A Sensitive Colour Reaction for the Paper Chromatographic Detection of Iodide, Iodinated Tyrosines and Thyronines

ROLF GMELIN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The most sensitive chemical reaction for the detection of iodide, iodinated tyrosines and thyronines uses the catalytic action of traces of iodide upon the reduction of ceric sulphate by arsenic acid (Bowden *et al.*[1]). It allows the detection of 0.1 μg thyroxine, for instance. Modifications of the method have been proposed by Fletcher and Stanley [2], Dragunova and Langer [3], Gawienowski [4], and Mandl and Block [5].

We have observed that in the presence of catalytical amounts of iodide also the systems $Fe^{3+} \rightarrow Fe^{2+}$ and $Fe(CN)_6^{3-} \rightarrow Fe(CN)_6^{4-}$ can be brought in reaction with the system $As^{V} \rightarrow As^{III}$ (Formulas 1 and 2). The reaction becomes especially sensitive when ferri- and ferricyanide-ions are reacting simultaneously, catalyzed by iodide, upon arsenic acid, since the formed ferro- and ferrocyanide-ions, respectively are fixed immediately, forming the insoluble pigment, prussian blue (Formula 3).

Table 1. Analytical data for HBP polysaccharide and subfractions.

	SO_4[7]/aminosugar[8] molar ratio	glucosamine/ galactosamine [9] molar ratio	anticoagulant activity [6] units/mg
HBP polysaccharide	1.69	1.17	6
0.7 M subfraction	0.92	1.12	< 4
1.1 M »	2.20	0.60	< 2
1.4 M »	0.96	0.48	8
2.5 M »	1.39	4.83	12—20

Nucleotides were eluted at considerably lower salt concentrations. Adenosine 5'-phosphosulfate (APS) * and adenosine 3'-phosphate-5'-phosphosulfate (PAPS) * could be separated from adenosine 5'-phosphate and adenosine 5'-triphosphate at neutral pH. (Fig. 2). The recovery of nucleotides from the columns was close to 100 %. Chromatography at acid pH caused some degradation of labile nucleotides but served the purpose of removing nucleotides from mucopolysaccharides.

Acknowledgements. We thank Dr. S. Gardell, Dr. B. Högberg and Vitrum Company for generous gifts of mucopolysaccharides. The α-heparin was a gift from Dr. R. W. Jeanloz to Dr. S. Gardell. We also wish to thank prof. E. Jorpes for advice and help in the determination of anticoagulant activity.

(3)

Iodide, iodinated tyrosines and thyronines appear in the ferrichloride-ferricyanide-arsenic acid (FFCA)-reaction as intense blue spots on a light blue background. The limit for the detection is 0.001 μg for iodide or 0.002 μg for thyroxine, triiodothyronine, diiodotyrosine, respectively. In practice it is advisable, however, to work with quantities between 0.01 and 0.1 μg per spot.

This means that the FFCA-reagent is about ten times more sensitive than the ceric sulphate-arsenic acid-reagent. Another advantage of the FFCA-reagent is that the paper chromatograms can be washed after the development of the spots and can be kept after drying indefinitely, while the paper chromatograms treated with the ceric sulphate-arsenic acid reagent will soon be destroyed under the corrosive influence of sulphuric acid.

Disadvantageous for the FFCA-reaction is the fact that also certain reducing substances (phenols, compounds with thiol groups, ascorbic acid, *etc.*) will respond to the reagent by formation of blue spots. Since these compounds are reacting, however, only in amounts above 1 μg per spot, and can be distinguished by their R_F-values, the usefulness of this new method is scarcely influenced by them.

Performance of the colour reaction. The carefully dried paper chromatograms are sprayed evenly from both sides with freshly prepared reagent and are put cautiously and without pressure between two clean glass plates. After a developing time of 15 min the paper is thoroughly washed with distilled water, pressed between filter paper and dried in a current of warm air. The spraying and development of the paper chromatograms has to be carried out in dim light or better in a dark room.

The blue spots which have been formed by iodide, iodinated tyrosines and thyronines can be measured photometrically and can be used for quantitative determinations. Good and reproducible values could be obtained in the same range of concentrations between 0.01 and 0.07 μg per spot with the Zeiss-Extinktionsschreiber II (Filter FE 54).

Preparation of the FFCA-reagent. (All reagents used are analytical grade, Merck.)

Solution A. 2.7 g $FeCl_3 \cdot 6H_2O$ are dissolved in 100 ml 2 N HCl-solution.

Solution B. 3.5 g $K_3Fe(CN)_6$ are dissolved in 100 ml distilled water.

Solution C. 5 g $NaAsO_2$ are dissolved under cooling in 30 ml N NaOH-solution. 65 ml 2 N HCl-solution are added under intense stirring.

Immediately before every use 5 parts of solution A, 5 parts of solution B, and 1 part of solution C are mixed. (Protection against light is important).

This investigation belongs to a research project under U. S. Public Law No. 480, 83rd Congress.

Thermal Conductivity of Solid Solutions and the Measuring of Molecular Weights

OLE LAMM

Royal Institute of Technology, Division of Physical Chemistry, Stockholm 70, Sweden

Investigations on the exact measuring of thermal conductivity of solids and certain liquids has resulted in a Report [1] and two publications [2-3]. The "hot wire resistance thermometer" method was chosen by Lars Rombén, and developed by him and H.-E. Nissen. Later, D. G. Gillam brought this method to a present accuracy of ± 0.3 %. One of the goals of this investigation was to find out whether thermal resistivity could be used as a method for determining molecular weights. This seemed especially hopeful in the case of a solid solvent, owing to the high conductivity and the consequently greater and more well-defined effect of the introduction of new centres of scattering of the elastic waves through the solute molecules.

Accurate values have recently been reported by Gillam on the conductivity at 20°C of naphthalene and of four substances dissolved in naphthalene; diphenylmethane, triphenylmethane, diphenyl-*m*-tolylmethane, and diphenyl-*p*-tolylmethane [4]. The results clearly show that in all four solutions the conductivity decreases along one and the same function of the mole fraction. This function is a straight line up to a mole fraction of about 0.03. This is all what is needed for a *method of molecular weight determination* according to a relationship rather analogous to the ones valid for osmotic pressure and light scattering. The validity range of such a simple course will have to be settled by further experimental work. As in the other methods, a more detailed theory will be needed in less ideal cases; a lack of ideality will express itself quite differently when going from one method to another. An essential factor is, in the case considered, the temperature dependency. As a whole, the use of rather low temperatures and solid solvents with high conductivity will give the simplest information. The field of liquid solutions also deserves increased attention.

The determination of molecular weights only represents one aspect of the many possible on the thermal conductivity of mixtures in general. With the exception of the well-known work by Eucken [5] on solid solutions of KCl, KBr, the effects on solids seem to have been mainly referred to as a high sensitivity of the conductance to "impurities". However, the views expressed above, originating from the general ideas of Debye and Eucken, are related to recent, mainly low-temperature investigations on the scattering cross sections of isolated lattice points and on isotope effects, and by the recognition of resistivity to heat conduction as a very sensitive means of studying crystal imperfections, see Berman [6], Klemens [7], Slack [8], and Cohen [9].

NMR Evidence for Hydrogen Bonding in Ethyl Mercaptan

STURE FORSÉN

Research Group for NMR, Division of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

Hydrogen bonding of the S—H... S type has for a long time been considered unlikely for mercaptans. Molecular weights determined by the method of freezing point depression have not revealed any tendency towards association [1]. Several investigators have failed to detect any dilution shifts in I.R. spectra of thiophenols and mercaptans [2,3]. Recently, however, Spurr and Byers [4] have studied the fundamental stretching region of the S—H group in some mercaptans and found two bands at about 2 580 cm^{-1} and 2 560 cm^{-1}, which they attribute to the monomer and dimer forms, respectively, of the mercaptans. They showed that the concentration dependent variations in the integrated adsorption coefficients for the two bands could be accounted for on the basis of a monomer-dimer equilibrium. As shown by a number of workers [5] the proton magnetic resonance (PMR) signal of the OH-proton in alcohols and phenols undergoes a shift towards higher fields as the compound is diluted in some inert solvent as CCl_4 or *cyclo*hexane. We have therefore looked for a corresponding dilution shift in the PMR-signal of the SH-group in ethyl mercaptan.

The measurements were carried out on a Varian V-4300 NMR-spectrometer operating at 40 Mc/s. All shifts were measured against an external water standard using coaxial glass cells [6] and correcting for the macroscopic susceptibility effects.

The shifts are discussed in terms of the dimensionless unit δ defined by the expression

$$\delta = 10^6 \cdot \frac{H_{sample} - H_{ext.water}}{H_{ext.water}}$$

The PMR spectrum of pure ethyl mercaptan is shown in Fig. 1 a. The SH-group gives rise to a triple-peak signal which partly covers the CH_3-group signal.

The ethyl mercaptan (Purum. FLUKA, freshly distilled) was diluted by CCl_4 (*pro analysi*, Merck, dried over P_2O_5) in steps down to $x = 0.01$ (mole fraction) and it was found that the SH-signal shifted totally $\Delta\delta_{SH} = 0.38 \pm 0.015$ towards higher fields. Within the accuracy of the measurements no shift of the CH_2- or CH_3-signals could be detected. We take the observed SH-dilution shift as evidence for a small but significant effect of hydrogen bonding. In Fig. 1 b the CH_3-region is shown at $x = 0.2$. The results are shown graphically in Fig. 2.

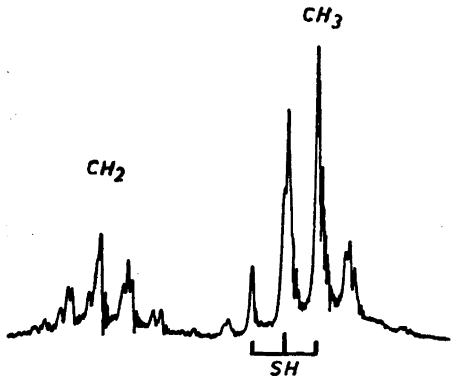

Fig. 1 a. The PMR spectrum of pure ethyl mercaptan. The position of the SH-group is indicated.

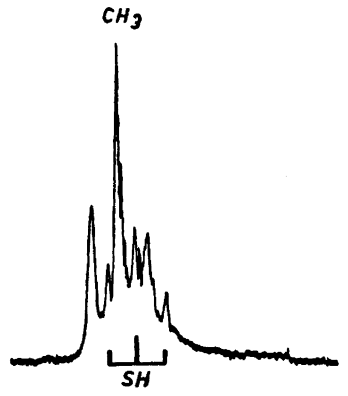

Fig. 1 b. The PMR spectrum of the CH_3-region in ethyl mercaptan diluted with carbon tetrachloride (mole fraction mercaptan = 0.2). The SH-signal has now moved to the right side of the CH_3-signal.

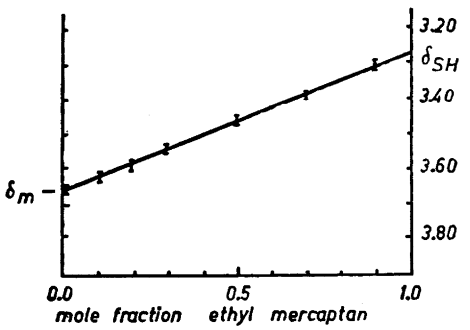

Fig. 2. The dilution shift in CCl_4-solution of the SH-proton resonance in terms of the dimensionless unit δ.

The SH-shift shows an almost linear dependence on the mole fraction mercaptan and this behaviour differs markedly from the one observed for alcohols [7]. The linear dependence and the smallness of the shift imply that the association constant in terms of mole fractions (K_x) should be small and that monomers and dimers dominate in the solution. Spurr and Byers give $K_c = 47$ mole/lit., which corresponds to $K_x = 0.22$. A rather crude approximation based on the formulas in Ref.[5a] is to set the slope of the δ_{SH} *vs.* x plot, $\left(\frac{d\delta}{dx}\right)$, equal to $2K_x\Delta_d$, and, somewhat arbitrarily, $\Delta_d = \delta_d - \delta_m$ to $\frac{1}{2} \cdot 0.38$ *. (See Ref.[5a] p. 1313). This gives $K_x = 0.38$ in reasonable agreement with the results of Spurr and Byers.

* δ_m is the shift of the monomer in relation to the reference ($H_2O_{ext.}$) and is given by δ_{SH} at $x = 0$. δ_d is the shift of the dimer and is not known exactly. It can not be taken as the value of δ_{SH} at $x = 1$.

Composition and Stability Constant of the Complex between Lead(II) and 4-(2-Pyridylazo)-resorcinol (PAR)

H. KRISTIANSEN and F. J. LANGMYHR

University of Oslo, Chemical Institute A, Blindern, Norway

For the EDTA-titration of lead(II) Weber [1] suggested PAR as metal indicator. Pollard, Hanson and Geary [2] recommended PAR as colorimetric reagent for cobalt, lead and uranium. The authors introduced [3] PAR as indicator by indirect EDTA-titration of macro and micro amounts of aluminium, the excess of EDTA being back-titrated with standard lead(II) solution.

In connection with the use of PAR as metal indicator, it is of interest to have information about the complex formed between the indicator and lead(II) ions. In this investigation the composition of the complex and its stability constant were determined spectrophotometrically.

Experimental. The sodium salt of PAR was synthesized according to a procedure given by Chichibabin [4]. The salt was purified by extractions with ether and transformed to the phenol by the passing of carbon dioxide. The phenol was extracted with ether, and again transformed to the sodium salt, which was recrystallized from alcohol. The product was finally dried *in vacuo* over phosphorus pentoxide. The

Composition and Stability Constant of the Complex between Lead(II) and 4-(2-Pyridylazo)-resorcinol (PAR)

H. KRISTIANSEN and F. J. LANGMYHR

University of Oslo, Chemical Institute A, Blindern, Norway

For the EDTA-titration of lead(II) Weber [1] suggested PAR as metal indicator. Pollard, Hanson and Geary [2] recommended PAR as colorimetric reagent for cobalt, lead and uranium. The authors introduced [3] PAR as indicator by indirect EDTA-titration of macro and micro amounts of aluminium, the excess of EDTA being back-titrated with standard lead(II) solution.

