction. The heterocyclic moiety of the oxidized fructose compound was probably undergoing destruction during hydrolysis (gas evolution).

3. Determination of acid strength

The apparent pK_A values at 20° were calculated from pH measurements on a Metrohm pH-meter E 196 S of 0.01 M aqueous (carbon dioxide free) solutions half neutralized with barium hydroxide. The following mean values were obtained: oxazolidine-2-thione, 11.05 (5,5-dimethyl-oxazolidine-2-thione [4], 11.05); D-glucooxazolidine-2-thione, 9.33; D-xylo-oxazolidine-2-thione, 9.48; L-arabo-oxazolidine-2-thione, 9.48; D-fructo-ozaxolidine-2-thione, 9.40.

4. Absorption spectra

The ultraviolet absorption spectra were recorded on a Beckman DU spectrophotometer using about 2×10^{-5} M solutions of the samples (Table 3). The infrared spectra of the samples (Table 2) in potassium bromide plates were recorded with a Perkin-Elmer Model 21 double beam spectrophotometer.

The authors are indebted to Mr. E. Manser, E. T. H. Zürich, for performing the elementary micro analysis and to siv.ing. J. Lothe, *Sentralinstituttet for Industriell Forskning*, Oslo, for discussion of the infrared spectra recorded in his laboratory. Gratitude is also expressed to *Norges Almenvitenskapelige Forskningsråd* for the award of a Research Fellowship to one of us (J.K.W.).

On the Metabolism of Bile Acids in the Guinea Pig

Bile Acids and Steroids 86

HENRY DANIELSSON and TARO KAZUNO*

Department of Chemistry I, Karolinska Institutet, Stockholm, Sweden

The catabolism of 4-^{14}C-cholesterol to bile acids has been studied in intact and bile fistulated guinea pigs. The only bile acid formed from cholesterol in the liver is chenodeoxycholic acid. During the enterohepatic circulation chenodeoxycholic acid is oxidized to 7-keto-lithocholic acid by the action of intestinal microorganisms. The 7-keto-lithocholic acid thus formed is reduced in the liver to chenodeoxycholic acid, as was shown by injection of 24-^{14}C-7-keto-lithocholic acid to intact and bile fistulated guinea pigs.

The bile of guinea pig is reported to contain chenodeoxycholic acid (3α, 7α-dihydroxycholanic acid) and 7-keto-lithocholic acid (3α-hydroxy, 7-keto-cholanic acid), present as conjugates with taurine [1]. The important part played by intestinal microorganisms in the metabolism of bile acids during their enterohepatic circulation has recently become apparent by work in this laboratory. Lindstedt and Sjövall [2] found, that deoxycholic acid, which makes up 90 % of the bile acids in gall-bladder bile of rabbit, is formed from cholic acid by the action of bacteria in the intestine. The same reaction has been shown also to occur in man [3], and in rat [4], that was also observed by Portman [5]. In the rat, however, the deoxycholic acid is rapidly rehydroxylated to cholic acid in the liver [6]. In the pig, hyodeoxycholic acid (3α,6α-dihydroxy-cholanic acid) is a microbial product of hyocholic acid (3α,6α,7α-trihydroxy-cholanic acid) [7]. In all above mentioned cases the intestinal microorganisms remove a 7α-hydroxyl from a trihydroxylated bile acid, whether the position of the hydroxyls is 3α,6α,7α or 3α,7α,12α. This reaction has been further studied *in vivo* by means of doubly labeled cholic acid (7β-tritio, 24-^{14}C-cholic acid) [8,9], and it has been found, that the removal of the 7α-hydroxyl occurs with retention of tritium that, however, apparently is shifted during this process from the 7β to the 7α position.

Norman and Sjövall [4] have recently made a detailed study of the metabolism of bile acids in the rat during their passage through the intestinal tract, and they have shown, that among microbially formed products of cholic acid

* Permanent address: Department of Biochemistry, Hiroshima University School of Medicine, Hiroshima, Japan.

small amounts of ketonic acids, mainly 3α,12α-dihydroxy -7-ketocholanic acid, are also absorbed from the large intestine and excreted in the bile.

Thus in the rat intestinal microorganisms are responsible for the removal of the 7α-hydroxyl from cholic acid and also for the oxidation of this group to a ketone. The latter reaction does not seem to be a quantitatively important intermediate step in the formation of deoxycholic acid, as the 7β-tritium in cholic acid is retained to a high extent in the deoxycholic acid.

In view of above mentioned data and considering that the guinea pig is reported to have no trihydroxylated bile acid, but only chenodeoxycholic and 7-keto-lithocholic acid in its bile, it was of interest to study the formation of bile acids in this species and the changes, if any, of the bile acids during their enterohepatic circulation.

EXPERIMENTAL

Male guinea pigs of the Danish State Serum Institute strain, weighing approx. 300 g, were used. Bile fistulas were prepared as described for rats [10].

Procedures for analysis of bile. Conjugated bile acids were extracted from acidified bile with *n*-butanol. Conjugates were split by hydrolysis with N sodium hydroxide at 120° for 8—12 h in a sealed steel tube, and the free bile acids were extracted with ether from the acidified reaction mixture. The bile acids were separated with reversed phase partition chromatography using phase system C for conjugated acids [11] and F for free acids [12].

Phase systems

	Moving phase	Stationary phase
C	150 ml methanol 150 ml water	15 ml chloroform 15 ml *iso*octanol
F	165 ml methanol 135 ml water	45 ml chloroform 5 ml heptane

Hostalene (Farbwerke Hoechst, G.m.b.H., West-Germany), prepared as earlier described [7], was used as supporting material for the stationary phase. Columns were prepared as described by Norman [11], using 3 ml of stationary phase per 4.5 g of Hostalene. Chromatograms were run at constant temperature of 23°. The effluent was titrated with 0.02 N methanolic sodium hydroxide, and suitable aliquots were assayed for radioactivity, which was determined with an automatic end-window counter, Frieseke und Hoepfner, West-Germany.

Labeled compounds. 4-^{14}C-cholesterol was obtained from the Radiochemical Centre, Amersham, England. Specific activity: $\sim$ 50 μC/mg. 24-^{14}C-7-ketolithocholic acid was prepared from 24-^{14}C-chenodeoxycholic acid according to the procedure described by Samuelsson [13]. Specific activity: $\sim$1 μC/mg.

RESULTS AND DISCUSSION

The formation of bile acids from cholesterol and the metabolism of these in guinea pig was studied by analyses of labeled products in gall-bladder and fistula bile after intraperitoneal injection of 4-^{14}C-cholesterol and of 24-^{14}C-7-keto-lithocholic acid. The 4-^{14}C-cholesterol in doses of 10—50 μC (0.2—1 mg) was injected as an emulsion with 1 % bovine serum albumin in saline. 1—5 days after administration of the isotope, a bile fistula was prepared and bile collected for 12—24 h or the animal was sacrificed and the gall-bladder removed.

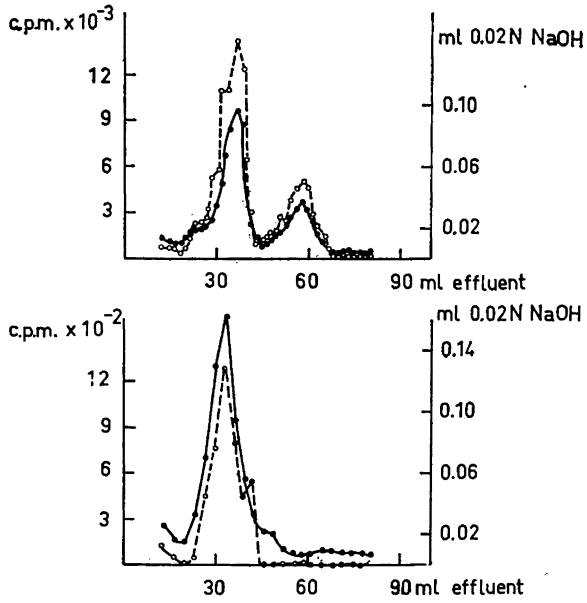

Fig. 1. Chromatogram of hydrolyzed bile collected from bile fistula between 0 and 4 h (upper curve) and between 8 and 20 h (lower curve) after fistulation. The animal had been injected with 50 μC 4-^{14}C-cholesterol 5 days before operation. Columns: 4.5 g Hostalene. Phase system F. Solid line: titration. Broken line: radioactivity.

The unhydrolyzed bile acids were chromatographed with phase system C, and it was found, that bladder bile and fistula bile collected 0—8 h after fistulation contained mainly glycine conjugates, about 80 % of total, the rest being taurine conjugates. Fistula bile collected later than 8 h after fistulation had a considerable part and sometimes all of the bile acids conjugated with taurine.

When the bile acids were chromatographed after hydrolysis on phase system F, it was found, that there appeared one or two radioactive titration peaks, depending on the time the bile samples were collected. Bile collected from bladder, and fistula bile collected during the first 4—6 h after fistulation contained two labeled acids, appearing in the chromatogram at the place for chenodeoxycholic and 7-keto-lithocholic acid, respectively, as is shown in the upper curve of Fig. 1. Bile collected later than 6 h after fistulation contained only one labeled acid with chromatographic mobility as chenodeoxycholic acid, *cf.* lower curve, Fig. 1. The identity of the labeled compounds with chenodeoxycholic, 7-keto-lithocholic and chenodeoxycholic acid, respectively, was established by co-crystallization with unlabeled material, the specific activity remaining constant through four crystallizations with a final weight of crystals about one quarter the original weight (chenodeoxycholic acid was crystallized from methanol/ethyl acetate twice and ethyl acetate twice; 7-keto-lithocholic acid from ethyl acetate, methanol/water, acetone/water and ethyl acetate).

Bladder bile and fistula bile collected 0—3 h after fistulation, when the preformed bile acids are being excreted, contained approximately the same

proportion of chenodeoxycholic to 7-keto-lithocholic acid, 3:1, whether the cholesterol had been injected 1 or 5 days before collection of bile, indicating that the microbial formation of 7-keto-lithocholic acid from chenodeoxycholic acid occurs rapidly and then reaches an equilibrium, which conceivably could be maintained by a continuous reduction of the 7-ketone to a 7α-hydroxyl in the liver. To test this, 24-^{14}C-7-keto-lithocholic acid in doses of 0.3 μC (0.3 mg) was injected intraperitoneally into intact and bile fistulated guinea pigs. The labeled products in bile were analyzed as described above.

Already after 1 day of enterohepatic circulation 73 % of the isotope in the bile was present as chenodeoxycholic acid; the remainder consisted of unchanged 7-keto-lithocholic acid. About the same distribution of isotope (83 % in chenodeoxycholic acid) was found in bile from an animal, in which the labeled 7-keto-lithocholic acid had taken part in the enterohepatic circulation for 3 days. When the 7-keto-lithocholic acid was injected into bile fistulated guinea pigs, the isotope appeared in bile rapidly, and after 4 h 70—80 % of the injected amount had been excreted. About 50 % of the isotope was present as chenodeoxycholic acid and the remainder as unchanged 7-keto-lithocholic acid.

Thus, the guinea pig liver efficiently reduces 7-keto-lithocholic acid to chenodeoxycholic acid. In this connection it is interesting, that the rat liver reduces 7-keto-lithocholic acid mainly to the 7β-epimer, ursodeoxycholic acid[13]. These experiments do not exclude the possibility, that the reduction of 7-keto-lithocholic acid to chenodeoxycholic acid is effected also by intestinal microorganisms, but this does not seem entirely likely in view of results obtained in the rat, where the microbial action on the bile acid nucleus mainly is oxidative or consists of dehydroxylations [4].

The results obtained in this investigation seem to establish, that the guinea pig, as the only species so far known, does not catabolize cholesterol in the liver to a trihydroxylated bile acid, but only to chenodeoxycholic acid. During the enterohepatic circulation of bile this acid is transformed by microbial action into 7-keto-lithocholic acid, which in turn is reduced in the liver to chenodeoxycholic acid.

Acknowledgments. This work is part of investigations supported by *Statens Medicinska Forskningsråd, Knut och Alice Wallenbergs Stiftelse*, Stockholm, and the *National Heart Institute, National Institutes of Health*, Bethesda, Maryland, USA (H 2842).

On the Metabolism of Bile Acids in the Mouse

Bile Acids and Steroids 87

HENRY DANIELSSON and TARO KAZUNO*

Department of Chemistry I, Karolinska Institutet, Stockholm, Sweden

The catabolism of 4-^{14}C-cholesterol to bile acids in the mouse has been studied. Cholic acid and small amounts of chenodeoxycholic acid are formed. The presence of chenodeoxycholic acid in mouse bile is therefore postulated. The latter acid was partially transformed into two more polar compounds having the same chromatographic mobility as the 6β-hydroxylated acids (3α,6β,7α- and 3α,6β,7β-trihydroxycholanic acid) formed from chenodeoxycholic acid in the rat.

24-^{14}C-Deoxycholic acid was hydroxylated to cholic acid in the mouse.

Recent work on the effect of intestinal microorganisms on bile acids has demonstrated, that the primary bile acids, *i. e.* those formed in the liver, often are modified during their enterohepatic circulation by the action of bacteria. Thus, deoxycholic acid in man [1] and rabbit [2] is a microbial metabolite of cholic acid. The same reaction occurs in rat [3,4], but the deoxycholic acid formed is in this species rehydroxylated to cholic acid in the liver [5]. The removal of a 7α-hydroxyl from a primary trihydroxylated bile acid by the action of intestinal microorganisms also occurs in the pig [6], where hyocholic acid is transformed into hyodeoxycholic acid.

These findings, that were discussed in more detail in the preceding paper [7], seem to suggest a general scheme of bile acid metabolism, irrespective of species. To obtain additional experimental support for such a hypothesis, and as a part of a more general survey of bile acid metabolism in different species, it was of interest to investigate the formation and metabolism of bile acids in the mouse, that is reported to have cholic acid in its bile [8].

* Permanent address: Department of Biochemistry, Hiroshima University School of Medicine, Hiroshima, Japan.

EXPERIMENTAL

White male mice of the Danish State Serum Institute strain, weighing approx. 25 g, were used. The animals were sacrificed by cervical dislocation. Bile was recovered from the gall-bladder and from 50 % ethanol washes of the upper part of the small intestine.

The analytical procedures for conjugated and free bile acids were essentially the same as those described in the preceding paper [7]. 4-^{14}C-cholesterol was obtained from Radiochemical Centre, Amersham, England, and was administered as an emulsion with 1 % bovine serum albumin in saline. 24-^{14}C-Chenodeoxycholic and 24-^{14}C-deoxycholic acid were prepared according to Bergström *et al.*[9] and were generous gifts from Dr. Arne Norman.

RESULTS AND DISCUSSION

10 μC (0.2 mg) of 4-^{14}C-cholesterol were injected intraperitoneally into each of 8 mice, and 24, 48, 72 and 120 h after injection 2 animals were sacrificed and the bile was collected. Chromatography of the unhydrolyzed bile samples revealed that the bile acids were present in bile exclusively as taurine conjugates. After hydrolysis the bile acids were chromatographed with phase system F and in Fig. 1 is shown a chromatogram of the free bile acids from 2 mice injected 48 h before sacrifice. The radioactive material in the first peak was identified as cholic acid by isotope dilution. The identity of the radioactive material in the second peak with chenodeoxycholic acid was established in the same manner. Chromatograms of hydrolyzed bile from the mice injected with 4-^{14}C-cholesterol 24, 72 and 120 h before sacrifice did not differ from the above mentioned, except that the amount of chenodeoxycholic acid varied from a few percent to 10 %.

The catabolism of cholesterol to bile acids in the mouse thus follows the same path as in rat. In the latter animal chenodeoxycholic acid is further metabolized to two 6β-hydroxylated acids (3α,6β,7α- and 3α,6β,7β-trihydroxycholanic acid), recently identified by Doisy and coworkers [10,11], and cholic acid is transformed by the action of intestinal microorganisms into deoxycholic acid [3], which in turn is rapidly rehydroxylated to cholic acid in the liver [5].

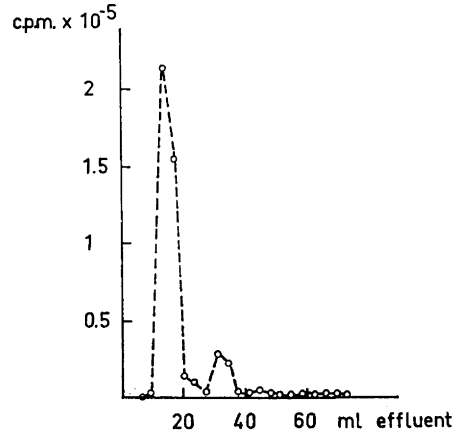

Fig. 1. Chromatogram of hydrolyzed bile collected 48 h after i. p. injection of 4-^{14}C-cholesterol. Column: 4.5 g Hostalene. Phase system F. Broken line: radioactivity.

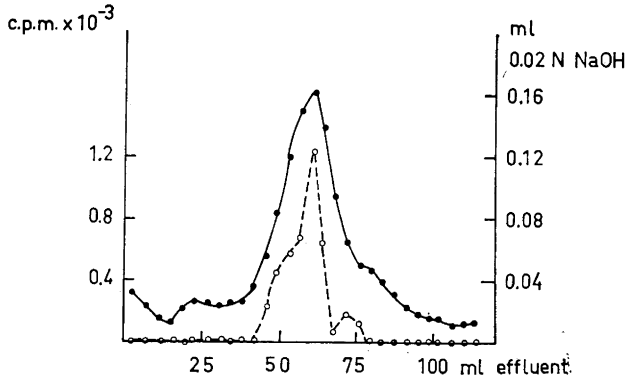

Fig. 2. Chromatogram of trihydroxycholanic acid fraction from bile collected 24 h after injection of 24-^{14}C-deoxycholic acid. Column: 4.5 g Hostalene. Phase system C. Solid line: titration. Broken line: radioactivity.

In order to provide further evidence for the similarity in the pattern of bile acid formation and metabolism in rat and in mouse, the metabolism of 24-^{14}C-chenodeoxycholic and 24-^{14}C-deoxycholic acid was studied in the mouse.

3 μC (0.3 mg) of 24-^{14}C-chenodeoxycholic acid were injected into each of 6 mice and another group of 6 mice received each 2 μC (0.3 mg) of 24-^{14}C-deoxycholic acid. 3, 24 and 72 h after injection, 2 animals in each group were sacrificed. The bile was hydrolyzed and chromatographed first on phase system F and then after addition of 5 mg unlabeled cholic acid on phase system C.

Bile collected 3 h after injection of either 24-^{14}C-deoxycholic or 24-^{14}C-chenodeoxycholic acid contained about 1/3 of the isotope in the trihydroxycholanic acid fraction, and the remainder was present as unchanged deoxy-

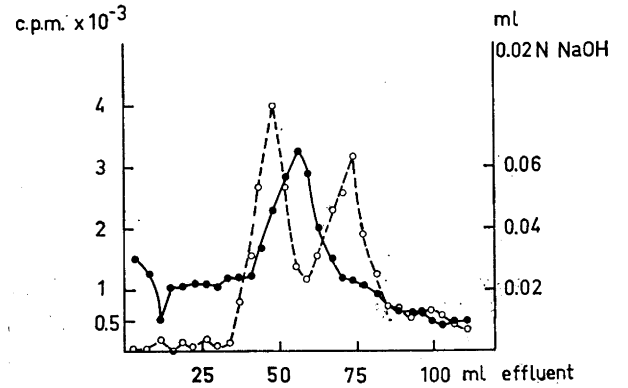

Fig. 3. Chromatogram of trihydroxycholanic acid fraction from bile collected 24 h after injection of 24-^{14}C-chenodeoxycholic acid. Column: 4.5 g Hostalene. Phase system C. Solid line: titration. Broken line: radioactivity.

cholic and chenodeoxycholic acid, respectively. The amount of isotope in the trihydroxycholanic acid band rose to 60—70 % in bile collected 24 h after injection and to 90—100 % after 72h. The trihydroxycholanic acid fractions were rechromatographed on phase system C. Fig. 2 shows the chromatogram of this fraction from animals injected 24 h before sacrifice with 24-^{14}C-deoxycholic acid. The radioactivity coincides with the titration peak of cholic acid. The identity of the isotope with cholic acid was confirmed by isotope dilution.

In the corresponding chromatogram of bile from animals injected with 24-^{14}C-chenodeoxycholic acid, the radioactivity is distributed in two peaks appearing before and after cholic acid, *cf.* Fig. 3. These two radioactive peaks have the same chromatographic mobility as the 6β-hydroxylated acids formed from chenodeoxycholic acid in the rat, 3α,6β,7α- and 3α,6β,7β-trihydroxycholanic acid [10,11].

The results obtained in this investigation indicate, that the bile acid formation and metabolism of the mouse is very similar to that of the rat.

α-Diethylamino-4-amino-2,6-dimethylacetanilide and Some Related Compounds

RICHARD DAHLBOM, CLAËS TEGNÉR and NILS-ERIK WILLMAN

Research Laboratories, AB Astra, Södertälje, Sweden

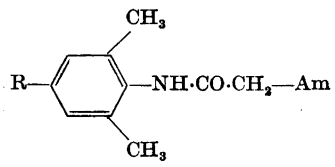
α-Diethylamino-4-amino-2,6-dimethylacetanilide and some alkyl and acyl derivatives have been prepared and tested for local anesthetic activity.

It has been stated by Fosdick and Rapp [1] that the introduction of an amino or a nitro group in the benzene nucleus of α-dialkylaminoacetanilides considerably lowered their anesthetic effect. The same observation was made by Löfgren and Fischer [2] who considered it to be a general rule in the α-dialkylaminoacetanilide series that the anesthetic activity was decreased by substituents with marked inductive or mesomeric effects. Beke, Lempert and and Gyermek [3] found, however, that the introduction of an amino group in the *para* position to the acylamido side chain of an α-diethylamino-2,6-dihalogenoacetanilide enhanced the anesthetic activity. These authors found that in general in this type of compound the introduction of an electron releasing group in the *para* position increased the activity whereas an electron attracting group decreased the activity independently of the mechanism of electron repulsion or attraction (inductive, mesomeric or both). β-Diethylaminobutyranilide and its *p*-amino derivative have been described by Hofstetter and Smith [4] but no definite conclusions can be drawn from their results.

In view of these facts we found it of great interest to study the *p*-amino derivative of α-diethylamino-2,6-dimethylacetanilide (Xylocaine ®). This paper describes the synthesis of this compound (III) and of some of its acyl and alkyl derivatives (IV—VIII). The *p*- amino derivative of α-*n*-propylamino-2,6-dimethylacetanilide (X) was also prepared.

Compound III was synthesised by chloroacetylation of 2,6-dimethyl-4-nitroaniline [5] followed by treatment with diethylamine to give α-diethylamino-4-nitro-2,6-dimethylacetanilide(II) and hydrogenation to the amino compound. This was then acylated with an acyl halide or alkylated by reductive alkylation.

Table 1.



Compound	R	Am	Anesthetic activity [a]	Toxicity [a] LD 50 g/kg

[a] See text for explanation.

In an attempt to obtain compound III *via* either the Hofmann or the Curtius reaction the 4-carbamoyl, 4-hydrazinocarbonyl, and 4-azidocarbonyl derivatives of Xylocaine were prepared and are described in this paper.

The new compounds were tested for local anesthetic action on rabbit cornea, using Xylocaine as standard. Toxicity tests were made by subcutaneous injection on white mice. The results of the biological tests * are summarised in Table 1.

It is evident from the table that both the electron releasing amino group and the electron attracting carbamoyl, hydrazinocarbonyl, and nitro groups decrease the anesthetic effect. Introduction of an acyl or alkyl residue of suitable size in the amino group restored the activity, but these compounds (VII, VIII) were very irritating and the butylamino compound VIII was extremely toxic.

EXPERIMENTAL

α-Chloro-4-nitro-2,6-dimethylacetanilide (I). Chloroacetyl chloride (6.0 ml, 0.079 mole) was added with vigorous stirring to a solution of 4-nitro-2,6-dimethylaniline [5] (12 g, 0.072 mole) and dry pyridine (5.8 ml, 0.072 mole) in benzene (500 ml). The precipitate formed was collected, washed with water and dried. Recrystallisation from benzene gave light yellow crystals (16.3 g, 93 %), m. p. 229–231°. (Found: 49.3; H 4.64; N 11.5. Calc. for $C_{10}H_{11}ClN_2O_3$: C 49.5; H 4.57; N 11.5.)

α-Diethylamino-4-nitro-2,6-dimethylacetanilide (II). The chloroacetyl derivative I (82 g, 0.34 mole) was refluxed for 10 h with diethylamine (87 ml, 0.85 mole) in dry benzene (400 ml). After cooling the reaction mixture was filtered and then extracted

* Acknowledgement is made to Dr. S. Wiedling for performing these tests.

thoroughly with 2 N hydrochloric acid. The extract was made alkaline with 4 N sodium hydroxide, and the precipitated base was collected and recrystallised from ethanol as light yellow crystals (82 g, 86 %), m. p. 98—99°. (Found: C 60.4; H 7.22; N 14.9. Calc. for $C_{14}H_{21}N_3O_3$: C 60.2; H 7.58; N 15.0.)

α-Diethylamino-4-amino-2,6-dimethylacetanilide (III). The nitro compound II (82 g, 0.29 mole), dissolved in ethanol (650 ml), was hydrogenated at 40° and normal pressure over Raney nickel (5 g, moist). The calculated amount of hydrogen was consumed after 2 h. The catalyst was filtered off, and the solvent was evaporated *in vacuo*. The residue was recrystallised from ether, m. p. 98—100° (70 g, 96 %). (Found: C 67.3; H 9.10; N 17.0. Calc. for $C_{14}H_{23}N_3O$: C 67.4; H 9.30; N 16.9.)

α-Diethylamino-4-acetamido-2,6-dimethylacetanilide (IV). A solution of α-diethylamino-4-amino-2,6-dimethylacetanilide (2.5 g, 0.01 mole) in acetone (30 ml), in which potassium carbonate (0.49 g, 0.005 mole) was suspended, was treated with acetyl chloride (0.71 ml, 0.01 mole) added dropwise with stirring. The reaction mixture was refluxed for half an hour and the solvent was then removed under vacuum. The residue was suspended in water and the suspension was made alkaline by the addition of sodium hydroxide. The precipitate was collected and recrystallised from benzene, m. p. 144—145° (2.4 g, 80 %). (Found: C 65.3; H 8.36; N 14.3. Calc. for $C_{16}H_{25}N_3O_2$: C 66.0; H 8.65; N 14.4.)

The following compounds were prepared by essentially the same procedure:

α-Diethylamino-4-propionamido-2,6-dimethylacetanilide (V). M. p. 152—153° (from benzene). Yield 62 %. (Found: C 67.0; H 8.86; N 13.8. Calc. for $C_{17}H_{27}N_3O_2$: C 66.9; H 8.91; N 13.8.)

α-Diethylamino-4-butyramido-2,6-dimethylacetanilide (VI). M. p. 142—143° (from benzene). Yield 62 %. (Found: C 68.0; H 9.09. Calc. for $C_{18}H_{29}N_3O_2$: C 67.7; H 9.15.)

α-Diethylamino-4-hexanoylamino-2,6-dimethylacetanilide (VII). This compound was prepared as described above with the difference that pyridine was used as proton acceptor instead of potassium carbonate. M. p. 118—120° (from benzene-ether). Yield 63 %. (Found: C 69.2; H 9.53; N 12.1. Calc. for $C_{20}H_{33}N_3O_2$: C 69.1; H 9.57; N 12.1.)

*α-Diethylamino-4-*n*-butylamino-2,6-dimethylacetanilide (VIII).* α-Diethylamino-4-amino-2,6-dimethylacetanilide (7.5 g, 0.03 mole) and *n*-butyraldehyde (4.3 g, 0.06 mole) were dissolved in ethanol (75 ml) in which anhydrous sodium acetate (0.3 g) was suspended. The mixture was hydrogenated at normal pressure and room temperature over Raney nickel for 40 min. The reaction mixture was then filtered, concentrated to dryness and the residue was dissolved in N hydrochloric acid. The acid solution was filtered, made alkaline with 4 N sodium hydroxide and the liberated base was extracted with ether. The ethereal solution was dried over sodium sulphate and the reaction product was precipitated as the hydrochloride by the addition of ethereal hydrochloric acid. Repeated recrystallisation from ethanol-benzene (1:1) gave colourless crystals (7.3, 71 %), m. p. 223—225°. The addition of sodium hydroxide to an aqueous solution of the hydrochloride gave the base, m. p. 42—44°. (Found: C 70.7; H 10.0; N 13.7. Calc. for $C_{18}H_{31}N_3O$: C 70.8; H 10.2; N 13.8.)

α-Propylamino-4-nitro-2,6-dimethylacetanilide (IX). The chloroacyl compound I (13 g, 0.054 mole) and *n*-propylamine (16 g, 0.268 mole) were refluxed in benzene solution as described for compound II. The base was crystallised from benzene-petroleum ether (b. p. 40—60°), m. p. 99—100° (11.5 g, 80 %). (Found: C 58.8; H 7.27; N 15.8. Calc. for $C_{13}H_{19}N_3O_3$: C 58.8; H 7.22; N 15.8.)

*α-*n*-Propylamino-4-amino-2,6-dimethylacetanilide (X).* The nitro compound IX (9 g, 0.034 mole) was hydrogenated over Raney nickel as described for compound III. The base was crystallised from benzene-petroleum ether (40—60°), m. p. 111—112° (5.5 g, 69 %). (Found: C 66.5; H 9.06; N 17.6. Calc. for $C_{13}H_{21}N_3O$: C 66.3; H 9.00; N 17.9.)

3,5-Dimethyl-4-nitrobenzamide (XI). An ice-cooled solution of 3,5-dimethyl-4-nitrobenzoyl chloride [6] (12 g, 0.056 mole) in benzene (150 ml) was treated with ammonia gas for 30 min. The temperature of the solution slowly rose to 30°. The solvent was evaporated and the residue was washed with water to remove ammonium chloride formed during the reaction. Recrystallisation from benzene gave colourless crystals, m. p. 169—171° (10.2 g, 93 %). (Found: C 55.4; H 5.36; N 14.3. Calc. for $C_9H_{10}N_2O_3$: C 55.7; H 5.19; N 14.5.)

4-Carbamoyl-2,6-dimethylaniline (XII). The nitro derivative XI (9.7 g, 0.05 mole) was dissolved in ethanol (200 ml) and hydrogenated over Raney nickel at room temperature and a pressure of 90 kg/cm². After 45 min the catalyst was filtered off and the solu-

tion was evaporated to dryness under reduced pressure. The residue was recrystallised from petroleum ether (40—60°)-ethanol, m. p. 181—182° (5.9 g, 72 %). (Found: C 65.9; H 7.43; N 17.0. Calc. for $C_9H_{12}N_2O$: C 65.8; H 7.37; N 17.1.)

α-Chloro-4-carbamoyl-2,6-dimethylacetanilide (XIII). 4-Carbamoyl-2,6-dimethylaniline was chloroacetylated in the same manner as described for compound I. The chloroacetyl derivative was obtained as colourless needles from ethanol, m. p. 241—243°. Yield 84 %. (Found: C 54.9; H 5.54; N 11.7. Calc. for $C_{11}H_{13}ClN_2O_2$: C 54.9; H 5.44; N 11.6.)

α-Diethylamino-4-carbamoyl-2,6-dimethylacetanilide (XIV). The chloroacetyl compound XIII (2.7 g, 0.011 mole) was refluxed with diethylamine (2.2 g, 0.03 mole) in benzene (50 ml) for 8 h at 70°. The base was isolated as described for compound II giving slightly yellow crystals, m. p. 175—177° (2.3 g, 74 %). On recrystallisation (charcoal) from ethanol-benzene (1:1) it gave colourless crystals, m. p. 176—178°. (Found: C 64.9; H 8.51; N 15.1. Calc. for $C_{15}H_{23}N_3O_2$: C 64.9; H 8.36; N 15.2.)

α-Diethylamino-4-hydrazinocarbonyl-2,6-dimethylacetanilide (XV). α-Diethylamino-4-methoxycarbonyl-2,6-dimethylacetanilide [6] (5.0 g, 0.017 mole) was refluxed with hydrazine hydrate (2.1 g, 0.043 mole) in propanol (5 ml) for 8 h and the reaction mixture was allowed to stand at room temperature over night. The hydrazide that separated was then recrystallised from ethanol, m. p. 185—186° (4.7 g, 94 %). (Found: C 61.4; H 8.35; N 19.0. Calc. for $C_{15}H_{24}N_4O_2$: C 61.6; H 8.27; N 19.2.)

α-Diethylamino-4-azidocarbonyl-2,6-dimethylacetanilide (XVI). The hydrazide XV (8.8 g, 0.03 mole) suspended in ice water (40 ml) containing hydrochloric acid (12.5 ml 5 N) was treated with a solution of sodium nitrite (2.2 g, 0.032 mole) in water (5 ml), added dropwise with stirring. The temperature of the reaction mixture was not allowed to rise above 10°. When all the nitrite had been added, the reaction mixture was neutralised by the addition of cold dilute ammonia and was then extracted thoroughly with ether. The extract was washed with water and dried over sodium sulphate. The solvent was removed and the residue was recrystallised from ether, m. p. 89—90° (7.2 g, 76 %). (Found: C 59.4; H 7.18; N 22.8. Calc. for $C_{15}H_{21}N_5O_2$: C 59.4; H 6.98; N 23.1.)

Immunologic Studies of the Old Yellow Enzyme. The Inhibition of Enzyme Activity by Antibodies

STEN KISTNER

Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

The effect of precipitating antibodies against the Old Yellow Enzyme on the activity of the enzyme and its apoprotein has been investigated. Immediately after the addition of antiserum to the enzyme a partial inhibition of the activity occurred, evidently due to the reversible formation of enzyme-antibody complexes. The inhibition increased if enzyme and antiserum were incubated for some time prior to the activity determination. The antibodies and reduced triphosphopyridine nucleotide, which is oxidized by the enzyme, did not compete for the same binding sites on the enzyme molecule. No immediate effect of antiserum on the association reaction between apoprotein and coenzyme could be demonstrated. After incubation, the apoprotein was precipitated by the antibodies. The influence of the complexity of the enzyme-inhibitor system on the kinetics of the inhibition is discussed.

In a previous study [1] precipitating antibodies reacting with crystalline Old Yellow Enzyme (OYE) * were obtained after immunization of rabbits with impure enzyme preparations. The experimental results indicated the existence of specific antibodies against the pure OYE in the antisera. A comparison between the immune reactions of the holoenzyme and the apoprotein, using the agar-gel diffusion technique, showed an identical behaviour of the two proteins. It was concluded that the coenzyme group, FMN, was not involved in the antigenically active part of the enzyme molecule, or in its binding sites to antibody. This, however, is no obstacle for the inhibition of enzyme activity by antibody. Preliminary studies showed that inhibition did occur.

The precipitin reactions had thus provided some information concerning the relationship between active groups of the enzyme and its binding sites to antibody, suggesting that these had different localizations on the enzyme molecule. It then appeared of interest to further investigate the mechanism of inhibition of enzyme activity by antibodies.

* In this paper the following abbreviations are used: OYE = Old Yellow Enzyme; FMN = flavin mononucleotide; TPN = triphosphopyridine nucleotide; TPNH = reduced TPN.

MATERIALS AND METHODS

OYE was prepared by the method of Theorell and Åkeson [2], and the *apoprotein* obtained from the enzyme according to Warburg and Christian [3]. Evaluation of enzyme and apoprotein solutions with regard to purity, concentration, and equivalence was carried out as in the previous investigation [1]. OYE and apoprotein preparations used in the activity studies were of purity 0.54—0.70.

Glucose-6-phosphate (di-sodium salt), *glucose-6-phosphate dehydrogenase (Zwischenferment)*, *FMN*, *TPN* and *TPNH* used in the experiments were all commercial preparations (Sigma Chemical Company). The concentrations of the FMN, TPN and TPNH solutions were determined in a Beckman DU spectrophotometer at 445 mμ[2], 260 mμ[4], and 340 mμ[5], respectively. The activity of the Zwischenferment preparation was stated to be approximately 800 Kornberg units [6] per gram under optimal conditions. The reduction of TPN in the presence of Zwischenferment and excess glucose-6-phosphate in 0.13 M sodium phosphate buffer of pH 7.4 at +37°C was studied spectrophotometrically at 340 mμ[7]. At TPN concentrations from 1 to 20 × 10^{-6} M a fluorimetric technique [8] was employed by measuring the fluorescence of the TPNH formed and comparing it to that of a TPNH standard.

Immunization and testing of the antisera with precipitin reactions were performed as described before [1]. Two rabbits were used in these experiments. Each received 51.5 mg of an enzyme preparation of purity 0.54, mixed into an adjuvant, in the first injection, and 25.8 mg of the same preparation as a boosterdose. Control sera were collected from the same animals before immunization. Antisera used in the inhibition studies reacted with the crystalline enzyme, forming one single precipitin line, when tested with the agar-gel diffusion technique according to Ouchterlony [9]. Also, they showed identical reaction with the OYE and an equivalent apoprotein solution.

Activity studies of the OYE. The activity of the OYE was tested by the conventional Warburg manometric technique [10] in an oxidative system with glucose-6-phosphate, Zwischenferment, and TPN [11]. The activity of the test system is inhibited by the presence of phosphate [12,13] and other ions [14]. Nevertheless, in the present investigation a sodium phosphate buffer of pH 7.4 in a final concentration of 0.13 M was used, since it was considered appropriate to obtain a similar ionic atmosphere as in other OYE-antibody experiments. The reaction mixture also contained 0.2 ml 0.04 M KCN, and 0.2 ml 10 % KOH was added in the central well of each Warburg flask. In the different experiments the concentration of OYE or TPN varied. The addition of Zwischenferment was 1 mg, and glucose-6-phosphate was always added in excess. The volume of the reaction mixture was 3.0—4.0 ml.

In the inhibition studies with antiserum, the OYE was usually added after the serum and other reactants to the main compartment of the reaction vessel, and the reaction was started by the addition of Zwischenferment from the sidearm. When the effect of incubation time was studied, the mixing of the reactants followed a different procedure, which is described in the result section.

The experiments were performed at +37.0°C. The filled reaction vessels were equilibrated with oxygen for 15 min, then with stopcorks closed for another 15 min, before the reactions were started. The activity was expressed as μl oxygen consumed during the first 30 min of the reaction, when the oxygen uptake was constant.

Activity studies of the apoprotein. The activity of the apoprotein could be determined by the method used for the OYE, when FMN was also added to the reaction mixture. In order to estimate the influence of antiserum on the association between apoprotein and FMN, it was necessary to consider its effect on the reaction product OYE. The experiments were arranged in the following way (also illustrated in Table 1). OYE was formed in the presence of antiserum by incubating apoprotein and serum and, later, adding FMN equivalent to the apoprotein. The activity of this enzyme was compared to the activity of that formed in the presence of control serum. To eliminate the effect of the antibodies on the formed OYE, antiserum was also added in the second case. Besides the effect of a different incubation time, which could be controlled in separate experiments, a difference in activity could now be attributed to the fact that in the first case antiserum reacted with the apoprotein before the FMN was bound.

The reaction between apoprotein and FMN was also studied fluorimetrically [15] by adding small aliquots of a FMN solution to an apoprotein solution in 0.13 M sodium

Table 1. A scheme of the method for testing the influence of antiserum on the apoprotein, which later reacted with FMN to form OYE, the activity of which was measured.

phosphate buffer of pH 7.4 and observing the quenching of the fluorescence of the FMN. In the inhibition studies, antiserum was mixed with the apoprotein a few minutes before the FMN was added. The experiments were performed at +37°C.

RESULTS

The activity of the OYE in the Zwischenferment-OYE system. The oxygen consumption of the test system varied with the concentration of the OYE, when all other reactants were added in excess, *i.e.* further addition of anyone of these did not increase the activity. Using an enzyme solution of purity 0.64, 0.10 mg OYE * caused an uptake of 100 μl oxygen per 30 min. The turnover number corresponding to this value is 155, expressed as moles of oxygen per mole of OYE per minute **.

Keeping the OYE concentration constant, the activity varied with the concentration of TPN. Plotting the oxygen consumption against the negative logarithm of the TPN concentration resulted in a sigmoid curve (Fig. 1). Raising the TPN concentration to values higher than those shown in Fig. 1 did not cause increased activity. The same reaction is drawn as a double reciprocal plot [16] in Fig. 2, bottom line. The Michaelis constant determined from such a plot was 0.90×10^{-5} M. Spectrophotometric and fluorimetric studies of the reduction of TPN by the amount of Zwischenferment, used in each Warburg experiment, showed that the rate of reduction exceeded the rate of oxygen uptake in the Zwischenferment-OYE system at all TPN concentrations tested.

* In the following the amounts of OYE are always expressed as the amount of pure OYE, as calculated from the light absorption at 464 mμ.

** The corresponding value, expressed as moles of oxygen per mole of protein-bound FMN, is 77.5. This figure is higher than the previously reported values [3,11]. This may be explained by the fact that purer reagents, especially Zwischenferment, were used in the present investigation. Similar results were obtained with other OYE preparations.

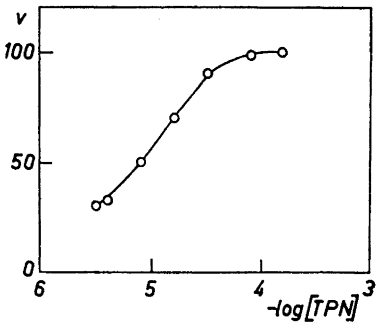

Fig. 1. The activity of 0.10 mg OYE at different concentrations of TPN, expressed as μl O_2 consumed per 30 min (v), and marked along the ordinate. Along the abscissa the negative logarithm of [TPN], expressed in moles per liter, is marked. Each reaction vessel also contained 1.75×10^{-2} M glucose-6-phosphate, KCN, and 0.13 M sodium phosphate buffer, pH 7.4. The reaction was started by adding 1 mg Zwischenferment. The total volume of the reaction mixture was 3.3 ml.

The results of the Warburg experiments were influenced by the ionic conditions. Thus it was found that lowering the phosphate concentration had no effect at high concentrations of TPN, but caused increased enzyme activity when less TPN was used, (*cf.* Refs.[12-13]).

The inhibition of the OYE by antiserum at different concentrations of TPN. The activity of 0.10 mg OYE (same preparation as in the preceding group of experiments) was tested at different TPN concentrations in the presence of antiserum of two different concentrations. The results are summarized in Fig. 2, where they are shown in a double reciprocal plot. The inhibition

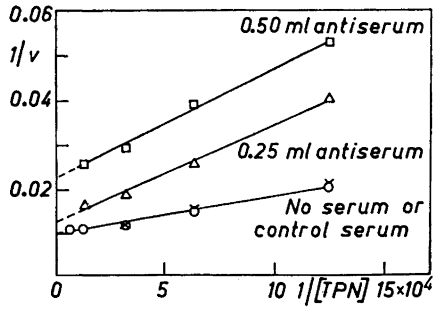

Fig. 2. The inhibition by antiserum of the activity of 0.10 mg OYE at different concentrations of TPN, shown in a Lineweaver-Burk plot. Along the ordinate $1/v$ is marked, along the abscissa 1/TPN. Antiserum and TPN were added before the OYE to the main compartment of the Warburg flask. Otherwise, the experimental conditions were as described under Fig. 1. Bottom curve O — O shows the activity without any serum added, × marks the activity in the presence of 0.50 ml control serum, □ — □ shows the activity in the presence of 0.50 ml antiserum, △ — △ the activity in the presence of 0.25 ml antiserum. Quantitive precipitin reaction between the OYE and antiserum used showed equivalence when 0.17 mg OYE was added to 1.00 ml antiserum.

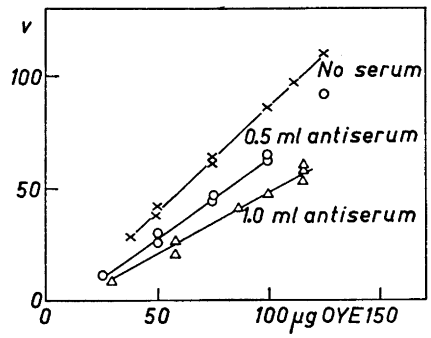

Fig. 3. The inhibition by antiserum at different concentrations of OYE. The activity (v) is marked along the ordinate, the amount of OYE added along the abscissa. Excess TPN was added in each reaction. Other experimental conditions essentially as described under Figs. 1 and 2. The top line × ——— × represents activity studies without the addition of antiserum, the other lines experiments where 0.5 ml (O — O) or 1.0 ml (△ — △) was added in each reaction. In quantitative precipitin reaction between the enzyme and serum used, 0.12 mg OYE was in equilibrium with 1.0 ml antiserum.

caused by the antiserum appeared to be non-competitive [16]. However, prolonging the lines, representing the inhibited and uninhibited reactions, to the left of the ordinate showed that it did not completely follow the kinetics of a non-competitive inhibition, but probably represented some intermediate form.

Control serum was practically without effect. In some experiments a slight inactivation was observed, perhaps due to an alteration of the ionic milieu. As can be seen in Figs. 2 and 5, the effect of control serum was by no means comparable to that of antiserum.

The inhibition of varying concentrations of OYE by antiserum. In these experiments different dilutions of an OYE preparation of purity 0.54 were used. TPN was added in excess. The results are shown in Fig. 3, where the top line shows the reaction without antiserum. The addition of 1 ml of control serum in each experiment gave essentially identical values. The prolongation of the line, representing the activity of the OYE without inhibitor, does not pass through the origin of the coordinate system. This is probably due to the fact that oxygen was released during the experiments, perhaps in connection with the tipping procedure. It might also be that a constant amount of enzyme was blocked by some impurity in the reaction mixture. There was a rectilinear relationship between the amount OYE added and the oxygen consumption. In the presence of antiserum there was a rather constant relative inhibition by the same amount of serum at the different OYE concentrations, at least at the low concentrations tested.

The inhibition by different concentrations of antiserum. The reactants were the same as in the preceding group of experiments, but the amount of OYE was 0.10 mg in each reaction, and the amount of antiserum added varied. Fig. 4 shows the relative activity of the OYE at the different serum concentrations. At the low concentrations the decrease in activity appeared to be pro-

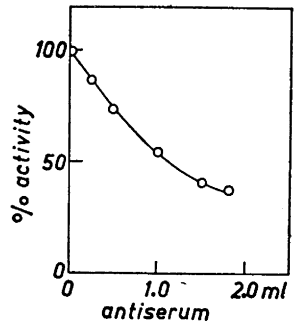

Fig. 4. The activity of 0.10 mg OYE at different concentrations of antiserum. Other experimental conditions were as described under Fig. 3, and the enzyme and antiserum were the same as those, used in the experiments illustrated in that figure. The relative activity is marked along the ordinate, where 100 % represents the activity in the absence of antiserum. (Addition of 1.0 ml control serum gave the same activity.) Along the ordinate the amount of antiserum, used in each experiment, is indicated.

portional to the amount serum added, but further increase in serum concentration was not as effective.

The effect of the incubation time on the inhibition of the OYE by antiserum. In all experiments described OYE was added to the main compartment of the Warburg flask, which contained glucose-6-phosphate, TPN, and antiserum, and Zwischenferment was added 30 min later from the sidearm. A series of experiments were performed in an identical way, except that the antiserum

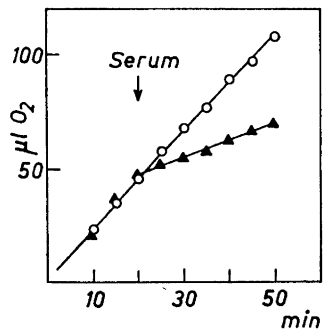

Fig. 5. The influence of antiserum on the "active" enzyme. 0.10 mg OYE was used in each reaction, the TPN concentration was 1.62×10^{-5} M. The reaction was started by the addition of Zwischenferment from one side-arm of the Warburg flask, the experimental conditions being the same as described under Fig. 1. After 20 minutes 0.50 ml serum was added from the other side-arm. Along the ordinate are marked consumed µl of O_2, along the abscissa the time in minutes from the start of the reaction. In the flask where antiserum was added (△ — △) there was a clear effect upon the reaction velocity. The addition of control serum (○ — ○) had some effect, although much less pronounced. Enzyme and antiserum were the same as those used in experiments illustrated in Fig. 2.

was not added at the beginning but kept in a second sidearm of the Warburg flask. After the reaction had been started, and the oxygen uptake studied for 20 min, the serum was added (Fig. 5). The inhibition caused by a given amount of antiserum under these conditions was of the same magnitude as when the antiserum was added at the same time as the TPN.

The inhibition was also studied when the OYE was added to the main compartment of the reaction vessel, containing glucose-6-phosphate, Zwischenferment, and antiserum, and the TPN was added 30 min later from the sidearm. This procedure did not cause any difference in the degree of inhibition except at low TPN concentrations, where a slight increase was noticed.

From these experiments it might appear that the inhibition was practically the same whether the antiserum was allowed to come in contact with the enzyme before, at the same time as, or after the TPN. However, when OYE and antiserum were first incubated for 30 min at + 37°C, then added to the Warburg flask, and the TPN was introduced 30 min later from the sidearm, the inhibiting capacity of the serum increased markedly. The antibodies could thus react with the OYE for 60 min before the appearance of the reduced TPN. Under the experimental conditions described in Fig. 4, 1.0 ml antiserum inhibited the activity of 0.10 mg OYE 45 %. Using the same reactants, but following the preincubation procedure described above, the inhibition was 71 %. This increase could not be due to the mere fact that OYE and antiserum had reacted for 60 min, because in the first case the inhibition was still approximately 45 % when OYE and serum had been mixed for a considerably longer time.

The effect of antiserum on the association reaction between apoprotein and FMN. No influence of the antiserum was observed when this reaction was studied by the manometric technique. These experiments were performed with concentrations of serum which had an immediate effect on an OYE solution, equivalent to the apoprotein used. Incubation with antiserum for a longer period of time, and removal of formed precipitate before the addition of FMN, decreased the activity of the apoprotein solution. When antiserum was added in excess, incubation performed overnight and the precipitate removed, no enzymatic activity remained.

The study of the reaction between apoprotein and FMN, using the fluorimetric technique, encountered certain difficulties, because the presence of serum caused a large background fluorescence, thus making the readings less accurate. Therefore, the experiments were carried out in excess antigen zone, but with serum concentrations that inhibited OYE solutions equivalent to the apoprotein used. The ability of the apoprotein to bind FMN was not impaired by the presence of antiserum. A typical experiment is shown in Table 2. Preincubation of apoprotein and antiserum before the addition of FMN resulted in the appearance of a precipitate, which made the fluorimetric technique unsuitable.

DISCUSSION

The special character of the enzyme-inhibitor system must be considered in interpreting kinetic data of the inhibition of enzyme activity by antibodies. Even if the antibodies possess a very specific affinity to the enzyme molecules,

Table 2. Results of a typical experiment for studying the influence of antiserum on the association reaction between apoprotein and FMN by the fluorimetric technique. The molarity of the FMN bound, and the association reaction velocity constant k_1 were determined as described in Ref.[15]. From the amount FMN bound in the sample of apoprotein, which did not contain serum, it was calculated that 0.19 mg apoprotein was added in each test. 0.17 mg of an equivalent OYE solution was needed to reach the equivalence zone in quantitative precipitin reaction with 1.0 ml of the antiserum used.

Reaction mixture to which FMN was added.	FMN coupled, M.	Association velocity constant, k_1, $M^{-1} \times sec^{-1}$.
3.0 ml apoprotein 0.5 ml buffer	1.058×10^{-6}	16.8×10^4
3.0 ml apoprotein 0.5 ml control serum	1.160×10^{-6}	17.6×10^4
3.0 ml apoprotein 0.5 ml antiserum	1.137×10^{-6}	15.9×10^4

there is no simple relationship in their reaction with the antigen. During the immunization antibodies of different reactivity may develop [17]. The inhibition may depend upon the number of antibody molecules bound to each enzyme molecule [18]. The enzyme-antibody interaction changes considerably with the time, and thus it is of importance at which stage in the reaction the enzyme is brought to act, that is to combine with the substrate [19,20]. The inhibition may be influenced by the fact that the inhibitor molecules are of equal magnitude as, or often larger than the enzyme [21]. Such characteristics emphasize the difficulties in arriving at definite conclusions from inhibition studies of enzyme-antibody reactions.

The OYE preparations used in the activity studies were not pure, and the antisera were obtained after immunization with impure OYE. Still it is reasonable to believe that the enzyme reacted with specific antibodies in the sera. Evidence in favour of this has been presented in a previous paper [1], and the antisera used in the activity studies reacted in an identical way when tested in precipitin reactions. The action of antiserum on Zwischenferment, which is also a yeast enzyme, was tested by measuring spectrophotometrically the ability of this enzyme to reduce TPN, and no effect was found.

In the system for testing the activity of the OYE this enzyme acts as an oxidant to the TPNH formed, when glucose-6-phosphate is oxidized in the presence of Zwischenferment and TPN. Observations have been made of the formation of a complex between the OYE and the reduced pyridine nucleotide [22,23], and it appeared likely that such a complex was formed in the present experiments. Confirmatory evidence seemed to be obtained, when the activity of the OYE was tested with different concentrations of TPN in the reaction mixture. Plotting the activity against the negative logarithm of the TPN

concentration resulted in a sigmoid curve (Fig. 1), similar to the dissociation curve typical of enzyme-substrate interactions [24]. This curve evidently described the activity of the OYE, since the activity of the Zwischenferment alone exceeded that of the Zwischenferment-OYE system. Also, further additions of TPN did not cause increased oxygen uptake when all reactants, except OYE, were in excess.

The inhibitory effect of antiserum on the OYE was immediate. From the experiments, illustrated in Fig. 3, where a constant amount of antiserum caused the same relative inhibition at different concentrations of OYE in the test system, it appeared that the enzyme-antibody association was reversible under the existing experimental conditions [25]. Also, the curvilinear relationship obtained, when the relative activity of a constant amount of OYE at different concentrations of antiserum was plotted against the amount antiserum added (Fig. 4), indicated a dissociation of the antigen-antibody complexes. When the OYE and antiserum were allowed to react for a long enough time before the enzymatic activity was tested, the inhibitory capacity of the antiserum increased. Since this occurred, when no changes were made in the experimental conditions except the preincubation of enzyme and serum, the effect must depend upon a firmer association between OYE and antibodies. Allowing the OYE to react with the TPNH seemed to protect the enzyme from the action of the antibodies. This observation is similar to the reduction of the inhibition, which has been found to occur in other enzyme-antibody systems, when the enzyme is incubated with the antiserum in the presence of substrate or coenzyme (see Ref.[21]), and which has been ascribed to the fact that the aggregation of enzyme-antibody complexes is prevented [19].

The studies of the inhibition with different concentrations of TPN in the reaction did not quite clarify, whether the antibodies and the pyridine nucleotide competed for the same binding sites. Since the enzyme-antibody reaction was reversible under the conditions of these experiments, and the K_M value in the OYE—TPNH system indicated a high affinity between enzyme and TPNH [24], the activity of the enzyme would have been completely dependent on the TPN concentration if the binding sites were identical. Therefore it seems more reasonable that the inhibition was non-competitive. That it nevertheless showed some trends of competitiveness could be due to the fact that the large inhibitor molecules caused a steric hindrance for the TPNH to reach its binding sites [21].

It appeared that concentrations of antiserum, having an immediately noticeable effect on the activity of the OYE, did not cause a corresponding inhibition of the ability of equivalent apoprotein solutions to bind FMN. In these experiments apoprotein and antiserum were mixed for a time, long enough to allow interaction, before the FMN was added. The affinity of the apoprotein to FMN is very high [15], and thus it is understandable that the FMN might have displaced the antibodies from the apoprotein, before the activity was tested in the Warburg experiments. However, the use of the fluorimetric technique, allowing direct registration of the association reaction and determination of the velocity constant, did not reveal any influence of the antiserum on the ability of the apoprotein to bind FMN, although this could only be tested at low serum concentrations. Such an effect has been demonstrated

after chemical modification of the apoprotein [26]. On the other hand, the apoprotein was precipitated by the antiserum. These results suggest that the antibodies were bound to other sites on the apoprotein molecule than the FMN, and thus they support the findings of previous precipitin reactions.

Besides the blocking of catalytic sites on the OYE, other factors might have contributed to explain the observed inhibition. The binding of large antibody molecules to the OYE must undoubtedly have altered the physical properties of the enzyme. It may also be that the association caused intramolecular changes in the enzyme, impairing its ability to function as an electron transmittor.

A Spectroscopic Study of Molecular Interaction with Phosphoryl Chloride

PER-OLOF KINELL, INGVAR LINDQVIST and MARGARETA ZACKRISSON

Institute of Physical Chemistry and Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Raman and infrared spectra of mixtures between $POCl_3$ and a number of other molecules have been studied. Two types of interaction have been found, one tentatively described as dipole-dipole, the other as electron-pair acceptor-donor interaction.

The phosphoryl (P—O) bond frequency in addition compounds with $POCl_3$ was first studied by Sheldon and Tyree[1,2] who correlated the decrease in frequency with the donor function of oxygen in the adduct formation with different acceptor molecules. In some cases, *e.g.* with $SnCl_4$ in $SnCl_4 \cdot 2POCl_3$, they obtained more than one infrared band in the expected phosphoryl frequency range, and explained this fact as due to the co-existence of two types of $POCl_3$, one bonded and one free. A recent crystal structure determination [3] proves, however, that both $POCl_3$ molecules in the solid compound are bonded in a very similar way, and another explanation must be sought. We therefore decided to make a more complete spectroscopic study of the molecular interaction with $POCl_3$, going from very weak to very strong interaction, covering a wider spectral range, using infrared and Raman spectroscopy. The present paper mainly deals with weak interaction.

EXPERIMENTAL

Chemicals. $POCl_3$, $AsCl_3$ and C_6H_5COCl were purified by distillation. (B. p. +105°, +129°, and +197°C.) CCl_4, CS_2, $CHCl_3$ and 1,2-$C_2H_4Cl_2$ were purified by fractional distillation (76°—77°, 46.5°, 61°—63° and 83°—84°C). $SnCl_4$ and $SbCl_5$ were purified according to Dodd and Robinson [4]. $SbCl_3$ was purified by sublimation.

Spectroscopic measurements. The Raman spectra, excited by Hg 4 358 Å, were photographed using an E 612 Hilger spectrograph equipped with two glass prisms and a camera having an aperture of f/5.7 (Exposure times 1—2 h). The illuminating system consisted of a Toronto type helical mercury lamp. A saturated solution of sodium nitrite in water was used as a filter. The temperature was 20°C. The spectroscopic arrangement is de-

scribed by Kinell [5]. Normally a Raman tube containing 20 ml was used. When the amount of solution was small, a 5 ml tube could be utilized. The tubes were filled very carefully in order to avoid as far as possible any contact between the liquids and moisture. For that purpose each tube had a ground joint by means of which it could be attached to the container holding the liquids.

The Ilford Zenith super sensitive plates used were processed with Kodak D-76 fine grain developer. The positions of the Raman lines were determined using Hartmann's disperson formula. As reference lines Hg 4 077, 4 339 and 4 916 Å were selected. Measurements were as far as possible made on several exposures for the same solution. The accuracy of the wave numbers is $\pm 1-3$ cm^{-1}, depending upon the shape of the line. In a few cases the lines were too weak to be measured in the comparator. The positions of such lines have been estimated approximately and are especially marked (with circles) in the figures. No measurements of the band width and the intensities were made. The spectral slit width was $5-10$ cm^{-1}.

The infrared spectra were recorded on a Perkin-Elmer Model 21 Spectrophotometer equipped with NaCl, KBr and CsBr prisms (in the Institute of Biochemistry). The spectra were run with the solutions in thin layers between two KBr plates. The spectral slit width was 3 cm^{-1}.

RAMAN SPECTRA OF $POCl_3$ MIXED WITH SOME OTHER MOLECULES

The following molecules, in order of increasing dipole moment and dielectric constant, have been studied: $CS_2 = CCl_4 < CHCl_3 < 1,2\text{-}C_2H_4Cl_2 < AsCl_3 = C_5H_5N < C_6H_5COCl < SbCl_3$. $POCl_3$ would come between C_5H_5N and C_6H_5COCl in this sequence and the spectrum of pure liquid $POCl_3$ has been placed accordingly in Fig. 1 showing the $POCl_3$ frequencies in the different mixtures. (A few lines could not be measured because of overlap with the spectrum of the other molecules.)

The very interesting molecules $SO(CH_3)_2$, $SeOCl_2$, CH_3CN and C_6H_5CN were also tried but gave complicating chemical reactions with $POCl_3$.

A brief summary and discussion of the results is given in the following.

1. The shifts in the four lowest frequencies are very small. The largest shift is obtained with $SbCl_3$ for the symmetrical P-Cl bond vibration frequency, 486 cm^{-1}, (+ 7 cm^{-1}).

2. The antisymmetrical P-Cl bond vibration frequency, 584 cm^{-1}, is shifted towards higher frequencies with all solvents except C_5H_5N, the largest shifts being found with $AsCl_3$ (13 cm^{-1}) and $SbCl_3$ (20 cm^{-1}).

3. The symmetrical phosphoryl bond vibration frequency, 1 297 cm^{-1}, shows both positive and negative shifts. The largest positive shift is obtained with the nonpolar CCl_4 (7 cm^{-1}), the largest negative shifts with $AsCl_3$ (13 cm^{-1}) and with $SbCl_3$ (29 cm^{-1}).

4. There is obviously no direct correlation between dipole moment and shift. It has been pointed out, however, that a dipole-dipole interaction depends also upon the charge distribution in the molecules [6].

5. Fig. 1 shows that $AsCl_3$ and $SbCl_3$ are exceptional compared with the other molecules. These two molecules differ in two respects from the others. Their molecular shapes offer good opportunities for approach to the center of the positive charge in the dipole, their charge distributions are thus favourable for dipole-dipole interaction. They are, however, also the only possible acceptor molecules (Lewis acids) among the compounds studied.

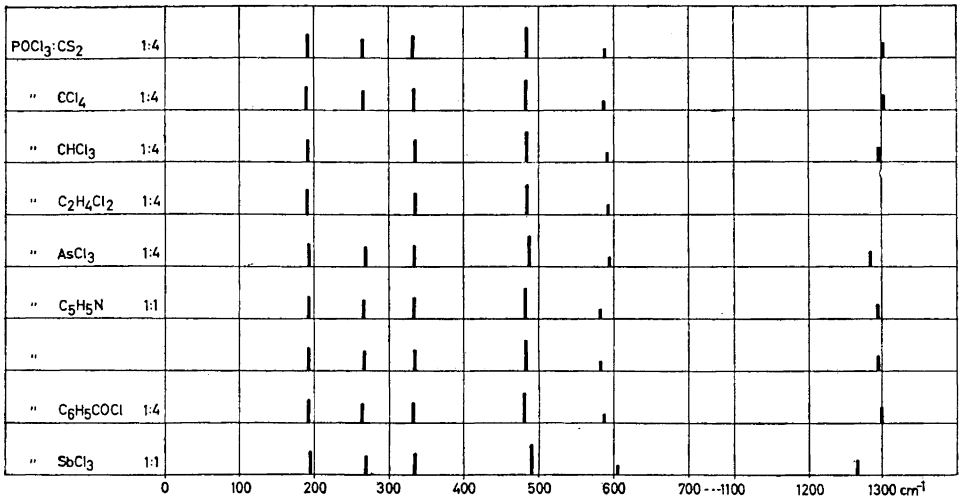

Fig. 1. Raman spectra of $POCl_3$ in different mixtures.

These two attributes are thus inseparable in this case. This is not the rule, however, as most Lewis acids are nonpolar molecules like $SnCl_4$ and $SbCl_5$.

6. The increase in the antisymmetrical P—Cl bond frequency has an analogy in the increases of the antisymmetrical C—C chain vibration frequency obtained by compound formation between acetone and acceptor molecules like BF_3 (52 cm^{-1}) or $AlBr_3$ (40 cm^{-1}) [7,8].

7. The large decreases in the symmetrical phosphoryl bond frequency by adduct formation were first measured by Sheldon and Tyree [1,2], who also found large negative shifts of the Se—O bond frequency in $TiCl_4 \cdot 2SeOCl_2$. Similar effects on the carbonyl bond frequency in ketones have also been reported [7,9]. In all these cases the shift has been caused by interaction with Lewis acids. This does not exclude the possibility, however, that the same effect can be obtained by favourable dipole-dipole interaction.

8. The spectrum with C_5H_5N is of particular interest because of the chloride ion transfer processes caused by C_5H_5N in $POCl_3$. Gutmann and Baaz [10] have recently studied the conductances in the similar system $(C_2H_5)_3N$-$POCl_3$ and conclude that the following equilibria exist:

$$POCl_3 + Et_3N = [POCl_2(Et_3N)^+Cl^-] \text{ (ion pair)} = POCl_2(Et_3N)^+ + Cl^-$$

The corresponding K values are 2.3×10^{-2} and 1.2×10^{-3}, and it is thus probable that the effect on the spectrum of $POCl_3$ should be small. (The ionic transfer process can in this case not be preceded by a compound formation $POCl_3 \cdot Et_3N$ because $POCl_3$ has no acceptor properties. The conditions are quite different with $SeOCl_2$ or $AsCl_3$ and amines [11].) The small shifts obtained with C_5H_5N in this case are thus easy to understand. The possibility cannot

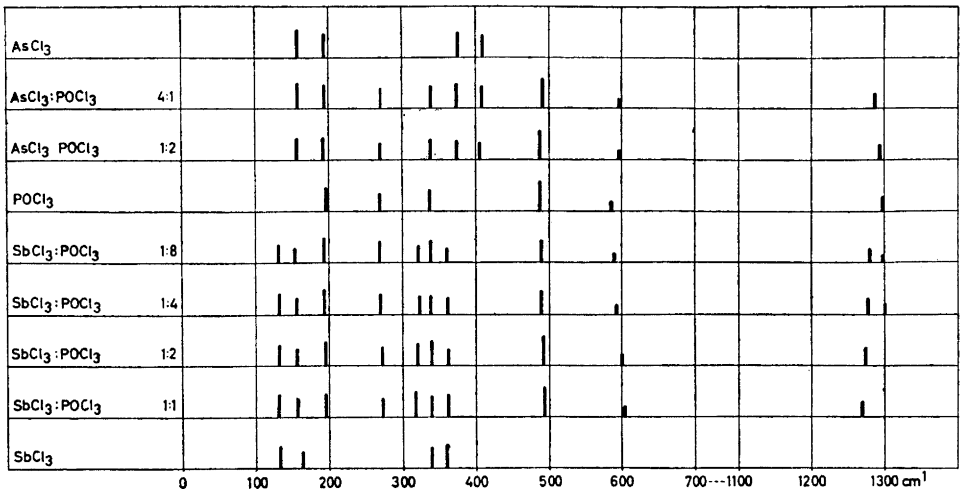

Fig. 2. Raman spectra of the systems $AsCl_3$—$POCl_3$ and $SbCl_3$—$POCl_3$.

be excluded, however, that the exceptional influence of C_5H_5N on the antisymmetrical P-Cl bond vibration (decrease in frequency instead of increase as obtained with all the other molecules) is associated with a tendency to loosen the P-Cl bond.

RAMAN SPECTRA OF THE SYSTEMS $AsCl_3$-$POCl_3$ AND $SbCl_3$-$POCl_3$

The Raman spectra of solutions with varying mole ratios $AsCl_3$:$POCl_3$ and $SbCl_3$:$POCl_3$ are given in Fig. 2. A brief summary and discussion of the results follows.

1. In both systems a *continuous* change in band positions is found.

2. This change is not connected with any obvious tendency to band broadening. The band profile of the antisymmetrical P-Cl band is slightly altered, however.

3. The continuous change would be expected for a dipole-dipole interaction without formation of stable molecules. The same effect has been reported for the system H_2O_2—$C_4H_8O_2$ where H_2O_2 has an exceptional influence upon the dioxane spectrum (over a range of 19 cm^{-1}). The authors [12] comment: "Die Wechselwirkung muss also dynamischer Art sein und von der ganzen Umgebung ausgehen".

4. The $AsCl_3$ spectrum is almost unchanged in the mixtures.

5. The $SbCl_3$ spectrum is changed more in the concentration range studied but not appreciably. The spectrum of liquid $SbCl_3$ (from Kohlrausch, *Hand- und Jahrbuch der chemischen Physik*, 9:IV, Leipzig 1943) is taken at + 250°C and cannot safely be used for comparisons.

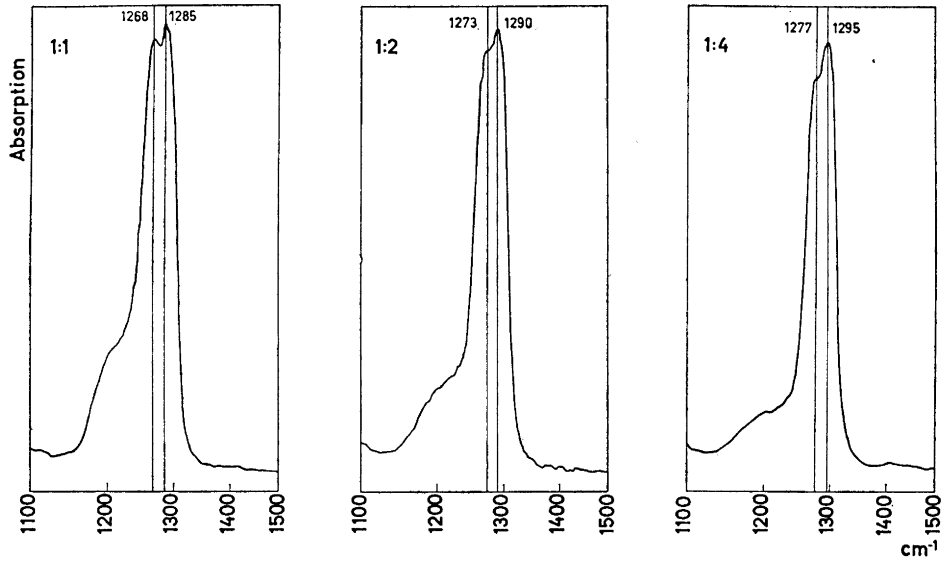

Fig. 3. Infrared spectra, in the phosphoryl band region, of the system $SbCl_3$—$POCl_3$. The shoulder near 1 200 cm^{-1} is a $POCl_3$ overtone band.

6. The typical Lewis acids usually change their structures by adduct formation with donor molecules like $POCl_3$ (*cf.* the structure of $SbCl_5 \cdot POCl_3$[13]). As a result the spectrum of the acceptor molecule disappears by the adduct formation.

7. In these cases therefore everything indicates dipole-dipole interaction. It would be very interesting to know the structure of the compound $AsCl_3 \cdot POCl_3$ [11] (M.p. —24°C) to find out whether the formation of the solid compound is also due to electrostatic interaction.

8. The only point of evidence indicating the existence of free and bonded molecules is the double phosphoryl band obtained with excess of $POCl_3$. One band is shifted towards lower frequencies, the other is almost fixed. The latter successively disappears with increasing concentration of $SbCl_3$ and cannot be seen at the composition $SbCl_3 \cdot 2POCl_3$. This evidence will be discussed in the next section.

INFRARED SPECTRA OF THE SYSTEM $SbCl_3$-$POCl_3$

Infrared spectra have been taken of all the systems discussed in the preceding section. They have confirmed the Raman spectroscopic results in all cases but one, and are therefore not reproduced here. The exception is the disappearance of the double phosphoryl band at mole ratios $POCl_3$:$SbCl_3$ smaller than 2:1 (Fig. 3). The trend in the intensity ratio is the same but the intensity of the high frequency band is not reduced as much as in the Raman spectrum. It is actually as strong as the low frequency band even at concentrations where

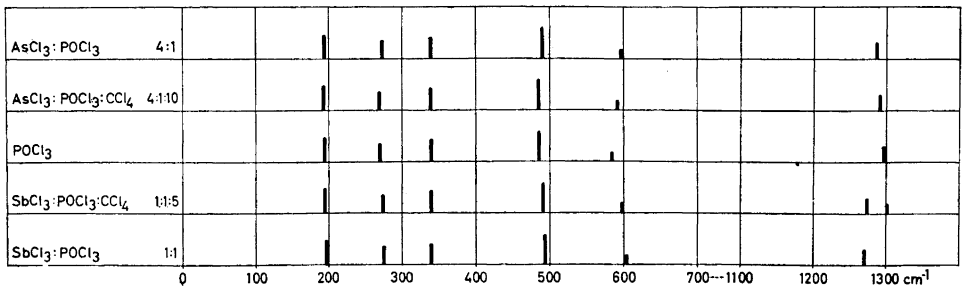

Fig. 4. Raman spectra of solutions in CCl_4.

it has disappeared in the Raman spectrum. This indicates that the disappearance in the latter at a composition $SbCl_3 \cdot 2POCl_3$ is purely incidental and is unrelated to compound formation. This result shows the importance of parallel work with Raman and infrared spectra. A study of the phosphoryl band only in the Raman spectrum would in this case have led to a completely erroneous interpretation.

RAMAN SPECTRA OF MIXTURES $POCl_3$-$AsCl_3$-CCl_4 AND $POCl_3$-$SbCl_3$-CCl_4

The Raman spectra of the solutions $POCl_3$:$AsCl_3$:CCl_4 = 1:4:10 and $POCl_3$:$SbCl_3$:CCl_4 = 1:1:5 have been studied. The $POCl_3$ bands are shown in Fig. 4 compared with the CCl_4-free mixtures.

The spectra indicate a diluting effect of CCl_4, reducing the shifts caused by $AsCl_3$ and $SbCl_3$ in agreement with the interpretation as dipole-dipole interaction.

RAMAN SPECTRA OF SOLUTIONS OF STRONG LEWIS ACIDS IN $POCl_3$

A preliminary study has been made of solutions of strong acceptor molecules in $POCl_3$ ($SbCl_5$:$POCl_3$ = 1:20 and $SnCl_4$:$POCl_3$ = 1:9). The results are shown in Fig. 5 together with the spectra of $SbCl_5$ (from Kohlrausch, *Hand- und Jahrbuch der chemischen Physik*, 9:IV, Leipzig 1943), $POCl_3$ and $SnCl_4$. A summary and discussion is given in the following.

1. The spectra of $SnCl_4$ and $SbCl_5$ have disappeared; as expected for strong Lewis acids.

2. The spectrum of free $POCl_3$ (in excess) is found in both cases as expected for strong compound formation of acceptor-donor type (in contrast to the continuous effect by electrostatic interaction).

3. New bands are formed. These have not been analysed but the knowledge of the exact crystal structure [13] has opened possibilities for a complete analysis.

4. Some of the free $POCl_3$ bands may also belong to the spectra of the adduct molecules $SbCl_5 \cdot POCl_3$ and $SnCl_4 \cdot 2POCl_3$ formed. Infrared spectra

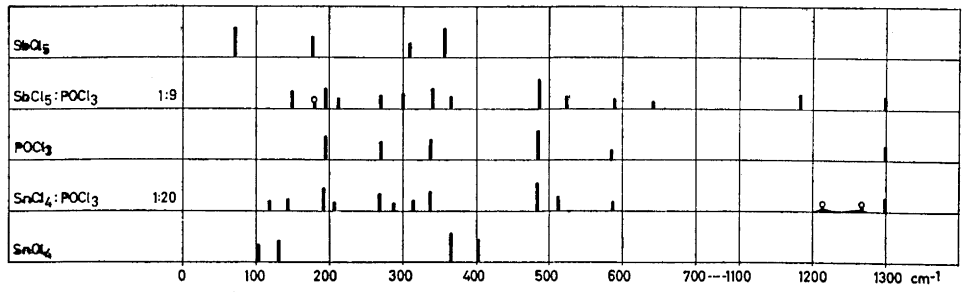

Fig. 5. Raman spectra of solutions of $SbCl_5$ and $SnCl_4$ in $POCl_3$.

of the solid compounds actually show that the phosphoryl band near 1 297 cm^{-1} is also present in the adduct spectra.

5. The phosphoryl band region thus shows two bands with $SbCl_5$ (the maximum shift is 117 cm^{-1}), and three bands with $SnCl_4$ (the maximum shift is 85 cm^{-1}).

6. Similar large negative shifts with strong Lewis acids have been mentioned earlier in this paper [1,2,7,9] and the splitting has also been found earlier. Examples of such splitting of carbonyl bands has been given by Susz and Chelandon [7,9]. It has also been reported for the Se—O band [2] in, *e.g.*, $SnCl_4 \cdot 2SeOCl_2$.

7. The opinion that the splitting is due to the existence of two types of donor molecules in the adduct has already been rejected in the introduction to this paper. We have no alternative explanation to offer at present but think that the common occurrence of the splitting should be emphasized.

8. A complicating fact is that the phosphoryl band splitting has also been found in some pure phosphoryl compounds [14]. In those cases the variation is largest in the high-frequency band which has therefore been considered as the typical phosphoryl band.

9. The magnitude of the shift for the lowest frequency phosphoryl band (obtained by the splitting by adduct formation) seems to be a rough measure of the acceptor strength of the acceptor molecule. An interesting survey of the shifts in the carbonyl band has been published recently [9]. If this relation has general validity a very simple method of determining relative acceptor strengths is available. It can, however, only be used if the acceptor molecules to be compared are under very similar conditions.

10. The donor strength of the oxygen atom is not reflected directly in the shifts. The weak donor molecule $SOCl_2$ does not show any shift [2], but $POCl_3$ gives a larger shift than POR_3[1] with the same acceptor molecule although the latter without doubt is a stronger donor (*cf.* the recent assessment of the relative donor strengths of $POCl_3$ and $PO(CH_3)_3$[15]).

CONCLUDING DISCUSSION

The preceding discussions can be summarized as follows: Negative shifts and splitting of the phosphoryl band can be caused by dipole-dipole interaction as well as by Lewis acid-base reactions. The former will give rise to a general medium effect (the shifts vary continuously with the mole ratios). The latter will lead to formation of kinetically stable adduct molecules (spectra of free and bonded molecules). The spectrum of the acceptor molecule will disappear if its structure is changed by the adduct formation. (This is not a necessary condition with molecules like $HgCl_2$).

If this description is correct (it can only be considered as a tentative suggestion) $AsCl_3$ and $SbCl_3$ give favourable dipole-dipole interaction with $POCl_3$ (in contrast to C_6H_5COCl), while $SnCl_4$ and $SbCl_5$ give adduct formation by acceptor-donor reactions. It is possible that there exist intermediate cases. We have here deliberately not discussed the nature of the acceptor-donor bond, pending the accumulation of more structural informations, but we intend to study these problems further by spectroscopic and X-ray methods.

A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged.
Finally we wish to thank Professor S. Claesson, Professor G. Hägg and Professor A. Tiselius for all facilities put at our disposal and Mr. S. Bergvall for valuable assistance.

Reappearance of Metachromasia after Digestion of Hyaluronate with Hyaluronidase

L. HANSEN, B. HEGNER and C. E. JENSEN

Københavns Universitets Fysisk-Kemiske Institut, Copenhagen, Denmark

The present investigation supports the recent theories on the metachromatic reaction. It is shown that the metachromatic colour can reappear after digestion of hyaluronate with testicular hyaluronidase. A difference exists between the absorption maxima of hyaluronate and heparin.

It has long been recognized that certain macromolecular substances present in animal tissues, *e.g.* acidic mucopolysaccharides, couple with basic dyes such as azure A, thionine and toluidine blue, forming coloured complexes. The term metachromasia is used to describe the phenomenon by which these tissue structures are stained by the dye solutions to a colour which is different from the dye solutions, the colours of the dye solution and of the stained tissue or solution being called orthochromatic and metachromatic, respectively. The metachromatic reaction combined with enzymic investigations is widely used for the detection and differentiation of substances such as hyaluronic acid, chrondroitin sulphuric acids and heparins.

MATERIAL AND EXPERIMENTS

The samples of the hyaluronate employed were prepared according to Jensen [1]. The preparation of toluidine blue used was a commercial one ("Toluidinblau nach Hoyer", Riedel de Haën A.-G., Seelze, Hannover, Germany). In some experiments this commercial product was recrystallized from water. The employed preparations of hyaluronidase were commercial Invasin "Lundbeck", Copenhagen, and "Penetrase" which was kindly supplied by Dr. Jørgen Ploug, Leo Pharmaceutical Products, Copenhagen. The sample of chondroitin sulphate used was prepared by Boström, Institute of Medical Chemistry, University of Uppsala, Sweden. The used sample of heparin was kindly placed at our disposal by Novo Terapeutisk Laboratorium, Copenhagen. All experiments were performed at pH 6.5.

The absorption of aqueous solutions of toluidine blue was measured in a Beckman Spectrophotometer in the interval of 200—800 mμ, the concentration of toluidine blue being 0.01 % (w/v). In Fig. 1 curve B shows two absorption

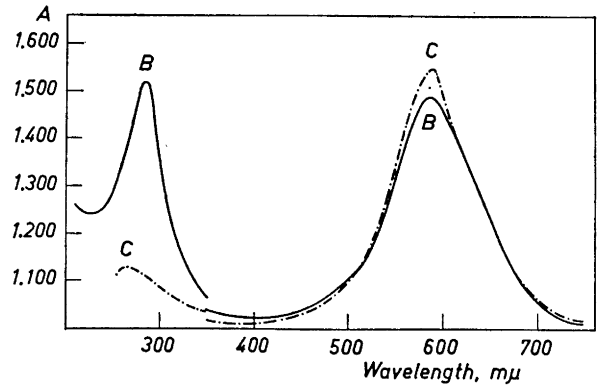

Fig. 1. Absorption spectra of commercial toluidine blue (B) and recrystallized toluidine blue (C). Ordinates are the absorbance $A = \log_{10} (1/T)$, where $T = I/I_0$. Length of cuvette 1 cm. Concentration of toluidine blue 0.1 g/l. Abscissae are the wavelengths in mμ.

maxima at 285 mμ and 590 mμ, respectively. The curve C (stippled) which is for recrystallized toluidine blue, likewise shows two maxima, at 265 and 590 mμ, respectively. It is seen that the first maximum has shifted towards a shorter wave-length after recrystallization.

Fig. 2 shows the absorption of a solution which was 0.03 % with regard to hyaluronate and 0.01 % with regard to toluidine blue, the solvent being a phosphate buffer (pH = 6.5). It is seen that the hyaluronate-toluidine blue complex has absorption maxima at 284 and 555 mμ.

It was found that the chondroitin sulphate-toluidine blue complex shows the same maxima as does hyaluronate-toluidine blue, whereas the heparin-toluidine blue complex shows a maximum at 540 mμ as seen in Fig. 3.

23	0.30	26.4	360	575	Penetrase
24	0.30	4.4	2	575	Penetrase
25	0.30	4.4	150	580	Penetrase
26	0.30	4.4	240	585	Penetrase
27	0.30	4.4	1 080	585	Penetrase

In the following experiments the hyaluronate solutions were incubated with testicular hyaluronidase. At different times aliquots were withdrawn and toluidine blue was added, whereafter the absorptions were recorded in order to follow the degradation of hyaluronate. Table 1 gives the results of these experiments. It is noted that toluidine blue has been added in all experiments, and that toluidine blue plus enzyme and buffer did not change the maximum of toluidine after 19 h.

It is evident from experiments 1,2,4 and 18—27 that the hyaluronate has been degraded by the hyaluronidase as the absorption maxima have shifted towards the maximum of pure toluidine blue during the incubation dependent upon concentration of enzyme and time. It is seen from the table that a difference exists between the two enzyme preparations. While penetrase always degrades hyalyronate at a certain (high) concentration, the invasin preparation causes only a temporary degradation (judged from the metachromatic reaction) as the absorption maximum starts moving towards the toluidine blue maximum, but later on the maximum shifts back to the hyaluronate-

toluidine blue complex maximum. (Expts. 11—17). Further it was noted that the solutions became more viscous from the time at which the maximum moved from 585 to 563 (Expts 1, 2 and 3 and 5,6 and 7 and 12—16 and 17).

DISCUSSION

According to recent theories (see, *e.g.*, McManus [2], Kinzel [3] and Larsen [4]) the reactions making the basis of the metachromatic reaction are the following: The positively charged dye-stuff ions are adsorbed to the negatively charged polyelectrolyte ions. Now, if the polyelectrolyte molecule has a sufficient size and electric surface charge density (Sylvén [5]) the dye ions will aggregate longitudinally, which means that a polymerization of the dye occurs. According to Michaelis and Granick [6] and others [7] the metachromatic colour of the dye depends on a polymerization of the dye itself.

The facts reported in the present paper seem to support the above theory. When a sample of high-molecular hyaluronate ($\overline{M}_{n\ (reduced)}$ = about 8×10^5) was used the metachromatic reaction was strong. With decreasing degree of polymerization caused by enzymic degradation the staining property or toluidine blue decreased markedly.

However, in some experiments the metachromatic colour reappeared after some time, and at the same time the viscosity of the solutions increased markedly. These observations suggest that a restructuration of hyaluronate has taken place resulting in a re-polymerization of the toluidine blue molecules.

Note added in proof: The observation that the viscosity of a solution of partly degraded hyaluronate can increase with time seems to agree with the results obtained by S. Zamenhof and E. Chargoff (*J. Biol. Chem.* **186** (1950) 207). They showed that considerably degraded DNA may have a tendency to repolymerize, attaining high viscosity. In contrast to this, undegraded DNA retains its η_{sp} constant during several hours.

We are indebted to Professor J. A. Christiansen, head of this institute, for his interest in this investigation. One of us (C.E.J.) wishes to thank Københavns Universitet for financial support.

A Phosphopeptide Isolated from Bovine α-Casein after Tryptic Hydrolysis

HANS BENNICH, BENGT JOHANSSON and RAGNAR ÖSTERBERG

Department of Medical Biochemistry, University of Gothenburg, Sweden

Bovine α-casein has been subjected to a short-time tryptic hydrolysis. From the mixture of phosphopeptides in the hydrolysate an apparently homogeneous phosphopeptide has been isolated through zone electrophoresis. From the amino acid composition and phosphorus analyses the empirical formula is suggested to be: Asp_3, Glu_9, Gly_1, Ala_2, Val_2, $Ileu_3$, Met_2, Ser_5, Thr_1, Pro_1, Lys_{1-2}, $(PO_4)_6$. The N-terminal position is occupied by an aspartic acid residue and a lysine residue is probably in the C-terminal position.

Enzymic degradation of cow's casein with pepsin, followed by pancreatic enzymes, yields a mixture of phosphorus-containing peptides [1,2], which has been prepared and studied by several authors; the literature has been reviewed by Mellander [3] and Perlmann [4]. Attempts to purify such a mixture at this institute resulted in the isolation of a phosphopeptide consisting of eleven amino acids and three phosphate groups [5].

Peterson *et al.*[6] diminished the number of possible phosphopeptides resulting from hydrolysis of casein by considering the inhomogeneity of this protein and by using one specific enzyme for the degradation. These authors thus found that only one phosphopeptide could be recovered after treatment of β-casein with trypsin. On the other hand, they found that tryptic digestion of α-casein furnished at least three different phosphopeptides. Later, Pantlitschko and Gründig [7,8] reported the preparation of "phosphopeptones" from α- and β-casein.

As part of a study of the structure and metabolic significance [9,10] of phosphopeptides from bovine casein this paper describes the preparation and main composition of an apparently homogeneous phosphopeptide from α-casein. The isolation of this phosphopeptide was undertaken through zone electrophoresis of a crude phosphopeptide fraction, obtained from a short-time tryptic hydrolysate of the α-casein.

MATERIAL

α-Casein was prepared from bovine casein according to the method described by Hipp *et al.*[11] The product obtained was homogeneous in moving boundary electrophoresis (0.1 M veronal buffer, pH 8.7). The preparation showed an atomic ratio N/P of 32.9.

The trypsin was a commercial preparation (Armour, twice crystallized, containing 50 % $MgSO_4$).

METHODS

Tryptic hydrolysis and preparation of a crude phosphopeptide fraction. 30 g of α-casein were suspended in 1 litre of distilled water, and the pH adjusted to 8.0 by addition of N NaOH. The solution was incubated in a water bath at 25°. Two hundred mg of trypsin, dissolved in a small volume of distilled water, were added to the substrate. The hydrolysis was carried out at a constant pH recorded by a pH-meter, titrator TTT 1a (Radiometer, Copenhagen). The course of hydrolysis was followed by measuring the amount of 0.5 N NaOH necessary for maintaining the pH at 8.0 in the reaction mixture. The reaction was almost complete after 50 min, and interrupted by boiling the solution for 2 min. The solution was cooled and the pH rapidly adjusted to 4.6 by addition of glacial acetic acid. Small amounts of precipitate was filtered off through a fluted paper (Munktell 95). From the slightly opalescent filtrate, a crude fraction containing phosphopeptides was precipitated by adding saturated lead acetate [8]. The precipitate was suspended in distilled water and the pH adjusted to 7.5 with NaOH. The lead was removed by a stream of hydrogen sulphide, the lead sulphide centrifuged off, and the supernatant precipitated by addition of several volumes of absolute ethanol. After lyophilization, the yield of substance was 2.2 g. Analyses of nitrogen and phosphorus gave an atomic ratio N/P of 6.2. In order to find out whether any carbohydrate from α-casein [12] could be recovered in this fraction, analyses of hexose [13], hexosamine [14] and sialic acid [15] were carried out. Only small amounts (0.12 %) of hexose could be detected.

Electrophoresis. Moving boundary electrophoresis of the crude fraction was run in 0.1 M sodium acetate buffer at pH 4.6. Three peaks appeared. Paper electrophoresis (apparatus manufactured by LKB, Stockholm; Schleicher and Schüll paper 2043 B, 4 × 41 cm) in 0.2 M formic acid, adjusted to pH 2.8 with triethyl amine, revealed at least six ninhydrin-positive zones (0.3 % ninhydrin dissolved in ethanol:glacial acetic acid, 99:1, v/v) (Fig. 1A). At least four of these gave positive reaction with the phosphorus reagent described by Hanes and Isherwood [16] (Fig. 1B).

Isolation of a zone electrophoretic component. Small amounts (20—30 mg) of the fastest moving component was eluted from cut out strips of 40 electropherograms with distilled water, after localization of zones in ultraviolet light. Up to 3 mg of crude phosphopeptide could be applicated on every paper. Re-electrophoresis under the same conditions of the eluted fraction showed an essentially homogeneous component (Fig. 1C). Isolation of other components in pure form by this method was not very successful.

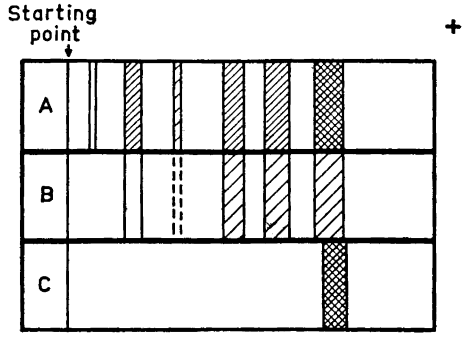

Fig. 1. Paper electrophoretic patterns. A. Crude phosphopeptide, ninhydrin color. B. Crude phosphopeptide treated with phosphorus reagent. C. Isolated component, ninhydrin color.

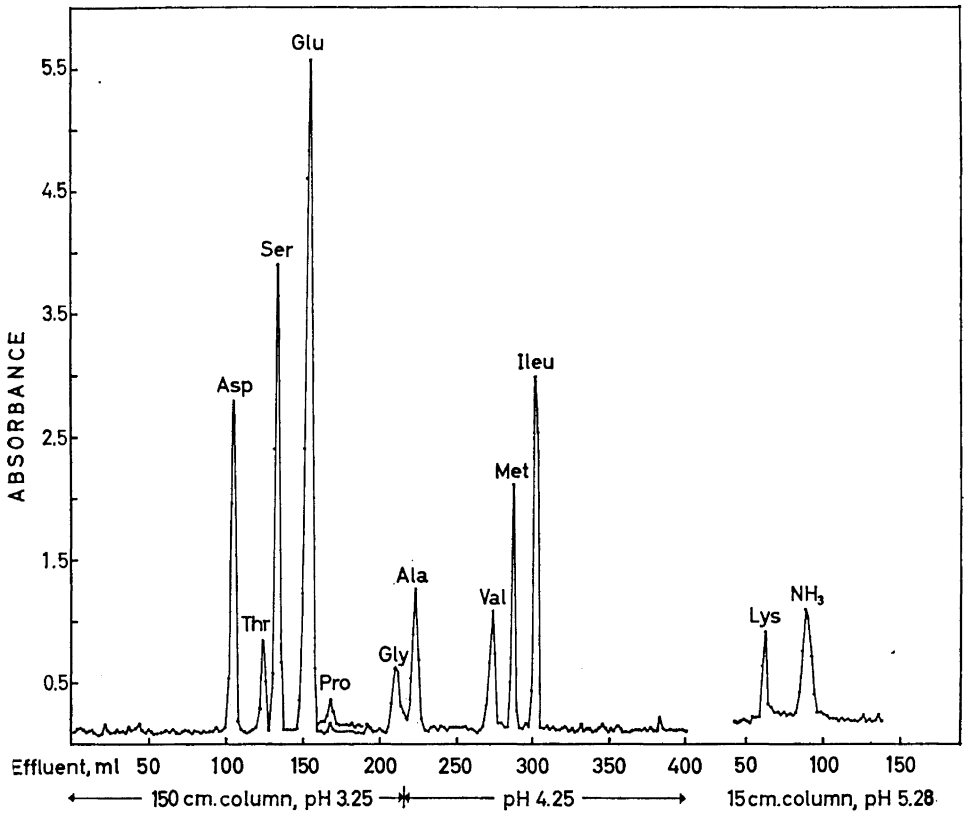

Fig. 2. Amino acid chromatogram according to Moore *et al.*[19] of the isolated component. The values of absorbance for lysine and ammonia should be multiplied with 2.6 to correspond to those of the other amino acids.

Analysis of the isolated component: N 8.56; P 3.20; S 1.1 % (dry weight, not corrected for ash content).* Atomic ratio N/P and N/S was calculated to 5.9 and 21.7, respectively.

N-Terminal amino acid residues were determined by Sanger's dinitrophenylation method[17]. The DNP-peptide was hydrolysed in 5.7 N HCl at 108° in sealed tubes for 10 and 16 h. Two-dimensional descending chromatography was carried out on Whatman No. 1 filter paper, using *tert*-amylalcohol: 0.1 M phthalate buffer, pH 6.0, in the first, and 1.5 M phosphate buffer, pH 6.0, in the second direction. This system was found to give satisfactory separation of DNP-amino acids. In the ether phase, DNP-aspartic acid only could be detected, whereas ε-DNP-lysine was present in the water phase.

Quantitative amino acid analysis. The amino acid composition of the isolated fraction was determined by the dinitrophenylation method as described by Koch and Weidel[18]. The chromatographic separation of the DNP-amino acids was, however, performed in the solvents mentioned above. Amino acid analysis was also performed by the chromatographic procedure on Amberlite IR-120, recently described by Moore *et al.*[19] A chrom-

* We are indebted to Analytiska Laboratoriet, Kemiska Institutionen, Lund, Sweden, for these analyses.

atographic run is shown in Fig. 2. In order to certify the identity of the three last peaks emerging from the 150 cm column, a known amount of leucine was added in one of the runs. This resulted in an extra peak, corresponding to the quantity of leucine added.

No tryptophan could be detected in the isolated fraction, using the method of Spies and Chambers [20].

RESULTS AND DISCUSSION

It is evident from the moving boundary electrophoresis and zone electrophoresis (Fig. 1) that a mixture of phosphopeptides is obtained by tryptic hydrolysis of α-casein. One of these zone electrophoretic components was isolated and its amino acid composition determined, the results of which are shown in Table 1. It is evident from this table that the same main amino acids, *i.e.* glutamic acid, serine, *iso*leucine, and valine are found in the present peptide, as earlier reported for phosphopeptides obtained from whole casein [5,10], as well as from α- and β-casein [6–8] after enzymic hydrolysis.

The results of paper electrophoresis, N-terminal amino acid analysis and quantitative amino acid analysis, indicate that the apparently homogeneous component may constitute a single peptide. If this is true, the minimum molecular composition of the phosphopeptide will be 30 amino acid residues and 6 phosphate groups, corresponding to a minimum molecular weight of about 4 000. The N-terminal position is occupied by aspartic acid and the C-terminal might be a lysine residue which would be in accordance with the specificity of trypsin.

The fact that the bovine α-casein fraction gives several phosphorus-containing peptides after tryptic hydrolysis has previously been pointed out by Peterson *et al.*[6], who found at least three peaks in boundary electrophoresis of the phosphopeptone fraction from a tryptic digest of α-casein. No data concerning these phosphopeptides were given by them. Boundary electrophoresis of our crude phosphopeptide preparation also revealed the existence of three or more components. Pantlitschko and Gründig [7] have recently reported the isolation of a "phosphopeptone" after tryptic digestion of α-casein.

It seems remarkable that no basic amino acids were found in their preparation and, furthermore, it contained a certain amount of acetylglucosamine. No certain criteria of homogeneity of the "phosphopeptone" are to be found in their communication. It seems also likely that α-casein, in accordance with our results, should furnish several phosphorus-containing peptides, as it is known that the α-casein fraction from cow's milk consists of at least two phosphoprotein components [21,22].

Further investigations concerning the separation of phosphopeptides from bovine α-casein by means of ion exchange chromatography and zone electrophoresis are in progress.

We are indebted to Professor O. Mellander for his kind interest and support of the work and also to Miss Anita Boman and Mrs. Birgit Johansson for skilful technical assistance.

Conversion of the Perkin-Elmer Infrared Microscope Attachment for Double-Beam Operation

CARL LAGERCRANTZ and MARGARETA YHLAND

Division of Medical Physics, University of Gothenburg, Sweden

The Perkin-Elmer Infrared Microscope Attachment, used together with model 13 spectrometer, has been converted to double-beam operation by removing the beam-chopper and inserting a shutter-disk in the image plane of the microscope. The shutter-disk, which is revolved synchronously with the spectrometer breakers, is equipped with two semi-circular slits so situated that the light is passed alternatively from the sampling and reference area to the detector. The arrangement allows for recording of spectra from microgram quantities with medium resolution.

The reflecting microscopes employed in infrared microspectrometers have been placed in two different positions in the spectrometer: (a) Between the source and the entrance slit of the monochromator. (b) Between the exit slit of the monochromator and the detector. Temperature and photochemical effects in the sample are generally considered to be of importance when the microscope is situated in position (a), where the sample is subjected to a concentrated beam of undispersed radiation. With the microscope in position (a) Ford *et al.*[1], however, found the rise to be only about 1°, when using a Nernst source. They consider also the ultraviolet radiation from this source to be of minor importance. On the other hand, the possible effects of concentrating an undispersed beam of radiation on the sample are certainly dependent on the material under investigation and the radiation source used. Since there is a general need of more intensive radiation sources in infrared microspectrometry than the Nernst and Globar sources, the disadvantage of position (a) will no doubt be more pronounced when, for instance, a carbon arc is employed. Therefore, the construction of microspectrometers which take advantage of both double-beam operation and of position (b) is of importance. As far as the present authors know, the only apparatus hitherto designed according to these specifications is that described by Haggis [2] which employs a rocking mirror to displace the optic axis through the microscope, so that the beam passes alternatively through the sample and an adjacent reference area.

The present paper describes the conversion of the Perkin-Elmer Infrared Microscope Attachment [3] for double-beam operation. The spectrometer used together with the microscope was a Perkin-Elmer model 13, equipped with a Nernst source and a sodium chloride prism.

GENERAL DESCRIPTION

In order to dispose the sample and the reference alternatively into the beam, experiments with a vibrating stage, placed in the sampling plane of the microscope, were performed by the present authors. However, neither a solenoid driver, nor a pure mechanical system synchronized with the beam-chopper and breakers of the filter circuits were found to give a reliable operation. The difficulties involved were no doubt connected with the rather high frequency of the oscillatory movement necessary to fit the 13-cps system of the spectrometer. Ford *et al.*[1], who employed such a technique successfully, used an oscillatory frequency of 4-cps only.

In consequence of these experiments, another method was developed, utilizing a rotating shutter-disk, placed in the image plane of the microscope. The shutter-disk is equipped with two semi-circular slits. Being of different radii, the two shutter-slits, termed I for sample and I_0 for reference, alternatively pass light from the sample and an adjacent clear area or reference. The relation between the rotating shutter-slits and the image of the spectrometer exit-slit is shown schematically in Fig. 1. The slits are situated in such a relation to each other, that the four operations described below take place when the shutter-slits cross the image of the spectrometer slit during one complete revolution of the shutter-disk:

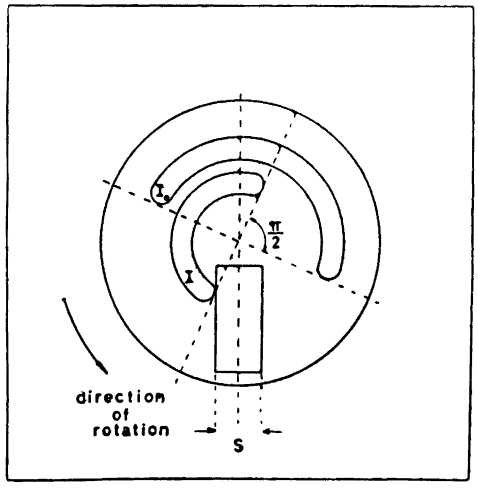

Fig. 1. Schematic diagram of the two semi-circular slits and the image of the spectrometer exit-slit of the width *S*.

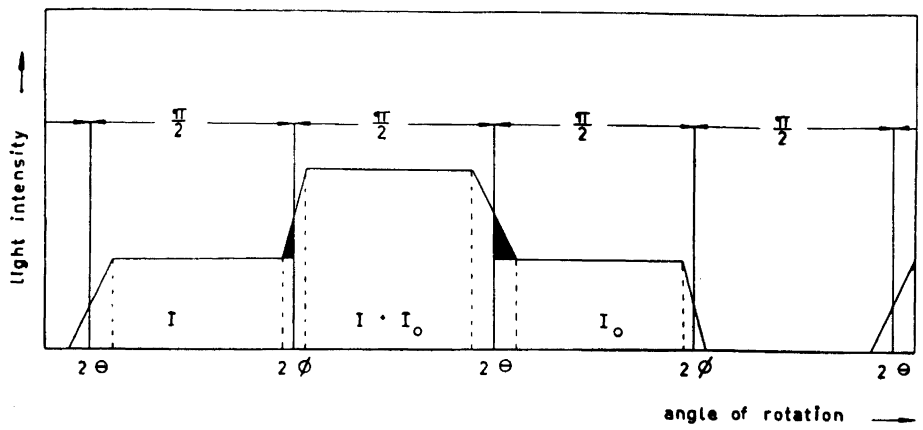

Fig. 2. Schematic diagram of the angular distribution and light transmission of the four spectrometer operations during one revolution of the shutter-disk. The solid vertical lines indicate the position in the cycle where the breakers are actuated. The dashed lines indicate the positions where the leading and trailing edges of the shutter-slits cross the lateral sides of the spectrometer slit image. The shaded areas correspond to the cross-talk. The diagram is constructed for a spectrometer slit-width of 500 μ.

(1) Light from the sample area passes through the I-slit to the detector.
(2) Light from both the sample and the reference areas passes simultaneously through the appropriate shutter-slit to the detector.
(3) Light from the reference area passes through the I_o-slit to the detector.
(4) No light passes through the shutter-disk.

By these means the cycle of operation of the model 13 ratio recording system is reproduced when the shutter-disk is revolved synchronously and in proper phase with the spectrometer breakers. In order to match the spectrometer system, the duration of each of the four operations listed above has to be equal to a quarter of a revolution. Such a condition, however, prevails only when the spectrometer slits are infinitely narrow. Obviously, the individual lengths of the four operations are functions of the actual slit-width, as seen from Fig. 1. These lengths, together with the distribution of light passed through the rotating shutter-disk are shown in Fig. 2. The solid vertical lines drawn in the diagram indicate the position in the cycle, where the spectrometer breakers are actuated. Under the conditions outlined in Fig. 2 it is evident that a certain amount of light from the I_o-channel is introduced into the I-channel and *vice versa* when the spectrometer slit is > 0. The cross-talk, $C(I)$ and $C(I_o)$, introduced into the sampling and reference channel, respectively, may be expressed as the ratio of the shaded area to the total area bordered by the solid vertical lines in Fig. 2 or, provided no sample is inserted into the beam, thus:

$$C(\mathrm{I}) = \frac{b \cdot \varphi}{\frac{1}{2}\pi - a \cdot \vartheta + b \cdot \varphi} \quad (1)$$

$$C(\mathrm{I_o}) = \frac{a \cdot \vartheta}{\frac{1}{2}\pi + a \cdot \vartheta - b \cdot \varphi} \quad (2)$$

where $\varphi = \sin^{-1} \frac{S}{2\,R_{\mathrm{I_o}}}$ and $\vartheta = \sin^{-1} \frac{S}{2\,R_{\mathrm{I}}}$

R_{I} denotes the radius of the sampling shutter-slit, and $R_{\mathrm{I_o}}$ that of the reference shutter-slit. S designates the width of the spectrometer slit in the image plane of the microscope objective. When the operating positions of the spectrometer breakers are in exact quadrature, and the centre of rotation of the shutter-disk is aligned symmetrically with the image of the spectrometer slit, the constants a and b are equal, and may be set approximately to 1/4. $C(\mathrm{I})$ and $C(\mathrm{I_o})$ are shown in Table 1 for some various slit-widths. The numerical values of R_{I} and $R_{\mathrm{I_o}}$ are those of the apparatus to be described, and are equal to 5.0 and 8.0 mm, respectively. The evaluation was performed under the assumption of an image reduction by the microscope condenser of 8.4 × and a magnification by the objective of 25 ×.