In connection with the use of PAR as metal indicator, it is of interest to have information about the complex formed between the indicator and lead(II) ions. In this investigation the composition of the complex and its stability constant were determined spectrophotometrically.

Experimental. The sodium salt of PAR was synthesized according to a procedure given by Chichibabin [4]. The salt was purified by extractions with ether and transformed to the phenol by the passing of carbon dioxide. The phenol was extracted with ether, and again transformed to the sodium salt, which was recrystallized from alcohol. The product was finally dried *in vacuo* over phosphorus pentoxide. The

disodium salt was not analyzed, but an infrared absorption spectrum confirmed the expected structure.

A solution of PAR in water is orange and showed an absorption maximum at 410 mμ. In the pH range 6—10 PAR and lead(II) form a red complex with an absorption maximum at 515 mμ. Curves of continuous variations were plotted at pH 10 (ammonia-ammonium chloride buffer) for solutions of PAR and lead(II), and a distinct maximum was obtained at the mole ratio 1:1. The curves of continuous variations were then utilized for the calculation of the stability constant, which was found to be $K = 3.0 \times 10^6$. Ionic strength of the solutions was about 0.01.

A New Type of Enzymatic Cleavage of Mustard Oil Glucosides. Formation of Allylthiocyanate in *Thlaspi arvense* L. and Benzylthiocyanate in *Lepidium ruderale* L. and *Lepidium sativum* L.

ROLF GMELIN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The cleavage of mustard oil glucosides to *iso*thiocyanate, sulphate, and glucose, which is effected by myrosinase, is considered to be a specific enzymatic process responsible for the characteristic pungent odour or taste of many representatives of the *Cruciferae, Tropaeolaceae, Capparidaceae, Resedaceae,* and some other plant families. After having worked out a revised structural formula for the mustard oil glucosides, Ettlinger and Lundeen [1] proposed that the enzymatic formation of *iso*thiocyanates takes place through Lossen-rearrangement (reaction 1). In some other representatives of the *Cruciferae* family an unpleasant garlic-like odour is characteristic. In the literature there is no real information on the chemical nature and the way of formation of these compounds. Some plant species even derive their names from the garliclike odour (*Thlaspi alliaceum* L., *Alliaria officinalis* Andrz., *Peltaria alliacea* Jacg.).

We have now investigated the chemical nature and formation of the substances that are responsible for this strong garlic-like odour, which has led to the use of the term "garlic oils" ("Lauchöle") [2] in the literature.

With fresh plants and seeds of *Thlaspi arvense* L., *Lepidium ruderale* L., and to a somewhat smaller extent of *Lepidium sativum* L., there appears an unpleasant odour and taste when the plant material is crushed with some water. Our investigations especially with seeds of *Thlaspi arvense, Lepidium ruderale,* and *Lepidium sativum* led to the following results:

1. An enzymatic process is responsible for the formation of the unpleasant smelling substances.

2. Sinigrin in *Thlaspi arvense* and glucotropaeolin in *Lepidium ruderale* and *L. sativum* are the precursors of the smelling substances.

3. In addition to glucose and sulphate allylthiocyanate in *Thlaspi arvense*, benzylthiocyanate in *Lepidium ruderale*, and a mixture of benzyl*iso*thiocyanate and benzylthiocyanate in *Lepidium sativum* are formed as fission products. Synthetic allyl- and benzylthiocyanates have the same odour and taste as is formed in *Thlaspi arvense* and *Lepidium ruderale*. The substances with similar, unpleasant odours, characteristic of many other *Cruciferae* plants when chewed, are accordingly alkylthiocyanates — a new class of natural S-containing compounds. Reactions 1 and 2 illustrate the formation of *iso*thiocyanates and normal thiocyanates.

Experimental evidence for the conclusions:

These smelling substances are not formed when the seedpowder is treated with boiling water or boiling alcohol. In methanolic extracts from seeds of *Thlaspi arvense*

disodium salt was not analyzed, but an infrared absorption spectrum confirmed the expected structure.

A solution of PAR in water is orange and showed an absorption maximum at 410 mμ. In the pH range 6—10 PAR and lead(II) form a red complex with an absorption maximum at 515 mμ. Curves of continuous variations were plotted at pH 10 (ammonia-ammonium chloride buffer) for solutions of PAR and lead(II), and a distinct maximum was obtained at the mole ratio 1:1. The curves of continuous variations were then utilized for the calculation of the stability constant, which was found to be $K = 3.0 \times 10^6$. Ionic strength of the solutions was about 0.01.

In the literature there is no real information on the chemical nature and the way of formation of these compounds. Some plant species even derive their names from the garliclike odour (*Thlaspi alliaceum* L., *Alliaria officinalis* Andrz., *Peltaria alliacea* Jacg.).

We have now investigated the chemical nature and formation of the substances that are responsible for this strong garlic-like odour, which has led to the use of the term "garlic oils" ("Lauchöle") [2] in the literature.

With fresh plants and seeds of *Thlaspi arvense* L., *Lepidium ruderale* L., and to a somewhat smaller extent of *Lepidium sativum* L., there appears an unpleasant odour and taste when the plant material is crushed with some water. Our investigations especially with seeds of *Thlaspi arvense, Lepidium ruderale,* and *Lepidium sativum* led to the following results:

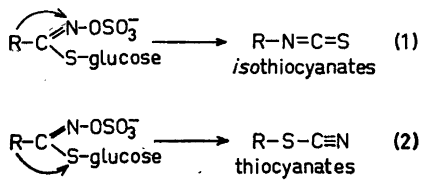
1. An enzymatic process is responsible for the formation of the unpleasant smelling substances.

2. Sinigrin in *Thlaspi arvense* and glucotropaeolin in *Lepidium ruderale* and *L. sativum* are the precursors of the smelling substances.

3. In addition to glucose and sulphate allylthiocyanate in *Thlaspi arvense*, benzylthiocyanate in *Lepidium ruderale*, and a mixture of benzyl*iso*thiocyanate and benzylthiocyanate in *Lepidium sativum* are formed as fission products. Synthetic allyl- and benzylthiocyanates have the same odour and taste as is formed in *Thlaspi arvense* and *Lepidium ruderale*. The substances with similar, unpleasant odours, characteristic of many other *Cruciferae* plants when chewed, are accordingly alkylthiocyanates — a new class of natural S-containing compounds. Reactions 1 and 2 illustrate the formation of *iso*thiocyanates and normal thiocyanates.

Experimental evidence for the conclusions:

These smelling substances are not formed when the seedpowder is treated with boiling water or boiling alcohol. In methanolic extracts from seeds of *Thlaspi arvense*



sinigrin can be detected by paper chromatography, while from seeds of *Lepidium ruderale* and *Lepidium sativum* the glucoside detected is glucotropaeolin. Both glucosides could be isolated (sinigrin in 1.4 % yield from *Thlaspi arvense* seeds, and glucotropaeolin in 1.5 % yield from *Lepidium ruderale*). They proved to be identical with authentic preparations from *Brassica nigra* Koch and *Tropaeolum majus* L. No other glucosides could be found by paper chromatography in *Thlaspi arvense* and in the two *Lepidium* species.

When the finely ground seeds are treated with cold water, after half an hour sinigrin and glucotropaeolin are no longer detectable. On the other hand the content of free glucose and sulphate increases and corresponds to the amount of cleaved glucosides. The formation of allyl*iso*thiocyanate (in *Thl. arvense*) and benzyl*iso*thiocyanate (in *Lep. ruderale*) which normally would be expected is lacking, however. In regard to the typical odour the S-containing compounds which are formed besides glucose and sulphate, are identical with synthetic allyl- and benzylthiocyanate. The identity of the two thiocyanates with allylthiocyanate and benzylthiocyanate was confirmed by the following reactions:

1. Cleavage by nascent hydrogen, by H_2S or by cysteine led to allylmercaptan and benzylmercaptan, respectively, which were isolated and analyzed as Hg-mercaptides.

2. By cleavage with NaSH thiocyanate ions were formed together with allylmercaptan and benzylmercaptan. The colorimetrically determined thiocyanate ions were in good agreement with the amounts of sinigrin or glucotropaeolin originally present.

3. In model experiments the synthetic preparations of allyl- and benzylthiocyanates behaved qualitatively and quantitatively analogously in the formation of mercaptans, mercaptides, and thiocyanate ions.

4. A small amount of benzylthiocyanate could be isolated in crystalline form from moistened, crushed seeds of *Lepidium ruderale* by steam distillation. Melting points and IR-spectra of the natural and synthetic products were identical.

The factors which are responsible for the formation of *iso*thiocyanates in most cases and of thiocyanates in some cases, are not known. Attempts to separate a thiocyanate forming enzyme led in every case to enzyme preparations with myrosinase activity which in the normal way split mustard oil glucosides to *iso*thiocyanate, glucose, and sulphate. If a certain factor which regulates or directs the migration of the alkyl residue to the S-atom instead of to the N-atom exists in the plants where thiocyanates are formed, could not yet be decided. There are, however, indications for this conclusion. It is possible that in the seeds of *Lepidium sativum*, in which benzylthiocyanate and benzyl*iso*thiocyanate are formed simultaneously by the enzymatic process, the factor is present in a smaller quantity than in *Lepidium ruderale*.

We have evidence that this new type of cleavage of the mustard oil glucosides into thiocyanates is rather common in the *Cruciferae* family. The new findings will be reported in a later communication.

Because of their reactivity with thiol-groups and because of their ability to form thiocyanate ions, normal alkylthiocyanates are by no means physiologically harmless substances. Since many important vegetable and fodder plants belong to the *Cruciferae* family, the question of the formation and physiological activity of the thiocyanates seems to be an important problem.

This investigation belongs to a research project under U. S. Public Law No. 480, 83rd Congress.

On the Biological Methylation of Histamine. 4

KERSTIN M. LINDAHL

Institute of Zoophysiology, University of Uppsala, Sweden

In the past few years Schayer and his coworkers have shown that methylation of histamine to 1,4-methylhistamine * and its further oxidation to 1-methylimidazole-4-acetic acid is the principal route of histamine inactivation in man, mouse, cat, and dog. The literature concerning the catabolism of histamine *in vivo* has recently been reviewed by Schayer [1].

In vitro studies concerning the histamine methylating enzyme system have been discussed in earlier communications under the above heading [2-4]. It was reported that the formation of 1,4-methylhistamine requires methionine plus an ATP generating system, this leading on to the finding that S-adenosylmethionine is a most effective methyl donor in this system. These results have later been confirmed in other laboratories [5].

The present communication deals with the influence of some commonly used SH-inhibitors on the histamine methylating enzyme in liver extract.

Enzyme preparation. Pig liver was homogenized in 0.1 M NaAc buffer pH 5.6, centrifuged at 10 000 *g*, heated to 47° for 7 min, and centrifuged at 20 000 *g*. The supernatant liquid was fractionated with $(NH_4)_2SO_4$ at pH 6. The precipitate obtained between 50 and 70 % saturation was dissolved in 0.05 M NaAc pH 5.6, dialyzed overnight, and the resulting solution used for the experiments after centrifugation.

Determination of enzyme activity. The method makes use of the fact that 1,4-methylhistamine is extracted by chloroform from an alkaline solution, while histamine is not [6].

25 μl of the enzyme preparation, containing 25 mg protein per ml, were incubated for 30 min at 37°C with 0.050 μC ^{14}C-histamine and 0.3 μmoles S-adenosylmethionine in 0.5 M Tris buffer of pH 8.0 to make 200 μl. The reaction was interrupted by dipping the test tubes in boiling water. After addition of 50 μl 10 N NaOH saturated with Na_2SO_4 at 100°C and cooling, the samples were extracted with 1 000 μl of chloroform by vigorous shaking for 10 min.

The phases were separated by rapid centrifugation. Samples of 200 μl were withdrawn from the chloroform layer, and evaporated on planchets. The radioactivity was counted under an end window Geiger-Müller tube. From these figures the percentage methylhistamine formed was obtained with the aid of a calibration curve. Details of the method will be published later.

Effect of inhibitors.

o-Iodosobenzoic acid in concentrations 1 to 25 × 10^{-4} M had no influence on the enzymic activity, when the inhibitor was brought in contact with the enzyme 10 min prior to the substrate.

p-Chloromercuribenzoic acid markedly inhibited the histamine methylation (Table 1). The concentration necessary for com-

* Correct name: 1-methyl-4-(β-aminoethyl) imidazole.

Table 1. The effect of *p*-chloromercuribenzoate on the histamine methylating enzyme in pig liver.

Conc. of *p*-chloromercuribenzoate M	No glutathione added		Glutathione added in conc. 5 × 10^{-4} M	
	Histamine methylated %	Inhibition %	Histamine methylated %	Inhibition %
—	70	—	70	0
5 × 10^{-6}	70	0		
5 × 10^{-5}	67	4.3		
1.25 × 10^{-4}	59	15.7		
2.5 × 10^{-4}	31	55.7	70	0
5 × 10^{-4}	0	100	62	11.4
12.5 × 10^{-4}	0	100		

plete inhibition is rather high, *viz.* 5×10^{-4} M, probably on account of the presence of comparatively large amounts of inactive protein in the enzyme preparation. The inhibition was not reversed by dialysis. However, glutathione in slightly higher than equimolar concentrations abolished the inhibition completely.

Chloroacetophenone in high concentrations inhibited the enzyme, to a certain extent, *viz.* 90 % at 2.5×10^{-3} M. *Iodoacetamide* had a similar effect.

Garlic extract contains allicin which is known as an inhibitor of SH-groups [7]. It may be noted that garlic extract, prepared in the proportion 1:200 w/v, inhibits the enzyme completely. Glutathione counteracts this inhibition.

The inhibition of the histamine methylation by *p*-chloromercuribenzoate and the counteraction of glutathione are taken as evidence that SH-groups might be essential for the activity of the methylating enzyme. The inefficiency of *o*-iodosobenzoate may be explained by a protecting effect of other proteins present.

Long Range Coupling of Nuclear Spins in Some Olefinic and Acetylenic Compounds

RAGNAR A. HOFFMAN and SALO GRONOWITZ

Institutes of Physics and Chemistry, University of Uppsala, Uppsala, Sweden

In view of the growing interest in the theory of the indirect coupling of nuclear spins [1-6] we wish to report some recent findings in connection with our study of long range couplings in proton magnetic resonance spectra.

In an earlier communication [7] one of us suggested that the coupling of methyl group protons over four bond distances with protons bonded to unsaturated carbon atoms should be understood in terms of hyperconjugation.

The need for new evidence for the existence of hyperconjugation in the ground state of unsaturated organic molecules has become obvious as Dewar and Schmeising have recently pointed out [8] that the earlier evidence is inconclusive. It is hoped that a continued investigation of the above mentioned spin couplings may provide such evidence.

In order to verify the interpretation given in Ref.[7], we have tested two predictions that follow from the discussion presented there.

1. The interaction of the π-electron, on an unsaturated carbon atom, with the protons of an attached methyl group is approximately equal to its interaction with a proton directly bound to the unsaturated carbon.

2. The coupling of methyl group protons (to other protons) over triple bonds should be considerably larger (about twice) than those over double bonds.

These predictions were tested in a number of substances. Thus we find, that the coupling between the two non-equivalent methyl groups in tiglaldehyde and in β-bromoangelic acid methylester are 1.0 c/s and 1.5 c/s, respectively *, or of the same order of magnitude as J^{I}_{ab} in *trans*-crotonaldehyde (I), which equals 1.6 c/s or the analogous coupling in *trans*-propenylbenzene, which is reported [9] to equal 1.8 c/s.

Since methyl acetylene is a gas at room temperature, we have instead studied propargyl alcohol and propargyl chloride. Here the coupling of the methylenic protons with the acetylenic proton equals 2.4 c/s and 2.6 c/s, resp., in agreement with the values 2.6—2.8 c/s for the propargyl halides reported by Whipple *et al.*[10]

When the acetylenic hydrogens are substituted by methyl groups, the long range coupling constants (here between the methyl and methylene protons) remain vir-

* All coupling constants reported here are given to $\pm$ 0.1 c/s. We use the symbol J^{I}_{ab} to denote the coupling constant J between groups a and b in compound I.

plete inhibition is rather high, *viz.* 5×10^{-4} M, probably on account of the presence of comparatively large amounts of inactive protein in the enzyme preparation. The inhibition was not reversed by dialysis. However, glutathione in slightly higher than equimolar concentrations abolished the inhibition completely.

Chloroacetophenone in high concentrations inhibited the enzyme, to a certain extent, *viz.* 90 % at 2.5×10^{-3} M. *Iodoacetamide* had a similar effect.

Garlic extract contains allicin which is known as an inhibitor of SH-groups [7]. It may be noted that garlic extract, prepared in the proportion 1:200 w/v, inhibits the enzyme completely. Glutathione counteracts this inhibition.

The inhibition of the histamine methylation by *p*-chloromercuribenzoate and the counteraction of glutathione are taken as evidence that SH-groups might be essential for the activity of the methylating enzyme. The inefficiency of *o*-iodosobenzoate may be explained by a protecting effect of other proteins present.

Long Range Coupling of Nuclear Spins in Some Olefinic and Acetylenic Compounds

RAGNAR A. HOFFMAN and SALO GRONOWITZ

Institutes of Physics and Chemistry, University of Uppsala, Uppsala, Sweden

In view of the growing interest in the theory of the indirect coupling of nuclear spins [1-6] we wish to report some recent findings in connection with our study of long range couplings in proton magnetic resonance spectra.

In an earlier communication [7] one of us suggested that the coupling of methyl group protons over four bond distances with protons bonded to unsaturated carbon atoms should be understood in terms of hyperconjugation.

The need for new evidence for the existence of hyperconjugation in the ground state of unsaturated organic molecules has become obvious as Dewar and Schmeising have recently pointed out [8] that the earlier evidence is inconclusive. It is hoped that a continued investigation of the above mentioned spin couplings may provide such evidence.

In order to verify the interpretation given in Ref.[7], we have tested two predictions that follow from the discussion presented there.

1. The interaction of the π-electron, on an unsaturated carbon atom, with the protons of an attached methyl group is approximately equal to its interaction with a proton directly bound to the unsaturated carbon.

2. The coupling of methyl group protons (to other protons) over triple bonds should be considerably larger (about twice) than those over double bonds.

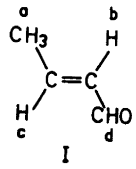
These predictions were tested in a number of substances. Thus we find, that the coupling between the two non-equivalent methyl groups in tiglaldehyde and in β-bromoangelic acid methylester are 1.0 c/s and 1.5 c/s, respectively *, or of the same order of magnitude as J^{I}_{ab} in *trans*-crotonaldehyde (I), which equals 1.6 c/s or the analogous coupling in *trans*-propenylbenzene, which is reported [9] to equal 1.8 c/s.

Since methyl acetylene is a gas at room temperature, we have instead studied propargyl alcohol and propargyl chloride. Here the coupling of the methylenic protons with the acetylenic proton equals 2.4 c/s and 2.6 c/s, resp., in agreement with the values 2.6—2.8 c/s for the propargyl halides reported by Whipple *et al.*[10]

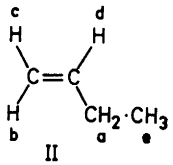
When the acetylenic hydrogens are substituted by methyl groups, the long range coupling constants (here between the methyl and methylene protons) remain vir-

* All coupling constants reported here are given to $\pm$ 0.1 c/s. We use the symbol J^{I}_{ab} to denote the coupling constant J between groups a and b in compound I.

tually unchanged and are found to be 2.4 c/s and 2.5 c/s in the 2-butyne-1-ol and 1-chloro-2-butyne, resp., in perfect agreement with our first prediction. Prediction 2) is reasonably well fulfilled.



I



II

In two compounds studied by us, crotonaldehyde (I) and tiglaldehyde, relative signs of the methyl group coupling constants could be determined. In tiglaldehyde the 40 Mc/s spectrum agrees with that calculated with second order perturbation theory [11] if all coupling constants are assumed to have equal sign. An Y_3 ABX-treatment [12] of the crotonaldehyde (I) spectrum at 40 Mc/s gave two possible assignments: one assuming J^{I}_{ab} and J^{I}_{ac} having equal sign, the other assuming unlike signs of these coupling constants. A well resolved (10^8) spectrum obtained at a radio frequency of 25 Mc/s * favours the latter assignment.

This is in agreement with the results obtained for the similar compound *trans*-propenylbenzene and for but-1-ene (II) by other workers [9,13]. Alexander concluded [13] that J^{II}_{ad} in this latter compound is of opposite sign to J^{II}_{ab} and J^{II}_{ac}. He ascribes the negative value to J^{II}_{ad}. Because the methylene protons have a large shift to the vinyl protons and the influence of the coupling constant J^{II}_{ac} seems to have been excluded from the calculation, we assume that the reverse assignment of signs would give the same calculated spectrum. If this assumption is valid we prefer to ascribe the negative coupling in crotonaldehyde (I) to J^{I}_{ab}. The cases of tiglaldehyde and crotonaldehyde would then form a neat parallel to the VB-calculations of π-electron couplings in even-alternant hydrocarbons by McConnell [5] (*cf.* also a recent note by McLachlan [14]), and also with the relative signs of coupling constants of a conjugated diene as reported by Elvidge and Jackmann [15].

A more comprehensive discussion of the above mentioned results with reference to related observations by other workers in this field will be submitted for publication at a later date.

The authors wish to express their gratitude to professors Kai Siegbahn and Arne Fredga for their interest in this work. A grant to one of us (RAH) from the *State Council of Technical Research* is gratefully acknowledged.

* We are greatly indebted to Dr. H. Primas and Dr. P. Bommer (Zürich) for providing this spectrum.

Preparation and Determination of Sodiumhydrogen S-(2-aminoethyl) Phosphorothioate (Sodiumhydrogen Cysteamine-S-phosphate)

STIG ÅKERFELDT

Eastern Pennsylvania Psychiatric Institute, Philadelphia, Pennsylvania, U.S.A.

In a study of S-phosphorylation in biological systems it became of interest to have access to S-(2-aminoethyl) phosphorothioic acid (cysteamine-S-phosphoric acid *). This substance could possibly be formed by enzymic S-phosphorylation of 2-aminoethanethiol (cysteamine).

The sodiumhydrogen salt of cysteamine-S-phosphoric acid has now been prepared from trisodium phosphorothioate and 2-bromoethylammonium bromide with N,N-dimethylformamide as catalyst according to the following scheme:

$$BrNH_3CH_2CH_2Br + Na_3SPO_3 \longrightarrow NH_2CH_2CH_2SPO_3HNa + 2\ NaBr$$

A slight excess of 2-bromoethylammonium bromide was used to ascertain complete reaction of the phosphorothioate. This reaction gave directly an analytically pure product in good yield (95 %).

From the above scheme it follows that the 2-aminoethyl residue could possibly be bound either to an oxygen or to the sulfur atom of the phosphorothioic acid residue (or to both in a mixture). Therefore, the actual position of this group in the molecule had to be established. From the following experiments it could be concluded that the 2-aminoethyl group in the synthesized substance is exclusively bound to the sulfur atom of the phosphorothioic acid residue: a) unlike phosphorothioate [1] the substance does not reduce iodine in strongly acid solution; b) hydrolysis in 1 M perchloric acid at 100° gave *ortho*-phosphate and a nitroprussiate positive substance. Hydrogen sulfide or phosphorothioate could not be detected. The hydrolysate consumed 98.2 atom-% iodine per mole of compound hydrolyzed *; c) paper chromatographic analysis of untreated and iodine oxidized hydrolysate ** (*n*-butanol: acetic acid: water, 4:1:1, and *n*-propanol: 29 % ammonia: water, 6:3:1) gave the same result as was obtained with authentical cysteamine treated the same way as the hydrolysate. No trace of 2-aminoethanol could be detected.

Mercury(II)ions (and 6-chloromercuri-2-nitrophenol [2]) were found to catalyze the hydrolysis of cysteamine-S-phosphate in acid solution. This fact has been utilized in the colorimetric determination of the substance. The optimum mercury(II)ion concentration was found to be about 45 μM (higher concentrations develop cloudiness in the samples). The same color yield was obtained with this method as is obtained with *ortho*-phosphate alone.

Methods and results. Trisodium phosphorothioate was prepared according to Yasuda and Lambert[3]. Phosphate determinations were based on the method by Gomori[4]. 2-Bromoethylammonium bromide was obtained from Eastman Kodak Company.

Synthesis of sodiumhydrogen cysteamine-S-phosphate. 9.0 g (50 mmole) of trisodium phosphorothioate were dissolved in 50 ml of water. 10.9 g (53 mmole) of 2-bromoethylammonium bromide and 25 ml of N,N-dimethylformamide were added. The solution was vigorously stirred for 40 min during which time a large amount of white crystals separated. (The reaction is conveniently followed by the disappearence of phosphorothioate, which is tested for by the addition of silver ions, whith which a black precipitate is obtained). 300 ml of ethanol were then added and the precipitated crystals (Found: P 12.3; H_2O 28.7***. Calc. for $NH_2CH_2CH_2SPO_3HNa, 4H_2O$: P 12.3; H_2O 28.7) were collected by filtration and washed thoroughly with ethanol. The crystals were dehydrated by stirring them in

* This is in line with the terminology adopted by *Chemical Abstracts* for certain biologically important phosphate esters, *e.g.*, creatine phosphate *etc.* However, to prevent confusion with the isomer cysteamine-N-phosphate the letter S is used to denote the position of the phosphate residue.

* This is about the same yield as was obtained with pure cysteamine after similar treatment.

** To avoid multiple spot formation, which was observed in the presence of perchlorate, hydrochloric acid was used for the hydrolysis in this experiment.

*** Water of crystallization was determined by drying to constant weight at 105°.

200 ml of dry methanol for 1 h. 8.5 g (95 %) of substance were thus obtained after drying *in vacuo*. (Found: C 13.5; H 3.9; P 17.3. Calc. for $NH_4CH_2CH_2SPO_3HNa$ (179.13):C 13.4; H 3.9; P 17.3). The dehydrated product was found to be more stable upon storage than the originally precipitated crystals, which easily lose water of crystallization.

Hydrolysis of cysteamine-S-phosphate. 2.668 mmole of cysteamine-S-phosphate were dissolved in 10 ml of 1 M perchloric acid and heated on a boiling water bath for 30 min in a stream of nitrogen. After hydrolysis this solution consumed 2.62 matom of iodine (98.2 atom-% per mole of cysteamine-S-phosphate) as titrated with a standardized iodine solution.

A similar procedure of hydrolysis was used in the early experiments to determine *ortho*-phosphate.

Determination of cysteamine-S-phosphate by mercury(II)ion catalyzed hydrolysis. To 0.50 ml of sample (containing 0—1 μmole cysteamine-S-phosphate) were added: 0.10 ml mercury(II) acetate (70 mg mercury(II)acetate dissolved in 100 ml of 5 % acetic acid), 2.90 ml of water, 0.50 ml of "elon"[4] and 1.00 ml of molybdate[4]. The solution was set aside for 1 h at room temperature and read against a similarily treated blank (water instead of sample) at 660 mμ in a 1 cm cuvette. One μmole of cysteamine-S-phosphate in the sample was found to give an absorbancy of 0.712. Some quantitative data are presented in Table 1.