The percentage cross-talk will increase enormously in a region of low transmission, and the absorption is thus erroneously decreased. In a 100 % transmission run, the presence of cross-talk will cause a deviation of the recorded curve. Being of negligible magnitude in the short-wave region, the error will increase towards that of long waves. The error introduced by the cross-talk can be reduced by the following procedures:

(1) By selecting the channel of less cross-talk, see Table 1, as the sampling channel, *i.e.* the channel corresponding to the shutter-slit of minor radius.

(2) By increasing the energy output from the source in order to obtain a narrower slit, especially in the long wave range.

(3) By inserting a rectangular diaphragm into the image plane of the microscope objective, thus limiting the effective maximum slit-width of the spectrometer.

(4) By moving the trigger position of the spectrometer breakers, so that the shaded areas of Fig. 2 are reduced.

Of the four procedures outlined above, (1) and (4) have been applied in the present work. Since no light source other than the standard Nernst filament

Table 1. Percentage cross-talk introduced into the sampling and reference channels for some different spectrometer slit-widths, evaluated from eqns (1) and (2). No adjustment for reduction of cross-talk.

Slit-width, μ	$C(\mathrm{I})$	$C(\mathrm{I_I})$
0	0	0
500	1.7	2.5
1 000	3.3	5.1
1 500	5.3	7.7
2 000	6.9	10.5

has been employed, the procedures (2) and (3) were not tried. In order to reduce the error by procedure (4), the cross-talk of either channel can be reduced by readjusting the phase between the rotating shutter-disk and the breaker assembly, or by displacing the centre of rotation of the shutter-disk. It is thus possible to displace all the vertical lines, *i.e.* the trigger positions of the breakers in Fig. 2, to the left, resulting in reduced cross-talk in the I-channel. To reduce the cross-talk of the I_o-channel also, the solid vertical line between the $(I + I_o)$ — and the I_o-operations has to be moved to the right by adjusting the individual position of the appropriate spectrometer breaker. It is not possible, however, to displace the trigger position of the breakers over a certain limit from the position of quadrature without seriously disturbing the operation of the model 13 rectifier system.

MECHANICAL DESIGN AND CONSTRUCTION

A photograph of the modified model 13 Spectrometer and Microscope Attachment is given in Fig. 3. Fig. 4 shows the rotating shutter-disk with the semi-circular slits.

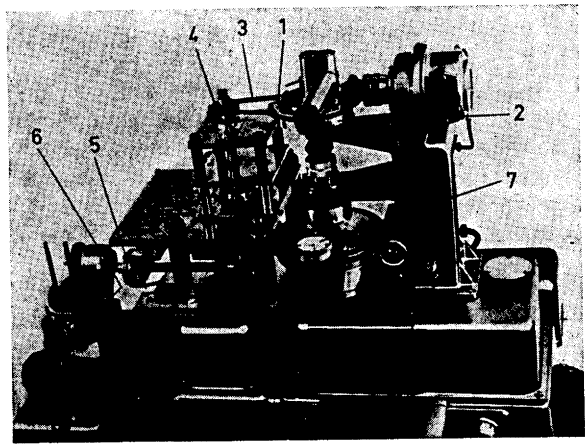

Fig. 3. Complete view of the apparatus. Refer to the text for numerical designations.

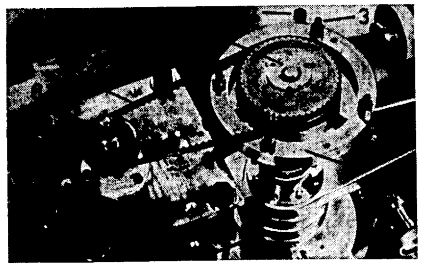

Fig. 4. The rotating shutter-disk with the semi-circular slits. The moulded housing containing the diaphragm field mirror has been removed. Refer to the text for numerical designations.

The diaphragm leaves of the microscope attachment, together with the leaf controls, were removed, and the standard diaphragm holder was replaced by a special holder (Fig. 3:1, 2, Fig. 4:2), intended to support the rotating shutter mechanism. The new holder was equipped with the appropriate spacers (Fig. 4:3) for supporting the moulded housing containing the diaphragm field mirror assembly, for the purpose of maintaining the accurate position of this mirror. The rotating shutter-disk with the two semi-circular slits (Fig. 4:1) was attached to the centre of a socket fitted into the inner ring of a ball bearing (SKF type 16007 X, 62 × 35 × 9 mm). The outer ring of the bearing was supported in a frame machined to the shape of a frustrum of a cone. This frame, together with the ball bearing and the rotating shutter-disk, was placed in a horizontal position on the special holder and was then accurately secured in position by three adjusting screws (Fig. 4:4).

The shutter-disk was caused to revolve by the aid of a Power Grip Timing Belt system. The driven pulley was attached to a flange on the socket supporting the shutter-disk. The timing belt (type 190 XL 025) (Fig. 3:3, Fig. 4:5) was led outside from the microscope assembly through the open space between the special holder and the diaphragm field mirror housing.

The driving pulley (Fig. 3:4, Fig. 4:6) was attached to the end of a vertical shaft supported by ball bearings in a heavy frame-work mounted on the lower of the two spectrometer source covers. After removal of the spectrometer beam-chopper, the pulley shaft was linked to the breaker shaft of the spectrometer by a gear and shaft train and a second timing belt system (Fig. 3:6) to provide direct transmission between the breaker shaft and the shutter-disk. As the standard chopper motor was not powered for driving this assembly, a synchronous motor (1500 rpm, 25 watts) was employed. This motor was placed beside the spectrometer. A pulley (Fig. 3:5) and belt system was used for transmission, so that the frequency of rotation of the breaker shaft was approximately 13-cps. This transmission system has been found to be very reliable and devoid of mechanical vibrations. The rotating shutter and the heavy frame-work were made of brass, the special holder and pulleys of duraluminium.

The two semi-circular slits are cut at a slightly larger angle than the theoretical value of π radians. After the spectrometer had been properly adjusted for the standard macro-operation, the angular values, to be used when cutting the slits, were obtained by reading the angular distribution of the four spectrometer operations from the position of a fixed index on a dial, engraved on the driven pulley (Fig. 3:5) of the spectrometer breaker assembly. The chopper shaft was rotated manually, and the positions at which the light from the source was obscured or just passed by the chopper-blade, were noted.

With shutter-slits of 2.0 mm width, the width of the sampling area amounts about 0.08 mm. The length of the sampling area depends upon the spectrometer slit-width and consequently varies with the wave-length. When the slit is fully opened, *i.e.* 2.00 mm, the sampling area becomes $0.08 \times 0.240 = = 1.92 \times 10^{-4}$ mm^2. In the sampling plane, the free space between the sampling and the reference areas is about 0.12 mm.

When adjusting the double-beam operated microscope to "Zero" and "100 % transmission", edge-formed shutters could be inserted into the appro-

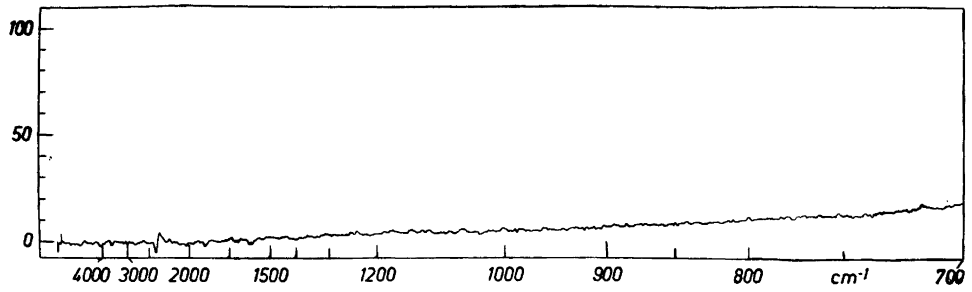

Fig. 5. Recorded curve of a 100 % transmission run. The y-coordinate gives the percentage absorption. Operating positions of the model 13 spectrometer controls: Ratio I/I_o, constant I_o, slit-servo 1.60, gain 18, full scale 6, response 3, speed 2 (1:1).

priate path in the sampling plane of the microscope. One of these shutters was also utilized for supporting the sample. The position of the shutters and the sample was controlled by a vernier screw and a dial displacement gauge (Fig. 3:7), mounted on the microscope stage. Precautions have to be taken to prevent the aperture of the microscope condenser and objective from being impaired when using these shutters.

ADJUSTMENTS

The apparatus was adjusted to minimum cross-talk by observing the position of the shutter-slits through the microscope viewer in visible light when the transmission system was manually revolved. The trigger position of each breaker was indicated by the lighting of a low-voltage lamp, connected in

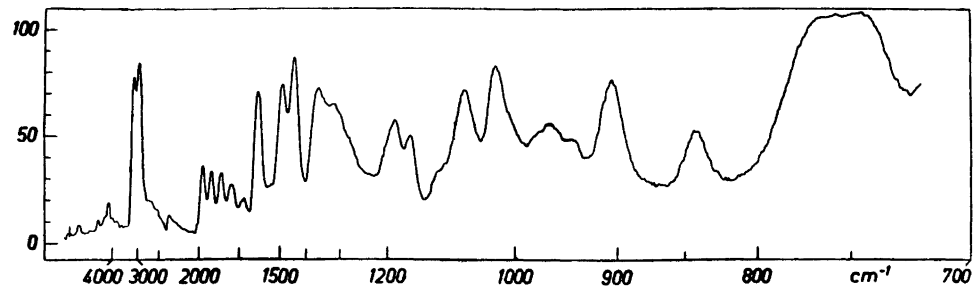

Fig. 6. Recorded spectrum of a polystyrene film. Maximum amount of substance in the sampling beam about 1.3 μg. The y-coordinate gives the percentage absorption. Operating positions of the spectrometer controls are the same as those given for Fig. 5. Reference channel: air.

series with the breaker and a small battery *. By these means it was possible to eliminate the cross-talk of the sampling channel. The cross-talk of the reference channel, however, could not be decreased much below the values given in Table 1 for the I_0-cross-talk without interfering with the spectrometer operation.

In order to make sure that the light, passed through both shutter-slits, falls well inside the sensitive area of the thermocouple, its position was aligned when observing the signals of the sampling and reference channels on a dual trace oscilloscope.

PERFORMANCE

The curve of a 100 % transmission record is shown in Fig. 5. The deviation from a constant level, increasing towards the long wave extreme, is a consequence of the light distribution already discussed above, and shown in Fig. 2. The compensation of atmospheric disturbances is found to be rather effective. The humidity of the air was about 80 % when the record was made.

The recorded spectrum of a polystyrene film of 0.07 mm thickness is shown in Fig. 6. Assuming the density of polystyrene to be equal to 1.0, the effective amount of substance present in the sampling beam is about $0.08 \times 0.240 \times 0.07 \times 1.0 = 1.3$ μg when the spectrometer slits are opened at their maximum width. Due to lack of sufficient energy, the record had to be interrupted at about 725 cm^{-1}, since the spectrometer slits had opened at maximum width at this wave-number. For the same reason the resolution is slightly lower than that generally obtained in macro-operation. The actual slit-width at 3 000 cm^{-1} was about 70 μ.

DISCUSSION

The problem associated with the presence of cross-talk might be simplified by the use of a breaker and filter system different from that of the model 13 spectrometer. However, the modification described above has the advantage of simplicity as it involves no changes either in the electronic system, or in the optics apart from the insertion of the shutter-disk instead of the beam-chopper. As compared with the system described by Haggis [2], the present arrangement has the advantage of avoiding abberations caused by the off-axis displacement inherent to this method.

The preparation of samples suitable for use with the present method will largely depend on the material to be investigated. Methods for preparation and handling of samples for infrared microspectroscopy have been described elsewhere [4]. With some forms of material, the problem of providing a clear space close to the sample will no doubt constitute a limiting factor of the present method.

* A similar technique is recommended by the makers when adjusting the breakers in the standard operation of model 13 spectrometer.

Acknowledgements. The authors are obliged to Mr. Elof Gustafsson for his excellent cooperation in the construction of the mechanical parts of the apparatus, and to Mr. Staffan Haeger for defraying the cost of the Microscope Attachment.

Studies Related to Naturally Occurring Acetylene Compounds. Part XXV. The Occurrence of Methyl *cis*-β(5-Propynyl-2-thienyl)-acrylate in the Roots of Tansy

ERLING GUDDAL and NILS ANDREAS SÖRENSEN

Institutt for organisk kjemi, Norges tekniske högskole, Trondheim, Norway

The roots of tansy *(Chrysanthemum vulgare* Bernh.) have been investigated for their content of acetylenic compounds, and a sulphur containing compound identified as methyl *cis*-β(5-propynyl-2-thienyl)-acrylate has been isolated.

As briefly mentioned previously [1], the investigation of the highly unsaturated compounds in the roots of *Chrysanthemum vulgare* Bernh. has revealed the presence of an ester of a sulphur containing C_{10}-carboxylic acid. This compound is present in approximately the same amounts in acetone extracts and in the volatile oil obtained by steam distillation of the roots. The isolation, however, is best achieved by the latter method. From the oil of roots collected in the autumn or the late summer, the unsaturated ester crystallized on cooling to —10°C. This would indicate a certain increase in the content of this compound during the summer season, accompanied by distinctly increasing amounts of volatile oil during the same period. (Calculated on fresh roots, the yields of volatile oil range form 160 p.p.m. in June to 250 p.p.m. in August.)

When chromatographed on deactivated alumina, the unsaturated ester was eluted with light petroleum-benzene (2:1), and crystallized in nearly colourless prisms from hexane. It showed a melting point of 101°C in an evacuated tube, and elementary analysis agreed with $C_{11}H_{10}O_2S$. Its infrared spectrum is shown in Fig. 1 A. The infrared absorption bands at 1 435 cm^{-1} and 800 cm^{-1} indicate that the sulphur atom is present in a thiophene nucleus [2], and the band at 2 220 cm^{-1} shows the presence of a triple bond. A strong band at 1 715 cm^{-1} followed by another strong band at 1 618 cm^{-1} indicates an α,β-unsaturated carbonyl group. The very strong band in the ethylenic stretching region and the very moderate absorption in the acetylenic stretching region makes it probable that the double bond and not the triple bond is conjugated with the carbonyl group [3].

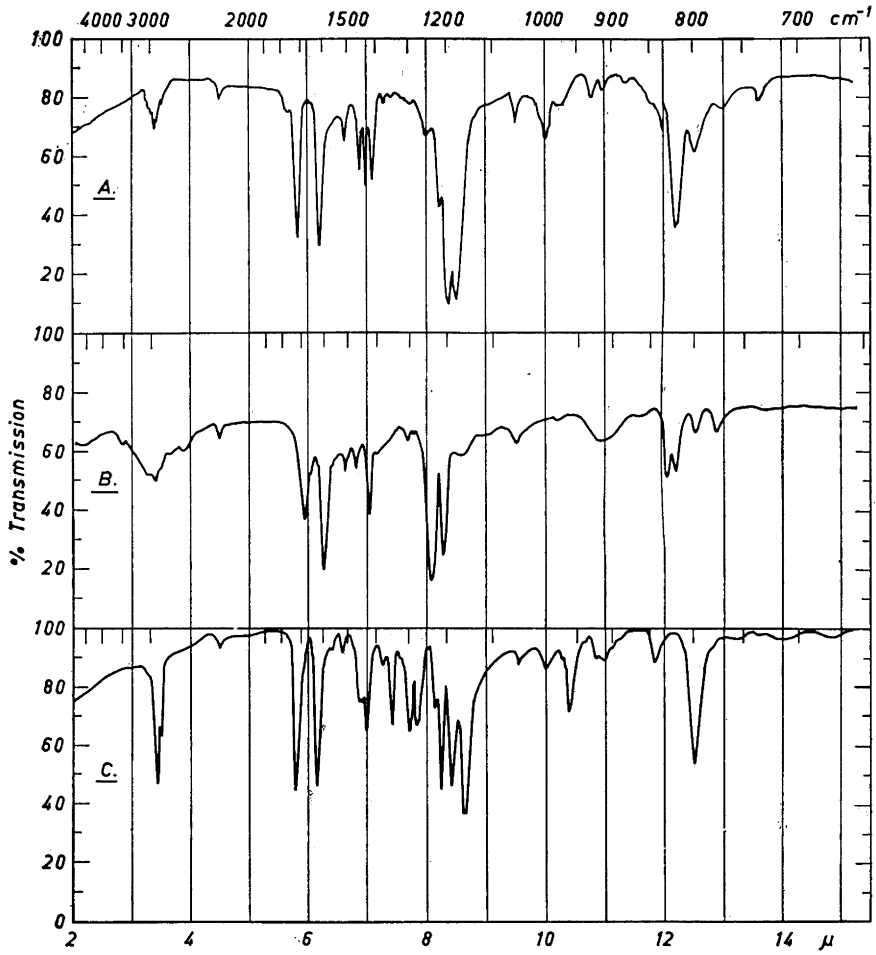

Fig. 1. Curve A: Methyl-*cis*-β(5-propynyl-2-thienyl)-acrylate. In $CHCl_3$ 2—12 μ, in CS_2 12—15 μ. Curve B: *Cis*-β(5-propynyl-2-thienyl)-acrylic acid. In KBr-disc. Curve C: Methyl-*trans*-β(5-propynyl-2-thienyl)-acrylate. In KBr-disc.

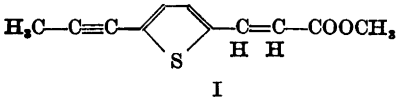
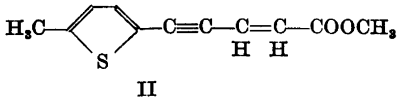
Hydrolysis under mild conditions gave an acid in poor yield which after recrystallisation from ether-hexane, was obtained as yellow needles melting at 148.5—149.5°C (decomp.), and the oxygen atoms thus obviously belongs to an ester grouping. The infrared spectrum of this acid is shown in Fig. 1 B.

The data leave only the two constitutional formulas I and II as reasonable structures.



I



II

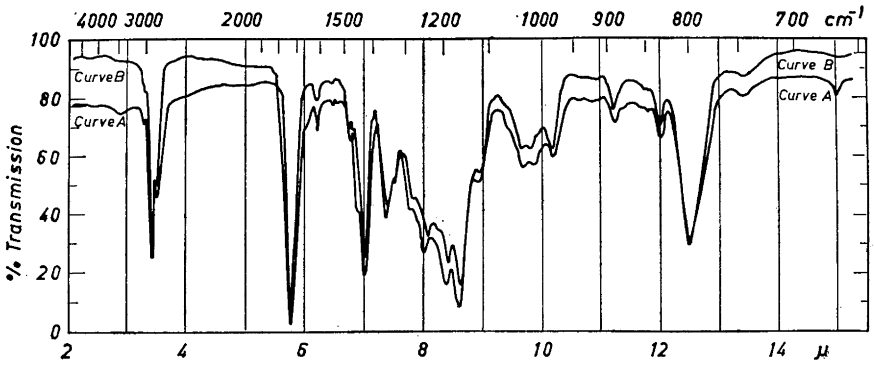


Fig. 2. Curve A: Hexahydro-methyl-β(5-propynyl-2-thienyl)-acrylate. Liq. Curve B: Synthetic Methyl-β(5-propyl-2-thienyl)-propionate. Liq.

The choice between I and II was made possible through a study of the hexahydro-compound. Catalytic hydrogenation of the unsaturated ester on $Pd/BaSO_4$ gave nearly colourless oil with a pleasant, sweetish odour, identical with synthetic methyl β(5-propyl-2-thienyl)-propionate, as shown by the identity of their infrared spectra which are reproduced in Fig. 2. The acid obtained upon saponification of this ester showed an infrared spectrum identical with that of synthetic β(5-propyl-2-thienyl)-propionic acid, and its melting point was not depressed on admixture of this compound. The synthetic specimens for these comparisons are readily obtained by hydrogenation of β(5-propyl-2-thienyl)-acrylic acid [4] with sodium amalgam according to Barger and Easson [5], and subsequent esterification of the acid. It thus follows that the new compound is methyl β(5-propynyl-2-thienyl)-acrylate (I).

When irradiated in the presence of iodine, the natural, unsaturated ester was partly converted to the *trans*-isomer which melted at 76°C and crystallized from hexane in thin leaflets. Its infrared spectrum, as shown in Fig. 1 C, contains a strong absorption band at 960 cm^{-1}, indicative of a *trans*-double bond. The *cis*-configuration of the natural ester could not conclusively be stated from its infrared spectrum because the *cis*-absorption band appeared at 820 cm^{-1}, very close to the band at 800 cm^{-1} characteristic of 2:5-disubstituted thiophenes [2]. Based on this evidence we conclude that the structure of the natural unsaturated ester is methyl *cis*-β(5-propynyl-2-thienyl)-acrylate (I).

Varying amounts of the *trans*-isomer have also been isolated from the plant material. An acetone extract worked up in the dark, however, contained only traces of this isomer, and it is most probably an artefact.

Methyl *trans*-β(5-propynyl-2-thienyl)-acrylate has recently been synthesized in this laboratory [6] and proved identical with the *trans*-isomer of the natural compound.

EXPERIMENTAL

Nine kg of fresh roots of *Chrysanthemum vulgare* Bernh. collected in August were steam distilled to give a yellowish brown volatile oil. On prolonged cooling at −10°C, slightly yellow prisms were deposited. The supernatant oil was submitted to chromatography on

deactivated alumina. The fraction eluted with light petroleum-benzene (2:1) afforded additional amounts of this crystalline compound. After two crystallisations from hexane, the compound melted at 101°C in an evacuated capillary. On heating in air, the compound showed destruction at 50—60°C, and was completely carbonized before melting occurred. The yield of this compound was 90 mg. (Found: C 63.5; H 5.05; S 15.1—15.4. Calc. for $C_{11}H_{10}O_2S$: C 64.0; H 4.88; S 15.5.) The ultraviolet spectrum has two broad maxima at 3 415 Å (log ε: 3.85) and 2 350 Å (log ε : 3.57). Infrared spectrum Fig. 1, curve A.

Saponification. 10 mg of the isolated compound was treated for one hour at room temperature with 5 % KOH in dilute EtOH (water : EtOH 2:1). From the reaction mixture 2 mg of an acidic compound was obtained. It crystallized from an ether-hexane mixture in beautiful, yellow needles, melting with destruction at 148.5—149.5°C. (Found: S 16.26. Calc. for $C_{10}H_8O_2S$: S 16.6.) The ultraviolet spectrum in hexane shows one maximum at 3 260 Å (log ε : 3.75). Infrared spectrum Fig. 1, curve B.

Hydrogenation. 26 mg of the isolated compound was hydrogenated with a 5 % $Pd/BaSO_4$ catalyst in ethanol solution. 8.6 ml hydrogen was consumed (755 mm Hg, 20°C), corresponding to 3.1 double bonds at a molecular weight of 206. The hydrogenation product was a nearly colourless oil with a pleasant, sweetish odour. It distilled at 40—45°C (bath temperature) at 3 × 10^{-3} mm Hg. n_D^{20} 1.5043. Infrared spectrum Fig. 2, curve A.

14 mg of the distilled hydrogenation product was saponified as above, and an acidic substance, which crystallized from hexane in ill-defined prisms, was isolated. It was obtained pure after distillation at 80—85°C (bath temperature) at 5 × 10^{-5} mm Hg, and subsequent crystallisation from hexane. The best preparation melted at 57—58°C, not depressed on admixture with synthetic β(5-propyl-2-thienyl)-propionic acid.

Isomerisation. To a solution of 10 mg of the natural, unsaturated ester in hexane was added a small amount of iodine, and the solution was irradiated with a mercury lamp for 45 min. Chromatography on deactivated alumina of the reaction mixture furnished 4 mg of unchanged material, and 4 mg of a new compound, eluted from the column with benzene-light petroleum (2:1). It crystallized from hexane in thin leaflets, melting at 76°C. Varying amounts of this compound also could be isolated from the volatile oil, the identity being proved by identical infrared spectra and mixed melting point determination. Its ultraviolet spectrum shows two broad maxima at 3 370 Å (log ε : 4.43) and 2 300 Å (log ε : 3.95). Infrared spectrum Fig. 1, curve C.

Preparation of β (5-propyl-2-thienyl)-propionic acid and its methyl ester. β(5-propyl-2-thienyl)-acrylic acid [4] was dissolved in saturated sodium bicarbonate solution and shaken with excess 3 % sodium amalgam at 10°C. Throughout the reaction, carbon dioxide was bubbled through the solution to avoid excessive rise in pH. After acidification, the acid obtained was taken up in ether and recrystallized from ether-hexane. M. p. 59.5—60°C. Yield 90 %. The acid was esterified by boiling with methanol and H_2SO_4, and the ester was distilled at 35—40°C (bath temperature) at 10^{-3} mm Hg. Yield 62 %. Infrared spectrum Fig. 2, curve B.

Acknowledgements. Kjemiingeniör Jörgine Stene Sörensen and Dr. Torger Bruun analysed the compounds for S and C—H, respectively. This work was carried out with a research grant from *Norges tekniske högskole.*

Synthesis of Dialkylaminoalkyl Esters of Sterically Hindered 4-Alkoxybenzoic Acids

ERKKI HONKANEN

Lääketehdas Orion Oy, Helsinki, Finland

A series of dialkylaminoalkyl esters of 2,6-dimethyl-4-alkoxybenzoic acids was prepared for pharmacologic evaluation.

A number of dialkylaminoalkyl esters of *p*-alkoxybenzoic acids have been prepared previously [1,2]. They were found to have a greater local anesthetic activity than procaine, β-diethylaminoethyl *p*-aminobenzoate. These esters, however, hydrolyze in an organism more easily than the corresponding *p*-aminoesters, and this shortens the length of the anesthetic action.

Rabjohn *et al.*[3] have synthesized some β-dialkylaminoethyl esters of sterically hindered benzoic acids which contained only alkyl substituents and reported that β-diethylaminoethyl 2,3,5,6-tetramethylbenzoate is twice as potent as procaine in infiltration anesthesia.

The Upjohn Co [4,5] has prepared dialkylamino alkyl esters of 2,6-dimethyl-4-aminobenzoic acid and reported that the *ortho* dialkyl substitution has an advantageous effect on the local anesthetic activity and that these esters do not hydrolyze readily. However, Lespagnol and Bar [6] claimed that that 1-(dimethylaminomethyl)-1-methylpropyl 2,6-dibromobenzoate hydrolyzes more readily than the unsubstituted benzoate. Childress *et al.*[7] reported that β-diethylaminoethyl 2,6-dichloro-4-aminobenzoate has an intradermal local anesthetic activity 3.5 times that of procaine.

As can be seen from the foregoing, the *ortho* dialkyl substitution not only increases the stability of the ester but also its local anesthetic activity. It was therefore also of interest to investigate the effect of the *ortho* dialkyl substitution on the esters of 4-alkoxybenzoic acids.

During the course of the present investigation two publications have appeared. In one, Reid [8] reported the synthesis of some pyrrolidylalkyl esters of 2,6-dimethyl-4-propoxybenzoic acid, and in the other Bernstein *et al.*[9] that of alkylaminoalkyl esters of 2,6-dimethyl-4-methoxy- and 4-ethoxybenzoic acids.

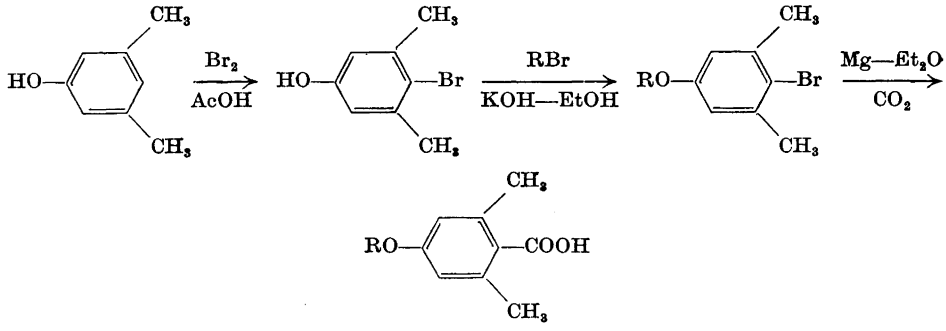
* Reid [8] reported the melting points 90—91° and 121—122° for the *n*- and *i*-propoxy-2,6-dimethylbenzoic acids, respectively.

In the present paper the synthesis of a number of dialkylaminoalkyl esters of 2,6-dimethyl-4-alkoxybenzoic acids is described. These esters have a high local anesthetic activity. In addition they are very resistant to hydrolysis. With the exception of β-diethylaminoethyl 2,6-dimethyl-4-ethoxybenzoate, which Bernstein *et al.*[9] have prepared, all the esters here described are new.

The esters of 2,6-dimethyl-4-alkoxybenzoic acids, which were prepared by allowing the corresponding 2,6-dimethyl-4-alkoxybenzoyl chlorides to react with a dialkylaminoalkanol in boiling benzene solution, are recorded in Table 1.

The 2,6-dimethyl-4-alkoxybenzoic acids were synthesized from 3,5-dimethylphenol by a series of reactions, first described by Fuson *et al.*[10] in the case of 2,6-dimethyl-4-methoxybenzoic acid.



The acid chlorides were prepared in the usual way with thionyl chloride. The 2,6-dimethyl-4-alkoxybromobenzenes from which the 2,6-dimethyl-4-alkoxybenzoic acids were prepared by carbonation of the magnesium compounds are presented in Table 2, the corresponding benzoic acids and acid chlorides in Table 3.

EXPERIMENTAL

The melting points were determined on a Kofler microscope. All boiling points are uncorrected. Microanalyses were performed by the Microanalytisches Laboratorium in Max-Planck-Institut für Kohlenforschung, Mülheim, Germany.

Synthesis of dialkylaminoalkyl esters of 2,6-dimethyl-4-alkoxybenzoic acids. 0.01 Mole of the required 2,6-dimethyl-4-alkoxybenzoyl chloride was dissolved in 50 ml of dry benzene. To this solution was added with stirring 0.02 mole of dialkylaminoalkanol dissolved in 20 ml of benzene. The mixture was refluxed and stirred for 24 h. The benzene solution was washed, first with 2 N aqueous sodium hydroxide, then with water, and dried over anhydrous sodium sulfate. The solvent was evaporated and the residue distilled in a high vacuum. The yield varied from 70 to 95 %.

An X-Ray Investigation of the Nickel-Boron System

The Crystal Structures of Orthorhombic and Monoclinic Ni_4B_3

STIG RUNDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The Ni-B system has been investigated with X-ray powder and single-crystal methods in the range Ni_3B-NiB. In addition to the previously known intermediate phases, Ni_3B, Ni_2B and NiB, the existence of two other phases, both with the ideal compositions Ni_4B_3 but one orthorhombic and the other monoclinic, has been established. The following two-phase regions have been found: Ni_3B + Ni_2B, Ni_2B + orthorhombic Ni_4B_3, orthorhombic Ni_4B_3 + monoclinic Ni_4B_3 and monoclinic Ni_4B_3 + NiB. The unit cell of orthorhombic Ni_4B_3 varies slightly with composition: the dimensions in two-phase Ni_2B + orthorhombic Ni_4B_3 alloys are the following: $a = 11.953$ Å, $b = 2.981$ Å, $c = 6.569$ Å and in two-phase orthorhombic Ni_4B_3 + monoclinic Ni_4B_3 alloys: $a = 11.973$ Å, $b = 2.985$ Å, $c = 6.584$ Å. The unit cell dimensions of monoclinic Ni_4B_3 are $a = 6.430$ Å, $b = 4.882$ Å, $c = 7.818$ Å, $\beta = 103°18'$. No unit cell variation of the latter phase has been found.

The crystal structures of the two new phases have been determined and refined from single-crystal intensity data. The space group of orthorhombic Ni_4B_3 is $P\,n\,m\,a$; the unit cell contains sixteen nickel atoms and twelve boron atoms situated in 4(*c*) positions. Two-thirds of the boron atoms form infinite zig-zag chains, while one-third have no close boron contacts. There are probably boron vacancies in the structure.

The space group of monoclinic Ni_4B_3 is $C\,2/c$. Sixteen nickel atoms are situated in two 8(*f*) positions, eight boron atoms in one 8(*f*) position and four boron atoms in one 4(*e*) position. All boron atoms are connected in infinite chains.

Among the borides of the iron group metals, the nickel borides have received comparatively little attention. The nickel-boron equilibrium diagram has not been accurately determined, but it appears that the Ni-B system is much more complex than either the Fe-B or the Co-B systems. A short summary of the previous work on the nickel borides is given below.

Giebelshausen [1] made a thermal and microscopic analysis in the range 0—60 atom-% boron and claimed the existence of the phases Ni_2B, Ni_3B_2, NiB and Ni_2B_3. Recently, Hoppin III [2] made a microscopic and thermal ana-

lysis in the range 0—17 atom-% boron and found a maximum solid solubility of boron in nickel of 3.7 atom-% at 1 082°C. Bjurström [3] studied the Ni-B system with X-ray powder methods and determined the crystal structure of Ni_2B to be that of the $CuAl_2$ (C 16) type. A phase analysis with X-ray powder methods by Andersson and Kiessling [4] showed the existence of at least four intermediate phases with compositions close to Ni_3B, Ni_2B, Ni_3B_2 and NiB. The crystal structure of NiB was determined by Blum [5] who found NiB to be isostructural with CrB [6]. The preparation of nickel borides by igneous electrolysis was studied by Marion [7], who prepared in addition to Ni_2B and NiB, two phases with compositions between 33 1/3 and 50 atom-% boron and one phase with a boron content larger than 50 atom-%.

At this Institute, the Ni-B system has been reinvestigated with X-ray powder and single-crystal methods, and in previous papers [8,9] the cementite type structure of Ni_3B has been reported. The structure of Ni_3B has been confirmed by Fruchart and Michel [10], and some physical and chemical properties of Ni_3B have been studied by Blok, Kozlova, Lashko and Shpunt [11], who also published X-ray powder data of Ni_3B. Their powder data are in agreement with the present author's findings [8,9].

EXPERIMENTAL

The samples were prepared by heating nickel powder (99.9 %, kindly donated by Mond Nickel Co., Ltd) and boron powder (99.7 % or better, kindly donated by Borax Consolidated Ltd) in evacuated, sealed silica tubes at temperatures between 750° and 950°C. It has been found that the silica tubes are attacked by Ni-B mixtures at elevated temperatures which results mainly in the formation of a ternary compound with the ideal composition Ni_6Si_3B [12]. Because of this the samples were protected from direct contact with the silica by placing them in small Al_2O_3 crucibles inside the silica tubes. No appreciable reaction between Al_2O_3 and the nickel borides was observed. However, the compositions of boron-rich alloys did not correspond to the weighed amounts of the starting materials, since varying amounts of boron were unavoidably lost during the reactions. It was, therefore, often necessary to make a large number of samples in order to obtain an alloy with a composition within a desired narrow range.

X-Ray powder photographs were taken with Guinier-type focusing cameras with Cu$K\alpha$ and Cr$K\alpha$ radiations. Each powder film was calibrated with CaF_2 as internal standard ($\lambda_{CuK\alpha} = 1.5418$ Å, $\lambda_{CrK\alpha} = 2.2909$ Å, CaF_2: $a = 5.4630$ Å). The accuracy of the lattice parameters given in this paper is greater than 0.05 %.

For the structure determinations, Weissenberg photographs were taken with MoK radiation of small single-crystal fragments selected from the crushed alloys. The multiple-film technique was used with thin iron foils between successive films, and the intensities were estimated visually by comparison with a standard intensity scale. No correction for absorption or anomalous scattering was applied. Fourier summations were made with the Hägg-Laurent machine and with Beevers-Lipson strips. Atomic scattering factors were interpolated from tables given by Thomas and Umeda [13] for nickel and by Ibers [14] for boron.

THE PHASE ANALYSIS

Since the main purpose of the present investigation was to study the crystal structures of the intermediate phases, the phase analysis was performed with X-ray powder methods only.

The existence of the previously reported phases Ni_3B, Ni_2B and NiB was confirmed. The unit cell dimensions were determined (see Table 1) and were

in agreement with the results of earlier measurements. No nickel boride with the composition Ni_3B_2, as reported by Giebelshausen [1], was found. Instead, the existence of two new phases, both with compositions near Ni_4B_3, was established. This is in agreement with the findings of Marion [7], who reported two phases of composition within the range Ni_2B-NiB. The X-ray measurements showed that the owo phases possessed orthorhombic and monoclinic symmetry, respectively, and the phases are therefore denoted in the following text as *o*-Ni_4B_3 and *m*-Ni_4B_3.

Since *o*-Ni_4B_3 and *m*-Ni_4B_3 appeared to have the same composition, the existence of a polymorphic transition was suspected. Samples of *o*-Ni_4B_3 and *m*-Ni_4B_3, the powder photographs of which were free from traces of Ni_2B or NiB, were subjected to various heat treatments and rapid quenchings, but no signs of transitions in the solid state were observed. For *m*-Ni_4B_3, no lattice parameter variations were found; but for *o*-Ni_4B_3, a small decrease of the unit cell was indicated in alloys quenched from higher temperatures.

The two-phase regions Ni_3B + Ni_2B, Ni_2B + *o*-Ni_4B_3 and *m*-Ni_4B_3 + NiB were found in the temperature range 750°—950°C, but no two-phase regions *o*-Ni_4B_3 + NiB or Ni_2B + *m*-Ni_4B_3 were observed. Attempts to prepare two-phase *o*-Ni_4B_3 + *m*-Ni_4B_3 alloys were successful in only a few cases. One alloy was heated for 14 days at 850°C, and the two phases still coexisted after the heat treatment. The lattice parameters of *o*-Ni_4B_3 were slightly larger in two-phase *o*-Ni_4B_3 + *m*-Ni_4B_3 alloys than in Ni_2B + *o*-Ni_4B_3 alloys (see Table 1); this indicates that the unit cell of *o*-Ni_4B_3 increases with increasing B/Ni ratio.

From the single-crystal structure determinations (*vide infra*) it was evident that the ideal composition of both *o*-Ni_4B_3 and *m*-Ni_4B_3 should be Ni_4B_3. A study of the available space in the structures showed that the lattices could hardly accommodate more boron or nickel atoms than the stoichiometrical number. Any deviation from stoichiometry must therefore be due either to the existence of lattice vacancies or to boron-nickel substitution.

It is quite clear that additional information, *e.g.*, from microscopic and thermal analytical investigations, must be available before any definite conclusions can be drawn about the phase relationships in the nickel-boron system. However, the following interpretation is suggested by the present observations.

Around the composition 40—43 atom-% boron, two discrete intermediate phases, *o*-Ni_4B_3 and *m*-Ni_4B_3, exist at least in the temperature range 750°—950°C. The two-phase range is probably very narrow, as indicated by the diffi-

culties of obtaining a two-phase *o*-Ni_4B_3 + *m*-Ni_4B_3 alloy (compare the experimental part of the paper). The monoclinic phase is believed to correspond closely to the stoichiometrical composition and may be assigned the formula Ni_4B_3. The crystal lattice of the orthorhombic phase probably contains a varying amount of boron vacancies, which are never completely filled. The formula of this phase may therefore be written Ni_4B_{3-x}, $x > 0$. The number of vacancies probably increases with increasing temperature.

Unit cell dimensions of the nickel borides are given in Table 1. For identification purposes, powder data for o-Ni_4B_3 and m-Ni_4B_3 are given in Tables 2 and 3. It may be noted that for o-Ni_4B_3, the ratio a/b is nearly equal to 4; this makes it somewhat difficult to index correctly the powder lines without knowledge of the intensities of the reflexions.

THE CRYSTAL STRUCTURE DETERMINATION OF ORTHORHOMBIC Ni_4B_3

It is evident from the foregoing text that a knowledge of the crystal structures of o-Ni_4B_3 and m-Ni_4B_3 is valuable from the phase-analytical point of view. Furthermore, the structures also seemed interesting for crystal-chemical reasons, and complete single-crystal structure determinations of both phases were therefore made.

From the measured density value, 7.4 g. cm^{-3} the unit cell content of o-Ni_4B_3 was calculated to be 16 nickel atoms and 12 boron atoms, the unit cell volume being 234—235 Å^3. The following conditions which limit possible reflexions were found: (h k 0) for $h = 2n$, (0 k l) for $k + l = 2n$. The two space groups $Pn2_1a$ and $Pnma$ where therefore possible. Since the b-axis was only 2.98 Å, the 8(d) position of nickel atoms in space group $Pnma$ was ruled out. A study of the intensity material from the layer lines 0—3 around the b axis showed that the corresponding (h 0 l) and (h 2 l) intensities were equal (apart from the normal decline), and the same was true for the (h 1 l) and (h 3 l) reflexions. The simplest interpretation of these facts was to assume that the space group is $Pnma$ with all nickel atoms (and possibly also the boron atoms) in 4(c) positions. The Patterson section $P(x\ 0\ z)$ was computed with the three-dimensional intensity material. The heights and positions of the maxima were in accordance with the above assumptions. Rough parameter values were obtained for the four sets of nickel atoms, and signs were calculated for the $F(h\ 0\ l)$ values. The electron density projection $\varrho\ (x\ z)$ was then calculated and, in addition to the expected nickel maxima, faint boron maxima corresponding to three 4(c) positions were discernible. The x and z parameters of the atoms were refined with successive difference syntheses. The final difference synthesis map, in which all nickel atoms were subtracted, showed well resolved boron maxima. The heights of the B_{II} and B_{III} maxima were almost equal, whereas the B_I maximum was lower and not symmetrical in shape. As measured on this map, the position of the B_I maximum corresponded to the parameters $x = 0.469$, $z = 0.428$, and resulted in a rather uneven distribution of Ni—B_I distances. The parameter values $x = 0.473$, $z = 0.430$ gave a more reasonable environment for the B_I atoms. Since this shift was permissible with regard to the accuracy of the experimental intensity material, these parameters were considered to be more reliable than those obtained directly from the electron density map. The difference in height between the B_I and the B_{II} and B_{III} maxima points to the possible existence of boron vacancies in the structure, but the experimental intensity data do not permit drawing any significant conclusion. After the last refinement, the R value 0.085 was obtained for the 117 observed $|F(h\ 0\ l)|$-values, when an empirical temperature factor with $B = 0.39$ Å^2 was applied. Observed and calculated $F(h\ 0\ l)$-values are given in Table 4.

The final structure of orthorhombic Ni_4B_3 is the following:

Space group $Pnma$—(D_{2h}^{16}), $Z = 4$

$a = 11.953$ Å, $b = 2.981$ Å, $c = 6.569$ Å, $U = 234.1$ Å^3.

(Unit cell dimensions were measured on powder photographs of the alloy, from which the actual single-crystal specimen was selected.)

All atoms in 4(*c*) positions:

	x	*z*
Ni_I	0.148_6	-0.009_7
Ni_{II}	0.449_8	0.751_1
Ni_{III}	0.199_7	0.378_0
Ni_{IV}	0.376_3	0.167_5
B_I	0.47_3	0.43_0
B_{II}	0.03_7	0.48_1
B_{III}	0.26_5	0.67_3

Interatomic distances are given in Table 5.

DESCRIPTION OF THE ORTHORHOMBIC Ni_4B_3 STRUCTURE

A projection of the structure on the *ac*-plane is shown in Fig. 1. The nickel atom lattice can be described as built-up by interconnected trigonal prisms of nickel atoms. The boron atoms are situated in the centers of these prisms. The B_I and B_{II} atoms form two separate boron chains running zig-zag throughout the structure in the *b* direction, whereas the B_{III} atoms have no close boron contacts.

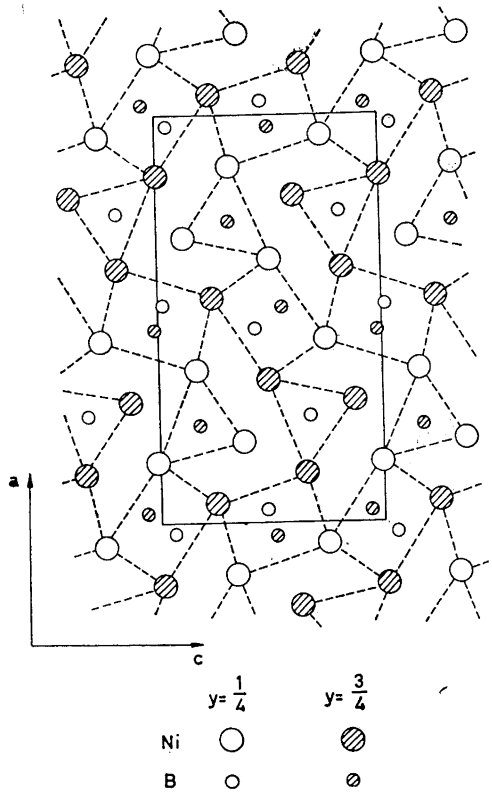

Fig. 1. The structure of orthorhombic Ni_4B_3 projected on (010).

From the crystal-chemical point of view, the *o*-Ni_4B_3 structure may thus be regarded as an intermediate between, *e.g.*, the Ni_3B (cementite type) structure [9], containing isolated boron atoms in the centers of trigonal metal atom prisms, and the FeB type structure [3] containing infinite chains of boron atoms, arranged in a way similar to *o*-Ni_4B_3. For comparison, the FeB structure (based on the same space group as *o*-Ni_4B_3) is shown in projection on the *ac*-plane in Fig. 2.

The three types of trigonal nickel atom prisms in *o*-Ni_4B_3 are shown in Fig. 3a, b and c, together with the environments of the B_I, B_{II} and B_{III} atoms. The triangular sides of the prisms are almost perpendicular to the rectangular sides; the deviations from 90° of the prisms I and II are at the limit of experimental error. The coordination number of the boron atoms is nine, the B_I and B_{II} atoms have seven nickel neighbours and two boron neighbours, and the B_{III} atoms have nine nickel neighbours.

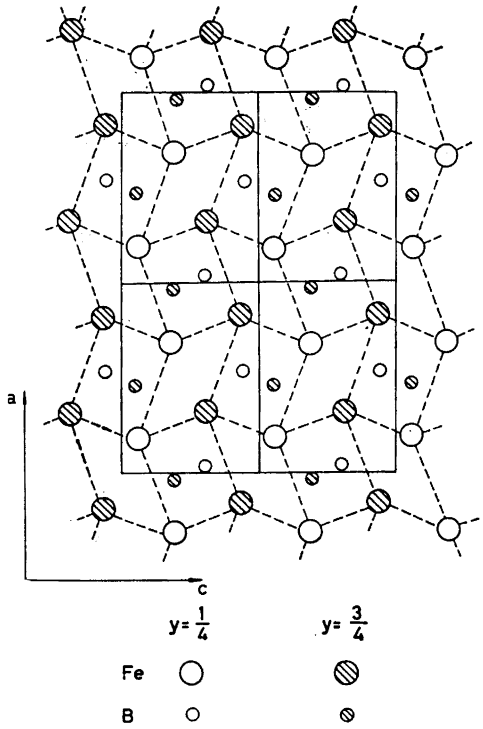

Fig. 2. The structure of FeB projected on (010).

THE STRUCTURE DETERMINATION OF MONOCLINIC Ni_4B_3

The unit cell volume of m-Ni_4B_3, 238.8 Å^3 is almost the same as that of o-Ni_4B_3, which shows that the unit cell content of m-Ni_4B_3 should be 16 nickel atoms and 12 boron atoms. The following conditions for possible reflexions were found: (h k l) only for $h + k = 2n$ and (h 0 l) only for $l = 2n$. This gives C c or $C/2c$ as possible space groups. The Patterson section $P(x$ 0 $z)$ was calculated with the threedimensional intensity material from the layer lines 0—6 around the b-axis. This section contained several large maxima, and indicated strongly that the space group is $C2/c$. Therefore, an attempt was made to interpret the Patterson section in accord with space group $C2/c$.

Large maxima were situated at the following approximate positions: (0, 0, 0) height 1; ± (0.08, 0, 0.46) height 1/4; ± (0.41, 0, 0.06) height 1/3 and (1/2, 0, 1/2) height 1/2. The maximum at ± (0.41, 0, 0.06) was unsymmetrically extended in the c direction. It was assumed that all these maxima corresponded mainly to Ni-Ni vectors. Since no maxima were found on either the a or the c axis, the positions 4(a) and 4(b) were ruled out. The 4(c) and 4(d) positions could not be occupied simultaneously, since in that case maxima at (1/2, 0, 0) and (0,0, 1/2) should exist. If the 4(e) position contained two four-fold sets of nickel atoms, the difference between their y parameters must be 1/2, because the b-axis is only 4.88 Å while the normal nickel atom radius is about 1.24 Å. The resulting maxi-

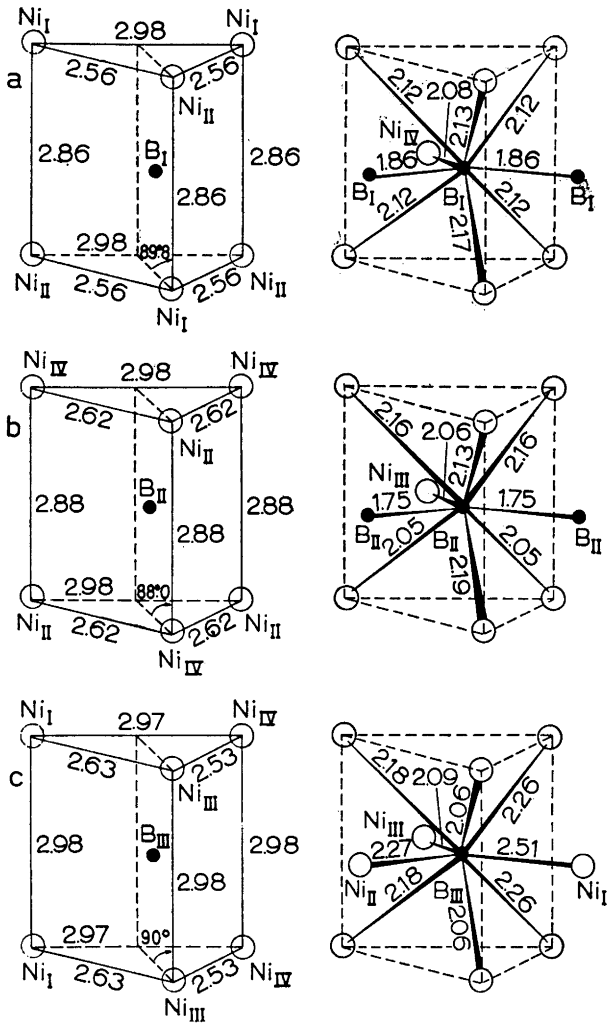

Fig. 3. The environment of the boron atoms in orthorhombic Ni_4B_3
a. the environment of the B_I atoms
b. the environment of the B_{II} atoms
c. the environment of the B_{III} atoms

mum at (0, 1/2, 0) is equivalent to a maximum at (1/2, 0, 0) and since no large maximum existed at (1/2, 0, 0), the 4(*e*) position cannot be occupied by more than four nickel atoms. The following possibilities thus remained: either sixteen nickel atoms in two 8(*f*) positions or eight nickel atoms in 8(*f*), four nickel atoms in 4(*e*) and four nickel atoms in either 4(*c*) or 4(*d*). An analysis of the last possibility did not lead to any acceptable solution, but a satisfactory explanation of the Patterson section $P(x, 0, z)$ was found by placing the nickel atoms in two 8(*f*) positions, one with $x_I = 0.04$; $z_I = 0.48$, and the other with $x_{II} = 0.20$; $z_{II} = 0.29$; this gives Harker maxima at $\pm$ (0.08, 0, 0.46) and $\pm$(0.40, 0, 0.08) with heights 1/4. If the Ni_I atoms have the y_I parameter $\pm$ 1/4, the observed maximum

at (1/2, 0, 1/2) is explained, and furthermore a maximum at ± (0.42, 0, 0.04), height 1/4, must exist. The large maximum observed at ± (0.41, 0, 0.06) is thus explained as resulting from an overlap of maxima at ± (0.40, 0, 0.08) and ± (0.42, 0, 0.04). From space considerations, the y_{II} parameter of the Ni_{II} atoms should have a value near 0.57, if the y_I parameter is taken to be 0.25.

The following approximate nickel positions were thus derived:

$$8\ Ni_I \text{ in } 8(f)\text{: } x_I = 0.04;\ y_I = 0.25;\ z_I = 0.48$$
$$8\ Ni_{II} \text{ in } 8(f)\text{: } x_{II} = 0.20;\ y_{II} = 0.57;\ z_{II} = 0.29$$

Signs of the $F(h\ 0\ l)$- and the $F(h\ k\ 0)$-values were computed from the model, and the electron density projections $\varrho\ (x\ z)$ and $\varrho\ (x\ y)$ were calculated, with the use of the intensity material from the zero layer lines around the b and the c axis. In addition to the nickel maxima, boron maxima corresponding to one 8(f) and one 4(e) position became visible. The two projections were refined

with successive difference syntheses. The final R-values obtained were 0.105 for the $|F(h\ 0\ l)|$-values and 0.103 for the $|F(h\ k\ 0)|$-values; an empirical temperature factor with $B = 0.20$ Å^2 was applied in both cases. The boron parameters obtained from the difference synthesis maps were not very accurate, but the following boron parameters were found: B_I in 8(f): $x_I = 0.234$; $y_I = -0.10_2$; $z_I = 0.437$ and B_{II} in 4(e): $y_{II} = -0.08_8$. From space considerations, the following B_I parameters seemed more reasonable: $x_I = 0.234$; $y_I = -0.091$; $z_I = 0.443$. These parameter values were wholly compatible with the experimental intensity data.

Observed and calculated $F(h\ 0\ l)$- and $F(h\ k\ 0)$-values are compared in Table 6.

The final structure of monoclinic Ni_4B_3 is the following:

Space group $C2/c$—(C_{2h}^6); $Z = 4$;

$a = 6.430$ Å; $b = 4.882$ Å; $c = 7.818$ Å; $\beta = 103°18'$; $U = 238.8$ Å^3; $D_x = 7.43$ g.cm^{-3}

		x	y	z

DESCRIPTION OF THE MONOCLINIC Ni_4B_3 STRUCTURE.

The m-Ni_4B_3 structure can be described as built-up by rather close-packed, slightly corrugated nickel atom layers with chains of boron atoms running through the channels in the metal atom lattice. The nickel atom layers are parallel with {202}, and the arrangement of the nickel atoms in one layer is shown schematically in Fig. 4. The {202} layers in m-Ni_4B_3 are closely related to the slightly corrugated {10$\bar{1}$1} layers in hexagonal close-packed structures, and are intermediates between the {103} layers in Ni_3B ($D\ O_{11}$ structure) and the {0 0 1} layers in Ni_2B (C 16 structure). (Compare Fig. 4 in the present paper

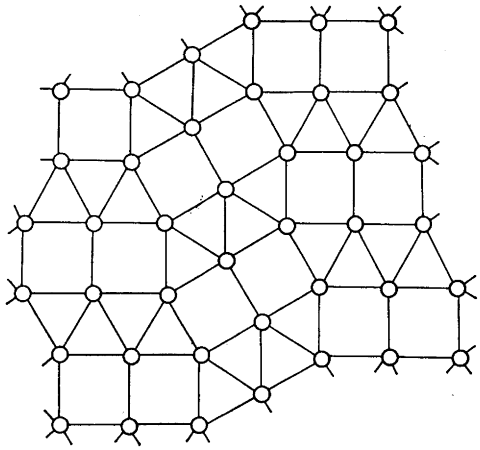

Fig. 4. Nickel atom layers parallel with {202} in monoclinic Ni_4B_3.

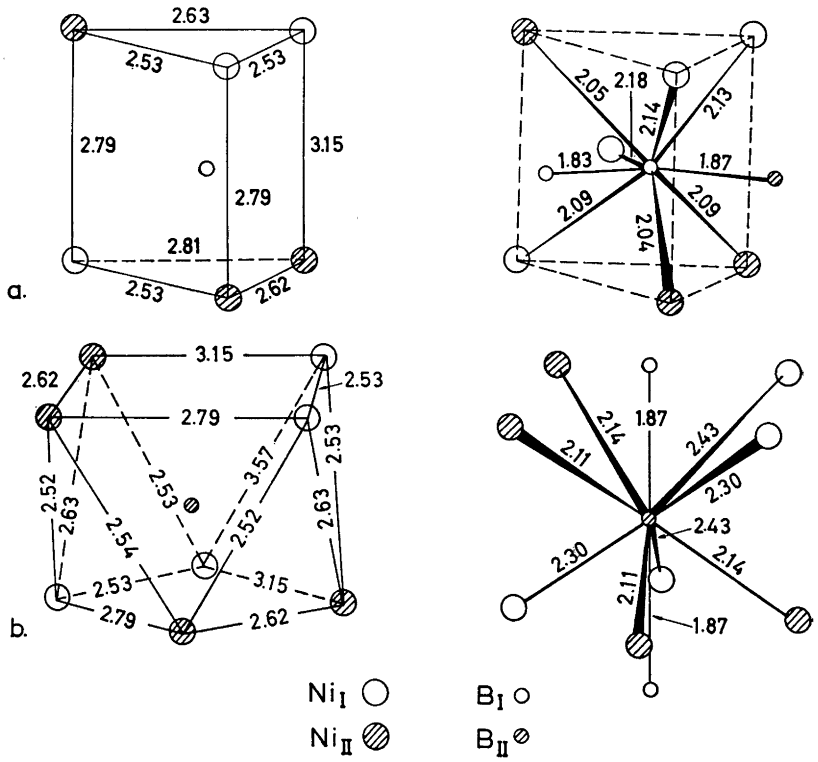

Fig. 5. The environment of the boron atoms in monoclinic Ni_4B_3
a. the environment of the B_I atoms
b. the environment of the B_{II} atoms

with Figs. 1, 2 and 3 in Ref.[9]). In Ni_3B, the boron atoms are situated in trigonal prismatic holes without forming any close B-B contacts. In Ni_2B, the boron atoms are situated in antiprismatic holes and form strings throughout the structure with a B-B distance of 2.12 Å. In *m*-Ni_4B_3, both types of holes exist; the B_I atoms occupy distorted trigonal prismatic holes, while the B_{II} atoms occupy distorted antiprismatic holes. The B_I environment is shown in Fig. 5a and the B_{II} environment in Fig. 5b. All of the boron atoms are connected in infinite chains, the sequence of which is $--B_{II}-B_I-B_I-B_{II}-B_I-B_I--$ with the B_I-B_{II} distance 1.8_7 Å and the B_I-B_I distance 1.8_3 Å. The mean Ni-B_{II} distance in the *m*-Ni_4B_3 antiprisms is 2.25 Å as compared with the Ni-B distance of 2.14 Å in the Ni_2B antiprisms.

GENERAL REMARKS

From the crystal-chemical point of view, the series of nickel borides Ni_3B, Ni_2B, *o*-Ni_4B_3, *m*-Ni_4B_3 and NiB provides a striking example of the gradually increasing B-B bond formation with increasing boron content in transition metal borides [15]. The structural similarities between the 'complicated carbides' and the nickel borides may also be noted; Ni_3B and Fe_3C are isostructural [9], while *o*-Ni_4B_3 and NiB are structurally related to Cr_3C_2 [16].

The present phase analysis has shown that the old equilibrium diagram given by Giebelshausen [1] is not reliable. The investigation of Hoppin III [2] provides accurate thermal data only up to 17 atom-% boron. It is desirable that the remaining part of the equilibrium diagram be investigated with modern metallographic and thermal analytical methods.

On the Effect of Ultrasonic Waves on Aqueous Solutions of 2-Chloro-Ethanol

JØRN THAMSEN*

Royal Danish School of Pharmacy, Copenhagen, Denmark

The present investigation deals with the influence of ultrasonic waves on the rate of hydrolysis of 2-chloro-ethanol (ethylene chlorohydrin) in pure aqueous solution at practically constant temperature. The experiments have been performed mainly with ultrasonic waves of frequency 0.8 Mcps.

The acoustic power from the transducer has been calculated from the radiation pressure, which is measured with a radiometer. It is established that the reaction is promoted in the ultrasonic field and the velocity of the reaction has been found dependent on certain experimental variables (the acoustic power, the concentration of 2-chloroethanol, and the ultrasonic field, *i. e.* the experimental arrangement).

The rate constant has been expressed by the experimental variables in a joint interpolation formula.

When certain alkyl halides, *e.g.* $C_2H_4Cl_2$, $CHCl_3$, $CHBr_3$, CCl_4 *etc.* are subjected to intense ultrasonic waves in aqueous solution (saturated with air)[1] the action of the ultrasonic waves is revealed by a partial liberation of halide from the alkyl halides. This effect has not been considered as being due to the oxidizing properties acquired by water containing air, when exposed to ultrasonic irradiation [2,3], and should thus be the result of a specific action of the ultrasonic waves on the alkyl halides. However, information in the literature about the action of the ultrasonic waves is often of a qualitative character and in particular there is not sufficient information about the sonic field.

The alkyl halides mentioned above are more or less insoluble in water, which reduces the experimental possibilities. Experiments with soluble chloro compounds such as chloroethanoic acid and 2-chloro-ethanol, however, have shown that these compounds in pure aqueous solution also partly liberate chloride ions, when exposed to ultrasonic waves. However, it should be noted that

* The investigation was carried out at The Laboratory of Technical Physics, Technical University of Denmark, Copenhagen, and supported by a grant from *Det teknisk-videnskabelige Forskningsraad.*

2-chloro-ethanol, without the influence of ultrasonic waves, is hydrolyzed very slowly in pure aqueous solution and that the reaction follows 1'-order kinetics to high degrees of conversion [4]. The reaction in the ultrasonic field could be due to such a hydrolysis, which is somehow accelerated by the ultrasonic waves. The present investigation deals with the rate by which chloride ion is formed in pure aqueous solutions of 2-chloro-ethanol subjected to ultrasonic waves under different experimental conditions, and with the dependence of the rate constant on certain experimental variables.

EXPERIMENTAL

In the present investigation the ultrasonic waves were generated by a Siemens sonostat universal piezoelectric generator, which is able to produce ultrasonic waves of the frequencies 0.8 and 2.4 Mcps corresponding to the 1′ and 3′ harmonic mode of vibration and deliver acoustic powers from 2 to 50 watts from a quartz with a radiating surface of 10 cm^2. A cross-section of the experimental arrangement is illustrated in Fig. 1. Since the ultrasonic field plays an important role in the experiments, it is necessary to be careful, in particular when transferring the ultrasonic waves to the test-samples. This transfer is carried out as follows. The transducer (1) is inserted into the bottom of a water thermostat (2). A cylinder made up of two parts, which forms a container in connection with the transducer (3), is mounted on top of the transducer. The lower narrow part, which fits on to the transducer, consists of a short cylinder provided with a packing groove, which is secured with a bayonet socket and a packing ring without causing injury to the transducer. The upper wider part is screwed on to the lower part, the former being provided with windows to ensure lighting inside the container. Another cylinder (6) of inner diameter 45 mm and with double walls so that the cylinder can be cooled by conducting a flow of water between the walls, is inserted inside this outer container. This reaction cylinder may be closed below by some sort of membrane ("acoustic window"), *e. g.* 0.05 mm triacetate foil * (5), which is distended between the cylinder and a screwed cap, and then constitutes a reservoir for the samples. This inside silverplated reaction cylinder is kept in a fixed position vertical to the transducer by a ring (4), which also provides for a practically constant distance between the transducer and the liquid surface of the sample (7) in the cylinder. The distance between the transducer and the membrane is about 50 mm. When the ultrasonic waves are transmitted vertically from the transducer through the "acoustic window" into the sample in the reaction cylinder, the space between the transducer and the membrane and around the reaction cylinder is filled up by water carefully freed from dissolved air. It is convenient to use such water, since the ultrasonic waves otherwise liberate small air bubbles from the water, which rise below the membrane and have a scattering effect.

When the sample in the reaction cylinder and the water between the transducer and the membrane are influenced by the ultrasonic waves the temperature immediately rises due to absorption. It is therefore necessary to use automatic cooling to keep the temperature practically constant in the sample during the experiment. This has been done by conducting cooling water through the reaction cylinder when the temperature in the sample rises. The flow of cooling water is directed by means of a Cu-constantan thermocouple with the junctions placed in the sample and in the water thermostat, respectively, (8), combined with a photo relay and a magnet valve. During the experiments the temperature in the sample is recorded by the voltage of a thermo-couple with the junctions placed in the sample and in crushed ice (9), respectively, on a "Speedomax"-recorder Type G. It is thus possible to keep the temperature practically constant to $25.0° \pm 0.8°$ C; otherwise the temperature would rise about 10 degrees.

In an experiment the sample, usually 50 ml, is treated for a definite time in the reaction cylinder, observing, before and after the treatment, the absence of air bubbles below the membrane. After the treatment the constancy of the volume of sample is also observ-

* The foil has been demonstrated to be impermeable to chloride ions.

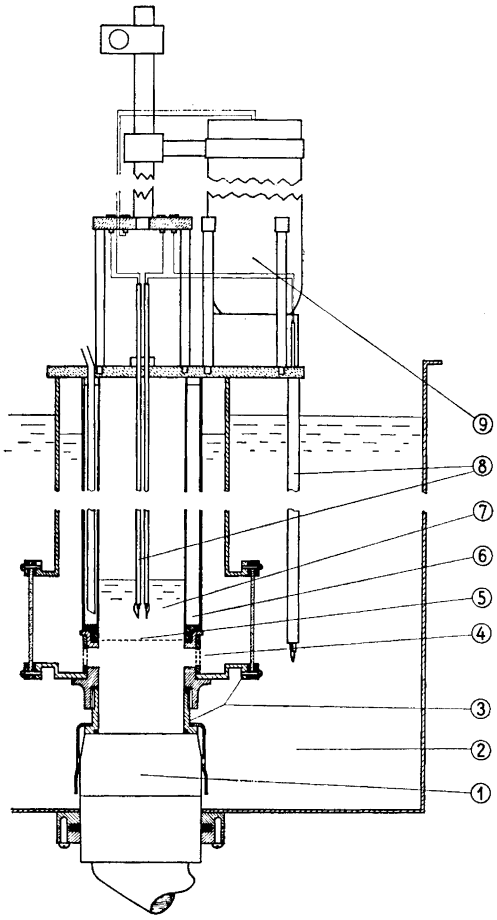

Fig. 1. Experimental arrangement in cross-section: 1, Transducer; 2, Water thermostat; 3, Outer container; 4, Distance-ring; 5, Membrane, "Acoustic window"; 6, Reaction cylinder; 7, Sample; 8, Thermo-couples; 9, Dewar flask for crushed ice.

ed to ensure that the sample has not been inadvertently diluted by water from the outer container, after which the chloride ions in a 20.0 ml sample are titrated with a 0.0028 N mercuric nitrate solution. Diphenylcarbazone is employed as indicator. This produces a red-purple color with excess of mercuric ions [5] in dilute acid solution. The color change during the end of the titration was followed by means of a Lange photoelectric colorimeter, which previously was adjusted against color-solutions for comparison prepared from the same quantities of reagents and an excess of 0.3 ml 0.0028 N mercuric nitrate. Since the initial solutions of 2-chloro-ethanol had a slight content of chloride ions, the data are corrected with regard to a blank value carried out with 20 ml solution. The blank values are about 0.4—3 ml 0.0028 N mercuric nitrate dependent on the concentration of 2-chloro-ethanol. The amounts of mercuric nitrate solution corresponding to the chloride ions formed during the experiments range from 1 to 40 ml 0.0028 N mercuric nitrate. In some of the long duration experiments the content of chloride ion was deter-

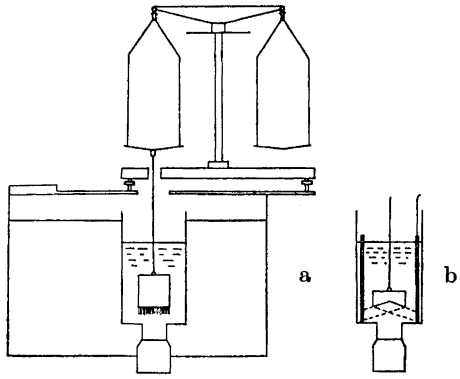

Fig. 2. Experimental arrangement for the measurement of the acoustic power.

mined by conductometric titration with 0.0028 N mercuric nitrate. The solutions of 2-chloro-ethanol were prepared from a fraction of 2-chloro-ethanol "Fluka" which distilled between 128.3° and 128.7°C at 753 mm Hg and had $n_D^{20} = 1.4422$. The boiling point of 2-chloro-ethanol is 128.6°C and $n_D^{20} = 1.4421$.

THE ACOUSTIC POWER FROM THE TRANSDUCER

When a beam of plane ultrasonic waves in a fluid encounters an obstacle, then the interaction of the obstacle with the plane wave motion results in a radiation pressure exerted upon the obstacle proportional to the mean energy density of the wave motion [6].

The power radiated in an ultrasonic field is closely related to the radiation pressure [7] and is usually determined by a measurement of the net force exerted on a proper "radiometer", which may be either a perfect reflector or a perfect absorber, placed in the path of the waves. For the present determinations of the total acoustic power emitted from the transducer two different radiometers have been used, one a nearly perfect absorbing nylon-brush, the other a nearly perfect reflecting hollow brass-radiometer. The experimental arrangement is shown in Fig. 2.

The brass-radiometer [8] which is provided with a conical turning out (135°) is filled with air. The air inside the radiometer ensures a practically complete reflection from the surface and the conical shape makes the radiometer self-centralizing and brings about a reflection parallel with the opposite surface. The reflected waves are absorbed in a cylinder of absorbing material to avoid standing waves acting back on the transducer (Fig. 2 b).

The radiometer is suspended below the pan of a balance in a thin nylon thread, and completely immersed in and surrounded by water freed from dissolved air, vertically above and as close as possible to the transducer. Air bubbles below the radiometer are carefully removed and the radiometer is tared. The resulting buoyancy when the ultrasonic waves interact with the

radiometer is finally counterbalanced with weights, q g. If the ultrasonic waves emitted from the transducer are assumed to be free plane waves in a lossless medium the alternating excess sound pressure p_e is related to the alternating particle velocity u by $p_e = u\varrho_o h_o$ and analogous $p_{e,rms} = u_{rms}\varrho_o h_o$ where ϱ_o is the static density of the medium, h_o the velocity of the waves and $\varrho_o h_o$ the characteristic impedance. The acoustic power W_P is

$$W_P = \frac{1}{T}\int_0^T up_e A\,dt = u_{rms}p_{e,rms}A = \frac{UPA}{2} = \frac{\varrho_o h_o U^2 A}{2} \text{ watts}$$

where T is the period, A the total area of the beam, and P and U are the respective amplitude values.

The radiation pressure Π is related to the particle velocity amplitude and the weights q g by

$$\Pi = \frac{\varrho_o U^2}{2} = q\ 9.81 \times 10^{-3} A^{-1} \text{ Newton m}^{-2}$$

With respect to the nylon-brush which is larger in section than the beam and as mentioned above acts as an absorber the counterbalanced weights q g corresponds thus, following the above expressions, with the acoustic power

$$W_P = \frac{\varrho_o U^2 h_o A}{2} = q\ 9.81 \times 10^{-3} h_o = 14.69\ q \text{ watts}$$

where the velocity of sound in water $h_o = 1\,497$ m sec^{-1} at 25°C.

In the case of the brass-radiometer, which is also larger in section than the beam and acts as a perfect reflector, the beam intersects the radiometer by an angle $\Theta = 22.5°$ and the acoustic power is then

$$W_P = \Pi\ h_o A = q\ 9.81 \times 10^{-3}\ h_o\ (2\cos^2\Theta)^{-1} = 8.61\ q \text{ watts}$$

Table 1. The acoustic power from the transducer at different primary voltages on the anode-transformer of the generator, as measured by a nylon-brush and a brass-radiometer.

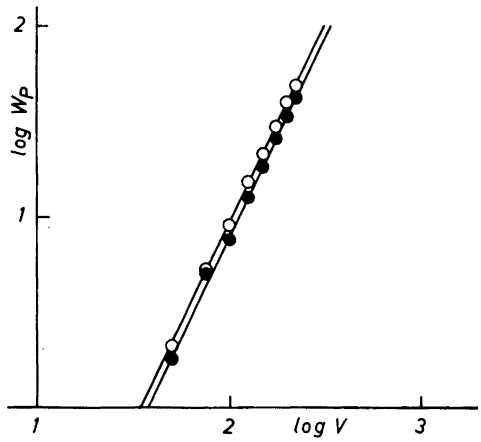

Fig. 3. A plot of log W_P against log V. W_P is the acoustic power as measured by the nylon-brush, V is the primary voltage on the anode-transformer of the generator. O, experiments performed at 0.8 Mcps; ●, experiments performed at 2.4 Mcps.

The results at different primary voltages on the anode transformer of the generator are shown in Table 1.

In Fig. 3 log W_P (as measured by the nylon-brush) is plotted against log V (primary voltage on the anode-transformer). From the figure it is inferred that approximately W_P = constant × V^2 in accordance with the expression for the acoustic power output from a piezoelectric quartz $W = V^2_{rms}/R_e$, where V_{rms} is the voltage applied to the quartz and R_e a motional resistance.

THE KINETIC OF THE REACTION IN THE ULTRASONIC FIELD

When 2-chloro-ethanol is hydrolyzed in dilute pure aqueous solution thus: $CH_2ClCH_2OH + HOH = CH_2OHCH_2OH + H^+ + Cl^-$, the reaction follows 1'-order kinetics, *i.e.* $-\frac{1}{c}\frac{dc}{dt} = k_1$, where $c = a-x$ is the concentration of 2-chloro-ethanol left at time t and a the initial concentration. When the reaction proceeds in the ultrasonic field the initial velocity $s = -\frac{dc}{dt}$ or $\frac{1}{c}s = -\frac{dc}{cdt}$ could be estimated from the experimental results.

1. The dependence on the acoustic power.

Experiments with samples of 0.05 litre at $\nu = 0.8$ Mcps and varying values of the acoustic power have shown that the initial velocity changes with the acoustic power.

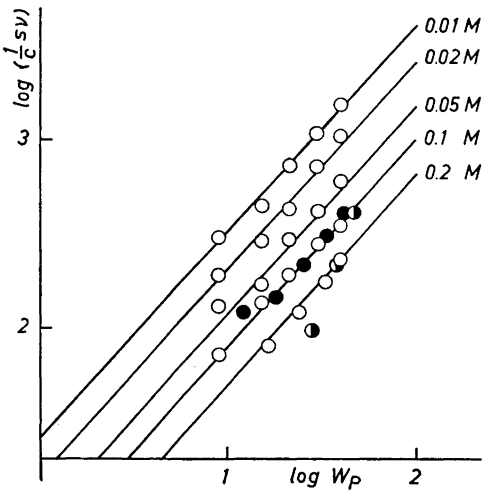

Fig. 4. A plot of $\log\left(\frac{1}{c}sv\right)$ against $\log W_P$. s is the initial velocity found in experiments with samples of 0.05 litre, c is the concentration of 2-chloro-ethanol, v the frequency and W_P the acoustic power. ○, experiments performed at 0.8 Mcps; ●, experiments with 0.1 M, and ◑ with 0.2 M, performed at 2.4 Mcps; 25°C.

In Fig. 4 for convenience $\log\left(\frac{1}{c}sv\right)$ is plotted against $\log W_P$. From the figure it could be inferred that $\frac{1}{c}sv = \text{constant} \times W_P^{1.1}$. In the figure are also indicated the results from experiments with 0.1 and 0.2 M solutions at $v = 2.4$ Mcps, whereof in all events the experiments with 0.1 M appear to follow the above relation fairly well. Similar experiments with a 0.01 M solution failed because the liberated amounts of chloride ion were too small for determining an initial velocity with any reasonable certainty.

2. The dependence on the concentration of 2-chloro-ethanol.

Experiments with samples of 0.05 litre at $v = 0.8$ Mcps, W_P kept constant and varying concentrations of 2-chloro-ethanol, have shown that the initial velocity also changes with the concentration. In Fig. 5 $\log\left(\frac{1}{c}sv\right)$ is plotted against $\log(10^2 c)$. From the figure it could be deduced that $\frac{1}{c}sv = \text{constant} \times c^{-0.62}$. By combining the results derived from Figs. 4 and 5 it could finally be inferred that the initial velocity in experiments with 0.05 litre sample, $v = 0.8$ Mcps, and the experimental conditions mentioned, follows the expression $s = 1.48\ v^{-1} W_P^{1.1} c^{0.38}$ mole litre^{-1} min^{-1}.

3. The dependence on the volume of sample.

Preliminary experiments with samples of 0.10 litre instead of 0.05 litre had shown that changes in the volume of sample had a marked effect on the initial velocity.

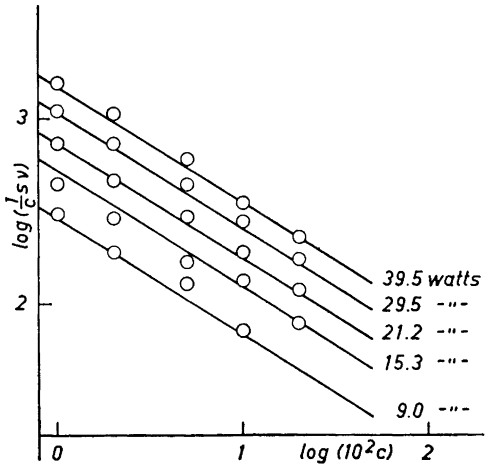

Fig. 5. A plot of $\log\left(\frac{1}{c}s\nu\right)$ against log (10^2c). Experiments with samples of 0.05 litre; $\nu = 0.8$ Mcps; 25°C.

Experiments with a 0.01 M solution of 2-chloro-ethanol at $\nu = 0.8$ Mcps, the acoustic power 43 watts and varying volume of sample have shown that this effect is closely connected with the dimension of the reaction cylinder (diameter 4.5 cm) and the ultrasonic field, *i.e.* the experimental arrangement.

In the present experimental arrangement the waves are radiated against the free liquid surface of the sample where the waves are almost completely reflected, which results in a field of standing waves. If we assume that the attenuation is small and the absorption coefficient nearly the same in the water below the membrane and in the sample, then we can say approximately that the acoustic energy absorbed in the sample is related to the part of the volume filled up by the ultrasonic waves, which is standing in the sample $\frac{V_1}{V_0 + V_1} = \frac{l_1}{l_0 + l_1}$, where l_0 is the distance from the surface of the transducer to the membrane in the reaction cylinder (about 5.0 cm), l_1 the height of sample in the reaction cylinder, and the radiating surface 10 cm^2.

When the absorbed acoustic energy finally is distributed in the sample, then the acoustic energy absorbed per unit volume of sample is related to $\frac{l_1}{(l_0 + l_1)V_s} = \frac{10^3}{(l_0 + l_1)A_R}$ where V_s litre is the volume of sample and A_R the area of the base of the reaction cylinder. In Fig. 6 $\log\left(\frac{1}{c}s\nu\right)$ is plotted against $\log\left(\frac{10^3}{(l_0 + l_1)A_R}\right)$. From this figure it could be inferred that $\frac{1}{c}s\nu = \text{constant} \times \left(\frac{10^3}{(l_0 + l_1)A_R}\right)^{2.0}$.

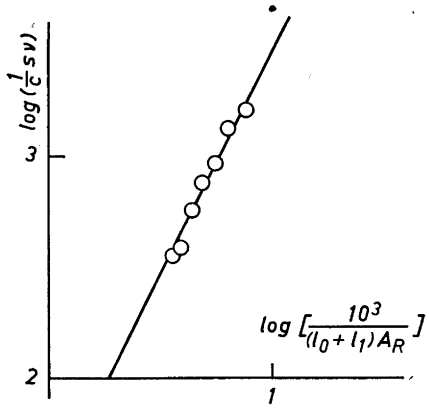

Fig. 6. A plot of $\log\left(\frac{1}{c}sv\right)$ against $\log\left(\frac{10^3}{(l_0+l_1)A_R}\right)$. Experiments with a 0.01 M solution of 2-chloro-ethanol and varying volume of sample; l_0 is the distance between the transducer and the "acoustic window", l_1 the height of sample in the reaction cylinder, A_R the area of the base of the reaction cylinder; $\nu = 0.8$ Mcps and the acoustic power $W_P = 43$ watts; 25°C.

By combination of this result with that previously obtained a joint interpolation formula could finally be deduced, thus

$$s = 2.48 \times 10^{-2}\left(\frac{10^3}{(l_0 + l_1)A_R}\right)^{2.0} W_P^{1.1}\nu^{-1}c^{0.38}$$

$= kc^{0.38}$ mole litre^{-1} min^{-1}, where $\nu = 0.8$ Mcps.

It is so established that

$$-\frac{d[CH_2ClCH_2OH]}{dt} = k[CH_2ClCH_2OH]^{0.38}$$

Table 2. Samples of 0.05 litre 0.01 M 2-chloro-ethanol subjected to ultrasonic waves of 0.8 Mcps and acoustic power 43 watts. 25°C. $t_{calc.} = \frac{1}{k_{graf.}} f(x)$; $k_{graf.} = 105 \times 10^{-6}$ and $k_{calc.} = 116 \times 10^{-6} \cdot (\text{mole/litre})^{0.62}\ \text{min}^{-1}$.

which equation by integration gives

$$t = \frac{1}{k} f(x) = \frac{1}{k} \frac{1}{0.62} [(a)^{0.62} - (a-x)^{0.62}]$$

Table 2 gives the results from experiments with a 0.01 M solution of 2-chloro-ethanol, $\nu = 0.8$ Mcps, and the acoustic power 43 watts. From the table it appears that the reaction follows the above integrated form of the rate equation fairly well. For comparison of the rate of reaction in the ultrasonic field with that without ultrasonic waves a value of the rate constant at 25°C extrapolated from the data of Radulescu and Muresanu [9] should be stated $k_1 = 6 \times 10^{-8}$ min^{-1} and thus the rate of reaction is considerably increased

Table 4. The dependence of the rate constant k at 25°C on the volume of sample V_s in experiments with a 0.01 M solution of 2-chloro-ethanol at $\nu = 0.8$ Mcps and the acoustic power 43 watts. $l_0 = 5.0$ cm and $A_R = 15.9$ cm^2.

Sample V_s litre	Height of liquid column of sample l_1 cm	$\frac{10^3}{(l_0 + l_1) A_R}$ litre^{-1}	$k_{exp.}10^6$	$k_{calc.}10^6$
0.050	3.15	7.72	105	116
0.075	4.72	6.47	88	81
0.100	6.29	5.57	66	60
0.125	7.86	4.89	53	46
0.150	9.44	4.36	40	37
0.175	11.01	3.93	27	30
0.200	12.58	3.58	24	25

in the ultrasonic field. In Table 3 are the experimental values of the rate constant k found in experiments with 0.05 litre sample and with varying values of the acoustic power W_P and the concentration of 2-chloro-ethanol at $\nu = 0.8$ Mcps and extended up to 100 min.

For comparison the values calculated from

$$k = 2.48 \times 10^{-2} \left(\frac{10^3}{(l_0 \times l_1) A_R} \right)^{2.0} W_P^{1.1} \nu^{-1} \text{ (mole/litre)}^{0.62} \text{ min}^{-1}$$

are also given in Table 3.

It is remarkable that the experiments at 2.4 Mcps, which is indicated in Table 3, also look as if they comply with the expression for the rate constant at $\nu = 0.8$ Mcps, but this fact is for the present not sufficient to elucidate the dependence on frequency, the previously mentioned experiments with a 0.01 M solution also being taken into account.

In Table 4 are the experimental and calculated values of the rate constant k originating from experiments with a 0.01 M solution of 2-chloro-ethanol, $\nu = 0.8$ Mcps, $W_P = 43$ watts and varying volume of sample V_s extended up to 120 min.

From the results of the experiments it has been established that the ultrasonic waves promote the liberation of chloride ions from 2-chloro-ethanol in pure aqueous solution and that there is a connection between the rate of reaction in the ultrasonic field and the experimental conditions by which the experiments are performed, which in this instance means the acoustic energy dissipated per unit volume. When the chemical activation is connected with the acoustic energy dissipated in the sample, a subsequent investigation on the absorption coefficients of sound in solutions of 2-chloro-ethanol may possibly give important information, whether the activation is connected with the absorption and thus a relaxation mechanism alone or also other factors are of importance.

The experiments with varying volumes of sample have revealed a deficiency as to the present experimental arrangement. Because of the distance l_0 between the transducer and the "acoustic window" in the reaction cylinder only a part of the acoustic energy emitted has been available for the present purpose of activation in the sample, and thus l_0 has to be as small as possible.

When all the experiments are carried out with solutions containing air and with free access to the air, oxidation is to be expected in the samples exposed to the ultrasonic waves. This fact may have nothing to do with the liberation of chloride ions from the 2-chloro-ethanol, but it should be noted that aldehyde, possibly originating from 1,2-ethanediol (glycol), has been demonstrated in the samples, and may thus be regarded as a secondary phenomenon.

Acknowledgements. I am much indebted to professor R. E. H. Rasmussen for his hospitality, kindness and many interesting discussions, and to professor Carl Faurholt for his kind interest in the work. Finally I wish to thank Mr. S. J. Gjendal, electrical engineer, M. Sc., for technical support and Mr. C. Hartvig Andersen for promptitude in making requisite instruments.

Über Merkurierungen mit Quecksilbercyanat

ERIK SÖDERBÄCK

Chemisches Institut der Universität Uppsala, Schweden

Es wurden Cyanatomerkuriverbindungen von Pyrrol, Furan und Thiophen sowie von den 2-Methylderivaten der beiden letzteren durch Einwirkung von Merkuricyanat in Wasser auf die Wasserstoffverbindungen dargestellt. Von Pyrrol wird dabei in sehr glatter Reaktion ausschliesslich Dimerkuriverbindung gebildet, von Furan und Thiophen Mono- nebst Diderivat und von 2-Methylfuran (Silvan) und 2-Thiotolen lediglich 5-Monoderivat. Die Monoderivate sind gut kristallisierte Verbindungen mit scharfen Schmelzpunkten, die Diderivate sind nicht ohne Zersetzung schmelzbar. Die Monoderivate konnten auch in glatt verlaufenden Reaktionen durch Einwirkung von Merkuricyanat auf die entsprechenden Merkuridiaryle in Aceton gewonnen werden; es zeigte sich, dass auch stark komplexe Merkurisaltze wie Cyanid und $Hg(SCN)_4Cl_2$ einer solchen Umsetzung fähig sind. Bei Behandlung von Monomerkuricyanate mit Natriumjodid in Aceton werden sie in Merkuridiaryle zurückverwandelt, wobei die Cyanatgruppe als Natriumcyanat quantitativ ausgeschieden wird.

Das Quecksilberchlorid gibt bekanntlich Addukte mit einer Menge von Stoffen, die als Elektrondonatoren fungieren können. Wegen der grossen Ähnlichkeit zwischen Chlorid und Cyanat kann vermutet werden, dass das Cyanat zu analoger Adduktbildung im Stande ist. Da die Merkurierung mit Quecksilbercyanat wenigstens nicht schneller als diejenige mit dem Chlorid verläuft, sind die Aussichten zur Isolierung von Cyanataddukten, z.B. mit in Petroleum vorkommenden Schwefelverbindungen, gut.

In einer früheren Mitteilung [1] ist über die Darstellung und Eigenschaften einiger Metallcyanate berichtet worden. Besonderes Interesse wurde dabei dem Merkuricyanat $Hg(OCN)_2$ gewidmet, namentlich wegen gewisser hervorstechenden Ähnlichkeiten mit Quecksilberchlorid. Von diesen wurde der merkurierende Effekt von $Hg(OCN)_2$ auf gewisse heterocyklische Kerne kurz gestreift. Diese Reaktion ist nun etwas ausführlicher studiert worden, und die dabei gewonnenen Resultate sollen hier besprochen werden.

Auf Benzol und Benzolhomologen ist $Hg(OCN)_2$ eben wie $HgCl_2$, wenigstens bei Zimmertemperatur, ohne Einwirkung; mit Pyrrol, Furan und Thiophen sowie deren Homologen treten in Wasser Merkurierungen ein und die dabei entstehenden Produkte sind mit denjenigen von $HgCl_2$ als merkurierendes Agens durchaus analog. Besonders lebhaft ist in beiden Fällen die Reaktion mit Pyrrol; es wird sofortiges Ausfallen einer weissen Substanz beobachtet, wenn eine alkoholische Lösung von Pyrrol zu einer wässrigen gesättigten

Lösung von $HgCl_2$ bezw. $Hg(OCN)_2$ getropft wird. Die bei der Reaktion mit $Hg(OCN)_2$ entstehende Cyansäure tritt in so grossen Konzentrationen auf, dass sie trotz ihrer grossen Hydrolysengeschwindigkeit leicht durch den stechenden Geruch und andere Eigenschaften nachgewiesen werden kann. Das Reaktionsprodukt ist in diesem Fall Dicyanatomerkuripyrrol $C_4H_2NH(HgOCN)_2$ über dessen Struktur gegenwärtig nichts bestimmtes ausgesagt werden kann.

Die Reaktion von $Hg(OCN)_2$ mit Furan und Thiophen hat einen wesentlich langsameren Verlauf als mit Pyrrol und in diesem Fall entstehen eben wie mit $HgCl_2$ teils Mono- und teils Dimerkurierungsprodukte, von denen erstere als 2- und letztere als 2,5-Derivate zu betrachten sind. Sie können durch die Löslichkeit der Monoderivate in Äther leicht separiert werden; die Reindarstellung der Diderivate kann durch Extraktion mit Aceton bewirkt werden. Das Produkt aus Pyrrol ist in Aceton reichlich löslich, dasjenige aus Furan weniger und dasjenige aus Thiophen am schwersten löslich. Wenn die 2- oder 5-Stellung in Furan oder Thiophen durch Methyl besetzt ist, werden ausschliesslich Monoderivate gebildet, wodurch die Annahme, dass die Dimerkurierung in 2- und 5-Stellung angreift, erhärtet wird.

Die bisher dargestellten Monoarylmerkuricyanate sind gut kristallisierbare, in Wasser unlösliche Verbindungen von bestimmten Schmelzpunkten, die wesentlich niedriger als diejenigen der entsprechenden Chloride liegen. Sie können auch nach einer zweiten Methode erhalten werden; es ist lange bekannt, dass Quecksilberverbindungen vom Typus R_2Hg, wo R ein aliphatisches oder aromatisches Radikal bedeutet, mit Merkurisaltzen leicht nach der Gleichung

$$R_2Hg + HgX_2 \longrightarrow 2\ RHgX$$

disproportioniert werden. Als Lösungsmittel werden meistens Alkohol oder Aceton verwendet. Die Reaktion mit $Hg(OCN)_2$ wurde in Aceton studiert und als Merkuride diejenige von Phenyl, 2-Furyl, 2-Thienyl sowie die 5-Methylderivate der beiden letzteren benutzt. Die daraus gebildeten Arylmerkuricyanate waren mit den durch direkte Merkurierung von den entsprechenden Wasserstoffverbindungen gewonnenen identisch. Der Reaktionsverlauf war schon bei Zimmertemperatur ein sehr glatter und Steigerung der Temperatur wurde deshalb nur zwecks Abschliessen der Reaktion zugegriffen.

Die obige Reaktion kann in gewissen Fällen auch mit stark komplexen Hg^{2+}-Salzen wie Cyaniden durchgeführt werden. So konnten mit der Verbindung $Hg(SCN)_4Cl_2$, also dem Hg^{2+}-Salz des Chlor-merkaptothiodiazols [3], und Merkuridiphenyl sowie Merkuri-2-di-thienyl gut kristallisierte Verbindungen von scharfen Schmelzpunkten, $C_6H_5Hg(SCN)_2Cl$ bzw. $C_4H_3S{\cdot}Hg(SCN)_2Cl$, dargestellt werden. Der Umstand dass auch stark komplexe Merkurisalze reagieren lässt vermuten, dass auch das mit Merkuricyanat isomere Fulminat sich mit gewissen Hg-Dialkylen oder Arylen umsetzen lassen wird, wodurch vielleicht Initialzünder mit variabler Explosivität gewinnbar wären.

Mono-chlormerkuriverbindungen von Thiophen und Furan setzen sich in acetonischer Lösung glatt mit einem Mol Jod- bezw, Rhodannatrium zu Jod- bzw. Rhodan-merkurithiophen oder Furan um. Ein weiteres Mol NaJ bewirkt aber Bildung von HgJ_2 als komplexes Jodid und danebst Merkuridiaryl. Da

das komplexe $NaHgJ_3$ in Aceton löslich ist, kann das gebildete Diarylquecksilber durch Ausfällen mit Wasser isoliert werden. Phenyl und *p*-Tolyl und α-Naphthylmerkurichlorid geben nur die erste Stufe der Reaktion [4]. Furyl- und Thienylmerkuricyanat reagieren mit NaJ in Aceton genau wie die Chloride, wobei die Cyanatgruppe als NaOCN quantitativ abgeschieden wird, das nach Waschen mit Aceton von grosser Reinheit, namentlich ganz frei von Karbonat, isoliert werden kann.

EXPERIMENTELLER TEIL

Das für die folgenden Versuche benutzte Merkuricyanat war aus Quecksilberchlorid und Silbercyanat in Äther nach dem in einer früheren Mitteilung gegebenen Verfahren dargestellt.

Merkurierung von Pyrrol. Zu einer Lösung von 5,54 g $Hg(OCN)_2$ in 100 ml Wasser wurden langsam und unter regem Umschütteln 0,8 (ber. 0,67) ml Pyrrol in 10 ml Alkohol gelöst, getropft. Ein weisser Niederschlag entstand sofort, und der Geruch von HOCN wurde beobachtet. Das Reaktionsgemisch blieb über Nacht stehen und der Niederschlag dann auf ein Glasfilter G4 gesammelt, mehrmals mit Wasser gewaschen und in Vakuum über H_2SO_4 getrocknet. Gewicht 5,24 g statt 5,22. Das wässrige Filtrat enthielt nur geringe Mengen von Hg-Salz. Das Präparat wurde mit 500 ml Aceton extrahiert, wobei 0,75 g ungelöst blieben. Durch Abdestillieren des Acetons konnten 4,33 g des Merkurierungsproduktes als rein weisses undeutlich kristallines Pulver isoliert werden. Die Substanz wird von Salzsäure glatt unter CO_2-Entwicklung aufgelöst, was bei der Hg-Analyse (gravimetrisch als HgS) ausgenutzt wurde. (Gef. Hg 73,10; N 7,68 (Kjeldahl). Ber. f. $C_4H_3N(HgOCN)_2$ (550,3): Hg 72,91; N 7,69).

Merkurierung von Thiophen. 26,9 g $Hg(OCN)_2$ wurden in 450 ml Wasser gelöst und zu der Lösung eine solche von 31 g NaAc (Anhydrid) in 140 ml Wasser nebst 10 ml Thiophen gegossen. Das Gefäss, eine Flasche von 1 Liter, wurde mit einem Kork verschlossen. Das Reaktionsgemisch blieb während 10 Tagen bei Zimmertemperatur stehen; dann und wann wurde umgeschüttelt und die gebildete Kohlensäure ausgelassen. Der Niederschlag von Merkurierungsprodukten löste sich anfänglich im Thiophenüberschuss auf, fiel aber in dem Masse als dieses verbraucht wurde wieder aus. Wenn die Reaktion abgeschlossen war, wurde der Niederschlag auf ein Glasfilter G4 gesammelt, mehrmals mit Wasser gewaschen und in Vakuum über H_2SO_4 getrocknet. Ausbeute 26,6 g. Das Präparat wurde mit 1 500 ml Äther extrahiert, der unlösliche Rückstand mit Äther gewaschen und getrocknet; Gewicht 8,8 g. Die Ätherlösung wurde auf dem Wasserbade konzentriert, wonach 17 g Monomerkurierungsprodukt isoliert und durch nochmaliges Umlösen aus Äther gereinigt wurden. Prismen von Schmelzp. 104—105°. Für die Hg-Bestimmung wurde mit konz. HCl zersetzt und in der verdünnten Lösung Hg als HgS bestimmt. Stickstoff nach Kjeldahl. (Gef. Hg 61,56; N 4,27. Ber.f. $C_4H_3SHgOCN$ (325,63): Hg 61,61; N 4,30). Löslichkeit in Äther bei 20° 1,75 g pro 100 ml.

Der in Äther unlösliche Rückstand von 8,8 g wurde mit heissem Aceton extrahiert, was ziemlich zeitraubend war. Es konnten dabei 6,2 g Substanz ausgelöst und durch Einengen der Lösung isoliert werden.

Für die Hg-Analyse wurde die Substanz mit Salzsäure zersetzt und aus der verdünnten Lösung HgS ausgefällt. Stickstoff nach Kjeldahl. (Gef. Hg 70,55; N 4,77. Ber.f. $C_4H_2S(HgOCN)_2$ (567,35): Hg 70,72; N 4,93). Löslichkeit in Aceton bei 20° 0,08 g pro 100 ml. Molverhältnis Mono:Dimerkuriprodukt betrug bei diesen Versuch 4,7. Merkurierungen von Thiophenen mit $HgCl_2$ sind in grosser Anzahl von Steinkopf [2] und Mitarbeitern ausgeführt worden.

Merkurierung von Furan. 14,23 g $Hg(OCN)_2$ wurden in 220 ml H_2O gelöst und diese Lösung mit einer solchen von 16 g NaAc in 75 ml H_2O gemischt. Es wurden nun 5 ml Furan zugestzt, wonach das Reaktionsgemisch bei Zimmertemperatur aufbewahrt wurde. Ab und zu wurde umgeschüttelt. Nach einem Tage war eine beträchtliche Quantität eines gelbweissen Niederschlags ausgefallen. Nach zwei Tagen wurde das gebildete CO_2 ausgelassen und dann weiter alle zwei Tage. Nach 14 Tagen konnte die Reaktion als beendet angesehen werden; der Niederschlag wurde abfiltriert, mit Wasser gewaschen und getrocknet. Ausbeute 13,22 g. Bei Extraktion mit 800 ml Äther wurde ein in Äther unlöslicher Rückstand von 4,80 g erhalten. Durch Einengen der Ätherlösung

auf dem Wasserbade konnten 7,9 g einer in glänzenden Prismen kristallisierenden Substanz isoliert werden. Die Substanz wurde durch Umlösen aus Äther gereinigt und schmolz dann bei 122—123°. (Gef. Hg 65,05; N 4,52. Ber. $C_4H_3O.HgOCN$ (309.69): Hg 64.78; N 4,53). Löslichkeit in Äther bei 20° 1,04 g in 100 ml.

Das in Äther nicht lösliche Reaktionsprodukt, 4,8 g, wurde mit 500 ml Aceton extrahiert, wobei 0,5 g ungelöst blieben. Die etwas braun gefärbte Lösung wurde durch Abdestillieren des Acetons konzentriert, wobei zuletzt eine weisse feinkristallinische Substanz ausfiel. Totalausbeute 3,91 g. (Gef. Hg 72,62; N 5,01; Ber. f. $C_4H_2O(HgOCN)_2$ (551,31): Hg 72,78; N 5,08). Löslichkeit in Aceton bei 20° 0,75 g pro 100 ml.

Die Verbindung ist wie die analoge Thiophenverbindung nicht ohne Zersetzung schmelzbar. Das Molverhältnis Mono:Diverbindung beträgt bei diesem Versuch 3,2.

Chlormerkurifurane sind von Gilman und Wright [5] dargestellt worden.

Merkurierung von 2-Methylthiophen. Zu einer Lösung von 25,5 g $Hg(OCN)_2$ in 400 ml H_2O wurde eine solche von 33 g NaAc in 110 ml H_2O gesetzt und ferner 9,5 ml 2-Thiotolen. Schon nach einigen Minuten Kristallausfällung. Das Reaktionsgemisch wurde bei Zimmertemperatur aufbewahrt und dann und wann umgeschüttelt; jeden Tag wurde die Flasche zwecks Druckausgleich geöffnet. Nach 6 Tagen konnte keine weitere Drucksteigerung beobachtet werden, und der Niederschlag wurde abfiltriert, mit Wasser mehrmals gewaschen und in Vakuum über Schwefelsäure getrocknet. Ausbeute 29,9 g. Teor. f $CH_3C_4H_2S.HgOCN$ 30,43 g. Die Substanz wurde mit 4 Liter Äther extrahiert, wobei 0,09 g ungelöst blieben. Der Äther wurde zum grössten Teil abdestilliert, wobei 28,4 g rein weisser Kristalle erhalten wurden. Schmelzp. 146—146,5°. Umlösen aus Äther bewirkte keine Änderung des Schmelzpunktes. Da die Verbindung durch konzentrierte Salzsäure recht träge zersetzt wird, wurde die Substanz zwecks Hg-Analyse mit Brom in Wasser zersetzt, das überschüssige Brom nach Filtrieren mit Hydroxylaminhydrochlorid reduziert und dann Hg als HgS mit H_2S ausgefällt. (Gef. Hg 59,50; N 4,05 Ber.f. $CH_3C_4H_2S.HgOCN$ (339,76): Hg 59,05; N 4,12).

Merkurierung von 2-Methylfuran (Silvan). Eine Lösung von 24,9 g $Hg(OCN)_2$ in 440 ml Wasser wurde mit einer solchen von 33 g NaAc in 150 ml Wasser gemischt und zu der Lösung 10,0 ml Silvan gegossen. Nach kurzer Zeit Ausfällung eines gelblich weissen Körpers. Das Reaktionsgefäss wurde jeden Tag geöffnet. Nach 5 Tagen konnte keine weitere Drucksteigerung beobachtet werden, und nach 8 Tagen wurde der Niederschlag mit Wasser gewaschen und in Vakuum getrocknet. Gewicht 26,0 g; teor. 28,3 g. Präparat wurde mit 1 200 ml Äther extrahiert, wobei 2,3 g einer graubraunen Substanz ungelöst blieb. Die fast farblose Ätherlösung wurde auf dem Wasserbade auf ein Volumen von 50 ml konzentriert, wobei reichliche Kristallisation in Tafeln eintrat. Nach Kühlen in Kälteschrank wurde abfiltriert und in Vakuum getrocknet. Gewicht 21,3 g Schmelzp. 114—115°. (Gef. Hg 62,35; N 4,27 Ber. f. $CH_3C_4H_2O.HgOCN$(323,73): Hg 61,98 N 4,32).

Darstellung von C_6H_5HgOCN aus $(C_6H_5)_2Hg$ und $Hg(OCN)_2$. 3,54 g Quecksilberdiphenyl wurden in 25 ml Aceton gelöst und dazu eine Lösung von 2,84 g $Hg(OCN)_2$ in 15 ml Aceton gegeben. Reaktion unter schwacher Wärmeentwicklung. Nach einiger Zeit wurde die Lösung filtriert und das Aceton fast vollständig abdestilliert, wobei zuletzt plötsliche Kristallisation eintrat. Gewicht der Kristalle nach Trocknen in Vakuum 6,13 g; teor. 6,38 g. Löslich mit einem kleinen Rückstand in 400 ml Äther. Nach Filtrieren wurde der Äther bis auf 50 ml abdestilliert, wobei Kristallisation in glänzenden Schuppen eintrat. Gewicht nach Trocknen 4,85 g. Schmp. 124—125°. (Gef. Hg 62,81. Ber. f. C_6H_5HgOCN (319,73): Hg 62,74).

Das entsprechende Cyanid C_6H_5HgCN kann in ganz analoger Weise aus $Hg(CN)_2$ dargestellt werden. Es schmilz bei 204—205° und ist in Äther sehr schwerlöslich. Kristallisiert aus Aceton in Prismen. Die Thiophen- und Furancyanide sind auch dargestellt worden. Sie schmelzen erheblich niedriger, ersteres bei 120—121° und letzteres bei 123—123,5°.

Einwirkung von $(C_6H_5)_2Hg$ auf $Hg(SCN)_4Cl_2$. 1,77 g $(C_6H_5)_2Hg$ wurden in 25 ml Aceton gelöst und zu dieser Lösung 2,52 g $Hg(SCN)_4Cl_2$ gesetzt. Nach wenigen Augenblicken war der Kolbeninhalt zu einem Kristallblei erstarrt. Durch Zusatz von weiteren 50 ml Aceton und Wärmen konnte praktisch vollständige Auflösung erreicht werden. Durch Abkühlen der heiss filtrierten Lösung konnte Kristallisation bewirkt werden. Abfiltrieren und Waschen mit kleinen Acetonmengen und Trocknen in Vakuum. Gewicht 2,65 g. Die Substanz wurde aus 50 ml siedendem Aceton umkristallisiert und schmolz dann bei 129,5—130°; Prismen. (Gef. Hg 46,42. Ber. f. $C_6H_5Hg(SCN)_2Cl$ (429,3): Hg 46,73).

Die aus Hg-2-Dithienyl in analoger Weise dargestellte Verbindung C_4H_3S-Hg(SCN)Cl_2 hat denselben Schmelzpunkt, 129—130°, was wahrscheinlich in der Grösse des Chlordithiocyanations seine Erklärung findet.

Darstellung von C_4H_3S-HgOCN aus $Hg(C_4H_3S)_2$ und $Hg(OCN)_2$. Quecksilber 2-Dithienyl wurde nach Steinkopf [4] dargestellt. 3,66 davon und 2,84 g $Hg(OCN)_2$ wurden in 40 ml Aceton zu einer etwas trüben Lösung aufgelöst. Nach etwa 12-stündigem Stehen bei Zimmertemperatur wurde die Lösung durch ein Glasfilter G4 filtriert und das Aceton auf dem Wasserbad vollständig abdestilliert. Der flüssige Rückstand erstarrte sofort bei Kühlen mit kaltem Wasser. Gewicht nach Trocknen in Vakuum 6,46 statt 6,51 g; löste sich vollständig in 370 ml Äther. Nacht Filtrieren durch Glasfilter G4 wurde der Äther bis auf ein Volumen von 50 ml abdestilliert, wobei Kristallisation eintrat. Abfiltrieren und Waschen mit etwas Äther und Trocknen in Vakuum. Gewicht 4,46 g. Schmelzp. 104—105°. Identisch mit der durch direkte Merkurierung von Thiophen mit $Hg(OCN)_2$ dargestellten Substanz.