Studies on Nitrosylruthenium Complexes in Nitric Acid Using Repeated Extractions

G. RUDSTAM*

The Gustaf Werner Institute for Nuclear Chemistry, University of Uppsala, Sweden

Repeated extractions using the system tri-*n*-butyl phosphate (TBP) — nitric acid have been applied to the study of nitrosylruthenium nitrates. A detailed investigation of the partition coefficients has been carried out. The equilibrium composition of a solution of nitrosylruthenium nitrates in aqueous nitric acid has been determined, and the kinetics of the interchange between the complexes have been studied.

In the presence of oxides of nitrogen, ruthenium easily forms strong nitroso complexes. These complexes have recently attracted much attention because some of them are effectively extracted by tributyl phosphate. The extraction with tributyl phosphate from nitric acid solutions is a method often used for the separation of uranium and plutonium from fission products. There are two ruthenium isotopes with long half-lives and high fission yields among the fission products [1], namely ^{103}Ru and ^{106}Ru, and ruthenium therefore causes difficulties in the separation process.

Several investigations of the nitrato complexes of nitrosylruthenium have been published [2–9]. In the present investigation an extraction method has been worked out which makes accurate determinations of concentrations and partition coefficients possible. This technique has been used for a study of (a) the composition of a solution of nitrosylruthenium nitrates in aqueous nitric acid as a function of the acidity, (b) the kinetics of the interchange between the complexes, and (c) the dependence of the partition coefficients on various factors such as the tributyl phosphate concentration, the nitric acid concentration, and the temperature.

* Now at CERN, Geneva, Switzerland.

THE METHOD OF REPEATED EXTRACTIONS

Independent constituents

A solution (water phase) containing i independent constituents of the concentrations c_i is extracted repeated times with the same volume of an immiscible liquid (organic phase). The coefficients for the partition of the constituents between the organic phase and the water phase are denoted by q_i. For the sake of simplicity, the symbols p_i are introduced by the relation

$$p_i = \frac{q_i}{1 + q_i} \tag{1}$$

The n:th organic phase will contain the compounds in the total concentration $(C_o)_n$:

$$(C_o)_n = \sum_i c_i q_i (1-p_i)^n \tag{2}$$

For large values of n the constituent with the smallest partition coefficient ($= p_1$) will dominate. If log $(C_o)_n$ is plotted *versus* n a straight line is then obtained:

$$\log(C_o)_n \rightarrow \log c_1 q_1 + n \log(1-p_1) \tag{3}$$

This line has the slope $\log(1-p_1)$, and its intercept with the log C_o-axis is equal to log $c_1 q_1$. Thus q_1 and c_1 can be determined. By the subtraction of $c_1 q_1 (1-p_1)^n$ from eqn. (2) a new function $(C_{o,d})_n$ is obtained. This function can be plotted *versus* n on a semilogarithmic scale and be used for a determination of the partition coefficient and the concentration of the constituent with the next smallest partition coefficient. The same procedure can be repeated to yield the partition coefficients and the concentrations of the remaining constituents of the solution provided that the partition coefficients are sufficiently different *.

If p_1 is very small, eqn. (3) corresponds to a line with a small slope, and it is difficult to determine the partition coefficient. For large values of n, however, one obtains

$$\frac{(C_o)_n}{(C_w)_n} \rightarrow q_1 \tag{4}$$

where $(C_w)_n$ is the total concentration in the water phase after the n:th extraction. The smallest partition coefficient q_1 is determined by plotting the concentration ratio *versus* n.

By repeated extractions of an organic phase with water phases (equal volumes) similar results are obtained:

$$(C'_w)_n = \sum_i \frac{c_i}{q_i} p_i^n \tag{5}$$

(Primed symbols refer in this work to repeated extractions of an organic phase).

* This method of analysis is analogous to the resolution of a complex decay curve of a number of radioactive isotopes into its components.

On a semilogarithmic scale, $(C'_w)_n$ can be resolved into a number of straight lines with their slopes equal to log p_i and their intercepts with the log C'_w-axis equal to log c_i/q_i. The concentration ratio (eqn. (4)) gives in this case the largest partition coefficient.

Repeated extractions of a water phase containing dependent constituents (nitrosylruthenium nitrates)

If the constituents of a solution are dependent of each other, the method of analysis just outlined must be changed in order to take this into account. The nitrosylruthenium nitrates interchange rapidly, and they cannot be considered as independent.

In a solution, which is not too strongly acidified with nitric acid, mainly four different nitrosylruthenium complexes are found [6], namely the trinitrate (RuT), the dinitrate (RuD), the mononitrate (RuM), and a nitrate-free complex (RuN). (Obviously, the complex RuN is not a "nitrato" complex. It is closely related to the others, however, and will therefore be considered in this work). The following formulas have been proposed for these compounds:

$$\begin{aligned} \mathrm{RuT} &= \mathrm{RuNO(NO_3)_3(H_2O)_2}; \\ \mathrm{RuD} &= \mathrm{RuNO(NO_3)_2(OH)(H_2O)_2}; \\ \mathrm{RuM} &= \mathrm{RuNO(NO_3)(OH)_2(H_2O)_2}; \\ \mathrm{RuN} &= \mathrm{RuNO(OH)_3(H_2O)_2}. \end{aligned}$$

These complexes interchange in the following way:

$$\mathrm{RuT} \underset{k_{\mathrm{DT}}}{\overset{k_{\mathrm{TD}}}{\rightleftharpoons}} \mathrm{RuD} \underset{k_{\mathrm{MD}}}{\overset{k_{\mathrm{DM}}}{\rightleftharpoons}} \mathrm{RuM} \underset{k_{\mathrm{NM}}}{\overset{k_{\mathrm{MN}}}{\rightleftharpoons}} \mathrm{RuN}$$

The symbols k_{XY} denote rate constants. The rates of these reactions are all of the first order with respect to ruthenium [6].

In the present investigation the time for each complete extraction step (1 min) was kept short in comparison to the half-time of the reactions. Thus, it is appropriate to assume that the amount of the complex X which is converted into the complex Y during one extraction step is given by the product of its concentration and the "effective" rate constant k_{XY} (in min^{-1}). The actual complex will be found partly in the organic phase and partly in the water phase during the extraction. This is taken into account by using an effective rate constant computed from the partition coefficient and the rate constants in both phases.

Immediately after the n:th extraction the total concentration of nitrosylruthenium nitrates in the water phase and in the organic phase can be written as follows:

$$\left.\begin{aligned} (C_w)_n &= B_{\mathrm{T}n}(1-p_{\mathrm{T}}) + B_{\mathrm{D}n}(1-p_{\mathrm{D}}) + B_{\mathrm{M}n}(1-p_{\mathrm{M}}) + B_{\mathrm{N}n}(1-p_{\mathrm{N}}) \\ (C_o)_n &= B_{\mathrm{T}n}p_{\mathrm{T}} + B_{\mathrm{D}n}p_{\mathrm{D}} + B_{\mathrm{M}n}p_{\mathrm{M}} + B_{\mathrm{N}n}p_{\mathrm{N}} \end{aligned}\right\} \quad (6)$$

Since the actual rate constants are fairly small (<0.1 min^{-1}), all terms which are small of the third or higher orders, *i.e.* which contain more than two rate constants as factors, are now neglected. The following expressions for the B_{Xn}'s can then be deduced:

$$\left.\begin{aligned}
B_{Tn} &= c_T(1-k_T)Q_T^{n-1} + c_D k_{DT} S_{DTn} + c_T P_{TDT} U_{DTn} + c_M P_{MDT} V_{MDTn} \\
B_{Dn} &= c_D(1-k_D)Q_D^{n-1} + c_M k_{MD} S_{MDn} + c_T k_{TD} S_{TDn} + c_D(P_{DMD} U_{MDn} + \\
&\qquad + P_{DTD} U_{TDn}) + c_N P_{NMD} V_{NMDn} \\
B_{Mn} &= c_M(1-k_M)Q_M^{n-1} + c_N k_{NM} S_{NMn} + c_D k_{DM} S_{DMn} + c_M(P_{MNM} U_{NMn} + \\
&\qquad + P_{MDM} U_{DMn}) + c_T P_{TDM} V_{TDMn} \\
B_{Nn} &= c_N(1-k_N)Q_N^{n-1} + c_M k_{MN} S_{MNn} + c_N P_{NMN} U_{MNn} + c_D P_{MDN} V_{DMNn}
\end{aligned}\right\} \quad (7)$$

The concentration symbols c_T, c_D, c_M, and c_N appearing in eqns. (7) denote the concentrations of RuT, RuD, RuM, and RuN, respectively, at the beginning of the experiment. The other symbols have the following meaning:

$$k_T = k_{TD};\ k_D = k_{DM} + k_{DT};\ k_M = k_{MN} + k_{MD};\ k_N = k_{NM}$$

$$Q_X = (1-k_X)(1-p_X)$$

$$P_{XYZ} = k_{XY}(1-p_Y)k_{YZ}$$

$$S_{XYn} = \frac{Q_X^n - Q_Y^n}{Q_X - Q_Y}$$

$$U_{XYn} = \frac{1}{(Q_X-Q_Y)^2}\left[(n-1)Q_Y^n - nQ_Y^{n-1}Q_X + Q_X^n\right]$$

$$V_{XYZn} = \frac{1}{Q_X-Q_Y}\left[Q_X\,\frac{Q_X^{n-1}-Q_Z^{n-1}}{Q_X-Q_Z} - Q_Y\,\frac{Q_Y^{n-1}-Q_Z^{n-1}}{Q_Y-Q_Z}\right]$$

The partition coefficients q_M and q_N are very small (<0.01) for extractions with tributyl phosphate. They will therefore be neglected in this work.

For large values of n both Q_T^n and Q_D^n become negligible. (At the extraction of 1 M HNO_3 with 30 % TBP at 20°, Q_T is about 0.02 and Q_D about 0.75.) In this case the following approximation holds:

$$(C_o)_n \to Q_M^n\left[\frac{c_M k_{MD} p_D}{Q_M-Q_D} + \frac{c_M P_{MDT} p_T}{(Q_M-Q_D)(Q_M-Q_T)} + \frac{c_D P_{DMD} p_D}{(Q_M-Q_D)^2} - \frac{c_N P_{NMD} p_D}{(Q_N-Q_M)(Q_M-Q_D)}\right] + \\ + Q_N^n\,\frac{c_N P_{NMD} p_D}{(Q_N-Q_M)(Q_N-Q_D)} \quad (8)$$

The last term in eqn. (8) is usually small. For this reason $\log(C_o)_n$ will tend to a straight line when plotted *versus* n. From the slope of this line, Q_M is determined. A more accurate value of Q_M can be obtained as a second approximation by taking the last term of eqn. (8) into account.

For somewhat smaller values of n, Q_T^n is still negligible but not Q_D^n. In this case the following difference is obtained by subtracting eqn. (8) (right part) from $(C_o)_n$:

$$\left.\begin{aligned}(C_{o,d})_n \to Q_D^n\Bigg[& c_D q_D - \frac{c_M k_{MD} p_D}{Q_M - Q_D} + \frac{c_T k_{TD} p_D}{Q_D - Q_T} + \frac{c_D k_{DT} p_T}{Q_D - Q_T} + \\ & + \frac{c_N P_{NMD} p_D}{(Q_M - Q_D)(Q_N - Q_D)} - \frac{c_M P_{MDT} p_T}{(Q_M - Q_D)(Q_D - Q_T)} + \frac{c_T P_{TDT} p_T}{(Q_D - Q_T)^2} + \\ & + \frac{c_D P_{DMD} p_D}{(Q_M - Q_D)^2}\left(n - 1 - n\frac{Q_M}{Q_D}\right) + \frac{c_D P_{DTD} p_D}{(Q_D - Q_T)^2}\left(n - 1 - n\frac{Q_T}{Q_D}\right)\Bigg]\end{aligned}\right\} \quad (9)$$

The last two terms within the square brackets are small. Therefore, log $(C_{o,d})_n$ gives a straight line when plotted *versus* n, and Q_D can be determined from the slope of this line.

By subtraction of the right part of eqn. (9) from $(C_{o,d})_n$ a new difference is obtained:

$$(C_{o,d,d})_n = Q_T^n\left[c_T q_T - \frac{c_D k_{DT} p_T + c_T k_{TD} p_D}{Q_D - Q_T} + \right.$$
$$\left. + \text{ smaller terms}\right]. \quad (10)$$

If $\log(C_{o,d,d})_n$ is plotted *versus* n a straight line is obtained with the slope equal to log Q_T. The line is very steep, however, and it is better to determine Q_T by other experiments (repeated extractions of an organic phase).

As an illustration C_o, $C_{o,d}$ and $C_{o,d,d}$ have been plotted *versus* n on a semi-logarithmic scale in Fig. 1.

If the partition coefficients and the rate constants are known, eqn. (10) can be used for a determination of c_T (the term containing c_D is very small and can be neglected).

$$c_T = \frac{(C_{o,d,d})_{n=1}}{Q_T\left[q_T - \dfrac{k_{TD} p_D}{Q_D - Q_T}\right]} \quad (11)$$

For the determination of the relative concentrations c_D, c_M and c_N the following relationships are chosen: (a) the value A_o of the right part of eqn. (9) for n equal to zero as determined by extrapolation of the straight line, and (b) the ratio $(C_o)_n/(C_w)_n = q_n$ for a large value of n (the value $n = 25$ was used). The former relationship depends essentially on the concentration of the dinitrate and the latter on the ratio between the concentrations of the mononitrate and the nitrate-free complex. Besides, all concentrations add up to unity so that a system of equations of the following type is obtained:

$$\left.\begin{aligned} & c_N + c_M + c_D = 1 - c_T \\ \text{(a)} \quad & \alpha_1 c_N + \alpha_2 c_M + \alpha_3 c_D = A_o - \alpha_4 c_T \\ \text{(b)} \quad & (\beta_1 - q_n\gamma_1)c_N + (\beta_2 - q_n\gamma_2)c_M + (\beta_3 - q_n\gamma_3)c_D = (q_n\gamma_4 - \beta_4)c_T\end{aligned}\right\} \quad (12)$$

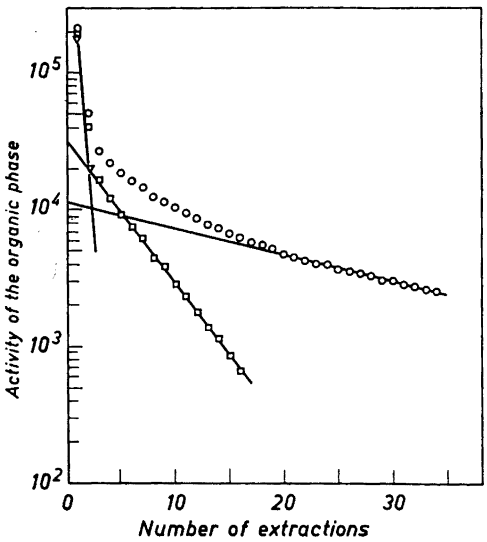

Fig. 1. The activity (proportional to the total concentration of nitrosylruthenium nitrates) of the organic phase *versus* the number of extractions for repeated extractions of a water phase. Circles: $(C_o)_n$; Squares: $(C_{o,d})_n$; Triangles: $(C_{o,d,d})_n$.

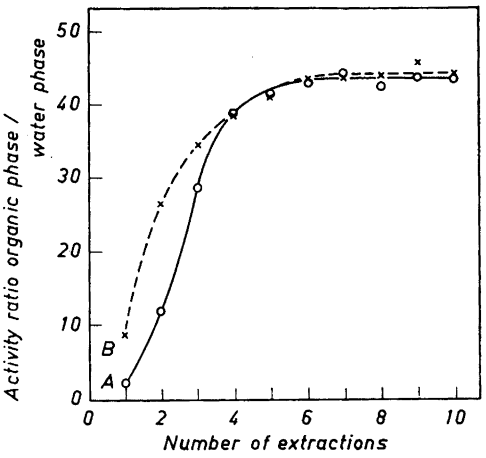

Fig. 2. The ratio between the activity of the organic phase and that of the water phase *versus* the number of extractions for repeated extractions of an organic phase. Curve A: The activity was originally in the water phase. Curve B: The activity was originally in the organic phase.

The α's, β's and γ's depend only on the partition coefficients and the rate constants. They are easily calculated from eqns. (6), (7), and (9). The expressions are somewhat lengthy, however, and they are therefore not written out here.

Repeated extractions of an organic phase containing dependent constituents (nitrosylruthenium nitrates)

For repeated extractions of an organic phase eqns. (6) and (7) are valid if the factor $(1-p_X)$ is changed into p_X in the expressions for Q_X and P_{XYZ}. Thus

$$Q'_X = p_X\ (1-k'_X)$$
$$P'_{XYZ} = k'_{XY} p_Y k'_{YZ}$$

The rate constants, which appear here, differ from the corresponding ones in the preceeding section. Since they turn out to be considerably smaller, terms which are small of the second order, *i. e.* terms containing P'_{XYZ} as a factor, can be neglected. Besides, Q'_N and Q'_M are negligible.

For large values of n, $Q_D'^n$ can be neglected, and the following relation is obtained:

$$\frac{(C_o')_n}{(C_w')_n} \rightarrow q_T\,(1-\delta) \tag{13}$$

with

$$\delta \sim \frac{k_{TD}'}{Q_T'-Q_D'}\left[q_T\,(1-p_D) - p_D\right]$$

From eqn. (13) q_T is determined by successive approximations.

The ratio $(C_o')_n/(C_w')_n$ has been plotted *versus* n in Fig. 2. It tends to become a constant after 4—5 extractions.

For large values of n, $(C_o')_n$ can be written:

$$(C_o')_n \rightarrow c_T Q_T'^n\,(1+\varepsilon) \tag{14}$$

with

$$\varepsilon \sim \frac{p_T\left[k_{TD}'\,\frac{p_D}{p_T} + k_{DT}'\,\frac{c_D}{c_T}\right]}{Q_T'-Q_D'}$$

The right part of eqn. (14) corresponds to a straight line when plotted *versus* n on a semilogarithmic scale. The intercept for n equal to zero can be used for a determination of c_T.

If log $(C_w')_n$ is plotted *versus* n, a straight line is obtained for large values of n. By a subtraction procedure similar to the one leading to $(C_{o,d})_n$ (eqn. (9)), the following difference results:

$$(C_{w,d})_n = Q_D'^n\left[\frac{c_D}{q_D} + \frac{c_M k_{MD}'}{q_D(1-k_D')} - \frac{c_T k_{TD}'(1-p_D) + c_D k_{DT}'(1-p_T)}{Q_T'-Q_D'}\right] \tag{15}$$

A straight line results when log $(C_{w,d}')_n$ is plotted as a function of n. The line has the slope log Q_D' and can be used for a determination of Q_D'. An approximate value of c_D is also obtained.

The accuracy of the determinations. The reproducibility of the determinations is high, especially with regard to RuT. Thus it is possible to determine c_T with an accuracy of better than 1 %, and the q_T-values are in many cases accurate to ± 2 %. The determinations of q_D are reliable to ± 5—10 %.

The accuracy of the determinations of c_D, c_M, and c_N depends essentially upon how well the rate constants are determined. It is probably not better than ± 10—20 %.

EXPERIMENTAL

Solutions. The nitrosylruthenium nitrate contained tracer of ^{106}Ru. A stock solution in 8 M nitric acid was prepared as described in Ref.[6]. The stock solution was carrier-free. An analysis was performed using the dithio-oxamide method [10] after the distilla-

tion of ruthenium as the tetroxide. The analysis showed that the ruthenium concentration of the samples was less than 10^{-7} M.

The tri-*n*-butyl phosphate was first washed with a 5 % solution of sodium carbonate and then distilled at vacuum. After the distillation it was diluted with an inert mixture of hydrocarbons.* The concentration of tributyl phosphate was determined analytically by the method of Allen and DeSesa [11].

The experimental procedure. Repeated extractions of a water phase were carried out using an extraction apparatus (Fig. 3) where the lighter organic phase could be easily removed after each extraction. The extractions were performed by stirring for 30 sec. After this, the phases were separated and a new portion of tributyl phosphate was added. The time allowed for this was also 30 sec. so that the time interval between two successive extractions was exactly 1 min. The experiment was usually carried out at 20° with 0.95 M nitric acid as the water phase and 30 % tributyl phosphate as the organic phase. The volume of each phase was 5 ml, and the number of extractions was 25—35. The activities of all organic phases and the water phase were measured with a scintillation counter. The activity was used as a measure of the concentration.

At the experiments with repeated extractions of an organic phase, a separation funnel was used. The number of extractions was 10.

The acidity of the water phases was determined by titration after the extractions.

RESULTS

Dependence on the extraction time

In a series of experiments with repeated extractions of an organic phase (30 % TBP) with 1 M nitric acid at 20°, the extraction time was varied. The partition coefficients obtained are tabulated in Table 1.

* Nysolvin 160/200, a mainly paraffinic kerosene fraction from Nynäs-Petroleum AB.

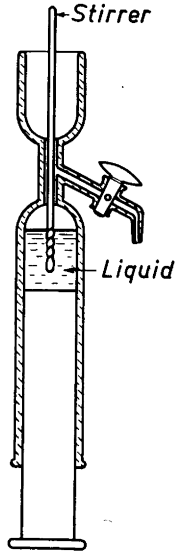

Fig. 3. Extraction apparatus for repeated extractions of the heavier phase.

Table 1. The dependence of the partition coefficients on the extraction time.

Extraction time	q_T	q_D
15 sec.	46.9	0.28
30 »	47.9	0.28
40 »	47.4	0.32

The partition coefficients are independent of the extraction time in the interval studied. Thus stirring for 30 sec is adequate for the equilibrium between the phases to be reached. Similar results regarding RuT have been obtained by Brown *et al.*[6]

Studies on the kinetics of the interchange between the nitrosylruthenium nitrates

(a) Rate constants in 0.95 M nitric acid. In order to make a determination of partition coefficients and concentrations from the extraction data possible, the rate constants must be known. Kinetic experiments are therefore essential. Since the analyses by the method of repeated extractions were usually carried out at 20° and with the system 0.95 M HNO_3—30 % TBP, it was of primary interest to determine the rate constants corresponding to these conditions.

In a series of experiments a pure solution of RuT in 30 % tributyl phosphate was first prepared by removing all other complexes by repeated extractions with 1 M nitric acid. The trinitrate was then reextracted into 8 M nitric acid, and the solution was diluted to 0.95 M with water. It was kept at 20° in a thermostate. Samples were taken at different times for repeated extractions, and the quantities $(C_{o,d,d})_{n=1}$, A_o, and q_{25} (eqns. (11) and (12)) were measured.

Starting from the approximations $k_{TD} = k_{NM} = 0$ and $Q_M = 1-k_{MD}$, the constants of eqns. (12) were calculated and the concentrations determined. Next, new rate constants were determined from the concentrations just obtained. The kinetic equations are of the following form:

$$\left.\begin{aligned} \frac{dc_T}{dt} &= -k_{TD}c_T + k_{DT}c_D \\ \frac{dc_N}{dt} &= -k_{NM}c_N + k_{MN}c_M \end{aligned}\right\} \qquad (16)$$

Now, k_{DT} can be expressed in k_{TD} and k_{MN} in k_{NM} using the concentrations at equilibrium. The derivatives in eqns. (16) are then replaced by the differences $\frac{\Delta c_T}{\Delta t}$ and $\frac{\Delta c_N}{\Delta t}$, and the rate constants k_{TD} and k_{NM} are determined graphically. They are combined with the relation $Q_M = 1-k_M$ and all equilibrium concentrations to yield the remaining rate constants, and the "effective" rate con-

stants are calculated. These are used for new determinations of the concentrations c_X. By successive approximations, values of c_X and k_{XY} are finally found which are not changed by further approximations. The final values of the rate constants in 0.95 M nitric acid and at the temperature 20° are tabulated in Table 2.

Table 2. Rate constants in 0.95 M HNO_3.

k_M	0.051	min^{-1}*
k_{TD}	0.025	»
k_{DT}	0.0024	»
k_{DM}	0.084	»
k_{MD}	0.047	»
k_{MN}	0.0041	»
k_{NM}	0.0025	»

* This value was obtained from $Q_M = 0.949 \pm 0.002$, average of 34 determinations.

The following value of Q_D (average of 34 determinations) has been obtained:

$$Q_D = (1-k_D)\ (1-p_D) = 0.742 \pm 0.007$$

The effective value of k_D is found to be 0.078 min^{-1} from the appropriate rate constants in 0.95 M nitric acid and tributyl phosphate. With this k_D-value one obtains

$$p_D = 0.195;\ q_D = 0.242$$

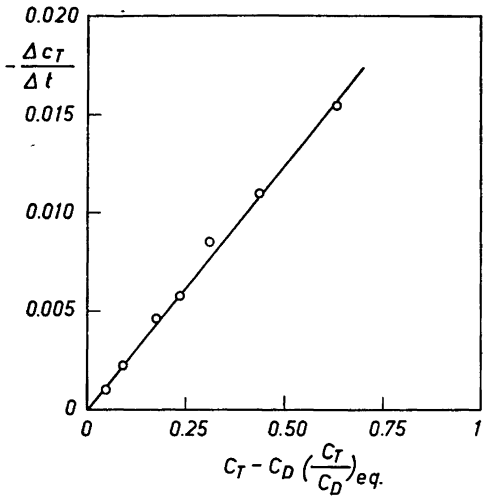

Fig. 5. $\frac{\Delta c_T}{\Delta t}$ *versus* $c_T - c_D \left(\frac{c_T}{c_D}\right)_{eq.}$ for RuT in 0.95 M nitric acid. Temperature: 20°.

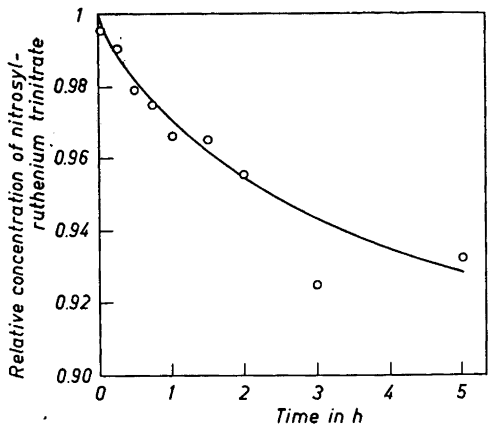

Fig. 6. Relative concentration of RuT *versus* time starting from a solution of pure RuT in 30 % tributyl phosphate. Temperature: 20°.

The concentrations of the nitrosylruthenium nitrates in 0.95 M nitric acid are plotted *versus* time in Fig. 4.

As an example of the rate constant analyses, $\frac{\Delta c_T}{\Delta t}$ has been plotted *versus* $c_T - c_D\left(\frac{c_T}{c_D}\right)_{eq.}$ in Fig. 5. The slope of the straight line corresponds to k_{TD}. The value 0.025 min^{-1} is found.

(b) Rate constants in 30 % tributyl phosphate saturated with 0.95 M nitric acid. The decrease of c_T in a solution of RuT in 30 % tributyl phosphate (saturated with 0.95 M nitric acid) has also been studied. The temperature was 20°. In this case only two components have to be considered, namely RuT and RuD. The following rate constants were obtained:

$$k_{TD,o} = 0.00067 \text{ min}^{-1}$$
$$k_{DT,o} = 0.0059 \text{ min}^{-1}$$

Fig. 6 shows c_T as a function of time.