Darstellung von C_4H_3O.HgOCN aus 2,2'Quecksilberdifuryl und $Hg(OCN)_2$. 2,2'Quecksilberdifuryl wurde nach Gilman und Wright [5] aus 2-Chlormerkurifuran und NaJ in Aceton dargestellt, wobei auf die etwas abenteuerliche Reinigung durch Vakuumdestillation verzichtet wurde. 1,20 g der Verbindung wurden in 10 ml Aceton gelöst und dazu eine Lösung von 1,04 g $Hg(OCN)_2$ in 5 ml Aceton gegeben. Nach einigem Stehen bei Zimmertemperatur wurde das Aceton abdestilliert. Der flüssige Rückstand erstarrte sofort bei Kühlen mit kaltem Wasser. Er wurde pulverisiert, mit 20 ml Wasser gewaschen und in Vakuum getrocknet. Gewicht 1,85 g; löste sich vollständig in 200 ml Äther. Nach Abdestillieren des Äthers konnten 1,7 g Substanz als glänzende farblose Prismen isoliert werden. Schmelzp. 122—122,5°. Identisch mit dem durch direkte Merkurierung von Furan dargestellten Cyanat.

Darstellung von Quecksilber-5,5'Dithiotolyl. 16 g $CH_3C_4H_2S$.HgOCN wurden glatt in 200 ml Aceton gelöst und zu dieser Lösung eine solche von 16 g NaJ in 75 ml Aceton gesetzt. Sofortiges Ausfällen einer weissen feinkristallinischen Substanz. Nach Stehen über Nacht wurde abfiltriert, mehrmals mit Aceton gewaschen und getrocknet. Gewicht 2,83 g. Die Substanz war reines NaOCN. Nach Konzentrieren der Acetonlösung auf ein Volumen von 50 ml wurden 400 ml Wasser zugestzt, wobei eine weisse Substanz ausfiel. Nachdem sich die Mutterlauge geklärt hatte, wurde der Niederschlag auf einem Glasfilter G4 gesammelt, mit Wasser gewaschen und in Vakuum getrocknet. Gewicht 11,97 g. Umlösen aus 700 ml Äther und Konzentrieren der Lösung auf dem Wasserbade bis auf 35 ml. Nach Kühlen in Kühlschrank wurden die Kristalle abfiltriert und getrocknet. Gewicht 9,03 g. Nach Reinigung durch Umkristallisation aus siedendem Alkohol schmolz die Substanz bei 158—160°. Nach Steinkopf schmilz die Substanz bei 162—162,5°.

Überführung von Quecksilber 5,5'Dithiotolyl in 5-Merkuricyanato-2-Thiotolen mit $Hg(OCN)_2$. 1,97 g $(CH_3C_4H_2S)_2Hg$ wurden in 50 ml Aceton suspendiert wobei partielle Auflösung eintrat. Es wurden nun 1,42 g $Hg(OCN)_2$ zugestzt, was schnelle Auflösung des Merkurids bewirkte. Nach Stehen über Nacht wurde die Flüssigkeit filtriert und das Aceton bis zum Eintreten von Kristallisation abdestilliert. Kühlen mit kaltem Wasser bewirkte reichliche Kristallisation und nach einigem Stehen wurden die Kristalle abfiltriert und getrocknet. Gewicht 2,07 statt 3,39 g. Reinigung durch Umlösen aus 280 ml Äther. Blättchen von Schmelzp. 145—146°. Aus Aceton konnte die Substanz als grosse Tafeln von rhombischem Habitus erhalten werden.

Für die Ausführung von Kjeldahlanalysen danke ich dem hiesigen Analytischen Centrallaboratorium, Vorstand Dr. F. Nydahl.

Amino-deoxy- and Deoxy-sugars from Methyl 3-Oxo-β-D-glucopyranoside

BENGT LINDBERG and OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

Methyl 3-oxo-β-D-glucopyranoside has been converted to the two corresponding 3-amino-3-deoxy-glucosides and to the 3-deoxy-glucoside.

Oxo-glucosides should be useful intermediates for syntheses in the carbohydrate field, where the recent isolation of a number of "non-classical" sugars from natural sources has created new synthetic problems. For example methyl β-D-glucopyranoside has been transformed into the D-alloside *via* the 3-oxo-derivative [1], thus proving the position of the oxo-group in the latter compound. A further example is the synthesis of a branched sugar, related to noviose by a sequence of reactions involving oxidation to an oxo-derivative followed by a Grignard reaction [2]. The present paper describes studies of some reaction routes, starting from methyl 3-oxo-β-D-glucopyranoside [3](I).

The oxo-glucoside (I) on treatment with hydroxylamine hydrochloride in aqueous solution was transformed into the oxime (II) in a yield of 95 % or better. The pH was kept at 4.0 by addition of sodium hydroxide, and this was also used to follow the oximation analytically [4]. The oxime proved to be quite labile and decomposed easily into the oxo-glucoside. Thus on paper chromatography in acid solvent systems or on attempted deionisation by carbon column chromatography, the oxo-glucoside was formed almost quantitatively. By careful concentration of the aqueous solution to dryness, after adjustment of the pH to 7.0, and extraction of the solid residue with butanol, the oxime was finally obtained reasonably pure, and this butanolic solution was used for further reactions.

Catalytic reduction of inososes [5] and oxo-glucopyranosides [6] with platinum catalysts is known to yield preferentially the isomer, in which the new hydroxyl is axial in the most stable chair form. Similar results have been obtained by catalytic reduction of oximes or hydrazones in the cyclohexane series [7,8]. Reduction with sodium amalgam, on the other hand, yields comparable amounts of equatorial and axial substituents or sometimes even higher proportions of the former, particularly in the case of oximes and hydrazones [8].

Catalytic reduction of the oxime (II) using Adams' catalyst, gave a crystalline compound, m.p. 199—200°, $[\alpha]_D$ —54° (water) in 85 % yield; this should be methyl 3-amino-3-deoxy-β-D-allopyranoside (III). A study of the optical rotations (Table 1) supports this conclusion. On reduction of II with sodium amalgam, a different compound, m.p. 205—207°, $[\alpha]_D$ —38° (water) was obtained in a yield of 45%. Peat and Wiggins [9] prepared methyl 3-amino-3-deoxy-β-D-glucopyranoside (IV) by another route and report the same m.p. but a lower optical rotation, —47°. The tetra-acetates of the two products, however, have identical constants, m.p. 159—160°, $[\alpha]_D$ —21.4° and —22°, resp. (chloroform). Our value for the optical rotation of the unacetylated product agrees somewhat better with the corresponding rotation for methyl β-D-glucopyranoside (—34°), which should be similar. The presence of the amino-alloside (III) in the mother liquors was demonstrated by paper chromatography and paper electrophoresis.

It is of interest that 3-amino-3-deoxy-D-glucose is identical with kanosamine, a component of the antibiotic kanamycin [10]. Lemieux and Chu [11] have recently demonstrated that some substances prepared by Freudenberg *et al.*[12] and claimed to be 3-amino-3-deoxy-D-glucose derivatives are actually the corresponding allose derivatives. The same seems to be true of some compounds recently prepared by Wolfrom *et al.*[13] by routes, analogous to those

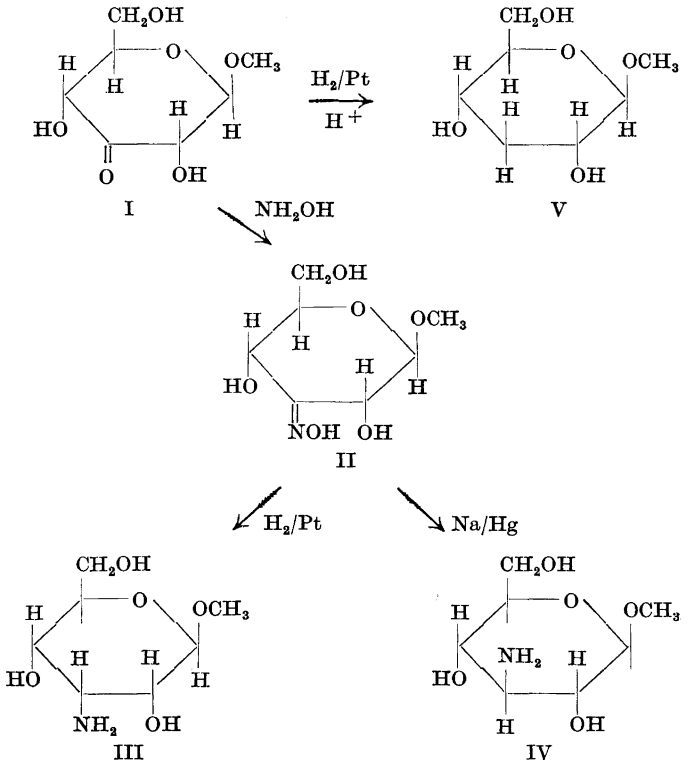

Table 1. Optical rotations of some methyl β-glycosides.

Substance		$[\alpha]_D$	$[M]_D$
Methyl β-D-glucopyranoside		−34°	6 600°
Methyl β-D-allopyranoside		−53°	10 300°
Methyl 3-amino-3-deoxy-β-D-glucopyranoside	(a)	−47°	9 100°
	(b)	−38°	7 300°
Methyl 3-amino-3-deoxy-β-D-allopyranoside		−54°	10 400°
Methyl 3-deoxy-β-D-glucopyranoside		−46°	8 200°
Methyl 3-oxo-β-D-glucopyranoside		−63°	12 100°

a. Ref.[9]
b. Present investigation.

used by Freudenberg *et al.* A new synthesis of 3-amino-sugars has recently been described by Baer and Fisher [14].

Posternak [15] has shown that the oxo-group in *myo*-inosose-2 is reduced to a methylene group on catalytic reduction with Adams' catalyst in acid solution. An analogous reduction of I yielded 59 % of methyl 3-deoxy-β-D-glucoside (V), m.p. 94—96°, $[\alpha]_D$—46° (water) together with smaller amounts of unchanged starting material and a mixture of methyl β-D-glucopyranoside and methyl β-D-allopyranoside. The glucoside was transformed into the β-tetraacetate of the free sugars, m.p. 130—131°, $[\alpha]_D$ −19° (chloroform). Richtmyer and Pratt [16] report m.p. 129—130°, $[\alpha]_D$ −14°, Černý and Pacák [17] m.p. 129—130°, $[\alpha]_D$ −20° for this substance. The free sugar, which was not isolated, had an electrophoretic mobility of 0.85, relative to glucose, in borate buffer. The corresponding value for 3-*O*-methyl-D-glucose is 0.76; close agreement between these values is to be expected [18].

Glycosides of deoxy-sugars hydrolyse faster than the corresponding glycosides of the parent sugars (*cf.* Ref.[19]). Thus Richards [20] reports rate constants of 1.7×10^{-2} and 2.3×10^{-3} for the hydrolysis of methyl 3-deoxy-α-D-glucopyranoside and methyl α-D-glucopyranoside, respectively, in N sulphuric acid at 100°. Under the same conditions, the values 6×10^{-2} and 7.8×10^{-3} (Briggs' logarithms, time in min) were now obtained for the corresponding β-glucosides. The first of these values is rather inaccurate, as the hydrolysis, which was followed polarimetrically, is accompanied by formation of the 1,6-anhydrosugar [16] and also because the reaction was inconveniently fast under the conditions used.

EXPERIMENTAL

Melting points are corrected. Solutions were concentrated under reduced pressure at a bath temp. of about 40°.

Paper chromatography was done on Whatman No. 1 and No. 3 MM filter papers using the solvent systems (v/v):

a. Ethyl acetate-acetic acid-water, 3:1:3 (upper phase)
b. Butanol-ethanol-water, 10:3:5

Table 2. Chromatographic and electrophoretic data for some methyl glycosides.

Substance	$R_{Glucose}$ (solvent a)	$M_{Glucose}$ (borate buffer)
Methyl β-D-glucopyranoside	1.94	0.16
Methyl β-D-allopyranoside	2.23	0.49
Methyl 3-deoxy-β-D-glucopyranoside	3.44	0.14
Methyl 3-oxo-β-D-glucopyranoside	3.57	0.60
Methyl 3-amino-3-deoxy-β-D-glucopyranoside	1.80	0.13
Methyl 3-amino-3-deoxy-β-D-allopyranoside	1.80	0.09

Paper electrophoreses were done on Whatman No. 1 filter paper in 0.1 M borate buffer of pH 10 and in 0.1 M acetate buffer at pH 4.

The following spray reagents were used: silver nitrate in acetone-ethanolic sodium hydroxide, *p*-anisidine hydrogen chloride in butanol, resorcinol-hydrochloric acid in ethanol and ninhydrin in ethanol-acetic acid. Chromatographic and electrophoretic data are summarised in Table 2.

Oximation of methyl 3-oxo-β-D-glucopyranoside (I). In a typical experiment, I (0.43 g) was dissolved in a solution of hydroxylamine hydrochloride (1.38 g) in water (40 ml) which had previously been adjusted to pH 4.0. The temperature was kept at 22° by external cooling and 0.1 N sodium hydroxide was added through an automatic titrator to keep the pH at 4.0. The reaction was followed by the consumption of sodium hydroxide; it was complete in about 8 h when the sodium hydroxide consumption corresponded to 97 % conversion. The aqueous solution was adjusted to pH 7, concentrated until the salts precipitated, and then further dried in a vacuum desiccator over silica gel. The solid residue was extracted with butanol (5 × 10 ml) and the filtered solution was concentrated to about 15 ml.

Methyl 3-amino-3-deoxy-β-D-allopyranoside. A solution of the oxime from 750 mg I in butanol (25 ml) was treated with hydrogen in the presence of Adams' catalyst (100 mg) for 20 h. The solution was filtered and concentrated to dryness. The crystalline residue on recrystallisation from ethanol gave pure III (435 mg), m. p. 199–200°, $[\alpha]_D^{20}$ −54° (water, c = 2). Fractionation of the material in the mother liquors on thick filter paper in solvent system a gave a further quantity of III (200 mg) together with smaller amounts of unidentified compounds, none of which seemed to be identical with IV. (Found: C 43.9; H 8.03; N 6.78. Calc. for $C_7H_{15}NO_5$: C 43.5; H 7.83; N 7.25.)

Acetylation with acetic anhydride in pyridine gave the tetraacetate, which was crystallised from butanone, m. p. 179–180°, $[\alpha]_D^{23}$ −43° (chloroform, c = 1). (Found: C 50.5; H 6.33. Calc. for $C_{15}H_{23}NO_9$: C 49.9; H 6·42.)

Methyl 3-amino-3-deoxy-β-D-glucopyranoside. A solution of the oxime from 450 mg I in butanol (15 ml) was diluted with ethanol (25 ml) and 2.5 % sodium amalgam (20 g) was added in portions with vigorous stirring over 4 h. The pH was kept at 6 by addition of 5 % aqueous acetic acid. The product was then put on a carbon-Celite column and the salts were eluted with water and the glycosides with 5 % aqueous acetic acid. The glycoside fraction was concentrated to dryness, dissolved in water, filtered through a column of Dowex 2 (OH^-) and concentrated to dryness. The crystalline residue (362 mg) on crystallisation from ethanol yielded almost pure IV (202 mg), m. p. 198–200°. After two further crystallisations the substance was pure, m. p. 205–207°, $[\alpha]_D^{20}$ −38 (in water, c = 2). The mother liquors contained IV, smaller amounts of III and minor amounts of other unknown substances.

Treatment of IV with acetic anhydride and pyridine yielded the tetraacetate, m. p. 159–160°, $[\alpha]_D^{2}$ −22° (chloroform, c = 2).

Methyl 3-deoxy-β-D-glucopyranoside (V). Hydrogen was bubbled through a solution of I (450 mg) in 5 % aqueous sulphuric acid (25 ml) containing Adams' catalyst (from

200 mg of platinum dioxide) for 4 h with the addition of a second portion of catalyst (100 mg) after 2 h. The catalyst was filtered off, the acid was neutralised with barium carbonate, the barium salts were filtered off and the solution was concentrated to a thick syrup (440 mg). The product on fractionation on a cellulose column (45 × 3.5 cm) using butanol saturated with water as eluent, yielded V (293 mg), unchanged starting material (27 mg) and a mixture of methyl β-D-glucopyranoside and -allopyranoside (92 mg). V crystallised from methyl ethyl ketone on standing and was recrystallised from the same solvent, m. p. 94—96°, $[\alpha]_D^{20}$ −46° (water, c = 2). (Found: OCH_3 16.6. Calc. for $C_7H_{14}O_5$: OCH_3 17.4.)

Part of the product was converted into the β-tetraacetate of 3-deoxy-D-glucose, m. p. 130—131°, $[\alpha]_D^{20}$ −19° (in chloroform, c = 2).

Studies on Mechanically Degraded Cellulose

ANDERS ASSARSSON, BENGT LINDBERG
and OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

Mechanically degraded cellulose was investigated by reduction with borohydride, hydrolysis and isolation of the glycitols in the hydrolysate. The major component was D-glucitol, but D-arabitol, erythritol and traces of glycerol were also found. These results show that carbon-carbon as well as carbon-oxygen linkages are ruptured and thus strongly indicate that the degradation is entirely a mechanical effect.

Mechanical treatment of cellulose by grinding in a ball mill and in other ways produces severe degradation. Previous studies, which have been summarised by McBurney [1], have shown that the DP is decreased during milling. The carboxyl content increases only slightly, and it has been definitely proved that the degradation is not due to oxidation by atmospheric oxygen. As the degradation is rather independent of temperature, a hydrolytic mechanism has also been considered less likely. The most probable explanation is that the degradation is entirely mechanical. Hess and Steurer [2] have shown that the kinetic energy available from the impact of the balls on the cellulose fibre should be sufficient if converted directly to molecular vibrational energy to rupture covalent bonds. The energy requirements for the rupture of carbon-carbon and carbon-oxygen bonds are of the same order, 80—90 kcal., and it could be expected that both types would be broken. The present paper describes a study of the linkages broken when cellulose is ground in a ball mill.

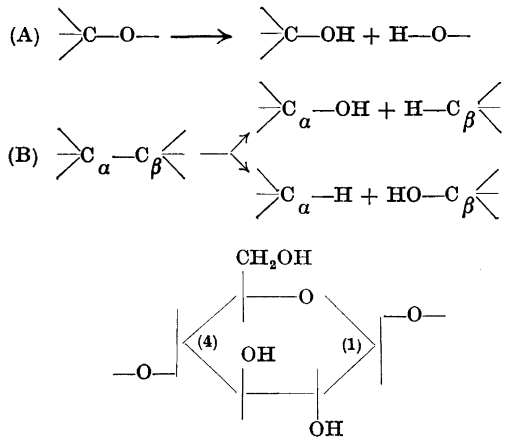
Cotton cellulose was ground in an agate ball mill and the copper number was determined at intervals (according to Hägglund). It rose from 0.2 to 6.5 in five days. A sample treated for 4 days was subjected to chemical investigation. A carbonyl determination by the borohydride method [3] indicated 2.7 carbonyl-groups per 100 glucose residues. According to a recent investigation [4], this value is somewhat too low and the real value should be about 35 % higher. The milled cellulose was treated with borohydride, filtered off and washed. The material that went into solution was recovered (0.5 %). Paper chromatographic investigation of this fraction indicated the presence of glucitol, cellobiitol and higher oligosaccharides together with glycitols with 3, 4 and 5

carbon atoms. The modified cellulose was subjected to a heterogeneous hydrolysis with N sulphuric acid. Most of the reducing sugars and any other aldehydes which might have been present were oxidised to acids by treatment with chlorite at pH 4 and removed by ion exchange. The last traces of sugars were removed by treatment with 0.5 N sodium hydroxide at 100°, followed by ion exchange. The neutral residue (0.6 %) contained components chromatographically indistinguishable from glucitol, arabitol, erythritol and glycerol. Their acetates were indistinguishable from the corresponding authentic acetates on chromatograms on dimethyl sulphoxide-impregnated paper [5], which gives good separation of the fully acetylated glycitols. Fractionation of the neutral mixture gave erythritol, D-arabitol and D-glucitol which were isolated and characterised as crystalline derivatives.

The relative proportions of glucitol, arabitol and erythritol were about 10:3:2, as estimated from the weights of the amorphous, not quite pure fractions obtained. 1,6-Anhydro-D-glucopyranose, which is known to be formed by the acid treatment of glucose [6], was also isolated. In many solvent systems it has the same R_F value as glycerol but the two substances can be separated by elution with butanone, saturated with water; traces of glycerol were detected using this solvent system.

Part of the residue from partial hydrolysis was hydrolysed completely and then worked up as above giving a small amount of neutral material (0.2 %) with the same chromatographic pattern as the material from the heterogeneous hydrolysis.

From these results it is obvious that both C—O and C—C linkages are broken. Rupture of these linkages could be either homolytic or heterolytic. A discussion of this and the subsequent reactions, leading ultimately to stable products, would be highly speculative, but for simplicity it may be assumed that the radicals or ions formed by rupture are stabilised by addition of the elements of water (A and B).



I

If a $C_{(1)}$—O or O—$C_{(4)}$ linkage in a glucose residue (I) of the cellulose molecule is broken, the final result should be equivalent to an acid hydrolysis, possibly accompanied in the second case by some inversion at $C_{(4)}$. Rupture of the linkage between the ring oxygen and either $C_{(1)}$ or $C_{(5)}$ would probably have a similar effect. Reduction and hydrolysis would then yield D-glucitol and possibly D-galactitol.

Rupture of a C—C linkage and subsequent reduction and hydrolysis should yield a glucitol with n carbon atoms together with an aldehyde of (6—n) carbon atoms, which would be removed by oxidation and ion exchange. It is easily seen that the glycitols which could be expected are D-arabitol, erythritol, glycerol and ethylene glycol. The first two were isolated and characterised and indications were found of the presence of glycerol, although in quite small quantities. The presence of ethylene glycol and of any methanol formed as a consequence of $C_{(5)}$—$C_{(6)}$ rupture might easily have been overlooked. D-Glucitol is, however, the major product, indicating that the C—O linkages are somewhat weaker than the C—C linkages. More detailed conclusions cannot be drawn from the results of this investigations, since a high percentage of the oxo-groups in the degraded cellulose is not accounted for and the determination of the relative proportions of the glycitols isolated is at best only semi-quantitative. In addition the course of the reactions leading to stabilisation of the primary products of the rupture of a linkage is quite unknown. As stated already the main result is the strong evidence of an entirely mechanical rupture of covalent linkages by mechanical treatment of cellulose, in agreement with the theory of Steurer and Hess [2].

EXPERIMENTAL

Melting points are corrected. Concentrations were done under reduced pressure at a bath temperature of about 40°.

Paper chromatograms were run on Whatman No. 1 and 3 MM filter papers, using the solvent systems (v/v):

a. Ethyl acetate-acetic acid-water, 3:1:3 (upper phase)
b. Butanone, saturated with water
c. Light petroleum. Paper impregnated with dimethylsulphoxide.

Silver nitrate in acetone-ethanolic sodium hydroxide was used as spray reagent for the detection of glycitols.

Preparation of degraded cellulose. Cellulose (cotton linters) was disintegrated in a Wiley mill and then milled in an agate ball mill for 4 days. During the milling the copper number, determined according to Hägglund [7], increased from 0.21 to 4.62. A borohydride analysis indicated the presence of 2.7 oxo-groups per hundred glucose residues.

Isolation of glycitols from the degraded cellulose. Mechanically degraded cellulose (25.0 g) was suspended in a solution of sodium borohydride (8.0 g) in water (250 ml) for 2 days at room temperature. It was then filtered off and washed with water. The filtrate and washings were concentrated, filtered through a column of Amberlite IR 120 (H^+), concentrated further and boric acid was removed by distillations with anhydrous methanol. A neutral residue (139 mg) was obtained.

This cellulose residue, which had a copper number of 0.37, was refluxed with N sulphuric acid for 4 h and then the undissolved residue (21.3 g) was removed by filtration. The filtrate was neutralised with barium carbonate and concentrated to a syrup (3.8 g). This syrup, dissolved in 0.1 M acetate buffer of pH 3.5, was treated with sodium chlorite (35 g) for 2 days at room temperature. Excess oxidant remaining was reacted with sulphur dioxide and the resultant solution was neutralised with barium carbonate, deionised by filtering through columns of IR 120 (H^+) and IR 4B (free base) and concentrated.

Table 1. Fractionation of the neutral products.

	Directly dissolved		Obtained after partial hydrolysis	
	I	II	I	II
Weight of sample, mg	139	230	150	331
D-Glucitol, mg	12	28	62	95
D-Arabitol, mg	5	10	15	27
Erythritol, mg	6	8	7	22
1,6-Anhydro-D-glucose + Glycerol, mg	Traces	Traces	42	59

The resulting syrup (430 mg) contained glycitols and 1,6-anhydro-D-glucose, together with reducing sugars, glucose, mannose and xylose, as shown by paper chromatography. It was therefore dissolved in 0.5 N sodium hydroxide and kept at 100° for 2 h and then deionised and concentrated, yielding a syrup (150 mg). An analogous experiment, starting from 42 g of degraded cellulose, yielded 230 and 331 mg of neutral material, obtained by direct solution and after partial hydrolysis, respectively.

Part of the residual cellulose (500 mg) was subjected to total hydrolysis in the usual manner and worked up as above, giving a small residue (1.3 mg). Chromatographic investigation showed the presence of 1,6-anhydro-D-glucose (60 %), D-glucitol (30 %) and smaller amounts of D-arabitol and erythritol.

Fractionation of the neutral products. The material that dissolved during the borohydride reduction was fractionated by chromatography on thick filter paper, using solvent a. Only glucitol and the components of higher R_F were recovered. The products obtained after partial hydrolysis were fractionated on a cellulose column, using butanol saturated with water, as eluant. The results of the fractionations are summarised in Table 1.

Characterisation of the components. The components found were chromatographically indistinguishable from authentic samples of D-glucitol, D-arabitol, erythritol, glycerol and 1,6-anhydro-D-glucose respectively, and the same was true for the corresponding acetates.

D-Glucitol was characterised as the hexaacetate, m. p. 99—100°, alone or mixed with an authentic sample.

D-Arabitol was obtained crystalline, m. p. 101—102°, undepressed on admixture with an authentic sample.

Erythritol was characterised as the tetrabenzoate, m. p. 189—191°, alone or mixed with an authentic sample.

1,6-Anhydro-D-glucose was characterised as the tribenzoate, m. p. 201—202°, alone or mixed with an authentic sample.

Glycerol was present in insufficient amount for a definite characterisation.

Partial Methylation of some Glucose Derivatives

INGEMAR CROON

Wood Chemistry Department, Swedish Forest Products Research Laboratory, Stockholm, Sweden

Methyl 4,6-*O*-ethylidene-β-D-glucopyranoside, methyl 4,6-*O*-benzylidene-β-D-glucopyranoside and amylose have been partially methylated with dimethyl sulphate in alkaline solution and the distribution of the methoxyl groups has been determined by hydrolysis and resolution of the hydrolysate by chromatographic methods. In the first two derivatives the hydroxyl groups at C_2 and C_3 had approximately the same reactivity ($k_2:k_3 = 1:1$ and $k_2:k_3 = 1.3:1$, respectively); for amylose $k_2:k_3:k_6$ equalled 6:1:7. This investigation supports the idea that intrachain hydrogen bonds play an important role in the reactivity of the hydroxyl groups at positions C_2, C_3 and C_6 in cellulose and amylose, but other factors which can influence the results are also pointed out.

Studies on the distribution of substituents in various ethers of cellulose have been reported in previous communications from this Department [1-4]. In these studies, the cellulose ether was hydrolysed to a mixture of glucose and glucose ethers. This mixture was fractionated by chromatographic methods into pure components which were characterized and identified. The technique also allowed for the quantitative determination of all the expected components, except in the case of hydroxyethyl cellulose from which, however, ten separate components were isolated and identified [1]. This method of studying the distribution of substituents should be more accurate than the indirect methods previously used, which were based upon group analyses, such as the determination of glycol groups by periodate oxidation and of primary hydroxyl groups by tosylation-iodination.

For methyl cellulose, prepared with methyl sulphate in a homogeneous medium (triethylbenzylammonium hydroxide as solvent) the results agreed fairly well with those which could be calculated statistically, using the following assumptions [2]:

1. All glucose residues are equally accessible.
2. The relative rate constants for methylation at carbon atoms $C_{(2)}$, $C_{(3)}$ and $C_{(6)}$ of the glucose unit are constant during the reaction.
3. The effect of end groups is negligible.

The values of $k_2 = 3.5$, $k_3 = 1$ and $k_6 = 2$ for the relative rate constants in methylation reactions with methyl sulphate at $C_{(2)}$, $C_{(3)}$ and $C_{(6)}$ gave the best agreement, but there were deviations which could not be explained as experimental errors. A better agreement was obtained if it was assumed that the reactivity at $C_{(3)}$ was doubled when the hydroxyl at $C_{(2)}$ was methylated. This should not be unreasonable, as the $C_{(2)}$-hydroxyl is the most acidic in the glucose residue and, when dissociated, should considerably reduce the acidity of the $C_{(3)}$-hydroxyl.

In order to study this effect and learn more about the factors which influence the relative reactivities of different hydroxyl groups in a glucose residue, the course of the partial methylation of methyl 4,6-*O*-ethylidene-β-D-glucopyranoside, methyl 4,6-*O*-benzylidene-β-D-glucopyranoside and of amylose has now been investigated, using the same technique as used for the cellulose ethers. The relative reactivities of hydroxyl groups of carbohydrates has been summarised by Sugihara [5]. Most of the results discussed by him were, however, obtained before the development of modern chromatographic technique and are probably rather uncertain.

Table 1. Composition of the hydrolysates of the partially methylated ethylidene and benzylidene glucose derivatives

	Ethylidene derivative						Benzylidene derivative	
	Sample I		Sample II		Sample III

[b] Calculated for homogeneous reaction in alkaline solution, $k_2:k_3 = 1:1$.
[c] Calculated for homogeneous reaction in alkaline solution, $k_2:k_3 = 1.3:1$.

The two cyclic acetals were methylated with methyl sulphate in sodium hydroxide; ethanol was added to the system to keep the products in solution. The results given in Table 1 were quite unexpected and contrary to those from all cellulose ethers studied, the reactivities at $C_{(2)}$ and $C_{(3)}$ being approximately the same. The percentage of 2,3-di-*O*-methyl-D-glucose (s_{23}), however, was in all cases higher than the calculated value, thus supporting the assumption that the reactivity in one of the positions is increased when the other is methylated. The low reactivity at $C_{(3)}$ in cellulose has been attributed to a hydrogen linkage between this hydroxyl and the ring oxygen of the neighbouring glucose residue [6,7]. On the other hand, the higher reactivity at $C_{(2)}$ has been explained as a result of the higher acidity of the hydroxyl at this position [5,8], due to the inductive effect of the two oxygen atoms at $C_{(1)}$. It must, however, be borne in mind that the observed effect, a change in relative reactivity from 3.5:1 to 1:1, corresponds to a quite small difference in the energy of activation, which might equally well have other explanations, *e.g.* a different magnitude of steric hindrance from the bulky groups in the 4-position, or a slight deviation from the chair conformation of the pyranose ring in the cyclic acetals.

* Calculated for a homogeneous reaction in alkaline solution $k_2:k_3:k_6 = 6:1:7$. (See the text.)
** As above, but with the further assumption that l_3 is doubled when the position at $C_{(2)}$ becomes methylated.

Amylose was dissolved in 18.9 % sodium hydroxide and methylated with methyl sulphate and the distribution of the methoxyl groups in the methylated product was studied as above. The results are summarised in Table 2. Here also, the percentage of s_{23} is higher than expected according to the direct statistical calculation, and a better agreement between observed and calculated values is obtained if it is assumed that the reactivity at $C_{(3)}$ is doubled when the position at $C_{(2)}$ is methylated [2]. The most interesting result is that the primary hydroxyl group showed the highest reactivity. The relative reactivity at $C_{(3)}$ is even lower than in cellulose. The conformation of the glucose residues in the amylose chain is not definitely known, but in a recent paper Reeves [9] assumed that there is an equilibrium between B1 and 3B (Fig. 1) and that in strongly alkaline solution a conformation approximating that of 3B predominates.

An inspection of a model of the amylose molecule in the 3B-conformation, using the Courtauld atomic models, shows that as in cellulose the atomic distances are favourable for the formation of a strong hydrogen bridge between the $C_{(3)}$-hydroxyl and the oxygen atom in the adjacent glucopyranoside ring. In the cellulose molecule a hydrogen bridge between the hydroxyl group at $C_{(6)}$ and a glycosidic oxygen atom is possible, but in the starch model this is not the case. The results thus favour the opinion that intramolecular hydrogen bridges play an important role in the relative reactivities in the methylation reaction, but for reasons discussed above great care must be used when trying to interpret these rather small effects. A careful study of a greater number of model substances might throw more light upon these questions.

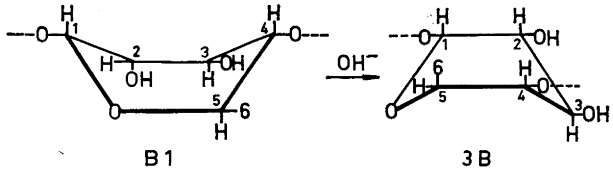

Fig. 1.

EXPERIMENTAL

Methyl 4,6-O-ethylidene-β-D-glucopyranoside (600 mg), prepared according to Helferich [10], was dissolved in 18.9 % sodium hydroxide (60 ml) and methyl sulphate (2 ml) was added during 15 min. After 30 min, traces of the dimethylated compound began to precipitate and, in order to keep the reaction medium homogeneous, ethanol (10 ml) was added. A further quantity (2 ml) of methyl sulphate was added during 30 min. The reaction was carried out for a total time of 4 h. The solution was neutralised with 6 N sulphuric acid and most of the sodium sulphate formed was precipitated with ethanol. The filtered solution was evaporated to 37 ml, and 72 % sulphuric acid was added until the concentration was 8 %. This solution was kept at 100°C for 4 h to remove the ethylidene and the glycosidic methyl groups. The sulphate ions were then removed by treatment with barium carbonate and the solution deionised by ion exchange with IR-120 and IR-4B exchange resins. Evaporation of the deionised solution yielded a light yellow syrup (370 mg) (sample 1 in Table 1). Two other samples were obtained by varying the amount of methyl sulphate and the time of reaction.

Methyl 4,6-O-benzylidene-D-β-glucopyranoside (500 mg), prepared according to Freudenberg, Toepffler and Anderson [11], was dissolved in 18.9 % sodium hydroxide (60 ml) and methyl sulphate (2 ml) was added during 15 min. After addition of ethanol (20 ml), additional methyl sulphate (2 ml) was added dropwise during 30 min. Ethanol (10 ml) was then added and the reaction was allowed to proceed for a total time of 4 h. Neutralisation, precipitation and hydrolysis were performed as above. The hydrolysate (50 ml) was shaken with ether (3 ml) to remove benzaldehyde. The neutralised and deionised solution on evaporation yielded a syrup (295 mg).

Amylose. The pure amylose (1.3 g) was dissolved in 18.9 % sodium hydroxide (60 ml) and methyl sulphate (8 ml) was added during 1 h. After a further 4 h, the solution was neutralised with 6 N sulphuric acid and was dialysed against tap water for a period of 14 days. The partially methylated amylose was recovered by freeze-drying, when a white, fluffy product (1.28 g) was obtained (sample 1 in Table 2). A higher methylated derivative was obtained by methylation of amylose (2 g) with methyl sulphate (20 ml) during 17 h (sample 2 in Table 2).

The amylose derivatives were hydrolysed exactly as previously described for the cellulose ethers [2] by treatment with 72 % sulphuric acid (16.7 ml) for 30 min, and dilution with water to 150 ml, after which the solution was kept at 100°C for 4 h.

All the methylations described above were carried out in an atmosphere of nitrogen.

Analysis of the hydrolysates. The hydrolysates were analysed by separation into pure components by carbon column chromatography, paper electrophoresis and paper chromatography as described in a previous paper [2].

Acknowledgement. The author is indebted to Docent Bengt Lindberg for his interest in this investigation and to Dr. Gunnar Neumüller for a gift of pure amylose.

Short Communications

Artificial Peroxidases

K. G. PAUL

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

A reinvestigation of the activities of some artificial peroxidases has given results somewhat at variance with those previously [1-3] reported. The reasons are at present unknown, and the results are presented without comment.

The horse radish peroxidase was prepared, split, and combined with various hemins as previously described [4,5]. The activities were measured by the mesidine method [6] which is well fitted even for the determination of weak activities since no appreciable decolourization occurs. For convenience the activities were expressed as the increase in absorbancy (A) at 490 mμ per min for a micromolar protein concentra-

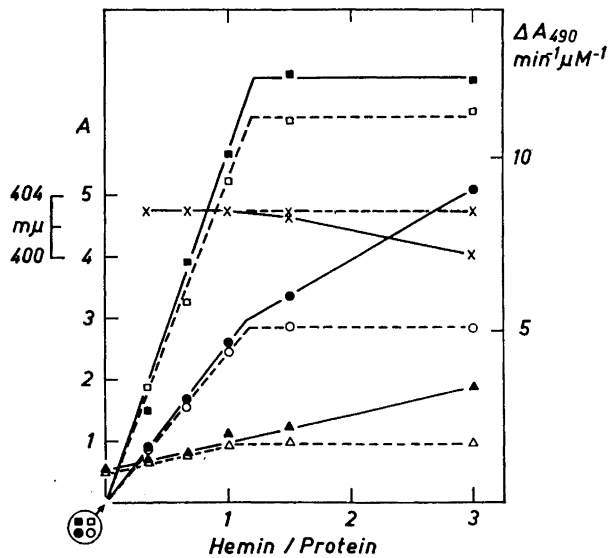

Fig. 1. Effect of the ratio between protohemin and apoprotein on enzymatic activity and light absorption in recombination experiments. All solutions were 28 μM in apo-HRP with 50 mM phosphate of pH 7.3 as buffer. Activities and spectra were determined after 40 h at 4°C (full drawn curves and filled symbols). Aliquots were chromatographed on Dowex 2, previously washed with the buffer until A< 0.01. Five retention volumes were collected and examined (dashed lines and open symbols). The next fifteen volumes gave no light absorption. Right scale and squares: Enzymatic activity of apoprotein with varying proportions of hemin. Left scale: Absorbances at the top of the Soret band (circles) and at 280 mμ (triangles) for 28 μM protein. Short scale and crosses: Wavelength for the maximum of the Soret band.

tion. The ratio of two for hemin to protein was used, thus ensuring that the native apoprotein was saturated with the prosthetic group. All protein concentrations were based upon micro-Kjeldahl determinations.

The activity of unsplit HRP has been determined for four preparations and ΔA_{490} min^{-1} μM^{-1} was found to be 10.6, 11.4, 12.1, and 11.8, average 11.5.

Fig. 1 confirms the observation that the hemin that is nonspecifically attached to the apoprotein is removed by an anion exchanger. The hemin bound as the prosthetic group of HRP and the hemin present in excess of the protein moiety differ in their effects on the light absorption in the Soret band region. At 280 mμ, however, no such difference can be seen. The activity of the recombined HRP in Fig. 1 was found to be 12.4 min^{-1} μM^{-1}.

Table 1. Enzymatic activities of some artifical peroxidases.

Hemin	Positions of the carboxyl groups in the prophyrin ring	Activity ΔA_{490} min^{-1} μM^{-1}	Positions of the α-band of pyridine hemochromogen, mμ
Protohemin IX	6,7	11.5	557
Hematohemin IX	6,7	15.5	548
Mesohemin IX	6,7	15.7	547
Deuterohemin IX	6,7	6.1	545
Diacetyl-deuterohemin IX	6,7	0.3	582
Mesohemin I	6,8	0.4	547
Coprohemin I	2,4,6,8	0.1	548
Coprohemin III	2,4,6,7	0.1	548

When seven different preparations of protohemin were used in recombination experiments with the same batch of apoprotein, the activities of the holoenzymes were found as 9.9 ± 0.8 (S.D.). Since all activity values are based on nitrogen determinations, the somewhat low value may be caused by a partial inactivation of the apoprotein.

Some results with various hemins are given in Table 1. Mesohemin IX peroxidase and hematohemin IX peroxidase were 1.3 times more active than the unsplit peroxidase, whereas deuterohemin IX peroxidase was only 0.5 times as active. Diacetyldeuterohemin IX does combine with the apoenzyme, as reported previously [5], but the resulting hemoprotein is inactive in this assay. The hemins with propionic acid residues in the six and eight positions are inactive, probably because of inability to react in an adequate way with the apoprotein. In the case of the four-carboxylic hemins the lack of activity may depend upon the nature of the hemin polymer.

There seems to be some correlation between the spectrum and the enzymatic activities of the meso-, hemato-, proto-, and diacetyldeuterohemin IX peroxidases.

A full report will be published.

Deuterohäminperoxydase

K. G. PAUL

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Schweden

H. S. GEWITZ und W. VÖLKER

Max Planck-Institut für Zellphysiologie, Berlin-Dahlem, Deutschland

In früheren Untersuchungen wurde festgestellt, dass Meerrettichperoxydase — Apoeiweiss (Apo-MRP) sich mit gewissen Häminen kuppeln lässt, wobei peroxydatisch aktive Verbindungen entstehen [1]. So geben Proto-, Meso- und Hämatohämin IX, die alle Propionsäuren in den Stellungen 6 und 7 besitzen, aktive Peroxydasen, während Diacetyldeuterohämin IX zwar gekuppelt wird, die Verbindung ist aber peroxydatisch inaktiv [2]. Deuterohä-

min IX-Peroxydase ist nun etwa halb so aktiv wie Protohäminperoxydase. Mesohämin I, das Propionsäuren an den Stellungen 6 und 8 besitzt, bildet keine Peroxydase [2].

In der vorliegenden Arbeit wurden einige Deuterohäminisomere bzw.-homologe sowie Cytodeuterohämin *, die als Porphyrinester aus früheren Arbeiten [4,5] zur Verfügung standen, in ihrem Verhältnis zu Apo-MRP untersucht.

Die Porphyrinester wurden mit 7 M HCl im Eisschrank verseift und in Hämine mittels Ferroacetat in Eisessig überführt. Die Einheitlichkeit der Hämine wurde papierchromatographisch mit silikonierten Papieren (Whatman Nr. 1), *n*-Propanol-Wasser-Pyridin 1:55:4 und aufsteigender Front geprüft [6]. Cytohämin teilte sich dabei so auf, dass der grösste Teil überhaupt nicht wanderte, der kleinere Teil mit R_F etwa 0,1. Ein Streifen mit abnehmender Intensität war aber bis an R_F 0,8 sichtbar. 2,3,4-H-6,7-Propionsäurehämin zeigte einen schwachen Schwanz, die übrigen Hämine aber wanderten als gut begrenzte Flecke.

Für jede Kuppelung wurde 1,0 ml Puffer (0,03 M Phosphat, pH 7,1), 0,5 ml Apo-MRP und 0,16 μMole des betreffenden Hämins in 0,1 ml 0,05 M NaOH abgemessen. Die Lösung von Apo-MRP war 160 μM (Kjeldahlbestimmung), und davon waren nach der Bestimmung mit Protohämin etwa 70 % nativ. Das Verhältnis Gesamthämin/Gesamtprotein war also 2,0. Kuppelung geschah während 40 Std. im Kühlschrank. Für die Aktivitätsmessung, die nach der Mesidinmethode [8] ausgeführt wurde, wurden immer 0,03 ml einer 15-fachen Verdünnung des Gemisches verwendet. In der Tabelle sind die Aktivitäten als Extinktionszuwachs pro Minute für eine mikromolare Enzymkonzentration im Rohr mit Mesidin und Peroxyd (2 + a ml [8]) ausgedrückt (ΔA).

Die Ergebnisse, im Tabelle 1 gesammelt, zeigen:

1. Die beiden Deuterohämin IX-Präparate geben die gleiche Aktivität und zwar etwa die Hälfte davon was mit Protohämin erreicht wird. Auch zeigen sie dieselben R_F-Werte. Die verwendeten Methoden scheinen also zuverlässig zu sein. Da inaktivierter Eiweiss sich mit Häminen nicht spezifisch kuppelt [7] kann die teilweise

* Cytodeuterohämin bezeichnet die Verbindung, die aus Cytohämin (die Wirkungsgruppe des sauerstoffübertragenden Ferments, der Cytochromoxydase) durch Schmelzen mit Resorcinol erhalten wird [3].

Tabelle 1. Ergebnisse der Papierchromatographie und der Aktivitätsbestimmung. Alle Hämine besassen Methylgruppen in den Stellungen 1 und 5, übrige Substituenten gehen aus der Tabelle hervor.

V = Vinyl, Et = Äthyl, Me = Methyl, S = Propionsäure

Substituent in Stellung 2	3	4	6	7	8	R_F	Aktivität in ΔA_{490} mμ min^{-1} μM^{-1}	% von Protohämin-Peroxydase

Inaktivierung des Apoeiweisses die relativen Aktivitäten der artifiziellen Peroxydasen nicht beeinflussen.

2. Die R_F-Werte der Deuterohäminisomere mit Propionsäuren in den 6- und 8-Stellungen sind höher als der des Deuterohämins IX, wo die Säuregruppen in 6- und 7-Stellung stehen. Dasselbe wurde auch bei den Mesohäminen beobachtet, wo die 6,7- und 6,8-Isomere die R_F-Werte 0,55 bzw. 0,70 gaben. Weil mit umgekehrten Phasen chromatographiert wurde bedeutet dies, dass die beiden Karboxylgruppen der 6,7-Isomere einander stärker beeinflussen bei ihrer Ionisation als die der 6,8-Isomere. pH der Eluierungsflüssigkeit ist etwa 7,5.

3. Die beiden Deuterohäminisomeren mit Propionsäuren in den 6- und 8-Stellungen geben keine Aktivität. Die Deuterohäminhomologen, die in 4-Stellung äthyl- bzw. wasserstoffsubstituiert sind, geben beide geringere Aktivität als Deuterohämin selbst. Das Homolog mit drei freien β-Stellungen erwies die schwächste Peroxydaseaktivität.

4. Das Chromatogram des zur Verfügung stehenden Cytohäminpreparates wurde von unbekannten Faktoren beeinflusst sodass sich keine gut abbegrenzte Flecken zeigten; es enthüllte aber, dass das Präparat nicht einheitlich war. Cytohämin ergab 16 % der Aktivität die mit Protohämin gefunden wurde. Lichtabsorptionsmessungen des Pyridinhämochromogens zeigten aber einen Gehalt von 7 % Protohämin in dem Cytohäminpreparat (D_{587} = 0,860, D_{557} = 0,309 und D_{540} = 0,255. $\beta_{587\ \text{Cytoh.}}$ = 6,4, $\beta_{557\ \text{Protoh.}}$ = 8,0, $\beta_{540\ \text{Protoh.}}$ = 2,3, alle β-Werte $\times$ $10^7 cm^2 Mole^{-1}$. Die Absorption bei 587 mμ des Protohämochromogens ist zu vernachlässigen.) Spektroskopisch war eine schwache Bande bei 557 mμ unterschiedbar. Da ein zweifacher Überschuss von Cytohämin im Verhältnis zum Eiweiss eingesetzt wurde, lässt sich die für Cytohämin beobachtete Aktivität vollständig durch den Protohämingehalt erklären. Cytohämin gibt also mit Apo-MRP keine peroxydatisch aktive Verbindung.

5. Der R_F-Wert des Cytodeuterohämins, der die Gegenwart von zwei Karboxylgruppen im Molekül bestätigt [3], war von denen des Deuterohämins IX, des 2,3,4-H-Hämins und des 2,3-H-4-Et-Hämins klar abweichend. Diese Beobachtung unterstützt den früheren Schluss, dass Cytodeuterohämin mit keiner dieser Verbindungen identisch sei. Es ist von Interesse, dass Cytodeuterohämin, das nach der Bromierung zu beurteilen drei freie β-Stellungen besitzt [3], dieselbe Peroxydaseaktivität wie das 2,3,4-H-6,7-Propionsäure-Hämin hervorrufen kann. Die Tatsache, dass Cytodeuterohämin eine zwar schwache aber doch gut messbare Peroxydase-aktivität erregte, deutet an, dass es Propionsäuren in den Stellungen 6 und 7 oder in zwei Stellungen in demselben Abstand von einander besitzt. Das verwendete Cytodeuterohämin stammte aus Cytohämin mit 7 % Protohämin, war aber über seinen mehrmals chromatographierten und krystallisierten Porphyrinester gereinigt und enthielt deshalb wahrscheinlich kein Deuterohämin IX.

Professor Otto Warburg sei für seine Interesse gedankt. K.G.P. dankt auch für Gastfreundschaft.

Liberation of an Amino Acid Derivative from its Copper Complex by means of Hydrogen Sulphide Generated *in situ* from Thioacetamide

GEORG FÖLSCH and
KLAUS SERCK-HANSSEN

Department of Medical Biochemistry, University of Gothenburg, Sweden

Thioacetamide, CH_3CSNH_2, may be smoothly hydrolysed to produce hydrogen sulphide[1], and generally allows easy domination of problems caused by the objectionable properties of the gas.

The use of thioacetamide for the detection of certain heavy metals was reported [2] in 1934, and during the last decade the reagent has been extensively used in inorganic analysis [3]. Compared with hydrogen sulphide [4], thioacetamide usually provides sulphide precipitates of superior coagulative properties.

When amino acids and derivatives are prepared or isolated *via* heavy metal compounds, the metal has hitherto been removed by means of hydrogen sulphide [5,6]. Heating is often necessary, and even in strongly acidic solution the reaction may take several hours, and frequently results in precipitates difficult to filter. It therefore appeared attractive to try thioacetamide in this field. The copper complex [7] of ε-benzoxycarbonyl-L-lysine was chosen as an example. In boiling water containing a little acetic acid, the precipitation of copper sulphide by means of thioacetamide was completed in a few minutes, and the precipitate was easily removed by filtration, with no visible colloidal sulphide passing the filter. The use of thioacetamide in similar cases is therefore indicated.

Experimental. Pulverized copper complex [7] (15.0 g) of ε-benzoxycarbonyl-L-lysine, prepared from 0.05 mole of L-lysine monohydrochloride with $[\alpha]_D^{25}$ + 24.5° ± 1.0° (6 N HCl, *c* 2, calc. as free base, *l* 1), was suspended in 350 ml of boiling water, and 20 ml of acetic acid added, immediately followed by 7.5 g (0.10 mole) of thioacetamide. The lysine derivative dissolved completely, and copper sulphide began to precipitate. After boiling 5 min the precipitate was filtered off on a hot Büchner funnel. ε-Benzoxycarbonyl-L-lysine crystallized immediately from the filtrate. After some hours at +4°, the crystals were collected, washed with a little cold water and dried *in vacuo* over potassium hydroxide. Yield 10.2 g (73 % calc. from L-lysine monohydrochloride), m.p. 252–254° (decomp.); $[\alpha]_D^{20}$ + 6.4° (2 N NaOH, *c* 6.6 *l* 1); reported [8] m.p. near 255°. (Found: N 9.8. Calc. for $C_{14}H_{20}O_4N_2$ (280.3): N 10.0).

To test the optical purity of the compound, 1.4 g (5 mmoles) were debenzoxycarbonylated in 5 ml of 12 N HCl (steam bath, 5 min.). Benzyl chloride separated, and when the reaction mixture had attained room temperature, 25 ml of ethanol and 50 ml of ether were added, causing 0.90 g (91 %) of L-lysine dihydrochloride to crystallize; $[\alpha]_D^{20}$ + 25.9° ± 1.5° (6 N HCl, *c* 1.3 calc. as free base, *l* 1). (Found: N 12.7. Calc. for $C_6H_{14}O_2N_2$, 2 HCl (219.1): N 12.8). Racemization is therefore not apparent.

The use of thiourea [9] or ethylenediaminotetraacetic acid (EDTA) for the removal of copper from the above complex has also been tried, with good preliminary results.

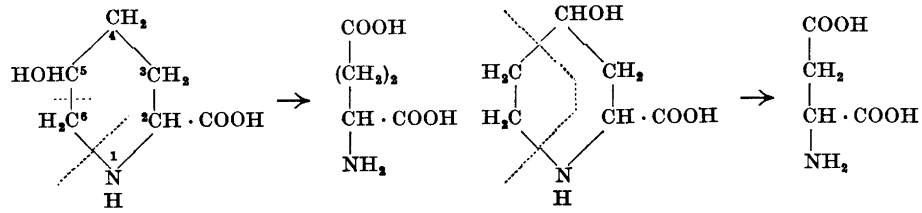
On the Structure of 4-Hydroxypipecolic Acid Isolated from Green Plants

ARTTURI I. VIRTANEN and ROLF GMELIN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Some years ago Virtanen and Kari [1] isolated from some *Acacia*-species a new cyclic imino acid and identified it as 5-hydroxy-piperidine-2-carboxylic acid (5-hydroxypipecolic acid). From the same plants also another cyclic imino acid could be isolated [2]. This was characterized as 4-hydroxypipecolic acid because it was reduced with hydrogen iodide and red phosphorus to pipecolic acid and was oxidized with potassium permanganate to aspartic acid. Glycine and two other amino acids, not nearer characterized, were also formed then, but no glutamic acid which was the main or only oxidation product of 5-hydroxypipecolic acid. The positions of the hydroxyl group in the isolated hydroxypipecolic acids were concluded from the oxidation products



5-hydroxypipecolic acid glutamic acid 4-hydroxypipecolic acid aspartic acid

Witkop and Foltz [3] later confirmed the structure of our 5-hydroxy compound through synthesis and presented evidence for the *trans* arrangement of the two functional groups.

Last year Fowden [4] described the isolation of an imino acid from *Armeria maritima* which he identified with the 4-hydroxypipecolic acid isolated by Virtanen and Kari. As oxidation products with $KMnO_4$ he could identify β-alanine, glycine, γ-aminobutyric acid, and aspartic acid. Comparisons with synthetic 3- and 4-hydroxypipecolic acids indicated that the amino acid may not be 4-hydroxypipecolic acid, but 3-hydroxypipecolic acid. A strictly identical behaviour of natural and synthetic 3-hydroxypipecolic acid could not be demonstrated by Fowden, since the two substances differed in their stereoisomeric composition.

Because the formation of aspartic acid as an oxidation product of a hydroxypipecolic acid is difficult to understand if the hydroxy group is not in 4-position, we have reinvestigated the structure of the imino acid which according to Virtanen and Kari would be 4-hydroxypipecolic acid. The acid was now isolated from the seeds of *Acacia willardiana* and *Lysiloma bahamense*. Analysis of the preparation. Found: C 49.91; H 7.48; N 9.35; Calc. for $C_6H_{11}O_3N$: C 49.65; H 7.46; N 9.65. On the basis of IR-spectra, paper chromatographical behaviour, and colour reactions, it was identical with the 4-hydroxypipecolic acid isolated by Virtanen and Kari from fresh plants of *Acacia pentadena* and *Albizzia lophantha*. The acid could be found also in different *Armeria*-species.

Optical rotation of 4-hydroxypipecolic acid:

$[\alpha]_D^{21} = -12.5°$ in H_2O
» $= +0.34°$ in 1 N HCl
» $= -18.5°$ in 1 N NaOH

As principal products of acidic (H_2SO_4) and alkaline (NaOH) permanganate oxidation of the imino acid β-alanine and aspartic acid were identified (Fig. 1). In addition small amounts of glycine and some unidentified substances, coloured by ninhydrin, which possibly were intermediate products of the oxidation, were found on the paper chromatogram. γ-Aminobutyric acid was

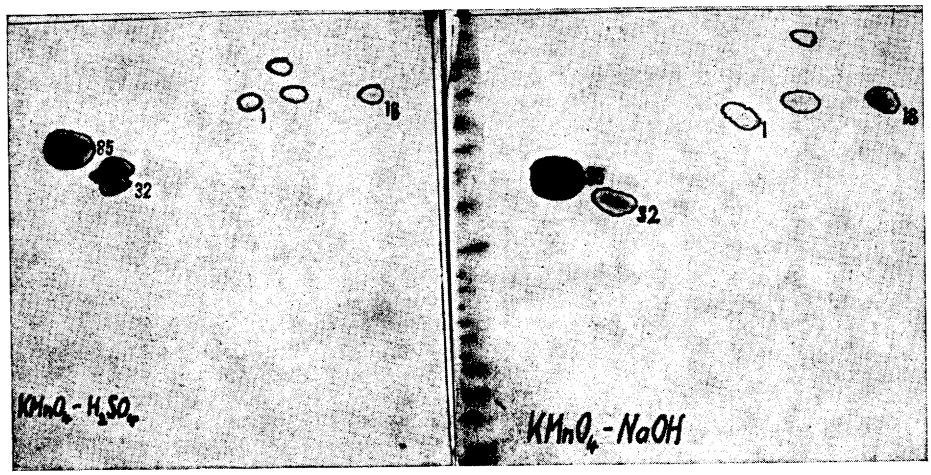


Fig. 1. Two-dimensional paper chromatogram of oxidation products of 4-hydroxypipecolic acid. Left: oxidation with $KMnO_4$ in 20 % H_2SO_4 solution; right: oxidation with $KMnO_4$ in NaOH solution. 1 gly, 16 asp, 32 β-ala, 85 unchanged 4-hydroxypipecolic acid. Solvents: butanol-acetic acid-water and phenol-NH_3.

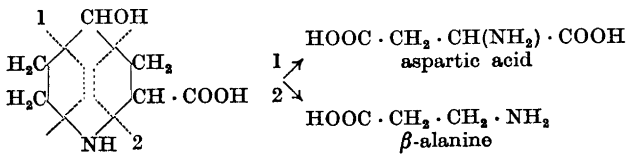
never found as an oxidation product. Excluding this important difference, the oxidation products were qualitatively the same as Fowden's. On the chromatogram of Virtanen and Kari [2] β-alanine was present as a "not nearer characterized" spot (*cf.* Fig. 3 in their paper).

The formation of aspartic acid and also of β-alanine as oxidation products from 4-hydroxypipecolic acid is reasonable, but not from 3-hydroxypipecolic acid.

Because γ-aminobutyric acid was not found as an oxidation product, there was no evidence for the 3-hydroxypipecolic acid.

In order to elucidate the properties of 3-hydroxypipecolic acid we have prepared this acid in the following way. The new antibiotic, etamycin, isolated by Heinemann *et al.*[5] and Bartz *et al.*[6] is according to Sheehan *et al.*[7] a *cyclo*peptide which contains 3-hydroxypyridine-2-carboxylic acid (3-hydroxypipecolic acid) as one member. 2.1 g of etamycin was hydrolyzed with 6 N HCl at 110°C for 24 h. The concentrated hydrolysate was dissolved in 1 l of water and passed through a column containing 100 ml of Dowex 50 (200 mesh) in the H-form. On elution with 1 % ammonia 3-hydroxypicolic acid emerged before the amino acids. The fraction was evaporated *in vacuo* and 3-hydroxypicolic acid was crystallized three times from methanol-ether. Yield 134 mg. M.p. 214—215°C. (Found: C 51.70; H 3.83; N 10.41. Calc. for $C_6H_5O_3N$: C 51.81; H 3.63; N 10.08).

100 mg of 3-hydroxypicolic acid was dissolved in 20 ml of water after addition of some drops of diluted HCl and was 48 h catalytically hydrogenated (50 mg PtO_2 as



4-hydroxypipecolic acid

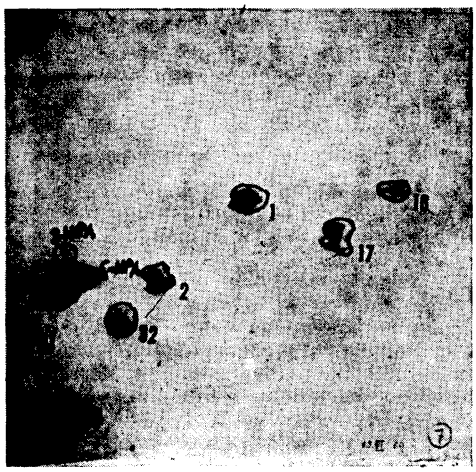


Fig. 2. Two-dimensional paper chromatogram of different amino acids including 3-, 4-, and 5-hydroxypipecolic acids. 1 gly, 2 ala, 11 pro, 16 asp, 17 glu, 29 γ-aminobut, 32 β-ala, 60 pipecol, 3-HPA, 4-HPA, and 5-HPA the corresponding hydroxypipecolic acids. Solvents as in Fig. 1.

catalyst). About seven ninhydrin-positive spots could be found on the paper chromatogram. The amino acids formed through ring splitting were removed with HNO_2 and the imino acids regenerated with HCl. After running through an Amberlite IR-120 column three compounds could be found: 3-hydroxypipecolic acid, pipecolic acid, and an unknown substance which on the basis of its R_F-values was possibly tetrahydro-3-hydroxypipecolic acid. The 3-hydroxypipecolic acid could be obtained in crystalline form by addition of acetone to a water solution. After recrystallization from water-acetone the substance was paper chromatographically pure. Yield 8.5 mg. Decomposition from about 250°C. (Found: N 9.96. Calc. for $C_6H_{11}O_3N$: N 9.66).

The position of the spots of 3-, 4-, and 5-hydroxypipecolic acid on a two-dimensional paper chromatogram can be seen in Fig. 2. As appears from the figure 3-, 4-, and 5-hydroxypipecolic acids can be separated from each other by paper chromatography using butanol-acetic acid-water and phenol-water-NH_3 as solvents. These imino acids also give different colours with ninhydrin, isatin, and naphthoquinonesulphonic acid (*e.g.* 3-hydroxy compound with isatin no colour, 4-hydroxy compound a very weak green colour, and 5-hydroxy compound a strong greenblue colour).

On the basis of optical rotation it is probable that the natural 4-hydroxypipecolic acid belongs to the L-series.

All known facts are in accordance with the structure Virtanen and Kari gave to the imino acid (4-hydroxypipecolic acid) they isolated from *Albizzia lophantha* and *Acacia pentadena*.

We are grateful to Dr. J. C. Sheehan for a smaller sample of etamycin and to Dr. B. Heinemann for a larger one.

Chromatography of Secretin on Carboxymethyl Cellulose

VIKTOR MUTT

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

In 1957 Ward and Guillemin [1] described a method for the purification of vasopressin in which the hormone is adsorbed on carboxymethyl cellulose from a solution of the crude material in 0.02 M ammonium acetate and selectively eluted by developing the column with a gradient to an ammonium acetate solution of higher concentration and pH. We decided to try a similar technique for the purification of secretin. Carboxymethyl cellulose has been used for the purification of secretin by Newton, Love, Heatley and Abraham [2] who adsorbed the activity from crude preparations on columns of carboxymethyl cellulose buffered with barium acetate at pH 4, eluted impurities with 0.02 N acetic acid and then a highly purified secretin with 0.1 N acetic acid.

We found, working with highly purified preparations, that secretin may be adsorbed on carboxymethyl cellulose * from solution in 0.02 M ammonium bicarbonate and eluted by increasing the concentration of the latter to 0.04 M. Further work showed, however, that it was unnecessary to change the concentration of the eluting solution. If elution was continued for a sufficiently long time with the 0.02 M bicarbonate the secretin emerged from the column in good yield and in a high state of purity. Large quantities of impurities were both eluted from the column before and left on it after the secretin. The impurities left on the column could be eluted by increasing the concentration of the ammonium bicarbonate to 0.2 M.

On lyophilizing the most active fractions of the eluated material with 150 000 Hammarsten cat units ** per mg has been obtained. The purity of the preparations is thus at least as good as that of preparations recently obtained on electrophoretic fractionation of highly purified material [3].

Experimental. Starting material. Crude secretin was prepared as described by Jorpes and Mutt [5] in 1956. For preliminary purification of this the technique outlined by Mutt [3] was followed until the extraction of the activity into methanol. The methanolic solution

* Prepared according to Peterson and Sober [4], obtained from the Brown company, New Hampshire, USA.

** One Hammarsten cat unit (HCU) is that amount of secretin activity which on intravenous injection stimulates the pancreas of the cat to the secretion of 0.1 ml 0.1 N alkali.

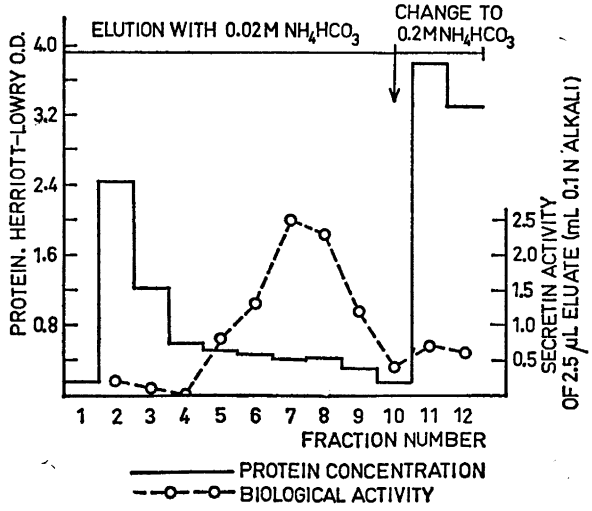

Fig. 1.

was brought to pH 7.5 with NaOH (glass electrode). Precipitated impurities were filtered off and discarded. The clear filtrate was acidified to pH 5.5 with HCl and the secretin precipitated with ether. After reprecipitation from water with sodium chloride at saturation it was collected on a suction filter and sucked as dry as possible. In repeated preparations the moist material had an activity of about 7 000 HCU per mg. This material was dissolved in water and the pH of the solution brought to 7.2. Three volumes of acetone were then added to the solution. The precipitate that formed was collected by centrifugation and discarded. The secretin was thrown out of solution by adding nine more volumes of acetone to the clear supernatant. The precipitate was collected by centrifugation and dissolved in water. The pH of the solution was adjusted to 5.5 with acetic acid and the secretin lyophilized from it. The lyophilized material had an activity varying in different preparations from 10 000 to 15 000 HCU per mg. The yield was 0.05—0.1 mg per hog.

Chromatography. 45 mg of a preparation with 12 000 HCU per mg was dissolved in 9 ml of 0.02 M ammonium bicarbonate and the solution allowed to sink into a column (7.5 × 1.4 cm) of 3 g of carboxymethyl cellulose which had been equilibrated with 0.02 M ammonium bicarbonate. Elution was carried out with 0.02 M ammonium bicarbonate. Fractions of 10 ml were collected. The flow rate was 40 ml/h. Collection of the fractions was started from the time when the secretin solution was applied to the column. Between the tenth and the eleventh fraction the eluting solution was changed to 0.2 M ammonium bicarbonate.

The approximate relative concentration of proteinaceous material in the fractions was determined by the Herriott reaction [6] as adapted by Lowry *et al.* [7], except that the copper salt containing stock solution of the latter authors was made up in 0.1 N NaOH instead of in water. The secretin activity was determined by injecting appropriate aliquots of the fractions intravenously into cats and titrating the amount of alkali secreted through a cannula in the main pancreatic duct in response to the injection.

The results are shown in Fig. 1.

The author wishes to thank the Head of the department Professor Erik Jorpes, for his advice and encouragement.

Polymorphism in Calcium Tantalum(V) Oxide $CaTa_2O_6$

LENA JAHNBERG, STEN ANDERSSON and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

It was recently reported by Gasperin [1] that an equimolecular mixture of tantalum(V)oxide and calcium carbonate upon heating at about 1 700°C gives a product possessing the composition $CaTaO_3$ with a multiple-cell, deformed perovskite structure, a of the pseudocubic subcell unit being 3.88 Å. The formation of the new compound should evidently be accompanied by a reduction of tantalum to the tetravalent state. Such a process however, seems rather unlikely in view of the high reluctance to reduction shown by tantalum(V)oxide and of the white colour of the specimen which rather suggests the presence of the state of maximum valency. The density reported for the product (7 $g.cm^{-3}$) likewise is not in good agreement with that calculated for the formula $CaTaO_3$ (7.6 $g.cm^{-3}$) but is in fair accordance with that of a compound such as $Ca_{0.5}Ta^{V}O_3$ (7.1 $g.cm^{-3}$). The validity of the latter formula was actually demonstrated by Gasperin in a subsequent analytical investigation of the

was brought to pH 7.5 with NaOH (glass electrode). Precipitated impurities were filtered off and discarded. The clear filtrate was acidified to pH 5.5 with HCl and the secretin precipitated with ether. After reprecipitation from water with sodium chloride at saturation it was collected on a suction filter and sucked as dry as possible. In repeated preparations the moist material had an activity of about 7 000 HCU per mg. This material was dissolved in water and the pH of the solution brought to 7.2. Three volumes of acetone were then added to the solution. The precipitate that formed was collected by centrifugation and discarded. The secretin was thrown out of solution by adding nine more volumes of acetone to the clear supernatant. The precipitate was collected by centrifugation and dissolved in water. The pH of the solution was adjusted to 5.5 with acetic acid and the secretin lyophilized from it. The lyophilized material had an activity varying in different preparations from 10 000 to 15 000 HCU per mg. The yield was 0.05—0.1 mg per hog.

Chromatography. 45 mg of a preparation with 12 000 HCU per mg was dissolved in 9 ml of 0.02 M ammonium bicarbonate and the solution allowed to sink into a column (7.5 × 1.4 cm) of 3 g of carboxymethyl cellulose which had been equilibrated with 0.02 M ammonium bicarbonate. Elution was carried out with 0.02 M ammonium bicarbonate. Fractions of 10 ml were collected. The flow rate was 40 ml/h. Collection of the fractions was started from the time when the secretin solution was applied to the column. Between the tenth and the eleventh fraction the eluting solution was changed to 0.2 M ammonium bicarbonate.

The approximate relative concentration of proteinaceous material in the fractions was determined by the Herriott reaction [6] as adapted by Lowry *et al.* [7], except that the copper salt containing stock solution of the latter authors was made up in 0.1 N NaOH instead of in water. The secretin activity was determined by injecting appropriate aliquots of the fractions intravenously into cats and titrating the amount of alkali secreted through a cannula in the main pancreatic duct in response to the injection.

The results are shown in Fig. 1.

The author wishes to thank the Head of the department Professor Erik Jorpes, for his advice and encouragement.

Polymorphism in Calcium Tantalum(V) Oxide $CaTa_2O_6$

LENA JAHNBERG, STEN ANDERSSON and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

It was recently reported by Gasperin [1] that an equimolecular mixture of tantalum(V)oxide and calcium carbonate upon heating at about 1 700°C gives a product possessing the composition $CaTaO_3$ with a multiple-cell, deformed perovskite structure, a of the pseudocubic subcell unit being 3.88 Å. The formation of the new compound should evidently be accompanied by a reduction of tantalum to the tetravalent state. Such a process however, seems rather unlikely in view of the high reluctance to reduction shown by tantalum(V)oxide and of the white colour of the specimen which rather suggests the presence of the state of maximum valency. The density reported for the product (7 $g.cm^{-3}$) likewise is not in good agreement with that calculated for the formula $CaTaO_3$ (7.6 $g.cm^{-3}$) but is in fair accordance with that of a compound such as $Ca_{0.5}Ta^{V}O_3$ (7.1 $g.cm^{-3}$). The validity of the latter formula was actually demonstrated by Gasperin in a subsequent analytical investigation of the

substance [2]. A compound of the composition $CaTa_2O_6$ was reported by Ismailzade [3] to have a complex structure.

In the present study mixtures of tantalum(V)oxide and calcium carbonate were heated at 1 200°C in air for several hours and then fused in an electric arc furnace in an argon atmosphere. The specimen rested on the water-cooled copper base of the furnace which caused rapid cooling upon discontinuing the arc. The products were characterized by their X-ray powder patterns, registered in a Guinier camera with strictly monochromatized CuKa_1 radiation and using potassium chloride (a = 6.2919 Å at 20°C) as an internal standard. The following results were thus obtained.

Starting composition	Colour of product	X-ray evidence
$CaCO_3 + Ta_2O_5$	greyish white	non-cubic perovskite-type pattern
$CaCO_3 + 0.5\ Ta_2O_5$	»	complicated pattern
$CaCO_3 + 0.4\ Ta_2O_5$	»	»

Obviously the first specimen, corresponding to a calcium to tantalum ratio of 1:2 is a monophasic, perovskite-type sample. In order to establish the valency of tantalum in this product it was heated for several hours in a stream of oxygen at 800°C. The weight of the sample was not affected by this treatment which shows the tantalum to be pentavalent and suggests the formula of the compound to be $Ca_{0.5}TaO_3$. The colour showed only a slight shift upon heating, from the original greyish to brownish white but the X-ray powder pattern displayed a considerable number of extra reflexions in addition to the lines corresponding to a perovskite-type phase.

In order to study the transformation thus found to occur at 800°C samples of the original preparation ($Ca_{0.5}TaO_3$) were heated for several hours at 1 300°C and 650°C, respectively. The following observations were made:

Heating temperature	Density	X-ray evidence
1 300°C	7.02	complicated pattern
650°C	6.75	cubic, perovskite-type

Upon melting both samples were reconverted to give the non-cubic perovskite-type pattern. The cubic perovskite, upon heating at 1 300°C, gave the complicated pattern mentioned above but this transformation could not be reversed.

The X-ray pattern of the sample which had been quenched from the melting temperature was not indexed. It showed a splitting up of several of the perovskite-type reflexions.

The pattern of the sample heat-treated at 1 300°C, was quite different from the perovskite type. It could be interpreted in terms of an orthorhombic unit cell with

$$a = 11.067\ \text{Å},\quad b = 5.380\ \text{Å},\quad c = 7.505\ \text{Å}$$

indicating a cell content of four formula units of $CaTa_2O_6$ (calculated density = 7.40). Studies on the crystal structure of this modification are in progress.

The unit cell edge of the cubic perovskite structure obtained at 650°C was found to be 3.886 Å. No lines indicating a multiple-cell structure were observed. The arrangement of the calcium atoms should thus be a random one and comparable with that of the alkali atoms in the cubic sodium [4] and lithium [5,6] wolfram bronzes of perovskite type.

This investigation forms part of a research programme on metal oxides and related compounds financiaily supported by the *Swedish Natural Science Research Council.*

Ion Exchange Properties of Alginate Fractions

ARNE HAUG

Norwegian Institute of Seaweed Research, N.T.H., Trondheim, Norway

Recently, two methods for the separation of alginates into chemically different fractions have been published. McDowell [1] separated alginate from *Laminaria hyperborea* (= *L. Cloustoni*) and *Ascophyllum nodosum* into fractions with different ion exchange properties, by precipitation with manganous salts. Haug [2] fractionated alginates from *Laminaria digitata* f. *stenophylla* by means of precipitation with potassium chloride, and the fractions differed in uronic acid composition. The present note reports an investigation of the ion exchange properties and uronic acid composition of the fractions obtained by the two methods.

Materials and methods. The sampling of seaweed and the preparation of alginate is described earlier [2]. The precipitation with potassium chloride was carried out by mixing equal volumes of saturated aqueous potassium chloride and a solution of 0.3 % sodium alginate in water. The amounts of alginate precipitated with manganous salts were found to depend on the pH and the concentration of potassium and sodium ions present. In this investigation, one part of a solution of 0.09 M manganous sulphate and 0.3 M potassium chloride was added to two parts of a solution containing approximately 0.3 % sodium alginate, adjusted to pH 5. After one hour the gellike precipitate was separated from the solution by centrifugation. The alginate was converted to the sodium salt by washing with a dilute solution of sulphur dioxide in water and dissolving in dilute sodium carbonate solution.

A procedure similar to that of Mongar and Wassermann [3] was used for the determination of ion exchange properties. Alginic acid fibers were made by forcing a viscous sodium alginate solution from a pipette with a narrow opening (0.5 mm) into 1 N hydrochloric acid, stirred with a magnetic stirrer. The alginic acid fibers were transferred to a 0.1 M calcium acetate solution. After thorough washing with water, the calcium alginate fibers were placed in 20—35 ml 0.2 M potassium chloride solution and allowed to stand overnight. The calcium concentration in the solution was determined by oxalate precipitation and titration. The calcium bound to the alginate was liberated by 1 N hydrochloric acid and determined.

The methods used for hydrolysis of alginates and chromatography of uronic acids were those given by Fischer and Dörfel [4].

Alginates from *Laminaria digitata* f. *stenophylla*, collected at Tarva, outside the Trondheimsfjord, 3/7 1957, and from *L. hyperborea*, stipes, collected at Munkholmen in the Trondheimsfjord, 26/8 1957, were investigated. The alginates were fractionated according to the two methods, and the ion exchange properties and uronic acid composition of the fractions investigated. The results are shown in Table 1. No attempts have been made to determine the amounts of uronic acids quantitatively, and the results given in the table are estimates based on the size and strength of the spots. The ion exchange properties are characterized by the selectivity coefficient

$$k = \frac{[Ca_g]\,[Na_s]^2}{[Na_g]^2[Ca_s]}$$

where subscripts g and s refer to gel and solution and the concentrations are given as equivalent fractions and normalities, respectively. No attempt has been made to determine the true equilibrium constant involving activities. All figures given in the table are an average of several determinations, and the conditions were chosen so that the equivalent fraction of calcium in the gel in all cases was between 0.4 and 0.7.

The results show that there is a marked difference in ion exchange properties and uronic acid composition between alginate from *Laminaria digitata* and *L.hyperborea* stipes. Preliminary experiments have shown that alginate from *L.hyperborea* fronds resembles that from *L.digitata*. In the latter plant, no large difference between alginate from stipes and fronds have been observed.

The results also show that for both alginates the soluble fraction contains more guluronic acid and has a higher selectivity coefficient than the precipitated fraction when fractionated with potassium chloride, while the opposite is the case when manganous ions are used as precipitating agent. This result indicates that the same type of fractions are produced by both methods, but that the fraction precipitated by potassium chloride corresponds to the fraction that is not precipitated by manganous sulphate. Combining the two methods

Table 1. Uronic acid composition and selectivity coefficients of alginate fractions.

Fractionation method	Fraction	*Laminaria digitata*			*L. hyperborea*, stipes		
		k	Mannuronic acid	Guluronic acid	k	Mannuronic acid	Guluronic acid
No fractionation		7.5	++	+	21.1	+	+++
Potassium chloride	Insoluble (K_i)	6.7	+++	+	15.5	+	++
» »	Soluble (K_s)	9.2	++	++	20.5	(+)	+++
Manganous sulphate	Insoluble (Mn_i)	8.4	++	++	22.9	(+)	+++
» »	Soluble (Mn_s)	7.4	+++	+	10.2	+	++
	Mn_sK_i	6.5	+++	(+)	8.6	++	++
	Mn_iK_s	11.2	+	++	20.3	(+)	+++
	$Mn_sK_iMn_sK_i$	5.1	+++	traces			
	$Mn_iK_sMn_iK_s$	13.1	+	++			

The number of +'s indicates approximately the proportion between the uronic acids in each fraction.

(+): One fifth or less of the total amount of uronic acids.

Traces: One tenth or less of the total amount of uronic acids.

should therefore offer a good opportunity for purifying the fractions. The fractions from the precipitation with manganous sulphate were subjected to fractionation with potassium chloride, and the selectivity coefficient and uronic acid composition were determined for the fraction soluble in manganous sulphate and insoluble in potassium chloride (Mn_sK_i) and the fraction insoluble in manganous sulphate and soluble in potassium chloride (Mn_iK_s). To obtain a further purification the procedure was repeated on the two purified fractions of *L.digitata* alginate. The results are given in Table 1.

The results confirm that alginate from *L.digitata* and *L.hyperborea* stipes is a mixture of macromolecules with different uronic acid composition and different ion exchange properties. Molecules containing a large proportion of guluronic acid residues are accumulated in the fractions which are soluble in potassium chloride solution and precipitated by manganous ions, while molecules rich in mannuronic acid residues are accumulated in the opposite fractions. The fractions containing molecules rich in mannuronic acid residues have a lower affinity for calcium in a calcium-potassium ion exchange reaction than fractions with molecules with predominately guluronic acid residues. Alginates from different sources may have different uronic acid composition, and, consequently, different ion exchange properties, a fact which stresses the necessity of defining the source of the alginate in investigations of these polyuronides.

Further investigations of the alginate fractions are in progress.

Complexes of Divalent Tellurium

OLAV FOSS and SVERRE HAUGE

Chemical Institute, University of Bergen, Bergen, Norway

Tellurium dioxide dissolved in hydrochloric or hydrobromic acid has been found to react with four moles of aqueous thiourea as follows:

$$Te^{IV} + 4\ SC(NH_2)_2 + 2\ X^- \rightarrow Te[SC(NH_2)_2]_2X_2 + [(H_2N)_2C\text{-}S\text{-}S\text{-}C(NH_2)_2]^{++}$$

where Te^{IV} represents tetravalent tellurium and X the halide. Tellurium is reduced to the divalent state, by two moles of thiourea which themselves become oxidized to formamidinium disulphide. The divalent tellurium compound crystallizes out on mixing of the tellurium dioxide and thiourea solutions.

The compounds, $Te(tu)_2Cl_2$ and $Te(tu)_2Br_2$ (tu = thiourea), dissolve in aqueous thiourea to give yellow solutions from which salts containing the cation $Te(tu)_4^{++}$ crystallize out. They also dissolve in aqueous potassium thiocyanate to give, similarly, the thiocyanate $Te(tu)_2(SCN)_2$.

X-Ray crystallographic data have been obtained from oscillation and Weissenberg photographs taken with copper radiation, $\lambda(\alpha) = 1.542$ Å.

Dichloro-dithiourea-tellurium(II), $Te(tu)_2Cl_2$. Monoclinic prismatic, $a = 9.90$ Å, $b = 7.62$ Å, $c = 14.10$ Å, $\beta = 100\frac{1}{2}°$. There are four molecules per unit cell; density, calc. 2.23, found 2.26 g/cm³. Systematic absences, hkl when $h + k + l$ is odd, $h0l$ when h is odd or l is odd.

From Fourier projections along the b and a axes [1], the space group is the centrosymmetric one, C_{2h}^6-I2/c. The tellurium atom lies on a twofold axis, with the other atoms in general positions. Sulphur and chlorine are bonded to tellurium in a planar or approximately planar, square arrangement, with equal atoms in *cis* positions.

Dibromo-dithiourea-tellurium(II), $Te(tu)_2Br_2$, is isomorphous with the dichloro compound. The unit cell dimensions are, $a = 10.10$ Å, $b = 7.74$ Å, $c = 14.67$ Å, $\beta = 100°$, and the density, calc. 2.59, found 2.58 g/cm³.

Dithiocyanato - dithiourea - tellurium (II), $Te(tu)_2(SCN)_2$. Orthorhombic pyramidal, $a = 18.48$ Å, $b = 18.64$ Å, $c = 7.90$ Å. There are eight molecules per unit cell; density, calc. 1.93, found 1.94 g/cm³. The space group, from systematic absences, is $C_{2v}^{19} - Fdd2$, which requires that the tellurium atom lies on a twofold axis.

Presumably the molecular structure is analogous to that of the parent dichloro and dibromo compounds. The slight increase in the length of the c axis relative to the twofold axis of the monoclinic analogs is indicative in this respect. The length, 7.90 Å, excludes the possibility that the atoms of the thiocyanate groups lie on the twofold axis.

The compound was obtained as well developed prisms {110} terminated by {111}, or when prepared from the dibromo compound, as plates {010} elongated in the direction of the c axis; the two forms gave identical X-ray photographs.

Tetrathiourea-tellurium(II) dichloride, $Te(tu)_4Cl_2 \cdot 2H_2O$. Monoclinic prismatic, $a = 6.01$ Å, $b = 16.49$ Å, $c = 9.95$ Å, $\beta = 98\frac{1}{2}°$. There are two formula units per unit cell; density, calc. 1.84, found 1.86 g/cm³. The space group, from systematic absences, is $C_{2h}^5-P2_1/c$. The tellurium atom is thereby required to lie in a centre of symmetry, which is also consistent with the intensity distribution of the $0kl$ reflections, those with $k + l$ even being in most cases markedly stronger than those with $k + l$ odd. It follows from the centrosymmetry that the TeS_4 grouping is planar.

The analytical data and the density point to the presence of two moles of crystal water per mole of salt. The crystals occur as six-sided prisms, bounded by {011} and {010} and terminated by {100}.

Tetrathiourea-tellurium(II) dibromide, $Te(tu)_4Br_2$. The crystals are triclinic, and form thin plates {001} normally elongated in the direction of the a axis. From oscillation and Weissenberg zero-layer photographs about the a and b axes and the shorter ab diagonal, $a = 5.95$ Å, $b = 7.16$ Å, $\gamma = 107°$ or $73°$, $d_{100} = 5.69$ Å, $d_{010} = 6.82$ Å, $d_{001} = 11.05$ Å, $a^* = 84°$, $\beta^* = 88°$. This gives a cell volume of 450 Å³ and one formula unit per unit cell; density, calc. 2.18, found 2.21 g/cm³. If the triclinic space group is the centrosymmetric one, the tellurium atom lies in a centre of symmetry also in this salt.

These are apparently the first instances of complexes of divalent tellurium, apart from the compound $(NH_4)_2TeCl_4$ reported by Lindner and Apolant [2] in 1924 which may possibly contain the ion $TeCl_4^{--}$. In the four-co-ordinated state, divalent tellur-

ium has six electron pairs in its valency shell; a square-planar arrangement of the four bonding pairs is in accordance with the two lone pairs occupying *trans* octahedral positions. The square-planar ICl_4^- ion represents an analogous case.

The compounds have a yellow colour, and are quite stable in the solid state. They blacken on contact with water, probably because of hydrolysis and subsequent rearrangement to zero- and tetravalent tellurium, in analogy with the alkaline hydrolysis of other derivatives of divalent tellurium as for example the telluropentathionate ion.

The $Te(tu)_4^{++}$ ion is probably the yellow species which forms the basis for the photometric determination [3-6] of tellurium with thiourea. The compounds $Te(tu)_2Cl_2$ and $Te(tu)_2Br_2$ may be the same as those isolated recently from thiourea and the tellurium tetrahalides by Aynsley and Campbell [7], and by these authors formulated with two hydrogen atoms less, as amidinothio derivatives of tetravalent tellurium.

Further preparative andstructural work is being made.

Gas Chromatographic Separation of 3- and 4-Methyl-1-pentene

BENGT SMITH and RAGNAR OHLSON

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The separation of 3- and 4-methyl-1-pentene by gas chromatography has, according to our knowledge, not been reported yet. Even on very long columns containing various polar or nonpolar liquids as stationary phases, no resolution of the pair was obtained [1]. This is due to the similarity in type and the close boiling points of the two compounds, the difference being only 0.2°C. It is obvious that this separation problem calls for a stationary phase with a highly selective action on the molecules of the two hexenes.

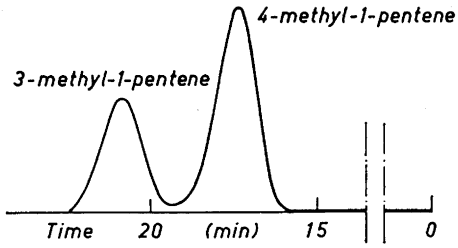

Fig. 1. Mixture of 3- and 4-methyl-1-pentene. Silver nitrate-glycol column, 4 m. Temperature 25°C. Flow of He 50 ml/min.

Such a phase is available in the form of silver nitrate in a suitable solvent, *e.g.* glycol [2,3]. In this case, there exist forces of attraction between the silver ions and the unsaturated hydrocarbons. Thus it was found that the pair in question could be resolved on a 4 m silver nitrate — glycol column containing 17 % of silver nitrate. It should be pointed out, however, that if the content of silver nitrate is appreciably diminished or increased the separation is impaired. The separation of these and other alkenes on a silver nitrate — glycol column will be more fully discussed in a forthcoming paper.

The column was prepared in the following way. Ethylene glycol was saturated with powdered silver nitrate under slight warming and agitation. The solution was decanted from undissolved silver nitrate and mixed with Chromosorb (30—60 mesh). Two parts of Chromosorb were taken to one part of the solution. The mixture was rotated in a round-bottomed flask to ensure thorough mixing of the carrier and the stationary phase. The mixture obtained was packed in two aluminium tubes each 2 m long and with a 4 mm internal diameter.

A Halogen Exchange Reaction in a Diazonium Compound

BO LAMM

Nobel Institute of Chemistry, Stockholm 50, Sweden

Some 60 years ago, Hantzsch [1,2] found that under suitable conditions, a halogen exchange reaction takes place in 2,4- and 2,6-dibromobenzenediazonium chloride, leading to mixtures of bromochlorobenzenediazonium bromides. An aromatic halogen atom, activated by electron-attracting groups in the positions *ortho* and *para* to the halogen, is known to be particularly reactive towards nucleophilic reagents [3]. 2,4-Dinitrohalobenzenes are well-known compounds of this kind. One might think that the diazonium group, $-N_2^+$, should have a considerably activating influence upon an *ortho*- or *para*-substituted halogen atom. In virtue of its formal positive charge, the diazonium group might be expected to attract the mobile π-electron cloud of the benzene ring even more than a nitro group would do. This idea has been emphasized by Bunnett and Zahler [3]. In a recent paper [4], Lewis and Johnson also give strong support to this concept.

Sihlbom [5,6] made a kinetic investigation of a rather unusual type of reaction occurring in some dinitroanilines, yielding corresponding dichloronitrobenzenes. The reaction was found to proceed with diazonium ions as intermediates.

Sihlbom's results suggested the present work, in which it has been found that 4-bromo-3-nitrobenzenediazonium chloride in dilute acetic acid containing excess hydrochloric acid exchanges its bromine atom for chlorine, thereby yielding 4-chloro-3-nitrobenzenediazonium chloride. This was shown by replacing the diazonium group with a chlorine atom in a Sandmeyer reaction with cuprous chloride. That the halogen exchange reaction did not occur during the Sandmeyer reaction was checked as described in the experimental part.

The reaction product from the Sandmeyer reaction would be 1,4-dichloro-2-nitrobenzene if the abovementioned halogen exchange had taken place, otherwise 1-bromo-4-chloro-2-nitrobenzene. In order to assay a mixture of these two compounds, IR-spectra (2—15 μ) of the pure components were run both in carbon disulphide and carbon tetrachloride solutions. The spectra, however, were too alike to make any quantitative analysis feasible. Therefore, a chemical method, previously used by Holleman [7], was employed. This involved a nucleophilic reaction with sodium methoxide converting the halogen atoms *ortho* to the nitro group into ionic form, thereby making it possible to precipitate them as silver salts after separation from the resulting 4-chloro-2-nitroanisole.

Experimental. 2.17 g (0.01 mole) of 4-bromo-3-nitroaniline, synthesized according to Blanksma [8], were dissolved in 25 ml of glacial acetic acid. This solution was carefully added to a solution of 0.7 g (0.01 mole) of sodium nitrite in 5 ml of conc. sulphuric acid while cooling in an ice-bath. The temperature of the reaction mixture was kept between + 10° and + 20°. 10 g of ice and 50 ml of conc. hydrochloric acid were added, and the resulting diazonium solution was left at + 25° for one week. It was then filtered from some brown sludge and poured into a cuprous chloride solution, prepared by dissolving 9.9 g of cuprous chloride in 35 ml of conc. hydrochloric acid (making 0.1 mole of cuprous chloride.) Nitrogen was evolved, and a yellowish substance was precipitated. By steam distillation, which was continued until no more organic material was carried over, this substance was purified and obtained as an almost colourless, crystalline mass. This, after washing and drying, was finally purified by sublimation *in vacuo*. Yield 1.15 g of colourless crystals, m.p. 53°, reported for 1,4-dichloro-2-nitrobenzene 53° [9]. Mixed with an authentic sample, m.p. found 53°. Hardly any material was left in the sublimation residue. Assuming the reaction product to be a mixture of 1,4-dichloro-2-nitrobenzene and 1-bromo-4-chloro-2-nitrobenzene, a halogen analysis was performed according to Holleman [7]. By this method, no bromine compound could be detected. The yield of 1,4-dichloro-2-nitrobenzene in the reaction series could then be calculated, being 60 %.

In order to prove that the halogen exchange had not taken place during the Sandmeyer reaction, the exchange experiment was repeated exactly as above, except that immediately after the conc. hydrochloric acid had been added to the diazonium solution, the Sandmeyer reaction was carried out. Steam distillation followed by vacuum sublimation yielded 1.8 g (76 %) of a colourless product melting at 68°, undepressed upon admixture with a sample of 1-bromo-4-chloro-2-nitrobenzene, synthesized according to Holleman [10], m.p. 69—70°. Thus it was concluded that halogen

exchange must have taken place in the diazonium compound at + 25°. The kinetics of this and similar reactions will be investigated.

All melting points were determined on the Kofler bank.

Butyrylcholine Esterase: Influence of pH on Enzyme Activity and Irreversible Denaturation

EDITH HEILBRONN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

There is much confusion in the literature concerning the shape of the pH-activity curves of choline esterases. It is obvious that there are several factors which together form the shape of these curves. Assuming that the substrate used does not change its charge in the examined pH-area, the following factors have to be considered. Concerning the substrate: The concentration of the substrate is important, as the substrate may compete with hydrogen or hydroxyl ions for an active group in the enzyme. Concerning the medium: In using buffers for maintenance of different pH-values from, *e.g.*, 5—10, both the charge of the ions (*e.g.* phosphate), and thus the ionic strength, and the kind of substance present has to be changed. Concerning the protein: A change in enzyme activity from one pH to another may depend on true reversible changes in one or more of the active centres in the enzyme. On the other hand, the irreversible denaturation of the protein has to be considered. This depends on the temperature used in the experiment, the incubation time, the buffer ions, the ionic strength, the kind of enzyme and the state of purity of the enzyme used. Also, the procedure used during the experiment influences the enzyme activity; in this laboratory (unpublished work) it has thus been observed that the shaking rate in a Warburg apparatus influences the activity. Vigorous shaking causes a lowering of the activity.

During experiments on the purification of choline esterases we had reason to look into the stability of serum fraction IV-6-3 from human retroplacentar serum (BuChE). The studies were performed by means of an automatic recording titrator [1]. The sample containing the enzyme was kept, under stirring, in 0.10 M potassium chloride at 25°C during 5 — 120 min and at pH-values between 6.00 and 10.00. These pH-values were obtained by the addition of minute amounts of sodium hydroxide from the syringe of an automatic titrator. Afterwards, the pH was adjusted to 8.00 and the enzyme activity was determined. The substrate was a 10^{-2} M solution of bu-

Butyrylcholine Esterase: Influence of pH on Enzyme Activity and Irreversible Denaturation

EDITH HEILBRONN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

There is much confusion in the literature concerning the shape of the pH-activity curves of choline esterases. It is obvious that there are several factors which together form the shape of these curves. Assuming that the substrate used does not change its charge in the examined pH-area, the following factors have to be considered. Concerning the substrate: The concentration of the substrate is important, as the substrate may compete with hydrogen or hydroxyl ions for an active group in the enzyme. Concerning the medium: In using buffers for maintenance of different pH-values from, *e.g.*, 5—10, both the charge of the ions (*e.g.* phosphate), and thus the ionic strength, and the kind of substance present has to be changed. Concerning the protein: A change in enzyme activity from one pH to another may depend on true reversible changes in one or more of the active centres in the enzyme. On the other hand, the irreversible denaturation of the protein has to be considered. This depends on the temperature used in the experiment, the incubation time, the buffer ions, the ionic strength, the kind of enzyme and the state of purity of the enzyme used. Also, the procedure used during the experiment influences the enzyme activity; in this laboratory (unpublished work) it has thus been observed that the shaking rate in a Warburg apparatus influences the activity. Vigorous shaking causes a lowering of the activity.

During experiments on the purification of choline esterases we had reason to look into the stability of serum fraction IV-6-3 from human retroplacentar serum (BuChE). The studies were performed by means of an automatic recording titrator [1]. The sample containing the enzyme was kept, under stirring, in 0.10 M potassium chloride at 25°C during 5 — 120 min and at pH-values between 6.00 and 10.00. These pH-values were obtained by the addition of minute amounts of sodium hydroxide from the syringe of an automatic titrator. Afterwards, the pH was adjusted to 8.00 and the enzyme activity was determined. The substrate was a 10^{-2} M solution of bu-

Incubation times: △ = 5 minutes, ○ = 30 minutes, ● = 60 minutes, × = 120 minutes. Temperature 25°C.

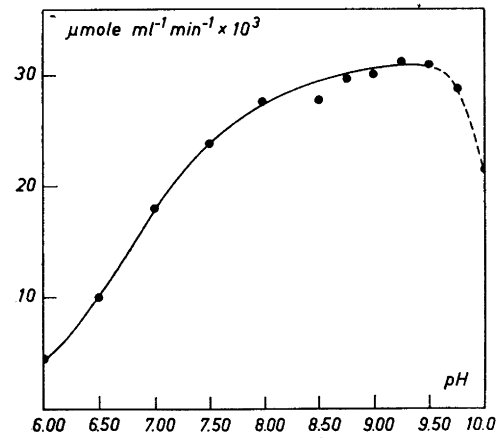

Fig. 2. pH-activity curve for butyrylcholine esterase at 25°C. Substrate: 10^{-2} M acetylcholine iodide.

tyrylcholine iodide (final concentration). The activity was recorded during a 5 min period immediately after addition of the substrate and after a small correction of the pH had been made. (This correction was necessary since the substrate was somewhat acid.) Fig. 1 shows the result. The activities are expressed in per cent of an initial enzyme activity obtained at pH 8.00. Irreversible denaturation was found to be slowest around pH 6.00 and increases with the pH and with the incubation time.

The automatic recording titrator was then used to reinvestigate the pH-activity curve for BuChE. A 10^{-2} M solution of acetylcholine iodide was used as substrate. The obtained values of the activity were corrected for spontaneous hydrolysis as described earlier [2]. Fig. 2 shows the curve, which agrees well with the experimental data published earlier by Wilson [3] and a curve published by Hase [4]. (Hase, however, used equine serum as source for the enzyme). The curve obtained in this work is, however, different from curves published by many others and is also different from two curves obtained in this laboratory. [5,6] The present curve and those published by Wilson and Hase were obtained with an automatic titrator, thus without buffer solutions, and in two cases without incubation times for the enzyme (Hase seems to have incubated for 15 min). The curves were determined with a 10^{-2} M or $10^{-2.4}$ M (Hase) concentration of the substrate. Wilson, furthermore, used a 0.1 % solution of gelatine to protect the enzyme. An earlier published curve by Heilbronn [5] was obtained in buffer solutions and at a lower substrate concentration. The different buffer ions may have caused denaturation of the enzyme during the incubation time of 30 min and may also have enhanced hydrolysis in different ways. Tammelin [6] used unpurified human serum, and also a lower substrate concentration. Obviously, the shape of the pH-activity curve depends on the method used.

Fractionation of Snake Venom by the Gel-Filtration Method

WALTER BJÖRK and JERKER PORATH

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

The use of gel-filtration as a fractionation method has recently been reported [1]. Attempts to apply the procedure to the fractionation of crude biological extracts have been successful [2,3], but in these cases only for separating proteins and protein-complexes from low-molecular weight material. It was shown, however [2], that proteins of low molecular weight like ribonuclease and cytochrome c could be retarded on a gel of suitable crosslinking, and Gelotte has recently obtained a separation of enzymes from pancreatic juice (private communication). In earlier work carried out at this institute [4] most of the UV-absorbing components of the venom from the ringhals cobra, *Hemachatus haemachates*, including lecithinase A, had been found to have a rather low molecular weight, and thus we thought it would be of great value to in-

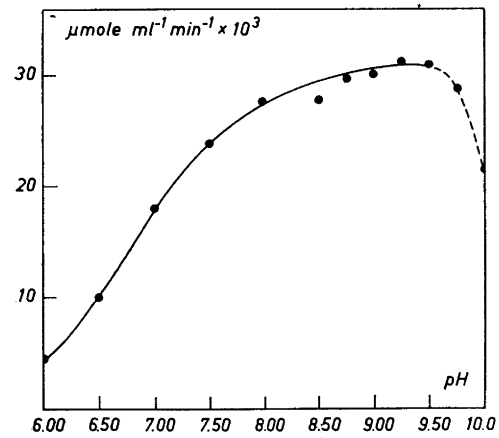

Fig. 2. pH-activity curve for butyrylcholine esterase at 25°C. Substrate: 10^{-2} M acetylcholine iodide.

tyrylcholine iodide (final concentration). The activity was recorded during a 5 min period immediately after addition of the substrate and after a small correction of the pH had been made. (This correction was necessary since the substrate was somewhat acid.) Fig. 1 shows the result. The activities are expressed in per cent of an initial enzyme activity obtained at pH 8.00. Irreversible denaturation was found to be slowest around pH 6.00 and increases with the pH and with the incubation time.

The automatic recording titrator was then used to reinvestigate the pH-activity curve for BuChE. A 10^{-2} M solution of acetylcholine iodide was used as substrate. The obtained values of the activity were corrected for spontaneous hydrolysis as described earlier [2]. Fig. 2 shows the curve, which agrees well with the experimental data published earlier by Wilson [3] and a curve published by Hase [4]. (Hase, however, used equine serum as source for the enzyme). The curve obtained in this work is, however, different from curves published by many others and is also different from two curves obtained in this laboratory. Fractionation of Snake Venom by the Gel-Filtration Method

WALTER BJÖRK and JERKER PORATH

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

The use of gel-filtration as a fractionation method has recently been reported [1]. Attempts to apply the procedure to the fractionation of crude biological extracts have been successful [2,3], but in these cases only for separating proteins and protein-complexes from low-molecular weight material. It was shown, however [2], that proteins of low molecular weight like ribonuclease and cytochrome c could be retarded on a gel of suitable crosslinking, and Gelotte has recently obtained a separation of enzymes from pancreatic juice (private communication). In earlier work carried out at this institute [4] most of the UV-absorbing components of the venom from the ringhals cobra, *Hemachatus haemachates*, including lecithinase A, had been found to have a rather low molecular weight, and thus we thought it would be of great value to in-

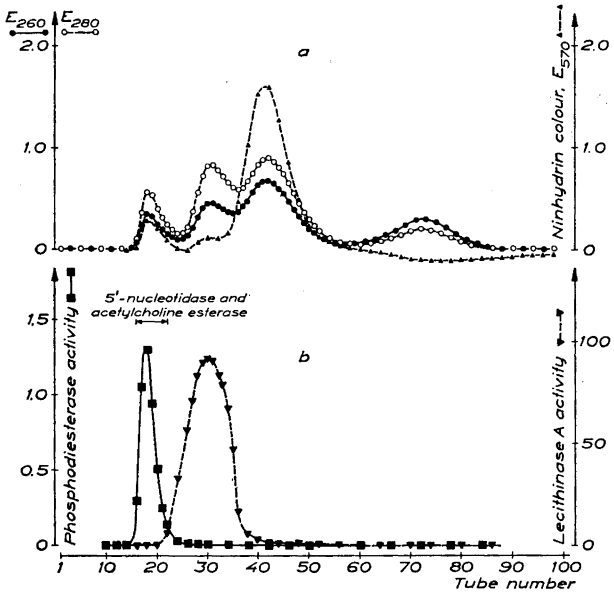

Fig. 1. Gel-filtration of 30 mg of freeze-dried ringhals cobra venom on a 60 ml column (1.9 × 21 cm) of dextran gel. The water regain of the gel was about 8 g/g. The venom was dissolved in 1 ml 0.05 M THAM-HCl of pH 7.6, and elution was performed with the same buffer. Fraction volumes about 1.0 ml. For the ninhydrin tests (▲ — — — ▲) 0.2 ml aliquots were taken. Phosphodiesterase activity (■——■) is given in mmoles of substrate split in 30 min per litre of incubation mixture, and lecithinase A activity (▼ — — — ▼) as increased extinction in 30 min at 540 mμ (hemoglobin).

vestigate the behaviour of this venom on gels of a low degree of crosslinking.

Freeze-dried ringhals venom was obtained from The South African Institute for Medical Research, Johannesburg. In order to compare it with another type of snake venom, we also used the venom of a rattle-snake, *Crotalus adamanteus;* this venom was bought from Ross Allen's Reptile Institute, Silver Springs, Florida.

Starch gel with a water regain of 5.1 g/g and dextran gel with a water regain of about 8 g/g were supplied by A.B. Pharmacia, Uppsala, Sweden. The buffer system used was tris(hydroxymethyl)aminomethane-hydrochloric acid (THAM-HCl). Before packing a column the gel was allowed to swell in the buffer overnight, and then it was deaerated in a suction flask. All the experiments were performed in a cold room at 4°.

The extinctions at 280 and 260 mμ were measured in a Beckman DU spectrophotometer using a 1-cm semi-micro cell. Phosphodiesterase, lecithinase A, L-amino acid oxidase and acetylcholine esterase activities were determined as described earlier [4,5]. For the estimation of 5'-nucleotidase activity a substrate solution of the following composition was used: 0.01 M adenosine-5'-phosphate, 0.01 M magnesium sulphate and 0.05 M THAM-HCl of pH 8.9. Of this solution 0.5 ml was incubated for 30 min at 37° with 0.05 ml of each fraction to be tested. The reaction was stopped with 1 ml of 2.5 % H_2SO_4, and the inorganic phosphate liberated was determined by a modification of King's method [6].

The ninhydrin curve was obtained according to Moore and Stein [7]. In the figures the colour given by the filtration buffer has been subtracted.