A conversion of the aquo-complexed nitrosylruthenium trinitrate into the corresponding TBP-complexed compound has been proposed to occur in tributyl phosphate solutions [6]. The latter compound is thought to have a much higher partition coefficient ($> 10^3$) than the former. The half-time of the reaction is estimated to be about 3 min and that of the reverse reaction to be about 6 min. In this work a great number of experiments with repeated extractions of organic phases have been performed in which the ruthenium was originally in the water phase. The experiments cover the temperature range

0°—50° and the acidity range 0.165 M—3.25 M (water phase). In all these experiments results similar to those in Fig. 2 were found. The activity ratio reaches a constant value after 4—5 extractions, *i. e.* after 4—5 min. The same results were obtained also in experiments where the ruthenium was originally in the TBP-phase, in some cases for as long as 18 days. This is not in accord with the hypothesis mentioned above. The conversion proposed would cause the activity ratio to approach a constant value much more slowly. On the other hand, it is quite possible that a more rapid interchange takes place. If this is the case, a measured q_T-value will be a function of the true partition coefficient of the aquo-complex and the rate constants of the interchange.

(c) The temperature dependence of the rate constants in 0.95 M nitric acid. Kinetic experiments have been carried out at three different temperatures: 10°, 20°, and 30°. The nitric acid concentration of the solutions was 0.95 M. The results are given in Table 3 and shown in Fig. 7.

Table 3. The temperature dependence of the rate constants.

Temperature	k_{TD}, min^{-1}	k_{DT}, min^{-1}	k_{MN}, min^{-1}	k_{NM}, min^{-1}
10°	0.0065	0.00096		
20°	0.025	0.0024	0.0041	0.0025
30°	0.068	0.0058	0.012	0.0085

An increase of the temperature by 10° corresponds to a threefold increase of the rate constants. Jenkins and Wain [5] have carried out a series of rate constant determinations. Their results for the rate constant k_{TD} in 0.7—0.8 M nitric acid obtained at 0°, 25°, and 35° have also been plotted in Fig. 7.

(d) The acidity dependence of the rate constants. The dependence of the rate constants on the acidity of the water phase has been studied at the temperature 20°. The results are given in Table 4 and shown in Fig. 8.

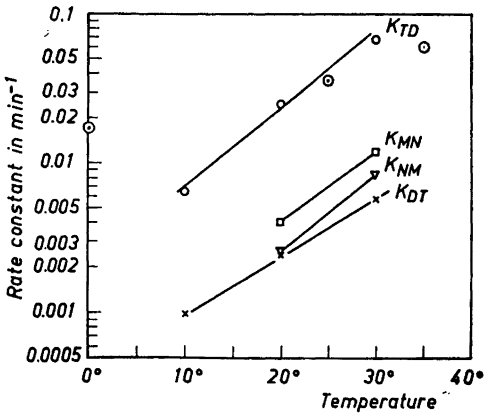

Fig. 7. The temperature dependence of the rate constants in 0.95 M nitric acid. Circles: k_{TD}; Crosses: k_{DT}; Squares: k_{MN}; Triangles: k_{NM}; Dotted circles: k_{TD} from Ref.[5].

Table 4. The acidity dependence of the rate constants.

Acidity	k_{TD}, min^{-1}	k_{DT}, min^{-1}	k_{MN}, min^{-1}	k_{NM}, min^{-1}
0.95 M	0.025	0.0024	0.0041	0.0025
1.92 M	0.019	0.0058	0.0046	0.014
3.80 M	0.018	0.013		
7.11 M	0.020	0.053		

The rate constant k_{TD} is almost independent of the acidity. This is in agreement with the results by Jenkins and Wain [5].

In Fig. 9 c_T has been plotted *versus* time for different acidities.

Relative concentrations of the nitrosylruthenium complexes at equilibrium in aqueous nitric acid solutions

A series of nitrosylruthenium solutions of varying nitric acid concentration were prepared and analysed after about one week by repeated extractions of an organic phase (determination of c_T and c_D) or repeated extractions of a water phase (determination of c_T, c_D, c_M, and c_N). The results are tabulated in Tables 5 and 6, respectively, and plotted *versus* the acidity in Fig. 10.

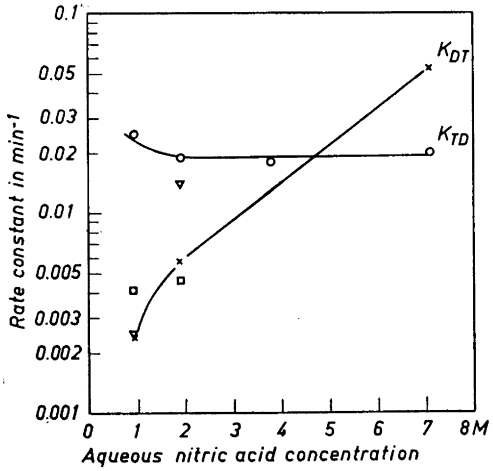

Fig. 8. The acidity dependence of the rate constants. Temperature: 20°. Circles: k_{TD}; Crosses: k_{DT}; Squares: k_{MN}; Triangles: k_{NM}.

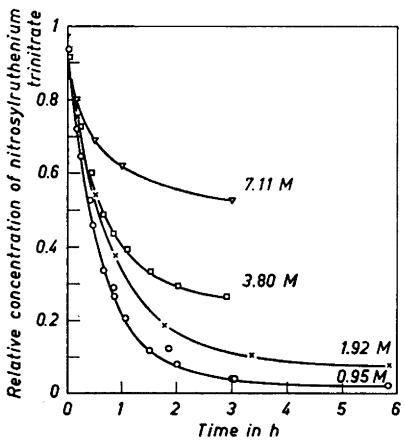

Fig. 9. Relative concentration of RuT *versus* time starting from a solution of pure RuT in aqueous nitric acid. Temperature: 20°. Circles: 0.95 M HNO_3; Crosses: 1.92 M HNO_3; Squares: 3.80 M HNO_3; Triangles: 7.11 M HNO_3.

Table 5. Relative concentrations of nitrosylruthenium nitrates.

Studies on the partition coefficients of the nitrosylruthenium nitrates

(a) Dependence on the tributyl phosphate concentration. Tributyl phosphate solutions with the concentration varying from 10 % to 50 % were extracted at 20° with 1 M nitric acid. The measured partition coefficients are tabulated in Table 7 and plotted *versus* the tributyl phosphate concentration in Fig. 11.

Table 7. Partition coefficients for different concentrations of tributyl phosphate.

Concentration of TBP, %	q_T	q_D
10.0	2.4	
15.6	8.5	0.13
21.0	19.5	0.18
25.9	33.2	0.23
31.2	45.1	0.39
36.1	67.5	0.56
40.9	88	0.54
45.4	113	0.52
50.0	150	0.63

As found by other investigators [6] a plot of log q_T *versus* log C_{TBP} gives a straight line with the slope about 2 (the value 2.3 is obtained from Fig. 11).

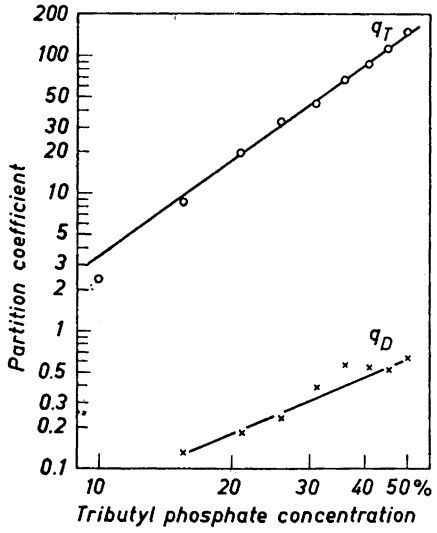

Fig. 11. The dependence of the partition coefficients on the tributyl phosphate concentration for extractions with 1 M nitric acid. Temperature: 20°. Circles: q_T; Crosses: q_D.

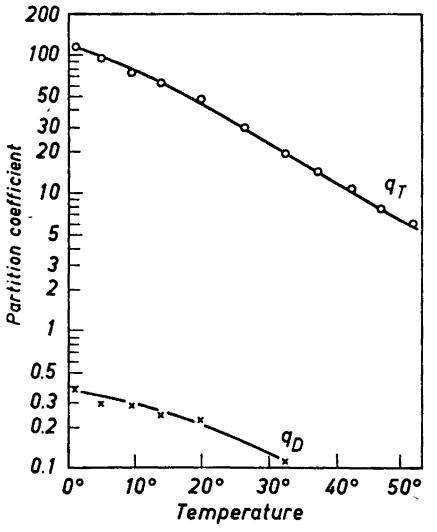

Fig. 12. The temperature dependence of the partition coefficients for extractions of 1 M nitric acid with 30 % tributyl phosphate. Circles: q_T; Crosses: q_D.

(b) Dependence on the temperature. The partition coefficients q_T and q_D were determined in experiments with repeated extractions of organic phases (30 % TBP) with 1 M nitric acid at different temperatures. Eqn. (13) was used for the evaluation of q_T. The effective rate constant k'_{TD}, which forms part of the correction factor δ, contains $k_{TD,w}$ and $k_{TD,o}$. The temperature dependence of $k_{TD,w}$ is obtained from Fig. 7. Only one $k_{TD,o}$-value has been determined, namely that for 20°. The temperature dependence is assumed to be the same as for $k_{TD,w}$, *i. e.* a temperature increase of 10° corresponds to a threefold increase of $k_{TD,o}$.

For the determination of q_D from the experimental values of $Q'_D = p_D(1-k'_D)$, the effective rate constant k'_D must be known. This contains $k_{DT,w}$, $k_{DT,o}$, and $k_{DM,w}$. The first of these three rate constants is obtained from Fig. 7. The others are assumed to vary with temperature in the same way as $k_{TD,w}$. Their values at 20° are known.

The resulting determinations of q_T and q_D are tabulated in Table 8 and plotted *versus* temperature in Fig. 12.

(c) Dependence on the acidity of the water phase. The acidity dependence of the partition coefficients was studied using two different methods for both q_T and q_D. First repeated extractions of an organic phase (30 % TBP) were carried out at the temperature 20° with water phases of the desired acidity. The results are tabulated in Table 9.

In the second method for the determination of q_T, a pure solution of the trinitrate in 30 % tributyl phosphate was prepared by 8—10 extractions with 1 M nitric acid. The organic solution was then extracted at 20° with nitric acid of the desired strength (the acidity was measured after the experiment), and the partition coefficient was determined from the ratio between the activities in the phases after a correction for the formation of dinitrate during the experiment. The results are given in Table 10.

7.22	0.073
10.3	0.073
13.5	0.022

The partition coefficient of RuD was also determined by a method similar to the second one for RuT. A solution of nitrosylruthenium nitrates in 1 M nitric acid was extracted four times with 30 % tributyl phosphate. Since q_T is high, all RuT is effectively removed. The solution was then extracted once more, and the organic phase, containing essentially pure RuD, was removed and extracted at 20° with nitric acid of the desired strength. The partition coefficient q_D was obtained from the ratio between the activities in the phases after due correction for the formation of RuT and RuM during the experiment. The results are tabulated in Table 11.

All the data from these experiments have been plotted *versus* the acidity of the water phase in Fig. 13. The agreement with other investigations is reasonable with respect to q_T. The values of q_D are in agreement with measurements using repeated extractions of a water phase (page 1490).

(d) The stability of nitrosylruthenium dinitrate in 30 % tributyl phosphate. A solution of RuD in 30 % tributyl phosphate (saturated with 0.95 M nitric acid) was prepared in the way described in the preceding section. The solu-

tion was kept at 20°. Samples were taken for extraction with 0.95 M nitric acid, and the ratio between the activity of the organic phase and that of the water phase was determined. This ratio is shown in Fig. 14 as a function of the time between the preparation of the solution and the extraction.

If it is assumed that the solution contains only RuT and RuD, their concentrations can be calculated from the activity ratios. From the time-dependence of the concentrations, the rate constant $k_{TD,o} = 0.0067$ min^{-1} is obtained. This agrees well with the value 0.0059 min^{-1} determined earlier.

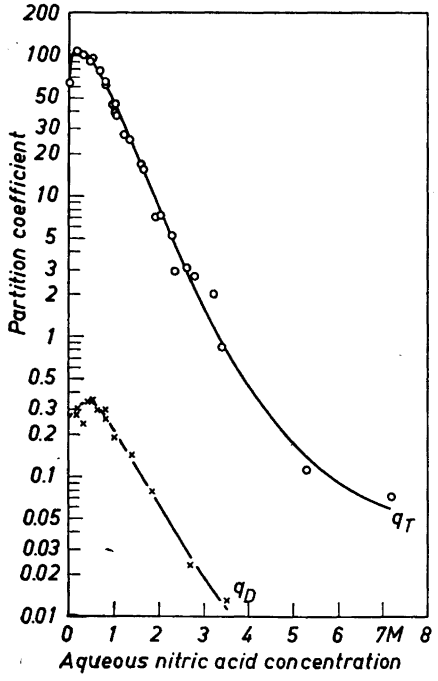

Fig. 13. The acidity dependence of the partition coefficients for extractions with 30 % tributyl phosphate at 20°. Circles: q_T; Crosses: q_D.

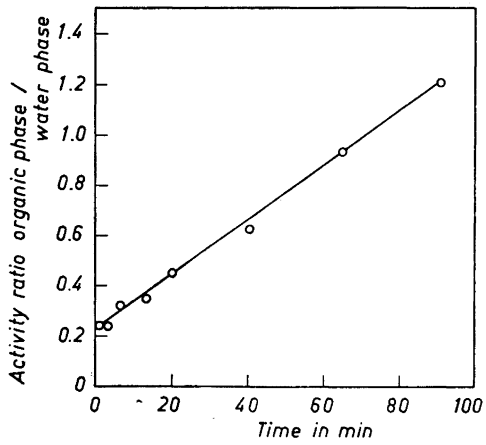

Fig. 14. The ratio between the activity of the organic phase and that of the water phase *versus* time for extractions of a solution of originally pure RuD in 30 % tributyl phosphate with 0.95 M nitric acid.