Fig. 1 shows the result of a gel-filtration of 30 mg of ringhals venom on a 60 ml column (1.9 × 21 cm) of dextran gel. The venom had been dissolved in 1 ml THAM-HCl of pH 7.6, and after applying the solution to the

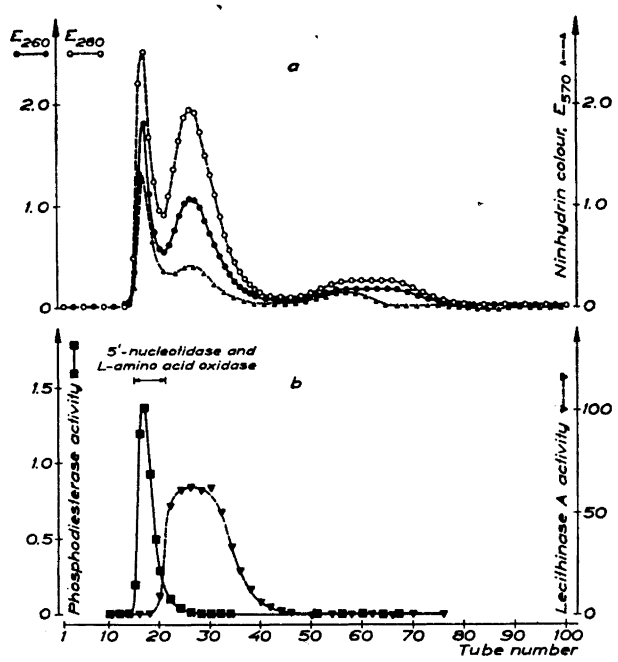

Fig. 2. Gel-filtration of 30 mg of rattle-snake venom on the same column and under the same conditions as in Fig. 1.

column, elution was performed with the same buffer. The rate of elution was about 6 ml/h, and 1 ml fractions were collected. In the upper part of the figure it can be seen that the venom was fractionated into four different zones, and that 90 % of it was retarded on the column. Three of the enzymes tested for, phosphodiesterase, acetylcholine esterase and 5'-nucleotidase, appeared together in the first peak (lower part of the figure), whereas the lecithinase A was eluted in the second peak, well separated from the other enzymes. In all the experiments performed the recovery of UV-absorbing material was about 100 %.

By chromatography on diethylaminoethyl (DEAE) cellulose the phosphodiesterase has been separated from cholinesterase and lecithinase A[4], but then the latter two enzymes left the column in a single zone. Gel-filtration would therefore be a useful step in the purification of the three enzymes, especially as a transference to another buffer could be achieved at the same time. Unfortunately, the recovery of cholinesterase from the dextran gel was very low, 10—20 %, probably depending on impurities in the gel. Washing with *ortho*-phenanthroline in order to remove traces of heavy metals had no significant effect, but after treating the gel with 10 % hydrochloric acid the recovery of cholinesterase was increased considerably. The inactivation could be ascribed neither to removal of a cofactor nor to reversible adsorption.

The recoveries of phosphodiesterase and lecithinase A were about 90 % and 100 %, respectively. In the experiments made on starch gel we also got a very high recovery of cholinesterase activity, but in that case the fractionation was not so good. One third of the UV-absorbing material was eluted in the first peak and more than half of it in the second peak, while the third peak had disappeared completely. However, with a more weakly cross-linked starch gel the separation properties would certainly be improved.

The quotient E_{260}/E_{280} was found to be higher than unity in the most retarded zone (tubes 60—85 in Fig. 1), which may be taken as an indication of a large proportion of nucleotides in this zone. It should also

be observed that the corresponding ninhydrin values are below zero. This might be caused by the formation of complexes between the substances eluted and the THAM buffer, and such a binding of THAM by some components of snake venom has already been suggested as an explanation of a phenomenon encountered in ion exchange chromatography of venom [4,5]. By gel-filtration of the chromatographic fractions in question we have indeed shown that they are partly identical with the fourth zone in Fig. 1.

Gel-filtration of the rattle-snake venom (Fig. 2) was performed on the same dextran-gel column and under the same experimental conditions as described above. This venom does not contain any cholinesterase but has a much higher concentration of L-amino acid oxidase and a considerably stronger UV-absorption than the cobra venom. As in the former case lecithinase A was the only enzyme retarded to any appreciable degree. The ninhydrin and UV-extinction patterns, however, were quite different from those obtained with the ringhals venom. About 85 % of the material applied appeared in the first two peaks, and the large ninhydrin zone corresponding to the tubes 35—50 in Fig. 1 was missing. The most retarded zone had a very flat and elongated shape, and the quotient E_{260}/E_{280} was lower than unity in all fractions. As the ringhals and the rattle-snake belong to different families (*Elapidae* and *Crotalidae*, respectively), it would be of great interest to know to what extent these differences are typical. In the general mapping of the components of snake venoms gel-filtration may prove to be a valuable tool.

We have also compared gel-filtration experiments carried out at different pH values and with buffers of varying concentrations. The only deviation found was a slightly more pronounced tailing of the lecithinase A at low ionic strengths. This might be interpreted as a weak adsorption tendency, but at present no definite opinion can be formed on this question.

We are indebted to professor A. Tiselius for his stimulating interest and to Dr. J. H. Mason, Johannesburg, for the supply of ringhals venom. The work has been financially supported by grants from the *Rockefeller* and *Wallenberg Foundations*.

Quantitative Determination of Carotene by Paper Chromatography

ARNE JENSEN

Norwegian Institute of Seaweed Research, N.T.H., Trondheim, Norway

It has been shown previously [1] that carotenes can be quantitatively separated from the other chloroplast pigments by chromatography on a filter paper with a kieselguhr filler. On the basis of this observation a method for the quantitative determination of carotene in dried grass and seaweed meal has been worked out.

Procedure. Approximately 1 g of the finely ground sample is moistened * with 2 ml of water in a 100 ml Erlenmeyer flask. After standing for 15 min (to allow swelling), acetone (25 ml) is added and the sample left over night under nitrogen in the dark. The solution is then decanted through a sintered glass funnel, and the residue is extracted with another 25 ml of acetone. The extraction is repeated until the filtrate remains colourless. Then the combined extracts are concentrated *in vacuo* to a small volume, transferred quantitatively to a volumetric flask (10 or 25 ml according to the content of carotene) and made up to the mark with acetone.

An aliquot of the extract (0.2—0.8 ml) is applied onto the centre of a circular filter paper; (Schleicher & Schüll, No. 287, Kieselguhr-filter, 18 cm diameter) the solvent being continuously evaporated by a stream of nitrogen. When the spot is dry, the paper is placed between similar halves of 15 cm petri dishes, and the chromatogram is developed with pure petroleum ether (b.p. 60—80°C) according to the technique of Rutter [2]. As soon as the carotenes, which migrate close to the solvent front, are separated from the other pigments,

* Essential for quantitative extraction of carotene from the seaweed meal.

be observed that the corresponding ninhydrin values are below zero. This might be caused by the formation of complexes between the substances eluted and the THAM buffer, and such a binding of THAM by some components of snake venom has already been suggested as an explanation of a phenomenon encountered in ion exchange chromatography of venom [4,5]. By gel-filtration of the chromatographic fractions in question we have indeed shown that they are partly identical with the fourth zone in Fig. 1.

On the basis of this observation a method for the quantitative determination of carotene in dried grass and seaweed meal has been worked out.

Procedure. Approximately 1 g of the finely ground sample is moistened * with 2 ml of water in a 100 ml Erlenmeyer flask. After standing for 15 min (to allow swelling), acetone (25 ml) is added and the sample left over night under nitrogen in the dark. The solution is then decanted through a sintered glass funnel, and the residue is extracted with another 25 ml of acetone. The extraction is repeated until the filtrate remains colourless. Then the combined extracts are concentrated *in vacuo* to a small volume, transferred quantitatively to a volumetric flask (10 or 25 ml according to the content of carotene) and made up to the mark with acetone.

An aliquot of the extract (0.2—0.8 ml) is applied onto the centre of a circular filter paper; (Schleicher & Schüll, No. 287, Kieselguhr-filter, 18 cm diameter) the solvent being continuously evaporated by a stream of nitrogen. When the spot is dry, the paper is placed between similar halves of 15 cm petri dishes, and the chromatogram is developed with pure petroleum ether (b.p. 60—80°C) according to the technique of Rutter [2]. As soon as the carotenes, which migrate close to the solvent front, are separated from the other pigments,

* Essential for quantitative extraction of carotene from the seaweed meal.

Table 1. Carotene content of dried grass and seaweed meal, mg/kg.

Material	Method: Paper chromatography	Column chromatography
Dried grass	274, 277, 284, 284	250
» »	248, 249, 252	240
Seaweed meal	101, 103	95

the development is interrupted, and the carotene zone is cut out immediately. The strip is then packed tightly in a glass tube (of approximately 8 mm inner diameter) which has a capillary end. The elution is carried out with 5 ml of acetone applied in several small portions and the eluate is made up to precisely 5 ml. The optical density is read in a spectrophotometer at 456 mμ and the carotene content calculated from the extinction coefficient of β-carotene ($E^{1\,\%}_{1\,cm}$ = 2 490 in acetone). No interference with the absorption at 456 mμ was obtained with the eluates from a blank chromatogram.

The method described above has certain advantages over the conventional method, mainly because it avoids time consuming transference of the carotenes from acetone to petroleum ether. It is simple, requires very little equipment, and may, with a few alterations, be used for microdetermination of carotenes. From Table 1 it is seen that the accuracy of the method was satisfactory. The results obtained with the above procedure were comparable with, although somewhat higher than, those obtained by the conventional analysis [3]. This is believed to be caused by the higher over all recoveries obtained with the new method.

The Structure of the Benzene Diazonium Ion

CHR. RØMMING

Universitetets Kjemiske institutt, Blindern-Oslo, Norway

The structure of benzene diazonium chloride ($C_6H_5N_2Cl$) has been examined by X-ray methods. As the general features of the diazonium group is settled after *one* Fourier projection owing to the high crystal symmetry, a preliminary report of the first part of the structure determination is given.

Benzene diazonium chloride single crystals were grown from an ethanol solution by slow precipitation with ether at 0°C. The space group is $C222_1$ and the unit cell dimensions are a = 15.16 Å, b = 4.95 Å, c = 9.05 Å as determined from oscillation and Weissenberg photographs taken at −90°C. With four molecules in the unit cell (calculated density 1.374) this space group demands the molecules to be in special positions, *i.e.* the molecules have twofold axes of symmetry parallel to the x or y axis.

Integrated Weissenberg photographs were taken at −90°C with rotation about the b axis and the intensities measured with a microphotometer. Approximate x and z parameters were determined from a Patterson projection and refined on the basis of successive Fourier syntheses. Finally, a few cycles of least squares refinements brought the reliability factor R down to 6.5 %. Absorption and secondary extinction corrections were not applied, and the thermal vibrations were regarded as isotropic.

A part of the Fourier projection (plane group *pmg*; $c' = c$, $a' = a/2$) along the b axis is shown in Fig. 1. The chloride ion is situated at the origin and the twofold axis of the diazonium ion has the coordinates (x, 1/4). The interatomic distances within the diazonium ion to be found in true lengths in this projection are as follows: N_1-N_2 = 1.11 Å, N_1-C_1 = 1.42 Å and C_1-C_4 = 2.70 Å. Supposing the line through C_2-C_3 to be parallel to the x axis

Charge Transfer Compounds with a Halogen Atom linked to Carbon as the Electron Acceptor

T. BJORVATTEN and O. HASSEL

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The crystal structures of several addition compounds have recently been determined in which halogen molecules act as electron acceptors. Structures of compounds in which a halogen atom is linked to carbon in the acceptor molecule have not been investigated, however. Compounds like those formed by iodoform with three molecules of quinoline or S_8 therefore appeared to be of considerable interest. The crystal structure of the former has now been determined and the investigation of the sulphur compound has been started.

The unit cell of the quinoline compound is rhombohedral with the hexagonal axes $a = 22.40$ Å and $c = 4.59$ Å. The rhombohedral unit cell contains *one* molecule of iodoform which is therefore situated on the trigonal axis (the space group is $R3$) whereas the three quinoline molecules occupy general positions. It was not difficult to localize the former, but the lack of symmetry elements others than a threefold axis made the localization of the quinoline molecules more cumbersome.

Fig. 1 shows a difference Fourier map (projection along the trigonal axis) with subtraction of the contribution from iodine atoms. The position of one iodine atom is indicated by an asterisk and the three axes indicated are the projections of the rhombohedral axes into the (111) plane. Already from this projection a linear arrangement N-I-C might be expected. This expectation is confirmed by the analysis. The N-I distance is found equal to 2.99 Å, the C-I distance to 2.12 Å.

These findings also confirm the suggestion that the iodine atoms act as electron acceptors towards the nitrogen atoms and

Charge Transfer Compounds with a Halogen Atom linked to Carbon as the Electron Acceptor

T. BJORVATTEN and O. HASSEL

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The crystal structures of several addition compounds have recently been determined in which halogen molecules act as electron acceptors. Structures of compounds in which a halogen atom is linked to carbon in the acceptor molecule have not been investigated, however. Compounds like those formed by iodoform with three molecules of quinoline or S_8 therefore appeared to be of considerable interest. The crystal structure of the former has now been determined and the investigation of the sulphur compound has been started.

The unit cell of the quinoline compound is rhombohedral with the hexagonal axes $a = 22.40$ Å and $c = 4.59$ Å. The rhombohedral unit cell contains *one* molecule of iodoform which is therefore situated on the trigonal axis (the space group is $R3$) whereas the three quinoline molecules occupy general positions. It was not difficult to localize the former, but the lack of symmetry elements others than a threefold axis made the localization of the quinoline molecules more cumbersome.

Fig. 1 shows a difference Fourier map (projection along the trigonal axis) with subtraction of the contribution from iodine atoms. The position of one iodine atom is indicated by an asterisk and the three axes indicated are the projections of the rhombohedral axes into the (111) plane. Already from this projection a linear arrangement N-I-C might be expected. This expectation is confirmed by the analysis. The N-I distance is found equal to 2.99 Å, the C-I distance to 2.12 Å.

These findings also confirm the suggestion that the iodine atoms act as electron acceptors towards the nitrogen atoms and

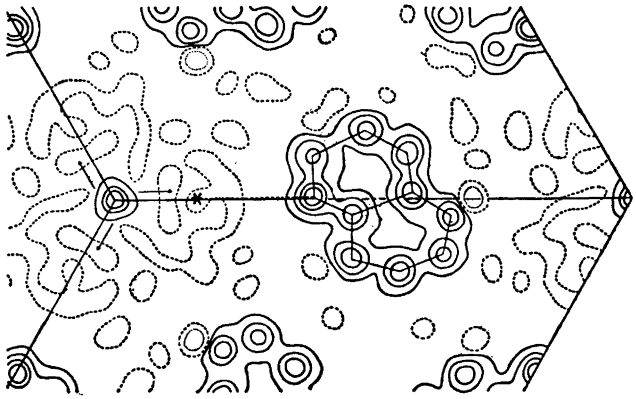

Fig. 1.

makes it appear probable that the iodine atoms have acquired ten electron systems resembling those of the "first" halogen atom in addition compounds formed by halogen molecules.

Apparently, addition compounds in which halogen atoms linked to carbon act as electron acceptors are not numerous. The 1:1 compounds, however, formed by oxalyl halides and dioxan are probably of this kind. X-Ray work on these oxalyl chloride and bromide compounds has therefore been started.

Fractionation of Polymers by Liquid-Liquid Distribution

II. Selection of Experimental Conditions

KARL ERIK ALMIN

Swedish Forest Products Research Laboratory, Paper Technology Department, Stockholm, Sweden

Polyglycols have been distributed between selected solvents in order to establish proper experimental conditions for countercurrent experiments. The concentration dependence of the partition coefficient has been discussed and the resolving power of a Craig apparatus has been discussed from theoretical point of view.

In previous communications [1,2] the fractionation of polymers by means of countercurrent methods was discussed from a theoretical point of view. In this paper, experiments will be reported which give information about the most suitable experimental conditions. The polymer used in these experiments was polyglycol

$$CH_2OH - [CH_2 - O - CH_2]_n - CH_2OH$$

SOLVENT SYSTEMS

The choice of solvents for these experiments must be made with due consideration to several factors. The mean partition coefficient of the polymer must not deviate too much from unity. This ensures that we do not have to use a volume ratio for the two phases which differs too much from one in order to get suitable amounts of the polymer in the different phases. A system composed of two immiscible or partly immiscible pure liquids cannot be expected to fulfil, at a fixed temperature, the requirements with respect to the partition coefficient since the polymer will most probably pass completely into one of the phases. A two phase liquid system composed of at least three pure liquids would therefore appear necessary. In a three component system, changes in the composition of the phases can be made in order to make it possible to obtain a suitable mean partition coefficient for the polymer. It is important from a practical point of view that the phases should separate easily, thus avoiding loss of time or the use of a centrifuge.

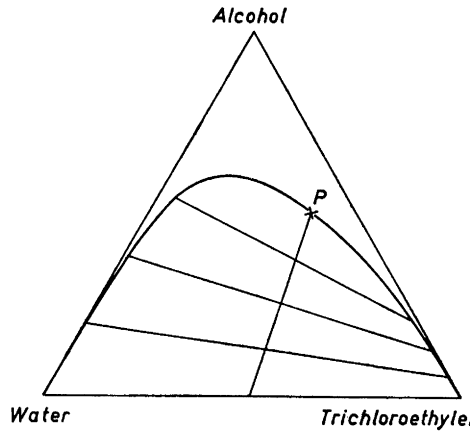

Fig. 1. Approximate phase diagram of the liquid system, trichloroethylene, alcohol (95 %) and water. P = plait-point.

Schulz and Nordt [3] have reported that the liquid system, water-chloroform-benzene, is not satisfactory for the fractionation of polyglycols because of the ease of formation of emulsions. For this reason, some other three component liquid systems have been chosen. The three component system, trichloroethylene-alcohol-water (TAW), proved to be very satisfactory in this respect. The three component system, trichloroethylene-chloroform-water (TCW), was nearly as good in this respect and had — as will be shown in the experiments — very good properties with respect to the resolving power.

In order to examine the possibility of using the liquid system TAW, the ternary phase diagram was first determined. The binodal curve was obtained by mixing suitable amounts of trichloroethylene and alcohol or water and alcohol and titrating with water or trichloroethylene, respectively, to the point of first appearance of turbidity. Approximate tie-lines were determined in the following way. The three components were mixed in suitable amounts in a graduated vessel and the volume ratio of the two phases was determined. The tie-lines were then considered to be divided into this ratio by the point which gives the composition of the system. The plait-point was obtained as the point where the binodal curve and the curve joining the middle points of the approximate tie-lines intersect. The phase diagram obtained, see Fig. 1, is thus not theoretically correct. On the other hand, it gave all the information necessary for the subsequent experiments. One can see how the three components should be mixed in order to obtain a two phase system with a predicted composition and volume ratio for the two phases. The author only dealt with equal volumes for the two phases and since the plait-point corresponds to the volume ratio 0.40: 0.51: 0.09 for trichloroethylene, alcohol (95 %) and water, it can be calculated that the three liquids should be mixed in the volume ratio

$$(0.5-0.20\ v) : v : (0.5-0.80\ v) \text{ with } v < 0.51.$$

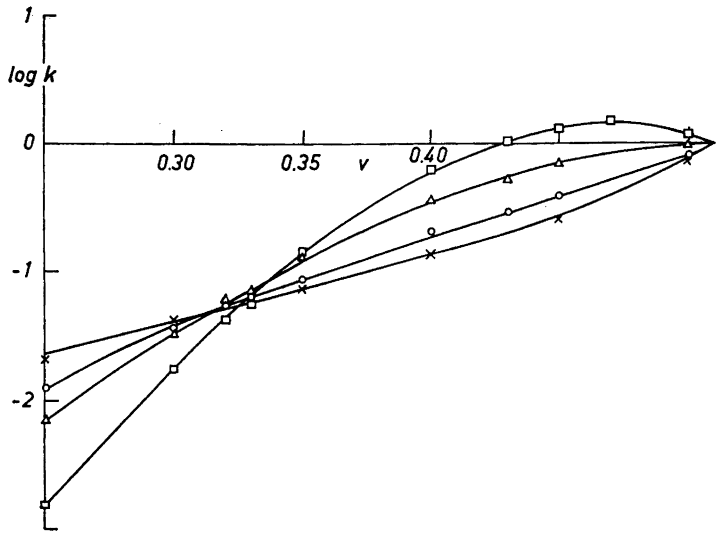

Fig. 2. Apparent partition coefficient for polyglycol in the liquid system TAW as a function of the composition. × A 300, O A 1 500, △ A 4 000, □ A 6 000.

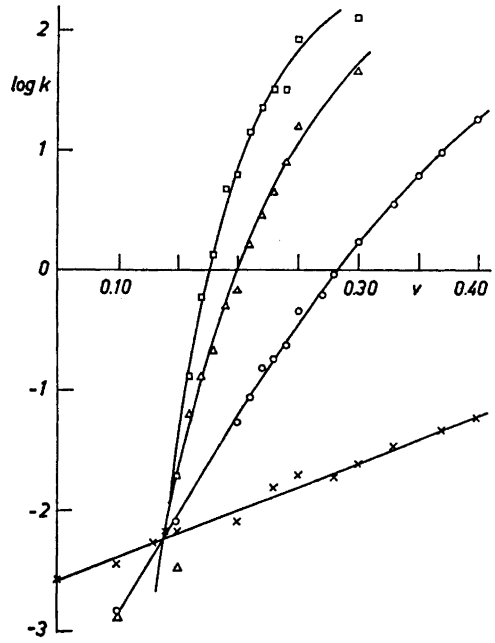

Fig. 3. Apparent partition coefficient for polyglycol in the liquid system TCW as a function of the composition (for notation see Fig. 2).

Both trichloroethylene and chloroform are practically immiscible with water. Equal volumes of the two phases of the liquid system TCW are thus obtained when the three liquids are mixed in the volume ratio $(0.5 - v) : v : 0.5$.

An analysis of this type is necessary in order to facilitate the planning of a systematic investigation of these liquid systems. Furthermore, any undesirable waste of solvents can be avoided.

APPARENT PARTITION COEFFICIENTS

In Fig. 2, the apparent partition coefficients for four commercial polyglycols in the liquid system TAW are plotted as a function of the composition parameter v. Since the upper phases will be used as the stationary phases in the forthcoming countercurrent experiments, the partition coefficient is, in accordance with the definition given in Ref.[1], the ratio between the weights of polyglycol in the lower and the upper phases. In Fig. 3, the apparent partition coefficients for the polyglycol preparations in the liquid system TCW are plotted as a function of the composition parameter v.

From Figs. 2 and 3, it can be seen that both solvent systems are suitable for fractionation purposes. The system TCW, in particular, shows large changes in partition coefficient for a change in molecular weight. At the same time it is very sensitive to small changes in the composition. For this reason, it was considered convenient to study the system TAW first.

However, a few comments of general interest must be made. The curves in Figs. 2 and 3 intersect each other. Owing to the experimental inaccuracy, it is impossible to decide whether the curves have a common point of intersection. The same observation has been reported by Schulz [4]. However, he has not investigated more than two polyglycol preparations in the solvent system chloroform-benzene-water. According to his theories, the point of intersection should occur for $k = 1$. Neither in his own experiments nor in those reported in this paper does this occur. Schulz explained this as being due to the difference in temperature which existed between the two series of experiments performed by him. In the present work, however, all experiments at a specified composition of the solvent system were carried out simultaneously. Thus, there is no doubt that the curves cut in a point or points at which the partition coefficient differs appreciably from unity. The reason for this deviation is that the Brønsted equation [5] for the relation between partition coefficient and molecular weight, on which Schulz' theories are based, is too approximate. In addition, the linear relation between the logarithm of the partition coefficient and the composition of the solvent system, proposed by Schulz [4], cannot be regarded as satisfactory.

EQUILIBRIUM CONDITIONS

Preliminary experiments with a conventional 20 tube allglass countercurrent apparatus, constructed according to Craig, showed that the amount of polyglycol in the different fractions was not independent of the shaking time unless at least a 30 min shaking time was used at each step.

Table 1. Countercurrent distribution of polyglycol A 6 000. Solvent system: TAW (v = 0.43).

Time of shaking at each step	30 min	240 min
Weight of sample (w_0)	2.0002 g	2.0002 g
p	$w(p)$ mg	$w(p)$ mg
0	2.1	2.9
1	3.3	3.1
2	5.4	6.2
3	13.8	13.2
4	32.8	30.2
5	64.3	63.4
6	108.5	112.1
7	171.4	162.5
8	216.8	226.9
9	259.0	250.5
10	256.6	249.2
11	238.0	234.5
12	203.0	204.3
13	156.3	152.5
14	113.4	111.0
15	73.9	71.3
16	43.3	41.5
17	23.4	19.7
18	9.5	9.7
19	4.3	3.9
$\sum w(p)$	1.9991 g	1.9686 g

Table 1 contains the results from two series of experiments in which polyglycol was distributed according to the fundamental countercurrent process, separatory funnels being used as contacting vessels. The two series only differ in the time of shaking at each step. In one case, the shaking time was 30 min, in the other 120 min. The differences in the results of the two series must be ascribed to random errors. For this reason, a shaking time of 30 min was used at each step in the subsequent countercurrent experiments.

In order to investigate the reversibility of the distribution process, two series of experiments were carried out, one in which the sample was dissolved in the upper phase before the lower phase was added, and one in which the sample was first dissolved in the lower phase. The results are shown in Fig. 4. It can be seen that the value of k is independent of the direction in which the distribution process proceeds. This means that the process is reversible and that no obstacles exist for its treatment as a real equilibrium process.

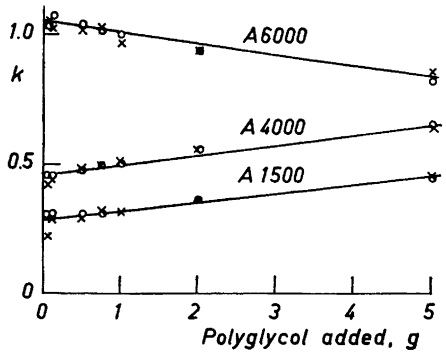

Fig. 4. Apparent partition coefficient for polyglycol at different sample weights. Solvent system: TAW ($v = 0.43$). Volume of each phase = 50 ml. × sample first dissolved in the upper phase. O sample first dissolved in the lower phase.

CONCENTRATION DEPENDENCE

The problem is, as can be seen from Fig. 4, complicated by the appreciable concentration dependence of the partition coefficient. This effect can be quite considerable at high concentrations. The slopes of the lines drawn in Fig. 4 have different signs, implying that reverse distribution conditions at high and low concentrations are conceivable. However, the matter is further complicated in the distribution experiments reported in this paper. The solvent system used was a three component system. Upon adding an appreciable quantity of a fourth component, polyglycol, the composition of the two solvents might have been changed. This change may have been different for different molecular weights of the polyglycol. No attempts have been made to determine whether such a change takes place. Corrections were introduced which were thought to make this effect negligible in the author's results.

In a multiple-contact-countercurrent experiment, the concentration of the substance to be distributed decreases appreciably as the experiment proceeds. This is especially striking when the partition coefficient is close to unity. The errors introduced due to the concentration dependence of the partition coefficient must therefore be most serious during the first stages of the countercurrent process. However, the results obtained are, at least qualitatively, comparable with the results obtained in a countercurrent experiment where the partion coefficient is independent of the concentration but where the sample has been added to more than one tube at the start of the process. As shown by Craig [6], no appreciable errors are introduced in this way. However, a mathematical analysis of the problem will be made.

As can be seen from Fig. 4, the apparent partition coefficient can be expressed by

$$k = k_o \ (1 + \varepsilon \ m) \tag{1}$$

where k_o is the partition coefficient at infinite dilution, m the amount of substance distributed between the two phases and ε a constant. (Indications of a slight curvature, at least for preparation A 4 000, are left out of consideration).

We assume that a pure compound containing molecules of only one size is distributed between two solvents according to the fundamental Craig distribution procedure. The partition coefficient is assumed to obey eqn. 1. The concentration is chosen so that $\varepsilon\, m \ll 1$. Using the notations given in Ref.[2], we obtain

$$w_n(p) = \frac{k_o[1+\varepsilon w_{n-1}(p-1)]}{1+k_o[1+\varepsilon w_{n-1}(p-1)]} w_{n-1}(p-1) + \frac{1}{1+k_o[1+\varepsilon w_{n-1}(p)]} w_{n-1}(p) =$$

$$= \frac{k_o}{1+k_o} w_{n-1}(p-1) + \frac{1}{1+k_o} w_{n-1}(p) + \Delta_n(p) \qquad (2)$$

where $\Delta n(p)$ is a correction term which has to be calculated. Rearrangement gives

$$\Delta_n(p) = \frac{\varepsilon k_o}{1+k_o}\left[\frac{[w_{n-1}(p-1)]^2}{1+k_o[1+\varepsilon w_{n-1}(p-1)]} - \frac{[w_{n-1}(p)]^2}{1+k_o[1+\varepsilon w_{n-1}(p)]}\right]$$

Approximating this expression by neglecting the terms in the denominators containing ε and exchanging the w's for their idealized values (*i.e.* ε is considered to be 0) gives

$$\Delta_n(p) = \frac{\varepsilon}{k_o} \cdot \frac{p^2 - k_o^2 \cdot (n-p)^2}{n^2} \cdot [w_n^*(p)]^2 \qquad (3)$$

where the asterisk indicates idealized values. From eqn. 2, we obtain by successive additions

$$w_n(p) = \binom{n}{p} \cdot \frac{k_o^p}{(1+k_o)^n} w_o(0) + \sum_{i=0}^{n-1} \sum_{r=0}^{i} \binom{i}{i-r} \cdot \frac{k_o^{i-r}}{(1+k_o)^i} \cdot \Delta_{n-i}(p-i+r)$$

Insertion of the Δ values from eqn. 3 and division with $w_o = w_o(0)$ give

$$W_n(p) - W_n^*(p) =$$

$$\frac{\varepsilon w_o}{k_o} \cdot \sum_{i=0}^{n-1} \sum_{r=0}^{i} \frac{(p-i+r)^2 - k_o^2(n-p-r)^2}{(n-i)^2} \cdot W_i^*(i-r) \cdot [W^*_{n-i}(p-i+r)]^2 \qquad (4)$$

This expression thus gives the difference between the experimental and the idealized relative amounts of the sample in each fraction as a function of the total amount of sample distributed, the partition coefficient of the sample at infinite dilution and ε. In Fig. 5, the expression $\frac{W_n(p) - W_n^*(p)}{\varepsilon w_o}$ is plotted as a function of the fraction number p for $k_o = 1$ and $n = 19$ (full-drawn curve). This curve is compared with the curve obtained when it is assumed that the partition coefficient of an ideal substance is changed by a small amount Δk_o. The expression for $W_n(p)$ (eqn. 2 in Ref.[2]) is differentiated with respect to k. Then

$$\Delta W_n(p) = W_n(p) \cdot \left(\frac{p}{k_o} - \frac{n}{1+k_o}\right) \cdot \Delta k_o \qquad (5)$$

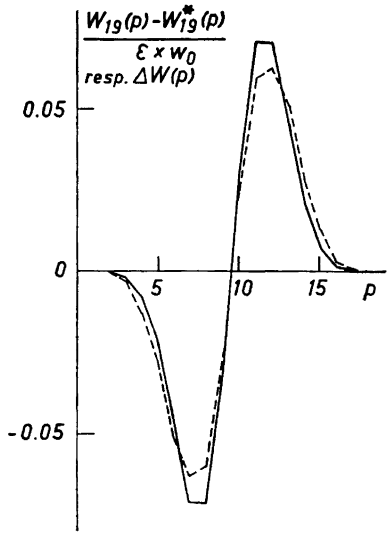

Fig. 5. Full-drawn curve: Graphical representation of eqn. 4 for $k = 1$ and $n = 19$. Dotted curve: Graphical representation of eqn. 5 for $k = 1$, $n = 19$ and $\Delta k = 0.28$.

The dotted curve in Fig. 5 gives this expression calculated for $k_0 = 1$, $n = 19$ and $\Delta k_0 = 0.28$.

The agreement between the two curves is good. The concentration dependence of the partition coefficient thus results in an effect comparable to an overall change in the partition coefficient rather than a broadening of the $W(p)$ *vs.* p curve. From eqn. 4, it can be seen that the $W(p)$ values at infinite dilution can be obtained by determining the $W(p)$ values at different values of w_0 and extrapolating them as a function of w_0 to the value $w_0 = 0$. Because of the initial assumptions, this extrapolating method is only applicable to substances containing molecules of the same size. The method will, however, be applied to common polymers as a first approximation. It is assumed that such a method, in addition, automatically corrects for small changes in the composition of the two liquid phases which might occur due to the addition of the polymer.

The reason for the concentration dependence is that there probably exists an interaction between molecules of the same size. The question now arises as to what extent molecules of different sizes interact in the distribution experiments. It is necessary to know whether micelles or complexes of some other type between molecules of different sizes occur, resulting in an effect closely related to the coprecipitation found in polymer precipitation fractionation. This problem will be treated in a separate paper. In the subsequent parts of this paper, this effect will be considered to be negligible.

RESOLVING POWER

As was pointed out by Craig [7], the peak of the curve representing the relation between the amount in each fraction and the fraction number in the funda-

mental Craig countercurrent distribution procedure can be approximately expressed by

$$p_{max} = \frac{nk}{1+k} \tag{6}$$

if molecules of only one size are present and if the volumes of the two phases are equal. If the ratio between the volumes of the lower and upper phases is φ, then the relation can be written

$$p_{max} = \frac{n\varphi k}{1+\varphi k} \tag{7}$$

When a polymer is distributed in a Craig apparatus, the derivative $|\partial p_{max}/\partial M|$ can be regarded as a measure of the resolving power of the apparatus. This derivative should of course be as large as possible, *i.e.* the positions of the peaks caused by two samples differing in molecular weight by an infinitesimal amount should differ as much as possible. By differentiation of eqn. 7 we obtain

$$\left|\frac{\partial p_{max}}{\partial M}\right| = \frac{\partial p_{max}}{\partial k} \cdot k \cdot \left|\frac{\mathrm{d} \ln k}{\mathrm{d}M}\right| = n \cdot \frac{\varphi k}{(1+\varphi k)^2} \cdot \left|\frac{\mathrm{d} \ln k}{\mathrm{d}M}\right| \tag{8}$$

The expression $\frac{\varphi k}{(1+\varphi k)^2}$ attains its highest value, *viz.* 1/4 for $\varphi k = 1$ and the derivate $\mathrm{d} \ln k/\mathrm{d}M$ is independent of φ. The highest resolving power is thus obtained if the distribution experiment is carried out employing a φ value equal to the inverse of the apparent partition coefficient of the substance. However, φ k can differ appreciably from unity without the above expression and thus the resolving power being too far below the maximum value.

It now remains to find the maximum value of $|\mathrm{d} \ln k/\mathrm{d}M|$. No current theory about the activity of polymer solutions is able to provide an acceptable expression for this derivative. The expressions provided are either too approximate or too unwieldy for the present purpose. An empirical method must therefore be used. The author has chosen to regard the curves in Figs. 2 and 3 as representative for polyglycols containing molecules of only one size, the molecular weight being identical with the one given by the manufacturer. By means of graphical methods, it was found that, for the solvent system TAW, the derivative $|\mathrm{d} \ln k/\mathrm{d}M|$ attains its maximum value for $v = 0.43$ independent of the molecular weight. For the solvent system TCW, the derivative attains its maximum value for each preparation when k is about unity, the latter condition being far from critical.

As can be predicted by the theory of Schulz, it is possible that, with the solvent system TAW, an extremely good resolving power can be obtained at compositions corresponding to $v < 0.32$ and, with the system TCW, at $v < 0.13$ or at v values rather close to 0.50. It is however probable that the gain is not sufficient to compensate for the enormous increase in experimental difficulty. Furthermore, when the experiments are carried out at a volume ratio for the two phases which differs appreciably from unity, the concentration of

polymer in the phase of less volume must be kept very high if sufficient quantities of polymer are to be obtained in the final fractions. In view of the above discussion of the concentration dependence of the partition coefficient, such experimental conditions should be avoided.

An exact analysis of the resolving power problem cannot be carried out until a more accurate relation between molecular weight and the partition coefficient is known. The above analysis was, however, regarded as sufficient for planning the subsequent countercurrent distribution experiments.

EXPERIMENTAL

All experiments reported in this paper were carried out at room temperature (20—21°C). Variations in temperature have been avoided.

Chemicals used. Trichloroethylene: Technical grade quality, distilled before use. Chloroform: pro analysi quality, stabilized with 1 % alcohol. Alcohol: 95 % ethyl alcohol ("Extra finsprit"). In the countercurrent experiments, spectroscopic grade quality alcohol was used. All solvents were checked with respect to evaporation residue before use.

Four different polyglycol preparations, *viz.* A 6 000, A 4 000, A 1 500, A 300, manufactured by Mo och Domsjö AB were used in the experiments — the figures indicating their approximate, number-average molecular weights. The first three samples were purified by dissolving them in trichloroethylene, shaking with water, shaking the water phase with chloroform and evaporating the chloroform. The preparations were finally dried in vacuum at 50°C.

Fisher & Porter Co 250 ml separatory funnels equipped with glass stoppers and teflon valve taps were used — they permitted an almost perfect separation of the two phases.

The one-stage extraction experiments were carried out by shaking a weighed amount of polyglycol with 50 ml of both solvents (the solvents had previously been shaken to equilibrium in separatory funnels). If nothing to the contrary is stated, the amount of polyglycol in each experiment was 500 mg. A 25 ml portion of each phase was evaporated to dryness and weighed after drying in vacuum at 50°C.

The countercurrent experiments. An all-glass countercurrent apparatus according to Craig could not be used because the transfer of liquid could not be performed without preventing parts of the lower phase following the upper phase and parts of the upper phase remaining with the lower stationary phase. For this reason, separatory funnels of the type described above were used as contacting vessels. The transfer of liquid was of course more laborious and time-consuming but the phases could be separated almost exactly from each other.

The shaking device consisted of a horizontal metal rod along which 20 clamps for the separatory funnels were attached on opposite sides. The funnels were situated at right angles to the rod at a distance of about 20 cm from the rod. Equilibrium was obtained by automatically turning the rod back and forth around its axis through an angle of $\pm$ 40° for 30 min, the mean position of the funnels being horizontal. The number of periods per min was 33. After allowing the two liquid layers to separate, the lower phases were transferred according to the general fundamental distribution pattern.

The substance to be distributed was added in the solid state to tube No. 0 which contained 50 ml of both phases. Equal volumes were used in all steps. At the end of the distribution experiment, the contents of the twenty tubes together with the necessary rinsing liquid were evaporated to dryness in warm air. The fractions were finally dried in vacuum at 50°C and weighed.

In order to show that the phases separate well and that no appreciable loss of solvents by evaporation or other reasons occurs, the volumes of both phases in each tube were determined at the end of a distribution experiment. The losses were small and were partly due to the liquid adhering to the walls of the funnels.

In order to demonstrate that the apparatus can be used as an analytical tool, a pure compound, N,N-dimethylaniline, twice distilled in vacuum, was distributed in the apparatus. The solvents used were *cyclo*hexane and aqueous phosphate-citrate buffer according

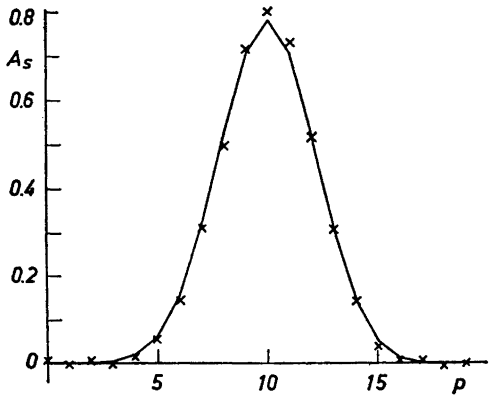

Fig. 6. Comparison at 251 mμ between experimental (points) and theoretical (curve) absorbancies of the upper phase for countercurrent distribution of N,N-dimethylaniline. Solvent system: *Cyclo*hexane aqueous buffer (pH = 2.75). Equal volumes of both phases.

to McIlvaine with pH = 2.75, the two liquids being shaken to equilibrium before use. A solution containing about 3×10^{-5} g N,N-dimethylaniline in 50 ml of the equilibrated *cyclo*hexane was prepared and used as the upper phase in tube No. 0. After completion of the distribution, the upper phases were collected and their absorbancies measured at 250 mμ in a Beckman spectrophotometer, the equilibrated *cyclo*hexane being used as the reference substance. The results are given in Fig. 6 where a comparison can be made with the theoretical values for a compound with a partition coefficient = 1.10_4. This value is in fairly good agreement with the value 1.16 which can be calculated from the paper of Columbic and Goldbach [8]. The agreement between experimental and calculated absorbancies must be regarded as good.

Acknowledgement. The author is indebted to Dr. Börje Steenberg for his encouraging interest in this work and to Mo och Domsjö AB for their kindness in providing the polyglycol preparations.

Fractionation of Polymers by Liquid-Liquid Distribution

III. The Interaction Problem

KARL ERIK ALMIN and RUNE LUNDBERG

Swedish Forest Products Research Laboratory, Paper Technology Department, and Royal Institute of Technology, Department of Paper Technology, Stockholm, Sweden

Fractionated polyglycols have been countercurrent distributed both separately and in mixtures. From the experimental data the conclusion has been drawn that no interferring interaction occurs between molecules of different sizes.

In polymer countercurrent distribution experiments, association phenomena between molecules of different sizes can be expected to influence the results [1]. It was suggested that such phenomena should result in effects closely related to the coprecipitation occurring during the precipitation fractionation of polymers.

This paper consists of a report on a theoretical and experimental investigation performed by the authors on this association effect. Because polymer specimens are always inhomogeneous with respect to molecular weight, the effect must be studied on samples containing molecules of different sizes.

We consider two polymer samples of the same monomer with frequency functions, $f_1(k)$ and $f_2(k)$, with respect to the partition coefficient and, in addition, a sample made up by mixing equal parts of these samples. These three preparations are then fractionated in a Craig apparatus. If ideal conditions prevail, the relative amount of polymer in each fraction of the three experimental series can be written [2].

$$W(p)^{(1)} = \int_0^\infty F(k,p) \cdot f_1(k)\ \mathrm{d}k \tag{1}$$

$$W(p)^{(2)} = \int_0^\infty F(k,p) \cdot f_2(k)\ \mathrm{d}k \tag{2}$$

$$W(p)^{(3)} = \int_0^\infty F(k,p) \cdot \frac{f_1(k) + f_2(k)}{2}\ \mathrm{d}k \tag{3}$$

where $F(k,p) = \binom{n}{p} \frac{k^p}{(1+k)^n}$.

It is easily deduced that $W(p)^{(3)}$ is equal to the arithmetical mean of $W(p)^{(1)}$ and $W(p)^{(2)}$. If interaction occurs, then the eqns. 1—3 become more complicated. The function $F(k,p)$ cannot then be identical for the three cases. This means that $W(p)^{(3)}$ must differ from the arithmetical mean of the two other $W(p)$ values.

The same type of discussion can be applied to the mean molecular weight of the fractions, using eqn. 13 of Ref.[2]:

$$\overline{M(p)}^{a} = \frac{1}{W(p)} \cdot \binom{n}{p} \cdot \int_0^\infty \frac{k^p}{(1+k)^n} \cdot f(k) \cdot M^a \cdot \mathrm{d}k \qquad (4)$$

as a basis for the discussion. Such a discussion leads to essentially the same result, *viz.* that the product of the measured property, which is proportional to $\overline{M(p)}^{a}$, and $W(p)$ in the third series should be equal to the arithmetical mean of the corresponding quantities in the other two series provided that no interaction occurs, but should differ from the mean if interaction occurs.

It is important that not only the relative weights of the different fractions in the three experimental series are compared but also the quantities closely related to the mean molecular weight of the fractions. From eqns. 1 and 4, it can be seen that the expression within the integral contains the molecular weight in the second case but not in the first. This indicates that, if the arithmetical mean law is valid by mere accident in one case, then it must be practically impossible for this law to be valid in the other case if interaction occurs.

In order to make any possible interaction effect easy to observe, polymer specimens with greatly different mean molecular weights and rather narrow molecular frequency functions should be used. The polymer used in this investigation was polyglycol. The solvent system was prepared by mixing trichloroethylene, alcohol (95 %) and water in the volume ratio 2 : 2 : 1. The viscosity numbers were used as a measure of the molecular weight.

Two preparations with relatively sharp-peaked frequency curves were obtained as fractions in a large-scale countercurrent fractionation of two polyglycol preparations with number-average molecular weights of about 1 500 and 6 000 (called A 1 500 and A 6 000). These two fractions were then countercurrent fractionated according to the fundamental Craig procedure ($n = 19$) both separately and using a mixture of equal parts. The weights of the fractions obtained were then determined, *cf.* Figs. 1 and 2. The curve in Fig. 2 was obtained as the arithmetical mean of the two curves in Fig. 1. The viscosity numbers of those fractions in which sufficient polymer was present were also measured. The results are given in Figs. 3 and 4. In Fig. 4, there is also shown a curve which was calculated from the curves (not the points) in Fig. 3 assuming that the viscosity numbers are additive with respect to weight. The experimental $W(p)$ values were used for the calculations.

The experimental points in Figs. 2 and 4 agree, within the experimental accuracy, with the corresponding calculated curves. The conclusion must be drawn that no interfering interaction occurs between molecules of different sizes apart from the concentration-dependent interaction discussed in Ref.[1] This means that intermolecular association, which results in irreversible

equlibrium conditions for the distribution of the polymer between the two solvents does not occur in this case. In the subsequent work, it will be assumed that this is valid at all compositions of the solvent system.

EXPERIMENTAL

Concerning temperature, solvents and purification of the polyglycols, see Experimental of Ref.[1] The solvent system used in this investigation was prepared by mixing trichloroethylene, alcohol (95 %) and water in the volume ratio 2:2:1. This volume ratio corresponds closely to $v = 0.39$ (*cf.* Ref.[1]).

Large scale fractionation. The purpose of this experiment was to prepare two polyglycol specimens, with relatively narrow molecular frequency curves and with greatly different mean molecular weights, by means of a 10 tube ($n = 9$) countercurrent fractionation according to the fundamental Craig procedure. The low molecular weight specimen was prepared from polyglycol A 1 500 and the high molecular weight specimen from polyglycol A 6 000. The procedure could be appreciably shortened since not more than one fraction was of interest in each fractionation series. The complete fractionation scheme for a 10 tube fractionation is shown by the triangle OAB in Fig. 5. The low molecular preparation from polyglycol A 1 500 was obtained by performing the operations within the rectangle OCDE and the high molecular weight preparation from polyglycol A 6 000 by performing the operations within the rectangle OFGH. The experiments were carried out using large separatory funnels.

The weight of sample was 200 g for A 1 500 and 600 g for A 6 000. The yields were 57.7 g and 11.8 g respectively. These two fractions (called Prep. I and Prep. II) were used for the three series of countercurrent experiments. (A mixture of equal parts of these two fractions was designated Prep. III.)

The countercurrent experiments were carried out as described in Ref.[1] The weight of sample was in all three cases 2.0000 g. The difference between the sample weight and the sum of the weights of the fractions was for Prep. I 5.6 mg, for Prep. II 19.0 mg and for Prep. III 31.6 mg.

Viscosity measurements were performed on solutions obtained by dissolving about 50 mg of the different fractions in 10.00 ml chloroform. Cannon-Fenske pipettes recommended for the range between 0.3 and 5.0 centipoises were used at 25°C ± 0.02.

Fractionation of Polymers by Liquid-Liquid Distribution

IV. Countercurrent Fractionation of Polyglycols

KARL ERIK ALMIN

Swedish Forest Products Research Laboratory, Paper Technology Department, Stockholm, Sweden

Three polyglycol preparations have been countercurrent distributed in the solvent system trichloroethylene-alcohol-water. Weights and limiting viscosity numbers of the different fractions have been determined. Curves of weight frequency *vs.* limiting viscosity number have been calculated.

In this paper, experiments will be reported in which polyglycols have been fractionated by means of liquid-liquid countercurrent distribution. The method has been described in earlier papers of this series from both theoretical and practical points of view [1,2]. Three different preparations, A 6 000, A 4 000 and A 1 500, have been investigated and equal volumes of the two phases obtained by mixing trichloroethylene, alcohol and water (TAW) in the volume ratio 0.414 : 0.43 : 0.156 have been used as solvent system.

In Tables 1—3, the experimental results from experiments with different weights of samples can be seen in columns 2—5. The notations are in agreement with those of Ref.[1]. Col. 6 of these tables contains $W(p)$ values at infinite dilution calculated by means of eqn. 4 in Ref.[2]. The method of least squares was applied. The slopes of the lines obtained in this way are given in Fig. 1 (points). In this figure, the $\Delta W(p)$ values calculated from eqn. 5 of Ref.[2]

$$\Delta W(p) = W(p) \cdot \left(\frac{p}{k_o} - \frac{n}{1+k_o} \right) \cdot \Delta k_o \qquad (1)$$

are also given (curves), suitable values for k_o and Δk_o being assumed. The statement in Ref.[2] that the concentration dependence of the partition coefficient results in an effect which can be compared with an overall change in partition coefficient has thus been experimentally verified. It can further be noted in the case of the preparation A 6 000 that the peak of the $W(p)$ *vs.* p curve moves to higher p values as the sample weight is increased while

A 4 000	1	9.84×10^{-1}	12	40	2
	2	1.6×10^{-2}	1	6	1

the opposite is the case for the two other preparations. This is in accordance with the signs of the slopes of the lines in Fig. 4 of Ref.[2]

The calculations of the frequency functions of the partition coefficient have been based on the calculated $W(p)$ values at infinite dilution. In accordance with Ref.[1], it is assumed that the frequency functions of the preparations A 6 000 and A 4 000 can be expressed as a sum of functions of the type

$$A_i \cdot k^{r_i} \cdot (1+k)^{19} \cdot \exp(-a_i \cdot k^{s_i}) \qquad (2)$$

The results of these calculations are given in Table 4. The differences between the $W(p)$ values in col. 6 of Tables 1 and 2 and the $W(p)$ values calculated from the calculated frequency functions can be seen in col. 7 of Tables 1 and 2. These differences are small considering the experimental errors and hence the calculated frequency functions must be regarded as satisfactory. The frequency curve of preparation A 6 000 shows a small peak at low k values.

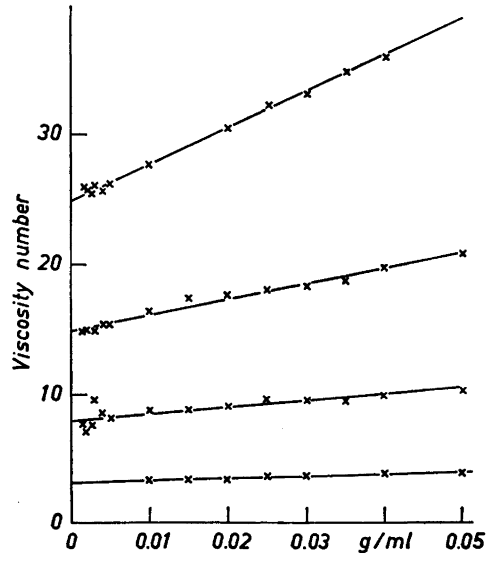

Fig. 2. Viscosity number of the polyglycol samples as a function of concentration. Solvent: chloroform.

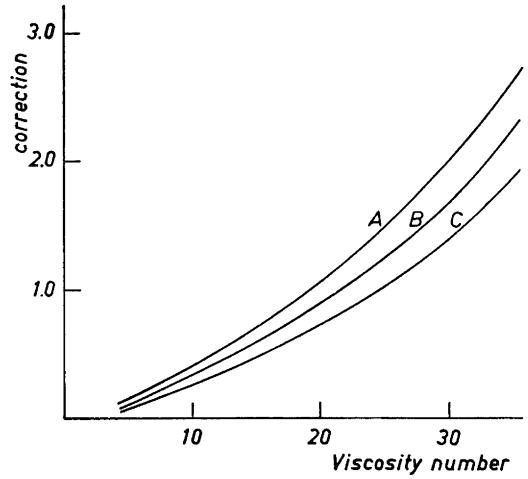

Fig. 3. Curves giving the correction to be subtracted from an experimentally determined viscosity number for polyglycol in chloroform in order to obtain the limiting viscosity number. A = 0.006 g/ml; B = 0.005 g/ml; C = 0.004 g/ml.

This peak must be a consequence of slight errors in the experimental and numerical methods.

No attempts were made to calculate a frequency curve for preparation A 1500. The reason for this was that the $W(p)$ *vs.* p curve for this preparation agreed so closely with the corresponding curve for a preparation containing molecules of only one size. The differences between the $W(p)$ values in col. 6 of Table 3 and the $W(p)$ values expected for a substance with $k = 0.285$ can be seen in col. 7 of Table 3. These differences are only slightly greater than the experimental errors. They show, however, a pronounced trend, thus indicating that molecules of different sizes are present. The frequency curve must therefore have been very narrow. The resolving power was thus too low in these experiments to permit a determination of the shape of the frequency curve. One of the reasons for this is the disadvantageous volume ratio of the phases in the experiment. It can be calculated that a volume ratio of about 1 : 0.285 for the two phases would increase the resolving power by about 45 %. Such an increase cannot, however, be regarded as sufficient. Thus, some other solvent system must be used. The results of the distribution experiment with polyglycol A 1 500 can therefore only serve as an aid in determining the relation between partition coefficient and molecular weight.

In order to determine the frequency functions of the limiting viscosity number, the latter quantity was calculated from the viscosities of chloroform solutions, for each of the fractions containing more than about 25 mg polyglycol. The calculations of the limiting viscosity numbers were carried out under the assumption that the slope of the line giving the relation between viscosity number and concentration is a function solely of the limiting viscosity number of the preparation. These slopes were determined from the relation

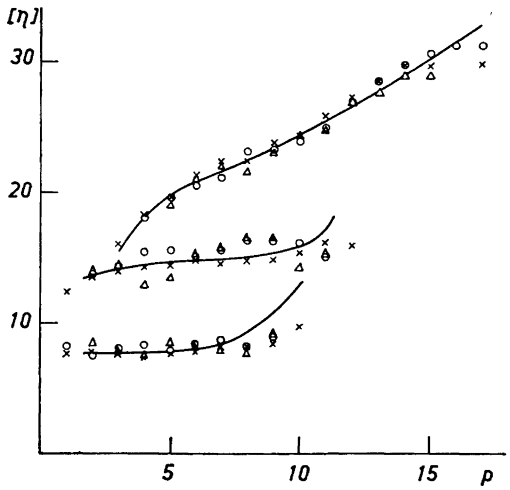

Fig. 4. Comparison between experimentally determined (points) and calculated (curves) limiting viscosity numbers for the polyglycol fractions obtained from polyglycols A 6 000, A 4 000 and A 1 500. × 5 g, O 2 g and △ 1 g experiments.

giving the viscosity number as a function of the concentration for the preparations A 6 000, A 4 000, A 1 500 and A 300. These relations can be seen in Fig. 2. The difference between the viscosity number and the limiting viscosity number was then plotted as a function of the viscosity number at different concentrations (Fig. 3). Using this figure, it is possible to find the correction which must be subtracted from a certain vicsosity number determined at a known concentration in order to obtain the limiting viscosity number.

In Fig. 4, the limiting viscosity numbers of the different fractions obtained from the 5 g, 2 g and 1 g distribution experiments are plotted as a function of the tube number. No systematic differences between results obtained from countercurrent experiments with different sample weights can be detected. The author has therefore regarded all the experimental points as being of

equal statistical weight and equal to the values which would have been obtained in a fictitious countercurrent experiment carried out at infinite dilution.

In Table 5, limiting viscosity numbers for the three fractionated samples, calculated from the limiting viscosity numbers and the corresponding fraction weights according to Philippoff [3], are compared with the directly determined limiting viscosity numbers of the original polyglycol preparations. Considering the accuracy of the viscosity determinations, the agreement must be regarded as satisfactory.

The relation between the limiting viscosity number and the partition coefficient was determined according to the method described in Ref.[1] The experimentally determined values for the limiting viscosity numbers of the fractions, $\overline{[\eta]}_p$, and the corresponding $S(p)$ values calculated from the $W(p)$ values at infinite dilution were used. The values of $\frac{\mathrm{d} \ln S(p)}{\mathrm{d}p}$ were obtained by an interpolation method. The i values chosen were -2, -1, 0, 1 and 2. In this way, a set of equations was obtained from which the constants of the relation

$$[\eta] = B \cdot \ln k + \sum_i C_i \cdot k^i \qquad (i = -2, -1, 0, 1, 2) \tag{3}$$

were obtained using the method of least squares. Because of the large number of equations and variables, an electronic computor (BESK) was used for the calculations. The results of these calculations can be seen in Table 6. The

Table 6. Numerical values of the constants of eqn. 3.

B	5.38	($\pm$ 6.05)
C_{-2}	0.2821	($\pm$ 0.1501)
C_{-1}	-4.519	($\pm$ 2.420)
C_0	26.52	($\pm$ 2.45)
C_1	1.608	($\pm$ 4.377)
C_2	-0.2649	($\pm$ 0.3456)
Standard deviation (eqn. 4)	1.02	

errors in the constants B and C_i are considerable. The reason for these large errors is that ln k can be expressed as a series of the type $\Sigma C_i k^i$ in a limited range of k and this makes it difficult for the numerical method to »decide» which term in the author's formula shall predominate. This difficulty can be overcome by decreasing the number of terms in eqn. 1, but then the solution would not be free from assumptions that may be biased. The reliability of the final relation between the limiting viscosity number and the partition coefficient should be judged from the standard deviation, σ, calculated from the formula

$$\sigma^2 = \frac{1}{m-n} \cdot \sum(\overline{[\eta]}_{p,\,\mathrm{obs}} - \overline{[\eta]}_{p,\,\mathrm{calc}})^2 \tag{4}$$

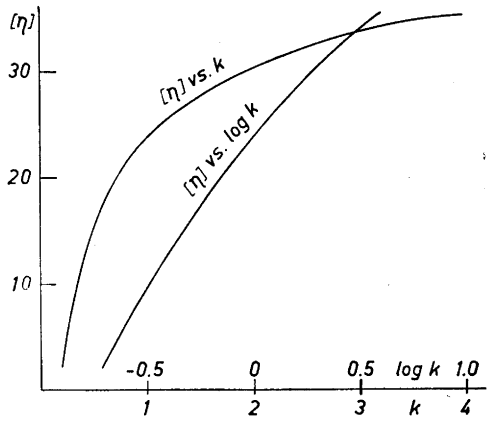

Fig. 5. Relation between the limiting viscosity number of polyglycol in chloroform and the partition coefficient of polyglycol in the solvent system TAW (v = 0.43).

where m = number of equations and n = number of coefficients. The value of σ (Table 6) must be considered consistent with the spread of the experimental $\overline{[\eta]}_p$ values. It should be pointed out that the final relation and its derivative are monotonic. The corresponding curve is shown in Fig. 5. The $[\eta]$ *vs.* log k curve is almost a straight line but it does not pass through the origin. This indicates that Brønsteds exponential formula for the partition coeffcient of polymers [4] has to be multiplied by a constant if it is to represent approximately the experimental results of this investigation. This circumstance must also be responsible for some of the discrepancies given by the partition coefficient formula of Schulz [5].

The $\overline{[\eta]}_p$ values calculated using the constants in Table 6 and the $W(p)$ values at infinite dilution are plotted in Fig. 4 (curves). The agreement between

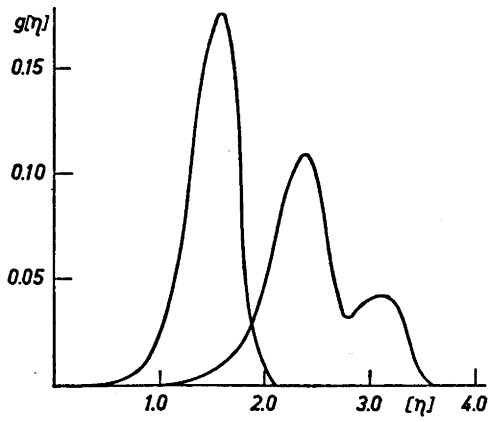

Fig. 6. Curves of weight frequency *vs.* limiting viscosity number in chloroform solutions for the polyglycol samples A 4 000 and A 6 000.

the experimental points and the calculated curves must be regarded as good, especially considering the appreciable molecular weight range of the substances investigated.

The derivative $\frac{d[\eta]}{dk}$ can now be calculated from the constants of eqn. 3. The curves of frequency *vs.* the limiting viscosity number in chloroform can thus be calculated using the method given in Ref.[1] The results of these calculations are given in Fig. 6 for the samples A 4 000 and A 6 000.

The accuracy of the frequency curves obtained will not be discussed completely in this paper because, as earlier reported [1], the results can only be checked by comparing them with results obtained under different experimental conditions. However, a few remarks can be made. The double peak in the frequency curve for polyglycol A 6 000 must be considered to be rather well established. This double peak can also be seen in the curve of frequency *vs.* partition coefficient and it has not been possible for the author to make the $W(p)$ values obtained consistent with an unimodal frequency curve. According to Flory [6], polymers prepared using a type of reaction which involves the successive addition of the monomer to a functional group and which can be characterized by a single rate constant have unimodal frequency curves. Polyglycol belongs to such a group of polymers. From this point of view, the double peak in the frequency curve for sample A 6 000 is suspect. However, the manufacturer of the samples used has informed the author that A 6 000 was produced by adding ethylene oxide to a mixture of two different polyglycol preparations of lower molecular weights and thus a double peak should appear. For the preparations A 4 000 and A 1 500, on the other hand, unimodal frequency curves should, according to the manufacturer, be expected.

In the case of sample A 4 000 the frequency curve is, as can be expected from the theory of Flory [6], rather narrow. It should, however, be pointed out that if the relation between limiting viscosity number and partition coeffient is calculated from only the experimental data obtained for preparation A 4 000, then a $[\eta]$ *versus* k relation with a smaller slope and thus a somewhat more sharply peaked curve is obtained. Such a treatment of the problem cannot be considered justified even if, as will be shown in a later paper, a sharper peaked curve is probably more correct.

Fractionation of Polymers by Liquid-Liquid Distribution

V. Countercurrent Fractionation of Polyglycols in the Solvent System Trichloroethylene-Chloroform-Water

KARL ERIK ALMIN

Swedish Forest Products Research Laboratory, Paper Technology Department, Stockholm, Sweden

Three polyglycol preparations have been countercurrent distributed in the solvent system trichloroethylene-chloroform-water. Weights and limiting viscosity numbers of the different fractions have been determined. Curves of weight frequency *vs.* limiting viscosity number have been calculated. The influence of formation of emulsions in the distribution experiments is discussed.

In the preceding paper of this series[1], data from the liquid-liquid countercurrent distribution analysis of three polyglycol preparations in the solvent system trichloroethylene-alcohol-water (TAW) were reported. The present paper will deal with analogous experiments in another solvent system, trichloroethylene-chloroform-water (TCW).

Preliminary liquid-liquid distribution experiments with the solvent system TCW have shown that the partition coefficients of polyglycols are more dependent on the temperature than is the case with the solvent system trichloroethylene-alcohol-water (TAW) [2]. For this reason, the countercurrent experiments with the solvent system TCW were carried out in a thermostat set at 25°C. This temperature is about five degrees higher than that used in the preliminary experiments reported in Ref.[2]

Difficulties have, however, arisen because of the ease of formation of emulsions in the solvent system TCW. The emulsions were especially prone to appear when the concentration was high, when the molecular weight of the polyglycol was large and when the partition coefficient of the polyglycols differed from unity. In these countercurrent experiments, the emulsions were allowed to remain with the stationary upper phases since the lower surfaces of the emulsions were smoother than the upper ones. The amount of emulsion was, however, found to decrease during the course of the distribution experiment. This was probably due to the decrease in the concentration of polyglycol. The volumes of especially the first ($p = 0$) and the last ($p = 19$) fractions

were thus appreciably less than the others at the end of the distribution experiments, these volume losses being more pronounced when the amount of emulsion formed was larger.

The influence of the emulsion formation can also be seen in the $W(p)$ *vs.* p curves and in the $\overline{[\eta]}_p$ values. For symbol notation see Ref.[3] The $W(p)$ *vs.* p curves became shifted towards lower p values and the relation between $\overline{[\eta]}_p$ and p became steeper when the sample weight and thus the amount of emulsion were increased. These changes can be explained in the following way. The emulsion layers contain varying amounts of the high molecular weight parts of the preparation which should belong to the lower phases. When the phases are separated, these high molecular weight parts remain with the upper phases. The possibility of accumulation of polymer and/or either of the solvents in the emulsion layer on account of surface phenomena will not be discussed.

The experimental data from experiments in which the mean partition coefficient differed appreciably from unity had to be discarded because of the very large emulsion formation. It has therefore not been possible to extend the range of validity of the relation between partition coefficient and limiting viscosity number in the same way as was possible in the case of the solvent system TAW [1].

In the cases where the formation of emulsion was less pronounced, the data from each experimental series were treated individually, exactly as if no emulsion formation had occurred. The curves of frequency *vs.* partition coefficient, $f(k)$, thus obtained are consequently more compressed than in the cases where no emulsions were obtained. At the same time, the curves of $[\eta]$ *vs.* partition coefficient, k, are steeper. The final frequency functions in terms of the limiting viscosity number can, however, be expected to be correct or nearly correct since the two above-mentioned effects counteract each other.

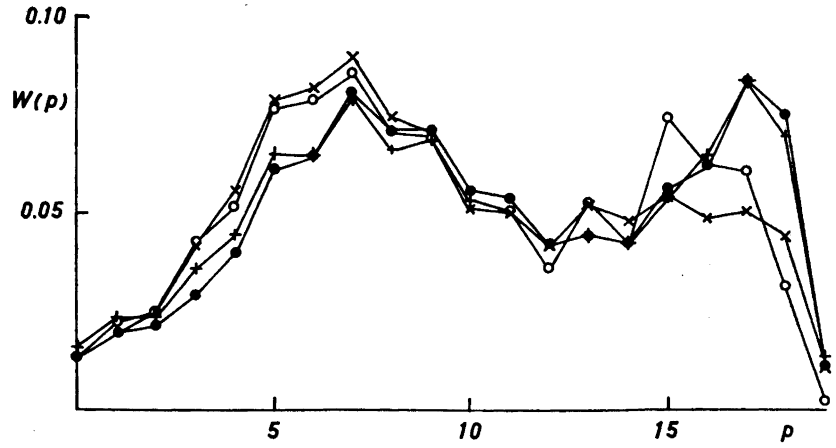

Fig. 1. Experimental $W(p)$ values obtained in the countercurrent experiments in TCW ($v = 0.165$) with polyglycol A 6 000. × 5 g, O 2 g, ● 1 g and + 0.5 g sample weight.

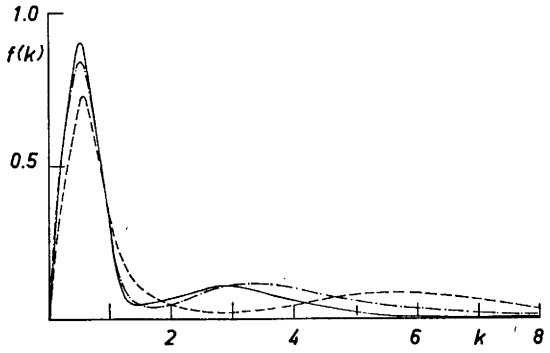

Fig. 2. Curves of weight frequency *vs.* partition coefficient, calculated from the experimental $W(p)$ values obtained in the experiments with polyglycol A 6 000. ——— 5 g, —.—.—.— 2 g and — — — — — 1.0 and 0.5 g sample weight.

The calculation of the relation between $[\eta]$ and k was found to be much simpler with the present solvent system than with the solvent system TAW [1] inasmuch as $[\eta]_p$ proved to be, in all cases, a linear function of the derivative $\frac{\mathrm{d} \ln S(p)}{\mathrm{d}\, p}$ (*cf.* Ref.[3]). The relation between limiting viscosity number and partition coefficient can thus be written,

$$[\eta] = C_0 + B \ln k \qquad (1)$$

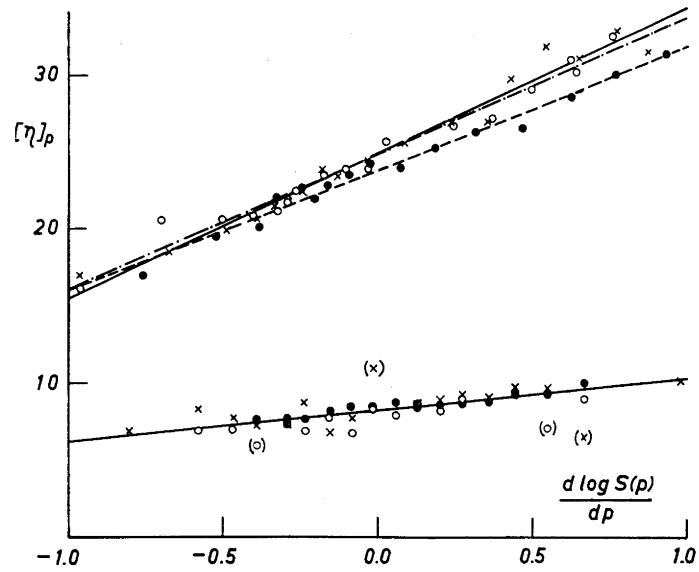

Fig. 3. Relation between limiting viscosity number and the derivative d log $S(p)$/d p for polyglycol A 6 000 and A 1 500 (Sample weights: *cf.* Fig. 1).

Table 1. The constants B and C_0 of eqn. 2 calculated from viscosity data.

Sample	Weight of sample, g	C_0	B
A 6 000	5	24.90	4.03
	2	24.87	3.86
	1 and 0.5	23.78	3.47
A 4 000	5	15.41	2.03
	2	14.88	2.23
	1 and 0.5	15.10	1.96
A 1 500	5, 2 and 1	8.19	0.93

The $W(p)$ values obtained from the experiments with polyglycol A 6 000 are given in Fig. 1. The composition of the solvents corresponds to $v = 0.165$ (*cf.* Ref.[2]). The influence of emulsion formation is obvious — especially in the 5 g and 2 g experiments. From the curves, it can be seen that the $W(p)$ values of every second fraction seem too low and those of every other one too high. The cause of these irregularities is unknown to the author. It may be pointed out that they seem to be more pronounced when the emulsion formation is large. The $f(k)$ curves calculated from the experimental data are given in Fig. 2. The experimental $\overline{[\eta]}_p$ values are plotted in Fig. 3 as a function of the derivative $\frac{\mathrm{d} \ln S(p)}{\mathrm{d} p}$. The numerical values of the constants C_0 and B, calculated from the lines in Fig. 3, are given in Table 1. In Fig 4, the frequency *vs.* limiting viscosity number curves are reproduced. The agreement is good in spite of the differences in the $f(k)$ curves. The differences in the frequency curves in the range $[\eta] > 32$ must be ascribed to slight errors in the experimental and numerical methods.

The results of the experiments with polyglycyol A 4 000 in the solvent system TCW ($v = 0.192$) are quite analogous to those reported for polyglycol

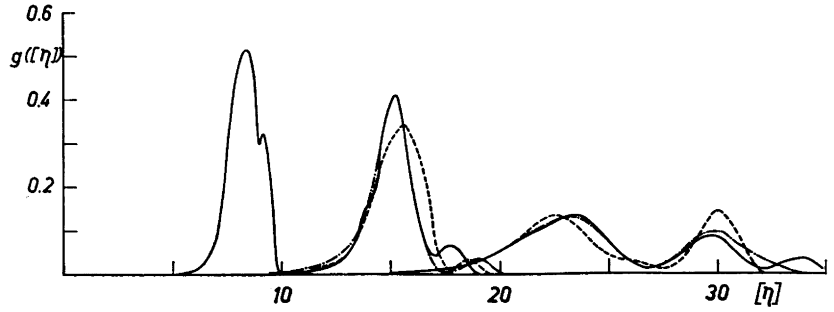

Fig. 4. Curves of weight frequency *vs.* limiting viscosity number for polyglycols A 6 000, A 4 000 and A 1 500 calculated from the corresponding curves in terms of partition coefficient. (Sample weights: *cf.* Fig. 2.)

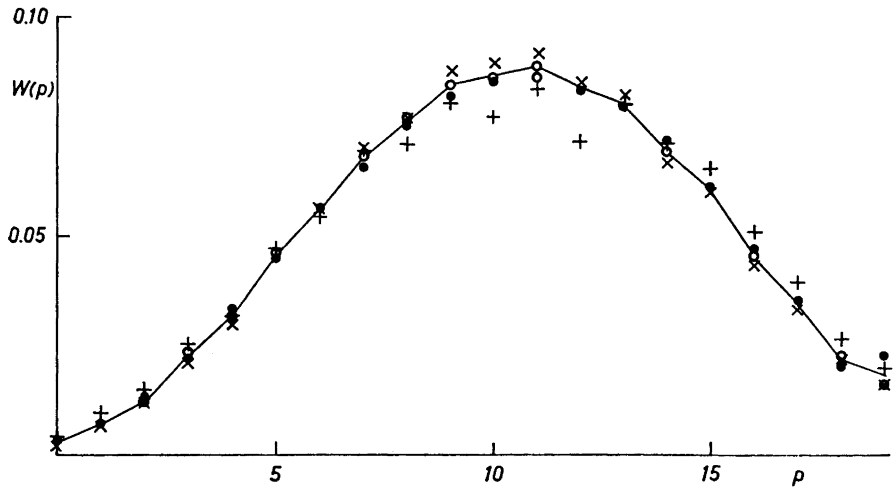

Fig. 5. $W(p)$ values obtained in the countercurrent experiments in TCW ($v = 0.83$) with polyglycol A 1 500. (Sample weights: *cf.* Fig. 1.) The curve represents the arithmetical mean of the $W(p)$ values from the 5 g, 2 g and 1 g experiments.

A 6 000. The irregularities in the experimental $W(p)$ *vs.* p curves were, however, less pronounced. The final results of the calculations can be seen in Table 1 and Fig. 4. The small peaks in the frequency curves at about $[\eta] = 18$ must, once again, be ascribed to slight errors in the experimental and numerical methods.

No emulsions appeared in the experiments in the solvent system TCW ($v = 0.283$) with polyglycol A 1 500. The experimental $W(p)$ values are given in Fig. 5. It can be seen that the points form curves with somewhat higher maxima at high concentrations. Craig [4] ascribes such a phenomenon to a nonmonotonic partition isotherm. The phenomenon is thus not equivalent to the concentration effect found in the experiments with the solvent system TAW [2]. The differences between the $W(p)$ values obtained at different sample weights are, however, small and the limiting viscosity numbers of the fractions proved to be independent of the sample weights. The calculations have therefore been made using the arithmetical mean of the experimental $W(p)$ values. The final results can be seen in Table 1 and Figs. 3 and 4. The small peak at $[\eta] = 9$ in Fig. 3 must be regarded as insignificant.

The final discussion concerning the accuracy of the frequency curves obtained will be given in the next paper of this series. It shall only be pointed out here that the double peak of the frequency curve of polyglycol A 6 000, as found in earlier experiments [1], has been verified once more.

From the experimental point of view, the work with the solvent system TCW did not differ from that with TAW, apart from the ease of emulsion formation and the dependence on temperature. As a compensation, however, the solvent system TCW has a higher resolving power. Furthermore, it has

been shown that small deviations from ideality do not appear in the final results provided that the experimental data are treated in the proper way.

EXPERIMENTAL

For experimental details, see earlier papers of this series [1,2]. The constant temperature (25°C) in the countercurrent experiments was obtained by placing the shaking device in an air thermostat.

The frequency *vs.* limiting viscosity number curves were calculated from the corresponding curves with respect to partition coefficient by means of a Litton digital differential analyzer equipped with graph follower and graph plotter.

Fractionation of Polymers by Liquid-Liquid Distribution

VI. Molecular Weight Frequency Curves for Polyglycols

KARL ERIK ALMIN

Swedish Forest Products Research Laboratory, Paper Technology Department, Stockholm, Sweden

The relation between the molecular weight and limiting viscosity number has been determined on unfractionated polyglycol preparations. By means of this relation earlier determined frequency functions of limiting viscosity number have been transformed into molecular weight frequency curves. The accuracy of the curves obtained is discussed.

Molecular weight frequency curves for polymers can be obtained from liquid-liquid countercurrent experiments in which the weights and the molecular weights of the fractions obtained have been determined. The mathematical treatment of the experimental data has been described in Ref.[1] The method for the molecular weight determination must be chosen so that absolute values are obtained for the molecular weights. Such determinations either require relatively large quantities of the samples or are time-consuming and require special techniques. In the experiments reported in the previous papers of this series [2,3], it was found that often only small quantities of the samples were obtained in the fractions. For this reason, the present author has chosen to determine the relation between the molecular weight and the limiting viscosity number on unfractionated samples and to then apply this relation to the previously determined curves of frequency *vs.* limiting viscosity number [2,3].

We assume that Mark's [4] modification of the Staudinger relation

$$[\eta] = K \cdot M^{x} \tag{1}$$

is valid *.

* In connection with work on polyglycols, the relation

$$[\eta] = K \cdot M + l$$

has been used by some other authors. Because the constants in eqn. 1 are sometimes of greater theoretical interest, this mathematical form has been preferred by the present author.

The average molecular weight of the sample can be written

$$\overline{M}^{a} = \int_{0}^{\infty} M^{a}\, g\, ([\eta])\, \mathrm{d}[\eta] \qquad (2)$$

where a is fixed by the conditions of the experimental method [4] and $g([\eta])$ is the weight frequency function in terms of the limiting viscosity number.

From eqns. 1 and 2, we obtain

$$\frac{1}{\overline{M}^{a}} \cdot \int_{0}^{\infty} [\eta]^{a/x} \cdot g([\eta]) \cdot \mathrm{d}[\eta] = K^{a/x} \qquad (3)$$

If $\overline{M}$ is measured for a number of different samples of the polymer with known $g([\eta])$ functions, the left hand side of eqn. 3 can be calculated for different x values. The correct value for x is the one which makes the value of the left hand side independent of the choice of sample.

Such a treatment of the problem has — as far as the author knows — not been performed earlier. The method generally used nowadays is to determine the molecular weight and the limiting viscosity number for fractionated polymer samples and to then regard the fractions as samples containing molecules of only one size. Eqn. 1 is then directly applicable to the experimental $\overline{[\eta]}$ values. Considering that the polymer samples prepared up to the present are far from homogeneous with respect to molecular weight, this method cannot be regarded as free from objections.

In this investigation, the end group molecular weight of the polyglycol preparations examined has been determined (Table 1). Thus $a = -1$ in the formulae above. In Table 2, the numerical values of the left hand side of eqn. 3 are given for different values of x for the polyglycol preparations reported in Parts IV and V [2,3] of this series. As can be seen, it is difficult to estimate the correct x value directly from the table. Because of this, the coefficient of variation ($= v$) has been calculated for the apparent constant at each x value. The magnitude v^2 has been plotted as a function of x. The values of x at which the minimum of this curve occurs is regarded as the correct value. The minimum value was determined under the assumption that the law concerning the rectilinear diameter is valid (Fig. 1). The value found is

Table 1. Number average molecular weights of the polyglycol preparations determined according to the end group method.

Sample	Number of dets.	Number average mol. weight
A 6 000	8	6 600 ± 40
A 4 000	9	3 620 ± 40
A 1 500	10	1 590 ± 30

Table 2. Left member of eqn. 3 calculated for the polyglycol preparations for different values of x.

	Left member of eqn. 3 ($a = -1$)				
Sample	A 1 500	A 4 000	A 4 000	A 6 000	A 6 000
Solvent system	TCW	TAW	TCW	TAW	TCW
$x = 0.5$	21.7	17.3	16.4	11.6	11.6
0.6	45.1	42.1	36.8	33.1	33.6
0.7	74.2	78.9	76.4	69.9	71.1
0.75	95.3	104.1	98.1	89.9	96.7
0.8	113.4	129.9	122.0	125.8	125.7
0.9	150.7	188.3	179.0	189.0	196.1
1.0	195.4	251.3	240.5	278.1	277.4
(∞)	(1 591)	(3 619)	(3 619)	(6 593)	(6 594)

$x = 0.74_5$. The arithmetical mean of the values of $K^{-1/x}$ interpolated from Table 2 was found to be 94.5. The Staudinger relation can thus be written

$$[\eta] = 3.38 \times 10^{-2} M^{0.75} \quad (4)$$

for polyglycol. The range of validity of this relation is difficult to estimate but a lower limit of about $M = 1\ 200$ and an upper limit of about $M = 9\ 000$ seem reasonable.

It is of interest to compare the above constants with those obtained when the calculations were carried out without regard to the width of the frequency curves. The $\overline{[\eta]}$ values used in these latter calculations were the arithmetical means of the values calculated from the experimental $[\eta]_p$ values for the fractions in the countercurrent experiments. The values of x and K were calculated according to the same principles as above. The v^2 *vs.* x curve obtained is given in Fig. 1 (dotted curve). The values found were $x = 0.77_4$ and $K = 2.68 \times 10^{-2}$. (The same result is obtained if the method of least squares is applied to the Staudinger relation after taking the logarithm of both sides). The $[\eta]$ *versus* M curve constructed using these latter x and K values differs only slightly from

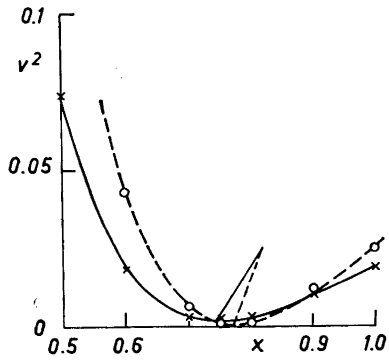

Fig. 1. Graphic determination of the exponent x in eqn. 1 for polyglycols.

the curve obtained from eqn. 4. In the range of validity, the differences amount to 0—3 %. However, the change in K is about 25 %. The experimental data on which the above calculations have been based are too few to permit a penetrating discussion, but the tendency is nevertheless clear.

Eqn. 4 has been used to transform the frequency curves. The results can be seen in Fig. 2. The full-drawn curves are the experimental curves. In the case of polyglycol A 4 000 and A 6 000, the curves from the experiments in the solvent system TCW are the arithmetical means of the curves obtained from the corresponding curves of frequency *vs.* limiting viscosity number. The dotted curves have been calculated using the formula derived by Flory [5].

The curves obtained with the solvent system TCW are more sharply peaked than those obtained with the solvent system TAW. This effect is more pronounced for polyglycol A 4 000 than for polyglycol A 6 000. The ratio of the resolving powers [6] of the systems TAW and TCW was calculated to be 1 : 7.4 in the case of polyglycol A 4 000, the molecules being assumed to have a molecular weight identical to the number average molecular weight of the sample. The curve obtained with the solvent system TCW must therefore be regarded to be the more reliable one. In the case of polyglycol A 6 000, the corresponding ratio was 1 : 3.0. The differences in the curves obtained are less pronounced than in the case of polyglycol A 4 000. The chief differences appear in the high molecular weight parts of the curves. The double peak of polyglycol A 6 000 could not be detected directly in the experimental $W(p)$ curves obtained in the TAW experiments [2]. This implies that the numerical treatment of the data from the TAW system, as well as the lower resolving power, can influence the results. In the case of polyglycol A 6 000, the results from the solvent system TCW must therefore be regarded as somewhat more reliable.

For polyglycol A 1 500, the resolving power is about 25 times higher in the solvent system TCW than that in the solvent system TAW. In view of the narrowness of the frequency curve, this ratio explains why it was impossible to perform any calculations of the frequency function using data from the TAW experiments.

The ratio of the resolving powers for the experiments with polyglycols A 6 000, A 4 000 and A 1 500 in the solvent system TCW was found to be 1 : 1.5 : 2.6. The final frequency curves obtained from data from the solvent system TCW must thus be regarded as nearly equivalent with regard to accuracy although, especially in the experiments with A 6 000, the formation of emulsions interfered considerably.

The agreement between the experimental frequency curves from the TCW experiments and the theoretically calculated frequency curves in Fig. 2 must be regarded as very good. The differences still remaining may be due to errors either in the author's experimental and theoretical treatment of the problem or in the theories of Flory [5]. The latter worker assumes that all steps in the polyreaction in which polyglycol is formed from glycol and ethylene oxide can be characterized by a single rate constant. If one assumes that the first steps of the reaction proceed with a higher velocity than the subsequent steps, then a sharper peaked frequency curve would be obtained. This assumption is only one of the possibilities for explaining the differences. Another

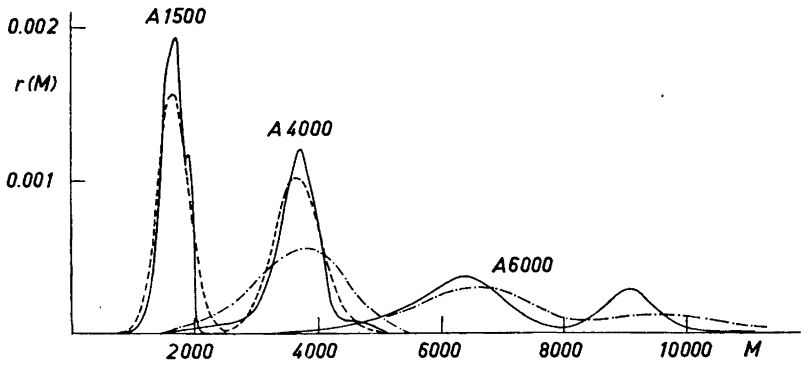

Fig. 2. Molecular weight frequency curves for the three polyglycol preparations investigated. ———— Curves obtained from the solvent system TCW; —·—·—·— Curves obtained from the solvent system TAW; — — — — — — Curves according to the theory of Flory.

possible reason for the differences between the calculated and experimental curves in Fig. 2 might be that the frequency curve of the sample is changed by the purification [2].

In any case, the frequency curves calculated using the theory of Flory are not consistent with the experimental $W(p)$ values if it is assumed that the experimentally obtained relation between limiting viscosity number and partition coefficient is correct. Approximate calculations show that the $W(p)$ values for preparation A 1 500 obtained from the theoretical frequency curve according to Flory [5], are about 0.010 lower than the experimental values for $8 < p < 11$. This difference must be considered to be far outside the experimental accuracy.

DISCUSSION

The countercurrent distribution of polymers between two immiscible solvents seems to lend itself admirably to the determination of molecular frequency functions. The chief difficulty is to find the two immiscible solvents. This problem will be treated in a forthcoming paper.

From the practical point of view, the method has the advantage over conventional methods that it is completely reproducible and this means that it is not necessary to make any time consuming calculations to decide whether two preparations of the same polymer are equal or not from the molecular frequency point of view. The equilibrium between the two phases is rapidly established, thus making it possible to obtain a large number of fractions in a relatively short time. The sensitivity to temperature is not so great in the investigated cases that an extremely accurate temperature control is required. In a given solvent system, the relation between molecular weight and partition coefficient is fixed. This means that, once this relation is known, only the relative amounts of polymer in each fraction have

to be determined. From these data, the frequency function can be calculated in terms of the partition coefficient and then converted, if required, into the molecular frequency curve. However, for a comparative study, such a recalculation may not be necessary. Sometimes the $W(p)$ *vs.* p curve gives all the information required.

The experimental results of this investigation confirm Flory's theoretical interpretation [5] of the reaction mechanism for the synthesis of polymers which are formed exclusively by the addition of monomers to a fixed number of polymer molecules.

Except for the highest molecular weight preparation examined in this investigation, the solvent system trichloroethylene-alcohol-water was shown to have a resolving power which was too low compared with the solvent system trichloroethylene-chloroform-water. The former solvent system, however, must not be regarded as useless. If the frequency curve of the polyglycol is broader than that for the preparations used in this investigation, then the system TCW might be unsuitable. Such polyglycol preparations can be obtained, for example, either from mixtures of preparations prepared in the common way or as a condensation polymer synthesized according to the method proposed by Flory [5]. It is then possible that all of the preparation may find its way into the first and last tubes of the countercurrent apparatus. An investigation in the solvent system TAW would, however, in such a case give the desired information.

For polyglycol preparations with molecular weights higher than the ones investigated in this series of articles it seems probable that the solvent system TAW or a solvent system composed of a mixture of trichloroethylene, chloroform, alcohol and water would be most suitable.

EXPERIMENTAL

The number average molecular weights of the polyglycol preparations investigated here were determined by titrimetric end group determinations. A weighed quantity of the preparation was heated under reflux for 1 h with 20 ml 6 % acetic anhydride solution in pyridine on a water bath. After cooling, 15 ml water was added and the refluxing continued for a further 10 min. The remaining liquid was then titrated with 0.5 N KOH in alcohol. A blank titration was carried out on the acetic anhydride-pyridine mixture under the same conditions as those for the sample. Phenolphthalein was used as indicator.

The apparent constants in Table 2 and the molecular weight frequency curves were calculated by means of a Litton digital differential analyzer equipped with graph follower and graph plotter.

Structure of a Glucomannan from *Pinus silvestris* L.

INGEMAR CROON, BENGT LINDBERG and HANS MEIER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm Ö, Sweden

Investigation of a glucomannan from *Pinus silvestris* has shown that it is built up very largely of β-1,4-linked sugar residues with about three branch points per molecule, most of which are attached to glucose residues at $C_{(3)}$.

A fractionation of the hemicellulose constituents of *Pinus silvestris* L. (Scots Pine) was reported in a previous communication from this Department [1]. A relatively pure glucomannan has now been prepared by similar methods from wood meal delignified by the chlorite method [2]. The polysaccharide fraction contained galactose, glucose, mannose, arabinose and xylose in the relative proportions 3.9:20.6:72.5:1.5:1.5 and had a $\overline{DP}_n$, determined osmometrically on the nitrate ester, of 97. It showed a typical lignin spectrum in the UV, with a lignin content estimated from the extinction at 280 mμ as 3—4 %. This lignin did not affect the DP-determination as it was completely lost during preparation of the nitrate ester. The lignin may be linked to the polysaccharide, and it seemed desirable to remove it before undertaking the structural investigation. Treatment with chlorine and ethanolic ethanolamine in a homogeneous medium repeated three times reduced the lignin content to about 0.2 %. The $\overline{DP}_n$ was reduced only to 93 by this treatment, which is an indication of the merit of this delignification method. Timell and Jahn [3] found that it causes only slight depolymerisation of polysaccharides, and this has been further confirmed by Glaudemans and Timell [4] in a recent investigation of birch wood hemicelluloses. — The relative proportions of galactose, glucose, mannose, arabinose and xylose in our delignified glucomannan sample were 3.0:21.1:74.0:traces:1.9, and were thus practically unchanged. The specific rotation was −31° in 2 N sodium hydroxide.

The glucomannan was methylated, first with methyl sulphate in sodium hydroxide and then with methyl iodide and silver oxide in dimethyl formamide. The product had a methoxyl content of 43.9 % and a $\overline{DP}_n$ value of 44. The methylation thus involved considerable degradation, which might also account for the rather low yield (45 %) of the methylated product. In a previous study [5] of the glucomannans from spruce (*Picea abies*), the $\overline{DP}_n$-values of the methylated products were not determined, but it must be assumed that the methylation, done in the same way as above, involved a similar depolymerisation.

The methylated polysaccharide was hydrolysed and the monomers obtained were fractionated by chromatography on a carbon-Celite column. The di-*O*-methyl ethers were only partially resolved and were further fractionated by paper chromatography and paper electrophoresis. This gave 2,6-di-*O*-methyl-D--glucose, which was the main component, smaller amounts of unidentified di-*O*-methyl-D-mannoses and of 2,3-di-*O*-methyl-D-xylose. 2,3,6-Tri-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-glucose were obtained in a pure state, followed by a small fraction that on demethylation gave galactose only. This latter fraction appeared homogeneous on chromatography in ordinary solvent systems but was resolved into two components by chromatography with *iso*propyl ether on dimethylsulphoxide-impregnated paper [6]. These had the same R_F-values as 2,3,4- and 2,4,6-tri-*O*-methyl-D-galactose, the substance corresponding to the first of these giving a much stronger spot than that corresponding to the second. 2,3,4,6-Tetra-*O*-methyl-D-mannose and 2,3,4,6-tetra-*O*-methyl-D-glucose were obtained in separate fractions. In a previous investigation [5] these components were obtained as a mixture, the successful fraction in the present case is probably due to eluation with aqueous acetone, which gives more distinct fractions of highly methylated ethers than the aqueous ethanol previously used.

2,3-Di-*O*-methyl-D-xylose is the predominant xylose ether expected from a methylated xylan. The tri-*O*-methyl-D-galactose ethers are also normal products from the arabogalactans isolated from various coniferous woods. Polysaccharides of this type have recently been isolated from two pine species [7,8]. As these polysaccharides are highly branched, one should expect to find some di- and tetra-*O*-methyl-D-galactose ethers too, but as the percentage of galactose residues in the original material was quite low, these ethers might easily have been overlooked. We believe that the xylose and galactose ethers arose from contaminating polysaccharides and they are therefore not taken into account in Table 1, which gives the molar percentages of the ethers in the hydrolysates.

Table 1. Molar percentages of monomers in the hydrolysate of the methylated glucomannan.

Ether	%
Di-*O*-methyl-D-mannoses	2.6
2,6-Di-*O*-methyl-D-glucose	5.3
2,3,6-Tri-*O*-methyl-D-mannose	67.6
2,3,6-Tri-*O*-methyl-D-glucose	19.5
2,3,4,6-Tetra-*O*-methyl-D-mannose	4.2
2,3,4,6-Tetra-*O*-methyl-D-glucose	0.8

These percentages are quite similar to those found in studies on the glucomannans from *Picea abies* [5], and it can be concluded that the polysaccharides have a similar structure with chains of 1,4-β-linked mannose and glucose residues. The high percentage of tetra-*O*-methyl-hexoses indicates that the molecules are branched, containing about 3 branches per 100 hexose residues. The percentage of di-*O*-methyl-hexoses found is certainly too high, due to incomplete methylation and possibly also to some demethylation during the

hydrolysis. As 2,6-di-*O*-methyl-D-glucose predominates among the di-*O*-methyl-hexoses, it is reasonable to assume that most of the branches start from 3-positions in glucose residues. Studies on partially methylated celluloses [9] have shown, however, that the hydroxyl in the 3-position is methylated at a slower rate than those in the 2- and 6-positions, so that 2,6-di-*O*-methyl-D-glucose is the only di-*O*-methyl-D-glucose which should occur in significant amounts in the hydrolysate of a slightly undermethylated product. It can also be seen from Table 1 that most of the non-reducing end groups are mannose residues, as would be expected if a statistical distribution of mannose and glucose residues in the polysaccharide is assumed.

On periodate oxidation the glucomannan consumed 0.90 moles of periodate per hexose residue, with the formation of 0.12 moles of acids. This result indicates a higher branching than was found by the methylation study, and most probably is due to over-oxidation. The hydrolysate of the oxidised polysaccharide contained more glucose than mannose, their relative proportions being about 2:1. This provides further support for the assumption that the polysaccharide is branched and that most branches start from glucose residues.

The chain of 1,4-β-linked glucose and mannose residues seems to be a common feature of glucomannans isolated from coniferous woods [5,10–14]. These show glucose to mannose ratios of between 1:4 and 1:2. The proportion of glucose is increased in the partially hydrolysed polysaccharides [5]. A high glucose content in a glucomannan might indicate that its isolation from the wood has involved degradation or that the material is contaminated with cellulose. It seems fairly certain that the glucomannans from pine and spruce [5,12] have a slightly branched structure. The partially degraded polysaccharide from a hemlock sulphite pulp [13] showed no such branching. The undegraded glucomannan from spruce was amorphous but the partially hydrolysed product obtained from it was highly crystalline [15]. This difference is easily understood if the crystalline material is made up of linear fragments of the branched polysaccharide.

Indications have been recorded that coniferous woods contain galactoglucomannans as well as glucomannans [14,16–18]. Studies here on hemicellulose fractions isolated from holocellulose from pine and spruce wood have not given any support for this hypothesis. It is true that glucomannan fractions often contain considerable amounts of galactose and xylose residues which cannot be removed by further fractionation. We found, however, that these samples always contained a small percentage of lignin. After further delignification the contaminating polysaccharides could usually be separated from the glucomannans. A typical example of such a fractionation is given in the experimental part. A glucomannan that had been extracted with alkali from a pine holocellulose, after fractionation with barium hydroxide, contained 11 % galactose- and 5.5 % xylose residues. After delignification of the sample the galactose residues could be reduced to about 1 to 2 % and the xylose residues to traces by precipitation with barium hydroxide followed by precipitation twice with Fehling's solution. At the same time an arabogalactan or galactan was obtained which was free from glucose and mannose residues and had not been precipitated on the addition of Fehling's solution. We therefore believe that different polysaccharides, glucomannans and xylans as well as galactans

or arabogalactans may be linked to the same lignin molecule, which of course would make fractionation prior to further delignification impossible. The existence of linkage between lignin and hemicelluloses in woods has been strongly indicated by recent investigations by Björkman [19] and Lindgren [20]. The small amounts of galactose and xylose residues in our glucomannan used for methylation could be explained in the same way. The isolation, after partial hydrolysis of the polysaccharide, of oligosaccharides containing galactose and either glucose or mannose residues would of course prove the presence of galactoglucomannans but such proof has not yet been obtained*.

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 and on 3 MM filter papers. Chromatographic solvents: (*a*) ethyl acetate-acetic acid-water (3:1:3)
(*b*) butan-2-one, saturated with water
(*c*) 4 % dimethyl sulphoxide in benzene

Paper electrophoresis was carried out on Whatman No. 3 MM filter paper in borate buffer at pH 10.

Solutions were always concentrated under reduced pressure at a bath temperature of about 40°C.

Isolation of the glucomannan. Wood meal (18—35 mesh) from *Pinus silvestris* was extracted with acetone in a Soxhlet-type extractor and the residue was delignified by the chlorite method [8]. The product remaining after delignification amounted to 67.2 % of the acetone-extracted wood and contained less than 1 % Klason lignin. The holocellulose (297 g) was extracted successively under nitrogen with dimethyl sulphoxide, boiling water, 14 % potassium hydroxide and finally with 24 % potassium hydroxide and 3 % boric acid. The hemicelluloses from the last extract after acidification of the solution were precipitated with ethanol, dissolved in water and a glucomannan was precipitated by the addition of barium hydroxide [21]. The glucomannan was further purified by redissolving in water and precipitating once more with barium hydroxide. A sample (5.3 g) on hydrolysis gave 3.9 % galactose, 20.6 % glucose, 72.5 % mannose, 1.5 % arabinose and 1.5 % xylose. It contained between 3 and 4 % lignin (determined by UV-absorption [1]) and was therefore dissolved in water, and delignified by three successive chlorine-ethanolamine treatments as described earlier [1]. This reduced the lignin content to about 0.2 %. The delignified product used in the following methylation study had $[\alpha]_D^{20}$ −31° (c = 0.8, in 2.5 N sodium hydroxide) and on hydrolysis gave 3.0 % galactose, 21.1 % glucose, 74.0 % mannose, a trace of arabinose and 1.9 % xylose.

Determination of the $\overline{DP}_n$-values. The $\overline{DP}_n$-values were determined osmometrically on the nitrate-esters before and after the final delignification of the glucomannan and also on the methylated product. These gave values of 97.6, 93.0 and 43.7, respectively. The determinations were carried out in a Zim and Myerson osmometer and butyl acetate was used as solvent. The procedure has been described in an earlier paper [15].

Fractionation of a galactose-rich glucomannan. A glucomannan fraction which had been extracted with alkali from a pine holocellulose was purified by two precipitations with barium hydroxide [21] and then contained galactose, glucose, mannose, arabinose and xylose in the proportions 11.0:21.3:59.7:2.5:5.5. The lignin content was 5.3 %. After delignification by the chlorine-ethanolamine method, the sample was precipitated once with barium hydroxide and then contained galactose, glucose, mannose, arabinose and xylose in the proportions 10.1:20.6:64:2.6:2.7. The lignin had been reduced to 0.3 %. Part of the fraction (800 mg) was dissolved in water (100 ml), Fehling's solution (30 ml)

* *Added in proof.* From a partial hydrolysate of an easily soluble spruce hemicellulose fraction, rich in galactose residues, we have now isolated a galactosyl-mannose and a galactosyl-mannobiose. From these results, the presence of either a galactoglucomannan or a galactomannan, in addition to the previously known glucomannan is indicated.

was added and the precipitate was centrifuged. After washing once with water it was dissolved in 1 N hydrochloric acid, the hemicelluloses were precipitated with ethanol and the whole procedure was repeated. This sample (420 mg) was then hydrolysed and was found to be an almost pure glucomannan containing 1—2 % galactose and only traces of arabinose and xylose. After centrifuging the first precipitate with Fehling's solution, the solution was acidified with hydrochloric acid and dialysed, acidified again and then precipitated with ethanol, yielding a polysaccharide fraction (140 mg) which, on hydrolysis, gave about 50 % galactose, 10 % glucose, 30 % mannose, 5 % arabinose and 5 % xylose. This hemicellulose in aqueous solution was again treated with Fehling's solution. The precipitate formed was found to be a rather pure glucomannan but the centrifugate was free from mannose- and glucose residues and contained a galactan or arabogalactan contaminated with an araboxylan. A synthetic mixture of a pure glucomannan and a galactan from spruce wood [22] was easily separated into pure components by the same method.

Methylation of the glucomannan. The glucomannan (2 g) was dissolved in 22.5 % sodium hydroxide (50 ml), under nitrogen, and methyl sulphate (10 ml) was added over 1 h with vigorous stirring while the temperature was kept at 20° by external cooling. After 6 h the solution was neutralised with 6 N sulphuric acid and the polysaccharide was recovered by dialysis. Yield 1.98 g (OCH_3, 26.1 %).

The partially methylated product was dissolved in dimethyl formamide (30 ml) and methyl iodide (6 ml) was added in one portion. Silver oxide (6 g) was added over 1 h with vigorous stirring. After 20 h the insoluble material was centrifuged off and washed with dimethyl formamide (10 ml) and chloroform (10 ml). The combined centrifugates were concentrated. The resulting syrup was treated with benzene-chloroform (1:1, 20 ml) and the undissolved salts were centrifuged off. The solid residue was washed with benzene (20 ml). The combined centrifugates were evaporated to dryness and then methylated again three times using the procedure described above. The product finally obtained (0.89 g) had a OCH_3-content of 43.9.

Hydrolysis of the methylated glucomannan. The methylated glucomannan (0.89 g) was dissolved in anhydrous formic acid and kept at 100°C for 6 h. The solution was concentrated and the resulting syrup was dissolved in 0.5 N sulphuric acid and kept at 100°C for 15 h. This solution was then neutralised with barium carbonate, giving finally a syrup (0.75 g). Chromatographic examination of the hydrolysate (Solvent *a*) revealed the presence of di-, tri- and tetra-*O*-methyl hexoses but no glucose, mannose or mono-*O*-methyl hexoses.

Examination of the hydrolysis products from methylated glucomannan. The hydrolysate from the methylated glucomannan (753 mg) was added to the top of a carbon-Celite column (43 × 3.5 cm) which was then developed by gradient elution with the following solvents:

10 % → 30 % aqueous ethanol	5 000 ml
30 % aqueous ethanol → 30 % aqueous acetone	3 000 »

The eluate was divided into fractions (30 ml) which were examined on paper chromatograms (Solvent *a*). Those fractions which were indistinguishable were combined and taken to dryness.

Fraction 1. (54 mg.) Five components were isolated by paper electrophoresis. The principal component on demethylation gave glucose only and was chromatographically and electrophoretically indistinguishable from authentic 2,6-di-*O*-methyl-D-glucose. The components were fractionated, in two separate experiments, on paper chromatograms (Solvent *b*) and on paper electrophoretograms, and quantitative determinations of the principal components were made by hypoiodite oxidation [23]. Three of the components isolated gave mannose only on demethylation but were not further investigated. The fifth component was shown to be 2,3-di-*O*-methyl-D-xylose (17 mg).

Fraction 2. (395 mg.) This fraction on demethylation yielded mannose only. An aniline derivative was prepared, m. p. 125—126°, alone or in admixture with authentic 2,3,6-tri-*O*-methyl-*N*-phenyl-D-mannosylamine. This fraction was chromatographically homogeneous.

Fraction 3. (99 mg.) The material crystallised when the solvent was evaporated. One crystallisation from ethyl acetate yielded the pure substance, m. p. 117—119°, undepressed on admixture with authentic 2,3,6-tri-*O*-methyl-D-glucose. Chromatograms of the mother liquor indicated traces of an unknown substance with a slightly higher

R_F-value (Solvent *a*) than 2,3,6-tri-*D*-methyl-D-glucose. This was probably the same substance as was previously isolated [5] and that had been shown to be a tri-*O*-methyl-D-glucose, distinguishable from 2,3,4- and 2,3,6-tri-*O*-methyl-D-glucose.

Fraction 4. (17 mg) on demethylation yielded galactose only. Chromatography on dimethyl sulphoxide treated paper with solvent *c* separated the fraction into two components with the same R_F-values as 2,3,4-tri-*O*-methyl-D-galactose and 2,4,6-tri-*O*-methyl-D-galactose. The spot corresponding to the former had the lowest R_F-value and was the principal substance in this fraction.

Fraction 5. (26 mg) gave mannose only on demethylation. The aniline derivative, m. p. 142—144°C, was not depressed on admixture with the aniline derivative of 2,3,4,6-tetra-*O*-methyl-D-mannose.

Fraction 6. (5 mg) on demethylation yielded glucose only. It was chromatographed on dimethyl sulphoxide treated paper using *iso*propyl ether as solvent, and gave an elongated spot with the same R_F-values as authentic 2,3,4,6-tetra-*O*-methyl-D-glucose (0.56) but higher than 2,3,4,6-tetra-*O*-methyl-D-mannose (0.47).

Periodate oxidation studies. The glucomannan (373 mg) was kept in water (50 ml) overnight in the refrigerator (2—4°). Sodium metaperiodate solution (0.32 M, 25 ml) was then added and the volume was adjusted to 125 ml. The solution was kept in the refrigerator and samples (5 ml) were withdrawn at intervals and analysed for periodate consumption and for the formation of acid. The results are summarised in Table 2.

Table 2. Periodate oxidation of the glucomannan.

Time, h	Moles of periodate consumed per $C_6H_{10}O_5$	Acid equivalents per $C_6H_{10}O_5$
60	0.71	0.061
72	0.86	0.076
100	0.89	0.108
140	0.92	0.136
200	0.95	0.144
350	0.97	0.148

XI.* 2-Amino-3-hydroxymethylphenol from Cinnabarin

JARL GRIPENBERG

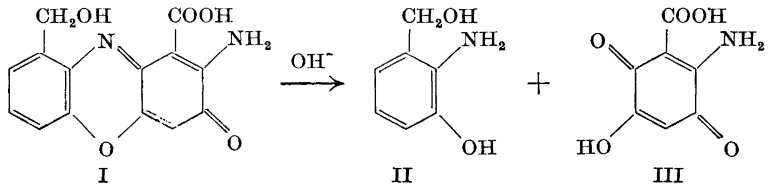
Department of Chemistry, Finland Institute of Technology, Helsingfors, Finland

Alkaline hydrolysis of cinnabarin has yielded 2-amino-3-hydroxymethylphenol, whose structure was established by synthesis. This definitely proved the presence of a hydroxymethyl group in cinnabarin.