(e) Upper limits for q_M and q_N. A large number of experiments concerning the partition coefficients q_M and q_N have been performed. The experiments were carried out at 20° with the system 30 % tributyl phosphate — 0.95 M nitric acid. Upper limits of the partition coefficients are immediately obtained from repeated extractions of water phases. For large values of the extraction number n, the ratio between the activity of the organic phase and that of the water phase varies from 0.03 for solutions containing much RuM and little RuN to less than 0.005 for solutions containing mainly RuN. Thus

$$q_M < 0.03 \text{ and } q_N < 0.005$$

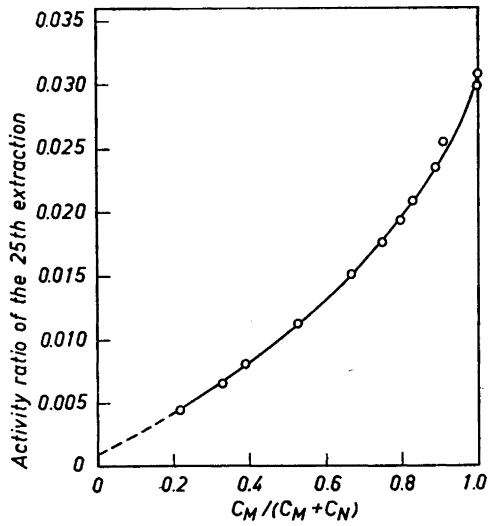

Fig. 15. The ratio between the activity of the organic phase and that of the water phase at the 25th extraction of a water phase with 30 % tributyl phosphate *versus* $c_M/(c_M+c_N)$. Temperature: 20°.

The activity ratio for n equal to 25 has been plotted *versus* the ratio $c_M/(c_M+c_N)$ in Fig. 15. By extrapolation the upper limit 0.001 is obtained for q_N.

A better estimate of the upper limit of q_M can be made. A solution of nitrosylruthenium nitrates in 0.95 M nitric acid was extracted four times with 30 % tributyl phosphate. The fourth organic phase was extracted with 0.95 M nitric acid at 20°, and the ratio between the activities of the phases was measured. Four determinations gave the value 0.260 $\pm$ 0.006 as an average. This corresponds to a q_D-value of 0.245, in excellent agreement with earlier results. In another series of experiments carried out at the same conditions, a water phase was extracted 25 times with 30 % tributyl phosphate, and the 25th organic phase was extracted with 0.95 M nitric acid. The activity ratio 0.237 $\pm$ 0.013 was obtained as an average of seven determinations. This is close to the q_D-value at the given conditions, and the conclusion can be drawn that almost all extracted ruthenium is in the form of RuD. The observed difference between 0.260 and 0.237 corresponds to a q_M-value of 0.003. It should be safe to estimate the upper limit of q_M to 0.01.

Since both q_M and q_N are small, their neglection in this work is justified.

DISCUSSION

The method of repeated extractions has proved to be very useful for the study of the nitrato complexes of nitrosylruthenium. Owing to the possibility of taking the interchange between the complexes during the experiment into account, reliable determinations of concentrations and partition coefficients can be made.

The values determined for rate constants, equilibrium concentrations, and partition coefficients make possible predictions of the behaviour of the nitrosylruthenium nitrates at different conditions with respect to the tributyl phosphate concentration, the nitric acid concentration, the temperature, and the time schedule followed during the experiment. Such predictions are of value in connection with those separation procedures for plutonium and uranium which are based on extractions with tributyl phosphate.

It must be pointed out that the present work has not been concerned with any confirmation of the formulas of the nitrosylruthenium complexes. The trinitrate has been identified merely by its partition coefficient and by comparison with other experiments [6,8]. The identities of the other complexes found have been inferred from their relationships (for instance: a solution of RuD in tributyl phosphate is converted into RuT; a solution of RuM in dilute nitric acid is converted into RuD and not directly into RuT). Furthermore, RuT is probably the most nitrate-rich complex since it dominates at high nitric acid concentrations. Thus, if the identification of RuT as the trinitrate is correct, the identification of the other complexes as the dinitrate, the mononitrate and a nitrate-free complex seems plausible.

The technique of repeated extractions should be useful also for other investigations where a complex mixture of extractable compounds is to be analysed.

Acknowledgements. The author wishes to express his gratitude to Professor The Svedberg for his interest in this work.

Thanks are due to Mrs. Carina Kjellson for her valuable help in carrying out the experiments.

The investigation has been financially supported by AB Atomenergi, which is gratefully acknowledged.

On the Structure of the Reversibly Oxidized and Reduced Group of Sperm Antagglutins

P. E. LINDAHL and S. ROSS

Institute of Zoophysiology, University of Uppsala, Sweden

When sperm antagglutins are inactivated by oxidation a carbonyl group is formed. This has been detected by blocking with sodium bisulphite of the reactivation of the antagglutin by reducing agents. The oxidized biologically inactive sperm antagglutins are reduced by DPNH. This reaction seems to be non-enzymatic, and to be blocked by diacetyl and lactate. The location of the easily reducible carbonyl group in the oxidized antagglutin molecule is discussed.

In semen from most mammals a factor occurs which prevents head-to-head agglutination of the spermatozoa. This anti-agglutinating factor, named male sperm antagglutin, is formed in the prostatic gland in cattle [1] and man [2]. Male sperm antagglutin has been isolated and purified by precipitation with ammonium sulphate and chromatography on calcium carbonate [3]. It is a proteid with an active group containing carbohydrate [1,3], sulphuric acid residues [4,5], and a probably carbocyclic compound [5,6,7].

Also in the female genital tract of several mammals a sperm anti-agglutinating factor, named female sperm antagglutin, has been detected and isolated by chromatography on silica [8]. It contains no protein, but seems to be very similar to the active group of the male sperm antagglutin. However, no sulphuric acid residues could be detected [8].

Both these sperm antagglutins are inactivated by being kept in aqueous solution at room temperature in contact with air. However, this process is very much accelerated by bubbling oxygen through the solution after addition of a minute amount of platinum black. When a reducing agent as sodium thioglycolate, sodium ascorbate, or hydrogen and platinum black is added to these biological inactive solutions the activity is recovered [1,3]. The inactivation of sperm antagglutins is thus brought about by oxidation of some group in the antagglutin molecules.

As the oxidation and the inactivation of the sperm antagglutins occur simultaneously, it was of interest to try to acquire some knowledge about the chemical structure of the group of the antagglutin molecule which is so

easily reversibly oxidized and reduced. To obtain such information we have to study the biological activity of pretreated samples of sperm antagglutin. By adding different reagents with known qualities to oxidized, biologically inactive sperm antagglutin some substances with the power of inhibiting the reactivation of the oxidized antagglutin might possibly be found. In case the same reagent, added to reduced antagglutin, should not influence the biological activity of the antagglutin, it could be concluded that the reagent reacts in some way with the oxidized form of the group of the antagglutin molecule which is reversibly oxidized and reduced, by preventing its reduction. In its oxidized form this group might be quinonelike or it might be a disulphide, carbonylic, carboxylic, epoxy, or ethylenic group. Since female sperm antagglutin has been shown to contain no sulphur [8], disulphide groups can be excluded from discussion. Quinones as well as carbonyls should react with carbonylic reagents, although in somewhat different ways. We have therefore used for this purpose sodium bisulphite, and also tried some other carbonyl reagents.

All substances so far studied with the ability of reducing the oxidized sperm antagglutins have an oxidation-reduction potential (E_o') equal to 0.06 or lower [9]. Among these sodium thioglycolate as well as reduced diphosphopyridine nucleotide (DPNH) were found to induce very high biological activity. Combined with one of several dehydrogenases DPNH has the ability of reducing different carbonyl compounds. On the other hand the possibility is not excluded that DPNH might by itself reduce oxidized antagglutin, although it is known to be rather inert. We have therefore tried to decide whether DPNH, when reducing oxidized sperm antagglutin is acting by itself or combined with an enzyme.

MATERIALS

The male sperm antagglutin was prepared according to Lindahl and Kihlström [3]. The relatively pure preparations were used in aqueous solution of about 50 μg antagglutin per ml, estimated according to Lindahl and Kihlström [3]. The female sperm antagglutin which was prepared according to Lindahl and Nilsson [8] has been used in an aqueous solution equivalent in its biological activity to the above mentioned male sperm antagglutin solution. The sperm antagglutin solutions were oxidized by aeration during one hour in presence of platinum black. Sodium thioglycolate ($4.4-5.7 \times 10^{-4}$ M) was regularly used as reducing agent in experiments in which reactions with reduced antagglutins were studied. When investigating the reduction of oxidized antagglutin by DPNH we used this compound, enzymatically reduced (Sigma), in a concentration of 5.7×10^{-4} M.

Bull spermatozoa were used for tests on biological activity. The spermatozoa in 0.5 ml semen were washed three times by suspending them in 8 ml of the diluter of Phillips and Spitzer [10], slightly modified, and by centrifugation. This diluter was prepared by mixing equal amounts of two solutions, one containing 0.6 % glucose, and 0.8 % galactose, and the other 0.2 % KH_2PO_4 and 0.2 % $Na_2HPO_4 12H_2O$, both made up with water twice distilled in glass, and autoclaved. This is here named diluter I. Another diluter with the double osmotic pressure must also be used to compensate for the very low osmotic pressure of the dilute antagglutin solutions and of the reagent solutions used. This diluter here named diluter II, contains twice as much solids as diluter I. — All reagents with exception of diacetyl were of *pro analysi* quality. All solutions have been freshly prepared every day.

EXPERIMENTS AND RESULTS

The experiments are arranged in such a way that conclusions may be drawn from comparisons between values of anti-agglutination index, AAI, found. Thus the AAI of any sample of antagglutin is determined with a control containing all the reagents with the exception of the antagglutin, and in the same final concentrations as in the relevant sample. In cases in which one or more reagents are brought to react with the sperm antagglutin the sample is prepared in the following way: To 0.03 ml of a solution of sperm antagglutin in a test tube an equal volume of solution of the reagent to be studied is added, the tube shaken, and left for 10 min at room temperature (time of reaction, *cf.* tables). The same volume of a second reagent solution may be added, the mixture shaken, and left for another 10 min, and in a few cases a third reagent may be added in the same way. A volume of diluter II equal to that of the mixture already in the tube is added, and the final volume (*cf.* tables) minus 0.03 ml made up with diluter I. Then 0.03 ml of the sperm suspension is added. Each addition is followed by thorough mixing. As the reduction of oxidized sperm antagglutin is a comparatively fast process a "reaction time" of less than 10 min is generally allowed to pass after the addition of his reagent, in case it being the last one, the time elapsing until the beginning of the counting being long enough.

The percentage of spermatozoa agglutinated head-to-head (P_2) in the experimental sample and the corresponding percentage (P_1) in the control are determined in a haemocytometer as described by Lindahl and Nilsson [8]. The anti-agglutination index (AAI) is expressed according to the formula:

$$AAI = \frac{P_2 - P_1}{P_1}$$

Differences in AAI determined with this method, when greater than 0.1 are generally significant. Negative values of AAI of oxidized antagglutin preparations are the result of agglutinating impurities, whereas positive values depend upon incomplete oxidation. Real quantitative comparisons of values of AAI's are possible only, when the same antagglutin preparation and the same spermatozoa have been used. However, considering that the errors in the many measurings of small amounts of liquids in some samples may accumulate, still greater differences may appear between samples which might be expected to give identical AAI values.

Reaction between oxidized sperm antagglutin and sodium bisulphite. When a dilute aqueous solution of sodium bisulphite is added to oxidized male or female sperm antagglutin, the biological activity remains zero also after addition of sodium thioglycolate (Table 1:III). Reduced sperm antagglutins on the other hand maintain their biological activity after addition of the sodium bisulphite solution (Table 1:V). The oxidized, but not the reduced form of the sperm antagglutins obviously reacts with sodium bisulphite, the complex formed preventing reduction of the antagglutins. The reaction between oxidized sperm antagglutins and sodium bisulphite is, however, reversible as is shown by the following: Addition only of sodium pyruvate which has a large affinity to bisulphite, and thus also to that in the complex formed by the

oxidized antagglutin and sodium bisulphite, does not change the biological activity from zero (Table 1:VI). When, however, the reducing agent sodium thioglycolate is then added, the activity is immediately recovered (Table 1:VII). The reaction studied may thus be written:

oxidized antagglutin + $NaHSO_3$ ⇌ oxidized antagglutin $H \cdot SO_3Na$

Sodium bisulphite is a wellknown carbonyl reagent which reacts reversibly. It is thus probable that the oxidized sperm antagglutins contain at least one carbonyl group which is reduced to a hydroxygroup by the reducing agent when the antagglutins are reactivated. It is further obvious that the velocity with which bisulphite combines with the carbonyl must be much higher than that of the reduction effected on the same group. The latter is readily reduced by sulphite [9].

* Tested against other spermatozoa than samples II—IV.

(Table 2:IV) male sperm antagglutin are inactivated by these two carbonyl reagents. Since these reagents react with sugars, we had to replace the sugars of the diluters by sodium chloride when determining biological activities. In order to prevent that the effects observed are due to influences of the reagents on the spermatozoa the experiments were performed with male sperm antagglutin, and the reaction mixtures II and IV of Table 2 dialyzed against 4×10^{-3} M sodium thioglycolate solution over night. Thus the surplus of the reagents was removed before the addition of the diluters and the spermatozoa, no thioglycolate solution being added. The activity of the oxidized antagglutin was estimated immediately (Table 2:I), and another volume of this solution, diluted with 2 volumes of distilled water, was dialyzed together with samples II and IV to give the AAI of untreated reduced antagglutin. The inactivation even of the reduced male sperm antagglutin by these compounds probably depends on a reaction with the sugar residues in the antagglutin molecule. Male sperm antagglutin is known to give a positive reaction with benzidine [3] which indicates the presence of reducing sugar. Experiments with these two carbonyl reagents therefore do not give any information as to the nature of the reversibly oxidized and reduced group. — In special control experiments the treatment of spermatozoa with the two relevant

reagents was found to be without any effect upon the estimations of the biological activity of female antagglutin. An experiment with phenylhydrazine on the same lines, however, with exclusion of the dialysis was performed with reduced female antagglutin with the same result. Here a reaction with sugar residues is less probable, as no positive reaction on reducing sugars with benzidine has been obtained [8]. The inactivation of reduced female sperm antagglutin by phenylhydrazine may possibly indicate the existence of a second carbonyl, much more resistant against reducing agents and not localized in the saccharide constituent. However, a possible coupling of this carbonyl with bisulphite should not result in inactivation.