In earlier papers of this series [1–3] evidence has been advanced supporting structure I for cinnabarin. The same structure was independently proposed by Cavill *et al.* [4,5].

Direct proof for the presence of the hydroxymethyl group was, however, lacking. That cinnabarin has a side chain in position 9 was shown by the formation of benzoxalone-4-carboxylic acid upon oxidation [1], but its nature was only indirectly deduced [2,6].

As has already been described,[2,3] cinnabarin treated with alkali yields cinnaquinone, which is most probably 3-amino-6-hydroxybenzoquinone-2-carboxylic acid (III). Cinnaquinone originates evidently from the quinonoid part of the phenoxazinone ring system. Assuming that its formation is due to a simple hydrolytic cleavage of the central ring, 2-amino-3-hydroxymethylphenol (II), should be formed from the benzenoid ring.



I II III

The mother liquor remaining after the sodium salt of cinnaquinone had been removed [2], upon saturation with carbon dioxide and extraction with ether did indeed give a compound with the properties to be expected of II.

Part X, *Acta Chem. Scand.* **12** (1958) 1762.

It had the composition $C_7H_9NO_2$ and was readily soluble in water but difficultly soluble in hydrocarbons. Acetylation gave a tri-acetate. The U.V.-spectrum had a maximum at 290 mμ (log ε 3.78) and an inflexion at $\sim$ 230 mμ. It showed great similarity to the spectrum of *o*-aminophenol [7]. In alkaline solution a bathochromic shift of the maximum to 302 mμ (log ε 3.63) occurred. In acidic solution the maximum was shifted to 275 mμ (log ε 3.36). The spectrum was then practically identical with that of *m*-cresol [8].

The spectrum of the acetate was somewhat anomalous. One would have expected it to be similar to the spectrum of *o*-aminophenol diacetate, which has a maximum at 236 mμ (log ε 4.06) with a very weak inflexion at 280 mμ. (Le Rosen and Smith [9] report 238 mμ (log ε 3.93) for this maximum). Instead, it had a weak maximum at 260 mμ (log ε 2.74) and only end absorption down to 220 mμ.

The maximum of *o*-aminophenol diacetate is certainly due to the acetanilide group, as shown by the very similar absorption of acetanilide, with maxima at 242 mμ (log ε 4.16) and 280 mμ (log ε 2.70) [10]. Apparently the acetoxymethyl group in 2-amino-3-hydroxymethylphenol triacetate sterically hinders the conjugation between the aromatic ring and the acetamide group and the absorption is probably essentially that of the benzene ring. Alkyl groups in the *ortho*-position interfere sterically with this conjugation as has been noted earlier [10,11].

The fact that the compound obtained from cinnabarin was indeed 2-amino-3-hydroxymethylphenol (II) was finally proven through its synthesis by the lithium aluminium hydride reduction of methyl 3-hydroxyanthranilate. This was prepared according to Angyal *et al.*[12], with minor modifications, as indicated in the experimental part.

The reduction of methyl 3-hydroxyanthranilate did not proceed very well. The reduction was first carried out in boiling ether using a large excess of lithium aluminium hydride. Although this method gave some of the desired compound, considerable hydrogenolysis to 2-amino-*m*-cresol occurred. This supports the results of Conover and Tarbell [13], who report considerable hydrogenolysis in the reduction of methyl anthranilate, particularily if the reaction time is extended to several hours. In order to minimise the hydrogenolysis, attempts were made to carry out the reduction by reverse addition of the theoretical amount of lithium aluminium hydride. A heavy precipitate was formed at once, however, and even after boiling the mixture for several hours, considerable unreacted lithium aluminium hydride remained in the solution. Only a very minute amount of 2-amino-3-hydroxymethylphenol could be isolated using this particular method. The use of methyl 3-acetoxy anthranilate was similarly unsatisfactory.

The best procedure was finally found to be by slowly adding methyl 3-hydroxy anthranilate at room temperature to a moderate excess of lithium aluminium hydride, and allowing the mixture to stand for some hours at room temperature. In this way, a yield of approximately 50 % 2-amino-3-hydroxymethylphenol was obtained. Its m.p. was slightly lower than that found for the substance obtained from cinnabarin but no m.p. depression was observed in a mixture test. Its rather high carbon content indicated the presence of some 2-amino-*m*-cresol. It was best characterised as its triacetate,

which was readily obtained in a pure state. There was no m.p. depression when this was mixed with the corresponding derivative obtained from cinnabarin, and their I.R.-spectra were identical.

EXPERIMENTAL

3-Methoxy-2-nitrobenzoic acid was prepared according to Nyc and Mitchell [14]. For the separation of 3-methoxy-2-nitrobenzoic acid from the other isomers, the reaction mixture was completely dissolved in the minimum quantity of hot ethyl alcohol. Upon cooling, large glass-like crystals first appeared. When small clusters of white needles began to separate on the surface of the big ones, the crystals were filtered off and recrystallised once from ethyl alcohol. In this way a very consistent yield of 1.15 g of 3-methoxy-2-nitrobenzoic acid (m. p. 260—265°; lit.[14] 260—263°) was obtained from 10 g *m*-methoxybenzoic acid. When attempts were made to carry out the reaction on a larger scale, difficulties were encountered in regulating the reaction temperature.

3-Hydroxy-2-nitrobenzoic acid was prepared according to Angyal *et al.*[12] The pyridine hydrochloride melt was dissolved in water and the solution thoroughly extracted with ethyl acetate. After drying this was evaporated under vacuum to a small volume. Light petroleum was then added. 3-Hydroxy-2-nitrobenzoic acid crystallised as yellow crystals, m. p. 178—180° (Hegedüs [15] gives m. p. 176—178° for a crude product). Yield 1.6 g from 2 g 3-methoxy-2-nitrobenzoic acid.

Methyl 3-hydroxy-2-nitrobenzoate was prepared from the foregoing by esterification with methyl alcohol and sulphuric acid. Recrystallised from water, it formed colourless needles, of m. p. 114—115° (lit.[16] 115°).

Methyl 3-hydroxy anthranilate. Methyl 3-hydroxy-2-nitrobenzoate (2 g) dissolved in alcohol was hydrogenated with a palladium-on-charcoal catalyst at room temperature and ordinary pressure. In four hours 680 ml of hydrogen were taken up. The solution was evaporated to dryness under vacuum. The residue was recrystallised from an ethyl-acetate-light petroleum mixture, giving almost colourless crystals (0.8 g), m. p. 97—98° (lit.[17] 94°).

The mother liquor contained more of the same substance, but this was contaminated with considerable red-coloured material, from which it was difficult to free the crystals.

Methyl 3-acetoxy-2-nitrobenzoate. Methyl 3-hydroxy-2-nitrobenzoate was acetylated with acetic anhydride and a drop of pyridine. After standing over night the mixture was poured into water. Methyl 3-acetoxy-2-nitrobenzoate separated as an oil which solidified on scratching the container. Recrystallisation from light petroleum gave colourless crystals m. p. 54—54.5°. (Found: C 50.58; H 3.89. $C_{10}H_9NO_6$ requires C 50.21; H 3.79).

Methyl 3-acetoxyanthranilate. Methyl 3-acetoxy-2-nitrobenzoate (2.25 g) dissolved in ethyl alcohol was hydrogenated with a palladium-on-charcoal catalyst at room temperature and ordinary pressure. The hydrogen consumption amounted to 600 ml (Theor. 635 ml). The solution was evaporated under vacuum and turned to a dark red colour. Benzene was added to the residue and a red precipitate was filtered off. Light petroleum was carefully added to the benzene solution precipitating dark impurities. The almost colourless solution was evaporated to dryness under vacuum. Sublimation (90—100°/0.02 mm) and further crystallisation from ligroin gave colourless crystals (0.66 g), m. p. 94—95°. (Found: C 57.05; H 5.36. $C_{10}H_{11}NO_4$ requires C 57.41; H 5.30). It gave a large m. p. depression when mixed with methyl 3-hydroxyanthranilate, m. p. 97—98°.

2-Amino-3-hydroxymethylphenol (II). a) Methyl-3-hydroxyanthranilate (500 mg) dissolved in ether was added dropwise to a stirred suspension of lithium aluminium hydride (500 mg) in ether. The mixture was allowed to stand 2 h. Water was then added carefully to destroy the excess of lithium aluminium hydride. A little sodium hydroxide was added to facilitate the dissolving of the precipitate. The aqueous layer was separated and saturated with carbon dioxide. It was then extracted thoroughly with ether until a sample of the extract left no crystalline residue. The precipitate which formed during the introduction of carbon dioxide did not interfere with the extraction. It was found advisable to introduce more carbon dioxide from time to time during the extraction because the pH showed a tendency to rise.

The ether extract was evaporated under vacuum and the residue dissolved in a small amount of water, filtered and evaporated under vacuum. The red oily residue was treated with benzene whereupon it crystallised. The crystals were filtered off and addition of light petroleum to the mother liquor gave more of the same crystals. Altogether 190 mg were obtained. Recrystallisation from ethyl acetate-benzene and subsequent sublimation (120—130°/0.01 mm) yielded colourless needles, m. p. 124—125°. (Found: C 61.37; H 6.49; N 10.33. $C_7H_9NO_2$ requires C 60.42; H 6.52; N 10.07). Main I.R.-maxima (KBr-disc): 3 510, 3 430, 3 330, 3 100, 2 880, 1 630, 1 583, 1 500, 1 472, 1 373, 1 305, 1 280, 1 265, 1 168, 1 080, 1 000, 980, 938, 925, 865, 773 and 721 cm^{-1}.

The acetate of 2-amino-3-hydroxymethylphenol was prepared by acetylation with acetic anhydride and a drop of pyridine. After standing over night the mixture was evaporated under vacuum and the crystalline residue recrystallised from benzene-light petroleum, m. p. 117°. (Found: C 58.64; H 5.66; N 5.69. $C_{13}H_{15}NO_5$ requires C 58.86; H 5.70; N 5.28.) Main I.R.-maxima (KBr-disc): 3 280, 3 040, 2 800, 1 778, 1 748, 1 656, 1 590, 1 517, 1 469, 1 451, 1 432, 1 371, 1 265, 1 218, 1 192, 1 088, 1 062, 1 018, 965, 860, 783, 753 and 733 cm^{-1}.

b) Cinnabarin (400 mg) was treated with 2 N sodium hydroxide as previously described [3]. After filtering off the sodium salt of cinnaquinone, the alkaline solution remaining was saturated with carbon dioxide, and thoroughly extracted with ether. The residue from the ether extract was dissolved in a small amount of water, filtered and evaporated under vacuum. The crystalline residue was sublimed at 100—110°/0.01 mm. The sublimate (40 mg) was recrystallised from ethyl acetate-benzene and found to have a m. p. of 125—126°. (Found: C 60.70; H 6.35; N 9.91. $C_7H_9NO_2$ requires C 60.42; H 6.52; N 10.07.) No m. p. depression was observed when the sublimate was mixed with material prepared according to a).

The acetate was prepared as described above and had m. p. 117°. It gave no m. p. depression when mixed with the corresponding derivative described under a), and their I.R.-spectra were identical.

The analyses have been carried out by Dr. A. Bernhardt, Mülheim, Germany. The I.R.-spectra have been taken by Mr. J. Miettinen of this department.

Benzaurinstudien

II. Gleichgewichte und Reaktionskinetik des 3,3′,5,5′-Tetrabrom-benzaurins und des 3,3′-Dibrom-5,5′-dimethyl-benzaurins in wässrigen Lösungen

HANS GUSTAF HANSSON

Abteilung für anorganische und physikalische Chemie des Chemischen Instituts der Universität Lund, Schweden

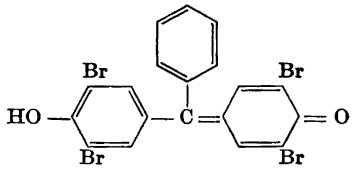
The equilibrium conditions of 3,3',5,5'-tetrabromo-benzaurin and 3,3'-dibromo-5,5'-dimethyl-benzaurin in aqueous solutions have been quantitatively investigated. They can be expressed in the scheme stated. The scheme is made up as follows. Three coloured forms are in instantaneous pH-equilibrium with each other. Further, there are three colourless forms likewise in instantaneous pH-equilibrium with each other. A coloured form is converted into the corresponding colourless form by the reaction with water. The taking up of water is, according to circumstances, a time reaction which appears as a fading of the colour of the solution. All the reactions are reversible.

By measurements of the light absorption at equilibrium in a series of solutions with different pH values and by determination of the reaction rate of the fading process at different pH values the author has succeeded in determining the equilibrium and velocity constants of the scheme.

The constants determined are referred to the ionic strength 0.50 M and a solvent with the composition 98 % water + 2 % acetone. The light absorption measurements were performed with a Beckman Quartz Spectrophotometer Model DU. The temperature was 20°C.

Während der letzten 'Jahre sind mehrere wichtige quantitative Untersuchungen über das Gleichgewichtsschema von Triphenylmethanfarbstoffen in wässrigen Lösungen ausgeführt worden. Bisher sind vor allem basische Triphenylmethanfarbstoffe vom Malachitgrüntypus untersucht worden [1–4]. Eine frühere Arbeit [5] über das Aurin, 4,4'-Dihydroxy-fuchson, (vgl. auch die Beobachtungen bei Phenolphtalein [6] und frühere einzelne Ergebnisse bei Benzaurin [7–14]) machen es wahrscheinlich, dass bei den sauren Triphenylmenthanfarbstoffen vom Benzaurintypus das Gleichgewichtsschema dem der basischen Triphenylmethanfarbstoffe vom Malachitgrüntypus ähnelt.

Die vorliegende Untersuchung über Tetrabrom-benzaurin und Dibrom-dimethyl-benzaurin hat diese Annahme bestätigt.



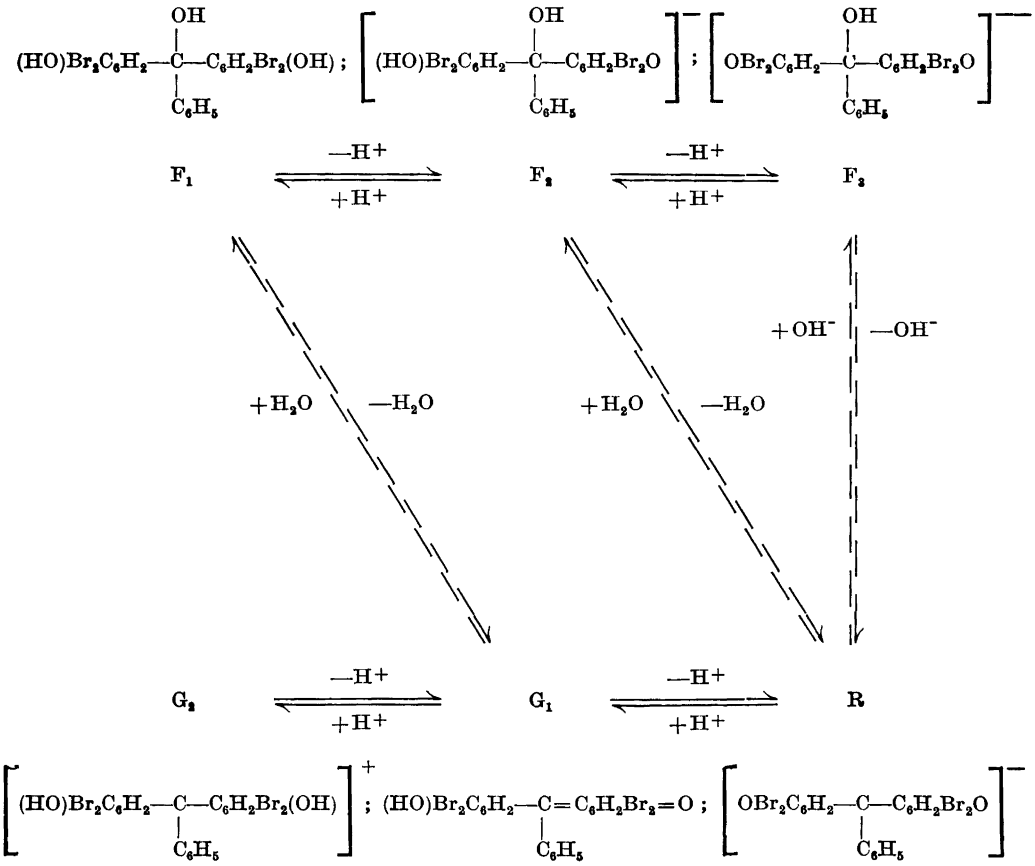
Tetrabrom-benzaurin (Anhydrid)

Das System kann also in wässrigen Lösungen durch das folgende Reaktionsschema beschrieben werden. Das Schema ist das möglichst Einfache und sagt über den Reaktionsverlauf in den einzelnen Stufen nichts aus.

In der Folge werden schematisch die Symbole R, G_1, G_2, F_1, F_2 und F_3 statt der vollständigen Formeln benutzt. Die Gleichgewichtskonstanten des Schemas werden wie folgt definiert:

Die Protolysenkonstanten

$$K_1 = \frac{[G_1]}{[H^+]\cdot[R]}\,;\; K_7 = \frac{[H^+]\cdot[G_1]}{[G_2]}\,;\; K_3 = \frac{[H^+]\cdot[F_2]}{[F_1]}\,;\; K_4 = \frac{[H^+]\cdot[F_3]}{[F_2]}$$



Die Hydratationskonstanten bei konstanter Aktivität des Wassers

$$K_2 = \frac{[F_1]}{[G_1]}\,;\, K_6 = \frac{[R]}{[F_2]}$$

Aus den Definitionen ergibt sich $K_1 \cdot K_2 \cdot K_3 \cdot K_6 = 1$. Ferner ist $K_5 = K_6/K_4$.

Die Geschwindigkeitskonstanten

k_1 für die Reaktion $G_1 + H_2O \rightarrow F_1$
k_2 » » » $F_1 \rightarrow G_1 + H_2O$
k_3 » » » $R + H_2O \rightarrow F_2$ einschliesslich $R + OH^- \rightarrow F_3$
k_4 » » » $F_2 \rightarrow R + H_2O$ » $F_3 \rightarrow R + OH^-$

k_1 und k_3 enthalten die Konzentration des Wassers. Es gilt:
$k_2 = k_1 \cdot 1/K_2$ und $k_4 = k_3 \cdot K_6$.

Folgende generelle Annahmen, die durch halbquantitative Vorversuche bestätigt worden sind, liegen der Bestimmung der zu dem Schema gehörigen Konstanten zu Grunde.

1. Die Reaktionen $R \underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} G_1 \underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} G_2$ sowie $F_3 \underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} F_2 \underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} F_1$ sind momentan. Die Reaktionen $G_1 + H_2O \rightleftharpoons F_1$ und $R + H_2O \rightleftharpoons F_2$ (einschliesslich $R + OH^- \rightleftharpoons F_3$) sind aber Zeitreaktionen, die wenigstens in gewissen pH-Gebieten * mit messbarer Geschwindigkeit verlaufen. Der Unterschied ist im vorangehenden Schema durch ausgezogene bzw. gestrichelte Reaktionspfeile angedeutet.

2. Die Anhydridformen R, G_1 und G_2 sind farbig, die Karbinolformen F_1, F_2 und F_3 dagegen farblos.

3. Eine Lösung der Farbstoffe in wasserfreiem Aceton enthält nicht die farblosen Karbinolformen F_1, F_2 und F_3.

Es wird auf diese Annahmen hier nicht näher eingegangen; es soll aber kurz darauf hingewiesen werden, dass die gute optische Beständigkeit und Reproduzierbarkeit von Lösungen des Farbstoffes in Aceton die Annahme 3 fast völlig begründet.

Von diesen Annahmen her kann man das Gleichgewichtssystem durch Messungen von zusammengehörigen Werten der Lichtabsorption und Wasserstoffionenkonzentration aufklären, da der molekulare Extinktionskoeffizient einer Lösung des Farbstoffes beim Gleichgewicht — bzw. bei der Zeit $t = 0$ (Moment des Mischens) — immer eine eindeutige Funktion der Wasserstoffionenkonzentration ist. In einigen Fällen ist es dabei möglich, die von Cigén [3] abgeleiteten Formeln bei den Malachitgrünfarbstoffen zur Berechnung zu verwenden.

Zur Ermittelung der Geschwindigkeitskonstanten, die im Gegensatz zum Verhalten der Malachitgrünfarbstoffe [3] von der Wasserstoffionen-(bzw. Hydroxylionen-)konzentration abhängig sind, misst man bei verschiedenen Wasserstoffionenkonzentrationen die Geschwindigkeit mit welcher sich ein frisch bereitetes Gemisch von 1—2 ml einer Acetonstammlösung des Farbstoffes mit einem geeigneten wässrigen Puffer (99—98 ml) durch teilweise Umlagerung in die farblosen Formen aufhellt.

* pH bedeutet in dieser Arbeit immer $-\log[H^+]$.

ABLEITUNG VON FORMELN

I. Berechnungen der Anfangsextinktionen. Bestimmung von K_1

Beim Mischen einer Pufferlösung mit einer Stammlösung des Farbstoffes in Aceton stellt sich das Gleichgewicht $R + H^+ \rightleftharpoons G_1$ momentan ein. Die Mischung wird allmählich durch die Reaktionen

$$G_1 + H_2O \rightarrow F_1 \text{ und } R + H_2O \rightarrow F_2$$

aufgehellt. Die Aufhellung, die ohne Änderung des Farbtons stattfindet, wird durch Messung der Lichtextinktion E der Lösung verfolgt. Log $(E - E_\infty)$, als Funktion der Zeit (t) aufgetragen, ergibt eine Gerade. Extrapolation auf $t = 0$ gibt E_0, welches die Lichtextinktion im Augenblick des Mischens ist. Bei $t = 0$ liegt der Farbstoff nur als G_1 und R vor *. E wird bei einer Wellenlänge gemessen, wo nur R absorbiert. Also gilt

$$K_1 = \frac{[G_1]}{[H^+] \cdot [R]} \; ; \; E_0 = E_R \cdot \frac{[R]}{C}$$

wo die Gesamtkonzentration des Farbstoffes $C = [R] + [G_1]$ ist und $E_R =$ die Extinktion für eine Lösung, in der $[R] = C$ ist (bei unveränderter Schichtdicke). Man bekommt

$$\frac{1}{E_0} = \frac{1}{E_R} + \frac{[K_1] \cdot [H^+]}{E_R} \qquad (1)$$

Für eine Reihe von Lösungen mit verschiedenen, geeignet gewählten $[H^+]$-Werten und mit gleicher Gesamtkonzentration des Farbstoffes werden bei gleicher Schichtdicke teils $[H^+]$, teils E_0 (durch Extrapolation wie oben erwähnt) bestimmt. $1/E_0$ wird als Funktion von $[H^+]$ aufgetragen und gibt nach (1) eine Gerade; aus deren Schnittpunkt a_1 mit der Ordinate und dem Richtungskoeffizienten b_1 erhält man

$$E_R = 1/a_1 \; ; \; K_1 = b_1/a_1$$

II. Berechnungen aus den Gleichgewichtsextinktionen

Beim Mischen von einer Lösung des Farbstoffes in Aceton mit einer Pufferlösung erfolgt, wie oben erwähnt, eine Aufhellung. Nachdem Gleichgewicht eingetreten ist, liegen in der Lösung die Formen G_1, R, F_1, F_2 und F_3 vor *.

A. Wenn $[H^+] \ll 1/K_1$ ist, kann $[G_1]$ vernachlässigt werden und man hat mit den Formen R, F_1, F_2 und F_3 im Gleichgewicht zu rechnen. Wenn C die Gesamtkonzentration des Farbstoffes, E_∞ die Lichtextinktion für eine Lösung beim Gleichgewicht und E_R wie oben (I) definiert ist, gilt:

* G_2 tritt erst in sehr stark sauren Lösungen auf.

$$E_\infty = E_R \cdot \frac{[R]}{C} \; ; \; C = [R] + [F_1] + [F_2] + [F_3]$$

$$K_3 = \frac{[H^+] \cdot [F_2]}{[F_1]} \; ; \; K_4 = \frac{[H^+] \cdot [F_3]}{[F_2]} \; ; \; K_6 = \frac{[R]}{[F_2]}$$

Aus diesen Relationen erhält man

$$E_\infty = E_R \cdot \frac{K_6}{1 + K_6 + [H^+]/K_3 + K_4/[H^+]} \qquad (2)$$

1. *Bestimmung von K_3K_6 und K_6.* Im allgemeinen kann man ein pH-Gebiet finden, wo (2) weiter vereinfacht werden kann, dadurch, dass $[H^+] \gg K_4$ wird. Dann wird $[F_3] \ll [F_1] + [F_2] + [R]$ und $K_4/[H^+]$ ist in Formel (2) zu vernachlässigen. Man bekommt

$$E_\infty = E_R \cdot \frac{K_6}{1 + K_6 + [H^+]/K_3}$$

welches umgeformt wird zu

$$\frac{1}{E_\infty} = \frac{1 + 1/K_6}{E_R} + \frac{1}{E_R \cdot K_3K_6} \cdot [H^+] \qquad (3)$$

Für eine Reihe von Lösungen werden $[H^+]$ und E_∞ bei gleicher Schichtdicke und Gesamtkonzentration des Farbstoffes bestimmt. $1/E_\infty$ wird als Funktion von $[H^+]$ aufgetragen. Man bekommt nach (3) eine Gerade. Aus deren Schnittpunkt a_2 mit der Ordinate und dem Richtungskoeffizienten b_2 erhält man

$$K_6 = 1/(a_2 \cdot E_R - 1) \; ; \; K_3K_6 = 1/b_2 \cdot E_R$$

Der E_R-Wert wurde bei Bestimmung von K_1 (siehe oben) erhalten. Er kann aber auch durch Messung der Aufhellungsgeschwindigkeit bei genügend kleiner $[H^+]$ ($[H^+] \ll 1/K_1$) erhalten werden. Extrapolation auf $t = 0$ gibt dann (bei evtl. grösserer $[H^+]$ nach Korrektion für vorhandenes G_1) E_R.

Anm. Aus praktischen Gründen mussten die Messungen sich auf ein Gebiet erstrecken, wo $[G_1]$ nicht ganz zu vernachlässigen ist. Da die Formeln (2) und (3) voraussetzen, dass $[G_1]$ vernachlässigt werden kann, soll man in diesen Fällen E_∞ durch einen korrigierten Wert E'_∞ ersetzen, wo $E'_\infty - E_\infty \approx E_\infty \cdot K_1 \cdot [H^+] \cdot E_\infty/E_R$ ist. Evtl. muss weiter korrigiert werden (siehe Anm. unten!).

2. *Bestimmung von $K_6/K_4 = K_5$ und K_6.* Wenn

$$[H^+] \ll K_3, \text{ ist } [F_1] \ll [F_2] + [F_3] + [R] \text{ und } [H^+]/K_3$$

in Formel (2) zu vernachlässigen. Man bekommt

$$E_\infty = E_R \cdot \frac{K_6}{1 + K_6 + K_4/[H^+]}$$

welches umgeformt wird zu

$$\frac{[H^+]}{E_\infty} = \frac{1}{E_R \cdot K_5} + \frac{1 + 1/K_6}{E_R} \cdot [H^+] \qquad (4)$$

Man bestimmt wie in 1. (siehe oben) die zusammengehörigen Werte von $[H^+]$ und E_∞. $[H^+]/E_\infty$ als Funktion von $[H^+]$ aufgetragen, gibt nach (4) eine Gerade; aus deren Schnittpunkt a_3 mit der Ordinate und dem Richtungskoeffizienten b_3 erhält man (mit bekanntem E_R)

$$K_5 = 1/a_3 \cdot E_R \; ; \; K_6 = 1/(b_3 \cdot E_R - 1)$$

Nachdem K_6 nach 1. und 2. bestimmt worden ist, werden K_3 und K_4 aus den Relationen $K_3 K_6 = 1/b_2 \cdot E_R$ bzw. $K_6/K_4 = K_5 = 1/a_3 \cdot E_R$ berechnet.

Anm. Nachdem K_3, K_4 und K_6 bestimmt worden sind, wird untersucht, ob die ausgeführten Näherungen (Vernachlässigung von $[F_3]$ in 1. und $[F_1]$ in 2.) erlaubt waren. Im allgemeinen ist dies bei den kleinsten (bzw. grössten) Werten von $[H^+]$ in den Mess-serien nicht ganz der Fall. Man wiederholt deshalb die Berechnungen, nachdem die Werte von E'_∞ bzw. E_∞ durch die korrigierten Werte E''_∞ bzw. E'''_∞ ersetzt worden sind. Diese sind mit Hilfe von den in der ersten Stufe berechneten Werten von K_3, K_4 und K_6 in entsprechender Weise wie oben (1. Anm.) erhalten. Man bekommt:

$$E''_\infty - E'_\infty \approx (E_\infty \cdot K_4/K_6 \cdot [H^+]) \cdot (E_\infty/E_R) \text{ und } E'''_\infty - E_\infty \approx (E_\infty \cdot [H^+]/K_3 \cdot K_6) \cdot (E_\infty/E_R).$$

Die Korrektionen unter 1. und 2. betragen in den vorliegenden Fällen nur einige Prozent in E_∞.

3. *Bestimmung des Maximums für* E_∞. Die Formel (2) definiert E_∞ als Funktion von $[H^+]$. Die Ableitung dieser Funktion nach $[H^+]$ hat die Nullstelle $[H^+] = \sqrt{K_3 \cdot K_4}$. Die Nullstelle entspricht dem Maximum bei E_∞. Man bekommt

$$\frac{(E_\infty)_{max}}{E_R} = \frac{K_6}{1 + K_6 + 2 \cdot \sqrt{K_4/K_3}} \tag{5}$$

Dadurch, dass man für die gleiche Gesamtkonzentration, Schichtdicke und Wellenlänge wie früher E_∞ als Funktion vom pH in der Nähe des Maximums aufträgt, kann $(E_\infty)_{max}$ graphisch ermittelt werden. Da E_R bekannt ist, kann das linke Glied in (5) getrennt berechnet werden, wobei der erhaltene Wert mit dem Wert übereinstimmen soll, welchen man vom rechten Glied in (5) nach Einsetzen der berechneten Werte von K_3, K_4 und K_6 erhält. Das rechte Glied in (5) ist jedoch in den vorliegenden Fällen verhältnismässig unempfindlich gegen Veränderungen in den Konstanten K_3 und K_4, weshalb oben erwähntes Verfahren als Kontrolle von begrenztem Wert ist.

B. Bestimmung von K_2. In einem Gebiet, in dem $[H^+]$ grösser ist als in A und in dem es als sicher gilt, dass $[H^+] \gg K_4$ ist, kann $[F_3]$ vernachlässigt werden, und man hat beim Gleichgewicht die Formen R, G_1, F_1 und F_2. Es gilt:

$$K_2 = \frac{[F_1]}{[G_1]} \; ; \; K_6 = \frac{[R]}{[F_2]} \; ; \; K_1 = \frac{[G_1]}{[H^+] \cdot [R]}$$

$$E_\infty = E_R \cdot \frac{[R]^*}{C} \; ; \; C = [R] + [G_1] + [F_1] + [F_2]$$

* Die Messungen finden bei einer Wellenlänge statt, wo nur R absorbiert.

Vereinfachung ergibt

$$K_2 = \frac{E_R - E_\infty(1 + K_1 \cdot [H^+] + 1/K_6)}{E_\infty \cdot K_1 \cdot [H^+]} \quad (6)$$

Nach Messung der zusammengehörigen Werte von $[H^+]$ und E_∞ wird K_2 aus (6) mit dem entsprechenden Wert von E_R und den oben bestimmten Werten von K_1 und K_6 eingesetzt, berechnet.

Schliesslich wird kontrolliert, dass, den Definitionen gemäss, $K_1 \cdot K_2 \cdot K_3 \cdot K_6 = 1$ ist.

C. Die Form G_2 bildet sich in stark sauren Lösungen, wobei man beim Gleichgewicht, das sich momentan einstellt, die Formen F_1, G_1 und G_2 hat. Da indessen G_2 erst dann nachzuweisen ist, wenn $[H^+] > 5$ bzw. 2 M ist, sind auf diesem Gebiet nur qualitative Versuche im Reagenzglas ausgeführt worden. K_7 ist also nicht bestimmt worden.

III. Berechnungen der Geschwindigkeitskonstanten

Beim Mischen von einer Stammlösung des Farbstoffes in Aceton mit einer Pufferlösung hellt sich die resultierende Lösung wegen der zwei Zeitreaktionen $G_1 + H_2O \rightarrow F_1$ und $R + H_2O \rightarrow F_2$ auf. Durch Messen der Lichtextinktion E als Funktion der Zeit t kann die Konstante k für die Reaktions-(Aufhellungs-) geschwindigkeit aus der Formel wie folgt [3,4] bestimmt werden.

$$k = \frac{1}{t} \cdot \ln \frac{E_0 - E_\infty}{E - E_\infty} \quad (7)$$

Ferner gilt:

$$k = \frac{k_2 \cdot [H^+]^2 + k_4 \cdot K_3 \cdot [H^+]}{[H^+]^2 + K_3 \cdot [H^+] + K_3 \cdot K_4} + \frac{k_1 \cdot K_1 \cdot [H^+] + k_3}{1 + K_1 \cdot [H^+]} \quad (8)$$

Bei der Ableitung von (7) und (8) geht man von der Differentialgleichung für die Aufhellung, nämlich

$$-\frac{d}{dt}([R] + [G_1]) = k_1 \cdot [G_1] - k_2 \cdot [F_1] + k_3 \cdot [R] - k_4 \cdot [F_2],$$

ferner von den im System geltenden Gleichgewichtsgleichungen und dem generellen Ausdruck $E = E_R \cdot [R]/C + E_{G_1} \cdot [G_1]/C$ aus, indem E_{G_1} auf entsprechende Weise wie E_R (I. oben) definiert wird.

k ist über einem pH-Gebiet von insgesamt 8—9 Einheiten experimentell bestimmt worden *. In dem Gebiet, wo $[R] \geq [G_1]$ ist, wird E im Absorptionsmaximum von R, bei geringerem pH im Absorptionsmaximum von G_1 gemessen.

A. Bestimmung von k_1 und k_2. In Lösungen, die so sauer sind, dass die Reaktion $G_1 + H_2O \rightleftharpoons F_1$ dominierend wird und folglich keine Rücksicht auf die Reaktion $R + H_2O \rightleftharpoons F_2$ genommen werden muss, geht Formel (8) in

$$k = k_1 \cdot \frac{K_1 \cdot [H^+]}{1 + K_1 \cdot [H^+]} + k_2 \quad (9)$$

über.

* Log $(E - E_\infty)$ wird als Funktion von t aufgetragen.

Da $k_2 = k_1 \cdot 1/K_2$ ist, kann man aus (9) k_1 berechnen, durch Einsetzen dieser Relation und durch Einsetzen von zusammengehörigen Werten von k und $[H^+]$, die experimentell bestimmt werden. Man findet dann dass k_1 linear mit $[H^+]$ gemäss der Formel

$$k_1 = k_1^0 + k_1' \cdot [H^+] \tag{10}$$

ansteigt.

Die Reaktion $G_1 + H_2O \rightleftharpoons F_1$ wird folglich durch die H^+-Ionen katalysiert. Ferner findet man, dass k_1^0 sicher von Null verschieden ist. k_2 erhält man aus der Relation $k_2 = k_1 \cdot 1/K_2$.

B. Bestimmung von k_3 und k_4. Bei höherem pH-Wert, wo die Reaktion $G_1 + H_2O \rightleftharpoons F_1$ nicht länger in erwähnenswertem Grad auf k einwirkt, geht Formel (8) in

$$k = k_4 \cdot \frac{K_3 \cdot [H^+]}{[H^+]^2 + K_3[H^+] + K_3 \cdot K_4} + k_3 \tag{11}$$

über.

Wenn weiter $[H^+] \ll K_3$ ist ($[F_1]$ kann vernachlässigt werden), bekommt man

$$k = k_4 \cdot \frac{[H^+]}{[H^+] + K_4} + k_3 \tag{12}$$

Aus Formel (12) kann k_3 durch Einsetzen von zusammengehörigen (experimentell bestimmten) Werten von k und $[H^+]$ und der Relation $k_4 = K_6 \cdot k_3$ berechnet werden. Unter Umständen wird diese Berechnung dadurch erleichtert, dass der erste Ausdruck des rechten Gliedes von (12) zu vernachlässigen und folglich $k = k_3$ ist.

Man findet, dass k_3, das wächst, wenn $[H^+]$ abnimmt, mit der folgenden Formel wiedergegeben werden kann:

$$k_3 = k_3^0 + k_3' \cdot [OH^-] \tag{13}*$$

Die Reaktion $R + H_2O \rightleftharpoons F_2$ wird also von OH^--Ionen katalysiert. Die Katalyse entspricht wahrscheinlich der Reaktion $R + OH^- \rightleftharpoons F_3$. Es soll doch bemerkt werden, dass k_3^0 nicht gleich Null ist. Man erhält k_4 aus der Relation $k_4 = K_6 \cdot k_3$.

C. k-Maximum. Wenn man auf dem Gebiet, wo Formel (11) gilt, annehmen kann, dass die OH^--Ionenkatalyse zu vernachlässigen ist (d.h., dass $k_3 = k_3^0$ und $k_4 = k_4^0$ ist), kann man zeigen [3], dass k das Maximum für $[H^+] = \sqrt{K_3 \cdot K_4}$ hat. Das Vorhandensein eines Maximums in k bei $[H^+] \approx \sqrt{K_3 K_4}$ ist in diesem Falle experimentell verifiziert worden.

D. Kontrolle. Nachdem sämtliche im Reaktionsschema eingehenden Protolysen-, Hydrations- und Geschwindigkeitskonstanten bestimmt worden sind, kann man mit Hilfe von Formel (8) die Aufhellungsgeschwindigkeit bei einem beliebigen $[H^+]$-Wert errechnen. Der errechnete Wert muss dann mit dem experimentell gefundenen übereinstimmen.

---

* $[OH^-]$ erhält man aus $[H^+] \cdot [OH^-] = K_w \cdot K_w$ wird separat bestimmt.

ALLGEMEINES ÜBER DEN EXPERIMENTELLEN TEIL

Es wurden Stammlösungen des Farbstoffes in wasserfreiem Aceton mit einer Farbstoffkonzentration von $(1/3-1) \times 10^{-4}$ M bereitet. Bei der Bereitung der Messlösungen wurden 1,050 ml Farbstoffstammlösung mit 49,0 ml Pufferlösung gemischt, oder — wenn die halbe Farbstoffkonzentration erwünscht war — 98,0 ml Pufferlösung und 1,050 ml Aceton. Die Mischung wurde in einem Kolben aus Pyrex- oder Jenaer Glas vorgenommen. Das Lösungsmittel in den Messlösungen hatte durchgehend die Zusammensetzung 98 % Wasser + 2 % Aceton. Die Gesamtionenstärke der Pufferlösungen wurde durch Zusatz von Natriumchlorid so gewählt, dass sie in den Messlösungen stets 0,50 M betrug. Der Beitrag von Natriumchlorid zur Gesamtionenstärke war fast immer mindestens 80 %. Man kann deshalb die Aktivitätskoeffizienten als konstant betrachten. Die bestimmten Gleichgewichtskonstanten sind also die sog. Konzentrationskonstanten bei der Ionenstärke 0,50 M.

Um reproduzierbare und definierte Mengen der Farbstoffstammlösung zu erhalten, wurde bei Bereitung der Messlösungen die Stammlösung stets mit einer 1 ml-Injektionsspritze aus Pyrex-Glas hinzugefügt. Beim Leeren der Spritze wurde ihre Kapillare etwa in die Mitte der Pufferlösung gebracht. Das Leeren dauerte 5—10 Sek. Auf diese Weise erhielt man schon von Anfang an eine gute Durchmischung, ohne den Kolben stark schütteln zu müssen. Die Spritze war mit besonderen, aussen angebrachten Vorrichtungen aus Metall versehen, die eine Volumengenauigkeit von 0,1 % gaben, was durch Auswägen mit Wasser kontrolliert wurde.

Für die Messungen der Lichtextinktion wurde ein Beckman-Quarz-Spektrophotometer, Modell DU, benutzt. Als Küvetten dienten verschiedene Paare Quarz- und Glasküvetten mit Schliffstopfen. Von jedem Paar diente eine, mit dest. Wasser gefüllt, stets als Nullreferenz. Im Gebiet $pH > 2,7$ wurde die Wasserstoffionkonzentration potentiometrisch bestimmt. Als Vergleichslösung wurde eine Lösung von der Zusammensetzung 0,480 M NaCl + 0,020 M HCl und als Trennlösung gesättigte KCl-Lösung verwendet. Die Elektroden waren blanke Platinbleche und Chinhydron für $pH \leqq 8$ und Platinwasserstoffgaselektroden für $pH > 8$. Meistens wurde die Wasserstoffionenkonzentration in den Endmesslösungen gemessen. Im Gebiet $pH < 2,7$ wurde die Wasserstoffionenkonzentration durch Zusatz von bestimmten Mengen HCl definiert. $K_w = [H^+] \cdot [OH^-]$ wurde für sich bei der Ionenstärke 0,50 M durch Messung von $[H^+]$ in einer Lösung der Zusammensetzung 0,480 M NaCl + 0,020 M NaOH bestimmt. $K_w = 1,22 \times 10^{-14}$.

Bei Messungen über die kinetischen Verläufe wurde die Zeit, t, gleich Null in dem Moment gesetzt, wo die Injektionsspritze zur Hälfte geleert war. Sobald die Messlösung gemischt war, wurde dann eine Küvette gefüllt und in die Beckmann-Apparatur gesetzt. Darauf wurde die Aufhellung durch Messung der Extinktion E (bei einer angemessen gewählten Wellenlänge) als Funktion von t verfolgt.

Die ausserordentlich kleine Konzentration des Farbstoffes ($3,5 \times 10^{-7}$ M) in gewissen Messreihen ist dadurch notwendigerweise bedingt, dass die Form G_1 sehr schwer löslich ist. Schon bei der doppelten Konzentration ($7,0 \times 10^{-7}$ M) erhielt man in sauren Lösungen ($pH < 3,0$) bei Messungen über die Geschwindigkeit der Reaktion $G_1 + H_2O \rightleftharpoons F_1$ Abweichungen vom linearen Verlauf der t-Funktion $\log(E-E_\infty)$. Die Abweichungen, die kleineren Geschwindigkeiten entsprachen, waren regelmässig nur im Anfang des kinetischen Verlaufes vorhanden. Nach ein paar Minuten nahm die Funktion einen geradlinigen Verlauf an. Die Neigung der Linie war jedoch um ein Geringes zu klein. Diese Beobachtungen lassen sich völlig dadurch erklären, dass der Farbstoff, wenn er aus der Injektionsspritze in die Lösung gelangt, wegen lokaler Überschüsse teilweise kristallisiert, um dann wieder bei vollständiger Mischung allmählich aufgelöst zu werden.

Obwohl die ersten Ablesungen der Totalextinktion wegen der kleinen Farbstoffkonzentration nur von einer ungefähren Grösse von 0,050 waren, war eine Reproduzierbarkeit der Geschwindigkeitskonstanten innerhalb einer Fehlergrenze von etwa 5 % möglich. Die Totalextinktionen in diesem Gebiet liegen keinen anderen Berechnungen zugrunde.

Die Gültigkeit des Beer'schen Gesetzes ist durch separate Messungen bei konstanter Extinktion und veränderlicher Konzentration und optischer Länge bestätigt.

Sämtliche untersuchten Reaktionen sind im vorliegenden pH-Gebiet völlig reversibel. Bei längerer Aufbewahrung in Lösungen mit $pH > 10$ scheinen doch irreversible Reaktio-

nen einzutreten. Die Messungen wurden bei 20°C ausgeführt. Besondere Anordnungen zur Gewinnung einer guten Temperaturkonstanz sind von Cigén [3] beschrieben worden. Vor Einstellung des Gleichgewichtes wurden die Lösungen im Thermostaten bei 20°C aufbewahrt. Die Wartezeit beim Messen von E_∞ war in der Regel 9—10 Halbwertzeiten.

Den Versuchsserien, die den Berechnungen der verschiedenen Konstanten zugrunde lagen, waren systematische, halbquantitative Versuche im Reagenzglas vorangegangen, wodurch die geeignetsten Bedingungen für die endgültigen Versuchsserien ermittelt wurden.

Die Geschwindigkeitskonstanten sind durchgehend mit Brigg'schen Logarithmen berechnet worden und enthalten also die Grösse $^{10}\log e$.

Die verwendeten Chemikalien waren pro-analysi-Produkte von Baker oder Merck.

Messfehler. Durch Untersuchung der Reproduzierbarkeit an verschiedenen Stellen in den Messungen und durch Schätzung der Messfehler, zufälliger sowohl als auch eventuell systematischer, ist versucht worden, ein Urteil über die Genauigkeit der Resultate zu gewinnen. Die bestimmten Konstanten sind demzufolge so angegeben worden, dass die Unsicherheit normalerweise 2—5 Einheiten in der letzten Ziffer beträgt. Bei evtl. grösserer Unsicherheit wurde die Ziffer in Klammern gesetzt.

MESSUNGEN UND ERGEBNISSE

I. 3, 3', 5, 5'-Tetrabrom-benzaurin

Präparat: Tetrabrom-benzaurin wurde durch Bromierung von Benzaurin* hergestellt [12], und durch mehrmaliges Umkristallisieren aus Nitrobenzol bis zu extinktiometrischer Konstanz gereinigt. (Gefunden: Br 54,35; 54,11. Ber. für $C_{19}H_{10}O_2Br_4$: Br 54,20).

Als *Puffersubstanzen* wurden Dinatriumhydrogenphosphat-Natriumhydroxyd, Borsäure-Natriumhydroxyd, Natriumdihydrogenphosphat-Dinatriumhydrogenphosphat, Essigsäure-Natriumacetat, Citronensäure-Natriumhydroxyd in folgenden ungefähren pH-Gebieten verwendet: 9,9—10,9; 8,1—9,9; 6,2—7,9; 3,6—6,2; 2,7—3,3. Für $pH < 2{,}7$ wurde $[H^+]$ durch Zusatz einer bestimmten Menge Salzsäure definiert.

Lichtabsorptionskurven. Fig. 1 stellt die Absorptionskurven vom blauen Ion R und vom gelben Molekül G_1 (den molekularen Lichtextinktionskoeffizienten ε als Funktion der Wellenlänge λ in mμ) dar. Die Kurve für R wurde durch Messung der Gleichgewichtsextinktion (E_∞) bei 10 cm Schichtdicke (d) in einer Lösung, in der der pH-Wert 6,32 betrug und die Gesamtkonzentration C des Farbstoffes $2{,}10 \times 10^{-6}$ M war, aufgenommen. ε wurde aus $E_R = \varepsilon \times 10 \times 2{,}1 \times 10^{-6}$ berechnet und E_R aus E_∞ aus Formel (2). Weiter fand man $(\varepsilon_R)_{max} = 7{,}7 \times 10^4$ für $\lambda \approx 580$ mμ.

Die Kurve für G_1 wurde in Lösungen (Acetatpuffer) mit pH = 3,085 aufgenommen, $C = 1{,}07 \times 10^{-6}$ M und $d = 10$ cm. Da G_1 bei Gleichgewicht nur in sehr kleiner Konzentration vorhanden ist (K_2 ist gross), wurden sämtliche (sieben) Punkte auf der Kurve durch Messung der Aufhellungsgeschwindigkeit und durch Extrapolation auf die Zeit Null erhalten. Aus dem so erhaltenen E_0 wurde ε_0 aus $E_0 = \varepsilon_0 \times 10 \times 1{,}07 \times 10^{-6}$ berechnet und ε_{G_1} aus

$$\varepsilon_0 = \frac{[H^+]}{[H^+] + 1/K_1} \cdot \varepsilon_{G_1} + \frac{1/K_1}{[H^+] + 1/K_1} \cdot \varepsilon_R$$

Es ging hervor, dass $(\varepsilon_{G_1})_{max} = 2{,}7 \times 10^4$ für $\lambda \approx 450$ mμ war.

* Benzaurin wurde nach Döbner [10] hergestellt.

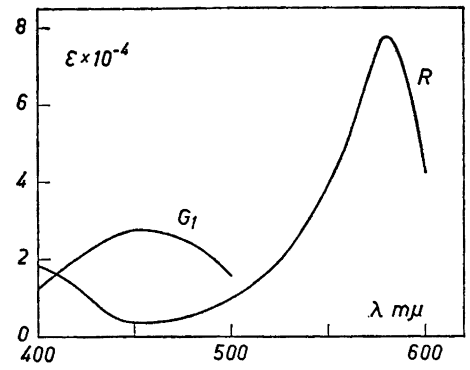


Fig. 1. Tetrabrom-benzaurin. Lichtabsorptionskurven. R ist das blaue Ion $[(OBr_2C_6H_2)_2C(C_6H_5)]^-$; G_1 ist das gelbe Molekül $(HOBr_2C_6H_2)C(C_6H_5)(C_6H_2Br_2O)$.

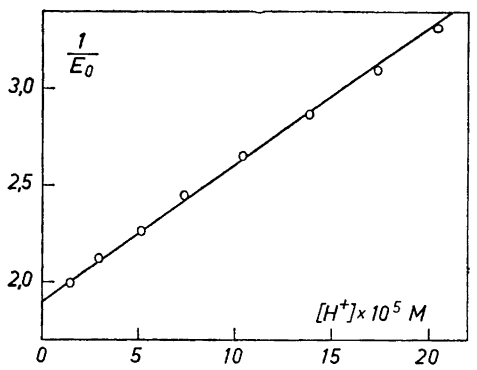

Fig. 2. Tetrabrom-benzaurin. $1/E_0$ als Funktion von $[H^+]$ für die Bestimmung von K_1 (und E_R). λ = 580 mμ, d = 10 cm und C = 7,0 × 10^{-7} M

Bestimmung von K_1 aus Formel (1). Aus einer Serie von Acetatpuffern (3,6<pH<4,8) wurden durch Mischung von 98 ml Puffer mit 1 ml Aceton und 1 ml einer Stammlösung des Farbstoffes in Aceton Messlösungen bereitet. Die Aufhellung wurde bei der Wellenlänge 580 mμ extinktiometrisch verfolgt und E_0 durch Extrapolation berechnet. Die Messungen fanden bei 10 cm Schichtdicke (d) statt. Die Gesamtkonzentration C des Farbstoffes war 7,0 × 10^{-7} M. Fig. 2 gibt $1/E_0$ als Funktion von $[H^+]$ wieder.

Resultat: E_R = 0,526 ; K_1 = 3,7(3) × 10^3.

In einer Serie, wo C 50,0 % grösser war (1,05 × 10^{-6} M), erhielt man: E_R = 0,792 ; K_1 = 3,9(7) × 10^3.

Mittelwerte: K_1 = 3,8(5) × 10^3, $1/K_1$ = 2,6(0) × 10^{-4}.

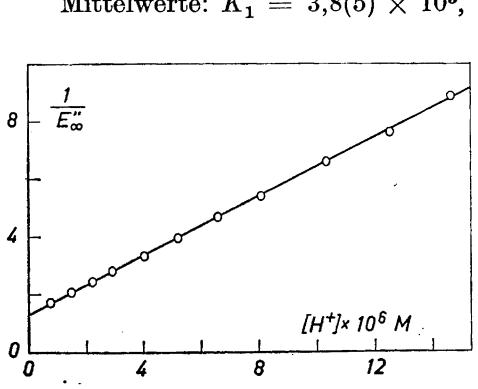

Fig. 3. Tetrabrom-benzaurin. $1/E''_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_3K_6 und K_6. λ = 580 mμ, d = 10 cm und C = 2,12 × 10^{-6} M

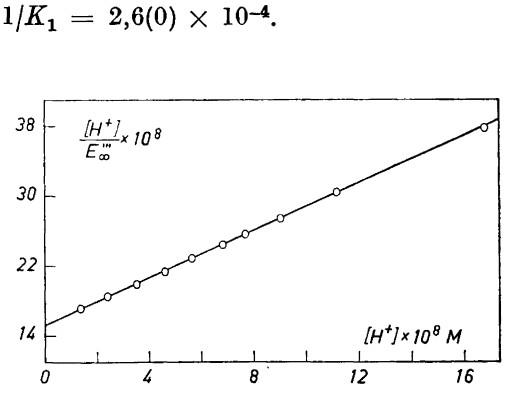

Fig. 4. Tetrabrom-benzaurin. $[H^+]/E'''_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_5 und K_6. λ = 580 mμ, d = 10 cm und C = 2,12 × 10^{-6} M

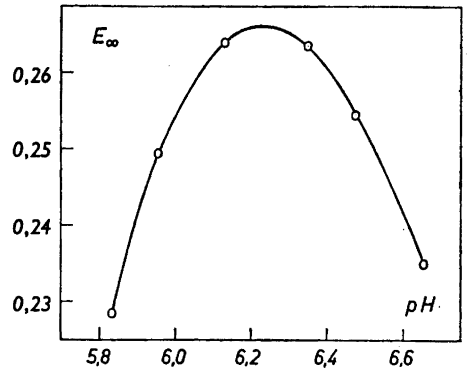

Fig. 5. Tetrabrom-benzaurin. E_∞ als Funktion von pH für die graphische Bestimmung von $(E_\infty)_{max}$. λ = 580 mμ, d = 10 cm und C = 1,06 × 10^{-6} M $(E_\infty)_{max}$ = 0,266.

Bestimmung von K_3K_6 *und* K_6 aus Formel (3). Im Gebiet 4,8<pH<6,1 wurden Messlösungen durch Zusatz von 2 ml Acetonstammlösung * des Farbstoffes zu 98 ml eines geeigneten Acetatpuffers bereitet; in den Messlösungen war $C = 2{,}12 \times 10^{-6}$ M. Nachdem Gleichgewicht eingetreten war, wurde die Extinktion (E_∞) bei 10 cm Schichtdicke und der Wellenlänge 580 mμ gemessen. Fig. 3 beschreibt $1/E''_\infty$ als Funktion von $[H^+]$. Das entsprechende E_R wurde bei 5,6<pH<6,2 durch Messung der Aufhellungsgeschwindigkeit und durch Extrapolation auf die Zeit Null bestimmt. Nach Korrektion für G_1 erhielt man aus sechs Versuchen bei d = 10 cm und mit $C = 1{,}06 \times 10^{-6}$ M (50,0 % des Obenerwähnten) im Durchschnitt $1/2 \cdot E_R = 0{,}810$ ($\pm$ 0,002).

Resultat: $K_6 = 0{,}88$; $K_3K_6 = 1{,}21 \times 10^{-6}$.

Bei Reproduzierung wurde

$$K_6 = 0{,}89 \; ; \; K_3K_6 = 1{,}22 \times 10^{-6}$$

erhalten.

Bestimmung von $K_5 = K_6/K_4$ *und* K_6 aus Formel (4) im Gebiet 6,8<pH<7,9. Die Versuche wurden mit derselben Stammlösung bei derselben Wellenlänge und mit gleichem C, d (und E_R) wie bei der bereits erwähnten Bestimmung von K_3K_6 und K_6 ausgeführt. Als Puffer dienten NaH_2PO_4—Na_2HPO_4-Lösungen. Fig. 4 gibt $[H^+]/E'''_\infty$ als Funktion von $[H^+]$ wieder.

Resultat: $K_5 = 4{,}06 \times 10^6$; $K_6 = 0{,}84(5)$.

Die Reproduzierung der Serie führte zu denselben Ergebnissen.

Aus den obenstehenden Resultaten wurden
$K_6 = 0{,}86(5)$; $K_3 = 1{,}40 \times 10^{-6}$; $K_4 = 2{,}1(3) \times 10^{-7}$ erhalten.

Bestimmung von $(E_\infty)_{max}$. Im Intervall 5,8<pH<6,7, wo E_∞ Formel (2) folgt, hatte E_∞ sein Maximum. Fig. 5 gibt E_∞ bei 580 mμ als Funktion vom pH-Wert in diesem Gebiet wieder. E_∞ wurde in sechs verschiedenen Lösungen gemessen, die für pH<6,2 aus Acetatpuffern und für pH>6,2 aus Phosphatpuffern bereitet waren, bei d = 10 cm und $C = 1{,}06 \times 10^{-6}$ M. Unter diesen

* nicht identisch mit der Stammlösung bei der Bestimmung von K_1.

Tabelle 1. Tetrabrom-benzaurin. Messungen bei 580 mμ zur Bestimmung von K_2; $d = 10$ cm; $C = 2{,}12 \times 10^{-6}$ M

$[H^+] \times 10^5$ M	2,96	1,46(0)	1,25(5)	1,03(5)	0,80(8)
E_∞	0,062	0,115	0,130	0,151	0,184
K_2	211	211	211	213	212

Bedingungen wurde oben E_R zu 0,810 bestimmt. Aus der Kurve in Fig. 5 wurde $(E_\infty)_{max} = 0{,}266$ bei pH≈6,24 (≈ —log $\sqrt{K_3 K_4}$) erhalten. Die beiden Glieder der Formel (2) wurden zu

$$\frac{(E_\infty)_{max}}{E_R} = 0{,}328 \; ; \qquad \frac{K_6}{1 + K_6 + 2\sqrt{K_4/K_3}} = 0{,}327$$

berechnet.

Bestimmung von K_2. Im Gebiet 4,5<pH<5,1 konnte K_2 aus Formel (6) berechnet werden. Die Messlösungen wurden wie früher aus Acetatpuffern und Farbstoffstammlösung bereitet und die Extinktionen (E_∞) beim Gleichgewicht bei der Wellenlänge 580 mμ gemessen. Ferner war $d = 10$ cm, $C = 2{,}12 \times 10^{-6}$ M und $E_R = 1{,}620$. Für K_1 und K_6 wurden die oben erhaltenen Werte verwendet. Die Ergebnisse sind in Tabelle 1 aufgeführt. Als Mittelwert wurde $K_2 = 212$ erhalten.

Die oben erhaltenen Konstanten ergeben das Produkt $K_1 \cdot K_2 \cdot K_3 \cdot K_6 = 0{,}99$.

Die Form G_2: Zu etwa 20 ml von teils einer Serie HCl-Lösungen, teils einer Serie $HClO_4$-Lösungen, mit der Säurestärke variierend zwischen 6 und 12 M, wurde 1/2 ml Farbstoffstammlösung zugesetzt. Die Lösungen der beiden Serien nahmen eine beständige rotgelbe Farbe der Form G_2 an. Die Farbe war stärker bei grösserer Säurestärke und, was den Farbton anbetrifft, deutlich unterschiedlich von der Farbe bei G_1.

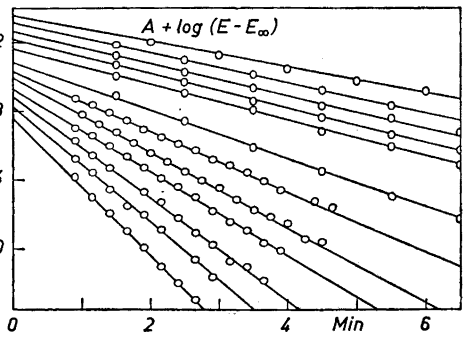

Fig. 6. Tetrabrom-benzaurin. Reaktionskinetik bei $\lambda = 450$ mμ, $d = 10$ cm und $C = 3{,}50 \times 10^{-7}$ M. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

A	3,55	3,48	3,43	3,35	3,30	3,20
	3,10	3,05	3,00	2,95	2,85	2,80
pH	3,235	3,100	3,030	2,960	2,884	2,610
	2,485	2,388	2,274	2,184	2,087	2,008

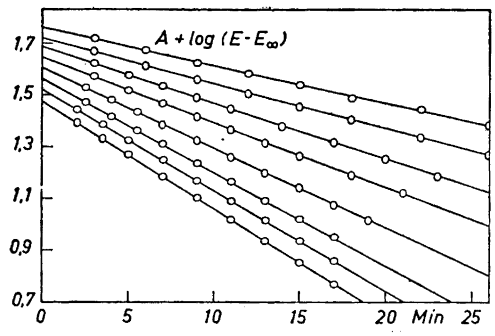

Fig. 7. Tetrabrom-benzaurin. Reaktionskinetik bei $\lambda = 580$ mμ, $d = 10$ cm und $C = 7{,}0 \times 10^{-7}$ M. Von oben nach unten gelten:

pH	4,909	5,099	5,181	5,393	5,531	5,653
	5,834	5,955	6,131	6,325	6,476	6,627

Messungen der Reaktions-(Aufhellungs-)Geschwindigkeiten. Die Geschwindigkeitskonstante k wurde über das ganze in Frage kommende pH-Gebiet (2,0—10,9) für mehr als fünfzig verschiedene Lösungen bestimmt, welche aus 98 ml Puffer + 1 ml Aceton + 1 ml Acetonstammlösung des Farbstoffes bereitet waren. Die Messungen der Extinktionen (E) wurden durchgehend bei einer Schichtdicke von 10 cm gemacht. Die Wellenlänge war 580 mμ (R's

	2,07	2,05	2,03	2,00		
pH	9,31	9,58(5)	9,83	9,88	10,03	10,21
	10,39	10,58	10,77(5)	10,89		

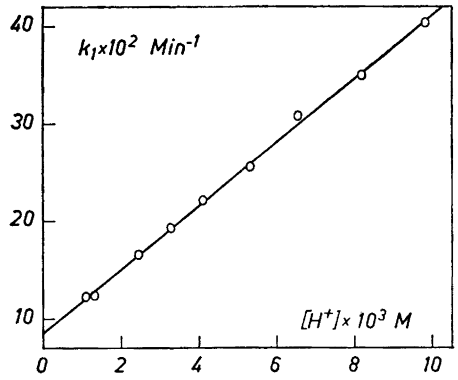

Fig. 11. Tetrabrom-benzaurin. Die Geschwindigkeitskonstante k_1 als Funktion von $[H^+]$.

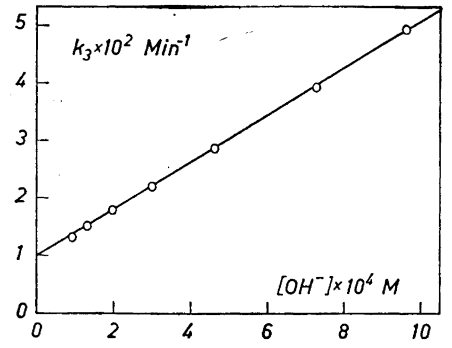

Fig. 12. Tetrabrom-benzaurin. Die Geschwindigkeitskonstante k_3 als Funktion von $[OH^-]$.

Absorptionsmaximum) für pH>3,6, 450 mμ (G_1's Absorptionsmaximum) für pH<3,6. C war $3{,}50 \times 10^{-7}$ M für pH<3,6, $7{,}0 \times 10^{-7}$ M für 3,6<pH<4,9 und $1{,}06 \times 10^{-6}$ M für pH>4,9. Die Resultate sind graphisch in den Figuren 6—10 aufgeführt; Fig. 13 zeigt k's Abhängigkeit vom pH-Wert.

Bestimmung von k_1 und k_2. Im Gebiet 2,0<pH<3,0 ist k_1 mit Hilfe der Formel (9) durch Einsetzen der Relation $k_2 = k_1 \cdot 1/K_2$ und zusammengehörigen Werten von $[H^+]$ und k berechnet worden. Fig. 11 zeigt, dass k_1 als Funktion von $[H^+]$ eine gerade Linie ist. Graphische Bestimmung gab als Resultat: $k_1^0 = 8{,}6 \times 10^{-2}$; $k_1' = 32{,}(5)$. Man erhält also $k_1 = 8{,}6 \times 10^{-2} + 32 \cdot [H^+]$; $k_2 = 4{,}1 \times 10^{-4} + 0{,}15 \cdot [H^+]$ (Min^{-1}); $[H^+]$ in Mol/l.

Bestimmung von k_3 und k_4. Im Gebiet pH>9,8 geht Formel (12) in $k = k_3$ über. Es geht aus Fig. 10 hervor, dass k_3 mit dem pH-Wert wächst. Fig. 12 zeigt, dass k_3 als Funktion von $[OH^-]$ eine Gerade ist. Durch graphische Bestimmung wurde das Resultat $k_3^0 = 1{,}00 \times 10^{-2}$, $k_3' = 40{,}8$ erhalten. Man bekommt also: $k_3 = 1{,}00 \times 10^{-2} + 41 \cdot [OH^-]$, $k_4 = 0{,}86 \times 10^{-2} + 35 \cdot [OH^-]$ (Min^{-1}); $[OH^-]$ in Mol/l.

k als Funktion von pH. In Fig. 13 sind die experimentell bestimmten Werte von k im ganzen untersuchten pH-Gebiet eingetragen. Aus Formel (8) ist ferner k bei verschiedenen pH-Werten, durch Einsetzen der experimentell bestimmten Werte der in die Formel eingehenden Konstanten, berechnet worden. Die Berechnungen sind nur bei den pH-Werten ausgeführt worden, wo das Verfahren wirkliche Kontrolle bedeutet. Die extrem sauren bzw. alkalischen Gebiete, die bei den früheren experimentellen Bestimmungen von k_1 und k_2 bzw. k_3 und k_4 verwendet wurden, sind demnach nicht berücksichtigt worden. Der ausgezogenen Kurve liegen diese Berechnungen zu Grunde. Man findet gute Übereinstimmung, bei pH<5 jedoch einige Diskrepanz zwischen berechneten und experimentell bestimmten Werten. Die nach (8) berechneten Werte von k sind bei pH<5 von K_1 stark abhängig, daher ist es möglich, dass die Diskrepanz nur auf einen geringeren Fehler in K_1 zurückzuführen ist.

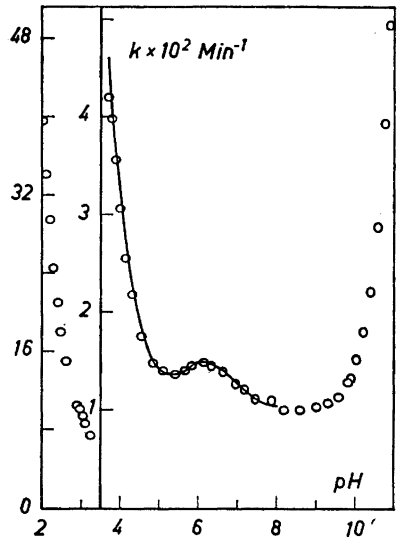

Fig. 13. Tetrabrom-benzaurin. Die Geschwindigkeitskonstante k als Funktion von pH. Die experimentellen Werte sind O. Die ausgezogene Kurve ist aus Formel (8) berechnet.

Aus der Kurve und den experimentellen Werten geht hervor, dass k sein Maximum bei pH$\approx$6,2 ($\approx -\log \sqrt{K_3 K_4}$) hat; im grossen und ganzen mit der Lage für $(E_\infty)_{max}$ übereinstimmend.

II. 3, 3'-Dibrom-5, 5'-dimethyl-benzaurin

Präparat: Dibrom-dimethyl-benzaurin wurde durch Bromierung von Dimethyl-benzaurin [15,*] hergestellt und aus wasserhaltigem Eisessig zu extinktiometrischer Konstanz umkristallisiert. Das Endprodukt bestand aus kompakten Kristallen mit blauem metallischem Glanz. (Gefunden: C 54,67; H 3,41; O 7,23; Br 35,61. Berechnet für $C_{21}H_{16}O_2Br_2$: C 54,80; H 3,50; O 6,95; Br 34,73.) Um die evtl. Empfindlichkeit der Acetonstammlösungen gegen Spuren von Wasser herabzusetzen, wurden sie mit Triäthylamin versetzt, wobei die molekulare Konzentration von Triäthylamin der des Farbstoffes etwa entsprach. Die Hydratation ist nämlich bedeutend kleiner für das Gleichgewicht R + $H_2O \rightleftharpoons F_2$ als für das Gleichgewicht $G_1 + H_2O \rightleftharpoons F_1$.

Puffersubstanzen: Dinatriumhydrogenphosphat-Natriumhydroxyd, Borsäure-Natriumhydroxyd, Natriumdihydrogenphosphat-Dinatriumhydrogenphosphat, Essigsäure-Natriumacetat in den pH-Gebieten 9,9—11,1; 7,9—9,8; 5,5—7,9; 3,4—4,6.

Lichtabsorptionskurven: Die Lichtabsorptionskurven der Formen G_1 (gelb) und R (blau) finden sich in Fig. 14 wieder, die den molekularen Lichtextinktionskoeffizienten ε als Funktion der Wellenlänge λ in mμ darstellt. Die Aufnahme der R-Kurve wurde in einer Lösung mit pH = 8,44 und $C = 1{,}09 \times 10^{-6}$ M vorgenommen. Die G_1-Kurve, die durch Extrapolationsverfahren er-

* Dimethyl-benzaurin wurde nach Schroeter [16] hergestellt. S. auch Hansson und Nilsson [17].

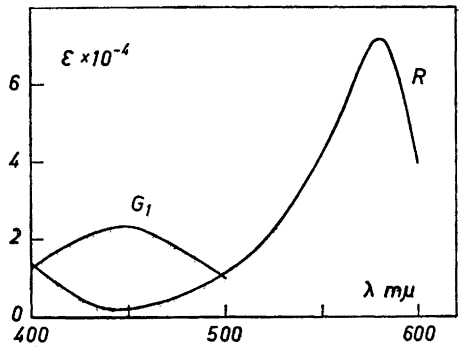

Fig. 14. Dibrom-dimethyl-benzaurin. Lichtabsoptionskurven. R ist das blaue Ion $[(OBrCH_3C_6H_3)_2C(C_6H_5)]^+$; G_1 ist das gelbe Molekül $(HOBrCH_3C_6H_3)C(C_6H_5)(C_6H_3CH_3BrO)$

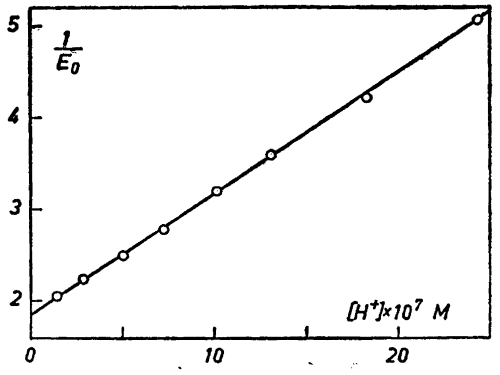

Fig. 15. Dibrom-dimethyl-benzaurin. $1/E_0$ als Funktion von $[H^+]$ für die Bestimmung von K_1 (und E_R). $\lambda = 580$ mμ, $d = 10$ cm und $C = 7{,}3 \times 10^{-7}$ M.

halten wurde, wurde bei pH = 3,87 und $C = 3{,}88 \times 10^{-7}$ M aufgenommen. Die Schichtdicke betrug in beiden Fällen 10 cm. Die Berechnungen wurden auf dieselbe Weise wie für Tetrabrom-benzaurin ausgeführt. Die Daten für die Maxima betrugen

für R: $(\varepsilon_R)_{max} = 7{,}2 \times 10^4$ bei $\lambda \approx 580$ mμ
für G_1: $(\varepsilon_{G_1})_{max} = 2{,}3(4) \times 10^4$ bei $\lambda \approx 450$ mμ.

Bestimmung von K_1 aus Formel (1) im Gebiet $5{,}6 < pH < 6{,}9$. Die Messlösungen wurden aus Phosphatpuffern (49 ml) und einer Stammlösung (1 ml) des Farbstoffes in Aceton bereitet. Die Extinktionsmessungen wurden wie bei Tetrabrom-benzaurin bei 580 mμ und 10 cm Schichtdicke ausgeführt. Fig. 15 gibt $1/E_0$ als Funktion von $[H^+]$ in einer Serie wieder, in der C $7{,}3 \times 10^{-7}$ M betrug.

Resultat: $E_R = 0{,}541$; $K_1 = 7{,}14 \times 10^5$.
In einer Serie, wo C 50,0 % grösser war ($1{,}09 \times 10^{-6}$ M), erhielt man: $E_R = 0{,}800$; $K_1 = 7{,}57 \times 10^5$.

Mittelwerte: $K_1 = 7{,}3(5) \times 10^5$; $1/K_1 = 1{,}36 \times 10^{-6}$.

Bestimmung von K_3K_6 *und* K_6 aus Formel (3) im Gebiet $6{,}8 < pH < 7{,}9$. Die Messlösungen wurden von 49 ml Phosphatpuffern + 1 ml Acetonstammlösung erhalten. Die Messungen wurden wie bei Tetrabrom-benzaurin ausgeführt; $\lambda = 580$ mμ; $C = 1{,}09 \times 10^{-6}$ M, $d = 10$ cm. Das entsprechende E_R wurde aus fünf Versuchen bei gleichem C und d im Gebiet $7{,}3 < pH < 7{,}9$ im Mittel zu 0,786 (± 0,002) erhalten. Fig. 16 zeigt $1/E''_\infty$ als Funktion von $[H^+]$. Resultat: $K_6 = 5{,}(7)$; $K_3K_6 = 5{,}4(2) \times 10^{-8}$.

Bei Reproduzierung erhielt man: $K_6 = 5{,}(6)$; $K_3K_6 = 5{,}3(6) \times 10^{-8}$.

Bestimmung von $K_5 = K_6/K_4$ *und* K_6 aus Formel (4) im Gebiet $8{,}7 < pH < 9{,}8$. Die Messlösungen wurden aus 49 ml Boratpuffer + 1 ml Acetonstamm-

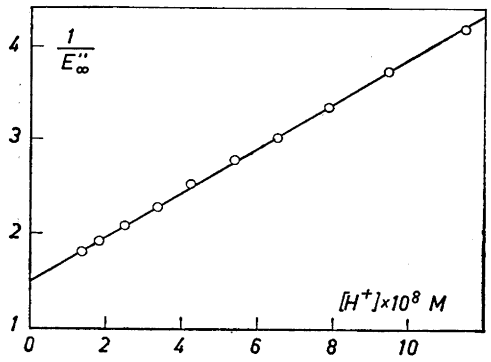

Fig. 16. Dibrom-dimethyl-benzaurin. $1/E''_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_3K_6 und K_6. $\lambda = 580$ mμ, $d = 10$ cm und $C = 1{,}09 \times 10^{-6}$ M.

lösung bereitet. E_∞ wurde bei $\lambda = 580$ mμ, $d = 10$ cm und $C = 1{,}09 \times 10^{-6}$ M gemessen. Da die Stammlösung nicht diegleiche war wie früher, wurde E_R aufs Neue bestimmt. Es wurde aus fünf Versuchen im Gebiet $8{,}5 < \text{pH} < 9{,}8$ mit obenstehendem C und d im Mittel $E_R = 0{,}781$ erhalten. Fig. 17 zeigt $[H^+]/E'''_\infty$ als Funktion von $[H^+]$.

Resultat: $K_5 = 2{,}7(8) \times 10^9$; $K_6 = 5{,}(1)$.

Aus obenstehenden Resultaten * wurde $K_6 = 5{,}(4)$; $K_3 = 1{,}0(0) \times 10^{-8}$; $K_4 = 1{,}9(4) \times 10^{-9}$ erhalten.

Bestimmung von $(E_\infty)_{max}$. Fig. 18 zeigt E_∞ als Funktion vom pH-Wert im Gebiet $7{,}8 < \text{pH} < 8{,}9$, in dem Formel (2) als geltend angesehen werden kann. E_∞ wurde in Boratpuffern bei $\lambda = 580$ mμ, $C = 1{,}09 \times 10^{-6}$ M und $d = 10$ cm gemessen. Aus der Kurve in Fig. 18 wurde $(E_\infty)_{max} = 0{,}574$ bei $\text{pH} \approx 8{,}36$ $(= -\log\sqrt{K_3K_4})$ erhalten. Mit $E_R = 0{,}781$ wurden die zwei Glieder der Formel (2) zu

$$\frac{(E_\infty)_{max}}{E_R} = 0{,}734 \; ; \quad \frac{K_6}{1 + K_6 + 2\sqrt{K_4/K_3}} = 0{,}742$$

berechnet.

Bestimmung von K_2 aus Formel (6) bei $5{,}7 < \text{pH} < 6{,}6$. Die Messlösungen wurden aus 49 ml Phosphatpuffer + 1 ml Acetonstammlösung bereitet. E_∞ wurde bei $\lambda = 580$ mμ gemessen. Ferner war $d = 10$ cm, $C = 1{,}09 \times 10^{-6}$ M und $E_R = 0{,}786$. Für K_1 und K_6 wurden die oben bestimmten Werte verwendet. Die Resultate sind in Tabelle 2 aufgeführt. Als Mittelwert wurde $K_2 = 26{,}(2)$ erhalten.

Aus den obenstehenden Konstanten wurde das Produkt $K_1 \cdot K_2 \cdot K_3 \cdot K_6 = 1{,}04$ *erhalten.*

* Bei beiden Bestimmungen wird K_6 aus dem Ausdruck $1 + 1/K_6$ erhalten und ist daher mit relativ grosser Unsicherheit behaftet.

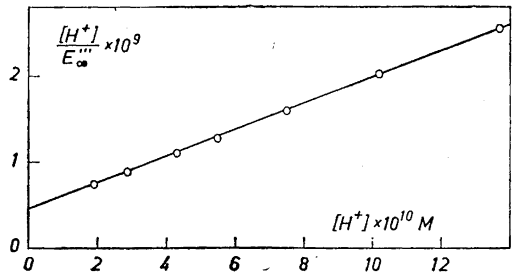

Fig. 17. Dibrom-dimethyl-benzaurin. $[H^+]/E'''_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_5 und K_6. $\lambda = 580$ mμ, $d = 10$ cm und $C = 1{,}09 \times 10^{-6}$ M.

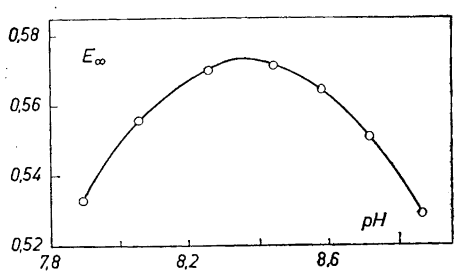

Fig. 18. Dibrom-dimethyl-benzaurin. E_∞ als Funktion von pH für die graphische Bestimmung von $(E_\infty)_{max}$. $\lambda = 580$ mμ, $d = 10$ cm und $C = 1{,}09 \times 10^{-6}$ M. $(E_\infty)_{max} = 0{,}574$.

Die Form G_2 wurde beim Zusatz von Farbstoffstammlösung zu HCl-Lösungen mit der Säurestärke ≥ 2 M qualitativ nachgewiesen. Dabei konnten dieselben Beobachtungen wie bei Tetrabrom-benzaurin gemacht werden.

Messungen der Aufhellungsgeschwindigkeit. Die Geschwindigkeitskonstante k wurde im Gebiet $3{,}4 < \text{pH} < 11{,}1$ bestimmt. Die Messlösungen wurden aus 49 ml Puffer + 1 ml Acetonstammlösung des Farbstoffes bereitet. Die Extinktionsmessungen wurden bei 10 cm Schichtdicke ausgeführt. Die Wellenlänge war 580 mμ für pH > 5, 450 mμ für pH < 5; C betrug $3{,}8(8) \times 10^{-7}$ M für pH < 5,0; $7{,}3 \times 10^{-7}$ M für $5{,}0 < \text{pH} < 7{,}0$ und $1{,}09 \times 10^{-6}$ M für pH > 7,0. Die reaktionskinetischen Verläufe wichen von denen des Tetrabrom-benzaurins nicht prinzipiell ab. Sie werden daher nur für diejenigen sauren bzw. alkalischen Lösungen dargestellt (Fig. 19—20), in denen die Messungen der Berechnung von k_1 und k_2 bzw. k_3 und k_4 zu Grunde lagen. Fig. 23 zeigt k's Ahbängigkeit vom pH-Wert.

Bestimmung von k_1 *und* k_2. Im Gebiet $3{,}4 < \text{pH} < 4{,}6$ ist k_1 aus Formel (9) durch Einsetzen der Relation $k_2 = k_1 \cdot 1/K_2$ und zusammengehörigen Werten

Tabelle 2. Dibrom-dimethyl-benzaurin. Messungen bei 580 mμ zur Bestimmung von K_2; $d = 10$ cm, $C = 1{,}09 \times 10^{-6}$ M

$[H^+] \times 10^7$ M	13,2(5)	10,2(0)	7,2(5)	5,00	2,86(5)	1,42(5)
E_∞	0,030(5)	0,034(5)	0,051(5)	0,068(5)	0,112(5)	0,194(5)
K_2	24,3	27,8	25,4	27,0	26,5	26,3

Tabelle 3. Zusammenfassung der

	$1/K_1$	K_3	K_4	K_5	K_6
Tetrabrom-benzaurin	$2{,}6(0)\times10^{-4}$	$1{,}40\times10^{-6}$	$2{,}1(3)\times10^{-7}$	212	0,86
Dibrom-dimethyl-benzaurin	$1{,}36\times10^{-6}$	$1{,}0\times10^{-8}$	$1{,}9\times10^{-9}$	26	5,(4)

von k und $[H^+]$ berechnet worden. Fig. 21 zeigt, dass k_1 annähernd linear mit $[H^+]$ wächst. Die graphische Bestimmung ergab das Resultat *:

$$k_1^0 = 0{,}3(1) \times 10^{-2} \; ; \; k_1' = 3{,}4 \times 10^2$$

Man erhält also

$k_1 = 3{,}(1)\times10^{-3} + 340 \cdot [H^+]$; $k_2 = 0{,}12\times10^{-3} + 13 \cdot [H^+]$ (Min^{-1}) ; $[H^+]$ in Mol/l.

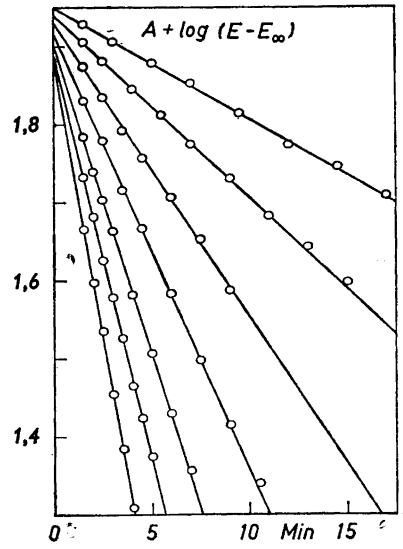

Fig. 19. Dibrom-dimethyl-benzaurin. Reaktionskinetik bei λ = 450 mμ, d = 10 cm und $C = 3{,}88 \times 10^{-7}$ M. Von oben nach unten gelten:

A 3,04 3,015 3,00 2,96 2,95 2,94, 2,91
pH 4,525, 4,292 4,045 3,866 3,690 3,535 3,408

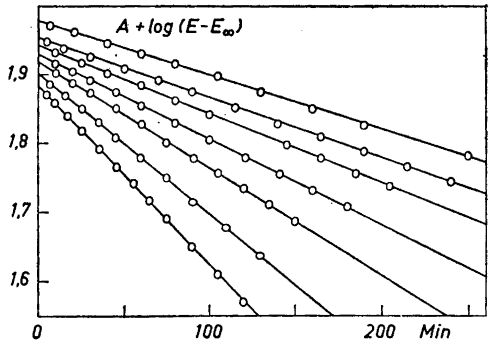

Fig. 20. Dibrom-dimethyl-benzaurin. Reaktionskinetik bei λ = 580 mμ, d = 10 cm und $C = 1{,}09 \times 10^{-6}$ M. Von oben nach unten gelten:

A 2,19 2,13 2,10 2,07 2,05 2,02 2,00
pH 9,99 10,20 10,38 10,57 10,72 10,90 11,04

* Bei der Bestimmung von k_1^0 wurden nur die vier ersten Messpunkte mit einbezogen, wobei das Bild vergrössert wurde. Da k_1^0 klein ist, wird die Bestimmung relativ unsicher.

Ergebnisse. [H+] und [OH⁻] in Mol/l.

k_1 Min^{-1}	k_2 Min^{-1}	k_3 Min^{-1}	k_4 Min^{-1}
$8{,}6\times10^{-2}+32\times[H^+]$	$4{,}1\times10^{-4}+0{,}15\times[H^+]$	$1{,}00\times10^{-2}+41\times[OH^-]$	$0{,}86\times10^{-2}+35\times[OH^-]$
$3{,}(1)\times10^{-3}+340\times[H^+]$	$0{,}12\times10^{-3}+13\times[H^+]$	$0{,}37\times10^{-3}+1{,}58\times[OH^-]$	$2{,}0\times10^{-3}+8{,}5\times[OH^-]$

Bestimmung von k_3 und k_4. Durch Einsetzen der Relation $k_4 = k_3 \cdot K_6$ und zusammengehöriger Werte von k und $[H^+]$ ist k_3 aus Formel (12) im Gebiet $9{,}9<pH<11{,}1$ berechnet worden. Fig. 22 gibt k_3 als Funktion von $[OH^-]$ wieder. Durch graphische Bestimmung wurde $k_3^0 = 0{,}44 \times 10^{-3}$; $k_3' = 1{,}58$ erhalten. Man bekommt also

$$k_3 = 0{,}44\times10^{-3} + 1{,}5(8)\times[OH^-]\,;\; k_4 = 2{,}4\times10^{-3} + 8{,}5\cdot[OH^-]\ (\text{Min}^{-1})\,;$$
$$[OH^-] \text{ in Mol/l.}$$

k als Funktion von pH. In Fig. 23 wird k als Funktion von pH wiedergegeben, wobei die experimentell bestimmten Werte im ganzen untersuchten Gebiet eingetragen sind. Wenn man in derselben Weise wie bei Tetrabrombenzaurin k aus Formel (8) berechnet, erhält man eine Kurve, die sich bei $pH>6{,}5$ von den experimentell bestimmten Werten von k erheblich unterscheidet. Wenn aber bei der Berechnung die Konstanten k_3^0 und k_4^0 korrigiert werden, schliesst sich die berechnete Kurve den experimentell bestimmten Werten an. Die ausgezogene Kurve in Fig. 23 ist mit $k_3 = 0{,}37 \times 10^{-3} + 1{,}58 \cdot [OH^-]$ und $k_4 = 2{,}0 \times 10^{-3} + 8{,}5 \cdot [OH^-]$ (Min^{-1}) berechnet; für die übrigen Konstanten sind die früher berechneten Werte verwendet worden. Bis auf einige Ausnahmen schliessen sich die experimentellen Punkte dieser Kurve gut an. Der graphisch bestimmte Wert von k_3^0 ist also fast 20 % zu

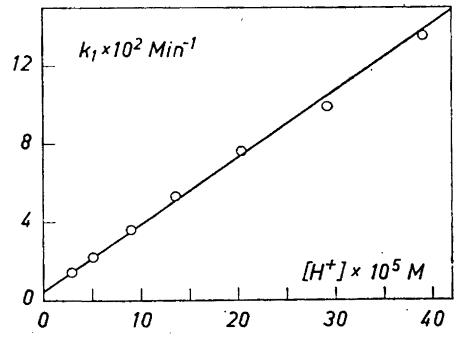

Fig. 21. Dibrom-dimethyl-benzaurin. Die Geschwindigkeitskonstante k_1 als Funktion von [H+].

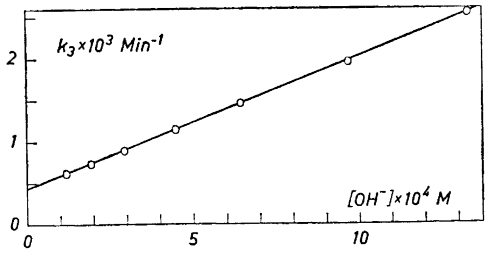

Fig. 22. Dibrom-dimethyl-benzaurin. Die Geschwindigkeitskonstante k_3 als Funktion von [OH⁻].

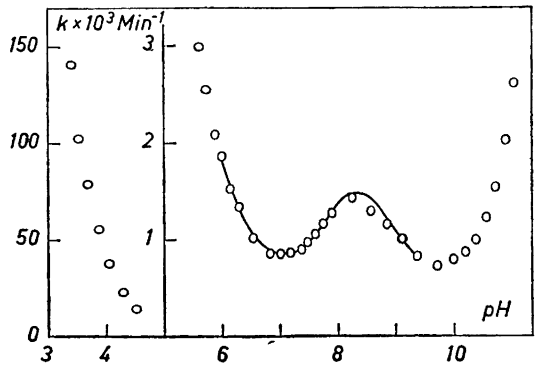

Fig. 23. Dibrom-dimethyl-benzaurin. Die Geschwindigkeitskonstante k als Funktion von pH. Die experimentellen Werte sind O. Die ausgezogene Kurve ist aus Formel (8) berechnet.

gross geworden! ($0{,}44 \times 10^{-3}$ statt $0{,}37 \times 10^{-3}$), als dass die berechnete k-Kurve mit den gefundenen Werten von k übereinstimmt. Warum das so ist, kann nicht mit Bestimmtheit ausgesagt werden. Eine Möglichkeit ist, dass k_3 nicht, wie angenommen wurde, eine linear ansteigende Funktion von $[OH^-]$ auch für *kleine Werte* von $[OH^-]$ ist, sondern dann stärker wächst. k_{max} findet sich bei pH≈8,35 wieder.

DISKUSSION

Tabelle 3 enthält eine Zusammenfassung der erhaltenen Konstanten. Aus dem Vergleich zwischen den Ergebnissen für Tetrabrom-benzaurin und Dibrom-dimethyl-benzaurin ist folgendes zu entnehmen: Eine Substitution von 2 Brom gegen 2 Methyl verringert im vorliegenden Falle die Protolysenkonstanten $1/K_1$, K_3 und K_4 um mehr als 2 Zehnerpotenzen. Gleichzeitig werden beide Hydratationsgleichgewichte stark gegen geringere Hydratation verschoben; K_2 nimmt ab, bzw. K_6 wächst mit dem Faktor 8,1 bzw. 6,2. Gleich auffallend ist die Wirkung auf die Hydratations-(Aufhellungs-)Geschwindigkeit, die sich um eine gute Zehnerpotenz verringert; k_1^0 und k_3^0 nehmen beide mit dem Faktor 27 ab. Dagegen wirkt die Substitution nur unbedeutend auf die Lichtabsorption sowohl bei R als auch bei G_1 ein.

Herrn Professor Sven Bodforss möchte ich meinen besonderen Dank dafür sagen, dass er mir die Anregung zu dieser Untersuchung gegeben und ein stetes Interesse für ihren Fortgang gezeigt hat. Ebenso danke ich Herrn Professor Sture Fronæus und Herrn Dozent Rune Cigén für wertvolle Ratschläge.

Fräulein Lena Hansson war als Assistentin bei Messungen und Berechnungen behilflich.

Die Synthese von Dibrom-dimethyl-benzaurin wurde von Herrn Olle Nilsson, die Mikroelementaranalysen wurden von Herrn Dr. Alfred Bernhardt, Max-Planck-Institut für Kohlenforschung, Mühlheim/Ruhr, ausgeführt.

Die Untersuchung wurde mit finanzieller Hilfe von *Statens Naturvetenskapliga Forskningsråd* und *Kungliga Fysiografiska Sällskapet i Lund* ausgeführt.

Die Übersetzung ins Deutsche ist von fil. mag. Ingrid Wartenberg ausgeführt.

ACTA CHEMICA SCANDINAVICA 13 (1959) 1332–1346

The Reaction between Streptokinase and Human Plasma

MOGENS LASSEN

Biological Institute of the Carlsberg Foundation, and University Institute of Physical Chemistry, Copenhagen, Denmark

1. The amount of activator formed from a given amount of streptokinase mixed with an excess of proactivator depends on the preparation of proactivator used. A probable explanation is that streptokinase is consumed by two competing reactions, the relative rates of which depend on the preparation of proactivator. The first reaction leads to the formation of the activator; the other is mentioned below (2).

2. Streptokinase is destroyed by small amounts of plasma. The reaction is probably catalyzed by the plasmin formed.

3. The reaction between streptokinase and proactivator initially leads to the formation of activator which is relatively stable at extreme pH values. The rapid transformation of the stable into the well known labile modification is probably catalyzed by the contaminating plasmin, the reaction resambling that mentioned above. Both reactions can be considered side reactions in so far as they are not involved in the formation of the activator.

The mixing of human plasma with the extracellular streptococcal product termed streptokinase results in the formation of a proteolytic enzyme termed plasmin. The following schemes summarize our present knowledge of the mechanism of this reaction:

$$\text{streptokinase} + \text{proactivator} \rightleftharpoons \text{activator}$$

$$\text{plasminogen} \xrightarrow{\text{activator}} \text{plasmin}$$

References and detailed informations are given by Lassen [1]. Yet, it must be emphasized that there is some uncertainty on the nature of the proactivator and the plasminogen, since it is not known wether we are concerned with two different compounds, or with a single precursor which can participate in both reactions. From the results of this paper it is apparent that large systematical errors may interfere with the estimations of proactivator and of streptokinase. Therefore, the author does not feel absolutely sure that the results of the stability experiments previously reported (Lassen [2]) substantiate the two component-theory; but to facilitate the discussion he wants to keep the double terminology.

The present paper deals with the reaction possibilities of the streptokinase after mixing with human plasma, including the first of the above reaction schemes, but excluding the last. The problem mentioned above is of minor importance for the conclusions drawn as the main assumptions are:

1. Activator and plasmin are chemically different. This assumption is based upon the fact that the activator can be destroyed without destroying the plasmin (Müllertz [3]).

2. When streptokinase and human plasma are mixed at neutral pH, activator as well as plasmin are always formed.

3. The activator is formed through a stoicheiometric reaction between streptokinase and a plasma factor (termed proactivator). The most striking evidence for this mode of reaction was given by Troll and Sherry [4], and in essentials their experiments were reproduced by Lassen (Ref.[5], and present paper).

MATERIALS AND METHODS

Veronal-gelatin buffer. 0.05 M sodium diethyl barbiturate buffer pH 7.75 to which was added NaCl to give a final ionic strength of 0.15. Furthermore gelatin to a concentration of 0.2 % was added in order to prevent adsorption of the fibrinolytic factors on glass surfaces (Lassen [8]).

Streptokinase (SK). "Varidase" was kindly placed at my disposal by the Lederle Laboratories Division, American Cyanamid Company. The units are those stated on the packages as determined according to Christensen [6].

Proactivator (PA). Human plasma or serum or acetone powders of these prepared as described by Lassen [1].

L-*Lysine ethyl ester (LEe).* The dihydrochloride of this compound was prepared according to the method of Werbin and Palm [7].

Witte peptone (WP). A commercial product (made by pepsin hydrolysis of bovine fibrin). Before use the powder was dissolved in veronal buffer, heated at 100° for 15 min, and cleared by centrifuging.

Measuring methods. The activator was determined by the lysis time method as described by Lassen [8]. The reported methods for measuring the precursors were modified by adding an equal volume of a 10 % solution of WP to the incubation mixtures of SK and PA. The advantage of this addition will be obvious from the experimental results presented in section 1.

RESULTS

1. Amount of activator formed in mixtures of its precursors.

The rate of formation. These experiments are preliminary investigations made in order to find an appropriate time of incubation usable in "equilibrium" studies. The rate of formation of the activator (A) was found to depend largely on the preparation of proactivator (PA) used. When different plasma samples were mixed with streptokinase (SK) in concentrated solutions the time necessary for obtaining maximum activity varied from 0 to 7 min at room temperature. With serum, the time was prolonged to 10 to 25 min. The rate of deterioration of A was found to depend mainly on the proportion of SK and PA, most commenly being at a maximum with equivalent amounts. Fig. 1 shows the results obtained by estimating A at different times in concentrated and diluted mixtures of SK with plasma or serum. The curves begin

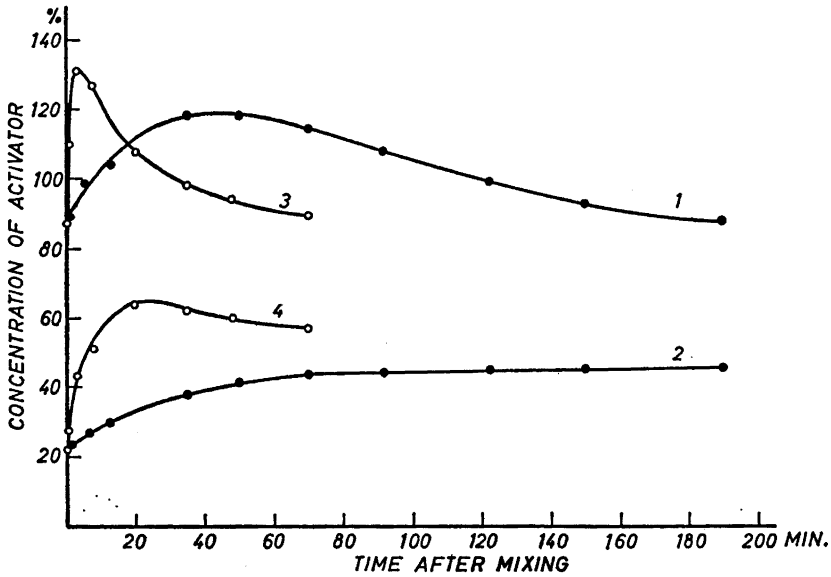

Fig. 1. Formation and deterioration of activator at room temperature. *Diluted incubation mixtures:* 20 ml veronal-gelatin buffer + 500 units of SK + 100 µl plasma (Curve 1) or serum (Curve 2). A was estimated without further dilution. *Concentrated incubation mixtures*: 500 µl plasma (Curve 3) or serum (Curve 4) + 500 µl buffer containing 2 500 units of SK. 50 µl aliquots were diluted with 5 ml buffer before the estimation of A.

above zero concentration, indicating that the formation of A continues during the lysis time determinations. Accordingly, the experimental results do not represent the true variation of the concentration of A in the incubation mixtures.

However, an impression of the "time of formation" is obtained, and since concentrated mixtures of SK and PA generally form maximum amount of A within 20 min at room temperature, this incubation time was used in the experiments described below.

Relationship between the concentration of activator formed and the concentrations of streptokinase and proactivator used. Müllertz [3] estimated the concentration of A formed in different mixtures of SK and human globulin and found it independent of the concentration of the precursor in excess and proportional to the concentration of the other precursor. The results obtained by investigating the relationship between the concentration of lysine esterase and of SK (Lassen [1]), and between the concentration of A and of SK (Lassen [5]) are in accordance with the results of Müllertz. However, later experiments have shown that the results depend largely on the precursor preparations used. Thus, the results presented below differ considerably from those obtained by Müllertz, and show the reaction to be much more complex than assumed earlier. In Fig. 2 A the concentration of SK was constant and the concentration of PA (plasma, curve 1 and 2; serum, curve 3 and 4) was varied, and in Fig. 2B PA

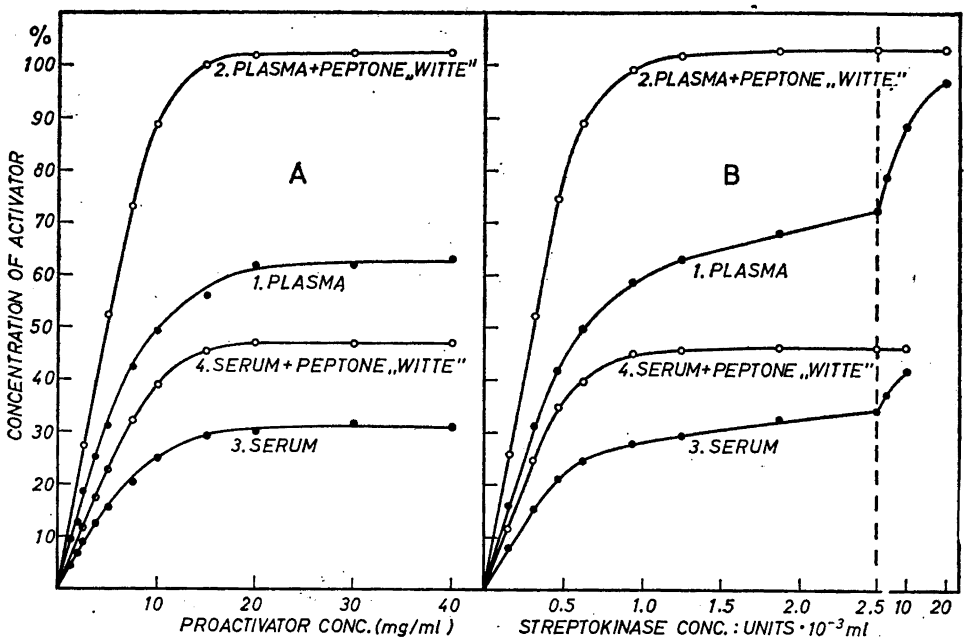

Fig. 2. Relationship between the concentration of activator and of PA (A) or SK (B) in solutions containing a constant concentration of the other precursor. All mixtures were incubated for 20 min at room temperature before estimating A. The mixtures contained: *A*: 625 units of SK per ml + the concentration of plasma acetone powder (Curves 1 and 2) or serum acetone powder (Curves 3 and 4) denoted on the abscissa. The mixtures used for the curves 2 and 4 contained additionally 25 mg of WP per ml. *B*: The concentration of SK denoted on the abscissa + 10 mg of plasma acetone powder (Curves 1 and 2) or 10 mg of serum acetone powder (Curves 3 and 4). The mixtures used for the curves 2 and 4 contained additionally 25 mg of WP per ml.

(plasma, curves 1 and 2; serum, curves 3 and 4) was constant and SK varied. For the curves designated 2 and 4, 2.5 % Witte peptone (WP) was present in all incubation mixtures. These curves resemble the curves obtained by Müllertz, but those without WP differ. The main differences in the shape of the curves are the obviously smaller equilibrium constants and the much more asymmetric behaviour of PA and SK in the experiments without addition of WP. The principal difficulties in understanding these curves become obvious by comparing the "saturation values" in the curves in Fig. 2 A. These values are the maximum amounts of A obtained in mixtures containing an identical amount of SK and excess of PA. If the large differences found are real (that is; really different amounts of A are present in the solutions) it means that the assumption that we are concerned with a simple equilibrium system must be wrong, since this assumption would require identical "saturation values" with different preparations of PA. That the difference between curves 1 and 2 is real is revealed by the experiment represented by Fig. 3. The figure shows

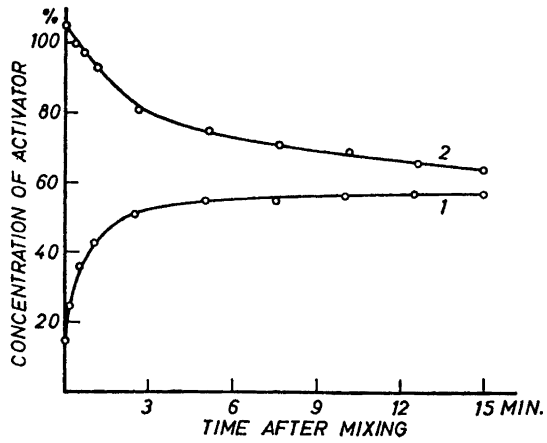

Fig. 3. At room temperature 75 mg of plasma acetone powder dissolved in 1 ml buffer were mixed with 1 000 units of SK dissolved in 1 ml buffer. At different intervals of time 100 µl aliquots were withdrawn and added to either 10 ml buffer for immediate estimation of A (Curve 1) or to 50 µl 10 % WP. After 20 min at room temperature the last samples were diluted with 10 ml buffer, and A was estimated (Curve 2).

that the effect of WP approaches zero, coincident with the completion of the reaction leading to the formation of A, and that WP is without effect on the activity of A already formed.

The stabilizing effect of WP. In addition to its activity-increasing effect WP was also found to have a stabilizing effect on A made from plasma but not on that made from serum. Table 1 shows that A in the case of serum with and without addition of WP, and in the case of plasma without addition of WP is very labile at 37° and nearly disappears within 24 h. By contrast A is nearly stable for 24 h at 37° in the case of plasma plus WP.

Calculation of the equivalent amounts of proactivator and streptokinase. This expression is defined on the basis of the following: From "saturation values" obtained with excess of one precursor in the presence of WP (curves 4 in Fig. 2) the maximum amounts of A which could be obtained from 1 ml of plasma (or from 1 mg of plasma acetone powder) and from 1 unit of SK were calculated. The proportion between these maximum amounts gives the equivalent amounts in units of SK per ml of plasma (or per mg of plasma acetone powder). Due to the uncertainty about the meaning of this value it has been used only for qualitative evaluations of the proportion between SK and PA in given mixtures. With six different plasma samples the equivalent amounts were found to be within the range of 3 500 to 6 000 units of SK per ml plasma.

Discussion. The results presented in this section indicate that the reactions which are initiated by the addition of SK to plasma or serum are much more complex than hitherto assumed. Especially, it must be emphasized that the results in Fig. 2 disagree with the simple introductory scheme. The assumption that A is formed through a stoicheiometric reversible reaction between PA and SK or modifications of these compounds is probably still valid, since

Table 1. The stabilizing effect of Witte peptone.

The following solutions were incubated at 37°.
1. 100 µl plasma + 100 µl SK solution containing 10 000 units per ml + 200 µl veronal-gelatin buffer.
2. 100 µl plasma + 100 µl SK solution as above + 200 µl 10 % WP.
3. 100 µl serum + 100 µl SK solution as above + 200 µl veronal-gelatin buffer.
4. 100 µl serum + 100 µl SK solution as above + 200 µl 10 % WP.

Incubation mixture	Incubation time	Relative amount of activator
1	2 min	45

3	»	0.5
4	»	0.5

this assumption is strongly supported by experiments presented by Troll and Sherry [4]. However, it is evident that this reaction and the subsequent conversion of plasminogen into plasmin are only two of more reactions which are initiated by the mixing of SK and plasma. As an example the different "saturation values" of curves 1 and 2 in Fig. 2, A can most easily be explained by assuming that, while perhaps all SK is used for the formation of A when mixed with excess of plasma + WP, a considerable part of the SK must be

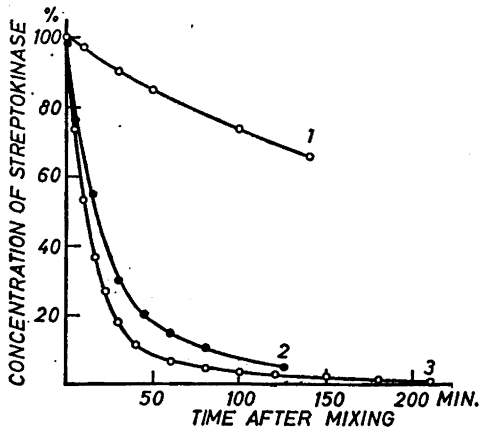

Fig. 4. Destruction of SK with small amounts of plasma. *Curve 1:* 1 ml of a solution containing 10 000 units of SK + 1 ml 20 % plasma were incubated at 25°. *Curve 2:* The same mixture as used for curve 1, but incubated at 37°. *Curve 3:* As for curve 2, but another plasma sample had been used.

consumed by another reaction when WP is omitted. More detailed investigations of this problem will be presented in the subsequent section.

2. Destruction of streptokinase.

This section deals with the possible side reaction mentioned in the above discussion. Below is shown that SK after mixing with plasma is consumed by two competing reactions; the first being the known reaction leading to the formation of A while the second leads to the destruction of SK. SK dissolved in veronal-gelatin buffer was found to be stable for hours at all temperatures below 50°. However, when small amounts of plasma or serum were added SK was found to be labile (Fig. 4). Comparing curves 1 and 2 of Fig. 4 it is apparent that for a rise of 10° the rate of reaction is increased tenfold.

In the next experiment (Fig. 5) solutions of SK were mixed with increasing small amounts of plasma acetone powder and incubated for 60 min at 37°, and the remaining concentrations of SK were then estimated. Although the reaction rates cannot be evaluated from these 60 min values it is evident however, that with small amounts of plasma acetone powder, the reaction rate is more than doubled when the concentration of plasma is doubled. With higher concentrations of plasma acetone powder this phenomenon is less significant, but a limited reaction rate was not obtained within the concentration range used.

Determination of SK destroying factor. The SK destroying factor present in plasma can be measured by determining the destroying effect in defined manner, provided that the relationship between concentration and effect is known. The following method was found convenient: The experimental sample was diluted to give a concentration of PA equivalent to less than 500 units of SK per ml. By reason of accuracy the concentration of destroying factor

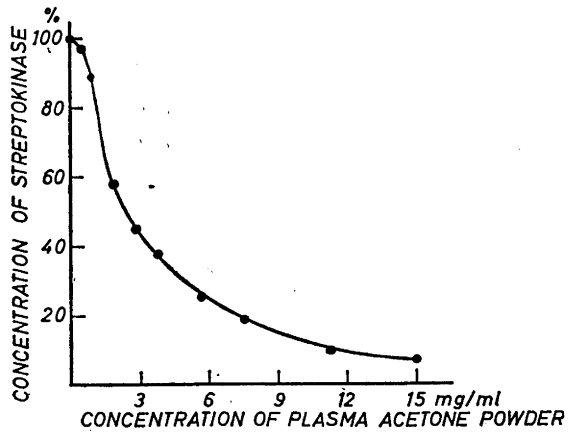

Fig. 5. Destruction of SK at 37° with small amounts of plasma. Mixtures containing 5 000 units of SK per ml and the concentrations of plasma acetone powder denoted on the abscissa were incubated for 60 min at 37°, and the residual concentrations of SK were then estimated.

must be within the range of 2 to 10 % of that found in plasma. 50 μl of the diluted sample was incubated for 60 min at 37° with 50 μl of a solution containing 5 000 units of SK per ml, which is a large excess of SK. The SK not destroyed was then converted into activator by adding 100 μl plasma, which now provides an excess of proactivator, and incubating for 20 min at room temperature. Finally, 10 ml veronal-gelatin buffer was added, and lysis time determined as described. Lysis times were converted into concentrations of destroying factor by interpolation on a standard curve obtained by testing serial dilutions of plasma as described for the experimental sample. Good results could be obtained within the range of 2 to 10 % of undiluted plasma (before mixing with SK).

Attempts to identify the streptokinase destroying component. 1 a. Plasmin (Müllertz [9]) and A (Müllertz [9], Lassen [5]) are adsorbed on fibrin. To find out whether the SK destroying factor is also adsorbed the following experiment was performed: 1 ml of plasma was mixed with 1 ml of a solution containing 5 000 units of SK (nearly equivalent amounts) plus 50 μl thrombin solution. After incubation for 20 min the fibrin clot was removed. Estimations revealed that plasmin, A, PA, and SK destroying component were completely absent from the serum (plasmin was estimated by the manometric method described by Lassen [1]).

1 b. In a control experiment in which no SK was added only slight differences between plasma and serum were found. The activities in serum expressed as percentages of the corresponding activities in plasma were: PA 55 %, plasminogen 90 %, and SK destroying component 70 %. Plasminogen was measured by adding an excess of SK and estimating the plasmin activities as above, ignoring the effect of plasmin inhibitors. These two experiments show that the SK destroying component resembles plasminogen and PA by being present in plasma as a precursor which is not adsorbed to fibrin, and which is transformed into another component by addition of SK; this component is strongly adsorbed to fibrin.

2. SK was found to be rapidly destroyed by preparations of human as well as bovine plasmin. The human plasmin was prepared according to Müllertz [3], but since the preparation contained considerable amounts of PA the observations obtained with this did not give further information as to the nature of the destroying component. The bovine plasmin was prepared according to Lassen [1] with the modification that a smaller amount of activator was employed (100 μl human plasma + 1 000 units of SK (excess) to 10 ml of 1.3 % of bovine fibrinogen). The plasmin activity of the final preparation was compared to that of SK activated human plasma. Assuming no inactivation of the original amount of A present in the preparation the proportion A/plasmin was about 1 /50 of that in SK activated human plasma. Solutions of bovine plasmin containing the same plasmin activity as did SK activated human plasma were found to destroy SK somewhat faster than did human plasma.

3. Inhibition studies: The destruction of SK by human plasma was found to be inhibited by L-lysine ethyl ester (Fig. 6) by WP (Fig. 7), by benzoyl-L-arginine ethyl ester and, to a smaller extent, by casein. The synthetic esters are known to inhibit plasmin and A (Troll and Sherry [4], Lassen [1]), and in the

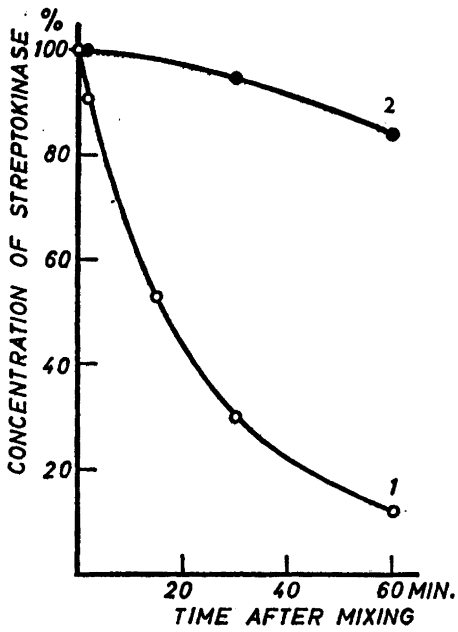

Fig. 6. The effect of LEe on the destruction of SK with small amounts of plasma at 37°. The following mixtures were employed. *Curve 1:* 1 000 units of SK dissolved in 100 µl buffer + 100 µl 10 % plasma + 100 µl 0.3 M NaCl. *Curve 2:* As for curve 1, except that 100 µl 0.1 M LEe were substituted for the NaCl solution.

lysis time method WP and casein were found to inhibit the fibrinolytic effect of bovine as well as human plasmin. Contrary to the inhibition of plasma neither WP nor casein seem to inhibit A as judged from preliminary experiments on the activation rate of bovine plasminogen in the presence or absence of these compounds. The formation of plasmin was followed by the semi-quantitative method described by Lassen [1].

Conclusion. SK is destroyed by small amounts of plasma. Studies on the adsorption on fibrin indicate that the destroying factor is identical with plasmin and/or activator. The isolated effects of human plasmin and activator on SK could not be studied as the necessary preparations were not available. However, the fact that the SK destroying activity of bovine plasmin is comparable to that of human plasma gives some evidence for the assumption that the destruction of SK caused by human plasma, is due to the proteolytic effect of the plasmin formed. This assumption was further supported by inhibition studies. Accordingly, the reaction may be described by:

$$\text{SK} \xrightarrow{\text{plasmin}} \text{destroyed SK}$$

As emphasized in the discussion of the preceding section the existence of a reaction like this is a necessary condition for explaining the fact that the maximum amount of A which can be formed from a given amount of SK depends on the source of PA (Fig. 2 A). The amount of A formed in a given mixture of PA and SK depends on the original concentrations of the precursors

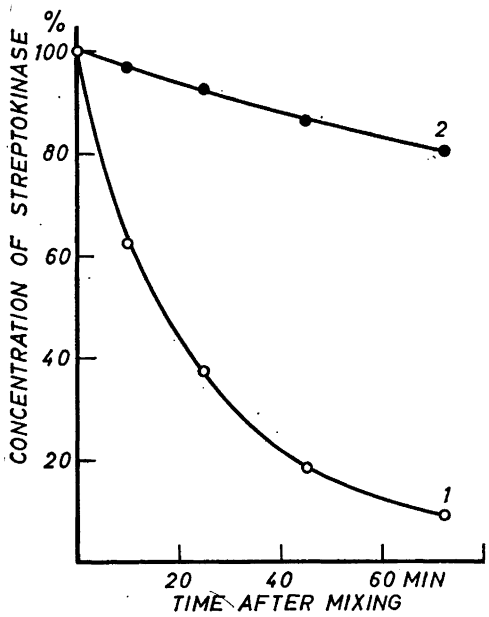

Fig. 7. The effect of WP on the destruction of SK with small amounts of plasma at 37°. The following mixtures were employed. *Curve 1:* 200 units of SK dissolved in 200 µl buffer + 200 µl 10 % plasma + 200 µl veronal buffer. *Curve 2:* As for curve 1, except that 20 mg of WP were dissolved in the buffer solution.

as well as on the relative rates of the two competing reactions; namely the stoicheiometric reaction leading to the formation of A and the above mentioned destruction of SK which is probably caused by the plasmin formed. The formation of A proceeds at a slower rate in serum than in plasma and supposing nearly identical rates of destruction the different "saturation values" of curve 1 and 2 in Fig. 2 A becomes understandable. The effect of WP on the "saturation values" can at least partly be explained by its inhibitory effect on the destruction of SK.

3. The transformation of stable into labile activator.

Troll and Sherry [4] found that a transformation of A into PA could be achieved by heating at 100° for 15 min at pH 2. Since SK is labile under these conditions they assumed the reaction to be caused by the isolated destruction of SK, leaving the more stable PA unchanged in the solution. Lassen [5] found the same transformation to proceed at milder conditions (37° and pH 3.5). The inactivation did not run to completion as a certain part of A was found to be stable under the experimental conditions used. It was later found that the same reaction can proceed at alkaline pH. Fig. 8, curve 1, shows the inactiva-

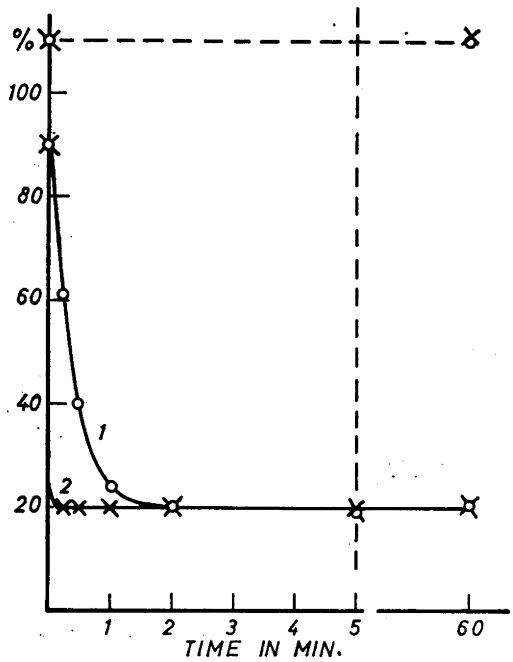

Fig. 8. Inactivation of activator in acid and alkaline solutions. Ordinate: Concentration of A (full lines) or PA plus A (dotted line) in per cent of the untreated solutions of A. The activator solution was prepared by adding 1 ml plasma to 1 ml of a solution containing 5 000 units of SK and incubating for 20 min at room temperature. The inactivation at acid reaction (Curve 1, (O)) was performed by adding 1 ml A solution to 1 ml 0.1 M HCl in water bath at 37°, yielding a pH of about 3. The inactivation at alkaline reaction (Curve 2, (×)) was performed by adding 1 ml A to 1 ml 0.1 M NaOH in an ice bath, yielding a pH of about 13. A was estimated in 100 μl aliquots diluted with 10 ml veronal gelatin buffer. For the estimations of PA + A 100 μl samples were diluted with10 ml-veronal-gelatin buffer containing 500 units of SK. These solutions were incubated for 60 min at room temperature before the lysis time determinations.

tion of A at 37° and pH about 3.0, while curve 2 shows the inactivation of the same preparation of A at 0° and at a pH between 12 and 13. The amount of stable A is seen to be independent of the mode of inactivation. This probably excludes the interpretation that the stable residue represents an equilibrium concentration in a reversible denaturation, and supports the assumption that labile and stable A are chemically different components. SK itself was found to be stable for at least 1 h under the conditions used for the inactivation of A. (At the acid pH this is true only when proactivator or denaturated activator is present in the solution, at the alkaline pH also uncontaminated SK was found to be stable). This makes the situation a little more complicated than assumed by Troll and Sherry [4]. The assumption that the denaturation of the activator at extreme pH values is caused by the isolated destruction of the SK part of the activator molecule may still be valid; but this SK part

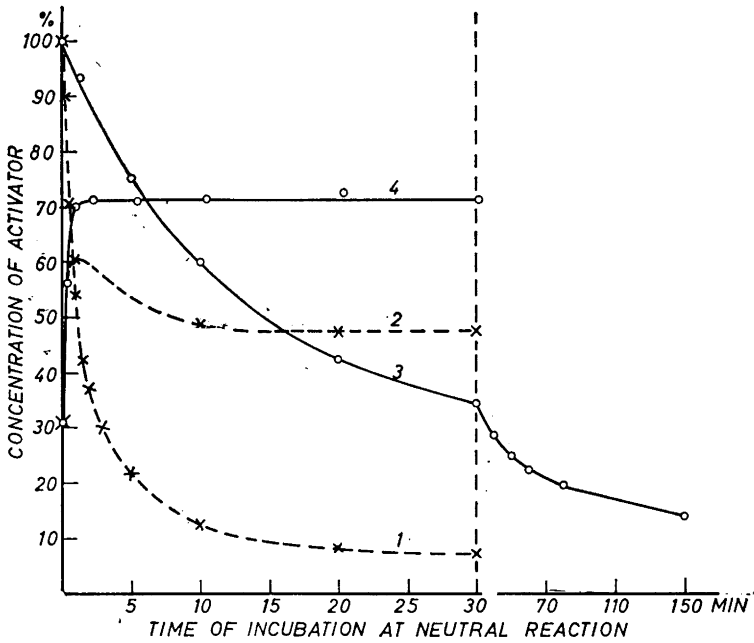

Fig. 9. The formation (and deterioration) of A (Curves 2 and 4), and the degree of inactivation at alkaline reaction (Curves 1 and 3) followed with time in mixtures of SK and PA without addition of WP (dotted lines), and with addition of WP (full lines). The experiments were performed at room temperature (22°). For the dotted curves a mixture of 1 ml plasma with 0.5 ml of a solution containing 4 000 units of SK was used. The mixture used for the full drawn curves contained in addition a final concentration of WP equal to 2.5 %. The activator was estimated in 100 μl aliquots diluted to 10 ml with veronal-gelatin buffer. The inactivations were performed by adding 100 μl samples to 50 μl 0.2 M NaOH at 0°. After standing for 10 min at 0° the residual amount of A plus SK was estimated by adding 50 μl 0.2 M HCl + 200 μl buffer containing 25 % plasma (v/v) and 10 % WP (w/v), incubating for about 20 min at room temperature, diluting with 10 ml veronal-gelatin buffer, and finally determining the lysis times as described. All results were converted into concentrations of A by interpolation on the same standard curve.

is not identical with the original SK-molecule, as some transformation into a more labile modification must have occurred during the previous incubation at neutral reactions. The nature of the stable residue cannot be evaluated on the basis of the above experiments. We may be concerned either with a stable activator molecule or with a residue of unreacted SK which during the assay reacts with PA to form A.

Since total A and labile A can be measured independently it might be possible to obtain further information of the whole problem by comparing the relative rates of the formation of these quantities, especially if it could be possible to find conditions under wich these formation rates differ significantly. Nearly equivalent amounts of plasma and SK were mixed at room temperature and at a neutral pH. At different intervals of time samples of this mixture

were treated at alkaline reaction, and the residual amounts of A plus SK were estimated by neutralizing, adding an excess of proactivator and measuring the total amount of activator formed (Fig. 9, curve 1). On the condition that SK and the activator formed is stable in the neutral mixture of plasma and SK the difference between the ordinate at zero time and that at the time t represents the amount of labile A present in the neutral solution at the time t. Since this condition is not fulfilled the curve obtained does not permit an exact calculation of the amounts of labile A formed, but a rough picture of the rate of formation can be obtained. Simultaneously with the performance of the estimations used for curve 1 the formation and deterioration of A in the original mixture were followed with time (Curve 2). Unfortunately, there is a high initial lability of A, and therefore the curve does give any information of the time of formation. Accordingly, no conclusions can be drawn from the results of the whole experiment.

More valuable information was obtained by adding Witte peptone (WP) to the neutral incubation mixture of SK and plasma. The rate of formation of labile A appears from curve 3 of Fig. 9 which correspond to curve 1 in the above experiment. Obviously the formation of labile A was strongly inhibited by WP, the rate of formation being reduced to about 1/10 of before. The formation of A in the mixture of plasma SK and WP is represented by curve 4. The activator formed is seen to be stable throughout the whole experiment and evidently the formation ceased 2 to 3 min after mixing. At this time nearly all activator was present as a stable modification (stable at alkaline pH), but during the next few hours this modification was transformed into the known labile modification. These results strongly suggest that PA and SK initially react to form an activator which is stable at extreme pH values. In mixtures of SK and plasma, this primarily formed activator is rapidly transformed into a labile modification having the same activating properties. (The transformation of the stable into the labile modification does not alter the activities as judged from curve 4). The rate of the formation of stable A is not significantly influenced by WP, while the secondary transformation is inhibited by this agent.

The effect of L-lysine-ethylester (LEe) was found to be comparable to that of WP. The experiment was performed as described in the legend to Fig. 9, except that 0.05 M LEe was substituted for WP. After incubation for 30 min only 5 % of the total amount of A plus SK were present as labile A. However, after 1 h the rate of reaction increased, and after 3 h only 10 % remained in the form of stable A. This increased rate was accomplished by a drift downwards in pH due to hydrolysis of the ester, and therefore quantitative details other than those given above are probably without significance.

Conclusion. The activator formed by the reaction between SK and PA is extremely labile at acid and alkaline reactions. The experimental results presented above strongly indicate that the reaction sequence leading to the formation of this labile A involves at least two consequtive steps, the first being the stoicheiometric reaction between the precursors, during which a more stable modification of A is formed, while the last step is a transformation of the stable into the well known labile modification. The temporary existance of the stable A was demonstrable in mixtures of plasma and SK to which

Witte peptone or L-lysine-ethylester was added. This was possible since these agents proved to reduce strongly the rate of the secondary transformation without significantly affecting the rate of the primary formation of the stable A.

DISCUSSION

The present work is an experimental investigation on the reaction possibilities of streptokinase (SK) after mixing with the fibrinolytic precursor(s) contained in human plasma. It is considered an experimental fact that SK reacts stoicheiometrically with a precursor in human plasma termed proactivator (PA) giving rise to the formation of an activator of plasminogen (A) (Müllertz and Lassen [10], Troll and Sherry [4] and Müllertz [3]). It seems probable that this reaction can be described by one of the following two schemes:

$$PA + SK \rightleftharpoons A \quad (1)$$

$$PA + SK \rightleftharpoons A + \text{inactive component} \quad (2)$$

This reaction is followed by the catalyzed transformation of plasminogen into plasmin:

$$\text{plasminogen} \xrightarrow{A} \text{plasmin}$$

In all probability the last reaction involves the splitting of a peptide bond (Troll and Sherry [4]).

The "equilibrium" studies presented in the first section of this paper indicate that these schemes do not represent all reaction possibilities of the precursors concerned, and therefore suggested a search for competing reactions. Evidence for the existence of such competing reactions were obtained in the case of SK as well as in the case of PA (not published) but owing to the irritating situation that the nature of the PA is still unknown a discussion of the last case is omitted. In the case of SK the competing reaction probably consists in a proteolytic splitting of one or more peptide bonds in the SK molecule caused by the plasmin formed, which is not surprising since SK is a protein and plasmin is a proteolytic enzyme. The quantitative importance of this reaction appears from Fig. 2 A. With excess of PA supplied as serum at least 70 % of the SK is consumed by the side reaction and only 30 % by the main reaction leading to the formation of A. Substitution of plasma for serum results in a higher rate of the main reaction and accordingly a smaller fraction of the SK is destroyed by the side reaction.

The last section deals with a reaction which seems to have a certain resemblance to this side reaction. The results show that the reaction between SK and plasma results in the formation of two chemically different modifications of A. One of these is relatively stable at extreme pH values, and may be considered the primary product of the reaction between SK and PA. This modification does have a temporary existence only, since it is rapidly transformed into the labile A ordinarily dealt with. If the above mentioned reaction (1) is valid the formation of labile A may be described by:

$$PA + SK \rightleftharpoons \text{stable A} \rightleftharpoons \text{labile A}$$

During the inactivation of labile A at acid and alkaline pH the sum of A and PA is constant, which means that the reaction consists in a transformation of labile A into PA plus some sort of inactivated SK.

$$\text{labile A} \rightarrow \text{PA} + \text{inactivated SK}$$

Since stable A as well as the original SK is stable under the conditions used for the inactivation of labile A the difference between stable and labile A must be due to a difference in the SK part of the activator molecule. Still supposing that the reaction (1) is valid the whole series of reactions may be described by:

at neutral pH: $\underset{\text{stable A}}{\text{PA} + \text{SK}} \rightleftharpoons \underset{\text{labile A}}{\text{PA, SK}'}$

at acid pH: $\underset{\text{labile A}}{\text{PA,SK}'} \rightarrow \underset{\text{inactivated SK}}{\text{PA} + \text{SK}''}$

If reaction (2) is valid the SK molecule must be present — partly or as a whole — in either the A molecule or in the inactive component. In this case more detailed conclusions must be omitted, but the general conclusion that it is this "modified SK molecule" on the right side of the equilibrium sign which is changed during the formation of labile A is still probable.

Since we have already seen that plasmin may attack SK there is some probability that the formation of labile A is due to a similar effect of plasmin:

$$\text{stable A} \xrightarrow{\text{plasmin}} \text{labile A}$$

This probability is further supported by the fact that both reactions are inhibited by L-lysine-ethylester and by Witte peptone.

Solvent Extraction of Metal Chelates

I. Application of a Titration Procedure to the Study of the Extraction of Metal Chelates

BROR SKYTTE JENSEN

Danish Atomic Energy Commission, Risø, Denmark

A two-phase titration procedure for the study of metalchelate equilibria is presented. Equations expressing the relationship between the apparent mean complexity constant in the two-phase system, the mean complexity constant in a water phase and the distribution coefficients of the uncharged species are derived. The pH-value of 50 % extraction of a metal ion is determined with good approximation by this method. The error introduced by the simplified theoretical treatment is discussed and the predictions are confirmed by independent distribution experiments done, employing lanthanum-140 as tracer.

Extraction is among the few separation procedures where in principle the same laws are valid both for macro and tracer concentrations. Its application thus ranges from large scale technical separations to radiochemical work with practically weightless amounts. In recent years extraction procedures have especially been applied for the separation of metals, thus in the reprocessing of spent reactor fuel and in numerous analytical and radiochemical separations.[1–4]

In the reprocessing of spent reactor fuel by extraction, methods based on the extractability of certain mixed complexes of UO_2^{+2} or Pu^{+4} with nitrate ion and organic solvents containing oxygen are presently the most favoured. The advantage of this method is an extraordinary selectivity of the metals which can be extracted.

The extraction and separation, on a tehnical scale, of actinides from fission products by chelating agents have been performed with thenoyltrifluoroacetone, an extractive agent evaluated by Reid and Calvin [5,6]. An advantage of this process is that there is no need for a salting-out agent, thus reducing waste disposal problems. A significant disadvantage, however, is that the rate of chelation is slow, which has serious consequences for a large scale countercurrent extraction.

Other chelating agents of possible use for reprocessing have been investigated mostly by Swedish chemists [7–9].

Apart from its possible use in the reprocessing of spent reactor fuels, an extractive chelating agent might possess other valuable properties, *e.g.* as an analytical reagent. It seems well worth to continue the investigations in a systematic manner to gain more insight into the influence of the properties of the molecule on its usefulness as an extractive agent.

The chelating agents, previously investigated, constitute a rather inhomogeneous assembly of chemically very different compounds, and only uncertain predictions can be made as to the improvement of an existing chelating agent in one or other respects by modifying its molecular structure. Therefore it seems interesting to perform an analysis on series of closely related compounds in the expectation that secondary effects of any nature will remain constant or nearly so throughout the series. The comparison of chelates is then expected to give a more clear picture of the trends in extractive behaviour as a function of the constants of the chelating agent, and as far as their magnitudes are influenced by substituents or steric arrangements of the molecules, as a function of those.

In a systematic investigation of a large assembly there is always the need for a rapid and reliable method to estimate the values to be compared. In the study of metal ion extraction by chelating agents rather laborious methods have been used to determine the distribution coefficients. The most favoured ones seem to be photometric and radiometric methods. This paper presents an easy titration procedure for the study of the extraction of metal chelates, and the signification of the measured constants is discussed and related to the extractive behaviour of the chelating agent. The method has been used on some 1-phenyl-3-methyl-4-acyl pyrazolones [10,11] and on some O-oxy-azocompounds.

THEORY

The formation of a complex of type MA_q from a metal ion M^{N+} and the anion of a monobasic chelating agent HA is now generally believed to occur stepwise through intermediates of composition

$$MA_i \; ; \; (i = 0,1,2,\text{---},q) \tag{1}$$

where q is the maximum coordination number of the metalion for the anion A^-. The notation of charge and of coordinated water has been omitted for simplicity.

Assuming the formation of polynuclear complexes, hydrolysis products and competing complexes negligible — an assumption which can be regarded valid in dilute acid solutions of a metalnitrate or metal-perchlorate and a chelating agent — the total concentration C_M of metal in a homogeneous solution can be expressed as

$$C_M = \sum_{i=0}^{i=q} [MA_i] = [M] \sum_{i=0}^{i=q} \beta_i [A]^i \tag{2}$$

where we have introduced the formation constants, K_i, and the complexity products, β_i [12,13], defined as

$$K_i = \frac{[MA_i]}{[A][MA_{i-1}]} \qquad (3) \qquad\qquad \beta_i = K_1 K_2 - - - K_i \qquad (4)$$

$$\beta_0 = 1 \qquad (5)$$

Similarily we may express the concentration $[A_b]$ of ligands A bound to metal ions as

$$[A_b] = \sum_{i=0}^{i=q} i\,[MA_i] = [M] \sum_{i=0}^{i=q} i\ \beta_i [A]^i \qquad (6)$$

The formation function $\bar{n}$ for a system of metal ions and ligands defined as the average number of ligands bound per metal ion present [12,13] can be expressed as

$$\bar{n} = \frac{[A_b]}{C_M} = \frac{\sum_{i=0}^{i=q} i\,[MA_i]}{\sum_{i=0}^{i=q} [MA_i]} = \frac{\sum_{i=0}^{i=q} i\,\beta_i [A]^i}{\sum_{i=0}^{i=q} \beta_i [A]^i}$$

$$= \frac{K_1[A] + 2K_1K_2[A]^2 + ..+ NK_1 - - K_N[A]^N + ..+ qK_1 - - K_q\,[A]^q}{1 + K_1\,[A] + K_1K_2[A]^2 + ..+ K_1 - - K_N[A]^N + ..+ K_1 - - K_q[A]^q} \qquad (7)$$

In a two phase system of equal columes of the phases, where only the uncharged species MA_N is assumed to be distributed between the organic phase and water with a distribution coefficient λ defined as

$$\lambda = \frac{[MA_N]^{org}}{[MA_N]} \qquad (8)$$

a new formation function $\bar{n}_E$ may be defined

$$\bar{n}_E = \frac{[A_{b,E}]}{C_M} = \frac{K_1[A] + 2K_1K_2[A]^2 + (1+\lambda)NK_1K_2 - - K_N[A]^N + - - - - - -}{1 + K_1[A] + K_1K_2[A]^2 + ..+ (1+\lambda)K_1K_2 - - K_N[A]^N + - - -} \qquad (9)$$

valid for the heterogeneous system, but expressed in variables occurring only in the water phase. The system will now behave as if the formation constant K_N has been multiplied by the factor $(1 + \lambda)$. If, as is often the case for chelates,

$$N = q \qquad (10)$$

then the mean complexity constant K_{av} for the two phase system determined by standard procedures [12–16] will be

$$K_{av} = \sqrt[N]{\beta_N(1 + \lambda)} \qquad (11$$

The spreading factor [12,13], x, which is a measure of chemical effects on the successive formation constants, is defined as

$$\frac{(i+1)(N-i+1)}{i(N-i)}\,x^2 = \frac{K_i}{K_{i+1}} \tag{12}$$

In a two phase system for $1 + i = N$ we get

$$\frac{2N}{N-1}\,x^2 = \frac{K_{N-1}}{K_N(1+\lambda)} \tag{13}$$

As $(1 + \lambda) \gg 1$ for systems of practical interest the spreading factor will be small. This means, according to Bjerrum [12,13], that a plot of $\bar{n}_E$ against log [A] will be steep at the inflection point, corresponding to almost simultaneous dissociation of the N ligands from the complex; especially so because the formation constants $K_1, K_2, \cdots K_N$ usually do not differ very much [18].

To determine $K_{av} = \sqrt[N]{\beta_N(1+\lambda)}$, $\bar{n}_E$ must be known as a function of [A].

In a two phase system containing HA and metal salt MX_N it is possible to write the material balance regarding HA in a way that relates the concentration of some species in the organic phase to the actual concentrations of the water phase, simply by dividing by the volume ratio of the phases, thus

$$C_A = [A] + [HA]^{org} + [A_{b,E}] + [HA] \tag{14}$$

In this expression [A] and [HA] are solely contained in the water phase, $[HA]^{org}$ represents the amount HA extracted into the organic phase and $[A_{b,E}]$ represents the sum of intermediary complexes in both phases.

An expression describing the behaviour of the chelating agent in the above system can be obtained from the following equations combined with (14) and (9)

$$K_d = \frac{[HA]^{org}}{[HA]} \tag{15}$$

$$K_a = \frac{[H][A]}{[HA]} \tag{16}$$

defining the acid dissociation constant K_a and the distribution coefficient K_d of the chelating agent.

We get

$$K_b = \frac{K_a}{1+K_d} = \frac{[H][A]}{C_A - \bar{n}_E \cdot C_M - [A]} = \frac{[H](C_A - [HA] - [HA]^{org} - [A_{b,E}])}{[HA] + [HA]^{org}} \tag{17}$$

This is an equation from which to determine [A], when $[A_{b,E}]$ or $\bar{n}_E$ is known.

For $[A_{b,E}] = 0$ this equation shows that an acid in a two phase system will behave as if it has an acid dissociation constant K_b, where

$$pK_b = pK_a + \log\,(1 + K_d) \tag{18}$$

This equation is derived under the assumption that no association or dissociation of HA occur in the organic phase (eqn. 15).

To determine $[A_{b,E}]$ a method proposed by Calvin and Melchior [14] has been further evaluated.

Assuming only uncharged species to be extracted it is possible to express the electroneutrality equation for the water phase during a titration with NaOH by

$$[H] + [Na] + \sum_{i=0}^{i=N} (N-i)\,[MA_i] = [X] + [A] + [OH] \tag{19}$$

Inserting

$$[X] = N \cdot C_M \tag{20}$$

and eqns (2) and (6) this reduces to

$$[H] + [Na] - [A_{b,E}] - [OH] = [A] \tag{21}$$

From (14) and (21) we obtain

$$C_A = [H] + [Na] + [HA] + [HA]^{org} - [OH] \tag{22}$$

Now assuming C_A constant, [H] constant and therefore [OH] constant we get, by differentiation

$$dC_A = 0 = d[Na] + d([HA] + [HA]^{org}) \tag{23}$$

This represents a relation between the change in $([HA] + [HA]^{org})$ as a function of a change in [Na] during a simultaneous addition of NaOH and MX_N to the system in such a way that pH is kept constant. Integrating between the case where no metal salt has been added and the case where C_M has been added we obtain

$$\int_a^b d[Na] = [Na_2] - [Na_1] = -\int_a^b d([HA] + [HA]^{org})$$

$$= -\int_0^{A_b} \frac{d([HA] + [HA]^{org})}{d[A_{b,E}]}\, d[A_{b,E}] \tag{24}$$

where the integration limit a corresponds to a point on the titration curve of the chelating agent without metal salt added and b to a point at the same pH on the titration curve obtained with MX_N added in total concentration C_M. It is assumed that no Na-complexes have been formed.

From eqn (17) upon differentiation with respect to $[A_{b,E}]$ we obtain

$$\frac{d([HA] + [HA]^{org})}{d[A_{b,E}]} = -\frac{[H]}{[H] + K_b} \tag{25}$$

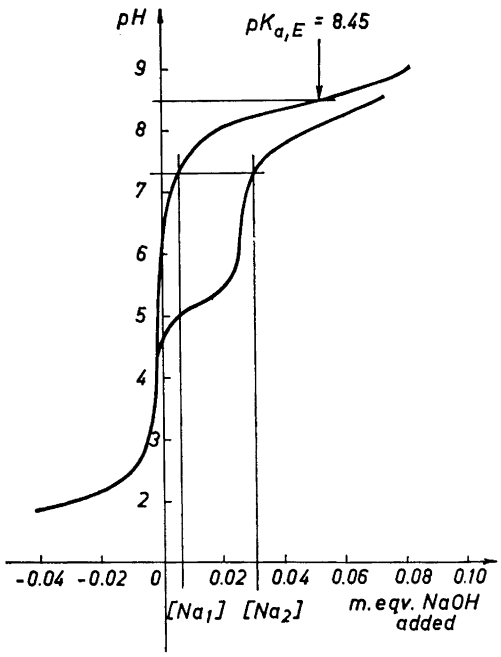

Fig. 1. Titration curve and complex-extraction titration curve for the system TTA, lanthanum ion, chloroform-water.

It is thus possible to integrate eqn (24) for [H] = constant leading to

$$([Na_2] - [Na_1]) \frac{[H]+K_b}{[H]} = [A_{b,E}] \tag{26}$$

As corresponding values are $[A_{b,E}] = 0$, and [Na] = $[Na_1]$, and [H] and [OH] may be neglected at not extreme pH values, we get

$$[A_{b,E}] = ([Na_2] - [Na_1]) \frac{C_A}{C_A - [Na_1]} \tag{27}$$

$([Na_2]-[Na_1])$ is the difference between the titration curves with and without added metal salt on a line of constant pH. An actual example of a two phase titration is shown in Fig. 1. The values necessary to calculate $[A_{b,E}]$ are indicated.

As a log [A] *versus* pH diagram for an acid is linear except at pH values near the pK_a value of the acid, a plot of $\bar{n}_E$ or $[A_{b,E}]$ against pH will have the same form as the formation function except at pH = $pK_a + \log(1 + K_d)$.

At the inflection point $\bar{n}_E = N/2$. Inserting this value into eqn (17) it is possible to calculate the log [A] value corresponding to the inflection point. This determines log K_{av} by the relation

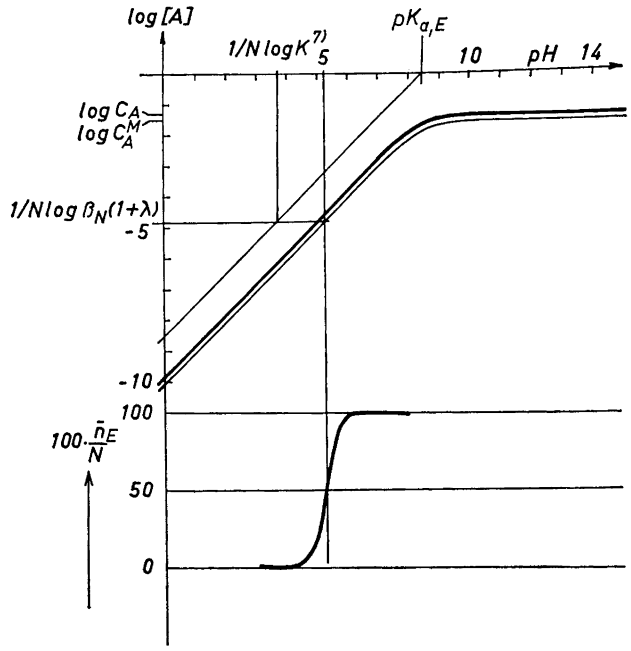

Fig. 2. The percent extraction curve for lanthanum ion in the TTA, chloroform-water system.

$$\log\,[\mathrm{A}'] = -\log K_{\mathrm{av}} = -\frac{1}{N}\log\,\beta_N\,(1+\lambda) \tag{28}$$

A graphical solution is most convenient and is shown in Fig. 2.
Assuming $\lambda \gg 1$ and [A] not too small, eqn (9) may be approximated to

$$\bar{n}_{\mathrm{E}} = \frac{[\mathrm{MA}] + 2[\mathrm{MA}_2] + \cdots + N[\mathrm{MA}_N] + \lambda N[\mathrm{MA}_N]}{C_{\mathrm{M}}} \cong \frac{\lambda N[\mathrm{MA}_N]}{C_{\mathrm{M}}} \tag{29}$$

Introducing an expression for the per cent metal extracted, % E, as

$$\%\ \mathrm{E} = \frac{[\mathrm{MA}_N]^{\mathrm{org}}}{C_{\mathrm{M}}}\ 100\ \% \tag{30}$$

and combining it with eqns (8) and (29) we obtain

$$\%\ \mathrm{E} = \frac{\bar{n}_{\mathrm{E}}}{N}\ 100\ \% \tag{31}$$

Eqn (31) shows that a plot of $100\ \bar{n}_{\mathrm{E}}/N$ against pH will conform with the per cent extraction curve for $\lambda \gg 1$.

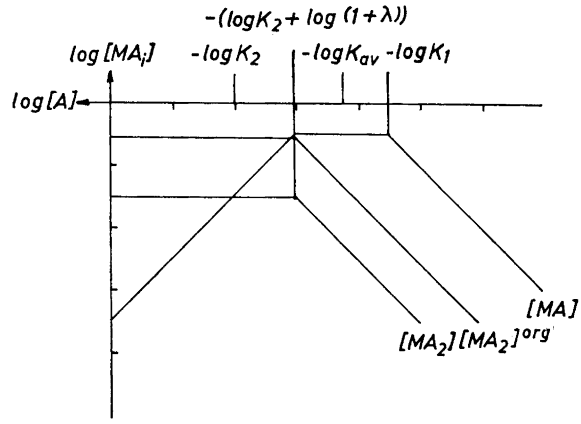

Fig. 3. A logarithmic diagram of metal chelate formation in a two phase system.

The log [A] *versus* pH diagram [17] in Fig. 2 is drawn using the experimental pK_b value determined graphically as shown in Fig. 1. $[A_b]$ is calculated by use eqn (27), and % E determined from eqn (31) is then plotted against pH as shown in Fig. 2.

A new log [A] *versus* pH diagram is then constructed according to a total concentration $C_A - \bar{n}_E \cdot C_M$, where $\bar{n}_E = N/2$, and the log [A'] value corresponding to % E = 50 % is found graphically. This represents a determination of the mean complexity constant K_{av} by relation (28). This constant is independent of the total concentration of the chelating agent. Assuming $C_A = 1$ and $[A_b]$ negligible, the pH of 50 % extraction of tracer concentrations of metal by a 1 M solution of extractive agent can be found graphically. This constant is equal to $\frac{1}{N} \log K$ defined by Dyrssen [7] and used by him to compare the chelating agents.

The general case where λ can have any value is better surveyed on a $\log[A] - \log[MA_i]$ ($i = 0, 1, 2, --, N$) diagram. For simplicity only the case $N = 2$ will be treated.

Noting the formal analogy between acid dissociation and complex dissociation, Fig. 3 can be constructed. The diagram resembles that of a dibasic acid [17]. The species MA_2, which alone is assumed to be extractable, have to be shared between the two phases with the distribution coefficient λ defined by eqn (8).

If λ is small the inflection point on the actual % E curve will correspond more to the second formation constant K_2 than to the mean complexity constant K_{av}, and accordingly, the inflection point on the actual extraction curve is expected to occur [12,13] for $\bar{n}_E = 3/2$.

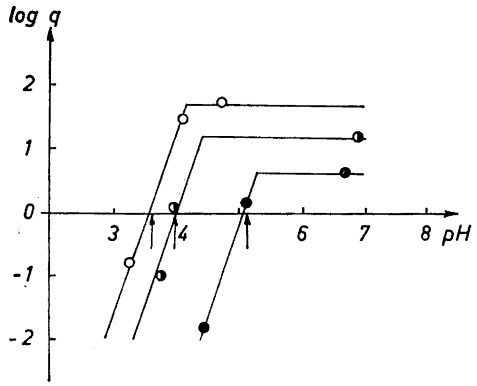

Fig. 4. Distribution data for the lanthanum ion with different chelating agents in chloroform. ○ 1-Phenyl-3-methyl-4-chloroacetyl-pyrazolone-5. ◑ Ethyl ester of 1-phenyl-3-methyl-4-carboxy-pyrazolone-5. ● Thenoyltrifluoroacetone.

If the formation curve ($\bar{n}_E$ — log[A]) has a rather large slope at the inflection point (larger than 0.5) indicating a small spreading factor x (less than 1) [12,13], then from eqn (13)

$$\frac{K_1}{K_2(1+\lambda)} < 4 \qquad (32) \qquad \log K_1 - \log K_2(1+\lambda) < 0.6 \qquad (33)$$

$$\log K_{av} = \frac{1}{2}[\log K_1 + \log K_2(1+\lambda)] < 0.3 + \log K_2(1+\lambda) \qquad (34)$$

$$\log K_{av} - \log K_2(1+\lambda) < 0.3 \qquad (35)$$

Eqn (35) indicates a systematic error in this case less than 0.3 pH units in the determination of the 50 % extraction value by this simple procedure. A correction may be made by the use of the relation between the average spreading factor and the midpoint slope of the formation curve [12,13], but if the slope is well above 0.5 a correction should not be nessessary, as in this case other errors are expected to dominate.

In the theoretical considerations given above certain approximations have been introduced. Generally they can be assumed to be justified under the specified conditions, but as actual systems deviate more or less from this simplified system, the ultimate precision of the equations obtained is hard to judge from theoretical considerations alone. Therefore as a check of the reliability of the method, some distribution experiments have been performed with ^{140}La as a tracer and with some chelating agents, to determine the actual pH's of 50 % extraction of La^{+3} to see how they correspond to the values obtained by the titration procedure.

METHODS

Titration procedures. The two phase titrations were made by equilibrating 2 ml of a 0.05 M solution of the chelate in chloroform with 2 ml of a water phase containing varying amounts of 0.1 N NaOH (or 0.1 N $HClO_4$) and 0.1 M $NaClO_4$ solution corresponding to different points on the titration curve. A set of 8—12 points were chosen corresponding to increasing amounts of base added, and the whole titration curve was obtained by simultaneous equilibration of the phases. Containers were 6 ml weighing bottles. After shaking to equilibrium — in most cases 10 min were sufficient — the pH of the water phase was measured when in contact with the organic layer.

The complex-extraction titrations were performed in the same manner except that 250 μl of the 0.1 M $NaClO_4$ solution was omitted and instead 250 μl of a *ca.* 0.05 M metal nitrate or metal perchlorate solution added. In the case of Th^{+4} only 100 μl was added. To be sure that equilibrium had been obtained some points were remeasured after a certain interval of time.

All measurements were performed at room temperature. (22 $\pm$ 1°C).

A Radiometer PHM-22 with a Radiometer glass-electrode type G 202 B and a Radiometer calomel electrode type K 100 with capillary drawn tip was used for the measurements.

Fig. 4 shows an actual set of curves obtained with thenoyltrifluoroacetone and $La(NO_3)_3$. Fig. 2 shows the plot of % E for the same combination.

Distribution experiments. 15 ml of a 0.05 M solution of the chelating agent in chloroform were shaken to equilibrium in a separatory funnel with 15 ml of a water phase containing varying amounts of $NaClO_4$ and NaOH at ionic strength 0.1 and tracer amounts of ^{140}La. (^{140}La was obtained by 2 h irradiation of 50 mg of $La(NO_3)_3$, 6 H_2O in D.R.1, Risø, at a flux of *ca.* 10^{10} n/sec.cm^2.) The sample was dissolved in 5 ml of water and 50 μl of the solution added to the separatory funnel.

The distribution coefficient q of La^{+3} was determined by measuring the γ-activity of 10 ml samples of the centrifuged water and chloroform phases with a conventional γ-counting unit equipped with a well-crystal. The pH of the water phase was measured for each distribution determination. The pH of 50 % extraction of La^{+3} was determined as the point where a curve representing a plot of log q against pH intersected the line log $q = 0$ shown in Fig. 4.

CONCLUSION

In Fig. 4 the pH's of 50 % extraction of La^{+3}, determined by the titration method is indicated by an arrow. The agreement between the two procedures is thus very good, as is to be expected, as often as the formation function $\bar{n}_E$ shows a large slope at the inflection point.

The present titration procedure is expected to offer an easy method by use of which the possibility of a given separation of metal ions by extraction with a given chelating agent can be checked, and a method by use of which the search for a useful extractive agent for a given separation of metal ions has become less tedious.

Synthesis of Thiamine Phosphates in Baker's Yeast

KARL-HEINZ KIESSLING

Institute of Zoophysiology, University of Uppsala, Sweden

The synthesis of thiamine di- and triphosphate has been investigated for Swedish and English baker's yeast. Four different types of buffers were used. The most suitable medium for both compounds was a succinate buffer, pH 3.7.

The biosynthesis of thiamine triphosphate was found to start with the formation of thiamine diphosphate. Then, by addition of another orthophosphate, this compound was transformed into thiamine triphosphate.

As to the biosynthesis of thiamine diphosphate the results agree with the earlier opinion that the compound is formed mainly by a transfer of a pyrophosphate group to thiamine.

The results give no definite information about the biosynthesis of thiamine monophosphate. Different alternatives are discussed.

The synthesis of thiamine diphosphate * by yeast enzymes has been thoroughly investigated in intact and plasmolyzed yeast cells [1–4] as well as in purified enzyme systems [5–9]. The major amount of TDP is synthesized in yeast by a transfer of a pyrophosphate group from ATP to thiamine [1,5,6,8]. Only a smaller amount of TDP can be synthesized by transfer of an orthophosphate group to TMP [4].

About the biosynthesis of TTP not very much has been published. It was shown that baker's yeast in addition to TDP also accumulates TTP, when incubated with an excess of thiamine [10,11]. Further Greiling [9] recently showed that a partly purified enzyme system from brewer's yeast could synthesize TTP from thiamine and ATP.

In the present paper the synthesis of TMP, TDP, and TTP in intact baker's yeast has been investigated.

MATERIALS AND METHODS

Yeast. The yeasts used are the English baker's yeast from the Distillers Company Ltd, London **, and the Swedish baker's yeast from The Yeast Company at Rotebro.

Incubation. 20 g of baker's yeast were suspended in a 0.1 M buffer, 0.2 g thiamine added, and the suspension incubated at 27°C with oxygen as the gas phase.

* Abbreviations: T thiamine, TMP thiamine monophosphate, TDP thiamine diphosphate, TTP thiamine triphosphate, AMP adenosine monophosphate, ADP adenosine diphosphate, ATP adenosine triphosphate, TCA trichloroacetic acid, $^{32}P_i$ radioactive inorganic phosphate.

** Kindly supplied by Dr. E. R. Dawson, The Distillers Company Ltd, London.

When searching for the best medium for the biosynthesis of TTP different buffers were used: sodium succinate buffer 0.1 M, pH 3.7 or 6.2, pyrophosphate buffer 0.1 M, pH 6.2, prepared from sodium pyrophosphate and HCl, and monophosphate buffer 0.1 M, pH 6.2, compounded from Na_2HPO_4 and NaH_2PO_4.

Samples taken from the yeast incubations were immediately centrifuged in the cold, the supernatant discarded, and the yeast cells suspended in cold 40 % TCA to a final concentration of 8 %. After 15 min at −10°C the yeast suspension was stirred strongly, centrifuged, and TCA removed from the yellow extract with ether.

Isolation of thiamine phosphates. From 20 g of yeast a final extract of about 15 ml was obtained. 0.25 ml were spread as a narrow line on a Whatman 52 filter paper washed with versene according to Eggleston and Hems [12]. The chromatograms were developed according to Kiessling [13], and the compounds localized by cutting off a strip from each chromatogram and spraying it with an alkaline potassium ferricyanide solution. The areas, containing TTP, TDP, and TMP were cut out, the compounds removed with water, and then re-chromatographed in the same solvent. The chromatography was repeated a third time in the solvent used by Greiling [14] or according to Siliprandi and Siliprandi [15] (*n*-butanol — 1 M HAc pH 5 — H_2O, 70 : 10 : 20). Finally TTP was purified by paper electrophoresis on Whatman 52 washed as described above. The solvent was an acetate buffer pH 5,4 (*cf.* Ref.[15]), the current 3 mA and the time 9 h.

Isolation of ATP and ADP. ATP and ADP were isolated by ion exchange chromatography according to Herbert and Potter [16].

Phosphate determination. Orthophosphate was determined according to Ernster *et al.*[17] whose method is a modification of that of Martin and Doty [18]. Hydrolyzable phosphate of TDP was determined after 15 min at 100°C in 0.5 M H_2SO_4, non-hydrolyzable phosphate of TTP, TDP, and TMP after wet ashing in 0.3 ml conc. $HClO_4$. γ and βP of TTP were removed by hydrolysis by means of potato apyrase according to Kiessling [11], or by hydrolysis for 3 min at 100°C in 0.1 M HCl for γP and for 15 min in 0.5 M H_2SO_4 for $\gamma + \beta$P.

The radioactivity of the phosphate was measured with an M-6 liquid counter tube on the samples used for ^{32}P determinations after dilution to 10 ml with ethanol.

Thiochrome method. In order to determine the amounts of TTP, TDP, and TMP synthesized in yeast after different time intervals the compounds were isolated by paper chromatography, hydrolyzed to thiamine by a yeast phosphatase according to Westenbrink *et al.*[19], transformed into the thiochrome form according to Hjarde, [20] and measured in a Beckman spectrophotometer with a special fluorescence attachment.

RESULTS AND DISCUSSION

Westenbrink has shown that, in the presence of an excess of thiamine, Dutch baker's yeast could go on synthesizing TDP for several hours [21]. Also for the Swedish baker's yeast I found this to be the case for at least 14 h (Fig. 1).

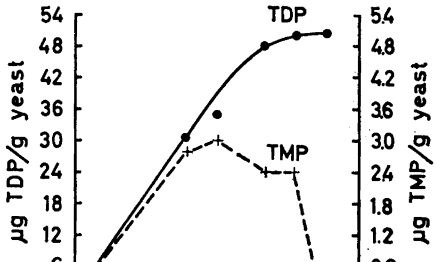

Fig. 1. Synthesis of TDP and TMP in baker's yeast. The yeast is the Swedish baker's yeast, incubated with an excess of thiamine in a 0.1 M succinate buffer, pH 3.7, at 27°C with oxygen as the gas phase. The compounds have been separated by means of paper chromatography, and measured as thiochrome after hydrolysis with yeast phosphatase.

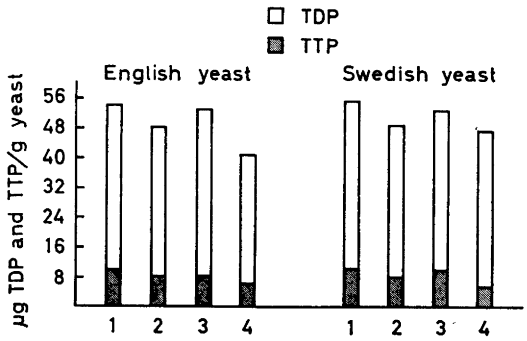

Fig. 2. Synthesis of TTP and TDP in baker's yeast. The yeasts used are an English and a Swedish baker's yeast. The yeasts have been incubated with an excess of thiamine in different buffers (1—4) during 16 h at 27°C with oxygen as the gas phase. The buffers are:

1. 0.1 M succinate buffer, pH 3.7
2. 0.1 M succinate buffer, pH 6.2
3. 0.1 M monophosphate buffer, pH 6.2
4. 0.1 M pyrophosphate buffer, pH 6.2

The compounds have been separated by means of paper chromatography, and measured as thiochrome after hydrolysis with yeast phosphatase.

At the same time the Swedish yeast as well as the English baker's yeast has been shown to synthesize TTP [10,11]. Without addition of special substrates the best medium for synthesis of TTP in the Swedish baker's yeast was found to be either succinate buffer, pH 3.7, or a monophosphate buffer, pH 6.2, and in the English yeast succinate buffer, pH 3.7 (Fig. 2). The same media were also the most favourable for the biosynthesis of TDP (Fig. 2). Buffers tested were succinate buffers, pH 3.7 and 6.2, monophosphate buffer pH 6.2 and pyrophosphate buffer, 6.2, all 0.1 M. In the following experiments with Swedish baker's yeast 0.1 M succinate buffer, pH 3.7, has been used.

Addition of thiamine phosphates to yeast cells immediately results in a hydrolysis of the phosphate by phosphatases, very likely situated at the cell

Table 1. Radioactivity of the different phosphate groups in thiamine phosphates isolated from baker's yeast. Incubation at 27°C with oxygen as the gas phase in a 0.1 M succinate buffer, pH 3.7 and with an excess of thiamine. $^{32}P_i$ was added after 4.5 h incubation, and samples for analysis were taken after another 2 and 4 h, respectively.

Thiamine compound	4.5 + 2 h (counts/5 min/µg P)			4.5 + 4 h (counts/5 min/µg P)		
	αP	βP	γP	αP	βP	γP
TTP	485	819	2 265	1 188	1 690	6 100
TDP	1 315	1 765	—	3 260	3 360	—
TMP	140	—	—	1 440	—	—

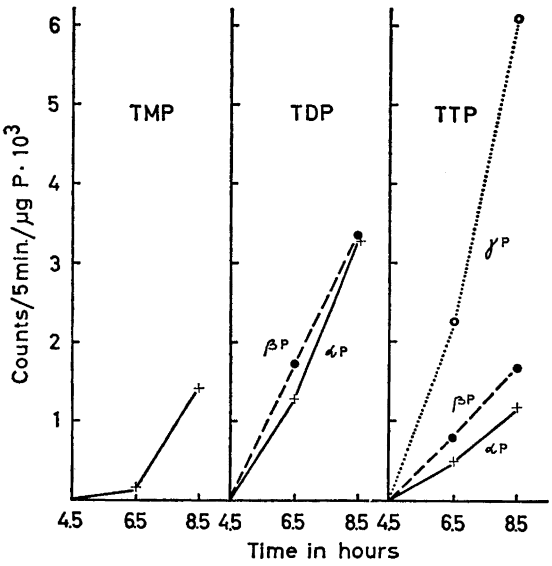

Fig. 3. Radioactivity of α, β and γP from TMP, TDP and TTP. Swedish baker's yeast was incubated with an excess of thiamine in 0.1 M succinate buffer, pH 3.7, with oxygen as the gas phase at 27°C. The first part of the incubation (up to 4.5 h) was performed in the absence, and the second part in the presence of radioactive phosphate. The compounds have been separated by means of paper chromatography.

surface. Besides it is doubtful, whether or not the phosphorylated compounds could penetrate the cell membrane. The yeast cells, however, transfer added thiamine, which easily penetrates the cell membranes, into thiamine phosphates which give origin to starting-points for further synthesis. Thus yeast was allowed to accumulate thiamine phosphates for a certain interval. Then radio-

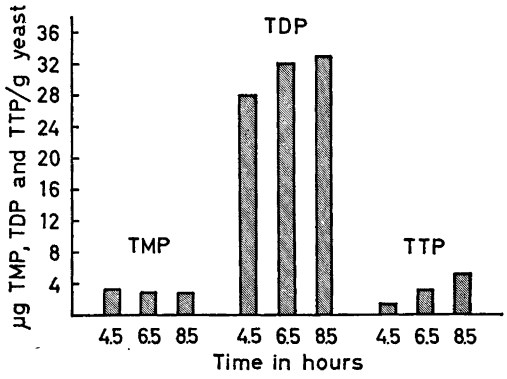

Fig. 4. Amount of TMP, TDP and TTP in baker's yeast after different time intervals. Incubation as in Fig. 3. The compounds were separated by means of paper chromatography, and measured as thiochrome after hydrolysis with yeast phosphatase.

active inorganic phosphate was added, and the incubation continued. Samples were taken after different time intervals, the thiamine phosphates isolated, and the radioactivity of the different phosphate groups determined. This permits to see how TTP and possibly also TDP are synthesized from already formed thiamine phosphates.

Results from an experiment are shown in Table 1 and Fig. 3. After 4.5 h incubation in the absence of $^{32}P_i$, radioactive phosphate was added, and samples taken after another 2 and 4 h incubation. Fig. 4 shows the amounts of TMP, TDP, and TTP at the end of the different intervals.

Two ways are open for the biosynthesis of TTP: either by a transfer of a pyrophosphate group to TMP or a monophosphate group to TDP. The biosynthesis of TDP is thought to be brought about by a transfer of a pyrophosphate group to thiamine. About the way of formation of TMP nothing is known, but it is generally assumed to be generated by hydrolysis of TDP.

From Table 1 and Fig. 3 it is seen that the radioactivity of γP of TTP increases much more rapidly than that of β and αP. As ATP has been shown to be the phosphate donor at the synthesis of TDP from thiamine as well as at the synthesis of TTP in isolated systems, the synthesis of TTP in intact yeast cells, according to Table 1 and Fig. 3 very probably may be written:

$$TDP + ATP \longrightarrow TTP + ADP$$

that is, TDP, already synthesized from thiamine and ATP, receives a third phosphate from ATP.

Another possibility for the synthesis of TTP is:

$$TMP + ATP \longrightarrow TTP + AMP$$

This possibility is, however, excluded by the circumstances that βP in TTP is much less labelled than γP. Very probably the βP of ATP becomes labelled somewhat slower than the γP, but the differences can't suffice for the explanation of the different labelling of β and γP of TTP. This becomes obvious from the synthesis of TDP. From experiments with partly isolated thiamino kinases [5,6,8,9], and with autholyzed yeast cells [4] the synthesis of TDP was found mainly to proceed according to the reaction:

$$T + ATP \longrightarrow TDP + AMP$$

The results in Table 1 and Fig. 3 show that αP of TDP is only slightly less radioactive than βP. The differences can be explained by one of two assumptions: either that βP of ATP does not exchange its phosphate as rapidly as γP, or that TDP to a small extent is also synthesized from TMP. Whatever the explanation may be the fact remains that the differences in radioactivity between βP and γP of ATP are too small to account for the differences between β and γP of TTP. It therefore seems most satisfactory to explain the results by ascribing the synthesis of TTP to a transfer of a phosphate group to previously formed TDP.

It is difficult to give a satisfactory explanation for the figures in Table 1 on the radioactivity of TMP. The general opinion is that TMP is more likely formed by hydrolysis of TDP than by a direct phosphorylation of thiamine. On the contrary Greiling reported that he had found an enzyme in brewer's

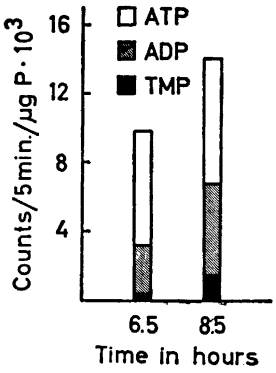

Fig. 5. Radioactivity of TMP and of hydrolyzable phosphate of ATP and ADP after 2 and 4 h incubation respectively. The samples are from the experiment described in Fig. 3. ATP and ADP were isolated on a Dowex 1 column according to Herbert and Potter [16], and the radioactivity measured on the phosphate hydrolyzed during 10 min at 100°C in 1 M H_2SO_4. TMP was isolated by paper chromatography (see Methods), and the radioactivity determined after wet ashing in $HClO_4$.

yeast which, at most to a small extent, is able to synthesize TMP from thiamine and ATP [9].

TMP accumulates only during the first hours, when yeast is incubated with thiamine (Figs. 1 and 4). Further incubation causes a decrease of the amounts of TMP. The decrease may either depend on the fact that TMP is hydrolyzed to thiamine or that it is transformed into another thiamine phosphate (TDP or TTP). However, it does not necessarily mean that TMP is no longer formed. The increasing radioactivity of TMP, isolated from the yeast during periods when the total amount of TMP is decreasing, indicates that a formation of the compound still takes place.

If TMP, as is generally believed, is formed from TDP, the quantity and also the radioactivity, as with αP of TDP, should increase altogether continuously. This is, however, not the case (Figs. 1 and 3). If TMP is synthesized by a transfer of a phosphate from ATP to thiamine, the radioactivity should likewise increase nearly straight-lined as in βP of TDP (the decrease in the total amount of TMP should cause the curve to bend only slightly upwards). The results in Fig. 3 makes, however, ATP a less probable phosphate donor at a possibly occurring synthesis of TMP.

Table 2. The radioactivity of TTP and TDP from yeast after further incubation with an excess of non-radioactive phosphate. First part of the incubation was performed as described in Table 1. Incubation time 16 h. $^{32}P_i$ was added after 8 h incubation and a sample taken after another 8 h. The remaining yeast was then washed twice with a succinate buffer, and the incubation continued in the presence of an excess of non-radioactive phosphate. Samples were taken after 1 and 2 h, respectively.

Thiamine compound	Counts of hydrolyzable P/5 min/µg P		
	16 h	17 h	18 h
TTP	743	762	808
TDP	440	503	495

From Fig. 5 it is seen that ADP becomes labelled at a slower rate than ATP. The increase along a straight line of the radioactivity of ADP eliminates also ADP as a possible phosphate donor.

Thus the results give no information about the way in which TMP is formed in baker's yeast. The comparison of the curve for TMP and αP of TDP (Fig. 3) allows only the conclusion that TMP is not at all, or only to a small extent, an intermediate in the biosynthesis of TDP from thiamine in intact baker's yeast when present in biological concentrations (*cf.* Ref.[4]).

Previously it has been shown that γP in yeast TTP rapidly becomes radioactive, when glucose is added together with radioactive phosphate to a yeast suspension.[22] This is not the case in the absence of glucose. The increase of radioactivity in the γP of TTP in the presence of glucose was therefore looked upon as depending on a turnover of the terminal phosphate in already existing TTP rather than on a further synthesis of TTP.

In order to make sure that in the present experiments (Table 1), performed in the absence of glucose, the high radioactivity of γP in TTP compared with that in β and αP did not depend on a turnover of the type described above, the following control was made: yeast was incubated 16 h as described in Table 1. After 8 h radioactive inorganic phosphate was added. At 16 h the yeast was washed twice with succinate buffer to remove excess of thiamine and $^{32}P_i$. It was then suspended in a new buffer consisting of three parts 0.1 M succinate buffer and one part 0.1 M phosphate buffer, pH 3.7. Samples were taken after 1 and 2 h incubation. The results are seen in Table 2. No decrease of the radioactivity in the hydrolyzable phosphate of TTP and TDP was found. Neither does any remarkable synthesis of TTP take place any longer, and the relatively constant radioactivity in its phosphate indicates that no exchange of the terminal phosphate is going on.

Greiling recently reported that he had been able to synthesize TTP from thiamine with a purified enzyme system from brewer's yeast [9]. He used ATP labelled in the terminal phosphate, and found the ratio between the activities of γ, β and αP in TTP to be 3:3:1. In TDP the ratio between β and αP was 3:1. The conclusions drawn from his results agree with those for the synthesis of TTP in intact yeast cells reported in the present paper.

Acknowledgements. I am indebted to Prof. P. E. Lindahl for the interest he has shown in my work and to Mr. Bo Molin for valuable technical assistance.

Action of Phenylalanine Metabolites on Glutamic Acid Decarboxylase and γ-Aminobutyric Acid—α-Ketoglutaric Acid Transaminase in Brain

ARNE HANSON

Department of Clinical Chemistry, General Hospital, Malmö, Sweden

Several intermediary metabolites of phenylalanine, namely phenylpyruvic, *p*-hydroxyphenylpyruvic, phenylacetic, *p*-hydroxyphenylacetic, and *o*-hydroxyphenylacetic acids have been found to inhibit the glutamic acid decarboxylase of brain *in vitro*. The inhibition is of the competitive type and appears to be localized in the apoenzyme.

No inhibitory effect could be demonstrated when the same metabolites were tested on the γ-aminobutyric acid—α-ketoglutaric acid transaminase system.

The significance of these findings in relation to phenylketonuria is briefly discussed.

In phenylketonuria hydroxylation of phenylalanine to tyrosine is markedly reduced. This results in an excess of phenylalanine in the tissues and an overproduction of intermediary metabolites of phenylalanine catabolism. The major metabolites of phenylalanine found in abnormal amounts in phenylketonuria are phenylpyruvic, phenyllactic and phenylacetic acids [1]. It has been suggested [1] that the mental deficiency is caused by an overproduction of one of these metabolites or by an excess of phenylalanine.

These aromatic metabolites of phenylalanine have recently been found to inhibit dihydroxyphenylalanine decarboxylase of beef adrenal medulla [2] and 5-hydroxytryptophan decarboxylase of guinea-pig kidney [3] *in vitro*. This inhibitory effect has been offered as an explanation of the low plasma levels of adrenaline [4] and 5-hydroxytryptamine [5] in phenylketonuria. Since much argues that both adrenaline and 5-hydroxytryptamine play a rôle in normal brain function [6], it appears that inhibition of these enzymes might reasonably be a contributing cause of mental deficiency.

The reported inhibition of dihydroxyphenylalanine decarboxylase and 5-hydroxytryptophan decarboxylase by aromatic phenylalanine metabolites

prompted us to examine the effects on GAD * and GABA-T of brain of these metabolites as well as of some others also occurring in phenylketonuria, namely *p*-hydroxyphenylpyruvic, *p*-hydroxyphenylacetic, and *o*-hydroxyphenylacetic acids and *o*-tyrosine.

The presence, in brain, of very large amounts of GAD and of ABA — the product formed by its action on GA — suggests that decarboxylation of GA may be a reaction of major importance in the metabolism of the central nervous system [7]. No other tissue has been found to show as high GAD activity as brain. This enzyme requires the presence of a coenzyme, namely pyridoxal-5-phosphate.

In studies on the metabolic fate of GABA evidence has also been obtained for its transamination with KGA in brain to form SSA and GA [7,8]. The transaminase catalyzing this reaction also requires pyridoxal-5-phosphate as coenzyme which, however, appears to be more firmly bound to the apoenzyme than is the case in the decarboxylase [9,10]. The SSA can be oxidized further to succinic acid and so enter the tricarboxylic acid cycle. This latter reaction appears to be catalyzed by a diphosphopyridine nucleotide dependent dehydrogenase [11].

In view of these findings it has been suggested that in brain a shunt operates around the KGA oxidase system of the tricarboxylic acid cycle by which KGA could be withdrawn through formation of GA by transamination with GABA and the carbon chain of GABA could enter the cycle at the succinic acid level. It is of special interest that this step in the tricarboxylic acid cycle has been considered to be the rate limiting reaction of the cycle; thus the whole cycle could be secondarily regulated by the activity of "the GABA cycle".

Recent findings also suggest that GABA may act in the cortex as an inhibitory transmitter substance [12,13]. Interference with its formation and/or metabolism may therefore be an example of a biochemical lesion of the central nervous system.

MATERIALS AND METHODS

Materials. The phenylalanine metabolites used were obtained from commercial sources. Phenylacetic acid from Eastman-Kodak Co.; phenylpyruvic acid, sodium salt, from Hoffman-La Roche & Co. Ltd.; *p*-hydroxyphenylacetic acid from K and K Laboratories, Inc.; *p*-hydroxyphenylpyruvic acid, sodium salt, from Sigma Chemical Co.; *o*-hydroxyphenylacetic acid and DL-a-phenyllactic acid from Light & Co. Ltd.; DL-*o*-tyrosine from California Foundation for Biochemical Research; DL-phenylalanine and L-GA from Merck & Co. Ltd.; GABA from Hoffman-La Roche & Co. Ltd.; KGA from Sigma Chemical Co. Pyridoxal-5-phosphate was generously supplied by Dr. W. W. Umbreit, Merck Institute for Therapeutic Research, Rahway, N. J.

The metabolites obtained as free acids were transformed into their sodium salts before use.

SSA was synthesized from glutamic acid according to Mosbach *et al.*[14] and isolated as 2,4-dinitrophenylhydrazone. After recrystallization from ethanol the product had a melting point of 200°.

Other chemicals used in the experiments were of reagent grade.

---

* The following abbreviations have been used: GA, glutamic acid; GABA, γ-aminobutyric acid; KGA, α-ketoglutaric acid; GABA-T, γ-aminobutyric acid — α-ketoglutaric acid transaminase; GAD, glutamic acid decarboxylase; SSA, succinic semialdehyde.

Enzyme preparations. GAD was obtained from either rat or guinea-pig brain. The animals were killed by decapitation and the brains immediately placed in small beakers containing cracked ice. Homogenates containing 500 mg of fresh weight of brain per ml were prepared in ice-cold 0.5 M phosphate buffer pH 5.9.

GABA-T was obtained from mitochondria isolated from either rat or guinea pig brains. For the isolation of mitochondria the brains were disrupted in 9 volumes of 0.25 M sucrose in a Potter-Elvehjelm homogenizer. The homogenate was centrifuged twice at 1 500 × *g* for 5 min to remove nuclear and cellular debris. The final supernatant was then centrifuged at 12 000 × *g* for 20 min to sediment the mitochondria. After being washed once in 0.25 M sucrose the mitochondria were suspended in 0.25 M sucrose and the suspension diluted so that 1 ml corresponded to 5 g of brain. The centrifugations were carried out in an International Refrigerated Centrifuge with multispeed attachment.

All steps in the preparation of the enzymes were carried out at 0 – 4°.

Assay of enzyme activity. The rate of GA decarboxylation was determined with a Warburg apparatus in an N_2 atmosphere at 37°. The main compartment of the flasks contained 1 ml of brain homogenate, 200 μg of pyridoxal-5-phosphate and inhibitor dissolved in phosphate buffer to make a final volume of 2.65 ml. One side arm contained GA solution (pH 7.0 to 7.4) to give a final concentration of 0.03 M. The substrate was added after an equilibration time of 10 min. The other side arm contained 0.3 ml of 3 N H_2SO_4. This was added to stop the reaction and to liberate bound CO_2, for which suitable corrections were made. Carbon dioxide output was determined for 60 mins.

To ascertain whether the formation of CO_2 and GABA took place in stoichiometric amounts under the conditions employed, the quantity of GABA in the incubation fluids was determined in some of the experiments. The GABA was separated by means of high voltage electrophoresis and determined quantitatively by treating the ninhydrin-developed spots with a copper nitrate solution, eluting the red colour of the copperninhydrin-complex with methanol and measuring the colour intensity spectrophotometrically [15].

The formation of SSA and GA was taken as a measure of the GABA-T activity. The assay method was as follows: Incubations were carried out, in air, with shaking in small conical flasks for 2 h at 37°. The incubation mixture contained 1.5 ml of 0.1 M phosphate buffer pH 7.4, 0.5 ml of mitochondria suspension, 0.2 ml of 0.1 M KGA (20 μM), 0.4 ml of 0.2 M GABA (80 μM), and inhibitor (usually in a volume of 0.6 ml). The final volume of the incubation mixture was usually 3.2 ml. At the end of the incubation period 1 ml of 15 % trichloroacetic acid was added to deproteinize the contents which were then centrifuged for 10 min.

For estimation of the SSA formation an aliquot of the supernatant was pipetted into a glass-stoppered test-tube placed in an ice-bath and 3 ml of a 0.5 % solution of 2,4-dinitrophenylhydrazine in 5 N HCl added. After 10 min 5 ml of xylene were added to the tube for extraction of the hydrazone formed. This extraction was repeated once. The pooled extracts were then extracted with 5 ml of a 0.1 M borate buffer pH 10. An aliquot of the borate extract was diluted with borate buffer to a volume of 6 ml and this was made alkaline with 0.5 ml of a 5 % alcoholic sodium hydroxide solution.

Exactly 2 min later the colour density was measured in a Beckman DU spectrophotometer at 420 mμ against a blank consisting of borate buffer and alcoholic sodium hydroxide. The concentration of SSA in the extract was assessed from a calibration curve made up from known amounts of a synthetic sample of SSA-2,4-dinitrophenylhydrazone. Only small amounts of the KGA present in the incubation mixture was found to react with the 2,4-dinitrophenylhydrazine to give a hydrazone under the conditions described, and xylene extracted but little of this hydrazone.

In some of the experiments the presence of SSA-2,4-dinitrophenylhydrazone in the borate extract was confirmed by paper chromatography. For this the extract was acidified to pH 2 with HCl and extracted with a mixture of ethanol and chloroform (20:80). This extract was evaporated to dryness and the residue taken up in a small volume of ethyl acetate and applied to the paper. Ascending chromatography with a mixture of *n*-butanol, ethanol and 0.5 N ammonia (70:10:20) as developing system was used. In this system SSA-2,4-dinitrophenylhydrazone gave two spots having the R_F values 0.09 and 0.43, respectively.

When the inhibitor tested was a carbonyl compound, such as phenylpyruvic and *p*-hydroxyphenylpyruvic acids, the transamination assay could not be based on the for-

mation of SSA since the inhibitors formed hydrazones. Here only the formation of GA was used for the assay.

The GA formed in the transamination was measured in the deproteinized incubation mixture by the high voltage electrophoresis method mentioned above [15].

RESULTS AND DISCUSSION

Several of the phenylalanine metabolites were found to inhibit the GAD. Some of the results of these experiments are given in Table 1. Phenylacetic

* In experiments 5 and 6 the incubation mixture contained *p*-OH-phenylacetic acid (50 μmole/l).

and phenylpyruvic acids were found to be the most effective inhibitors of the unsubstituted compounds. Phenyllactic acid and phenylalanine had very little activity. Of the *para*-hydroxylated compounds studied, *p*-hydroxyphenylacetic acid proved a more active inhibitor than *p*-hydroxyphenylpyruvic acid. Two *ortho* compounds were also tested. Of these, *o*-hydroxyphenylacetic acid was rather active, while its precursor, *o*-tyrosine, was inactive.

Table 2 gives the results of experiments performed to determine whether the formation of CO_2 and GABA takes place in stoichiometric amounts under the conditions employed. The experiments were performed both with and without added inhibitor. Good equivalence was found and it may be said that, within experimental error, there was a mole for mole formation of CO_2 and GABA.

It may be of interest to compare some of these results with those obtained from similar studies on other decarboxylases. Davison and Sandler [3] in their study of 5-hydroxytryptophan decarboxylase from guinea-pig kidney as well as Hartman *et al.*[16] in their study of dihydroxyphenylalanine decarboxylase from hog kidney obtained comparable inhibitions of their enzyme preparations with phenylacetic and phenylpyruvic acids and less or no inhibition with phenyllactic acid. In Fellman's study of the dihydroxyphenylalanine decarboxylase from beef adrenals phenylpyruvic and phenyllactic acids were the most effective inhibitors while phenylacetic acid was a poor inhibitor [2]. An inhibitory effect of *p*-hydroxyphenylpyruvic acid on dihydroxyphenylalanine decarboxylase has been reported by Hartman *et al.*[16]. Its effect was equal to that of phenylpyruvic acid.

The equations of Hunter and Downs [17] were used for characterizing the type of inhibition observed in the present experiments. If α is defined as the fractional activity, *i. e.* v_1/v, where v_1 is the activity in the presence of inhibitor and v the activity in its absence, with the same substrate concentration, these equations are, for a competitive inhibition,

$$[I]\ \frac{\alpha}{1-\alpha} = K_i + \frac{K_i}{K_m}\ [S]$$

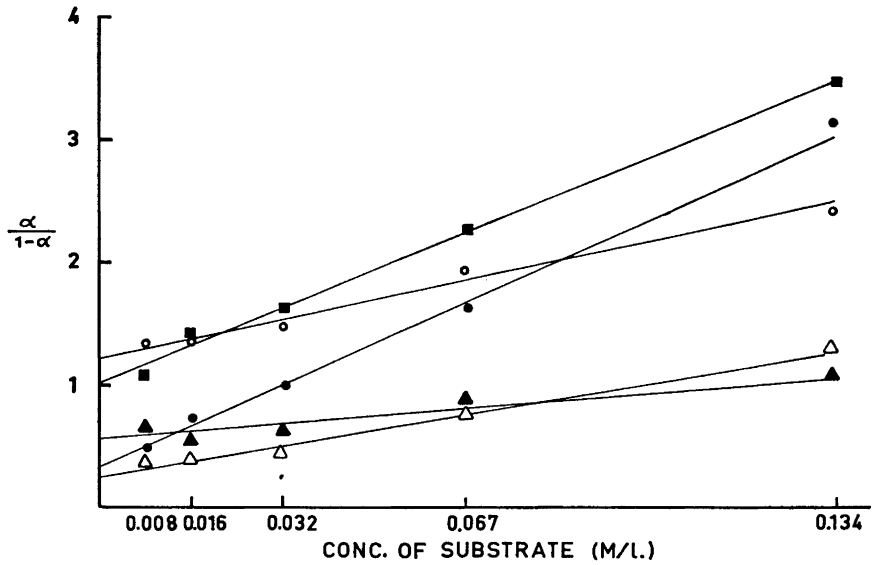

Fig. 1. Inhibition of glutamic acid decarboxylase of brain by phenylalanine metabolites. Experimental conditions as described in text. The results are plotted according to the equation derived by Hunter and Downs [17]: $a/(1-a)$ against substrate concentration. Values of a are determined as the ratio of inhibited velocity to uninhibited velocity with the same concentration of the substrate. Inhibitor concentration 100 μmole/l. Inhibitors: ● Phenylpyruvic acid; ○ *p*-OH-Phenylpyruvic acid; ▲ Phenylacetic acid; △ *p*-OH-Phenylacetic acid; ■ *o*-OH-Phenylacetic acid.

and, for a non-competitive inhibition,

$$[I]\ \frac{a}{1-a} = K_i$$

where [I] is the inhibitor concentration, K_i the dissociation constant of the enzyme-inhibitor complex, [S] the substrate concentration, and K_m the Michaelis constant. By plotting $a/(1-a)$ against [S] one obtains for competitive inhibition a straight line with slope K_i/K_m and intercept K_i; and, for non-competitive inhibition, a straight line of zero slope and intercept K_i. The value of K_i represents the amount of inhibitor required for 50 % inhibition.

When $a/(1-a)$ was plotted against [S] with the different inhibitors the graphs obtained were found to be straight lines with different slopes (Fig. 1). This indicates that the inhibition is dependent of the substrate concentration, [S], *i. e.* it is of the competitive type. The value of K_i can be calculated from each of the lines by multiplying the value of [I] by the value of the intersection point obtained by extrapolating the line to the vertical axis (Table 3).

To ascertain whether the inhibition noted was due to any interference with the coenzyme of GAD, *i. e.* pyridoxal-5-phosphate, determinations were made of the influence of increasing amounts of the latter on systems inhibited by the

Table 3. K_i values of different competitive inhibitors of glutamic acid decarboxylase. (Values of K_i were calculated form $a/(1-a)$ values obtained by the graphical method shown in Fig. 1).

Inhibitor	Inhibitor conc. (μmole/l)	Calculated K_i (μmole/l)
Phenylpyruvic acid	100	30
p-OH-Phenylpyruvic acid	100	120
Phenylacetic acid	100	55
p-OH-Phenylacetic acid	100	25
o-OH-Phenylacetic acid	100	100

various inhibitors. It is clear from Table 4 that increasing concentration of the pyridoxal-5-phosphate produced no demonstrable effect. The inhibition thus seems to be localized in the apoenzyme and not to be of the type caused by hydrazides or certain pyrocatechol derivatives. The former compounds have been shown by Killam and Bain [18] to inhibit the brain GAD, the inhibition being competitively reversed by pyridoxal-5-phosphate, however. Of the pyrocatechol derivatives, primary phenylalkylamines containing a phenolic hydroxy group in *meta* position such as dopamine, noradrenaline, and *m*-hydroxyphenylserine have been found by Holtz and Westermann [19] to inhibit the same enzyme. In this case, however, the inhibition is not of the competitive type but has been interpreted as a reaction of the inhibitor with the coenzyme with formation — *via* Schiff base formation — of tetrahydro*iso*-quinoline derivatives resulting in strong inhibition of the enzyme. If added in excess, pyridoxal-5-phosphate can counteract the inhibition.

When tested on the GABA-T system none of the inhibitors had any effect in the concentrations found to inhibit the GAD. Some of the results of these experiments are shown in Table 5. It appears from the data that there is a formation of about 0.5 μM of SSA for each micromole of GA. This difference in equivalence between the compounds formed in the transamination reaction is probably due to the SSA being utilized by the brain mitochondria and thus

Table 4. Influence of increasing amounts of pyridoxal-5-phosphate on the inhibition of glutamic acid decarboxylase. (The reaction mixture was as described above. Concentration of inhibitor 100 μmole/l. The figures refer to CO_2 output in μl).

partially disappearing spontaneously. Oxygen uptake of guinea-pig brain slices [20] as well as esterification of phosphate by cat cortex mitochondria [21] have been shown to be supported by SSA and brain homogenates have also been found to catalyze a diphosphopyridine nucleotide dependent oxidation of SSA [11].

It is difficult to say whether these findings are of any significance in the investigation of the cause of the mental defect in phenylketonuria because no figures are available on the concentration of the different phenylalanine metabolites in the central nervous system. It is therefore impossible to decide whether the *in vitro* findings reported here have any counterpart *in vivo*.

In a search for the cause of the mental defect in phenylketonuria, however, it seems reasonable to consider the rôle played by the phenylalanine metabolites as inhibitors of enzymes believed to be important for normal function of the central nervous system. The fact that these metabolites are able to inhibit three different decarboxylases, all producers of possible transmitter substances, *i. e.* adrenaline, 5-hydroxytryptamine and GABA, is not without interest.

This work was supported by a grant from the *Magnus Bergvall Foundation*, Stockholm.

Determination of L-5-Vinyl-2-thiooxazolidone from Plant Material and Milk

MATTI KREULA and MARTTI KIESVAARA

Laboratory of Valio and Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

A quantitative micromethod for the determination of L-5-vinyl-2-thiooxazolidone in different parts of plants, in silage, and in milk, is presented. The method is based on the separation of this substance by paper chromatography and its spectrophotometric determination. The absorption maximum is at 240 mμ.

Astwood *et al.*[1] have presented a quantitative method for the determination of the L-5-vinyl-2-thiooxazolidone (VTO) contents in the seeds and the roots of cruciferous plants. No method for the determination of the small amounts of VTO formed enzymatically in the green parts of cruciferous plants has, however, been described earlier. The formation of this substance in the green parts of many cruciferous plants was in fact found in this laboratory only two years ago [2]. Later Long *et al.*[3] also isolated VTO from cabbage. The development of a method for the determination of VTO in milk, in which it can be present only in extremely low concentrations [4], has met with considerable difficulties.

EXPERIMENTAL

I. VTO in green parts of plants.

Equipment (*cf.* Fig. 1). 1. A Mojonnier flask (12 ml); the volume of the lower part 2 ml and that of the upper part 10 ml; glass plug.
2. A conical flask for vacuum evaporation (100 ml) and a glass suction adapter.
3. Chromatography equipment for ascending development; a. A glass cylinder, ø 11 cm, height 26 cm, b. Paper, Whatman No. 1.

Reagents. 1 Water saturated ethyl acetate.
2. Phosphate buffer, pH 6.5, M/15 KH_2PO_4 + M/15 Na_2HPO_4.
3. Ethyl ether-methanol, 1:1. Ether shaken peroxide-free with $FeSO_4$ and distilled.

Determination. 10 g of minced plant material is allowed to stand for 7 h at room temperature in a beaker covered with a polytene membrane. The beaker with its contents is heated on a water bath for 5 min, the plant material is transferred to a piece of cloth (gauze) in which it is tightly pressed. 1.5 ml of the filtered press juice is measured into a Mojonnier flask as well as 0.5 ml of phosphate buffer. The mixture, the pH of which is 6.3–6.5, is extracted with 5 ml of water saturated ethyl acetate by thorough

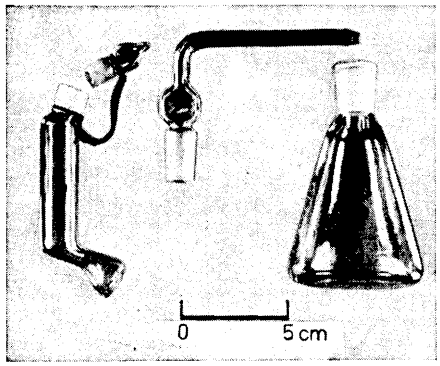

Fig. 1. Equipment for the determination of VTO. A Mojonnier flask (1), a glass adapter (2), and a 100 ml vacuum evaporation flask.

shaking for 20 sec. The clarified extract is poured into a 100 ml conical flask. A second extraction is performed with another 5 ml amount of ethyl acetate. The combined extracts are evaporated to dryness *in vacuo* (water pump). To prevent overheating, the liquid in the conical flask has to be kept in rotatory motion. Using water bath heating as well, evaporation can be effectively speeded up. The residue is now dissolved in 0.5 ml of hot water and 250 μl of the extract obtained is used in two-dimensional paper chromatography, first in methanol-water and then in methanol-ether. Ascending development is used.

On the papers dried at room temperature the boundaries of the spots are drawn using UV-light. The spot of VTO is first cut off and then cut into small slips which are extracted twice with 2.5 ml of hot water in a test tube on a boiling water bath. The combined extracts are estimated photometrically with a Beckmann Spectrophotometer at 220, 240, and 260 mμ.

In calculating the results the method reported by Astwood *et al.*[1] is used. The average of the extinction values at 220 and 260 mμ are subtracted from the extinction value at 240 mμ and the obtained difference is multiplied with the factor 1.16. The correction is justified since the VTO separated by paper chromatography is not yet quite pure. A calibration curve is constructed with pure VTO. The μg-values of the solutions to be investigated are read from this curve, and the results are multiplied with the dilution factor. The results are given in μg/ml of press juice.

In calculating the results *Lamber-Beer*'s law can also be used, in which case the *E*-value obtained by the correction made according to Astwood is multiplied with the factor 7.5. The concentration of the solution to be measured is obtained in μg/ml. The coefficient is equivalent to log *E* 4.23 of the VTO isolated from the seeds of pure big-leafed turnip, rutabaga (Bangholm), and winter turnip rape (Lembke).

II. VTO in silage.

From silage the analysis is made in much the same way as is reported above in connection with the investigation of green parts of plants. Since silage is acid (pH in good silage 3—4) the superfluous acid has to be neutralized first. Such an amount of 1 N NaOH is then added to the juice, obtained from the silage by pressing, that the pH reaches the value 5.5—6. 1.5 ml of the press juice thus treated is pipetted into a Mojonnier flask as well as 0.5 ml of M/15 phosphate buffer, whereafter the analysis is continued in the normal way.

III. VTO in seeds.

1.0 g of finely ground (Willey laboratory mill) seeds are moistened with 5.0 ml of water in a 30 ml beaker, covered with a polytene membrane, and allowed to stand for 9 h at room temperature. The beaker with its contents is heated on a boiling water

bath for 5 min and filtered. The residue on the filter is washed twice with in all 3 ml of hot water. 1.0 ml of the combined filtrates is pipetted into a Mojonnier flask, and the analysis is then continued in the same way as is reported for the analysis of green parts of plants. This time a smaller amount, *e.g.* 100 μl, will, however, suffice in the paper chromatography run.

IV. VTO in milk.

A. Whole milk.

Equipment. Equipments 2 and 3 from section I, and in addition:

4. 3 l and 60 ml separatory funnels.
5. An all-glass vacuum evaporating apparatus with a 1 l flask.

Reagents. 1. Water saturated ethyl acetate.
2. 1 % ammonia.
3. 18 % and 0.5 % acetic acid.
4. Methanol-ether, 1:1.
5. Water-saturated chloroform.

Determination. 300 ml of milk, heated to 85°C and rapidly cooled, is shaken twice with 500 ml of ethyl acetate in a separatory funnel. The combined extracts are evaporated almost to dryness *in vacuo* by slight warming. The residue is treated with 5 ml of 1 % ammonia by gentle shaking and warming in a water bath simultaneously. The ammonia treatment is repeated four times in all. The ammonia extracts obtained are combined and neutralized with 18 % acetic acid to pH 6.5—7.5. Milk fat is removed by treating the extract twice in a separatory funnel with 5 ml of petroleum ether. To avoid emulsion this extraction has to be performed very carefully. The water phase, the volume of which is about 20 ml, is extracted in a small separatory funnel twice with 30 ml of chloroform. The chloroform extract is evaporated to dryness *in vacuo* by slight warming in a 100 ml conical flask. The residue is dissolved in 0.5 ml of hot water and 0.3 ml of it is used in the chromatography run. In the ascending two-dimensional run 1) 0.5 % acetic acid, and 2) methanol-ether, are used as solvents.

A control solution for spectrophotometric measurement is prepared thus that beside the spot of VTO an equally large piece of filter paper is cut out, which piece is then treated in the same way as the spot. The spectrum is measured with a Beckman Spectrophotometer at 220—290 mμ. In calculating the results the extinction value between the maximum point at 240 mμ and the straight line connecting the points at 225 and 260 mμ is used. (E_0, *cf.* Fig. 2).

This extinction value is multiplied with the correction factor 1.16 and the product further with the constant 7.5. The content of VTO in the measuring solution is thus given in μg/ml. The content of the substance to be determined in the milk is obtained when the product is multiplied with the dilution factor.

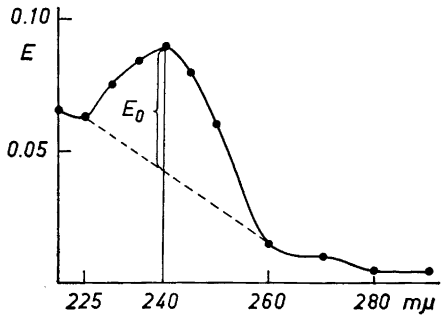

Fig. 2. Extraction curve of the VTO excreted from milk. E_0 used in the calculations, *cf.* text.

B. Skim milk.

This method has been used by Virtanen *et al.*[4]

Equipment and reagents. Equipments 1, 2, and 3 from section I and a 3 l separatory funnel as well as an all-glass vacuum evaporating apparatus with a 1 l flask. Reagents 1, 2, and 4 from section IV and 0.5 % acetic acid.

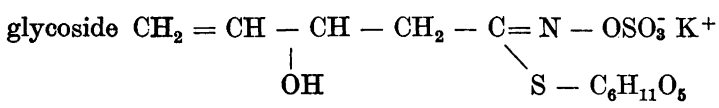
Determination. 500 ml of skim milk is extracted twice in a separatory funnel with 500 ml of ethyl acetate. The acetate is evaporated to dryness *in vacuo* by slight warming, and the residue is treated with 5 ml of 1 % ammonia, and after that also twice with 5 ml of hot water. The extracts are evaporated to dryness in a 100 ml conical flask (vacuum). The residue is washed quantitatively with 2 ml of 0.5 % acetic acid in small amounts into a Mojonnier flask and are shaken twice with 5 ml of ethyl acetate. The ethyl acetate extracts are evaporated to dryness in a 100 ml conical flask (vacuum) and dissolved in 0.5 ml of water. In paper chromatography a two-dimensional ascending run is made from as large a part of the extract as possible in 0.5 % acetic acid and methanol-water. The place for the VTO spot is examined in UV-light whereafter it is cut out from the paper and dissolved in 5 ml of hot water (2 × 2.5 ml). The UV-spectrum is measured at 220—290 mμ. Distilled water is used as control solution. In calculating the results the method described in the section for green parts of plants is used.

RESULTS

Green parts of plants.

Paper chromatograms. In the paper chromatographic run a chromatogram with several spots is obtained from green parts of plants. Fig. 3 shows such a chromatogram. The spot of VTO is marked with S. In the seeds the share of interfering substances is very small although the concentration of VTO is very high.

Enzymatic formation of VTO. VTO is rapidly formed [5] from the progoitrin glycoside



The progress of the reaction can be seen in Fig. 4 which shows experiments performed with (1) rape seeds, and (2) green parts of rape plants.

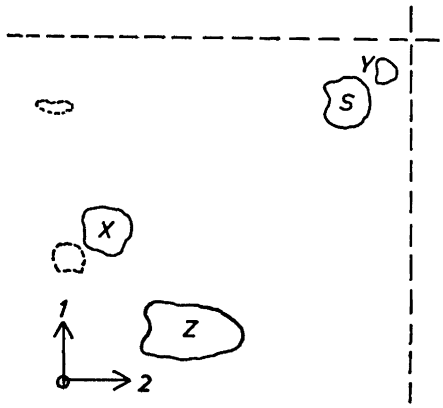


Fig. 3. A two-dimensional paper chromatogram of green parts of winter turnip rape. Solvents used in direction 1: methanol-water, and in direction 2: methanol-ether. Spot S is VTO

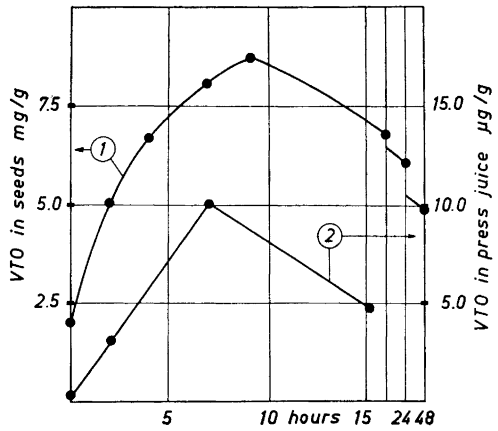

Fig. 4. Enzymatic liberation of VTO at room temperature (1) in crushed seeds and (2) in crushed green parts of Liho rape.

A very rapid enzyme action is obtained when higher temperature is used. In the experiments the maximum value has been obtained after an incubation time of 2 h at 42°C.

The accuracy of the determination of VTO in green parts of plants and seeds. To test the accuracy of the method known amounts of pure VTO was added to the water extract of crushed seeds and to the press juice of fresh as well as preserved green parts of plants. The results of the tests can be seen in Table 1.

The table shows that the developed analytical method worked quantitatively. In the column for µg-amounts in the table pure VTO could also be recovered quantitatively in a determination performed with reagents only.

VTO in the plant material. Using the above methods of determination, the seeds of various cruciferous plants, their green parts, and silage prepared

Table 1. L-5-Vinyl-2-thiooxazolidone contents in water extracts of green parts of rape, silage, and rape seeds as well as the values found after the addition of VTO.

Material	VTO in the extract µg/ml	VTO addition µg/ml	VTO total 1 + 2 µg/ml	VTO found µg/ml	VTO found %

from cruciferous plants by the AIV method, were investigated. Part of the plants were grown in a greenhouse, but the bulk of the samples investigated came from field cultivations, however. The results of the tests are collected in Tables 2, 3, and 4.

VTO in milk.

Whole milk. Preliminary experiments showed that VTO very rapidly disappears in the milk. To eliminate this factor which hampered the determination, milk into which a known amount of the substance was added under different test conditions was investigated. Heating of the milk appeared to be of most decisive importance for the stability of VTO. Also by deep freezing the milk the stability could be improved. An artificial lowering of the pH again had a harmful effect on the yield. The effect of heating and the test temperature is shown in Tables 5 and 6. From the results shown in the tables

Table 5. The effect of heating on the yield of VTO in whole milk. 300 ml of milk heated immediately after the addition of the substance and cooled rapidly.

Treatment °C	VTO		
	Added μg	Yield	
		μg	%

* sour milk.

it appears that about 75 % of the VTO added to milk is recovered, and that hence about 25 % remains as a loss of analysis. A considerable part of this loss is due to the chloroform extraction used in the method, which causes a loss of about 10 %. When the milk is heated to 85°C and is kept at −15°C, the substance to be determined is very stable and even when kept at room temperature it disappears comparatively slowly.

In the experiment with reagents only, 154 μg of VTO were recovered from the 170 μg eluted into 300 ml of distilled water, corresponding to 90.5 % of the amount added.

Skim milk. In order to test the accuracy of the method 110 μg of VTO was added to 500 ml of skim milk the fat content of which was 0.06 %. Of the amount added 84 % were recovered in the analysis. The result corresponds to the yield in the method for whole milk when the methodical loss of 10 % in this method is taken into consideration. When, in addition to fat, casein is also removed from the milk recovery is not improved.

The determinations performed on skim milk or whey do not yet show with certainty the real content of VTO in the milk used in the experiment. Because the substance is fat soluble it can, for instance, be retained in the milk fat to a large extent. This is also indicated by an experiment in which melted milk fat was mixed into a water solution of VTO. When analyzing the water phase after shaking, it did not contain more than 80 % of the original amount of VTO.

A fellowship from the *Finnish Government Scientific Commission (Valtion luonnontieteellinen toimikunta)* to the senior author is gratefully acknowledged.

Proton Magnetic Resonance Studies of Enolised β-Triketones

STURE FORSÉN and MARTIN NILSSON

Research Group for Nuclear Magnetic Resonance, Division of Physical Chemistry and Division of Organic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Triacetylmethane together with some 2-acyl*cyclo*hexane-1,3-diones and the fern pigment ceroptene and its transformation products have been investigated by proton magnetic resonance (PMR) and infrared spectroscopy.

In the PMR spectra, very large shifts ($-\delta_{aq}$ = 12.6–14.1) were observed for the enolic protons, the largest shifts being shown by the conjugated β-triketones. The shifts were correlated with the infrared chelate carbonyl absorptions.

The results indicate that, in solution, ceroptene is present as a mixture of two enol forms of 5-methoxy-2-cinnamoyl-6,6-dimethyl-*cyclo*hex-4-ene-1,3-dione (IV, R = Ph–CH=CH–).

Interest in β-triketones (α-acyl-β-diketones) has been mainly devoted to the 2-acyl*cyclo*hexane-1,3-diones and -1,3,5-triones. These types of β-triketones form an important group of natural products; *cf.* the recent review by Hassall [1].

Our interest in this type of compound arose from work on the natural colouring matter of the fern *Pityrogramma triangularis*. This pigment, ceroptene, was recently investigated by one of us and was shown to be a methyl enol ether of 2-cinnamoyl-6,6-dimethyl*cyclo*hexane-1,3,5,-trione (III, R=Ph–CH=CH–), either 5-methoxy-2-cinnamoyl-6,6-dimethyl*cyclo*hex-4-ene-1,3-dione (IV,R = Ph–CH = CH–) or 3-methoxy-2-cinnamoyl-6,6-dimethyl*cyclo*hex-3-ene-1,5-dione (V, R = Ph–CH = CH–) [2]. Of these, structure IV was considered more likely since the infrared data indicated a pronounced conjugated chelation (*cf.* discussion below) similar to that suggested by Chan and Hassall [3] for 2-acyl*cyclo*hexane-1,3-diones. However the chelate carbonyl absorption (1 515 cm^{-1}) occurred at a lower frequency than any previously reported and it was considered desirable to check this assignment by some independent method.

An opportunity arose of studying this problem by nuclear magnetic resonance as part of the general hydrogen bond research programme of the NMR group at this institute.

To provide background information a survey was made of the hydrogen bonding of some simple β-triketones as well as of ceroptene and its transformation products. The basic compound of the series, triacetylmethane (I), was prepared in a state of purity. 2-Acetyl-5,5-dimethyl*cyclo*hexane-1,3-dione ("acetyldimedone", II, R = CH_3) which was readily accessible by synthesis was taken as a convenient model compound for ceroptene, especially since condensation with aromatic aldehydes afforded conjugated analogues.

METHODS

Proton magnetic resonance measurements. The measurements were made with a Varian V—4 300 NMR spectrometer operating at a fixed frequency of 40 Mc/s and equipped with a Varian V-K 3 506 Super Stabilizer.

The sample cells used in all low concentration measurements were thin-walled glass tubes with a good filling factor [4]. Measurements against an external water standard were made in coaxial glass tubes containing water in the central capillary and the solution to be measured in the annular space. Using the notation of Reilly, McConell and Meisenheimer [5], the concentric tube had the following dimensions: $2\,a = 1.3$ mm, $2\,b = 1.8$ mm and $2\,r = 2.45$ mm.

The resonance shifts were determined in c/s by the audiofrequency sideband method employing a Hewlett-Packard 200 CD Audio Oscillator. The sign of the shift was taken as positive when the resonance occurred at a higher field than that of the water reference. The shift measurements were generally reproducible to within $\pm$ 1 c/s.

Resonance shifts are sometimes discussed in terms of the dimensionless unit δ defined by the expression

$$\delta = 10^6 \frac{H_{\text{sample}} - H_{\text{ref}}}{H_{\text{ref}}}$$

To avoid confusion, the reference substance is specified here by a lower index, *e.g.* δ_{aq}.

Where not otherwise stated the sample temperature was 22 $\pm$ 1°. For the measurement at —30°, an apparatus permitting simultaneous cooling and spinning of the sample was employed.

As has been pointed out by Allred and Rochow [6], diamagnetic anisotropy effects in the interaction between solvent and solute may introduce errors and make the direct comparison of different PMR spectra less satisfactory. Thus benzene is known to cause solvent shifts that vary with the nature of the solute. This is probably due to the magnetic anisotropy effects of the benzene ring [7]. The PMR shifts of all compounds were therefore determined using dilute carbon tetrachloride solutions against an external water standard in order to keep the bulk diamagnetic susceptibility practically constant in all measurements and, also, to eliminate to some extent the anisotropy effects of the solvent.

Infrared measurements. The infrared spectra were recorded on a Perkin-Elmer No 21 instrument using a sodium chloride prism, carbon tetrachloride solutions (*ca.* 0.1 M) and rock salt cells of 0.1 and 1 mm thickness. The solvent absorption was compensated with a Hilger-Watts variable cell. The calibration of the wavelength scale was checked against atmospheric moisture. The frequencies should be accurate to within $\pm$ 5 cm^{-1}. The sample temperature was *ca.* 25°.

MATERIALS

Solvents. For the PMR measurements, carbon tetrachloride (*Merck pro analysi*) was dried over phosphorus(V)oxide and distilled. The benzene used was a redistilled product (*Merck pro analysi*). For the IR measurements, commercial carbon tetrachloride as above was used without further treatment.

Triketones. Melting points were determined on a Kofler block.

3-Acetylpentane-2,4-dione (»triacetylmethane», I). Since there is some discussion in the literature about this compound, the detailed experimental procedure will be given.

A suspension of sodium hydride (1 mole, 50 % in paraffin oil) in dry ether (1 000 ml) was cooled to 0° and acetylacetone (1 mole) in ether (100 ml) was added during 30 min. When hydrogen evolution had ceased, acetyl chloride (1 mole) in ether (100 ml) was added during 30 min. The reaction mixture was left overnight. Water (500 ml) was then added to dissolve the sodium chloride, and the ethereal solution obtained was washed with water and exhaustively extracted with sodium hydrogen carbonate (sat.). The hydrogen carbonate extract was washed thoroughly with ether to remove all traces of neutral material, acidified with dilute sulphuric acid and the triacetylmethane was extracted with ether. The ether extract was washed with several portions of water, dried and evaporated giving crude triacetylmethane (*ca.* 20—25 %) in which no enol acetate could be detected (IR). Distillation gave pure triacetylmethane in 15—20 % yield. For the NMR and IR measurements a fraction was taken of b.p. 85—86°/7 mm, n_D^{25} 1.4893, d_4^{20} 1.096, equiv. wt. 142 (by titration with standard alkali against phenolphtalein; calc. 142). The b.p. has been given as 104°/19 mm [8,9] and the density as d_4^{20} 1.0658 and d_4^{22} 1.0742 [9]. The measurements were made within 24 h of the preparation because of the instability of the compound.

The ether phase remaining after the hydrogen carbonate extraction contained neutral material (*ca.* 60 g, excluding paraffin), which according to its IR spectrum (compare Rasmussen *et al.*[10]), consisted mainly of the enol acetate of acetylacetone. This decomposed both on distillation and on extraction with 2 M sodium hydroxide. Repeated extraction with sodium carbonate (5 %) gave additional quantities of triacetylmethane, thus indicating that the enol acetate is slowly converted to the triketone.

Essentially the same results were obtained using powdered sodium. This shows the correctness of the original work by Nef [8] and also indicates the cause of the aberrant results of Birkenbach *et al.*[9] (see also Schwarzenbach and Lutz [11]).

*2-Acetyl-5,5-dimethyl*cyclo*hexane-1,3-dione* ("acetyldimedone", II, R = CH_3) was prepared according to Dieckmann and Stein [12]. It was purified *via* the copper salt and then distilled, b.p. 132—133°/20 mm, m.p. 36—38°. The authors cited give m.p. 36°.

*2-Cinnamoyl-5,5-dimethyl*cyclo*hexane-1,3-dione* ("cinnamoyldimedone", II, R = Ph—CH=CH—) was prepared by condensation of acetyldimedone with benzaldehyde on the water bath for 1 h using piperidine as catalyst. The product was distilled, b.p. *ca.* 190°/1 mm, and recrystallised from methanol, m.p. 98—100°. Ukita *et al.*[13] report m.p. 96.5°. Yield 50 %.

*2-Hydrocinnamoyl-5,5-dimethyl*cyclo*hexane-1,3-dione* (II, R = Ph—CH_2—CH_2—) was obtained in 70 % yield from cinnamoyldimedone by hydrogenation over palladised charcoal in ethanol. It was recrystallised from *cyclo*hexane and sublimed, m.p. 57—58.5°. (Found: C 74.9; H 7.4. Calc. for $C_{17}H_{20}O_3$: C 75.0; H 7.4.)

*2-(4-Methoxycinnamoyl)-5,5-dimethyl*cyclo*hexane-1,3-dione* was obtained from acetyldimedone and anisaldehyde using piperidine as catalyst. It was recrystallised from methanol and sublimed, m.p. 136—138°. Yield 60 %. (Found: C 71.8; H 6.6. Calc. for $C_{18}H_{20}O_4$: C 72.0; H 6.7.)

*2-(4-Methoxyhydrocinnamoyl)-5,5-dimethyl*cyclo*hexane-1,3-dione* was prepared, in 60 % yield, by hydrogenation of the above compound. It was recrystallised from *cyclo*hexane and sublimed, m.p. 71—72.5°. (Found: C 70.8; H 7.4. Calc. for $C_{18}H_{22}O_4$: C 71.5; H 7.3.)

For details of the ceroptene derivatives, *cf.* Ref.[3]

O-Methyl-3-acetylfilicinic acid. A synthetic product was recrystallised from *cyclo*hexane and sublimed, m.p. 107—109°.

Dihydroceroptene was obtained by hydrogenation of the natural product. It was recrystallised from methanol, m.p. 98—100°.

Ceroptene. Samples of the natural product were recrystallised from methanol, m.p. 137—140°.

RESULTS

Proton magnetic resonance measurements

Triacetylmethane (I). Investigations by Schwarzenbach and Lutz [11] indicate that this compound is completely enolised in aqueous solution. As indicated

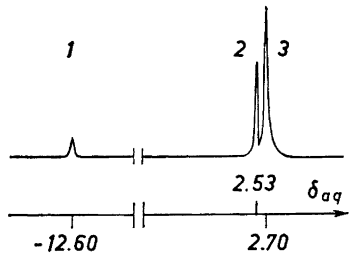

Fig. 1. PMR spectrum of triacetylmethane in carbon tetrachloride (mole fraction $x = 0.1$). Chemical shifts given as δ_{aq}.

above, the "triketo form" discussed by Birkenbach *et al.* [9] is apparently the enol acetate of acetylacetone. The PMR spectrum of the pure liquid showed a minor peak ($\delta_{aq} = 0.3$) which may be due to the central hydrogen atom of the triketo form and corresponds to the presence of *ca.* 5 % of non-enolised material. This signal could not be detected in the spectra of the solutions and it may be concluded that triacetylmethane is almost completely enolised in solution. In the IR spectrum of the pure liquid, there was a shoulder at 1 700 cm^{-1}, possibly also due to the triketo form.

The PMR spectrum of the carbon tetrachloride solution was simple (Fig. 1). Signal 1 was assigned to the enolic proton. The chemical shift was large ($\delta_{aq} = -12.6$) compared with that for acetylacetone ($\delta_{aq} = -10$, *cf.* Reeves [14]). In acetylacetone, the methyl groups are identical in the PMR spectrum and Reeves has attributed this to the rapid movement of the enolic proton along the hydrogen bond. In the PMR spectrum of triacetylmethane, there were two methyl signals (2 and 3) and the intensity ratio was 1:2. Signal 2 was attributed to the methyl group not directly attached to the hydrogen bond system and signal 3 to the two methyl groups adjacent to the intramolecular hydrogen bond. The existence of two separate methyl signals indicated that the interconversion of identical forms (for instance I b and c) was slow.

In benzene solution the methyl signals coincided. This may be due to a solvent anisotropy effect or to the rapid interconversion of identical forms. It was interesting to note that the enol proton signal occurred at a still lower field ($\delta_{aq} = -13.1$).

Acetyldimedone (II, R = CH_3). This compound is known to be completely enolised in both polar and non-polar solvents [3].

The PMR spectra of solutions in carbon tetrachloride, benzene and a mixture of these solvents are shown in Fig. 2. Signal 1 in the first spectrum was considered to be due to the enolic proton. The chemical shift was larger than that for triacetylmethane ($\delta_{aq} = -13.3$). Signal 4 was evidently caused by the gem-dimethyl group since the chemical shift was close to the expected value and the intensity corresponded to six of the fourteen protons. Signal 3 ($\delta_{aq} = 2.69$) judging by its intensity, should correspond to two protons and should therefore be due to a ring methylene group. Signal 2 was at first difficult to explain. The intensity indicated, however, that it was due to five protons. In benzene solution, the magnitudes of peaks 2 and 3 were reversed and, in mixtures of these solvents, they were resolved into three peaks with relative intensities 3:2:2. This clearly indicated that peak 2 in the first spectrum was

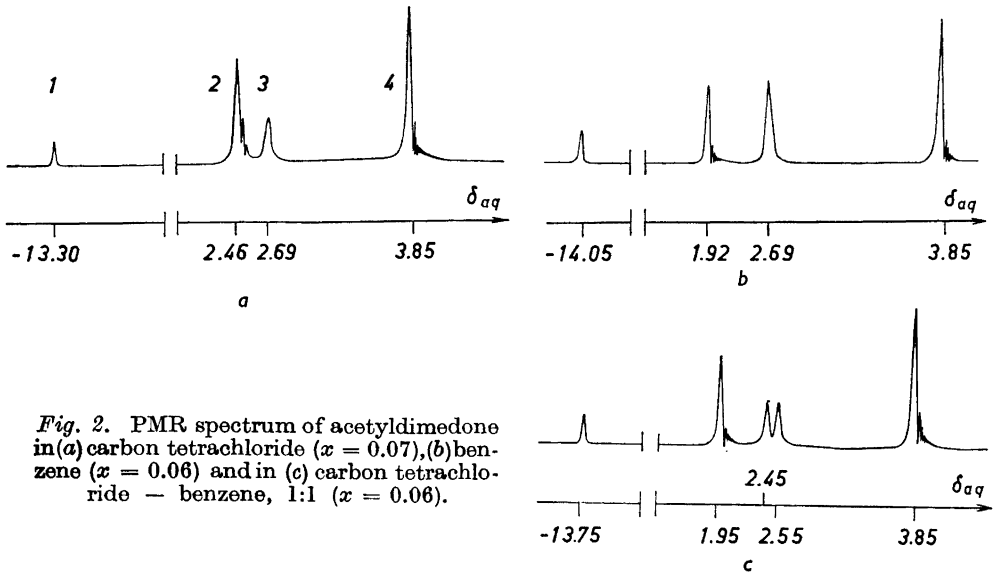

Fig. 2. PMR spectrum of acetyldimedone in (*a*) carbon tetrachloride ($x = 0.07$), (*b*) benzene ($x = 0.06$) and in (*c*) carbon tetrachloride — benzene, 1:1 ($x = 0.06$).

the sum of signals from the acetyl group and one methylene group. In the PMR measurements on the benzene solution, the methylene groups were equivalent; this is analogous to the results obtained with triacetylmethane. The separation of signals 2 and 3 in the carbon tetrachloride solution was not affected by lowering the sample temperature to −30°.

Hydrocinnamoyldimedone (II, R = Ph—CH_2—CH_2—). The PMR spectrum (Fig. 3) was clearly reminiscent of that of acetyldimedone. The protons of the benzene ring and the methylene groups between the rings gave signals at the expected field (signals 2 and 3). The enol proton signal (1) occurred at the same field as in acetyldimedone. Approximately the same splitting and shifts for the methylene groups in the ring (4) were recognised.

Cinnamoyldimedone (II, R = Ph—CH = CH—). In the spectrum for this compound (Fig. 3), the enolic proton appeared as a signal at a very low field ($\delta_{aq} = -13.8$). The gem-dimethyl group gave a signal at the same field as in acetyldimedone (5) and the methylene signals (4) were quite separate. Signal group 2, consisting of two signals of high intensity ($\delta_{aq} = -3.23$ and -3.10,) and two signals of lower intensity ($\delta_{aq} = -3.80$ and -2.70 hidden in signal group 3), possessed the characteristic appearance of two spin-coupled non-identical protons of a —CH = CH— group [15]. The spin-coupling constant, J, was 15 c/s, indicating *trans*-configuration [16]. The PMR spectrum of ethyl cinnamate ($x = 0.1$ in carbon tetrachloride) was recorded for comparison. It showed a spin-coupling constant for the *trans*-ethylenic double bond protons of 16.0 c/s.

The benzenoid protons in cinnamoyldimedone gave a complex signal (3) of the type often obtained from conjugated aromatic nuclei.

4-Methoxycinnamoyldimedone and its dihydroderivative showed no relevant differences and the enol proton resonances occurred at the same fields as those for cinnamoyldimedone and hydrocinnamoyldimedone respectively.

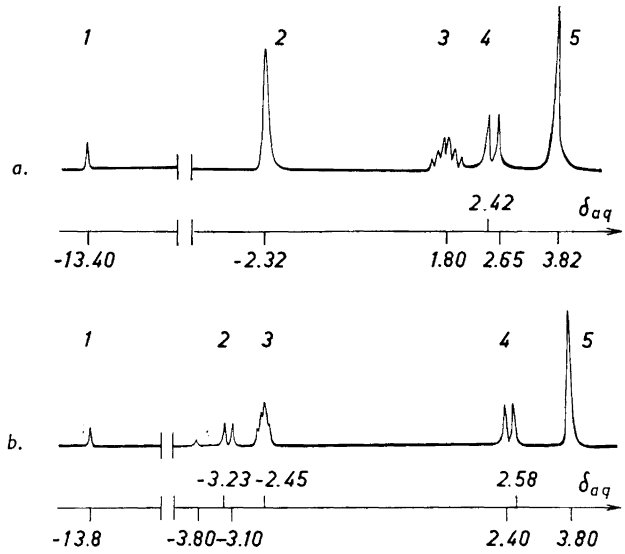

Fig. 3. PMR spectra of (*a*) hydrocinnamoyldimedone ($x = 0.05$) and (*b*) cinnamoyldimedone ($x = 0.04$) in carbon tetrachloride.

O-Methyl-3-acylfilicinic acids. It was shown previously [2] that ceroptene is a methyl ether of 3-cinnamoylfilicinic acid (III, R = Ph—CH = CH—).

3-Acylfilicinic acids could give several methyl ethers; only two are however capable of giving enols with strong intramolecular hydrogen bonds (IV and V). The ether indicated in formula IV in addition to the wholly ketonic form, might also give two different conjugated chelate enols (IV b and c). The ether indicated in V can only give one enol stabilised by strong intramolecular hydrogen bonding (V b). The other form (V c) is of the dimedone type and is unlikely to be present in appreciable amounts in dilute solutions in non-polar solvents. As discussed under triacetylmethane, the movement of protons along the hydrogen bond is very rapid and the corresponding additional forms need no separate discussion.

In previous work [2], it was shown that in ceroptene, dihydroceroptene and O-methyl-3-acetylfilicinic acid the methoxyl group has the same position and thus a choice has to be made between structures IV and V.

O-Methyl-3-acetylfilicinic acid (R = CH_3). The PMR spectrum is shown in Fig. 4. There are five main bands, four of which have small side bands. The ratio of the intensities of side and main bands was fairly constant — 1:6. In benzene solution, the splitting persisted although the side bands were smaller — the intensity ratio was 1:8. The most reasonable explanation for the splitting seems to be that two tautomeric forms are present and that these forms are very similar but not rapidly interconvertible. A change of solvent is likely to change the equilibrium proportions and the rate of interconversion but apparently this rate is low even in benzene. Assignments will be made without reference to the splitting.

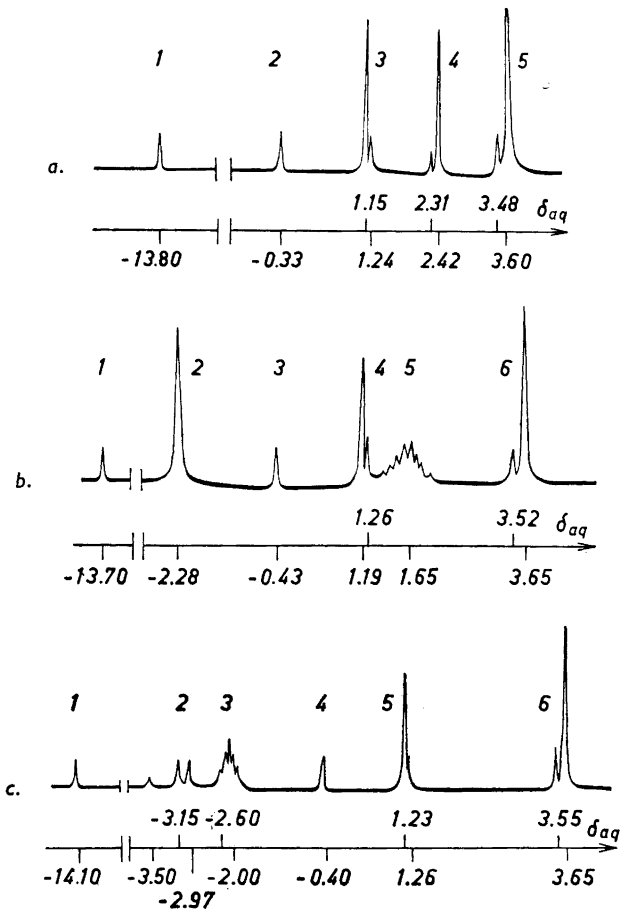

Fig. 4. PMR spectra of (*a*) O-methyl-3-acetylfilicinic acid ($x = 0.05$), (*b*) dihydroceroptene ($x = 0.06$) and (*c*) ceroptene ($x = 0.03$) in carbon tetrachloride.

Signal 1 was found at a very low field ($\delta_{aq} = -13.8$). It was undoubtedly due to the enolic proton. Signal 2 was assigned to the $-CH =$ group of the filicinic acid ring because of the chemical shift and the intensity. Signal 3 was considered to be due to the methoxyl protons. A change of solvent brings about a remarkable displacement of the resonance field ($\delta_{aq} = 1.05$ in carbon tetrachloride solution to $\delta_{aq} = 1.89$ in benzene solution; $\Delta\delta = 0.84$). Similar solvent-dependent shifts have, however, also been observed with aromatic methyl ethers, *e.g.* anisole and guaiacol ($\Delta\delta \approx 1.0$). Signal 4 was assigned to the acetyl group by analogy with acetyldimedone. Signal 5 was found to have approximately double the intensity of signals 3 or 4. Its position in the high field side of the spectrum provided further evidence that it was caused by the gem-dimethyl grouping.

Dihydroceroptene (R = Ph—CH_2—CH_2—). Apart from the "isolated" benzene ring, this compound is analogous to O-methyl-3-acetylfilicinic acid as shown by the almost identical ultraviolet spectra [2]. The similarities recur also in the PMR spectra (Fig. 4). The same splitting of the signals can be observed and the ratio of side band to main band is close to that for the previous compound (1:5). This indicates that the splitting is not due to impurities since the dihydroceroptene was obtained from the natural product whereas the O-methyl-3-acetylfilicinic acid was an independent synthetic product and the same amount and type of impurities cannot be expected to be present in both. In benzene solution, the intensity ratio was 1:4.5.

Signal 1 ($\delta_{aq} = -13.7$) was considered to be due to the enolic proton while signal 2 was assigned to the protons of the benzene ring and peak 3 to the —CH = group of the filicinic acid ring. Signal 4 was caused by the methoxyl group and showed the same solvent displacement as that discussed above. Signal 5 was composed by a number of peaks and undoubtedly was due to the methylene groups between the rings. Signal 6 was due to the gem-dimethyl group.

Ceroptene (R = Ph—CH = CH—). The splitting effects in this spectrum were slightly more marked than those in the two compounds above and the ratio was *ca.* 1:4. No splitting of signal 4 was observed but this was probably due to the low concentration. Ceroptene is not very soluble in carbon tetrachloride and this made it necessary to operate the spectrometer at the sensitivity limit. There was no appreciable splitting of the signals in benzene solution, which may indicate that one of the forms predominates.

Signal 1 was assigned to the enolic proton — it occurred at the lowest field yet reported for a proton resonance signal ($\delta_{aq} = -14.1$).* Signal group 3, consisting of two signals of high intensity and two of low intensity, was analogous to signal group 2 in the spectrum of cinnamoyldimedone. It was therefore attributed to the protons at the *trans*-ethylenic double bond. The spin-coupling constant, J, was 16 c/s. Signal 3 was assigned to the protons of the benzene ring and signal 4 to the proton of the filicinic acid ring. Signal 5 was due to the methoxyl group — it showed a strong solvent dependence. Signal 6 was assigned to the gem-dimethyl group.

Infrared measurements

The following list gives absorptions in the 1 500—1 700 cm^{-1} region with assignments and — in brackets — the approximate molecular extinction coefficients ($mole^{-1}$ 1 cm^{-1}).

All compounds investigated showed a very broad absorption in the region 3 200—1 900 cm^{-1}. It was however weak, ε *ca.* 20), and it was not possible to define a fixed hydroxyl stretching frequency. The chelate carbonyl absorptions were also rather broad and intensity comparisons could therefore be

* The proton involved in the symmetrical hydrogen bond in potassium hydrogen maleate has been found at a still lower field ($\delta_{aq} = -15.40$). Forsén, S. *J. Chem. Phys.* **31** (1959) 852.

misleading. It is not possible in these complicated spectra to make satisfactory measurements of the integrated absorption intensities.

All cinnamoyl derivatives gave absorption close to 1 310 and 970 cm^{-1} due to the *trans* ethylenic double bond.

The data for ceroptene and its transformation products have been taken in part from previous work [2].

DISCUSSION

The concept of conjugated chelate systems was proposed by Rasmussen, Tunnicliff and Brattain [10] to cover the phenomenon of strong intramolecular hydrogen bonding and simultaneous conjugation between the electronegative atoms connected by the hydrogen bond. The term has been used mostly in connection with the interpretation of the infrared spectra of β-dicarbonyl compounds and related substances but has also been extended to cover some intermolecular hydrogen bonding phenomena, *e.g.* in the dimer of dimedone [10]. The applications have been discussed by Bellamy [18]. In the infrared spectra conjugate chelation gives rise to very broad and weak hydroxyl stretching absorptions at low frequencies (in general below 3 000 cm^{-1}) and to carbonyl absorption of unusual intensity shifted to a lower frequency than that for ordinary conjugated carbonyl compounds.

In the present investigation no evidence was obtained for the presence of non-enolised species of β-triketones in solution and it is evident that the β-triketones investigated are completely enolised in solution. The infrared spectra of the solid compounds in potassium bromide discs also indicated complete enolisation.

It is evident from the results obtained that the conjugated chelate system in the enolised β-triketones has rather exceptional properties, which are particularly marked in those compounds where further conjugation is present. Ceroptene appears to have the lowest proton resonance field and the lowest chelate carbonyl absorption frequency yet reported (*cf.* Reeves [14] and Bellamy [18]).

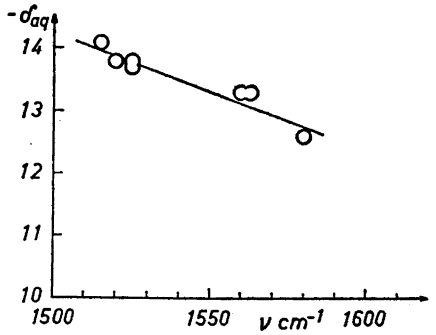

Fig. 5. Correlation of the PMR enol proton shift with the infrared chelate carbonyl frequency.

In Fig. 5, an attempt has been made to correlate the PMR enol proton resonance shifts with the infrared chelate carbonyl absorption frequencies. Although the number of measurements is limited, the general tendency is clear: a large negative enol proton PMR shift is accompanied by a low chelate carbonyl absorption frequency. This indicates a very strong interaction between the enol proton and the carbonyl group and may be taken as a proof that the assignment of the chelate carbonyl absorption is justified. The same conclusion can be drawn qualitatively from a study of the hydroxyl stretching absorption but, unfortunately, these bands are too weak for a quantitative study. Deuteration experiments have been started in order to investigate other hydroxyl absorptions. It has already been found that the rate of hydrogen exchange between acetyldimedone and heavy water is very low. This is in marked contrast to the behaviour of simple β-diketones, *e.g.* acetylacetone, and is an additional indication of the very strong intramolecular hydrogen bonding present.

In a discussion of the enolisation and acidity of carbonyl compounds, Hammond [19] points out that the formation of intramolecular hydrogen bonds and the separation in space of the oxygen atoms are important factors influencing the enolisation of β-dicarbonyl compounds. The first factor is well known and the second is exemplified by the pronounced enolisation of *trans*-fixed β-diketones which cannot form intramolecular hydrogen bonds although the enols may sometimes be stabilised by dimerisation [10].

In β-diketones, these tendencies, however, may work in the same direction since *trans*-conjugation to the non-chelated carbonyl group is possible. That this conjugation is very strong indeed is indicated by the infrared absorption of the non-chelated carbonyl group [3], which occurs at approximately the same frequency as that in dimedone methyl ether [18]. This conjugation effect has also been discussed by Schwarzenbach and Lutz in connection with the acidity of triacetylmethane [11].

The differences between the two unconjugated β-triketones, triacetylmethane and acetyldimedone, are to be expected by analogy with the well-known tendency of cyclic ketones to enolise more readily than the acyclic analogues [19].

The pronounced influence of external conjugation on the properties of the conjugated chelate system could be ascribed in part to steric factors but further experimental material is required for a discussion.

As far as the structure of ceroptene and the choice between structures IV and V for the O-methyl-3-acylfilicinic acids are concerned, the splitting found in the PMR spectra indicates that two enolic species are present in the solutions. The rate of interconversion is apparently low and the equilibrium proportions are dependent on the solvent. As calculated from the relative intensities of the split signals, the equilibrium constants are mostly of the order of 3—8 which means a free energy change of less than 1 kcal/mole. The tautomeric forms must therefore be very similar and the hydrogen bonds should be of approximately the same strength. Since only structure IV permits the existence of two tautomeric enols with intramolecular hydrogen bonds of similar properties (IV b and c), the results strongly indicate that ceroptene is actually 5-methoxy-2-cinnamoyl-6,6-dimethyl*cyclo*hex-4-ene-1,3-dione (IV, R = Ph—CH=CH—). Other structures, such as 5-methoxy-4-cinnamoyl-6,6-dimethyl-*cyclo*hex-4-ene-1,3-dione, which have not been discussed above, are ruled out by these considerations.

Acknowledgements. The authors would like to thank Professor H. Erdtman and Dr. E. Forslind for their kind encouragement and for valuable discussions. Thanks are also due to Miss Gurli Hammarberg for able assistance with the infrared measurements, to Mr. E. Pettersson for assistance with the preparative work and to Dr. D. Gillam and Dr. B. R. Thomas for linguistic criticism. *Atomkommittén, Statens naturvetenskapliga forskningsråd* and *Statens tekniska forskningsråd* have provided financial support for the NMR group. The Chemistry of the Natural Order Cupressales XXIII *

L-Arabinoic Acid from the Heartwood of *Austrocedrus chilensis* (D.Don), Florin et Boutelje

ANDERS ASSARSSON, BENGT LINDBERG and HELMUT VORBRÜGGEN

Institutionerna för träkemi och organisk kemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

L-Arabinoic acid was isolated in the form of the 1,4-lactone from the heartwood of *Austrocedrus chilensis*.

A water soluble carbohydrate fraction was isolated from the heartwood of *Austrocedrus chilensis* (natural order Cupressales) during the course of an investigation by one of us (H.V.) of the terpenoid and phenolic constituents **. A paper chromatographic investigation of this fraction revealed the presence of arabinose and galactose, which are generally found in these woods, and of smaller amounts of other reducing sugars, with both high R_F-values such as rhamnose and fucose, and with low R_F-values, similar to those of di- and trisaccharides. Indications were also found of the presence of several non-reducing carbohydrates, one of which seemed to occur in fairly large amount. This component was enriched by carbon column chromatography and obtained in a pure crystalline state by chromatography on a cellulose column; m.p. 97—99°, $[\alpha]_D$—72°. It gave a positive hydroxamate test for an ester, and the IR spectrum showed a strong peak at 1 760 cm^{-1}, the carbonyl frequency characteristic of a γ-lactone. This data agreed with that reported for L-arabino-1,4-lactone [1]. The m.p. was not depressed on admixture with an authentic sample of that substance and the IR spectra of the two substances were identical.

The 1,4-lactone is in equilibrium with the free acid and the 1,5-lactone, and spots due to these substances were also observed on paper chromatograms of the carbohydrate fraction. It is obvious that all three components occur in

* Part XXI, *Tetrahedron* 4 (1958) 361.

the wood, but the 1,4-lactone, being the most stable, was most easily isolated in a state of purity. The 1,4-lactone was isolated in a yield of about 0.01 % but the total percentage of L-arabinoic acid present both as lactones and as free acid is probably about twice this value.

L-Arabinoic acid has not been found in nature before. It is almost certainly formed by oxidation of L-arabinose, which is present in the wood in a fairly high concentration. Some bacteria [2], especially those of the genus *Pseudomonas*, are known to oxidise L-arabinose to L-arabinoic acid in the presence of air. The possibility that the L-arabinoic acid found in the heartwood of *Austrocedrus chilensis* is not a wood constituent but is formed by bacterial oxidation cannot be excluded but seems highly improbable since this extremely durable wood contains unusually large amounts of the highly toxic α-thujaplicin [3].

EXPERIMENTAL

Melting points are corrected.

Paper chromatography was done on Whatman No. 1 filter paper, using the solvent system (v/v): Ethyl acetate:acetic acid:water, 3:1:3 (upper phase).

The milled, airdried heartwood (40 kg), was extracted with acetone in a continuous extractor for two days. On concentration the extract separated into two layers, a brown oil and a yellow aqueous phase (1.5 l). On cooling, yellow crystals (52 g) separated from the aqueous phase, m.p. 240–241°, which were identified as taxifolin. The mother liquors were concentrated to about 200 ml, treated with decolourising carbon and concentrated to a thick syrup. On crystallisation from methanol this gave L-arabinose (70 g), m.p. 158°, $[\alpha]_D$ + 103°.

The mother liquors, which still contained some phenolic material, were concentrated to dryness. The product obtained was disolved in 50 % aqueous ethanol (1 l) and half of this solution was shaken with decolourising carbon (200 g) for two hours. The carbon was filtered off and washed with the same solvent. Extraction of the carbon with boiling ethanol gave phenolic material (1.5 g) which was not further investigated. The decolourised solution was concentrated and deionised by filtration through columns of IR 120 and IR 4B resins. The acid material recovered from the resin (3.45 g) was found by chromatography to be mainly L-arabinoic acid and its lactones.

The deionised solution was concentrated to a syrup (18.4 g), adsorbed on the top of a carbon-Celite solumn and then eluted with aqueous ethanol, using gradient elution. The first fractions contained traces of cyclitols, and the next contained the majority of the reducing sugars. The fractions following that contained the component that was later found to be the arabino-1,4-lactone. They were combined (7.6 g) and rechromatographed on a cellulose column, using butanol, saturated with water as eluant. The fraction containing the 1,4-lactone crystallised on concentration and was recrystallised from propanol, m.p. 97–99°, $[\alpha]_D^{20}$ −72° (water, *c*, 2).

Authentic L-arabino-1,4-lactone was isolated from the mixture of acid and lactones by chromatography on a cellulose column as above. It melted at 97–99°, alone or in admixture with the natural product.

The authors are indebted to Professor Holger Erdtman for his interest in this work.

Vibrational Mean-Square Amplitude Matrices

IV. Treatment of Tetrahedral X_4 Molecules with Application to Phosphorus

S. J. CYVIN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The theory of mean-square amplitude matrices previously evaluated, is applied to the tetrahedral X_4 molecular model. Numerical values of six mean-square amplitude matrix elements, including two interaction terms, are given for the phosphorus molecule at two temperatures.

In this paper the previously reported theory [1] of mean-square amplitude matrices will be applied to the tetrahedral X_4 molecular model, and numerical values of mean-square amplitude quantities for the phosphorus molecule will be given.

The vibrations of the considered model (Fig. 1) are described by the six interatomic distance deviations. The notations applied for these coordinates, as well as a set of symmetry coordinates, are given by Fig. 1 and the adherent legend. For the F and G matrices in Wilson's [2] notation, that will not be specified here, see Refs.[3,4] The symmetrized mean-square amplitude matrix in the case considered is specified in the following.

Symmetry species A_1: $[\sigma + 4\sigma' + \sigma'']$
Symmetry species E: $[\sigma - 2\sigma' + \sigma'']$
Symmetry species F_2: $[\sigma - \sigma'']$

The symbols here appearing are defined by:

$$\sigma = \overline{r_1^2}, \qquad \sigma' = \overline{r_1 r_2}, \qquad \sigma'' = \overline{r_1 r_4} \tag{1}$$

It should be noticed that σ' and σ'' are the so-called interaction mean-square amplitudes, corresponding to an adjacent and an opposite pair of bonds, respectively. The reported secular equations [1] may in the present case be

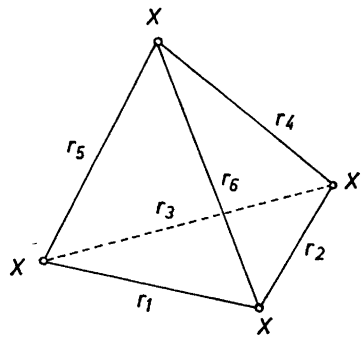

Fig. 1. Notation used for the interatomic distance deviations. Symmetry coordinates:

Symm.species A_1: $S_1 = (1/\sqrt{6})(r_1 + r_2 + r_3 + r_4 + r_5 + r_6)$

Symm.species E: $S_{2a} = (1/2\sqrt{3})(2r_1 - r_2 - r_3 + 2r_4 - r_5 - r_6)$; $S_{2b} = (1/2)(r_2 - r_3 + r_5 - r_6)$

Symm.species F_2: $S_{3a} = (1/\sqrt{2})(r_1 - r_4)$; $S_{3b} = (1/\sqrt{2})(r_2 - r_5)$; $S_{3c} = (1/\sqrt{2})(r_3 - r_6)$

factorized into linear equations, and the following result is found for the symmetrized mean-square amplitude elements.

$$\sigma + 4\sigma' + \sigma'' = 4\Delta_1\mu \quad (2)$$
$$\sigma - 2\sigma' + \sigma'' = \Delta_2\mu \quad (3)$$
$$\sigma - \sigma'' = 2\Delta_3\mu \quad (4)$$

These equations yield the following expressions for the quantities of eqn (1).

$$\sigma = (2\Delta_1 + \Delta_2 + 3\Delta_3)\mu \quad (5)$$
$$\sigma' = (4\Delta_1 - \Delta_2)\mu \quad (6)$$
$$\sigma'' = (2\Delta_1 + \Delta_2 - 3\Delta_3)\mu \quad (7)$$

In eqns (2)—(7) μ denotes the inverse atomic mass. The values of Δ_k ($k = 1, 2, 3$) are connected with the vibrational normal frequencies through the relation

$$\Delta_k = (h/8\pi^2\nu_k)\coth(h\nu_k/2kT);\ k = 1,\ 2,\ 3 \quad (8)$$

Here h is Planck's constant, k is Boltzmann's constant, and T the absolute temperature. ν_1, ν_2 and ν_3 are the normal frequencies belonging to the symmetry species A_1, E and F_2, respectively.

The equilibrium structure of the phosphorus molecule is definitely proved to be the tetrahedral one [5,6]. The evaluation of a complete set of harmonic force constants of this molecule has been given by Pistorius [3], who also made a semiquantitative anharmonicity correction of the observed fundamentals. His corrected values, *viz.* 604, 381 and 506 cm^{-1}, were inserted for ν_1, ν_2 and ν_3, respectively, in eqns (2)—(7). Table 1 shows the numerical values obtained

Table 1. Mean-square amplitude quantities in phosphorus.

Species	Mean-square amplitude (Å²) $T = 0$	298 °K
A_1	0.0036042	0.0040174
E	0.0014284	0.0019687
F_2	0.0021511	0.0025611
Symbol	**Mean-square amplitude (Å²) $T = 0$**	**298 °K**
σ	0.0021524	0.0026064
σ'	0.00036263	0.00034145
σ''	0.00000128	0.00004526

for the six mean-square amplitude quantities at the temperatures $T = 0$ and 298 °K. The mean amplitude of vibration for the interatomic distance is given by

$$u = \sqrt{\sigma} \tag{9}$$

in the present notation. For P_4 at $T = 0$ and 298 °K, Bakken [7] has reported values of u equal to 0.0478 Å and 0.0533 Å, respectively. These values [7,8] were based on vibrational frequencies without anharmonicty corrections, quoted by Herzberg [5]. From the present calculations, the corresponding numerical u-values are 0.0464 Å and 0.0511 Å, respectively.

Added in proof: In connection with the paper of Pistorius [3] it should be noted that Slater was the first one to give a discussion of the most general harmonic force field in phosphorus, including a set of calculated force constants; see: Slater, N.B., *Trans. Faraday Soc.* **50** (1954) 207.

Vibrational Mean-Square Amplitude Matrices

V. Treatment of Bent Symmetrical XY_2 Molecules with Application to Nitrogen Dioxide

S. J. CYVIN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The theory of mean-square amplitude matrices is applied to the bent symmetrical XY_2 molecular model. Numerical computations for nitrogen dioxide are reported, including the calculation of ten mean-square amplitude quantities for $^{14}NO_2$ and for $^{15}NO_2$, both at the temperatures $T = 0$ and 298 °K. An application of the isotope rule for mean-square amplitude matrix elements is also given.

Spectroscopical studies of bent symmetrical XY_2 molecules have been the subject of many publications (see, *e.g.* Refs.[1–6]). In the present article, some of the theoretical results for this type of molecules will be summarized and supplied with the study of the mean-square amplitude matrix. Numerical calculations for nitrogen dioxide will be reported.

THEORETICAL TREATMENT

The harmonic vibrations of the considered molecular model are described by three internal coordinates, which may be chosen as a set of valence force coordinates (see Fig. 1). The following symmetry coordinates have been formed as normalized linear combinations of the valence force coordinates.

Symmetry species A_1: $\begin{cases} S_1 = (1/\sqrt{2})(r_1 + r_2) \\ S_2 = R\alpha \end{cases}$

Symmetry species B_1: $S_3 = (1/\sqrt{2})(r_1 - r_2)$

For the notations applied, see Fig. 1. It should be noticed that the angle displacement coordinate α is multiplied by R, designating the equilibrium X—Y distance.

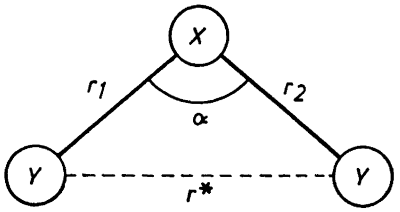

Fig. 1. Notation used for the bent symmetrical XY_2 molecular model. The symbols denote deviations from the equilibrium values.

The potential energy matrix in terms of the given symmetry coordinates may be written

$$F = \begin{bmatrix} F_1 & F_{12} & 0 \\ & F_2 & 0 \\ \text{(symm.)} & & F_3 \end{bmatrix}$$

where

$$F_1 = k + k', \qquad F_2 = f, \qquad F_{12} = \sqrt{2}\, g, \qquad F_3 = k - k' \tag{1}$$

The potential energy function (V) in terms of the valence force coordinates will be written down, in order to explain the symbols used in eqn (1).

$$V = \tfrac{1}{2}[k(r_1^2 + r_2^2) + 2k' r_1 r_2 + fR^2\alpha^2 + 2Rg(r_1 + r_2)\alpha] \tag{2}$$

The inverse kinetic energy matrix (G matrix) will not be given here. References are made to [7–10].

The symmetrized mean-square amplitude matrix [11,12] is given by

$$\Sigma = \begin{bmatrix} \Sigma_1 & \Sigma_{12} & 0 \\ & \Sigma_2 & 0 \\ \text{(symm.)} & & \Sigma_3 \end{bmatrix}$$

where

$$\Sigma_1 = \sigma + \sigma', \qquad \Sigma_2 = \tau, \qquad \Sigma_{12} = \sqrt{2}\,\varrho, \qquad \Sigma_3 = \sigma - \sigma' \tag{3}$$

The symbols introduced here are defind by:

$$\sigma = \overline{r_1^2} = \overline{r_2^2}, \qquad \sigma' = \overline{r_1 r_2}, \qquad \tau = R^2\,\overline{\alpha^2}$$
$$\varrho = R\,\overline{r_1\alpha} = R\,\overline{r_2\alpha} \tag{4}$$

The following equations exist for the vibrational normal frequencies ($\lambda_k = 4\pi^2\nu_k^2$).

$$\lambda_1 + \lambda_2 = F_1(2\mu_X\cos^2 A + \mu_Y) + 2F_2(2\mu_X\sin^2 A + \mu_Y)$$
$$2\sqrt{2}\, F_{12}\mu_X\sin 2A \tag{5}$$

$$\lambda_1\lambda_2 = 2(F_1F_2 - F_{12}^2)(2\mu_X + \mu_Y)\mu_Y \tag{6}$$

$$\lambda_3 = F_3(2\mu_X\sin^2 A + \mu_Y) \tag{7}$$

Here μ_X and μ_Y denote the inverse masses of the X and Y atoms, respectively. The equilibrium value of the inter-bond angle is denoted by $2A$. Another set of equations, containing the mean-square amplitude quantities instead of the force constants, has been evaluated as given below. The values of Δ are connected with the normal frequencies by $\Delta_k = (h/8\pi^2\nu_k)\coth(h\nu_k/2kT)$, where h is Plack's constant, k Boltzmann's constant, and T the absolute temperature.

$$\begin{aligned}\Delta_1 + \Delta_2 = [&\Sigma_1(2\mu_X\sin^2A + \mu_Y) + \tfrac{1}{2}\Sigma_2(2\mu_X\cos^2A + \mu_Y) \\ &+ \sqrt{2}\Sigma_{12}\mu_X\sin 2A](2\mu_X + \mu_Y)^{-1}\mu_Y^{-1}\end{aligned} \tag{8}$$

$$\Delta_1\Delta_2 = \tfrac{1}{2}(\Sigma_1\Sigma_2 - \Sigma_{12}^2)(2\mu_X + \mu_Y)^{-1}\mu_Y^{-1} \tag{9}$$

$$\Delta_3 = \Sigma_3(2\mu_X\sin^2A + \mu_Y)^{-1} \tag{10}$$

Additional mean-square amplitude quantities are to be taken into acconut when the non-bonded Y...Y distance is considered. If the corresponding distance deviations are identified by the symbol r^*, the following mean-square amplitude quantities are defined.

$$\tau^* = \overline{(r^*)^2}, \qquad \varrho^* = \overline{r_1 r^*} = \overline{r_2 r^*} \tag{11}$$

These quantities may be expressed in terms of those given by eqn (4) with the following result, deduced from geometrical considerations.

$$\begin{aligned}\tau^* &= 2(\sigma + \sigma')\sin^2A + \tau\cos^2A + 2\varrho\sin 2A \\ \varrho^* &= (\sigma + \sigma')\sin A + \varrho\cos A\end{aligned} \tag{12}$$

NUMERICAL COMPUTATIONS

Normal frequencies. The normal frequencies [13] applied in the present calculations are shown in Table 1. It should be pointed out that the three frequencies of a specific bent symmetrical XY_2 molecule, say $^{14}NO_2$, are not sufficient for the complete determination of the harmonic vibrational constants.

Table 1. Experimental vibrational frequencies of nitrogen dioxide molecules.

Species	No.	Normal frequencies in cm^{-1} units [a] $^{14}NO_2$	$^{15}NO_2$
	1	1 357.8 [b]	1 343.3 [b]
A_1	2	756.8	747.1
B_1	3	1 665.5	1 628.6

[a] From Ref. [13]; all values are corrected for anharmonicity. The frequencies of $^{15}NO_2$ were revised to fit accurately the product rule with the physical constants here applied, the discrepancies from the values in the cited paper being insignificant.

[b] Based on estimated fundamentals from vibrational analysis.

Table 2. Calculated force constants for nitrogen dioxide.

Symbol	mdyne/Å	Symbol	mdyne/Å
F_1	12.8754	k	10.8840
F_2	1.1290	k'	1.9914
F_{12}	0.51315	f	1.1290
F_3	8.8927	g	0.36285

The value of $2A = 134° 15'$ for the valence angle, quoted in Ref. [13], has also been adopted in the present work.

Force constants. The normal frequency 1 665.5 cm^{-1} (see Table 1) gives the value $F_3 = 8.8927$ mdyne/Å without ambiguity for the force constant of the species B_1. The force constants of the species A_1, *viz.* F_1, F_2 and F_{12}, are going to be discussed in the following. To obtain real values of the force constants consistent with a set of normal frequencies, only limited ranges of the constants are allowed. With the normal frequencies of $^{14}NO_2$ given in Table 1, it is found from eqns (5), (6) for the interaction constant F_{12} in mdyne/Å

$$-0.55788 \leq F_{12} \leq 4.5686$$

All the possible values of the force constants here considered have been represented graphically by an ellipse, this being a usual procedure (*see, e.g.* Refs [3,5,6,14-18]). The stippled curve (see Fig. 2) represents one of the alternative solutions for the force constants, arising from the quadratic secular equation.

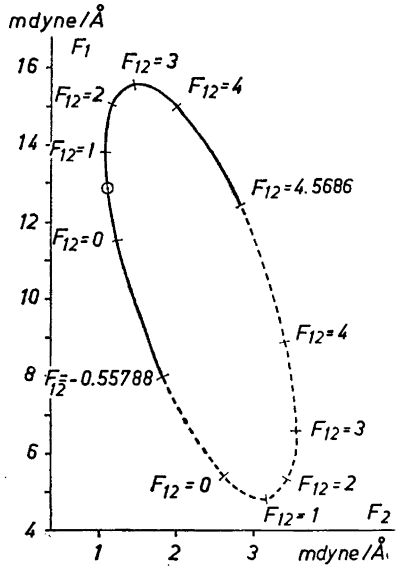

Fig. 2. Values of force constants for NO_2, consistent with $\omega_1 = 1357.8$ and $\omega_2 = 756.8$ cm^{-1}. ⊙ indicates the best calculated values (see the text).

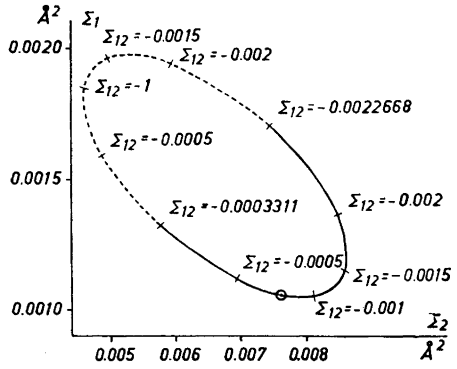

Fig. 3. Values of mean-square amplitude matrix elements at 298 °K for $^{14}NO_2$, consistent with $\omega_1 = 1357.8$ and $\omega_3 = 756.8$ cm^{-1}. ⊙ indicates the best calculated values (see the text).

With the additional knowledge of the normal frequencies of the $^{15}NO_2$ molecule, it is possible to calculate definite values of the force constants. The result of these calculations is given in Table 2, and the values of F_1 and F_2 in particular, are indicated on the curve of Fig. 2.

Mean-square amplitude quantities. An analogous procedure to that of the preceding paragraph is applied to the mean-square amplitude quantities of $^{14}NO_2$ at 298 °K. Eqn (10) gives the value 0.0018612 Å² for Σ_3. From eqns (8), (9), the remaining three mean-square amplitude matrix elements have been calculated and represented graphically in Fig. 3. The range for the interaction mean-quare amplitude in Å² is found to be

$$-0.0022668 \leq \Sigma_{12} \leq -0.0003311$$

The mean-square amplitudes of vibration of the two types of interatomic distances, *viz.* σ and τ^* in the present notation, are the most important ones.

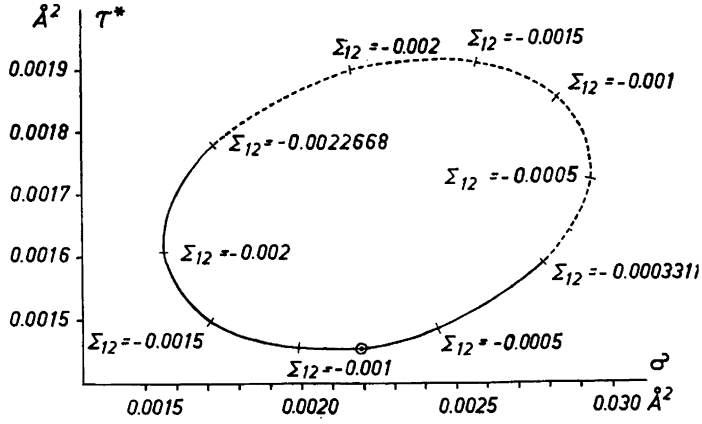

Fig. 4. Values of mean-square amplitudes of vibration at 298 °K for $^{14}NO_2$, consistent with $\omega_1 = 1357.8$ and $\omega_3 = 756.8$ cm^{-1}. ⊙ indicates the best calculated values (see the text).

Table 3. Calculated mean-square amplitude quantities for nitrogen dioxide molecules.

Symbol	Mean-square amplitudes in Å² units for $^{14}NO_2$ $T = 0$	298 °K
Σ_1	0.0010522	0.0010561
Σ_2	0.0072833	0.0076139
Σ_{12}	−0.0007502	−0.0007355
Σ_3	0.0018600	0.0018612
σ	0.0014561	0.0014586
σ'	−0.0004039	−0.0004025
τ	0.0072833	0.0076139
ϱ	−0.0005305	−0.0005201
τ^*	0.0021060	0.0021984
ϱ^*	0.0007632	0.0007709

Symbol	Mean-square amplitudes in Å² units for $^{15}NO_2$ $T = 0$	298 °K
Σ_1	0.0010438	0.0010477
Σ_2	0.0071348	0.0074809
Σ_{12}	−0.0007160	−0.0007026
Σ_3	0.0018187	0.0018201
σ	0.0014312	0.0014339
σ'	−0.0003875	−0.0003862
τ	0.0071348	0.0074809
ϱ	−0.0005063	−0.0004968
τ^*	0.0021249	0.0021975
ϱ^*	0.0007649	0.0007722

These quantities are observable from electron-diffraction (see Ref.[19] and references cited therein), the measurements for nitrogen dioxide being in progress [20]. In the present calculations the quantities in question are obtainable by means of eqns (3) and (12). Fig. 4 shows a graphical representation of all the possible real values of of σ and τ^*.

The best calculated values of mean-square amplitudes were obtained by including the normal frequencies for $^{15}NO_2$. The ten mean-square amplitude quantities defined in this paper were calculated for both $^{14}NO_2$ and $^{15}NO_2$ at the temperatures $T = 0$ and 298 °K. The numerical results are given in Table 3, and some of them indicated on Figs. 3 and 4.

Isotope rules. The normal frequencies given in Table 1 are adjusted to fit accurately the product rule. In consequence, also the isotope rules for mean-square amplitude quantities [11,12] will be fulfilled. In accordance with the theory of the cited papers, one has in the present case

$$\frac{\nu_1\nu_2}{\nu_1^*\nu_2^*} = \frac{\Sigma_1\Sigma_2-\Sigma_{12}^2}{\Sigma_1^*\Sigma_2^*-(\Sigma_{12}^*)^2} = \sqrt{\frac{(2\mu_X+\mu_Y)\mu_Y}{(2\mu_X^*+\mu_Y^*)\mu_Y^*}} \tag{13}$$

$$\frac{\nu_3}{\nu_3^*} = \frac{\Sigma_3}{\Sigma_3^*} = \sqrt{\frac{2\mu_X\sin^2A+\mu_Y}{2\mu_X^*\sin^2A+\mu_Y^*}} \tag{14}$$

Table 4. Mean amplitudes of vibration in nitrogen dioxide molecules.

Molecule	Distance	Mean amplitude of vibration (Å) $T = 0$	298 °K
$^{14}NO_2$	N−O	0.0382	0.0382
	O...O	0.0459	0.0469
$^{15}NO_2$	N−O	0.0378	0.0379
	O...O	0.0461	0.0469

Here the mean-square amplitude matrix elements are referred to the absolute zero. By inserting the appropriate atomic masses according to $\mu_X = 1/14.00754$, $\mu_X^* = 1/15.00489$ and $\mu_Y = \mu_Y^* = 1/16.00000$, and with the value $2A = 134°15'$, the numerical results 1.0239 and 1.0227 are obtained for the respective ratios of eqns (13) and (14). If the interaction mean-square amplitudes are neglected as an approximation, eqn (13) reduces to

$$\nu_1\nu_2/\nu_1^*\nu_2^* \approx \Sigma_1\Sigma_2/\Sigma_1^*\Sigma_2^* = 1.0290 \qquad (15)$$

Mean amplitudes of vibration. In the present notation, the square-roots of σ and τ^* represent the mean amplitudes of vibration for the two types of interatomic distances, such quantities being suitable as parameters in molecular structure studies [19]. In Table 4 the mean amplitudes of vibration from the present calculations for the nitrogen dioxide molecules are given.

Synthesis of Phosphopeptides

II.* O-Phosphorylated Dipeptides of L-Serine

GEORG FÖLSCH

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

Diphenylphosphoryl and dibenzylphosphoryl chlorides have been used for phosphorylation of six N-carbobenzoxy dipeptide benzyl esters of L-serine with amino acid sequences shown to occur in phosphoproteins. Catalytic hydrogenolysis of the dibenzylphosphoryl derivatives yields pure phosphopeptides, whereas the products obtained from the diphenyl analogs frequently contain partially hydrogenolysed derivatives.

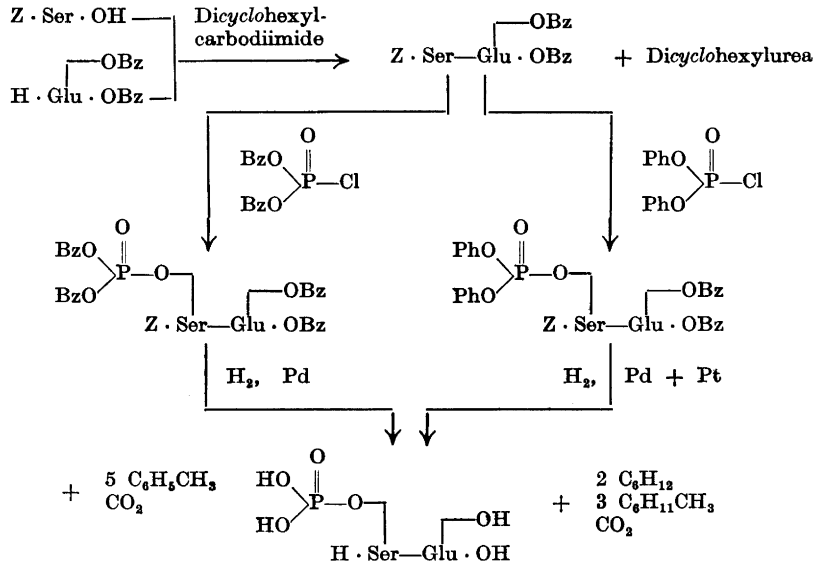
Phosphoproteins and phosphopeptide fractions obtained from phosphoproteins usually have a high content of the two dicarboxylic acids glutamic acid and aspartic acid [1-5], and several peptides have been isolated after degradation of such proteins in which O-phosphorylated serine residues were bound by peptide linkages to these acids. The peptide O-phosphoryl-L-seryl-L-glutamic acid was isolated from casein as early as 1933 [6-7]. Also the reverse sequence, Glu-SerP, seems to be present in casein as well as SerP-Asp apart from other sequences, such as Leu-SerP and SerP-SerP [8-9]. The last-mentioned sequence seems to build up a large portion of phosvitin **, whereas, in pepsin, the lone phosphorylserine residue, again, is bound to glutamic acid in the sequence Thr-SerP-Glu [10]. Finally, after acid hydrolysis, the two phosphorus atoms of ovalbumin are found in the fragments Glu-SerP-Ala and Asp-SerP-Glu, of which only the former is dephosphorylated by prostatic phosphatase [10].

For a more detailed study of the biological and chemical properties of phosphorylated peptides, *e. g.* their behaviour towards different phosphatases and proteolytic enzymes or their metal binding properties [11-17], synthetic preparation of these compounds seemed to be of interest. Synthetic preparation also permits considerable structural variations. In previous papers [17-21], a

* Paper I, see Ref.[20]. Abbreviations and symbols used as previously. The symbol SerP is used for an O-phosphorylserine residue, $-NH \cdot CH[CH_2OPO(OH)_2]CO-$; Z for carbobenzoxy, $C_6H_5CH_2OCO-$; Bz for benzyl, $C_6H_5CH_2$- and Ph for phenyl C_6H_5-groups (*cf.* also Goodman, M. and Kenner, G. W. *Advances in Protein Chem.* **12** (1957) 509–518).

** Mellander, O. and Strid, L. of this laboratory; *Personal communication.*

general route to O-phosphorylated serine peptides, applicable also to threonine peptides [22] has been reported. The synthesis of the L, D and DL forms of O-phosphorylserine [19] as well as of di and tri-peptides of this amino acid and glycine [18,20] were described. In the route followed, the peptide sequence in question is first synthesized by resorting to coupling methods which allow the use of unprotected serine hydroxyl groups. Protecting groups for the amino and carboxyl functions (N-carbobenzoxy groups [23]; benzyl esterification [24]) are selected, which are stable under the conditions of phosphorylation but which afterwards are eliminated by mild treatment (catalytic hydrogenolysis). The compounds so obtained, *i. e.* the N-carbobenzoxypeptide benzyl esters, are then phosphorylated with dibenzylphosphoryl [25] or diphenylphosphoryl [26,27] chloride, and the resulting triesters of phosphoric acid finally catalytically hydrogenolysed into free phosphopeptides, and into the volatile degradation products of the protecting groups, benzene (or *cyclo*hexane in platinum catalysed hydrogenation), toluene (methyl*cyclo*hexane) and carbon dioxide:



Such procedures are avoided as much as possible, that are suspected of causing racemization, hydrolysis of phosphate ester or peptide bonds, and acyl migrations [28-29] or β-elimination [22], *e. g.* treatment with strong acids or alkalies. The present paper describes the use of this procedure in the synthesis of six dipeptides of O-phosphorylated L-serine, combined with L-glutamic acid, L-aspartic acid and L-leucine.

DIPEPTIDE DERIVATIVES OF L-SERINE

The N-*carbobenzoxy dipeptide benzyl esters* required for the phosphorylation were prepared from N-carbobenzoxyamino acids [23] and amino acid benzyl

esters by the application of the carbodiimide procedure [30-31], which, besides its simplicity, allows the use of unprotected serine hydroxyl groups. The yields obtained by this procedure are frequently excellent, providing acylurea formation [30-32] can be avoided. For this purpose a mixture of tetrahydrofuran and acetonitril as recommended by Zahn and Diehl [32], was used as solvent in couplings with N-carbobenzoxy-L-serine, and in no case could a formation of N(N-carbobenzoxyseryl)-N,N'-di*cyclo*hexylurea [32] be observed. Couplings with more soluble carbobenzoxy derivatives were made in a methylene chloride solution. Although serine is considered to be one of the most easily racemizing α-amino acids [33], no signs of racemization were observed in the coupling reactions, a fact which supports the general view that N-acylamino acids, in contrast to N-acyl peptides, produce fully optically pure compounds when coupled by the carbodiimide or mixed anhydride procedure *. It should, however, be kept in mind, that minor quantities of diastereoisomers possibly formed may be eliminated in the isolation and purification of the reaction product, as the solubility of diastereoisomeric peptide derivatives is often sufficiently different to allow their separation (*cf.* the following paper [21]). The optical purity of two of the protected peptide derivatives was clearly demonstrated by hydrogenolysis forming the free peptides L-seryl-L-glutamic acid and L-seryl-L-serine, which had already been prepared by the *azide procedure* [38-39]. The additional four dipeptides of L-serine, obtained in the present work, had not been previously reported. The peptides and their protected derivatives are listed in Tables 2 and 3.

PHOSPHORYLATION OF PROTECTED L-SERINE PEPTIDES AND HYDROGENOLYSIS OF THE TRIESTERS OBTAINED

Among the various methods of phosphorylation reported in the literature, only those could be considered at the present time, in which a monofunctional phosphoryl chloride [25-27, 40-42] or a suitably protected pyrophosphate [43-45] was used for the phosphorylation of the free hydroxyl groups. Diphenylphosphoryl and dibenzylphosphoryl chlorides were used exclusively for the experiments, owing to their availability and simplicity in operation.

A. Peptide derivatives of diphenylphosphoric acid

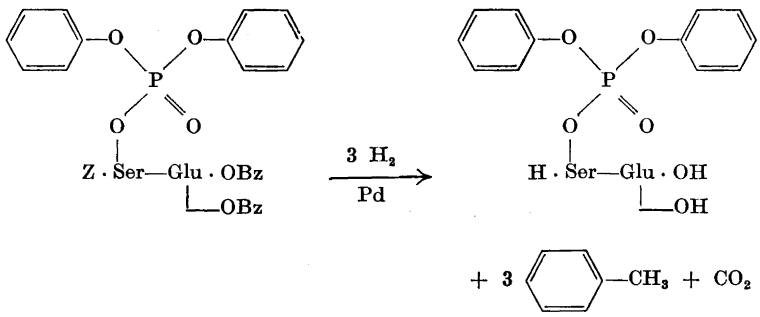
Diphenylphosphoryl chloride reacts readily with primary (serine) and secondary (threonine) alcohols, yielding 90 % or more of O-diphenylphosphoryl derivatives [17, 19-22]. For the conversion of such triesters into free O-phosphorylated amino acids and peptides, two different routes have been reported. Riley *et al.*[22] have used alkaline dephenylation with simultaneous saponification of carboxylic ester groups, the N-carbobenzoxy group having first been removed

* Partial racemization has been observed when N-acylated peptides have been coupled by these methods [34-36]. On the other hand, two tetrapeptide derivatives were recently condensed by carbodiimide, yielding an apparently optically pure octapeptide derivative [37].

with hydrogen bromide in glacial acetic acid. Keeping the well established sensitivity of serine peptide derivatives to alkali in mind * the low yields of the two phosphopeptides obtained by this process, H·SerP-Gly·OH and H·SerP-Glu·OH and the low melting point of the former and optical rotation of the latter as compared with the compounds prepared by hydrogenolysis may be explained. Furthermore, this route can be used for *N-terminal* O-phosphorylserine peptides only, as a free α-amino group at the phosphorylated serine residue is necessary to avoid the β-elimination reaction in alkaline solution [22].

A second method for the removal of the phenyl, benzyl and N-carbobenzoxy groups consists in applying catalytic hydrogenolysis. Although exceptionally mild conditions can be used in such a case, this route shows a disadvantage in the difficulty by which complete hydrogenolytic removal of the phenyl groups is obtained [17, 19–21].

The hydrogenolysis of diphenylphosphorylated derivatives of amino acids and peptides is usually performed in two stages, first using a palladium catalyst and then a platinum catalyst [19,49]. It has been stated [50], that only benzyl groups are eliminated by *palladium-catalyzed* hydrogenolysis:

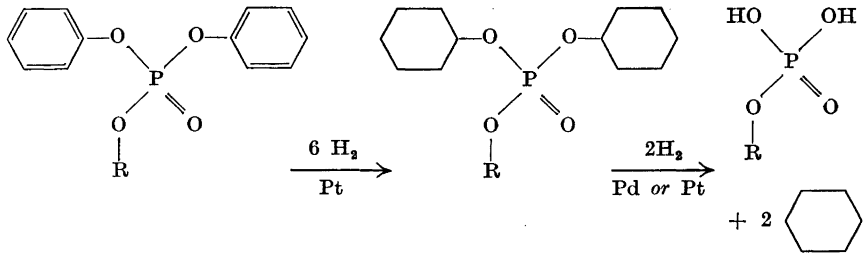


Mostert *et al.* [50] suggest that the claimed inertness of phenylic esters to H_2/Pd/C depends on the fact that the phenyl ring has to be converted to *cyclo*hexyl derivative prior to elimination, and that only platinum ** catalyzes this ring hydrogenation. (see p. 1411).

Our work does not confirm the *absolute* selectivity of the palladium (on charcoal) catalyst, but the cleavage of phenyl groups seems to be very slow, as indicated, for example, in the following experiment. Palladium catalyzed hydrogenolysis of O-diphenylphosphoryl-N-carbobenzoxy-DL-serine benzyl ester [19] in ethanol-water solution was followed by measuring the hydrogen

* Saponification of N-carbobenzoxypeptide esters containing serine frequently produces low yields of carbobenzoxypeptide owing to side reactions [46-47]. *Selective* racemization of the serine residue in N-carbobenzoxy-L-serylglycyl-L-alanine ethyl ester has been produced by treatment with triethylamine [48].

** The palladium catalyst of Kuhn and Haas, which catalyzes hydrogenolytic cleavage of N-aryl groups has been shown to catalyze ring hydrogenation of several aromatic compounds [51].



uptake and by paper chromatographic analysis, the results of which are shown in Table 1.

Table 1.

Reaction time in min	Hydrogen consumption ml (moles)	Derivatives of serine identified by paper chromatography		
		Diphenyl-phosphoryl	Monophenyl-phosphoryl	O-phosphoryl
10	200 (1.8)	++++	0	0
20	235 (2.05)	++++	Traces	0
60	245 (2.1)	+++	+	0
180	250 (2.2)	+++	++	Traces

From the final product 56 % of recrystallized O-diphenylphosphoryl-DL-serine was isolated. The appearance of monophenyl derivative after prolonged reaction time is very probably a result of hydrogenolytic cleavage and not of hydrolysis *, since diphenylphosphorylserine is comparatively stable in neutral solution. In alkaline solution **, however, phosphate is readily released (Fig. 1).

Results obtained by palladium catalyzed hydrogenolysis of peptide derivatives are very similar although hydrolysis forming unphosphorylated peptide and free amino acids thereby seems to occur to a somewhat greater extent as evidenced by paper chromatography.

Platinum catalysts have been successfully used for hydrogenolytic cleavage of numerous O-diphenylphosphorylated sugar derivatives. Complete removal of the phenyl groups of O-diphenylphosphorylated peptide derivatives, however, is very difficult ***. Appreciable amounts of O-monophenylphosph-

* Bevan *et al.*[52] obtained *O-monophenylphosphoryl* derivatives in similar experiments either with a palladium or platinum catalyst.

** Zervas and Katsoyannis [53] converted N-diphenylphosphorylated amino acid derivatives to N-monophenylphosphorylated compounds by treatment with barium hydroxide. Similar results have been obtained by Moffatt and Khorana [45].

*** Moffatt and Khorana [45] observed a similar difficulty in the hydrogenolysis of di-*p*-nitrophenylphosphorylated derivatives, the addition of a strong acid, such as hydrochloric acid, being necessary to eliminate the aryl group from the mono-*p-amino*-phenyl-phosphoryl derivatives initially formed.

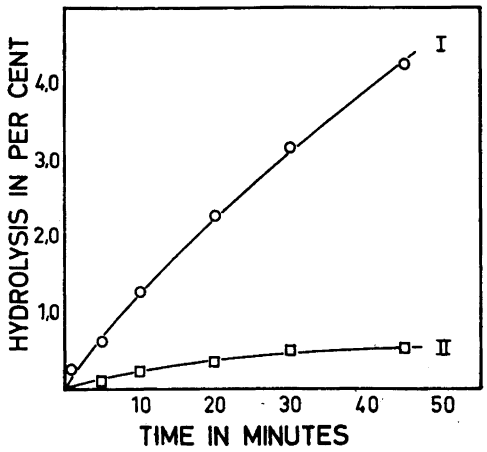


Fig. 1. Release of phosphoric acid from 0.01 M solutions of O-diphenylphosphoryl-DL-serine (I) and O-monophenylphosphoryl-DL-serine (II) at pH 9.5 (0.1 M ethanolamine — hydrochloric acid buffer) and 25°. Phosphorus determined according to Beerenblum and Chain, *Biochem. J.* **32** (1958) 295.

orylated peptide remain unaffected after hydrogenolysis with palladium on charcoal as catalyst, removal of this catalyst together with possibly occurring catalyst poisons and the repeated hydrogenolysis with platinum oxide as catalyst, regardless if acetic acid, ethanol-water or ethanol-water-hydrochloric acid is used as the solvent. This incomplete hydrogenolysis cannot be the result of insolubility [52], since several monophenylphosphorylated derivatives, *e.g.* those of serylglutamic and serylaspartic acid, are easily dissolved by the solvents used. Furthermore, isolated and purified monophenylphosphorylated derivatives are rapidly and completely hydrogenolysed to form free phosphopeptides in either of these solvents.

B. Derivatives of dibenzylphosphoric acid

In contrast to the diphenylphosphates, *dibenzylphosphorylated* derivatives [54] of peptides are rapidly and completely hydrogenolysed to form free phosphopeptides in a single stage, using a palladium catalyst. Although it has been stated to the contrary [55], dibenzylphosphoryl chloride does react with serine hydroxyl groups [18]. By careful working at low temperature the triester yield will be as high as 75 %. Some of the triesters have been obtained in a crystalline state (Table 5). They can rapidly be hydrogenolysed with the use of palladium on charcoal as catalyst, 1/2—2 h being sufficient. As a consequence of the rapid hydrogenolysis, very slight hydrolysis, if any, takes place. The yield of purified phosphopeptide is about 80 %, which corresponds to an overall yield of about 40 %, calculated from L-serine.

PURIFICATION AND PROPERTIES OF O-PHOSPHORYLATED PEPTIDES

The only by-products observed when preparing phosphopeptides *via* hydrogenolysis of dibenzylphosphorylated derivatives have been traces of unphosphorylated peptides and amino acids. By recrystallization, or by

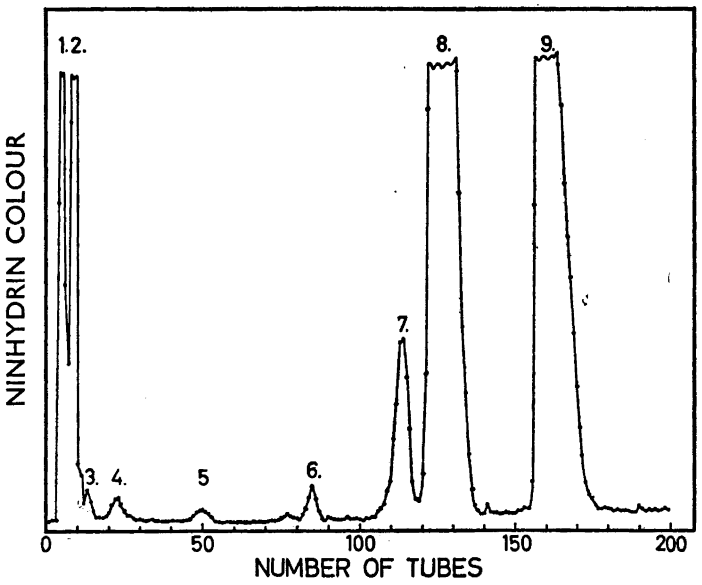

Fig. 2. Anion exchange chromatographic separation of the products obtained by platinum catalyzed hydrogenolysis of O-diphenylphosphoryl-N-carbobenzoxy-L-seryl-L-glutamic acid dibenzyl ester, as indicated by quantitative ninhydrin reaction. The two main products are: (8)O-phosphoryl-L-seryl-L-glutamic acid and (9) its monophenyl derivative. Fractions (5) and (6) are probably glutamic acid and O-phosphorylserine. Fraction 7 has not been identified.

treatment in water solution with a cation exchange resin (Amberlite IR 120 or Dowex 50, H^+-form), followed by evaporation and recrystallization (or precipitation), the phosphopeptides are easily obtained in a chromatographically and analytically pure state.

The reaction products obtained after hydrogenolysis of O-diphenylphosphorylated derivatives contain variable amounts of amino acids, unphosphorylated and monophenylphosphorylated peptides in addition to the desired phosphopeptides (Fig. 2). The latter have in several cases been successfully purified by fractional crystallization, with or without additional use of cation exchange resin [17, 19-20]. Several O-phosphorylated peptides, especially those of the more acidic type, containing glutamic and aspartic acid, however, are hygroscopic compounds and therefore difficult to crystallize. Separation of the reaction products is then most successfully accomplished by chromatographic procedures. Partition chromatography on cellulose has been applied to the reaction products obtained by hydrogenolysis of O-diphenylphosphoryl-N-carbobenzoxy-DL-serylglycine benzyl ester, using *n*-butanol-acetic acid-water as an eluent *. Another process [57], using anion exchange resin, has also been successfully used in several cases in this laboratory, (*cf.* Fig. 2).

* The author, unpublished experiments. Jones and Lipkin [56] have used acetone-acetic acid-water for similar purposes.

Purification of phosphorylated peptides may also be achieved, with the use of barium, lead and brucine salts [6,7,22].

Among the peptides reported in this paper, the O-phosphoryl-L-seryl-L-glutamic acid (compound 13, Table 4) may be of special interest, being the first phosphopeptide isolated from casein. The peptide isolated by Levene and Hill [6] and by Schmidt [7] was shown by Posternak and Pollaczek [11] to have the serine in N-terminal position, since this amino acid was absent in the hydrolysate of the peptide subsequent to deamination with nitrous acid. The analytical data of the barium and brucine salts, and the melting point of the latter, 171—172°, were reported. Riley *et al.* [22] have obtained this phosphopeptide by the alkaline dephenylation process mentioned above. Their peptide, isolated as the barium salt, $[\alpha]_D^{22}$ —1.3° (1 N HCl, *c* 3.12), was converted to free peptide, m.p. 145—147°, and to the brucine salt, m.p. 160—162°.

Our compound (13) which does not posess a sharply defined melting point but sinters at about 145° without decomposition has a much higher value of optical rotation, $[\alpha]_D^{21}$ —9.5°±0.5° (1 N HCl, *c* 4.2, *l* 1). Although this higher value, by no means, is proof of higher optical purity in view of the fact that two asymmetric centers are present, a comparison with the rotation of unphosphorylated L-seryl-L-glutamic acid (compound 7, Table 3) indicates that the value of rotation appears to have the correct magnitude since substitution of the β-hydroxyl group in serine peptides with phosphoric acid has little influence on the *molar* rotation. Compound (13) was also converted to its brucine salt, which, after a single recrystallization from water-acetone, melted at 171—173° with decomposition, thus confirming the results achieved by Levene and Hill. The action of intestinal alkaline phosphatase on O-phosphorylated peptides and their derivatives [16], and the acid hydrolysis [58] and acid ionization constants [17] of some of the phosphopeptides have been reported elsewhere.

EXPERIMENTAL

Where not otherwise stated, the compounds were dried at room temperature *in vacuo* over phosphorus pentoxide. The melting points were determined by the use of capillary tubes and are uncorrected. In the matter of paper chromatography on Whatman No. 1 paper, the following solvent systems were used: (I) Phenol-water (80/20 v/v), ascending, 6 h and (II) *n*-butanol-acetic acid-water (40/10/50/ v/v), descending, 18 h (cf. Table 6).

L-Serine benzyl ester

The racemic form of serine benzyl ester has been prepared by various procedures [22,32,55,59]. The pure optical antipodes have been obtained as hydrochlorides after separation of the dibenzoyl-D-tartrates [59]. The L-form was prepared in this laboratory several years ago by the process evolved by Cipera and Nicholls [60]:

a) *Benzenesulphonic acid salt.* A mixture of 4.2 g (40 mmoles) of L-serine, 8.0 g (44 mmoles) of recrystallized benzenesulphonic acid and 20 ml of benzyl alcohol was distilled with carbon tetrachloride on a water bath until no more water was formed (3—5 h). The ester salt was precipitated with dry ether and was, after some hours at +4°, filtered off, washed with ether and dried. The yield amounted to about 13.5 g, m. p. 85—90°. After recrystallization from *i*-propanol-ether, 10.2 g (72 %), m. p. 110—112° was obtained. (Found: N 4.1. Calc. for $C_{16}H_{19}O_6NS$ (353.4): N 4.0.) The reaction product is frequently difficult to crystallize, since no doubt by-products caused by, for example, selfesterification (forming O-peptide derivatives,) and O-benzylation [32] are formed.

b) p-*Toluenesulphonic acid salt.* With the use of the above process, but employing *p*-toluenesulphonic acid monohydrate instead, 11.0 g (75 %) of recrystallized L-serine benzyl ester *p*-toluenesulphonate, m. p. 94—95°, was obtained. (Found: N 3.8. Calc. for $C_{17}H_{21}O_6NS$ (367.4): N 3.8.)

c) *Hydrochloride,* prepared from a) and b). To a cold solution of 10 mmoles of a) (3.5 g) or b) (3.7 g) in 20 ml of chloroform and 1.4 ml (10 mmoles) of triethylamine, 100 ml of dry ether was added. The cooled and filtered solution was then saturated at 0° with hydrogen chloride. The precipitate was collected and recrystallized from *i*-propanol-ether, yielding 1.7 g (74 %), m. p. 172—174°, $[\alpha]_D^{21}$ −4.1° ± 0.5° (Methanol, *c* 4.4, *l* 1); reported [59] $[\alpha]_D^{20}$ −4.19° (Methanol, *c* 4.53). (Found: N 6.1. Calc. for $C_{10}H_{14}O_3NCl$ (231.7): N 6.1.)

N-Carbobenzoxy dipeptide benzyl esters

Procedure a) To a solution of 20 mmoles of an amino acid benzyl ester salt (L-serine benzyl ester benzenesulphonate, 7.1 g; L-leucine benzyl ester *p*-toluenesulphonate [61], 8.7 g; L-aspartic acid dibenzyl ester *p*-toluenesulphonate [61], 8.7 g ; L-glutamic acid dibenzyl ester *p*-toluenesulphonate [61], 9.0 g), 2.8 ml (20 mmoles) of triethylamine and 4.8 g (20 mmoles) of N-carbobenzoxy-L-serine [47] in 80—100 ml of tetrahydrofuran-acetonitril (1:1), was added 4.2 g (20 mmoles) of di*cyclo*hexylcarbodiimide. On the following day the precipitate of urea derivative was removed by filtration and the solution poured into 2 l of ice-cold water under vigorous stirring. After 4—12 h at +4° the precipitated peptide was collected, dried and recrystallized from ethyl acetate-light petroleum. The compounds obtained are listed in Table 2.

Table 2. N-Carbobenzoxy dipeptide benzyl esters. All compounds are of L—L configuration.

6	Z · Leu-Ser · OBz	86	122—123	$C_{24}H_{30}O_6N_2$, 442.5	6.1	6.3

Procedure b) To a solution of 7.1 g (20 mmoles) of L-serine benzyl ester benzenesulphonate and 2.8 ml (20 mmoles) of triethylamine in 100 ml of methylene chloride was added, first, 20 mmoles of a carbobenzoxy derivative (N-carbobenxoxy-L-leucine, 5.3 g; N-carbobenzoxy-L-glutamic acid γ-benzyl ester [62], 7.4 g) and then 4.2 g (20 mmoles) of di*cyclo*hexylcarbodiimide. On the next day the solution was filtered, washed with hydrochloric acid, water, sodium bicarbonate and water, and finally, after drying over sodium sulphate, evaporated to dryness *in vacuo*. The residue was then recrystallized from ethyl acetate-light petroleum (Table 2).

Peptides of L-serine

Catalytic hydrogenolysis of the protected peptides (compounds 1—6; 2—5 mmoles) in ethanol-water solution, using a 10 % palladium on charcoal catalyst, after filtration, evaporation to dryness and recrystallization from water-ethanol, resulted in the free peptides (compounds 7—12) listed in Table 3.

Phosphorylation with diphenylphosphoryl chloride

To a solution of 10 mmoles of an N-carbobenzoxypeptide benzyl ester (compounds 1—3, 5—6) in 10 ml of anhydrous pyridine was added 3.2 g (12 mmoles) of diphenylphosphoryl chloride, the temperature being kept below 40°. In the case of compound

4, only 5 mmoles (2.1 g) were used, the two equivalents of chloride reacting readily with strong heat evolution. After 4 h at room temperature, the excess of acid chloride was destroyed by adding 1 ml of water, and half an hour later the reaction mixture was taken up in 100 ml of water and 100 ml of ethyl acetate. The ethyl acetate layer was washed with cold 5 N sulphuric acid, water, bicarbonate solution and water, then dried over sodium sulphate and evaporated to dryness *in vacuo*. The triesters remained normally as colourless or slightly yellowish oils, of which those obtained from compounds 2 and 5 crystallized spontaneously (*c.f.* Table 5). The yield varied between 90 and 95 %.

Phosphorylation with dibenzylphosphoryl chloride

A solution of 10 mmoles of an N-carbobenzoxypeptide benzyl ester (compounds 1, 3 and corresponding derivatives of LD-serylglycine and glycyl-DL-serine) in 10 ml of anhydrous pyridine was cooled to just above the freezing point in an ethanol-carbon dioxide bath, and dibenzylphosphoryl chloride, prepared from 3.7 g (14 mmoles) of dibenzyl phosphite [25], was added. The mixture was shaken at this temperature for 15 min and then left over nigh at 0°. On the following day the almost colourless solution was worked up as above, yielding 75 % of triesters as colourless oils (if the oils are considered to be 100 % pure; they may contain some unphosphorylated neutral material). Two of them crystallized readily (Table 5).

In early experiments, phosphorylations were made at 0°. The yield of triester was then appreciably lower (about 50 %) and the product always more or less coloured.

Hydrogenolysis of O-diphenylphosphorylated derivatives of amino acids and peptides

$$\text{Z·Ser(OPO(OPh)}_2\text{)·OBz}$$

a) *Palladium catalyzed hydrogenolysis of Z·Ser·OBz.* To a solution of 2.8 g (5 mmoles) of O-diphenylphosphoryl-N-carbobenzoxy-DL-serine benzyl ester [19] in 75 ml of ethanol, water was added to slight turbidity, and hydrogenolysis started with 0.5 g 10 % palladium on charcoal. The shaking was stopped at intervals for the purpose of taking samples for paper chromatography, and then restarted. The results are shown in Table 1. After 3 h, the catalyst was filtered off and washed with hot acetic acid-water (1:1), the solution evaporated to dryness and the residue recrystallized from acetic acid-water, yielding, in the cold, 0.95 g (56 %) of O-diphenylphosphoryl-DL-serine, m.p. 130−131° (decomp.), reported [19] 129−130°.

b) *Palladium catalyzed hydrogenolysis of O-diphenylphosphorylated peptide derivatives.* In the hydrogenolytic conversion of the triesters obtained from diphenylphosphoryl

chloride and compounds (1—6) to free phosphorylated peptides, palladium on charcoal was used in the first stage as per above. When the hydrogen uptake ceased, the catalyst was filtered off, and the solution and washings were evaporated to dryness. (The residue was then hydrogenolysed with a platinum catalyst as described below (c)). Paper chromatographic analysis of the residue showed at this stage the presence of large amounts of O-diphenylphosphorylated peptides, one of which was isolated and purified by recrystallization (comp. 23). Appreciable quantitites of other ninhydrinpositive compounds were also present.

c) *Platinum catalyzed hydrogenolysis.* The palladium-hydrogen treated product above (b) was dissolved in glacial acetic acid and rehydrogenolysed, now with Adams platinum oxide as catalyst. After an initial rapid hydrogen consumption lasting from 1/2 to 2 h, the reaction slowed down, and after 4—8 h no further hydrogen was consumed. The addition of a new catalyst or water had no marked effect. The filtered solution was evaporated to dryness and the residue analyzed by paper chromatography. In addition to the desired O-phosphorylated peptide, and its monophenylphosphoryl derivative, hydrolysis products were present. Re-hydrogenation with new catalyst in either acetic acid, ethanol-water or ethanol-water-hydrochloric acid did not increase the yield of phosphopeptide. Pure phosphopeptides (compounds 13—18, Table 4) were obtained by treatment in water solution with cation exchange resin (Dowex 50, H^+-form), evaporation to dryness and repeated recrystallization or precipitation from water with ethanol-ether. Compounds 13, 14, 16, 24 and 25, being difficult to obtain chromatographically pure by this method, were also obtained by separation of the products of hydrogenolysis by anion exchange column chromatography on a 2 × 30 cm column of Dowex 1, X 2 resin in formate form, using gradient elution with pyridinium formate [57]. The fractions emerging from the column were tested by quantitative ninhydrin reaction and the peaks

* $R_{ser} = \frac{R_F \text{ for the compound}}{R_F \text{ for serine}}$. Solvent systems used for the paper chromatography are (I) phenol-water (80/20 v/v) and (II) *n*-butanol-acetic acid-water (40/10/50 v/v). R_F for serine is (I) 0.35; (II) 0.18.

thus obtained (Fig. 2) analyzed by paper chromatography. Those fractions containing phosphopeptide or monophenylphosphorylated peptide were evaporated to dryness *in vacuo*. The residues, probably being monopyridinium salts as indicated by elementary analysis, were dissolved in a small volume of water and converted to free acid by passage through a small column of Dowex 50 (H^+) resin and then lyophilized (Tables 4 and 5).

d) *Rehydrogenation of O-monophenylphosphorylated derivatives.* The solution of 1 mmole of compounds (24—26) in 15 ml of glacial acetic acid, water or ethanol-water was shaken with 0.1 g of platinum oxide in an atmosphere of pure hydrogen. Complete removal of the phenyl group was effected in 1/2—2 h, as shown by paper chromatography and by isolation of pure phosphopeptide in about 85 % yield by evaporation to dryness of the filtered solution.

When left for shaking in solvents containing water, appreciable hydrolysis into unphosphorylated peptide and into amino acids occurred, as found by paper chromatography.

Preparation of O-phosphorylated peptides from O-dibenzylphosphorylated derivatives

A solution of 5—10 mmoles of an (oily or solid) O-dibenzylphosphoryl-N-carbobenzoxy dipeptide benzyl ester in 75—100 ml of ethanol, water being added to slight turbidity, was shaken together with 0.5—1 g of 10 % palladium on charcoal in an atmosphere of pure hydrogen. In the first hour, at least 85 % of the theoretical amount of hydrogen (4—5 equiv. H_2) was absorbed, and the reaction was normally completed within a further hour, no more hydrogen being used. The catalyst was filtered off and washed with a small amount of hot distilled water, and the filtrate and washings evaporated to dryness. The crystalline residue was washed with acetone or ethanol-ether, and dried. Paper chromatography of the product showed the presence of traces of unphosphorylated peptide and (or) free amino acids. In the case of well crystallizing compounds such as H·SerP—Gly·OH [18, 20, 22] H·Gly—SerP·OH [20] and H·SerP—Leu·OH (compound 15), one or two recrystallizations from hot water-ethanol produced chromatographically and analytically pure phosphopeptides. Since H·SerP—Glu·OH (compound 13) did not crystallize well from solvents containing water * it was purified as follows. The solution

* No other solvents have been found sufficiently effective; although boiling methanol dissolves appreciable amounts of phosphopeptides, we cannot at the present time exclude the possibility of partial esterification of these strongly acidic compounds.

of 1.0 g in 40 ml of water was shaken with 2 ml of Dowex 50 cation exchange resin (H^+-form) for 10 min. The mixture was then filtered through a column, the resin washed with 5 ml of water and the solution evaporated to dryness, yielding 0.9 g. The compound was dissolved in 4 ml of water and precipitated with 25 ml of ethanol and 25 ml of ether, the yield of collected and dried precipitate of pure phosphopeptide then being 0.85 g (Table 4).

Brucine and barium salts of H·SerP-Glu·OH

a) *Brucine salt.* The solution of 0.95 g (3 mmoles) of compound 13 (Table 4) in 25 ml of water was treated with an excess of brucine (5 g) dissolved in 25 ml of methanol. Further 75 ml of water was added, and the excess of brucine extracted with 3 × 30 ml of chloroform. The water solution was filtered and evaporated to dryness, and the remaining crystalline product recrystallized by dissolving in 15 ml of water and adding aceton at the boiling point. After 4 h at +4°, the compound was collected and dried, the yield then being 2.3 g, m.p. 171—173° (decomp.), after a slight change in colour at 165°. (Found: N 7.9. Calculated, according to Levene and Hill [6], for the *mono*brucine salt, $C_{31}H_{41}O_{13}N_4P$ 708.7): N 7.9.)

b) *Barium salt.* The above brucine salt (2.0 g) was dissolved in 25 ml of water and neutralized (to phenolphthalein) with barium hydroxide solution. The precipitate of brucine was extracted with chloroform, the water solution concentrated *in vacuo* to 35 ml and the barium salt of compound 13 precipitated with 100 ml of ethanol. After centrifugation and reprecipitation from 50 ml of water with 50 ml of ethanol, the salt was collected by centrifugation and dried, yielding 0.9 g. (Found: N 5.4. Calculated for the tribarium salt $(C_3H_9O_{10}NPBa)_2Ba$ (1034.4): N 5.4.)

Synthesis of Phosphopeptides

III *. Derivatives of D-Seryl-L-leucine Obtained by Separation from a DL-L Diastereoisomeric Mixture

GEORG FÖLSCH

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

The two diastereoisomers of N-carbobenzoxy-DL-seryl-L-leucine benzyl ester, were separated by fractional crystallisation. The D-seryl derivative was converted to D-seryl-L-leucine, O-phosphoryl-D-seryl-L-leucine and O-monophenylphosphoryl-D-seryl-L-leucine.

The use of racemic amino acids in peptide synthesis yields mixtures of diastereoisomers when α-amino acids other than glycine are used, as all other α-amino acids contain at least one asymmetric center. The components of such diastereoisomeric mixtures are sometimes separated by fractional crystallisation [2-3]. For large scale preparation of dipeptides containing a difficultly accessible antipode of an amino acid, such procedures may be of value, as the amino acid in question can be used in the generally more easily accessible racemic form.

In this paper the resolution of the carbobenzoxy peptide benzyl ester (I) obtained from DL-serine and L-leucine is described. The difference in solubility of the two isomers made it comparatively easy to isolate the higher melting isomer, *i.e.* N-carbobenzoxy-D-seryl-L-leucine benzyl ester (II). After two recrystallizations, the m.p. and optical rotation had the values of an authentic sample, prepared from pure D-serine. The isolation of pure L-L derivative (III) was, however, somewhat more difficult since this isomer, in none of the solvent systems tried, was less soluble than compound (II), and five recrystallizations were necessary to obtain the m.p. and rotation values of a previously prepared [1] sample of (III).

Compound (II) was converted to D-seryl-L-leucine by hydrogenolysis, and to O-phosphoryl-D-seryl-L-leucine and O-monophenylphosphoryl-D-seryl-L-leucine by phosphorylation with diphenylphosphoryl chloride followed by hydrogenolysis. The phosphopeptides may be of considerable interest in

* For part II, see Ref.[1]

current studies on the action of phosphatases [4] and proteolytic enzymes on phosphorylated peptides, as it has been shown, that the enzyme phosphoserine phosphatase acts on O-phosphoryl-D-serine as well as on the L-isomer [5-7].

EXPERIMENTAL

*N-Carbobenzoxy-*DL*-seryl-*L*-leucine benzyl ester* (I). To a solution of 12.0 g (50 mmoles) of N-carbobenzoxy-DL-serine [8], 13.0 g (50 mmoles) of L-leucine benzyl ester hydrochloride [9] and 7.2 ml (50 mmoles) of triethylamine in 400 ml of tetrahydrofuran-acetonitrile (1:1) was added 10.5 g (50 mmoles) of N,N'-di*cyclo*hexylcarbodiimide. The mixture was shaken for 2 h and then left over night. After filtration, the solvent was distilled off *in vacuo* and the residue dissolved in ethyl acetate. After washing with water, 1 N hydrochloric acid, water, saturated bicarbonate solution, and water, followed by drying over sodium sulphate, the ethyl acetate was distilled off *in vacuo* and the residue brought to solid state by addition of light petroleum. The product was collected and then dried. Yield 20.0 g (90 %) of crude (I).

Separation of isomers. The above mixture of diastereoisomers was dissolved in 200 ml of ethyl acetate, and light petroleum was added to slight turbidity. When left for 24 h at +4°, crystals were formed which, after filtration, washing with ethyl acetate-light petroleum (1:1) and drying weighed 8.1 g (73 % of theory). M. p. 110–111°. After one additional crystallization from the same solvent system, 7.1 g (64 %) of a compound (II) with m. p. 115° $[\alpha]_D^{21}$ −19.9° (ethanol, *c* 6.7, *l* 1); $[\alpha]_D^{21}$ −4.0° (chloroform, *c* 11, *l* 1) was obtained. For the L–L derivative, a m. p. of 83–84° has been reported [1]. Therefore, the actual compound had to be the D–L isomer, and this was proved by comparison with an autenthic sample of N-carbobenzoxy-D-seryl-L-leucine (III). This was synthesized by the carbodiimide procedure from 0.6 g (2.5 mmoles) of N-carbobenzoxy-D-serine [8] as described above, whereby a yield of 0.95 g (86 %) was obtained after recrystallization from ethyl acetate-light petroleum. M. p. 114 *; mixed with II, m. p. 114°. $[\alpha]_D^{21}$ −20.2° (ethanol, *c* 3.4, *l* 1); $[\alpha]_D^{21}$ −4.2° (chloroform, *c* 12, *l* 1).

The mother liquors and washings from compound (II) were evaporated to dryness and the residue repeatedly crystallized from methanol-water. After five crystallizations, 4.6 g (42 %) were collected (IV). M. p. 83–84°, mixed with pure N-carbobenzoxy-L-seryl-L-leucine benzyl ester, m. p. 83–84°; $[\alpha]_D^{21}$ −26.5° (ethanol, *c* 6.1, *l* 1).

D-*Seryl-*L*-leucine* (V). By catalytic hydrogenolysis of 2.2 g of compound (II) in ethanol-water, using palladium catalyst, followed by filtration, evaporation to dryness and recrystallization from water-ethanol-ether, a yield of 0.9 g (76 %) of the free peptide as the monohydrate was obtained. $[\alpha]_D^{21}$ −38° (1 N HCl, *c* 6.7, *l* 1). (Found: C 45.9; H 8.3; N 11.8. Calc. for $C_9H_{18}N_2O_4$, H_2O (236.3): C 45.7; H 8.5; N 11.8.)

*O-Phosphoryl-*D*-seryl-*L*-leucine* (VI). To 4.4 g (10 mmoles) of compound II in 10 ml of anhydrous pyridine was added 3.2 g (12 mmoles) of diphenylphosphoryl chloride, the temperature being kept below 40°. After 4 h, the excess of acid chloride was destroyed by addition of water, and the product taken up in 100 ml of water and 100 ml of ether. The ether layer was washed with 4 N sulphuric acid, water, saturated sodium bicarbonate and water and was then dried over sodium sulphate. After the ether had been distilled off *in vacuo*, 6.2 g (92 %) of oily O-diphenyl-phosphoryl-N-carbobenzoxy-D-seryl-L-leucine benzyl ester was obtained. This oil was dissolved in 100 ml of ethanol and the solution, after addition of water to slight turbidity was then shaken in an atmosphere of pure hydrogen, 1.0 g of 10 % palladium on charcoal being used as catalyst. In 4 h, 480 ml of hydrogen was used. The catalyst was filtered off and was well washed with a small quantity of hot acetic acid. The filtrate and washings were evaporated to dryness and

* In a study of O → N acyl shifts in serine derivatives, Josefsson and Edman [10] reported the preparation of compound (I) *via* the mixed chlorocarbonic anhydride of N-carbobenzoxy-DL-serine. The isolated compound was obviously practically pure D-seryl-L-leucine derivative and had a m. p. 107°.

the residue again hydrogenolysed, but this time in glacial acetic acid solution and with 1.0 g of Adams platinum oxide as catalyst. The hydrogen uptake was completed in 8 h. After filtration and evaporation *in vacuo*, 2.8 g of crystalline residue was obtained. This residue was recrystallized from boiling water. Insoluble material (VII) was filtered off, and in the cold room the aqueous solution gave nicely crystallizing O-phosphoryl-D-seryl-L-leucine as monohydrate, 2.1 g (66 %). M. p. 138—140° (decomp.); $[\alpha]_D^{21}$ −28.1 (1 N HCl, *c* 3.6, *l* 1). (Found: C 33.8; H 6.9; N 8.6; P 9.6. Calc. for $C_9H_{19}O_7N_2P$, H_2O (316.2): C 34.2; H 6.7; N 8.9; P 9.8.) A sample dried to constant weight at 65° and 0.05 mm Hg lost 7.7 % of weight and the compound then analyzed correctly for anhydrous phosphopeptide. (Found: C 36.3; H 6.3; N 9.4; P 10.4. Calc. for $C_9H_{19}O_7N_2P$ (298.2): C. 36.2; H 6.4; N 9.4; P 10.4.)

*O-Monophenylphosphoryl-*D*-seryl-*L*-leucine* (VII). The water-insoluble material from the recrystallization of (VI) was monophenylphosphoryl-D-seryl-L-leucine and crystallized from acetic acid-water, as monohydrate at a yield of 0.35 g (9 %). M. p. 213—215° (decomp.). (Found: C 45.8; H 6.4; N 7.1; P 7.8. Calc. for $C_{15}H_{23}O_7N_2P$, H_2O (392.4): C 45.9; H 6.4; N 7.1; P 7.9.)

Phosphorylmuramic Acid in *Lactobacillus casei*. Its Presence in Protein and in a Nucleoside-pyrophosphate Fraction

CARL-HENRIC de VERDIER and GUNNAR ÅGREN

Institute of Medical Chemistry, University of Uppsala, Sweden

A method has been developed for the isolation of nucleotide bound muramic acid peptides from *Lactobacillus casei*. The amino acid composition of these peptides has been studied and compared with acid resistant phosphopeptides from hydrolyzed phosphoproteins. A closely related amino acid composition has been found. Evidence for the existence of nuleotide bound phosphorylmuramic acid is given and the specific activity for such a compound is consistent with the view that it could be a precursor in the synthesis of phosphoproteins in *Lactobacillus casei*.

In 1955 a new phosphorylated amino acid was isolated from a hydrolysate of the protein residue of *L. casei* [1,2]. Recently it was identified as a phosphorylated derivative of 3-O-α-carboxyethyl-D-glucosamine [3] which has also been named muramic acid *. In one of the earlier communications [2] we also reported the presence of several UDP-derivatives in a cold 10 % TCA extract of the microorganism.

Park and Johnson [4] in 1949 observed that uridine nucleotides accumulated in *Staphylococcus aureus* which was inhibited by penicillin. Later they were identified as UDP linked to Mur or Mur-peptides [5]. Uridine nucleotide accumulation was also found in a penicillin-sensitive *Lactobacillus helveticus* [6] where the effect of penicillin was far less conspicuous. Evidence has also been obtained which suggests that the UDP-Mur-peptides are precursors of the bacterial cell wall in a metabolic pathway inhibited by penicillin.

* The following abbreviations are used: Mur = muramic acid; MurP = O-phosphorylmuramic acid; P = inorganic phosphate; ^{32}P = radioactive inorganic phosphate; cpm = counts per minute; cps = counts per second; AMP = adenylic acid; ADP = adenosine diphosphate; ATP = adenosine triphosphate; $AT^{32}P$ = radioactive adenosine triphosphate; CMP = cytidylic acid; GTP = guanosine triphosphate; UMP = uridylic acid; UDP = uridine diphosphate; UTP = uridine triphosphate; DPN = diphosphopyridine nucleotide; TCA = trichloroacetic acid; Ala = alanine; Glu = glutamic acid; Leu = leucine; UV = ultra violet; E_{260} = optical density at 260 mμ.

The previous observations [2,3] may also throw some light on the mechanism for the synthesis of protein bound MurP where the phosphoryl group most probably is bound to the sixth carbon atom of the glucosamine moiety. The UDP-linked MurP reported in this paper may be an intermediate in the biosynthesis of protein bound MurP.

MATERIALS AND METHODS

Lactobacillus casei (7469) was grown in the medium previously described [3]. Bacterial growth was estimated by measuring the turbidity of suspensions with filter No. 59 in the Klett-Summerson photometer. The growth of the microorganism was inhibited by penicillin as shown in Table 1.

Chromatographic separation of acid soluble nucleotides. The cultivations were made with the suspension of microorganisms of step 5 according to previous description [3] grown for 18 h and diluted with fresh medium 1:30. Most of the experiments were made with 90 liter cultures and with the addition of 10 μg of benzylpenicillin per ml when one-half the maximum of growth was reached. The cultivation technique and the extraction methods were the same as in the preceding paper [3]. In all radioactivity experiments the medium contained 0.33 mC ^{32}P per liter from the time of incubation. The cold TCA extract from each experiment was shaken with ether to remove the TCA and then neutralized to pH 6 to 7 by the addition of a few drops of 1 N NaOH. The solution was evaporated *in vacuo* to a volume of about 30 ml and mostly run on two 70 × 3 cm Dowex 1 formate (2 % DVB) columns and eluted mainly according to Hurlbert *et al.*[7] The eluate was collected in fractions of about 30 to 40 ml every 15 min.

The elution was started with water and about 25 fractions were collected. In the system, which followed, a 600 ml mixing volume was used. The four elution ranges which approximated 1 N formic acid, 4 N formic acid, 0.2 M ammonium formate in 4 N formic acid and 0.4 M ammonium formate in 4 N formic acid were obtained by changing the reservoir to contain these solutions at tubes 25, 100, 250 and 350. Altogether 500 to 600 fractions were collected in each series. In two experiments the TCA extract was run with the elution system of Strominger [6].

Partial hydrolysis of the Schneider protein residue was performed with 11 N HCl at 37°C during 3 days according to Flavin [8]. The hydrolysate was evaporated *in vacuo*

several times to remove excess of HCl and applied to a 7 × 50 cm Dowex 50 (8 % DVB) column. Elution with 0.01 N HCl was used as for the elution of MurP [3]. Excess of HCl was then removed from the different fractions separated on the Dowex 50 column as described above. The residues were dissolved in small volumes of water and applied to Dowex 1 formate columns (dimensions 2 × 45 cm). Elution was carried out with a gradient 0 → 1 M formic acid and with a volume of 200 ml in the mixer.

Analytical methods. The nucleotides were assayed by optical density determinations of suitable dilutions from each tube using a 1 cm quartz cuvette in a Beckman model DU spectrophotometer at 250, 260 and 280 mμ. The ratios used for identifying the UDP-derivatives were the following [9]: 250/260 = 0.73 and 280/260 = 0.39.

The radioactivity of the different fractions from the column chromatography of the TCA soluble nucleotides and protein residue was measured in glass cups with a L.K.B. Robot Scaler. Scanning of the paper chromatograms of nucleotides and MurP-peptides was made according to Ågren *et al.*[10] Determinations of specific activity values were made on stainless steel planchettes with the Tracerlab Superscaler. At least 1 000 counts were measured. The specific activities of the different nucleotides and of MurP were calculated as counts per min per μmole of compound. All activity values were recalculated to the time of incubation.

The amino acid composition of the UDP-peptides and the peptides isolated by partial hydrolysis of phosphoproteins was determined by two dimensional paper chromatography [11]. The UDP-peptides were hydrolyzed with 1 N HCl for 3 h at 100°C and the peptides from phosphoproteins with 2 N HCl for 20 h at 120°C in sealed tubes. In some cases the solvents used for the identification of Mur were suitable, as listed in a preceding paper [1]. In chromatography Whatman No. 1 or Munktell OB papers were used, and for ionophoresis Whatman No. 3 where the buffer solutions were either a 0.1 M solution of pyridine-acetic acid at pH 5 or 1 N acetic acid.

RESULTS

Isolation of UDP-linked Mur-peptides. In Fig. 1 an elution diagram is presented for the TCA extract prepared from a 45 liter culture passing through a Dowex 1 column with the formic acid system. 15 mC radioactive phosphate had been added at the inoculation and penicillin after 3.5 h of growth. The culture was harvested after 4.5 h of growth in the middle of the log phase. In several points the diagram was similar to that obtained with TCA extracts of yeast [12,13]. The peaks corresponding to CMP, DPN and AMP appeared in the same position. UMP and ADP were found in the expected position after the inorganic phosphate. After ADP eight or sometimes nine E_{260}-absorbing peaks appeared, in Fig. 1, Nos. 1—8. The two first peaks after ADP generally coincided with the elution of two yellow coloured fractions from the columns. The first fraction appeared in the same position as a UDP-linked peptide containing Mur and up to four other amino acids. The 280/260 ratio of the eight different UV peaks were 0.40, 0.50, 0.40, 0.51, 0.37, 0.40, 0.38 and 0.39, respectively.

Only peak 1 and 7 seemed to contain a muramic acid peptide linked to UDP. Paper chromatograms of the hydrolyzed peptides showed the presence mainly of muramic acid, alanine, glycine, glutamic acid and another ninhydrin positive substance which so far has not been identified. The total yield of UDP-linked Mur-peptides was about 10 μmoles which is much less than Strominger [6] obtained from cultures of *L. helveticus*. This yield was not increased to any greater extent when penicillin was present in the log phase cultures. Of interest is the observation that ATP, GTP and UTP were not present in

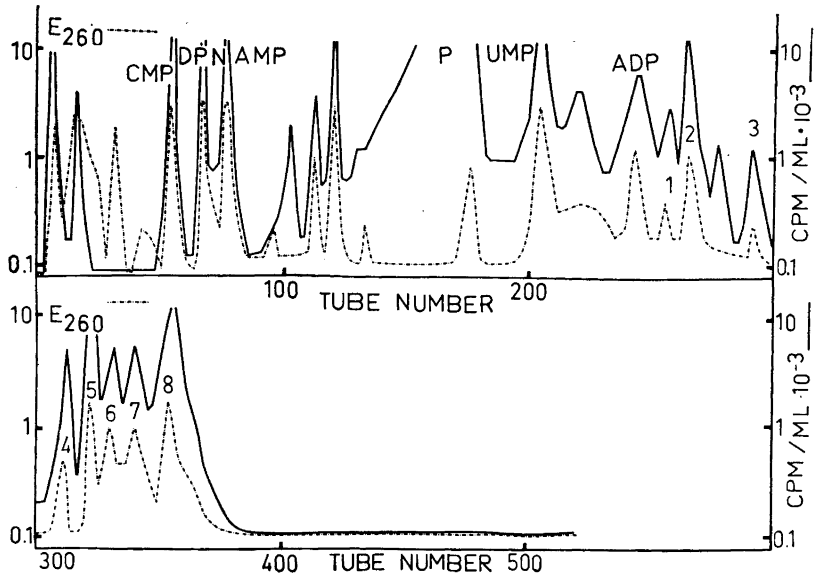

Fig. 1. Acid-soluble nucleotides from 80 g of wet cells after 4 h of incubation with 15 mC of radioactive inorganic phosphate. The nucleotides were separated by gradient elution with the reservoir content changed at the tubes numbered as follows: *25*, 1 N formic acid; *100*, 4 N formic acid; *250*, 0.2 M ammonium formate + 4 N formic acid; *350*, 0.4 M ammonium formate + 4 N formic acid; column dimensions 3 × 70 cm; Dowex 1 formate form. The continuous line represents radioactivity values, the broken line represents E_{260} values.

our TCA extracts of *L. casei*. The elution system used by Strominger [6] has also been used but according to our experience has no advantage over that used by us. It is worth mentioning that in the region between peaks C and D in the Strominger system there was no Mur-containing material in the TCA extracts of *L. casei* while Strominger found considerable amounts in extracts from *S. aureus*. The stepwise elution system used by Strominger we also found more laborious.

Isolation of UDP-linked MurP. It has been previously mentioned in this paper that UDP-linked MurP could be an intermediate in the biosynthesis of protein bound MurP. Several experiments were carried out to isolate such a compound in the TCA extracts of *L. casei*. As it could be supposed that the yield of such a compound should be very low no attempts were made to isolate a separate fraction, containing this material. Instead, all substances emerging from the columns after the ADP peak had appeared were pooled. Ammonium ions were removed by rapidly passing the eluate through a short cooled Dowex 50 filter which was afterwards washed with an equal volume of cold water. The formic acid eluate was lyophilized and extracted with a small volume of water. Hydrolysis was carried out with 0.1 N HCl at 100°C for 7 min which is far in excess of that used by Caputto *et al.*[14] for the liberation of glucose

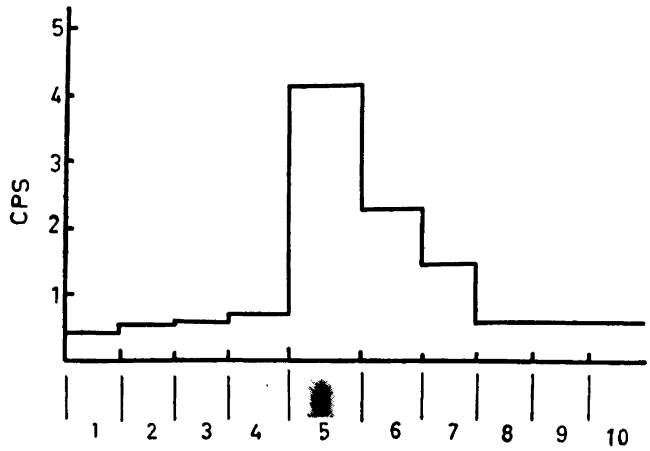

Fig. 2. Scanning curve (upper part of the figure) from a paper chromatographic strip of a hydrolysate of radioactive nucleotide bound MurP run parallelly with unlabeled MurP giving the ninhydrin spot on the lower strip. The paper strip with the chromatographically purified radioactive hydrolysate was cut in 10 equal pieces and the time for 1 000 counts was measured for each piece of paper.

from UDP-glucose. HCl was removed from the hydrolysate which was afterwards concentrated to a small volume and put on a Dowex 50 column and eluted with 0.01 N HCl. In the expected position for MurP a radioactive peak appeared. The identity of the material in this peak was checked by ionophoresis in a pyridine-acetate buffer at pH 5 and in paper chromatography (Fig. 2) and with a *iso*butyric acid-ammonia system [15]. In both cases radioactivity run parallel with added MurP. From Fig. 2 it is also obvious that the presence in this material of MurP-peptides could not be excluded. As described below such peptides leave the Dowex 50 column in about the same column volume as MurP.

It could not be excluded that the isolated MurP had been formed by splitting of UDP-linked Mur by a migration of the phosphoryl group from 1- to

Table 2. 25 mg sodium salt of UDP-acetyl glucosamine corresponding to 39.8 μmoles was hydrolyzed. The following products were obtained:

	μmoles	yield, %
Glucosamine-6-phosphate	0.01	0.025
Uridine-monophosphate	15	38 *
Inorganic phosphate	39	98
Glucosamine	23	58

* Calculated per uridine residue.

6-position. However, a more likely explanation seemed to be the existence of a UDP-linked MurP. As an example of a closely connected substance may be mentioned the recently isolated UDP-acetylglucosamine phosphate from the oviduct of laying hen [16]. The possibility of the postulated migration was tested in a model experiment with UDP-glucosamine. 25 mg of a commercially available substance (Sigma, 95—100 % pure, from yeast) was hydrolysed under the same conditions as the rest protein fraction (2 N HCl, 20 h and at 100°C).[15] The different components of the hydrolysate were separated on a Dowex 1 (2 % DVB) column by gradient elution with formic acid and the results are given in Table 2.

Glucosamine was determined in the fraction eluted with water according to Blix' modification of the Elson-Morgan reaction [17]. To detect the phosphate a small amount of carrier free ^{32}P-labeled orthophosphate was added before the separation. Phophorus was determined according to an earlier described method [10]. Glucosamine-6-phosphate was essayed by comparison on the paper chromatogram strips with known amounts of the pure substance prepared mainly according to Brown [18]. For development of the chromatograms *iso*-butyric acid-0.5 N ammonia (10:6) and propionic acid-benzene-water (58:25:25) were used. UMP was determined from UV absorption data at 260 and 280 mμ of a aliquot of the collected UMP peak.

The extremely low yield of glucosamine phosphate obtained in this experiment seemed to be insignificant when considering a possible migration of the phosphoryl group from 1- to 6-position as a source of error. The small amount found may be due to an impurity in the UDP-glucosamine preparation obtained from yeast.

Isolation of phosphorylated peptides from the cell protein residue. If UDP-linked Mur or rather, similarly bound MurP or MurP-peptides, were intermediates in the biosynthesis of protein bound MurP this hypothesis would be supported by the isolation of phosphopeptides with the same amino acid content as in the UDP-linked peptides. Attempts were accordingly made to isolate such peptides from the partially hydrolyzed protein residues (11 N HCl at 37° during 3 days). In Fig. 3 a typical elution curve from a Dowex 50 column is presented for the protein hydrolysate from a 90 l culture of *L. casei* cultivated in the presence of penicillin. The peak after inorganic phosphate eluted between

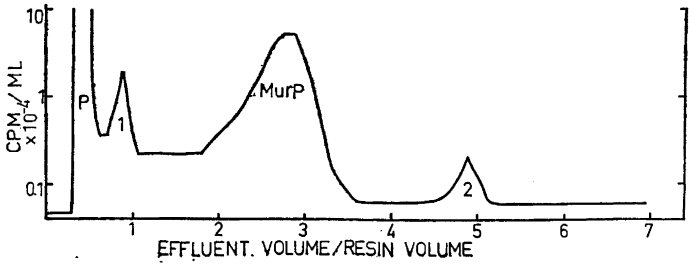

Fig. 3. Radioactivity curve from a hydrolysate of the protein residue from *L. casei* incubated for 4 h in a ^{32}P-containing medium. The curve is obtained by plotting the number of impulses per min (cpm) in 1 ml aliquots of each tube.

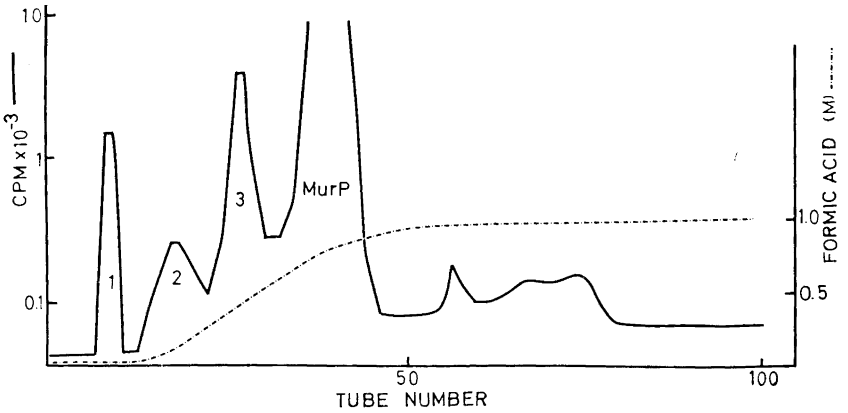

Fig. 4. Radioactivity curve from a mixture of MurP and MurP-peptides separated on a Dowex 1 column. The radioactivity curve (the continuous line) is obtained by plotting the number of impulses per min (cpm) in 1 ml aliquots of each tube. The broken line represents formic acid concentration.

0.72 to 0.96 column volumes (effluent volume/resin volume) and the MurP peak appearing between 1.9 to 3.3 column volumes were separately rechromatographed on Dowex 1 formate columns after removal of excess HCl (column dimensions 0.9 × 50 cm and 2 × 40 cm, respectively). A few times the peak emerging from the Dowex 50 column between 4.9 and 5.1 column volumes was also rechromatographed on the smaller type of Dowex 1 column. Fig. 4 gives a typical elution curve for the rechromatography of the MurP peak from the Dowex 50 column on a Dowex 1 formate column. Elution was carried out with the gradient 0 → 1 M formic acid with a volume of 200 ml in the mixer. The large peak appearing when the acidity of the eluate reached a value which corresponded to about 0.60 M formic acid was practically pure MurP. The peak 3 eluted somewhat earlier at about 0.40 M formic acid was homogeneous by analysis with inophoresis and chromatographic procedures. After hydrolysis of a small part of the material paper chromatographic analysis showed three strong spots corresponding to Mur, alanine and glutamic acid and five weaker spots. After rechromatography of the phosphopeptide on a small Dowex 50 (4 % DVB) column and hydrolysis the peptide contained only alanine and Mur. The first peak in Fig. 4 appearing with water was also homogeneous when analyzed with ionophoretic and chromatographic methods. After hydrolysis paper chromatographic analysis showed spots for Mur and alanine and possibly for glutamic acid. Compared with peak 3 there was less alanine in relation to Mur in the material from peak 1. The small amounts of material available did not permit rechromatography on a second Dowex 50 column. A peak in the same position as 1 could also be eluted from the MurP fractions obtained by hydrolysis in the usual way [10] and then separated on a Dowex 50 column. This material was not homogeneous when analyzed by paper chromatography or ionophoresis in 1 M acetic acid. Three different

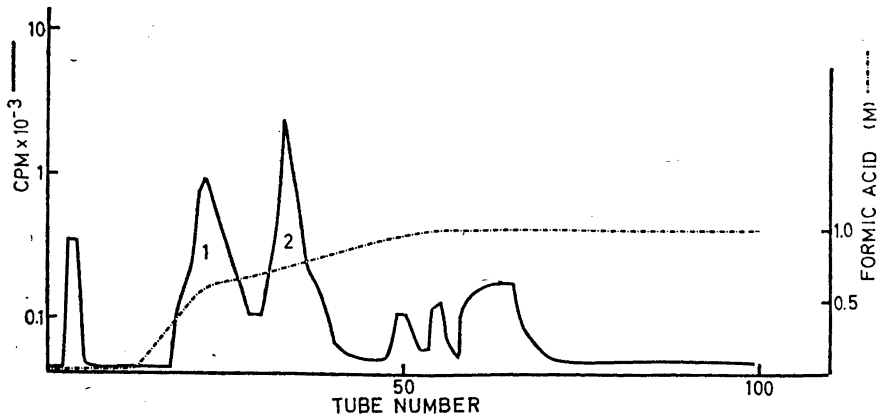

Fig. 5. Radioactivity curve from a mixture of MurP-peptides separated on a Dowex 1 column. The radioactivity curve is obtained by plotting the number of impulses per min (cpm) in 1 ml aliquots of each tube. The broken line represents formic acid concentration.

fractions were obtained. They all contained Mur, alanine and glutamic acid with about the same relation of Mur to alanine as in peak 1 (Fig. 4).

Fig. 5 demonstrates a typical Dowex 1 elution curve at the rechromatography of the material from peak No. 1 of the Dowex 50 curve (Fig. 3). The material corresponding to the two larger peaks 1 and 2 were homogeneous when analyzed with ionophoretic and paper chromatographic methods. After hydrolysis fraction 1 showed paper chromatographic spots corresponding to glutamic acid, alanine, Mur, valine, leucine and a spot in the position of γ-amino butyric acid. The amount of material corresponding to peak 1 allowed a rechromatography on a second Dowex 50 (4 % DVB) column. Only one radioactive fraction was obtained by elution with 0.01 N HCl. After hydrolysis of this material paper chromatographic analysis showed the presence of glutamic acid in reduced amounts, alanine, Mur and leucine. Fraction 2 from the Dowex 1 column (Fig. 5) was also hydrolyzed and analyzed by paper chromatography. Spots were obtained corresponding to the position of Mur, alanine and glutamic acid. Available amounts did not allow a rechromatography on a second Dowex 50 column.

The material from peak 2 on the Dowex 50 column (Fig. 3) was also rechromatographed on Dowex 1 columns. At least eight small radioactive fractions were obtained. The amounts of material in each fraction were extremely small and not further analyzed. A summary of the phosphopeptide compositions is given in Table 3. While a detailed sequence so far has not been established a certain agreement in amino acid composition between the different phosphopeptides can be noted.

Specific activity values of protein bound MurP. In Table 4 a summary is given of the MurP values obtained from different types of experiments. 30 mC ^{32}P per 90 liter of culture were used in experiments Nos. 1 to 6, otherwise 40 mC except in experiment Nos. 13 and 14 where 60 and 100 mC, respecti-

at the time of inoculations was 5 010 in one experiment where 1.1 mC ^{32}P per liter of medium was used.

In order to increase the utilization of isotopic phosphate added to the medium inorganic phosphate was excluded in all experiments. Experiments Nos. 3 and 5 are comparable pairs and demonstrate that penicillin in these series had no significant influence on specific activity values of MurP when added in the log phase of growth. A comparison with the corresponding TCA extracts also seem to show rather similar amounts of UDP-linked Mur in the presence or absence of penicillin. Likewise experiments 1 and 2 are comparable pairs. Since penicillin had no influence on specific activity values in experiments Nos. 3 and 5 these series seem to show a dilution of radioactive MurP with already synthesized unlabeled or slightly labeled material. Whether MurP-phosphoproteins take an active part in exchange and transfer reactions or MurP represents structurally bound MurP cannot be decided from these figures only [19].

The experiments in series No. 6 were carried out in the same manner as by Strominger [6] with material from 6 comparable 15 liter cultures. The effect of penicillin on the specific activity is rather striking. The weight figures in Table 4 seem to indicate that when penicillin is present there is no growth and only a wery small incorporation of radioactivity in MurP. In the controls the weight figures and the photometer readings in Table 1 seem to indicate that as usual with the amount of inocula used the limit between lag phase and log phase is found after 1 h of incubation. Of special interest is the high specific activity in MurP at this time when it is questionable whether any new cell walls have been formed. The results are not in agreement with those obtained by Trucco and Pardee [20]. They studied the incorporation of uniformly labeled ^{14}C glucose in different cell fractions of *E. coli* up to 180 min of incubation and did not find any differences between specific activity values in controls and penicillin cultures for cell walls, cytoplasm or unbroken cells.

The specific activity of MurP from UDP-linked MurP was determined in experiment No. 5. To obtain sufficient amount of material all UDP peaks after ADP from 5a and 5b (Fig. 1) were pooled and MurP was isolated as previously described. The specific activity of this MurP phosphorus was 5 070 as compared with the mean value of 2 470 of the protein bound MurP phosphorus. This means that UDP-linked MurP could be a precursor to protein bound MurP.

DISCUSSION

With the method described in this paper it has been possible to isolate also from penicillin inhibited *L. casei* UDP-linked Mur-peptides of similar composition as previously found by Park and Strominger [5] in *S. aureus* and *L. helveticus*. Nucleotides of this type isolated from normal *L. casei* seemed to be identical with or closely related to the nucleotides from penicillin inhibited cultures. These observations suggest that the nucleotide bound peptides are normal metabolites and that they are themselves not toxic to the cell. The occurrence of these compounds in several species also suggests that they may have some general significance in bacterial metabolism.

The amino acids present in the UDP-linked Mur-peptides were of considerable interest. So far only glutamic acid, alanine, and Mur have been identified while a fourth amino acid also present is still of unknown character. According to Cummins and Harris [21] a hydrolysate of the bacterial cell wall of *L. casei* contained the following amino acids: aspartic acid, glutamic acid, alanine, Mur, and lysine. The unknown amino acid in our UDP-linked Mur-peptide was not identical with diaminopimelic acid or lysine which was found by Park [22] in his UDP-linked peptide by side of alanine, muramic acid and glutamic acid, also present in our UDP-linked peptide.

Under our experimental conditions there was usually no accumulation of UDP-linked peptides as a consequence of penicillin inhibition. That may be due to the fact that penicillin was added rather late in the log phase of growth when the effect of penicillin could be expected to act only for a comparatively short time. The conditions of experiment 6 might have been more favourable for studying an accumulation of UDP-linked peptides.

Park and Strominger [5] have suggested that the UDP-linked Mur-peptides are biosynthetic precursors of the bacterial cell wall and accumulate in penicillin treated *S. aureus* as a conseuqence of the interference by penicillin with the biosynthesis of the cell wall. From our point of view the biosynthesis of phosphoproteins is of general interest and with regard to the cell wall composition it has previously been demonstrated that about 80 % of the phosphoproteins in *E. coli* are located in the cell wall protein fraction [23]. It has previously been pointed out that UDP-linked MurP could be an intermediate in the biosynthesis of protein bound MurP. Of considerable interest was therefore the isolation of UDP-linked MurP with higher specific activity than protein bound MurP.

If it is assumed that UDP-linked Mur-peptides are in equilibrium with protein bound MurP-peptides it could be expected that phosphopeptides with a similar composition should be isolated from the hydrolyzed cell protein residue, containing the phosphoproteins. This actually was the case. One phosphopeptide containing Mur and alanine was found and a second one contained Mur, alanine and glutamic acid.

Some preliminary experiments have been carried out in an attempt to elucidate how a phosphorylation of Mur could be effected. Lyophilized cells of *L. casei* were disintegrated with a Raytheon magnetostriction oscillator and different fragment fractions were separated by differential centrifugation at 2 C°. Media containing the different fragment fractions, Mur, AT^{32}P, and magnesium ions were incubated for different times, but so far Mur^{32}P could not be isolated. There may be two explanations of the failure to find a muramic acid kinase. Either the phosphorylation may only take place when Mur is activated by a nucleotide linkage or the phosphorylation may occur before the muramic acid moities are fused together.

This investigation was supported by grants from the *Swedish Medical Research Council.*

On the Complex Chemistry of the Tervalent Rare-Earth Ions

IV. Ion-Exchange Studies of the Gadolinium Acetate and Glycolate Systems

ARTUR SONESSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund Lund, Sweden

The gadolinium acetate and glycolate systems have been investigated by means of both cation and anion exchangers. The measurements have been performed at 20°C using the radioactive isotope ^{153}Gd. For the investigation with cation exchanger solutions with the constant ionic strength $I = 1.0$ M have been used ($NaClO_4$ was added). The solutions used for the investigation with the anionic exchanger had varying ionic strength.

The complexity constants obtained for both the acetate system and the glycolate system by means of the cation-exchange method are in good agreement with the constants obtained potentiometrically (pages 1444 and 1446). Anionic complexes, however, could not be proved by the cation-exchange method.

The investigation of the glycolate system by means of an anion exchanger confirms the existence of anionic glycolate complexes. The maximum point of the φ-curve (Fig. 3) indicates that $\bar{n} = 3$ in a water solution having $[AcOH^-] \approx 100$ mM, which is quite in accordance with the potentiometric measurements. The ligand numbers computed from data obtained by the anion exchange method are in good agreement with the ligand numbers obtained potentiometrically in the whole region investigated. Attempts have also been made to compute the stability constants.

According to the measurements with the anion exchanger no anionic complexes should be formed in the gadolinium acetate system for $[Ac^-] < 800$ mM (Fig. 3). However, the low φ-values may also be caused by steric effects which depress the sorption of the acetate complexes into the exchanger below measurable values.

In the Parts I, II, and III (Sonesson [1–3]) we have given an account of our investigations of the complex formation in acetate and glycolate solutions of some rare earths. The complexity constants have been computed from the hydrogen-ion concentration of the complex solutions. It is not

possible in investigations of this kind to eliminate completely the errors caused by the variation of the activity factors when the perchlorate ions of the initial solution are replaced by acetate or glycolate ions. The constants computed from data obtained at high ligand concentrations are especially uncertain. Therefore it is necessary to check the results obtained potentiometrically by new investigations, which are independent of the potentiometric measurements.

The erbium acetate system and the neodymium glycolate system have been examined extinctiometrically as well as potentiometrically. The accordance between the complexity constants obtained potentiometrically and those obtained extinctiometrically is good, but the constants obtained by the latter method must be considered as relatively uncertain. Therefore investigations by means of ion exchangers have also been performed.

Fronæus [4] has used a cation exchanger for an examination of the cerium acetate system. For the first three complexity constants the accordance between the values obtained by the cation-exchange method and those obtained by the potentiometric method was very good. The present author has used the method given by Fronæus for the examination of the acetate and the glycolate systems of gadolinium.

The formation of anionic complexes in solutions containing cerium and acetate ions has also been examined by Fronæus [5] by means of anion exchange. According to the potentiometric measurements the ligand number exceeds three when $[Ac^-] > 500$ mM. In the examination with the anion exchanger anionic complexes could not be proved, although $[Ac^-]$ was increased to about 1 000 mM. Now both the acetate and the glycolate systems of gadolinium have been examined by means of an anion exchanger.

A. INVESTIGATION BY MEANS OF A CATION EXCHANGER

Theoretical

The method employed in the present investigation has been developed by Fronæus [4].

The same notations as in the previous Parts I, II and III have been used as much as possible, but in some cases the definitions of the symbols have been altered in some respects.

C'_M, C'_A = the total concentrations of the rare earth and the ligand, respectively, in the solution before the exchanger is added.

C_M = the total concentration of the rare earth in the solution at equilibrium with the exchanger.

$[M^{3+}]$, $[A^-]$ = the concentration of free central ion and free ligand, respectively, in the solution at equilibrium.

Then, as earlier, we have

$$C_M = [M^{3+}](1 + \sum_{j=1}^{N} \beta_j \cdot [A^-]^j) = [M^{3+}] \cdot X \qquad (1)$$

In addition the following notations are introduced:

$[M^{3+}]_R$, $[MA^{2+}]_R$, etc. = the concentrations in the resin phase at equilibrium with the solution. The concentrations are expressed in moles per gram of the air-dried resin.

β_{jR} = the complexity constants for the complexes MA_{jR}^{3-j} in the resin.

C_{MR} = $[M^{3+}]_R + [MA^{2+}]_R + [MA_2^+]_R$ =

$$= [M^{3+}]_R(1 + \beta_{1R} \cdot [A^-]_R + \beta_{2R} \cdot [A^-]_R^2) \quad (2)$$

$\bar{n}_R$ = the ligand number in the resin. For the cation exchanger we have

$$\bar{n}_R = ([MA^{2+}]_R + 2\ [MA_2^+]_R) \cdot C_{MR}^{-1} \quad (3)$$

m = the weight in grams of the air-dried resin.

v = the volume of the solution before the resin is added.

$v \cdot \delta$ = the volume at equilibrium with the resin. δ is a factor caused by the swelling of the resin.

The following equilibrium is obtained between a cation exchanger in the sodium form and a solution containing rare-earth ions M^{3+} and complex ions MA_j^{3-j}:

$$(3\text{-}j)\ Na_R^+ + MA_j^{3-j} \rightleftharpoons (3-j)\ \overline{Na}^+ + MA_{jR}^{3-j};\ (j = 0,\ 1,\ 2)$$

If we apply the law of mass action to this exchange equilibrium, we get

$$\frac{[MA_j^{3-j}]_R}{[MA_j^{3-j}]} = k_j \frac{[Na^+]_R^{3-j}}{[Na^+]^{3-j}} = l_j;\ (j = 0,\ 1,\ 2) \quad (4)$$

In the cation-exchange investigations described in this paper the total concentration of the rare earth is very low ($C_M \leq 3.0$ mM, $C_{MR} < 0.07$ mmole·g^{-1}). Therefore both $[Na^+]$ and $[Na^+]_R$ have been approximately constant. The load C_{MR} has been very low compared with the total exchange capacity (≈ 3.85 mequiv. g^{-1}) and the ionic strength of both the exchanger and the water phase has been nearly constant. In the calculations all values have been referred to a constant value of C_{MR} and then both k_j and l_j may be considered approximately constant.

If we denote by φ the distribution of the rare earth between the resin phase and the solution, then

$$\varphi = \frac{C_{MR}}{C_M} = l_o \frac{1 + l_1' \cdot [A^-] + l_2' \cdot [A^-]^2}{X} \quad (5)$$

$$l_o = \frac{[M^{3+}]_R}{[M^{3+}]}\ ;\ l_j' = \beta_j \frac{l_j}{l_o}\quad (j = 1,\ 2) \quad (6)$$

To facilitate the calculations Fronæus introduced two new parameters

$$\varphi_1 = \frac{l_o \cdot \varphi^{-1} - 1}{[A^-]} \quad (7)$$

$$f = \frac{l_o \cdot \varphi^{-1}[(\beta_1 - l_1')\ [A^-] - 1] + 1}{[A^-]^2} \quad (8)$$

It can be shown by combining eqns. (5), (7) and (8) that

$$f = \beta_1 \cdot \varphi_1 - X_2 + l_2' \cdot l_o \cdot \varphi^{-1} \tag{9}$$

After having introduced the value of φ from eqn. (5) into eqns. (7) and (8), we get

$$\lim_{[A^-]\to 0} \varphi_1 = \varphi_1^\circ = \beta_1 - l_1' \tag{10}$$

$$\lim_{[A^-]\to 0} f = f^\circ = \beta_1 \cdot \varphi_1^\circ - (\beta_2 - l_2') \tag{11}$$

From eqns. (9), (10) and (11) it can be deduced that

$$\left.\begin{array}{c} \Delta f \cdot [A^-]^{-1} = \beta_1 \cdot \Delta\varphi_1 [A^-]^{-1} - \beta_3 - X_4[A^-] + l_2'\varphi_1 \\ \Delta f = f - f^\circ \text{ and } \Delta\varphi_1 = \varphi_1 - \varphi_1^\circ \end{array}\right\} \tag{12}$$

The last two terms of (12) vary with $[A^-]$. At low values of $[A^-]$, however, they are only correction terms and we can calculate an approximate value of β_1 by plotting $\Delta f \cdot [A^-]^{-1}$ as a function of $\Delta\varphi_1 \cdot [A^-]^{-1}$.

Now β_1 being known, an approximate value of $\beta_2 - l_2'$ can be calculated by means of eqn. (11). Then a new parameter g is introduced

$$g = \frac{f - \beta_1\varphi_1 + l_o \cdot \varphi^{-1}(\beta_2 - l_2')}{[A^-]} = \beta_2\varphi_1 - \beta_3 - X_4 \cdot [A^-] \tag{13}$$

At so low $[A^-]$ that X_4 can be neglected, g is a linear function of φ_1. The slope of the line gives β_2, and the intercept an approximate value of β_3.

X_2 can be computed according to eqn. (9), but we must know l_2'. As l_2' seems to be very small compared with β_2, we get only a very rough value of l_2' from β_2 and $\beta_2 - l_2'$. Another way of computing l_2' is shown by Frønæus [4, p. 20]. With the assumption that $\beta_{1R}^2 \cdot \beta_{2R}^{-1}$ has about the same value as $\beta_1^2 \cdot \beta_2^{-1}$ it can be deduced that

$$\frac{\beta_1^2}{\beta_2} = \frac{(l_1')^2}{l_2'} \tag{14}$$

For the glycolate system eqn. (12) could not be used for the computation of β_1, as $\Delta\varphi_1 \cdot [A^-]^{-1}$ and $\Delta f \cdot [A^-]^{-1}$ are approximately constant. However, if only four complexes are formed, eqn. (12) can be written

$$\beta_1 = \frac{\Delta f}{\Delta\varphi_1} + \beta_3 \cdot \frac{[A^-]}{\Delta\varphi_1} + \beta_4 \cdot [A^-] \cdot \frac{[A^-]}{\Delta\varphi_1} - l_2'\varphi_1 \cdot \frac{[A^-]}{\Delta\varphi_1} \tag{15}$$

The first term, $\Delta f \cdot \Delta\varphi_1^{-1}$, dominates. Then, an approximate value of β_1 can be calculated if rough values of β_3, β_4 and l_2' are known.

All the equations above have been deduced on the assumption that only mononuclear complexes are formed both in the solution and in the resin. The

potentiometric measurements on the $Gd^{3+}-Ac^{-}$-system reported in Part I showed a slight tendency for formation of polynuclear complexes. However, the tendency is so slight that it may be neglected in the present investigation, as both C_M and C_{MR} are very low.

Experimental

Chemicals used. A known amount of radioactive Gd_2O_3 (from A.E.R.E., Harwell, England) was dissolved in perchloric acid. After the addition of a known amount of inactive gadolinium perchlorate, the solution was evaporated to remove the excess perchloric acid.

The concentration of the stock solution of radioactive gadolinium perchlorate was calculated from the known amounts of radioactive and inactive materials. The stock solution contained $NaClO_4$ to make the ionic strength 1.0 M.

The cation exchanger was Dowex 50 converted into the sodium form and air-dried. The same batch was used for all of the measurements. The exchange capacity was 3.85 mequiv. g^{-1}.

The value of the factor δ was determined by shaking a solution with a known concentration of $NaClO_4$ and a known amount of the resin until equilibrium was reached. Then the value of δ was given by the ratio between the initial and the equilibrium sodium-ion concentrations, which were determined by means of a cation-exchanger column in the hydrogen state. δ was determined to be 0.985.

Other chemicals were of analytical grade as in Parts I, II, and III.

The apparatus. The total gadolinium concentration of the solutions was determined by measurement of the gamma activity of ^{153}Gd. A scintillation detector type P-20 from Tracerlab was used. The scintillation tube was immersed to a fixed depth in the centre of a lead shielding. A glass cup containing 10 ml of the solution to be measured was placed in a fixed place in the lead shielding. A satisfactory reproducibility of the geometry was assured. A solution of radioactive $Gd(ClO_4)_3$ was diluted with varying amounts of 1 M $NaClO_4$ and the solutions were counted. It was found that the relation between the cpm and the gadolinium concentration was linear within the limits of the statistical errors ($\sim$ 1 %).

The gadolinium acetate system

The complex solutions to be measured were prepared by mixing two solutions, S_1 and S_2, in varying proportions.

$$S_1 = \begin{cases} C_M^\circ \text{ mM } Gd(ClO_4)_3 \\ C_H^\circ \text{ mM } HClO_4 \\ 1000 \text{ mM } NaClO_4 \end{cases} \quad \text{and} \quad S_2 = \begin{cases} C_{HA}^\circ \text{ mM HAc} \\ C_A^\circ \text{ mM NaAc} \\ (1\,000 - C_A^\circ) \text{ mM } NaClO_4. \end{cases}$$

Four S_1 solutions were used with C_M° = 0.566, 1.010, 2.020 and 3.010 mM, respectively. All solutions had $C_H^\circ \approx 0.03$ mM. At this pH the hydrolysis of the gadolinium ions can be neglected, as shown in Part I.

One buffer solution had $C_{HA}^\circ = C_A^\circ = 500$ mM, and the other $C_{HA}^\circ = C_A^\circ = 1\,000$ mM.

A fixed volume (v liters) of the complex solution was shaken (about 20 h) in a thermostat at 20°C with a fixed amount (m gram) of the dried resin. The value of $v \cdot m^{-1}$ was kept at 0.025 l · g^{-1}. After exchange equilibrium was reached, the resin phase was separated from the solution. The equilibrium concentration C_M was computed by comparing the radioactivity of 10 ml of the complex solution with the radioactivity of 10 ml of solution S_1.

The results for the four series are shown in Table 1. C_{MR}, the total equilibrium concentration of gadolinium in the resin phase, has been calculated according to the equation

$$C_{MR} = v \cdot m^{-1}(C'_M - \delta \cdot C_M) \qquad (16)$$

As φ varies with C_{MR}, all φ-values used in the calculations must be referred to a constant value of C_{MR}. The relation between φ and C_{MR} at a constant value of $C'_A \cdot \delta^{-1}$ proves to be practically linear. Then φ in Table 2 has been determined by graphic interpolation for $C_{MR} = 10 \times 10^{-3}$ mmole . g^{-1}.

[A$^-$], the equilibrium concentration of the free ligand in the solution, must be known before the functions φ_1 and f can be computed. We know the total concentration C'_A before the resin is added and must, when computing [A$^-$], correct for:

1) ligand ions bound in the complexes MA_j^{3-j} in the solution (correction term: $a_1 = \bar{n} \cdot C_M$),
2) ligand ions bound in the complexes MA_R^{2+} and MA_{2R}^{+} in the resin phase (correction term: $a_2 = \bar{n}_R \cdot C_{MR} \cdot m \cdot v^{-1} \cdot \delta^{-1}$),
3) ligand ions produced by the protolysis of the acid HA (the correction term a_3 can be neglected in this investigation of the acetate system as the starting pH of the solutions to be measured is about 4.5),
4) ligand ions produced when hydrogen ions replace sodium ions in the resin (as the acetate buffers have pH $\approx$ 4.8, this correction term, a_4, can be neglected in the investigation of the acetate system).

Then we have

$$[A^-] + \bar{n} \cdot C_M + \bar{n}_R \cdot C_{MR} \cdot m \cdot v^{-1} \cdot \delta^{-1} = C'_A \cdot \delta^{-1} + a_3 + a_4 \qquad (17)$$

As both C_M and C_{MR} are low, the terms a_1 and a_2 are small compared with [A$^-$]. Then it may be allowed as a first approximation to consider $[A^-] = C'_A \cdot \delta^{-1}$.

However, as we have already examined the gadolinium system potentiometrically (Part I), we can use the potentiometrically obtained values of $\bar{n}$ for the computation of $\bar{n} \cdot C_M$.

In the second correction term $\bar{n}_R$ can be computed according to Fronæus [6] by means of the formula

$$\bar{n} - \bar{n}_R = - \frac{[A^-]}{\varphi} \left(\frac{\partial \varphi}{\partial [A^-]} \right) C_{MR} \approx - \frac{C'_A}{\varphi} \left(\frac{\partial \varphi}{\partial C'_A} \right) C_{MR} \qquad (18)$$

The second approximate expression has been used for the computation of $\bar{n}_R$.

Table 2. The cation-exchange measurements on the acetate system. The corresponding values of φ, $[A^-]$ and the functions formed from these quantities are valid for the constant load on the resin of $C_{MR} = 10 \times 10^{-3}$ mmole·g^{-1}. (4), (18), *etc.* refer to the equations with these numbers

φ_1° and f° in Table 2 have been determined by graphic extrapolations of φ_1 and f, respectively, to $[A^-] = 0$. The extrapolations could be performed with rather great accuracy.

As seen in Fig. 1, $\Delta f \,.\, [A^-]^{-1}$ is approximately a linear function of $\Delta\varphi_1 \cdot [A^-]^{-1}$. The slope of the line gives $\beta_1 = (66 \pm 3)$ M^{-1}.

According to eqn. (11) we obtain $\beta_2 - l'_2 \approx 1\,350$. Then g is computed by means of eqn. (13). The slope of the line in Fig. 2 gives $\beta_2 = 1\,347$ and the intercept gives $\beta_3 \sim 9\,000$. Then X_3 is computed from the expression $X_3 = \beta_2 \,.\, \varphi_1 - g$. The extrapolation of X_3 to $[A^-] = 0$ gives also $\beta_3 \sim 9\,000$.

X_3 seems to increase somewhat with increasing values of $[A^-]$, which should indicate the formation of a fourth complex. However g is a quite linear function of φ_1 in whole the region, indicating that X_4 is negligible. Therefore, the formation of anionic complexes is very uncertain.

The accordance is good between the complexity constants obtained by the potentiometric method and those obtained by the cation-exchange method.

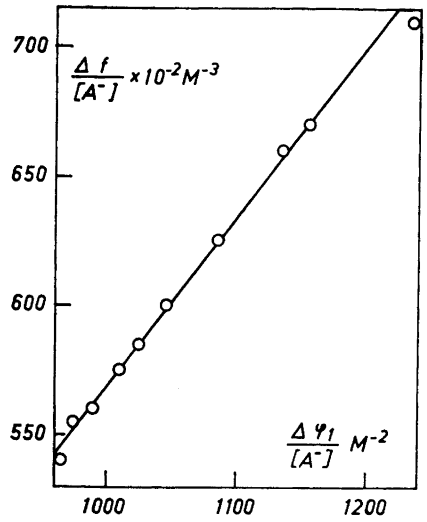

Fig. 1. The cation-exchange measurements on the acetate system. $\Delta f \cdot [A^-]^{-1}$ is represented as a function of $\Delta\varphi_1 \cdot [A^-]^{-1}$ for acetate-ion concentrations between 8 and 218 mM. The slope of the line gives β_1.

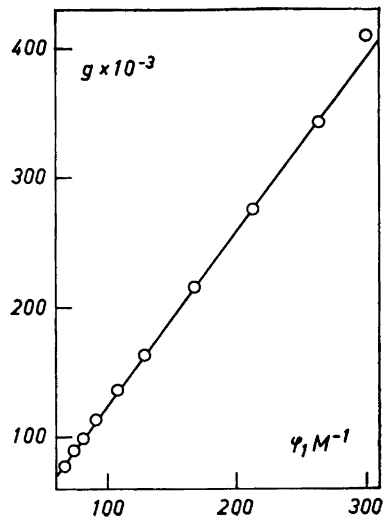

Fig. 2. The cation-exchange measurements on the acetate system. g is represented as a function of φ_1 for acetate concentrations between 8 and 218 mM. The slope of the line gives β_2 and the intercept for $\varphi_1 = 0$ gives $-\beta_3$.

The gadolinium glycolate system

The complex solutions were obtained by mixing the solutions S_3 and S_4 in varying proportions:

$$S_3 = \begin{cases} C_M^\circ \text{ mM } Gd(ClO_4)_3 \\ C_H^\circ \text{ mM } HClO_4 \\ 1\,000 \text{ mM } NaClO_4 \end{cases} \quad \text{and} \quad S_4 = \begin{cases} C_{HA}^\circ \text{ mM HAcOH} \\ C_A^\circ \text{ mM NaAcOH} \\ (1\,000 - C_A^\circ) \text{ mM } NaClO_4 \end{cases}$$

The measurements were performed with three S_3 solutions having C_M° = 0.550, 1.000 and 2.000 mM and C_H° = 0.03 mM. The buffer solution S_4 had $C_{HA}^\circ = C_A^\circ$ = 300 mM. The investigation was performed exactly in the same way as for the acetate system.

The results of the measurements on the glycolate system are shown in Table 3. For the calculation of $[A^-]$ at equilibrium eqn. (17) was used. The potentiometrically obtained values of $\bar{n}$ were used in the computation of the

correction term a_1. An approximate value of $\bar{n}_R$ has been determined according to eqn. (18). For the glycolate system a_3 and a_4 cannot be neglected for the lowest values of C'_A. For the ionic strength $I = 1.0$ M the acid constant of glycolic acid is 2.4×10^{-4} M (*cf.* Fronæus [7, p.67]). Using this value we get $a_3 = 0.16$ mM for $[A^-] = 1.4$ mM and $a_3 = 0.20$ mM for $[A^-] = 28$ mM. The correction term a_4 has been computed on the assumption that $[H^+]_R \cdot [H^+]^{-1} \approx [Na^+]_R \cdot [Na^+]^{-1}$. Then we get $a_4 \approx 0.03$ mM.

β_1 for the glycolate system has been computed by means of eqn. (15) instead of eqn. (12) as both $\Delta f \,.\, [A^-]^{-1}$ and $\Delta\varphi_1 \,.\, [A^-]^{-1}$ are approximately constant. For β_3 and β_4 the potentiometrically obtained constants have been used. A probable value of l'_2 has been calculated by means of eqn. (14) in the following way. We know that $\varphi_1^\circ = \beta_1 - l'_1 = 322$ M^{-1}. In most cases l'_1 is about 10 % of β_1. Then we have assumed that $l'_1 \approx 30$ M^{-1} and $\beta_1 \approx 350$ M^{-1}. As $f^\circ = \beta_1 \cdot \varphi_1^\circ - (\beta_2 - l'_2) = 82\,500$ we can write $\beta_2 \approx \beta_2 - l'_2 \approx 30\,000$ M^{-2} (in most cases $l'_2 \ll \beta_2$). This value of β_2 is in good accordance with the potentiometric value. Then eqn. (14) gives $l'_2 \approx 200$ M^{-2}.

As seen in Table 4 the β_1-values calculated by means of eqn. (15) are very close to 350. It should be emphasized that l'_2 has only a slight influence on β_1. Therefore the values of β_1 calculated from eqn. (15) are practically independent of the value of l'_1 assumed above.

$\beta_1 = 350$ M^{-1} gives $\beta_2 - l'_2 = 29.5 \times 10^3$ M^{-2}. Then β_2 can be determined by means of eqn. (13). The function $g(\varphi_1)$ seems to be linear over the whole region and therefore X_4 must be negligible for $[A^-] < 55$ mM. The slope of

Table 4. The cation-exchange measurements on the glycolate system. The values of $[A^-]$, φ and the various functions are valid for $C_{MR} = 10 \times 10^{-3}$ mmole.g^{-1}. In calculating β_1 the potentiometric obtained values $\beta_3 = 62 \times 10^4$ and $\beta_4 = 26 \times 10^5$ have been used.

$[A^-]$ mM	$\varphi \times 10^3$ l . g^{-1}	φ_1 M^{-1}	$f \times 10^{-2}$ M^{-2}	β_1 from eqn. (15)	(13) $g \times 10^{-4}$ M^{-3}
0	323	*322*	*825*		
1.40	216	353	915		
3.00	150	385	1 030	325 + 31 + 0 − 4 = 352	1 060
5.00	103.5	424	1 165	333 + 32 + 1 − 4 = 362	1 205
7.00	75.5	468	1 300	325 + 31 + 1 − 5 = 352	1 320
10.00	51.2	531	1 500	323 + 31 + 1 − 5 = 350	1 505
14.00	33.5	617	1 775	322 + 31 + 2 − 6 = 349	1 755

B. INVESTIGATION BY MEANS OF AN ANION EXCHANGER

Theoretical

Fronæus [5] has given a theory for the equilibrium distribution of the central ion M^{3+} between a solution containing a complexing ligand A^- and an anion exchanger saturated with A^-.

In the anion-exchange investigation the ionic strength of the outer solution is not kept constant by addition of sodium perchlorate as perchlorate ions would displace ligand ions in the resin. Then the activity coefficients will vary when the buffer solution is added.

For the distribution of the ions M^{3+} and A^- between the resin and the solution, we have according to the Donnan equation

$$[M^{3+}]_R \cdot [A^-]_R^3 = K \cdot [M^{3+}] \cdot [A^-]^3 \qquad (19)$$

The factor K includes the activity coefficients of the two ion species in both phases.

For the load on the exchanger we have the equation

$$C_{MR} = [M^{3+}]_R(1 + \sum_{j=1}^{N} \beta_{jR} \cdot [A^-]_R^j) = [M^{3+}]_R \cdot X([A^-]_R) \quad (20)$$

Then we get according to eqn. (19)

$$\varphi = \frac{C_{MR}}{C_M} = K \frac{X([A^-]_R)}{[A^-]_R^3} \cdot \frac{[A^-]^3}{X[(A^-])} = l_3 \cdot \frac{\alpha_3}{\alpha_{3R}} \quad (21)$$

with $l_3 = K \cdot \beta_{3R} \cdot \beta_3^{-1}$

Here l_3 is the Nernst distribution coefficient for the third uncharged complex and can be assumed to be approximately constant. α_3 and α_{3R} denote the fractions $[MA_3] \cdot C_M^{-1}$ and $[MA_3]_R \cdot C_{MR}^{-1}$, respectively.

As shown by Fronæus [5] the function $\varphi([A^-])$ shows a maximum for a ligand concentration in the outer solution corresponding to $\bar{n} = 3$.

Then, if anionic complexes are formed, φ will to begin with increase with increasing $[A^-]$. After the maximum point has been reached at $\bar{n} = 3$, φ will decrease with increasing values of $[A^-]$.

If anionic complexes are not formed, φ ought to increase uniformly for increasing $[A^-]$.

However, the possibility must be taken into consideration that a part of C_{MR} is due to gadolinium ions or complexes adsorbed on the surface of the resin particles. This has been discussed by Fronæus [8]. In addition to the quaternary ammonium groups the anion exchanger possibly contains amine groups, which might form complexes with the central ion M^{3+} and, most likely to a lesser extent, with the complexes MA_j^{3-j}. Then the presumed amine complexes ought to be found preferably on the surface of the resin. The contribution of the surface adsorption to φ is denoted by $\Delta\varphi^s$. As $[M^{3+}]$ decreases when $[A^-]$ increases, this surface adsorption ought to decrease with increasing $[A^-]$ — that is, $\Delta\varphi^s$ decreases when $[A^-]$ increases.

Experimental

Chemicals used. Dowex 1 × 4, an anion-exchanger containing fixed quaternary ammonium groups, was used. It was converted to the acetate or the glycolate form and air-dried. The swelling factor δ was determined to be 0.96.

Method of investigation. The complex solutions had the initial composition

$$C'_M \text{ mM } Gd(ClO_4)_3 + C'_{HA} \text{ mM HA} + C'_A \text{ mM NaA}$$

The gadolinium perchlorate contained the radioactive isotope ^{153}Gd. C' was kept constant in a series (0.0730 mM and 0.0630 mM in the investigations of the acetate and the glycolate systems, respectively).

The quotient $C'_{HA} : C'_A$ was 2.0 for the acetate buffer and 1.0 for the glycolate buffer. The pH of the initial solution of $Gd(ClO_4)_3$ was about 4.5.

The complex solution (v liters) together with m grams of air-dried exchanger was shaken during 20 h in a thermostat at 20°C. The value of $v \cdot m^{-1}$ was always 0.025 l · g^{-1}.

As the measurements of the equilibrium concentration C_M of the water phase showed that the sorption was very slight at all concentrations of acetate and glycolate ions, C_{MR} could not be calculated indirectly by means of eqn. (16) from the difference $C'_M - \delta \times C_M$. For this reason C_{MR} was determined directly by eluting the resin, which had been carefully separated from the solution, with v_1 liters of 2 M $HClO_4$ in small portions. After having determined the gadolinium concentration C''_M of this solution, it was possible to calculate C_{MR} from the relation $C_{MR} = v_1 \cdot m^{-1} \cdot C''_M$. Here $v_1 \cdot m^{-1}$ had the value 0.042 1 . g^{-1}. However, a certain amount of radioactive solution adhered to the particles of the separated resin, which could not be washed before the elution. Thus the C_{MR}-value included a quantity C^a_{MR} caused by this adherent solution. As $v \cdot m^{-1}$ had the same value for all the complex solutions and as the experiments were performed in quite the same manner, we have $C^a_{MR} \approx k \cdot C_M$, where k is a constant. The C^a_{MR} contributes to φ in the term $\Delta\varphi^a = C^a_{MR} \cdot C_M^{-1}$ — that is, all φ-values differ from the true φ-values by the constant term $\Delta\varphi^a = k$.

The gadolinium acetate system. The data from the measurements on the Gd^{3+}—Ac^--system are collected in Table 5 a. Curve *a* in Fig. 3 shows φ plotted against $[Ac^-]$. In the calculation of $[Ac^-]$ it is supposed that the perchlorate ions in the initial solution are nearly completely replaced by an equivalent amount of acetate ions from the resin.

According to the potentiometric measurements anionic complexes are formed in the Gd^{3+}-Ac^--system and the ligand number $\bar{n} = 3$ is reached at $[Ac^-] \approx 500$ mM. However, the function $\varphi([Ac^-])$ does not show any maximum at this acetate concentration. For 100 mM $< [Ac^-] <$ 800 mM, φ has a very low value and is approximately constant. At low $[Ac^-]$, φ is somewhat higher,

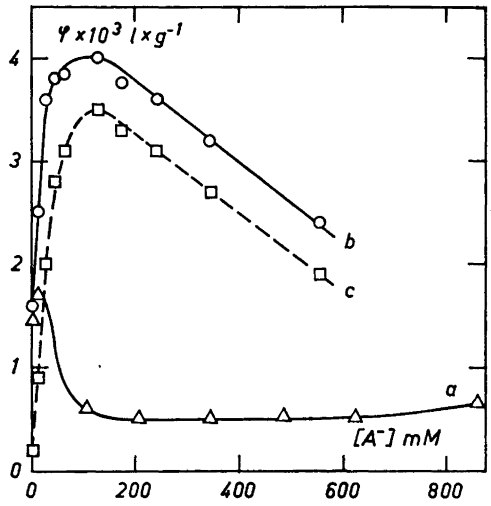

Fig. 3. The anion-exchange measurements on the acetate and the glycolate systems. Curve *a* represents the function $\varphi([Ac^-])$ and curve *b* the function $\varphi([AcOH^-])$. Curve *c* is the function $\varphi_c([AcOH^-])$, where φ_c means the φ-values of the glycolate system reduced by the φ-values of the acetate system.

certainly depending on the surface adsorption, which increases for decreasing $[Ac^-]$.

Then, according to these measurements anionic gadolinium acetate complexes cannot be formed by appreciable amounts in the resin phase. However, this does not necessarily mean that anionic complexes are not formed in the water phase.

The gadolinium glycolate system. The results from the measurement on the Gd^{3+}—$AcOH^-$-system are collected in Table 5 b. As shown in Fig. 3 (curve *b*) the function $\varphi([AcOH^-])$ has a distinct maximum for $[AcOH^-] \approx 100$ mM. This agrees with the potentiometric measurements as $\bar{n}_{pot} = 3$ for $[AcOH^-] \approx 100$ mM. Thus it is very probable that anionic glycolate complexes are formed both in the resin phase and in the water phase.

We may assume that the φ-values of the acetate system are due to surface adsorption and to solution adherent to the resin particles — that is, $\varphi_{Ac} \approx \Delta\varphi^s_{Ac} + \Delta\varphi^a_{Ac}$. We may also assume that these two $\Delta\varphi$-values have about the same values for the acetate and the glycolate systems. Then the true φ-values for the glycolate system should be $\varphi_c = \varphi - \varphi_{Ac}$. Curve *c* in Fig. 3 shows φ_c as a function of $[AcOH^-]$.

If we take the logarithm of eqn. (21), derivate $\ln\varphi$ with respect to $\ln[A^-]$ and introduce the ligand numbers $\bar{n}_R$ and $\bar{n}$ according to the definitions ($\bar{n} = d\ln X/d\ln[A^-]$), we get

$$\frac{d\ln\varphi}{d\ln[A^-]} = \frac{d\ln[A^-]_R}{d\ln[A^-]}(\bar{n}_R - 3) - (\bar{n} - 3) \qquad (22)$$

In this investigation we may consider $[A^-]_R$ as constant. Then we get

$$\frac{d\ln\varphi}{d\ln[A^-]} = 3 - \bar{n} \qquad (23)$$

Table 6. The anion-exchange measurements on the gadolinium glycolate system. The function $\frac{1}{k} \cdot X$ is computed according to eqn. (24) and the functions $\frac{1}{k} \cdot X_n$ according to eqn. (8) in paper II.

555	1.9	4.0	3.9	90	162	290	510	600

The values of $\bar{n}$ in Table 6 are calculated from the corrected φ_c-values by means of this equation. The accordance with the ligand numbers obtained potentiometrically is good.

Attempts have also been made to calculate approximate values of the complexity constants from the anion-exchange measurements. The φ_c-values have been used. Eqn. (21) can be transformed to

$$\frac{[A^-]^3}{\varphi} = \frac{1}{k} \cdot X = \frac{1}{k} + \frac{\beta_1}{k}[A^-] + \frac{\beta_2}{k}[A^-]^2 + \ldots . \qquad (24)$$

where

$$k = l_3 \cdot \beta_3 \cdot \alpha_{3R}^{-1}$$

α_{3R} is assumed to be constant as the ligand concentration of the resin is approximately constant.

Theoretically, the value of $1/k$ and the complexity constants can be calculated by means of the X/k-functions by extrapolation to $[A^-] = 0$.

However, the X-function decreases so rapidly with decreasing $[A^-]$ that it is impossible to obtain even an approximate value of $1/k$ (*cf.* Table 6), but for the X_n/k-funtions we have obtained the following approximate values for $[A^-] = 0$:

$$\frac{\beta_1}{k} = 0.10; \qquad \frac{\beta_2}{k} = 4.0; \qquad \frac{\beta_3}{k} = 200; \qquad \frac{\beta_4}{k} = 500$$

As we have no value of $1/k$ we can compute only the stability constants $b_n = \beta_{n+1} \cdot \beta_n^{-1}$. Thus $b_2 = 40$, $b_3 = 50$, $b_4 = 2.5$. These values are of the same order of magnitude as the potentiometrically obtained values $b_2 = 90$, $b_3 = 20$, $b_4 = 4$, but there are considerable differences between the two

sets of constants. One of the reasons may be that the potentiometric measurements are performed at the constant ionic strength 2.0 M whereas the anion-exchange experiments have been performed with solutions having an ionic strength increasing from about 0.01 M for the lowest value of $[A^-]$ (12.5 mM) to about 0.5 M for the highest value of $[A^-]$. In this region the activity coefficients are, of course, not constant. On the whole the stability constants obtained from the anion-exchange measurements are very uncertain. The cause of the too low value of b_2 may be a too high value of $\beta_1 \cdot k^{-1}$, because we have used the same value of $\Delta\varphi^s$ for the glycolate system as for the acetate system. If especially non-complex gadolinium ions are adsorbed on the surface of the resin, $\Delta\varphi^s$ ought to decrease more rapidly for the glycolate system than for the acetate system.

DISCUSSION

The investigations by use of the cation exchanger confirm the potentiometrically obtained values for the first three complexity constants for both the acetate and the glycolate system. It is true that the constants obtained for the glycolate system by the cation-exchange method are not quite independent of those obtained potentiometrically, but the potentiometric influence is so slight that it falls for the most part within the limits of the maximum random errors.

The question whether anionic complexes are formed can be answered definitely only for the glycolate system. The φ-curve obtained in the anion-exchange investigation of this system shows a rather pronounced maximum for $[AcOH^-] \approx 100$ mM, and, according to the potentiometric measurements, we should have $\bar{n} \approx 3$ for just this concentration of free glycolate ions. We may then conclude that anionic glycolate complexes are formed.

The φ-function obtained for the acetate system by means of the anion exchanger has an aspect quite different from that of the φ-curve of the glycolate system. We must conclude that anionic acetate complexes are not formed in the resin phase (*cf.* Fronæus [5]), but this does not necessarily mean that anionic complexes are not formed in the water phase. The low φ-values at the maximum point for the glycolate system indicates that it is very difficult for the complexes to be formed in the anionic resin phase. There may be a steric hindrance reducing the tendency to form complexes. This may be the reason why the considerably weaker acetate complexes cannot be formed in the resin phase. The relation between the heights of φ_{max} of systems of equal type should, according to Fronæus [5, p.3], give a qualitative measure of the difference in strength of the anionic complexes. However, it is also possible that the potentiometric measurements have given too high values for the complexity at high ligand concentrations, so that anionic complexes are not really formed to a measureable extent at the concentrations used in the anion-exchange measurements.

As seen in Fig. 3 the φ-values of the acetate system increase slightly at high ligand concentrations. This is probably due to the presence of a non-exchange electrolyte in the resin. Calculations show that this ought to increase the φ-values appreciably when $[A^-] > 0.7$ M. As $[A^-]_R \approx 3$ M for $[A^-] = 0$,

the increase in $[A^-]_R$ ought to be ~ 5 % at $[A^-] \approx 0.7$ M (*cf.* Fronæus [8, p.1181]). The presence of a non-exchange electrolyte probably does not influence the calculations for the glycolate system at lower ligand concentrations.

The sorption of the complex ions in the cation exchanger is very low compared with that of the non-complex gadolinium ions. For the acetate system we get $l_1' = (7 \pm 3)$ M^{-1} and $l_2' \approx 15$ M^{-2} (according to eqn. (14)). Eqns. (6) and (4) give for the distribution of the non-complex gadolinium ions and the acetate complexes between the resin phase and the water phase $l_o = 0.323$ $l \cdot g^{-1}$, $l_1 = 0.035$ $l \cdot g^{-1}$ and $l_2 = 0.0035$ $l \cdot g^{-1}$. For the glycolate system the corresponding values are $l_o = 0.323$ $l \cdot g^{-1}$, $l_1 = 0.025$ $l \cdot g^{-1}$ and $l_2 = 0.002$ $l \cdot g^{-1}$. This shows that the equilibrium concentration of $Gd(AcOH)_2^+$ is only about twice as high in the resin phase as in the water phase. Then, when $Gd(AcOH)_2^+$ is tranformed to higher complexes, the absolute decrease of φ will be rather small (relatively however, the decrease may be large). Therefore the random errors will seriously affect the determination of β_3 and the higher complexity constants, and this is probably the reason why the existence of the anionic glycolate complexes could not be detected by the cation-exchange method.

The author wishes to express his sincere gratitude to Professor S. Bodforss and to Professor S. Fronæus for their kind interest that has promoted the work.

This investigation has been supported by a grant from the *Swedish Natural Science Research Council* which is gratefully acknowledged.

On Vitamins in Sewage Sludge

IX. Production of Vitamin B_{12} by Methane Bacteria

HALINA Y. NEUJAHR and DANLEY A. CALLIERI

Royal Institute of Technology, Division of Food Chemistry, Stockholm 70, Sweden

Twelve different enrichment cultures of methane-producing bacteria have been prepared and their ability to produce vitamin B_{12} has been studied.

Most of the cultures produced small amounts of vitamin B_{12}. The enrichment cultures grown in the media containing either methanol, acetate or butyrate were shown to produce considerably larger amounts of vitamin B_{12} than those grown in the other media. The amount of vitamin B_{12} produced in the methanol-containing medium seems to be higher than that reported in the literature for many other microorganisms.

It was shown that the kind of factors produced by the enrichment cultures depends upon the composition of the medium. The formation of cyanocobalamin depends upon the supply of 5,6-dimethyl benziminazole.

In the two preceding papers [1,2], the authors have reported investigations on the ability of an enrichment culture of *Methanobacterium omelianskii* to produce vitamin B_{12}. This culture proved to have a rather limited synthetic ability with respect to vitamin B_{12}. The greatest yield of cyanocobalamin obtained using certain modifications of a simple synthetic medium did not exceed 100 mμg/ml. Since the high contents of vitamin B_{12} in sewage sludge evidently could not be explained by only the activity of *Methanobacterium omelianskii*, the synthetic ability of other methane bacteria, active during the digestion of sewage sludge, was investigated. Enrichment cultures of methane-producing bacteria were successfully prepared by many workers already in the beginning of this century (*cf.* Barker: *Bacterial Fermentations*, 1956 [9]). Such cultures are usually characterized by a high degree of morphological and physiological homogeneity. Wikén [3] gives a review of the earlier works and describes the preparation of several enrichment cultures as well as the isolation of some pure strains of methane bacteria. Using the technique described by Wikén, the authors prepared twelve enrichment cultures from digesting sewage sludge and investigated their ability to produce vitamin B_{12}, both in

a simple synthetic medium containing only one low molecular organic compound and also in the same medium modified by the addition of Co^{2+}, 5,6-dimethyl benziminazole and Bacto Peptone.

EXPERIMENTAL

Basal medium. The basal medium used was that described by Wikén [3] — it had the following composition: NH_4Cl, 1.0 g; K_2HPO_4, 0.4 g; $MgCl_2 . 6H_2O$, 0.1 g; tap water, 1 000 ml. To each 100 ml of this medium, a separately sterilized solution consisting of 2 ml of 1 % $Na_2S . 9H_2O$ solution + 8 ml of 5 % $Na_2CO_3 . 10H_2O$ solution was added. The pH of the medium was adjusted with separately sterilized HCl (1:5) to 6.5—7.5.

Elective media. Twelve different elective media were used to obtain the various enrichment cultures. These media were prepared by supplementing twelve portions of the basal medium with the following organic compounds (one compound only was added to each portion of the basal medium): methanol 1 %, ethanol 2 %, *n*-propanol 1 %, *iso*-propanol 1 %, *iso*amyl alcohol 0.5 %, acetone 0.5 %, calcium formate 2 %, calcium acetate 2 %, calcium propionate 2 %, and calcium *n*-butyrate 2 %. The media containing alcohols were further supplemented with 2 % of $CaCO_3$ in order to neutralize the acid formed during the fermentation and to form a sediment which, according to many workers, is very favourable for the growth of methane bacteria. The media containing acids (as salts) were instead supplemented with 2 % fine asbestos powder.

The preparation of the enrichment cultures was carried out by inoculating a few milliliters digesting sludge into the appropriate media. When a vigorous gas evolution was established, a reinoculation was performed into an identical medium. This procedure was repeated until altogether 10 reinoculations had been made in the same medium. To the last (the tenth) reinoculation, Co^{2+} was added (2 500 mμg/ml). After two further reinoculations into Co^{2+}-containing media, a reinoculation was made into a medium containing both Co^{2+} (2 500 mμg/ml) and 5,6-dimethyl benziminazole (1 000 mμg/ml), see Table 1. Finally, the media were also supplemented with Bacto Peptone (0.25 %) as seen in Table 1.

All cultures were grown in conical flasks of 100—300 ml capacity and incubated at 37°C.

Anaerobic conditions. All manipulations with the media and cultures were made in the carbon dioxide chamber described in a preceding paper [1]. The cultures were always covered with a layer of paraffin oil.

Samples were taken from the cultures at the end of the fermentation just before each reinoculation and were analyzed for vitamin B_{12} activity using *E. coli* 113—3 as test organism in a plate assay and by bioautography as described elsewhere [4].

RESULTS AND DISCUSSION

The results of the investigation can be seen in Table 1. The enrichment cultures grown in the media containing methanol, ethanol, *n*-propanol, *n*-butanol, *iso*butanol, *iso*amyl alcohol, acetate or butyrate grew relatively easily and considerable gas evolution usually occurred after incubation at 37°C for 5—15 days. The cultures grown in media containing methanol, acetate or butyrate were especially active — the most intensive gas evolution occurring only 1—2 days after the inoculation. The remaining four media produced much poorer growths and culturing times up to several months were required before a subsequent reinoculation could be made. An examination of Table 1 reveals that, apart from media containing methanol, acetate or butyrate, only small amounts of vitamin B_{12} activity (comparable with those produced in the ethanol-containing medium in which *Methanobacterium omelianskii* is dominant) were produced.

The cultures which were grown in the media containing methanol, acetate or butyrate (especially the first named) provide, however, a striking exception. When supplied with Co^{2+}, 5,6-dimethyl benziminazole and Bacto Peptone, the methanol culture produced vitamin B_{12} activities up to 6 000 mμg/ml estimated as *E. coli* activity in the cup plate assay and calculated as cyanocobalamin. The amounts of *E. coli* activity produced by this culture are thus 80—300 times greater than those produced by the cultures developed in most of the other media and even ~3 resp. 6 times greater than the amounts produced by the butyrate resp. acetate cultures. The yields of vitamin B_{12} activity obtained with the methanol culture seem to be even higher than those reported for *Streptomyces olivaceus* [5].

All three cultures produce sufficient amounts of *E. coli* activity to explain the high vitamin B_{12} activity of digested sewage sludge. Moreover, it seems as if the amount of vitamin B_{12} activity which can be obtained with the three most active cultures, especially when calculated on a dry solids basis, is even higher than the vitamin B_{12} activity of digested sludge. A possible explanation of this phenomenon is that digested sludge, as suggested in a previous work [6], probably contains organisms which consume vitamin B_{12}. Furthermore, the essential substrates, *viz.* methanol, acetate or butyrate may be present in the sludge only in limited quantities or the rate of their formation may not be rapid enough to provide the appropriate organisms with adequate quantities of the substrates. This may also be true for 5,6-dimethyl benziminazole. However, it has been shown in a previous work [1] that an increase above 1 000 mμg/ml in the content of 5,6-dimethyl-benziminazole in the medium fermented by *Mb. omelianskii* does not produce any increase in the yield of vitamin B_{12} and that the addition of 10 000 mμg/ml of benziminazole, *i.e.* a tenfold increase, seems instead to bring about an inhibition of the growth. Similar observations have also been made with the methanol culture — more detailed results will be reported in a separate communication. It can further be seen in Table 1 that the addition of Co^{2+} may stimulate the growth of certain cultures (as judged by the gas evolution), *e.g.* the cultures grown in the media containing methanol, ethanol, acetate or butyrate. This effect was most pronounced in the last two cases — the addition of Co^{2+} seemed to be essential for the production of any appreciable growth. In most cultures, even those in which the Co^{2+} addition had no effect on the gas evolution, it was found that the formation of *E. coli* activity was stimulated by this addition. An exception in this respect was the culture grown on *iso*butanol.

The *E. coli* activity produced by the different cultures could in most cases be separated into at least two spots by the usual chromatographic-bioautographic technique. One of these spots corresponded to cyanocobalamin, R_c (= R_F relative to R_F of cyanocobalamin) = 1.0. Although cyanocobalamin was formed in most cultures, its formation in some cultures was dependent upon the addition of Co^{2+} alone (*e.g.* cultures on ethanol, *n*-propanol, *iso*propanol, acetone, butyrate) while, in others, both Co^{2+} and 5,6-dimethyl benziminazole had to be added in order to obtain the formation of cyanocobalamin (*e.g.* cultures on methanol, *n*-butanol, *iso*amyl alcohol and acetate).

Even in those cultures in which the addition of Co^{2+} alone stimulated the synthesis of cyanocobalamin, a simultaneous addition of 5,6-dimethyl benzi-

minazole directed the synthesis towards the formation of cyanocobalamin at the expense of the other factors. In two cases (ethanol and *iso*amyl alcohol), such a simultaneous addition resulted in the formation of cyanocobalamin as the only factor, although in rather smaller amounts. In these two and certain other cultures, the addition of 5,6-dimethyl benziminazole seemed to decrease the *E. coli* activity estimated in the cup plate assay as compared with a corresponding culture grown with the addition of Co^{2+} only. It cannot, however, be concluded whether this was a real decrease in the vitamin B_{12} activity or merely a reflection of the differences in activity towards *E. coli* in the cup plate assay between the other factors and the cyanocobalamin to which they had been converted due to the addition.

* and/or possibly some incomplete factor with R_c-value (R_F-value relative to that of cyanocobalamin) in the range 0.6—0.7; *cf.* discussion and Ref [7].

** calculated as cyanocobalamin in plate assay.

*** identified by paper chromatography in solvent system I [7].

The second chromatographic spot of *E. coli* activity obtained in most cultures had an R_c-value in the range 0.6—0.7. It has been reported earlier [7] that the presence of at least 8 different vitamin B_{12} factors can be attributed to such a spot, *viz.* factor III, (Bernhauer) [8], factor A (Ford, Kon and Porter)[11], pseudovitamin B_{12} (Pfiffner) [12] and the factors X1, X2, X3, X4, and W isolated from sewage sludge in this laboratory [7].

More accurate chromatographic and electrophoretic studies, however, indicated that it was improbable that factor A or (and) pseudovitamin B_{12} were present in the spot.

It has also been shown in a previous work [1] that one of the methane bacteria, *viz. Mb. omelianskii*, cannot utilize adenine in the presence of Co^{2+} or even in the presence of added factor B to produce pseudovitamin B_{12}. It is therefore probable that neither pseudovitamin B_{12} nor factor A was formed by the various enrichment cultures. The ever increasing number of vitamin B_{12} factors reported in the literature makes the identification of any factor by the chromatographic-bioautographic technique quite uncertain. However, certain interesting observations can be made concerning the occurrence of certain factors (chromatographic spots) in certain cultures while not in others. It has been found in an earlier study and confirmed by the present investigation that the enrichment culture grown in the ethanol-containing, but not further supplemented, basal medium produces only one vitamin B_{12} factor, *viz.* factor Met. This factor has an R_c-value ($\sim$ 0.7) close to that for the eight factors mentioned above and its occurrence in sewage sludge has never before been noticed (probably partly due to its very low concentration in this material). It is interesting to note that factor Met was not formed by any other enrichment culture. It seems therefore to be in some way characteristic for the enrichment culture of *Mb. omelianskii* prepared in the ethanol-containing medium. As far as the remaining factors which may be present in the second chromatographic spot (R_c = 0.6—0.7) of *E. coli* activity are concerned, no conclusions could be made about which of these factors were formed by the respective cultures. The results of paper electrophoretic studies indicated that, in most cultures, the spot with R_c = 0.6—0.7 corresponded mainly to factor W (and/or factor III) possibly accompanied by minor quantities of the incomplete factors X4 and (or) X3. In the culture grown on butyrate, these last two factors were formed in considerably greater amounts than in the other cultures.

The culture grown in the methanol-containing medium produced the greatest number of vitamin B_{12} factors. As pointed out above, this culture also produced the largest amount of *E. coli* activity. A chromatographic separation of the activity gave 4 spots when both Co^{2+} and 5,6-dimethyl benziminazole were added to the medium, but only 3 spots when the benziminazole was omitted. The four spots corresponded to factors: B (R_c = 1.3—1.5), Cy (R_c = 1.0), W and (or) factor III + minor quantities of X4 and (or) X3 (R_c = 0.6—0.7) and finally some of the factors Z. When 5,6-dimethyl benziminazole was lacking, but Co^{2+} present, in the medium, the spot corresponding to cyanocobalamin was always absent after chromatographic separation.

It can, in addition, be seen in Table 1 that the enrichment culture grown in the methanol-containing medium was the only one which produced factors Z [7]. This culture was exceptional also with respect to the occurrence of factor B since the chromatographic spot corresponding to this factor was not (or not completely) converted to the cyanocobalamin-spot in the presence of added 5,6-dimethyl benziminazole and Bacto Peptone. In a preliminary study of this problem, we investigated whether greater additions of 5,6-dimethyl benziminazole to this culture cause a more complete conversion of factor B (and possibly also of factors Z) to cyanocobalamin. However, the results indicated that greater additions of this compound ($>$ 1 μg/ml medium) may have an inhibiting effect on the growth of the culture.

It is possible that the spots corresponding to factors B and Z contained also some other factors which could not be converted to cyanacobalamin by the culture.

Microscopic examinations of the enrichment culture grown in the basal medium supplemented with methanol revealed the presence of at least two kinds of organisms. One of them was a coccus of about 1.5 μ diameter, the second was a rod-shaped organism the size of which was greater than that of *Methanobacterium omelianskii*. Both were Gram variable. The coccoidal form was the dominant one. A rough estimation indicated that the coccoidal form was 1 000 times more abundant than the rod shaped one.

The enrichment culture grown in the butyrate-containing medium consisted of rods 3—6 μ long and 1 μ thick, whereas the culture obtained in the acetate-containing medium contained almost exclusively coccoidal forms of 1.5—2 μ diameter. In agreement with our previous experience, the culture grown in the ethanol-containing medium was composed of rods, sometimes slightly bent, which corresponded morphologically to the *Mb. omelianskii* described by Barker [10]. All those forms were Gram variable. Attempts to isolate pure strains form the enrichment cultures have so far failed. As soon as a single colony form a semi-solid medium was transferred to a fresh medium, the growth ceased in spite of great precautions for the maintenance of anaerobiosis.

Studies Related to Naturally Occurring Acetylene Compounds, XXVI. The Synthesis of 5-(1-propynyl)-2-formylthiophene, Junipal, and *trans* Methyl 5-(1-propynyl)-2-thienylacrylate

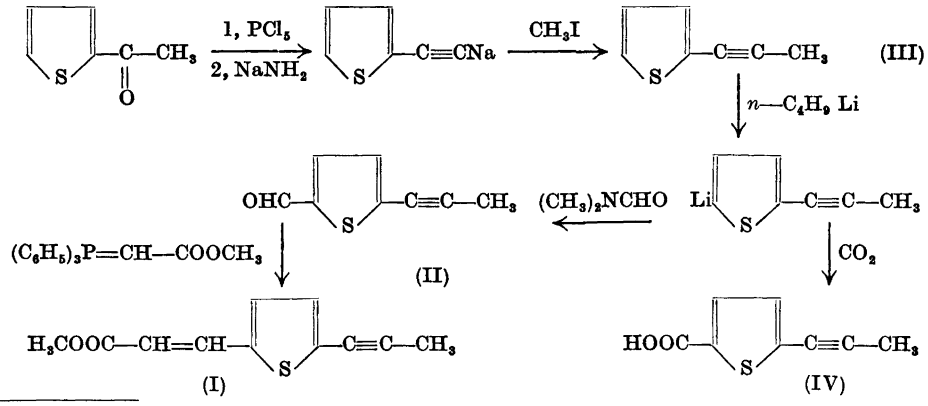
LARS SKATTEBÖL*

SINTEF, Norges Tekniske Högskole, Trondheim, Norway

The synthesis is described of junipal (II), a metabolic product from a wood-rotting fungus, and also of *trans* methyl 5-(1-propynyl)-2-thienylacrylate (I), the steric isomer of a naturally occurring substance isolated from a *Compositae* plant.

In the previous communication of this series [1] Guddal and Sörensen described the isolation of a naturally occurring thiophene derivative from the root of Tancy (= *Chrysanthemum vulgare* Bernh.) of the *Compositae* family. The compound was deduced as *cis* methyl 5-(1-propynyl)-2-thienylacrylate (I) on the basis of analysis, characterisation of the hydrogenation product and evidence obtained from ultraviolet- and infrared spectra.

In order to confirm this structure the synthesis of (I) was undertaken through the following route:



Present address: European Research Associates, 95, rue Gatti de Gamond, Bruxelles 18, Belgium.

An intermediate in this synthesis, *viz.* 5-(1-propynyl)-2-formylthiophene (II), has the same structure as that proposed for junipal, a metabolic product isolated by Birkinshaw and Chaplen [2] from the wood-rotting fungus *Daedalea juniperina* Murr.

2-Thienylacetylene was prepared from 2-acetylthiophene by chlorination with phosphorus pentachloride and subsequent dehydrochlorination with sodium amide in liquid ammonia, in the way described by Vaitiekunas and Nord [3]. The ethynyl compound was not isolated but reacted further, as the sodium salt, with methyl iodide to give 2-(1-propynyl)-thiophene (III) in 30 % overall yield. The compound turned dark brown fairly rapidly, when stored at room temperature. With butyl lithium in ether (III) readily formed a lithium derivative. The lithium is most probably substituted in the 5-position. This is analogous to previous results from this reaction with thiophenes [4], and it is also in agreement with kinetic measurements [5,6]. Reaction of the lithium compound with N-dimethylformamide [7] gave the corresponding aldehyde (II) in 21 % yield, as almost colourless crystals, m.p. 81—82°. A good deal of polymeric material was formed. The ultraviolet- and infrared spectra were in agreement with those published for junipal [2], and a mixed melting point determination with the natural substance, kindly provided by Professor J.H. Birkinshaw, showed no depression.

Carbonation of the lithium derivative yielded 2-(1-propynyl)-thiophene-5-carboxylic acid (IV), = junipic acid [2].

The aldehyde (II) readily underwent a Wittig reaction [8] with methylcarbethoxytriphenylphosphonium chloride. From the reaction mixture the wanted ester (I) was obtained in 55 % yield as colourless needles, m.p. 77°. The band at 962 cm^{-1} in the infrared spectrum strongly indicated that the configuration about the double bond was *trans*.[9] The compound was found to be in all respects identical with the photo-isomerised naturally occurring substance [1]. Theoretically the *cis*-isomer should also be formed in the Wittig reaction, and this has been confirmed in some instances [8,10]. We were not able, however, to isolate any of the *cis*-isomer from our reaction mixture.

Birkinshaw and Chaplen [2] also reported the isolation of a second thiophene derivative, accompanying junipal. They were only able to obtain it pure as the 2,4-dinitrophenylhydrazone. The analysis and ultraviolet spectrum pointed to a structure similar to junipal, but with an additional double bond. It was suggested [11] that the substance was the aldehyde corresponding to the ester(I), *viz.* 2-(1-propynyl)-5-thienylacraldehyde. The synthesis of this aldehyde, however, showed that this unfortunately was not so. Further work on the structure of this metabolic product is in progress.

EXPERIMENTAL

All melting points are uncorrected. The carbon-hydrogen analyses were carried out by Alfred Bernhardt, Mühlheim, Ruhr, Germany.

2-(1-Propynyl) thiophene (III). The sodium salt of 2-ethynylthiophene in liquid ammonia was prepared from 75 g of 2-acetylthiophene according to the method of Vaitiekunas and Nord [3]. Methyl iodide (70 g) was then added over a period of 25 min and the mixture was stirred overnight. 400 ml of water were carefully added and the dark brown solution extracted with ether. The extract was washed with water and dried over anhydrous sodium sulphate. The ether was removed under vacuum, and the residue purified by chromatography on deactivated alumina (1 % water). A yellow oil was eluted

with light petroleum and fractionation of this gave 22.0 g (30 % from acetylthiophene) of 2-(1-propynyl) thiophene as a colourless liquid, b. p. 65—66°/7 mm, n_D^{17} 1.5950. (Found: C 69.05; H 4.75. Calc. for C_7H_6S: C 68.81; H 4.95.) Ultraviolet absorption, in ethanol: λ_{max} 267.5 mμ; log ε 3.82.

5-(1-Propynyl)-2-formylthiophene, junipal (II). 2-(1-propynyl) thiophene (III) (1.3 g) was dissolved in 10 ml of dry ether, and 9.6 ml of a 1.1 N butyl lithium solution in ether was added with stirring. After 15 min at room temperature the red-coloured solution was cooled to −10° and 0.8 g of N-dimethylformamide in 2 ml of dry ether was added with stirring. The mixture was allowed to attain room temperature (15 min) and then decomposed with a saturated aqueous solution of ammonium chloride. Extraction with ether, drying and evaporation of the solvent under vacuum gave a crystalline residue. Recrystallisation from light petroleum-ether yielded the aldehyde (330 mg, 21 %), m. p. 79—81° as slightly yellow-coloured needles. Almost colourless crystals were obtained by sublimation at 50°/0.4 mm, m. p. 81—82°. (Found: C 63.87; H 4.11. Calc. for C_8H_6OS: C 63.97; H 4.03.) Ultraviolet absorption, in ethanol: λ_{max} 286 and 320 mμ; log ε 3.91 and 4.27, respectively. Birkinshaw and Chaplen [2] report m. p. 80°. Ultraviolet absorption in ethanol: λ_{max} 216.5, 286.5 and 320 mμ; log ε 3.73, 3.95 and 4.29, respectively. A 1:1 mixture with the natural substance melted at 80—81.5°.

5-(Propynyl) thiophene-5-carboxylic acid (IV). 2-(1-Propynyl) thiophene(III) (2.0 g) was dissolved in 10 ml of dry ether, and 14.5 ml of a 1.13 N solution of butyl lithium in ether was added with stirring. After 15 min at room temperature the solution was poured into a stirred slurry of solid carbon dioxide and dry ether. When the excess carbon dioxide had evaporated, water was added and the organic phase separated. The aqueous phase was acidified with dilute hydrochloric acid and extracted with ether. Evaporation of the solvent and recrystallisation of the residue from light petroleum-ether gave the acid (1.1 g; 37 %) as yellow needles, m. p. 175—177°. Further purification by sublimation and recrystallisation raised the melting point to 176.5—177.5°. (Found: C 57.65; H 4.20. Calc. for $C_8H_6O_2S$: C 57.80; H 3.60.) Ultraviolet absorbtion, in ethanol: λ_{max} 293 mμ; log ε 4.02. Birkinshaw and Chaplen [2] record m. p. 180°.

Methyl 5-(1-propynyl)-2-thienylacrylate (I). Methylcarbethoxy-triphenyl-phosphonium chloride (550 mg) was dissolved in 2 ml absolute methanol, and 8.0 ml of a 0.185 N solution of sodium methoxide was added with stirring. After 30 min at room temperature, 215 mg of 5-(1-propynyl)-2-formylthiophene (II) was added with stirring. The solution was left at room temperature for 40 h. The methanol was distilled under vacuum, and the residue extracted with ether. The extract was washed with 2 N hydrochloric acid, then with water and finally dried over magnesium sulphate. Chromatography on neutral alumina and subsequent recrystallisation from light petroleum yielded the ester (I) (156 mg; 55 %) as colourless needles, m. p. 77°. (Found: C 64.19; H 5.09. Calc. for $C_{11}H_{10}O_2S$: C 64.05; H 4.89.) Ultraviolet absorption, in ethanol: λ_{max} 235 and 341.5 mμ; log ε 3.98 and 4.50, respectively.

Acknowledgements. I am indebted to Professor N. A. Sörensen and lic.techn. E. Guddal for their interest in this work. I also wish to thank Professor J. H. Birkinshaw for a sample of natural junipal.

Short Communications

Studies on the O,N-Acyl Shift

JOSEPH L. RABINOWITZ*

Carlsberg Laboratorium, Chemical Department, Copenhagen, Denmark

Elliott [1], Lucas [2], and others demonstrated the occurrence of an O,N-acyl shift [3] in various proteins and model peptides [4] under the influence of concentrated sulfuric acid, anhydrous phosphoric acid and other strong reagents. Josefsson and Edman [5] reported the reversible inactivation of lysozyme and ribonuclease due to an O,N-acyl shift induced by the mild action of "100 % formic acid" at 22° for 24 h. This preliminary note presents the results of studies of the action of anhydrous formic acid on various model compounds.

The infrared spectra of the above compounds were determined by the use of the Scheidt method [6]. The infrared spectra were also determined on the recovered materials after treatment with anhydrous formic acid and with concentrated sulfuric acid. The differences between the spectra of the original compounds and those of the formic acid treated peptides were not extensive, whereas the spectra of materials recovered after sulfuric acid treatment differed greatly from both those of the formic acid treated material and the original. Due to its waxy appearance, however, the sulfuric acid treated material gave poor infrared spectra by the Scheidt technique.

Table 1 shows the results obtained from the incubation of ^{14}C-formic acid with various substrates at 22° for 24 h.

Contrary to the findings of Josefsson and Edman [5] these results clearly indicate that formylation occurred in the serine polypeptide during the action of the formic acid, yet this data do not show if an O,N-acyl shift occurred.

Table 1. Radioactivity recovered in c.p.m. per mg carbon.

		Ext 1	Ext 2
1	Anhydrous ^{14}C—formic acid used	6 050	68 000
2	Poly-DL-serine after treatment	1 095	19 500
3	The above (2) after repeated washings	1 165	19 400
4	The recovered formate hydrolysis of the washed material (3)	5 310	63 000
5	The recovered poly-DL-serine after hydrolysis of the washed material (3)	4	11
6	Poly-DL-alanine after ^{14}C-formic acid treatment	4	—

Poly-DL-serine incubated at 22° for 24 h with anhydrous acetic acid produced a compound that by infrared spectra and independent synthesis [7] was found to be poly-O-acetyl-DL-serine. Poly-DL-serine is exceedingly water soluble and deliquescent; both the prepared poly-O-acetyl-DL-serine, as well as the recovered product after treatment with formic acid, were water insoluble. The Biuret test [8] was found to be positive for poly-DL-serine as well as for its

* Present address: Dept. Biochem., University of Pennsylvania, and Radioisotope Dept., Veteran Administration Hospital, Philadelphia, Penna., USA.

formic acid product and for poly-O-acetyl-DL-serine, but not for the material obtained after poly-DL-serine underwent treatment with concentrated sulfuric acid. These tests are suggestive of the absence of peptide-bond alterations for the formic acid treated materials and for elimination of all peptide bonds in the sulfuric acid treated materials.

The presented results as well as the additional evidence obtained by the use of model compounds indicate that formic acid under the conditions used is undoubtedly an excellent formylating agent. Recently Narita [9] and Neurath [10] have reported similar conclusions on the use of formic acid on various proteins. A more extensive article is in preparation for *Compt. Rend. trav. lab. Carlsberg.*

Effect of Lysine on the Purification of Human Plasminogen on Cellulose Ion Exchangers

PER WALLÉN and KURT BERGSTRÖM

Kemiska Institutionen II, Karolinska Institutet, Stockholm, Sweden

Plasminogen, the precursor of the proteolytic enzyme plasmin, is present in mammalian blood plasma. Experience has shown that it is rather difficult to purify it. One of the reasons seems to be that the plasminogen has a marked tendency to coprecipitate with other proteins (Remmert and Cohen [1]). The purest plasminogen preparations have been prepared according to the method of Kline [2]. This method is based on the resistance of plasminogen to acid and alkali denaturation. In the present work an alternative method is outlined.

According to Müllertz and Lassen [3,4] there are in human plasma two different factors concerned in the fibrinolytic system when streptokinase is used as activator, the plasminogen and the proactivator. After activation with streptokinase the former gets proteolytic and the latter plasminogen activating activity. Test methods, in which bovine fibrin containing plasminogen is used as substrate measure mainly the activator activity whereas those methods in which casein or another protein is used as substrate measure the proteolytic activity.

The preparations and fractions obtained in this work have been tested with the caseinolytic method of Müllertz [4] and the fibrinolytic method of Christensen [5]. As no significant separation between the two plasma factors has been obtained and because the caseinolytic method seems to be the more reliable one of the two methods, the figures in the text concerning yield and specific activity refer to this method.

Attempts have been made to reproduce the method of Kline. The proteolytic potency of the preparations obtained has varied considerably. The activity per mg substance has been 5 to 10 times that of Fraction III (Cohn) as prepared by Oncley *et al.*[6] According to our calculations this should mean an increase in activity of about 100 to 200 times as compared to plasma on a protein basis, which is 2 to 4 times lower than the result published by Kline. The yields have been low, only 5 to 15 % from Fraction III.

In order to avoid this rough handling and the accompanying low yields we have tried other, milder forms of separation. A partial purification of plasminogen has been obtained by dialysing a suspension of Fraction III paste against a 0.02 M sodium phosphate buffer of pH 7.0 during 20 h at +5°C. A precipitate is obtained, which contains 12 to 15 % of the protein in the starting material. The precipitate has a specific caseinolytic and fibrinolytic activity which is 4 to 5 times that of Fraction III. The yield of plasminogen is about

Effect of Lysine on the Purification of Human Plasminogen on Cellulose Ion Exchangers

PER WALLÉN and KURT BERGSTRÖM

Kemiska Institutionen II, Karolinska Institutet, Stockholm, Sweden

Plasminogen, the precursor of the proteolytic enzyme plasmin, is present in mammalian blood plasma. Experience has shown that it is rather difficult to purify it. One of the reasons seems to be that the plasminogen has a marked tendency to coprecipitate with other proteins (Remmert and Cohen [1]). The purest plasminogen preparations have been prepared according to the method of Kline [2]. This method is based on the resistance of plasminogen to acid and alkali denaturation. In the present work an alternative method is outlined.

According to Müllertz and Lassen [3,4] there are in human plasma two different factors concerned in the fibrinolytic system when streptokinase is used as activator, the plasminogen and the proactivator. After activation with streptokinase the former gets proteolytic and the latter plasminogen activating activity. Test methods, in which bovine fibrin containing plasminogen is used as substrate measure mainly the activator activity whereas those methods in which casein or another protein is used as substrate measure the proteolytic activity.

The preparations and fractions obtained in this work have been tested with the caseinolytic method of Müllertz [4] and the fibrinolytic method of Christensen [5]. As no significant separation between the two plasma factors has been obtained and because the caseinolytic method seems to be the more reliable one of the two methods, the figures in the text concerning yield and specific activity refer to this method.

Attempts have been made to reproduce the method of Kline. The proteolytic potency of the preparations obtained has varied considerably. The activity per mg substance has been 5 to 10 times that of Fraction III (Cohn) as prepared by Oncley *et al.*[6] According to our calculations this should mean an increase in activity of about 100 to 200 times as compared to plasma on a protein basis, which is 2 to 4 times lower than the result published by Kline. The yields have been low, only 5 to 15 % from Fraction III.

In order to avoid this rough handling and the accompanying low yields we have tried other, milder forms of separation. A partial purification of plasminogen has been obtained by dialysing a suspension of Fraction III paste against a 0.02 M sodium phosphate buffer of pH 7.0 during 20 h at +5°C. A precipitate is obtained, which contains 12 to 15 % of the protein in the starting material. The precipitate has a specific caseinolytic and fibrinolytic activity which is 4 to 5 times that of Fraction III. The yield of plasminogen is about

60 %. The precipitate is very slightly soluble in buffers of neutral reaction.

The preparations were purified chromatographically on DEAE-cellulose of the Sober and Peterson type [7]. They were dissolved in 0.02 M ammonium acetate buffer pH 9.0 and applied to DEAE-cellulose columns previously equilibrated with the same buffer. Under these conditions most of the protein as well as the plasminogen is adsorbed on the DEAE-cellulose. The elution was performed stepwise with buffers of increasing acidity, from pH 9.0 to pH 4.0. Plasminogen appeared in several of the fractions but no or very slight increase in specific activity was obtained. The yields were very low.

Recently Alkjaersig, Fletcher and Sherry [8] reported that ε-aminocaproic acid, lysine and certain other basic amino acids in low concentrations increased the solubility of plasminogen and plasmin at neutral pH. This effect of lysine may depend on a specific interaction between plasminogen and lysine. To see if an addition of lysine to the buffers used for elution would give a better separation of plasminogen at the chromatography on DEAE-cellulose the following experiment was performed.

About 5 g of DEAE-cellulose (Brown Comp. New Hampshire, USA) were suspended in 0.02 M ammonium acetate buffer, pH 8.9 to 9.0, containing lysine to a concentration of 0.01 M. The slurry was poured in a column with a diameter of 2 cm and allowed to settle under a slight hydrostatic pressure. The column was equilibrated with the same buffer. 125 mg of the partially purified plasminogen preparation obtained through dialysis against phosphate buffer were dissolved in 12.5 ml of the equilibration buffer at pH 8.9. Some of the material did not dissolve and was removed by centrifugation. It contained about 10 % of the protein and 3 % of the plasminogen activity. The opalescent supernatant was applied to the column, which was then developed with about 200 ml of the equilibration buffer. The elution was performed stepwise with the following buffers: 0.02 M sodium phosphate pH 6.5, 0.02 M sodium citrate pH 5.5, 5.0 and 4.0. All buffers contained lysine to a concentration of 0.01 M. The effluent was collected in fractions of 10 ml/h. The protein content of each fraction was estimated with the color reaction of Herriott-Lowry [9,10]. The fractions corresponding to each peak in the chromatogram were pooled, lyophilized and redissolved in 0.15 M sodium phosphate buffer pH 7.3. After dialysis against the same phosphate buffer the volumes were made up to 50 ml and the fractions analysed in respect to protein concentration, caseinolytic and fibrinolytic activity. For comparison another chromatogram was made at the same time and in exactly the same way but with the exception that lysine was replaced by sodium chloride. The results are shown in Fig. 1.

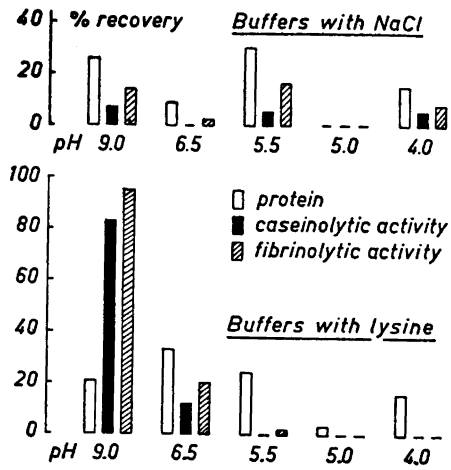

Fig. 1. Chromatography of partially purified plasminogen on DEAE-cellulose. The diagrams show the distribution of protein, caseinolytic and fibrinolytic activity among the fractions that appear at different pH. Upper diagram shows the pattern obtained when 0.01 M NaCl is added to the buffers. Lower diagram shows the pattern obtained when 0.01 M lysine is added to the buffers.

The upper part of Fig. 1 is an example of the pattern obtained in the chromatography without lysine. About 10 % of the plasminogen appears with the front. In the subsequent eluates the activity appears in the fractions containing most protein (pH 5.5 and 4.0). The yield and the specific activity in these fractions is low. The total yield of plasminogen is 20 to 25 %.

If lysine is added to the buffers the behaviour of plasminogen is markedly changed. The main part of the caseinolytic and fibrinolytic activity is not adsorbed to the DEAE-cellulose but appears in the front. The remaining part of the activity appears when elution is performed with 0.02 M phosphate buffer pH 6.5. In the frontal

peak about 20 % of the protein of the starting material appears together with about 80 % of the plasminogen. Consequently the starting material has been purified 4 times. This means an increase in purity of 16- to 20-fold as compared to Fraction III and the yield from Fraction III is about 50 %.

The reason for this behaviour of plasminogen is not understood. Attempts to adsorb the plasminogen to CM-cellulose equilibrated with buffers of pH 8.9 containing lysine have not been successful, which indicates that there is no reversal in the electric charge of the plasminogen.

Separation of Glycerol Ethers by Gas-liquid Chromatography

ROLF BLOMSTRAND and JOSEF GURTLER

Department of Clinical Chemistry, University of Lund, Lund, Sweden

In the course of studies [1,2] on the metabolism of the 1-mono-ethers of glycerol with hexadecyl, octadecyl and 9-octadecenyl alcohol, *i.e.* chimyl, batyl and selachyl alcohol, a method for the separation of the individual glycerol ethers was needed. This separation has also earlier been made with adsorption chromatography on alumina [3], but any separation of batyl from selachyl alcohol was not obtained.

The separation of methyl esters of high molecular weight fatty acids by gas-liquid chromatography (GLC) has been reported [4-6]. Since GLC permits microgram mixtures of methyl esters of fatty acids to be resolved, analysis of mixtures of glycerol ethers has been investigated.

The present paper describes the complete separation of chimyl, batyl and selachyl alcohol by GLC after acylation of the two hydroxyl groups of the glycerol ethers.

Apparatus and procedure. The GLC experiments were carried out with an Argon Pye Chromatograph. The temperature of operation was 218°C and the inlet pressure of the gas 72 cm Hg. The rate of flow of the carrier gas (Argon) was 20 cm³/min. The detector voltage was set on 1 250 V. Each 4-foot column was packed with 5 g of acid-washed, alkali-treated Celite (mesh 100—140). As stationary phase a polar polyester LHC-1R-296 (obtained from Cambridge Inc., Mass. U.S.A.) was used in the ratio Celite: stationary phase 4:1. Acylation of the two hydroxyl groups of the glycerol ethers was carried out with acetic anhydride in the presence of pyridine after boiling on a water bath for 12 h. The esterified mixture of glycerol ethers was isolated and dissolved in a few microlitres of ethyl acetate, and the solution taken up in a micropipette and applied to the column.

The retention volumes of the different glycerol ethers were determined using a mixture of known compounds (Table 1). The retention volumes are expressed relative to synthetic batyl alcohol, which was used as internal standard. When determining the retention volumes of the pure compounds, special care was taken not to overcharge the column in order to obtain symmetrical peaks on the chromatogram. The polyester column had a retention time of batyl alcohol diacetin of 49 min.

Table 1. GLC characteristics on LHC-1R-296 as stationary phase of three glycerol ethers after acylation. Temperature 218°C. Argon flow rate 20 cm³/min.

	Apparent retention volume relative to batyl alcohol-diacetin = 1.00
Chimyl alcohol	0.61
Batyl alcohol	1.00
Selachyl alcohol	1.11

peak about 20 % of the protein of the starting material appears together with about 80 % of the plasminogen. Consequently the starting material has been purified 4 times. This means an increase in purity of 16- to 20-fold as compared to Fraction III and the yield from Fraction III is about 50 %.

The reason for this behaviour of plasminogen is not understood. Attempts to adsorb the plasminogen to CM-cellulose equilibrated with buffers of pH 8.9 containing lysine have not been successful, which indicates that there is no reversal in the electric charge of the plasminogen.

Separation of Glycerol Ethers by Gas-liquid Chromatography

ROLF BLOMSTRAND and JOSEF GURTLER

Department of Clinical Chemistry, University of Lund, Lund, Sweden

In the course of studies [1,2] on the metabolism of the 1-mono-ethers of glycerol with hexadecyl, octadecyl and 9-octadecenyl alcohol, *i.e.* chimyl, batyl and selachyl alcohol, a method for the separation of the individual glycerol ethers was needed. This separation has also earlier been made with adsorption chromatography on alumina [3], but any separation of batyl from selachyl alcohol was not obtained.

The separation of methyl esters of high molecular weight fatty acids by gas-liquid chromatography (GLC) has been reported [4-6]. Since GLC permits microgram mixtures of methyl esters of fatty acids to be resolved, analysis of mixtures of glycerol ethers has been investigated.

The present paper describes the complete separation of chimyl, batyl and selachyl alcohol by GLC after acylation of the two hydroxyl groups of the glycerol ethers.

Apparatus and procedure. The GLC experiments were carried out with an Argon Pye Chromatograph. The temperature of operation was 218°C and the inlet pressure of the gas 72 cm Hg. The rate of flow of the carrier gas (Argon) was 20 cm³/min. The detector voltage was set on 1 250 V. Each 4-foot column was packed with 5 g of acid-washed, alkali-treated Celite (mesh 100—140). As stationary phase a polar polyester LHC-1R-296 (obtained from Cambridge Inc., Mass. U.S.A.) was used in the ratio Celite: stationary phase 4:1. Acylation of the two hydroxyl groups of the glycerol ethers was carried out with acetic anhydride in the presence of pyridine after boiling on a water bath for 12 h. The esterified mixture of glycerol ethers was isolated and dissolved in a few microlitres of ethyl acetate, and the solution taken up in a micropipette and applied to the column.

The retention volumes of the different glycerol ethers were determined using a mixture of known compounds (Table 1). The retention volumes are expressed relative to synthetic batyl alcohol, which was used as internal standard. When determining the retention volumes of the pure compounds, special care was taken not to overcharge the column in order to obtain symmetrical peaks on the chromatogram. The polyester column had a retention time of batyl alcohol diacetin of 49 min.

Table 1. GLC characteristics on LHC-1R-296 as stationary phase of three glycerol ethers after acylation. Temperature 218°C. Argon flow rate 20 cm³/min.

	Apparent retention volume relative to batyl alcohol-diacetin = 1.00
Chimyl alcohol	0.61
Batyl alcohol	1.00
Selachyl alcohol	1.11

Before having a gas-liquid chromatography technique available a similar separation was made by reversed phase partition chromatography using 50 % aqueous *iso*propanol as moving phase and 20 % chloroform in heptane as stationary phase. The band containing chimyl and selachyl alcohol was then subjected to renewed chromatography after hydrogenation, when the selachyl alcohol originally present is obtained as batyl alcohol which is easily separated from the chimyl alcohol.

Material. Hexadecyl-α-glyceryl ether (chimyl alcohol) and octadecyl-α-glyceryl ether (batyl alcohol) was prepared according to Holmes *et al.* [7]

Specimens of purified glycerol ethers mainly containing selachyl alcohol were prepared from tiger shark *(Galeocerdo curvier)* liver fat [1,2,6]. The samples obtained were run on the gas-chromatograph before and after hydrogenation.

This method has proved to be useful for biological work with glycerol ethers and it may also be used for purification of such substances.

Using the column and conditions described acylated monoglycerides of different saturated and unsaturated fatty acids can also be separated.

Chromatography on ECTEOLA * of Sulphate Containing Mucopolysaccharides and Nucleotides

NILS R. RINGERTZ and PETER REICHARD

Department of Cell Research and Genetics and Department of Chemistry I, Karolinska Institutet, Stockholm 60, Sweden

During a study on the enzymatic synthesis of heparin [1] it was found difficult to remove traces of ^{35}S-containing nucleotides from mucopolysaccharides prepared by the cetylpyridinium method [2,3]. We therefore tried chromatography on ECTEOLA * cellulose for the separation of these substances. ECTEOLA has previously been found especially valuable for the chromatography of nucleotides and polynucleotides [4].

Fig. 1 shows the chromatographic behaviour of five different polysaccharides during step-wise elution from ECTEOLA. For good separations it was found necessary to work at a quite acid pH. In the experiments of Fig. 1 the increase in chloride concentration was obtained by adding equimolar amounts of NaCl and HCl. Similar chromatograms were obtained when a constant concentration of 0.05 M HCl was used in all steps, while the chloride concentration was regulated by increasing the amounts of NaCl in the eluent. $CaCl_2$ could be used instead of NaCl. $CaCl_2$ can be removed from the polysaccharide fractions by extraction with alcohol-ether. It interferes, however, strongly with the carbazol reaction [5] and it was therefore not used extensively. The recovery of polysaccharides was found to be close to 100 %. All operations were performed at 0–5°C.

Hyaluronic acid, chondroitinsulfuric acid and heparin had very different affinities for ECTEOLA which allowed their separation.

* ECTEOLA cellulose (E. A. Peterson and H. A. Sober, *J. Am. Chem. Soc.* **78** (1956) 751) was obtained from Brown Company, Berlin, New Hampshire, USA.

Before having a gas-liquid chromatography technique available a similar separation was made by reversed phase partition chromatography using 50 % aqueous *iso*propanol as moving phase and 20 % chloroform in heptane as stationary phase. The band containing chimyl and selachyl alcohol was then subjected to renewed chromatography after hydrogenation, when the selachyl alcohol originally present is obtained as batyl alcohol which is easily separated from the chimyl alcohol.

Chromatography on ECTEOLA * of Sulphate Containing Mucopolysaccharides and Nucleotides

NILS R. RINGERTZ and PETER REICHARD

Department of Cell Research and Genetics and Department of Chemistry I, Karolinska Institutet, Stockholm 60, Sweden

During a study on the enzymatic synthesis of heparin [1] it was found difficult to remove traces of ^{35}S-containing nucleotides from mucopolysaccharides prepared by the cetylpyridinium method [2,3]. We therefore tried chromatography on ECTEOLA * cellulose for the separation of these substances. ECTEOLA has previously been found especially valuable for the chromatography of nucleotides and polynucleotides [4].

Fig. 1 shows the chromatographic behaviour of five different polysaccharides during step-wise elution from ECTEOLA. For good separations it was found necessary to work at a quite acid pH. In the experiments of Fig. 1 the increase in chloride concentration was obtained by adding equimolar amounts of NaCl and HCl. Similar chromatograms were obtained when a constant concentration of 0.05 M HCl was used in all steps, while the chloride concentration was regulated by increasing the amounts of NaCl in the eluent. $CaCl_2$ could be used instead of NaCl. $CaCl_2$ can be removed from the polysaccharide fractions by extraction with alcohol-ether. It interferes, however, strongly with the carbazol reaction [5] and it was therefore not used extensively. The recovery of polysaccharides was found to be close to 100 %. All operations were performed at 0–5°C.

Hyaluronic acid, chondroitinsulfuric acid and heparin had very different affinities for ECTEOLA which allowed their separation.

* ECTEOLA cellulose (E. A. Peterson and H. A. Sober, *J. Am. Chem. Soc.* **78** (1956) 751) was obtained from Brown Company, Berlin, New Hampshire, USA.

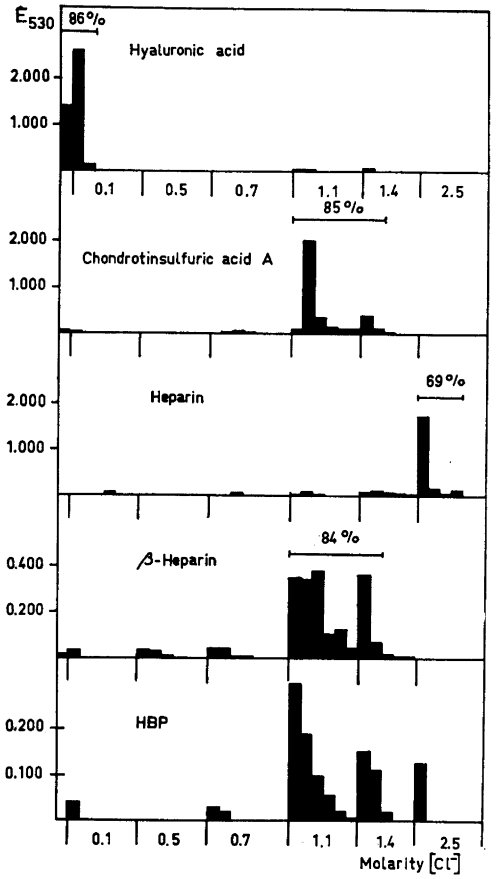

Fig. 1. Chromatography of mucopolysaccharides on ECTEOLA. The resin was washed with 5 liters of 0.5 M NaOH, 5 liters of 3 M NaCl and 3 liters of 0.1 M NaCl-HCl (1:1). Each polysaccharide (10—15 mg dissolved in 10—15 ml of 0.05 M NaCl-HCl) was adsorbed to a separate column (10 × 1 cm). The columns were eluted step-wise with buffers of increasing chloride concentrations (6 × 12 ml step). The fractions were analyzed by the carbazol method [5]. The figures over the main peaks in the chromatograms indicate the recovery of polysaccharides.

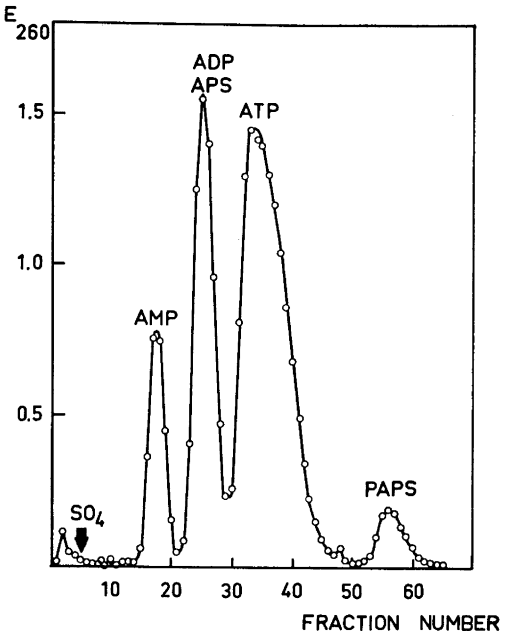

Fig. 2. Chromatography of nucleotides (20 μmoles, pH 7) on an ECTEOLA column (10 × 1 cm). Elution: Linear gradient; vessel 1 = 400 ml 0.01 M NaCl, 0.01 M tris-HCl, (tris-(hydroxymethyl)-aminomethane) pH 7; vessel 2 = 400 ml 0.4 M NaCl, 0.01 M tris-HCl, pH 7. Fractions 7 ml/30 min.

Such separations were actually performed with mixtures of these polysaccharides. It was also evident that the polysaccharides used were inhomogeneous. This was particularly true for a by-product obtained during heparin preparation. This polysaccharide (HBP) separated into four distinct fractions. Upon rechromatography the materials from each of the major fractions were recovered in their original positions. Table 1 shows some analytical data for these HBP-fractions. Evidently they differed largely in composition, *e.g.* as regards the relative proportions of glucosamine and galactosamine.

The anticoagulant activity [6] of heparin after chromatography using the most acid method (equimolar amounts of NaCl and HCl) was 94 Units/mg compared to 105 Units/mg before chromatography. Heparin recovered after elution according to the less acid method (0.05 M HCl) had an activity of 100 Units/mg. Because of the methodological errors involved, these three values are not considered to be significantly different. Analysis of heparin before and after chromatography showed that no loss of sulfate had occurred. This is further support for the absence of degradation.

Table 1. Analytical data for HBP polysaccharide and subfractions.

	SO_4[7]/aminosugar[8] molar ratio	glucosamine/ galactosamine [9] molar ratio	anticoagulant activity [6] units/mg
HBP polysaccharide	1.69	1.17	6
0.7 M subfraction	0.92	1.12	< 4
1.1 M »	2.20	0.60	< 2
1.4 M »	0.96	0.48	8
2.5 M »	1.39	4.83	12—20

Nucleotides were eluted at considerably lower salt concentrations. Adenosine 5'-phosphosulfate (APS) * and adenosine 3'-phosphate-5'-phosphosulfate (PAPS) * could be separated from adenosine 5'-phosphate and adenosine 5'-triphosphate at neutral pH. (Fig. 2). The recovery of nucleotides from the columns was close to 100 %. Chromatography at acid pH caused some degradation of labile nucleotides but served the purpose of removing nucleotides from mucopolysaccharides.

Acknowledgements. We thank Dr. S. Gardell, Dr. B. Högberg and Vitrum Company for generous gifts of mucopolysaccharides. The α-heparin was a gift from Dr. R. W. Jeanloz to Dr. S. Gardell. We also wish to thank prof. E. Jorpes for advice and help in the determination of anticoagulant activity.