The non-enzymatic reduction of oxidized sperm antagglutins with DPNH. In order to be able to decide, whether or not an enzyme is involved in the oxidation of DPNH by oxidized antagglutin, experiments were performed with female sperm antagglutin as this does not contain any protein, and thus is free from contaminating enzymes. The spermatozoa used in the tests for biological activity represent another possible source of enzymes. In order to exclude the participation of enzymes of the test spermatozoa in the studied reaction the experiments were arranged in such a way that the reaction between DPNH and the oxidized antagglutin takes place before the addition of the sperm suspension. This was secured by adding bisulphite to the mixture of the two compounds, blocking in this way any oxidized antagglutin before the addition of the spermatozoa. Thus a sample (Table 3:II) was prepared in the following way: Sodium bisulphite was added to female sperm antagglutin. Ten minutes later DPNH, and after another 10 min the diluters and the sperm suspension were introduced into the mixture. In another sample (Table 3:III) DPNH

was mixed with the antagglutin solution, and sodium bisulphite added only 10 min later. From Table 3 it is obvious that in the first case the sodium bisulphite blocks the reduction of the antagglutin, whereas in the second case the antagglutin is reduced by DPNH. The reduction of oxidized female sperm antagglutin by DPNH thus seems to be non-enzymatic, and this probably also applies to the male sperm antagglutin.

Spectrophotometric recording of the oxidation of DPNH by oxidized male sperm antagglutin. A few experiments were performed in order to study the decrease in the absorption maximum of DPNH at 340 mμ, expected to occur, when oxidized sperm antagglutin is reduced by DPNH. The result of such an experiment is shown in Table 4. To 0.7 mg of oxidized male sperm antag-

glutin in 2.8 ml of distilled water 0.1 ml of 3×10^{-3} M DPNH was added in a quarz cell. Immediately after mixing the absorption at 340 mμ was read on a Beckmann DU spectrophotometer against a blanc containing 0.1 ml of 3×10^{-3} M DPNH and 2.8 ml of distilled water. The absorption of the sample was then read after 1, 2, 3, and 5 min, and was found to decrease during this time in relation to that of the blank, DPNH being oxidized to DPN by the sperm antagglutin (Table 4).

Inhibition of the reduction of oxidized sperm antagglutins with DPNH by diacetyl and sodium lactate. Starting from the idea that the reaction between DPNH and oxidized sperm antagglutin could be involved in the regulation of sperm metabolism we investigated the influence of a substance, reacting as metabolite with the diphosphopyridine nucleotide, *viz.* lactate, and diacetyl.

If diacetyl or sodium lactate in concentrations of 4.5×10^{-3} M are added to a solution of oxidized sperm antagglutin before the addition of DPNH, the biological activity is not restored (Table 5:III, expts b and c). If other reducing agents, like sodium thioglycolate or sodium ascorbate, are used neither diacetyl nor sodium lactate inhibit the reduction (Table 5:IV). Diacetyl obviously is the more potent of the two compounds in this respect. In another experiment (Table 5:III, expt d) increased quantities of diacetyl were mixed with a constant quantity of antagglutin prior to the addition of DPNH. In this case the inhibition of the reduction of the oxidized antagglutin was complete, when the added quantity of diacetyl was about equivalent to the amount of DPNH present (Table 5:III, expt e). It is probable that the inhibition of the reduction of antagglutin by DPNH is dependent on some interaction between DPNH and diacetyl or sodium lactate, respectively, which brings about a blocking in the reducing power of DPNH. In the oxidized state diphosphopyridine nucleotide forms additive compounds with dihydroxyacetone and similar α-hydroxy carbonyl compounds [11]. Additive compounds between DPNH and carbonyl compounds seem not to be known.

How the ability of inhibiting the reaction between DPNH and oxidized sperm antagglutin is connected with the structure of the compounds studied is so far poorly understood.

DISCUSSION

The easiness with which the sperm antagglutins are oxidized into a biological inactive compound, and are reactivated by reducing agents is notable. The inhibition of the reduction of oxidized antagglutins by sodium bisulphite points to a carbonyl or possibly a quinone-like structure in the oxidized antagglutin. It is thus probable that at least one hydroxyle in the reduced form is oxidized into a carbonyl, when the antagglutins are reversibly inactivated at oxidation. Depending on stereochemical configurations quinones may react with sodium bisulphite either irreversibly producing hydroquinone sulphonic acids or reversibly leading to α-hydroxysulphonic acids like those of aliphatic carbonyl compounds. A quinone should have a specific absorption

in the ultra-violet part of the spectrum. The oxidized male sperm antagglutin, however, has the same absorption curve as the reduced antagglutin [3]. This speaks against a quinone-like structure in the oxidized male sperm antagglutin.

On previous occasions a compound has sometimes been extracted in this laboratory with ethyl ether from male sperm antagglutin, and spectrophotometrically compared with tocopherols [5]. This aromatic compound seems to be of diphenolic character as it gives after oxidation a substance with a quinone-like spectrum in ultra-violet light. It appears most probable that this aromatic compound is an artefact, originating from an aliphatic precursor bound in the antagglutin molecule. When male sperm antagglutin is heated in molten potassium bisulphate, a product is formed which has some properties in common with corresponding products obtained in the same way from α- and δ-tocopherols, and also with p-benzoquinone disulphonic acid [12].

It is a notable fact that the reduction of oxidized antagglutins with DPNH is a non-enzymatic reaction. Carbonyl compounds are inert to DPNH, whereas a compound as p-benzoquinone is reduced by DPNH [13]. From this it is obvious that the carbonyl group of the oxidized antagglutin is more reactive than those, *e.g.*, in sugars, having other neighbouring groups. In this connection it must, however, be stressed that we have not been able to detect ascorbic acid as a constituent of the sperm antagglutin.

A Moving-Bomb Method for Combustion Calorimetry of Organic Bromine Compounds

LARS BJELLERUP

Department of Organic Chemistry, University of Lund, Lund, Sweden

For the purpose of developing a method for obtaining accurate heat of formation data for organic bromine compounds, a moving-bomb calorimeter for measuring heats of combustion at 25°C of solid and liquid samples has been constructed. The calorimetric system is calibrated by combustion of standard benzoic acid under certified bomb-calibrating conditions. However, in order to obtain well-defined, equilibrium final states in the bomb in combustion experiments with bromine compounds the bomb liquid must differ both in nature and amount from that specified for calibration experiments with benzoic acid. This may give rise to non-cancelling systematic errors. As a first step in defining errors, the reproducibility in calibration as well as combustion experiments has been studied. The paper describes in detail the apparatus, the procedure and the calculation of results, and reports data obtained in calibration experiments and in combustion experiments with paraffin oil and *p*-bromobenzoic acid.

Results from calibration experiments with benzoic acid and combustion experiments with paraffin oil demonstrated that the moving-bomb apparatus, the experimental procedure and the method of calculation of results, presented in this paper, were capable of giving results having a precision slightly better than 0.01 % which is comparable to that obtained with best available modern bomb-calorimetric techniques for compounds containing carbon, hydrogen and oxygen. Furthermore, the experiments with *p*-bromobenzoic acid showed that the various additional complications introduced into the procedure by the presence of a reasonable percentage of bromine in the sample did not affect the precision obtainable with the given apparatus and procedure.

Although the precision of the present method was found to be satisfactorily high, no conclusions could be drawn as to the accuracy of heat of combustion data obtained with this method. Experimental work designed to give information on this point has been done and will be reported in another paper.

The available heat of formation data for organic bromine compounds are few, and only a small number have an uncertainty interval * comparable

* The terms *uncertainty interval, reproducibility, precision, accuracy* and related quantities used in this work have the same meaning as given in Ref.[1] The terms *reproducibility* and *precision* are used synonymously.

to that of modern heat of formation data for other groups * of organic compounds **. Experimental data, from which heat of formation values with small uncertainty intervals can be calculated, have been reported on: (i) heats of bromination of certain alkenes [4,5] and *cyclo*-alkenes [5], (ii) heats of hydrobromination of *cyclo*-propane [6,7], propene [6,7] and the normal butenes [8], (iii) the heat of hydrogenation of vinyl bromide [9], and (iv) equilibrium constants for the system ethylene — hydrogen bromide — ethyl bromide [10]. Therefore, heat of formation values of low uncertainty are at present available for the following sixteen organic bromine compounds: bromoethane, bromoethene, 1-bromopropane, 2-bromopropane, 2-bromobutane, 1,2-dibromoethane, 1,2-dibromopropane, 1,2-dibromobutane, *meso*-2,3-dibromobutane, *dl*-2,3-dibromobutane, 2,3-dibromo-2-methylbutane, 1,2-dibromoheptane, 1,2-dibromo*cyclo*pentane, 1,2-dibromo*cyclo*hexane, 1,2-dibromo*cyclo*heptane, and 1,2-dibromo*cyclo*octane. It is striking, however, that data are lacking for a number of organic bromine compounds of considerable interest to pure as well as to applied chemistry, including most of the lower monobromoalkanes, several of the lower dibromoalkanes, bromobenzene, the dibromobenzenes, benzyl bromide *etc.* Evidently, further work is required, aiming at the determination of experimental thermochemical data from which accurate heats of formation of organic bromine compounds can be calculated.

One of the heat of formation values referred to above was derived from experimental data obtained in a study of chemical equilibria, and the others could be calculated from data obtained by application of the methods of reaction calorimetry *** to various chemical reactions each involving one of the mentioned organic bromine compounds with other compounds of accurately known heats of formation. However, the experience of earlier experimental work on the thermochemistry of organic compounds suggests that neither equilibrium studies nor reaction calorimetry could compete in versatility and width of applicability with combustion calorimetry for obtaining experimental data leading to high-accuracy heat of formation values for organic bromine compounds. Therefore an accurate combustion-bomb calorimetric method for organic bromine compounds would certainly be capable of providing the majority of heat of formation data for such compounds. Heat of combustion work has been applied to organic bromine compounds in eight previous investigations [11–18]. None of the methods used in these can, however, be considered fully satisfactory for present-day requirements on accuracy.

---

* "Group" should here be understood as "containing a certain combination of elements" such as C,H,O or C,H,O,N or C,H,O,Br or C,H,O,S.

** The uncertainties attached to the best available heat of formation data for groups of organic compounds vary according to the nature of the groups. As a rough generalization, however, it can be stated that modern thermochemical apparatus and technique [2,3] is capable of giving experimental results leading to standard heat of formation values having uncertainty intervals for the lower members of various homologous series in the range ± 0.1 to ± 0.6 kcal/mole.

*** Although no general agreement exists it has become practice among workers in thermochemistry to use the name *reaction calorimetry* only for the measurement of heats of reactions other than combustion in oxygen.

From, (i), the results obtained using the various combustion techniques for bromine compounds mentioned above, (ii), experience from recent applications of moving-bomb methods to organic sulfur compounds [23,24], and (iii), results from recent systematic studies of certain details of various moving-bomb techniques [25,26], it was evident that further development of the moving-bomb methods described in Refs.[15,17,18] should provide a combustion-bomb calorimetric method for organic bromine compounds capable of yielding data of comparable accuracy to those given by the best present-day methods for other groups of organic compounds [3].

Work on such a development has been in progress in this laboratory for some time. This paper describes the present status of development of apparatus and experimental technique, and reports results sufficient to indicate the precision of the method.

METHOD

The conventional substitution method was used, comprising two types of experiments: calibration experiments with benzoic acid and combustion experiments with bromine compound. In all experiments the temperature rise of the calorimeter was virtually the same.

The calorimetric system was calibrated by combustion of a standard sample of benzoic acid under certified bomb-calibrating conditions.

The bromine compound was burned in the platinum-lined bomb with paraffin oil of known heat of combustion as a burning aid. The amounts of sample and paraffin oil were so adjusted that virtually the same quantities of heat were released in the combustion experiments as in the calibration experiments. From 95 to 98 % of the bromine content of the sample was transformed to elemental bromine through the combustion process and the rest to hydrogen bromide. In these experiments the bomb contained an appropriate amount of arsenious oxide solution for reduction of the elemental bromine to bromide ion. Bomb and calorimeter vessel were so designed that during part of the reaction period of the calorimetric measurement a rotating motion could be imparted to the bomb to bring about proper agitation of the bomb contents. Hereby the elemental bromine was quantitatively reduced to bromide ion, the whole interior of the bomb was well rinsed by the final bomb solution and equilibrium between the liquid and the gaseous phase was attained. This established a homogeneous, stable and thermodynamically definable final liquid-gas system in the bomb. After completion of the calorimetric measurement the bomb liquid was quantitatively analyzed for the various constituents, in particular, arsenious oxide and nitric acid.

APPARATUS

The calorimetric system was of the stirred-liquid-calorimeter with constant-temperature-jacket type. The construction, and the influence of various constructional details on the performance of such calorimetric systems, have been discussed in considerable detail by several authors [27-33]. The adaptation of this type of calorimetric system for use with moving-bomb techniques has also been described in detail previously [23,24]. Furthermore, certain experimental details of various moving-bomb techniques have also been treated in some detail previously [25,26]. For these reasons and because several of the characteristics of the apparatus used in the present investigation are similar to those described in Refs.[23,24], the description of the apparatus and the discussion of its functioning will be more thorough on certain selected points than on others.

Calorimetric assembly. The calorimetric assembly, shown diagrammatically in Fig. 1, consisted of the following main parts: combustion bomb B, calorimeter vessel C_1-C_{10} with moving mechanism M_1-M_{13} and other accessories, thermometer T, and jacket J_1-J_{25}.

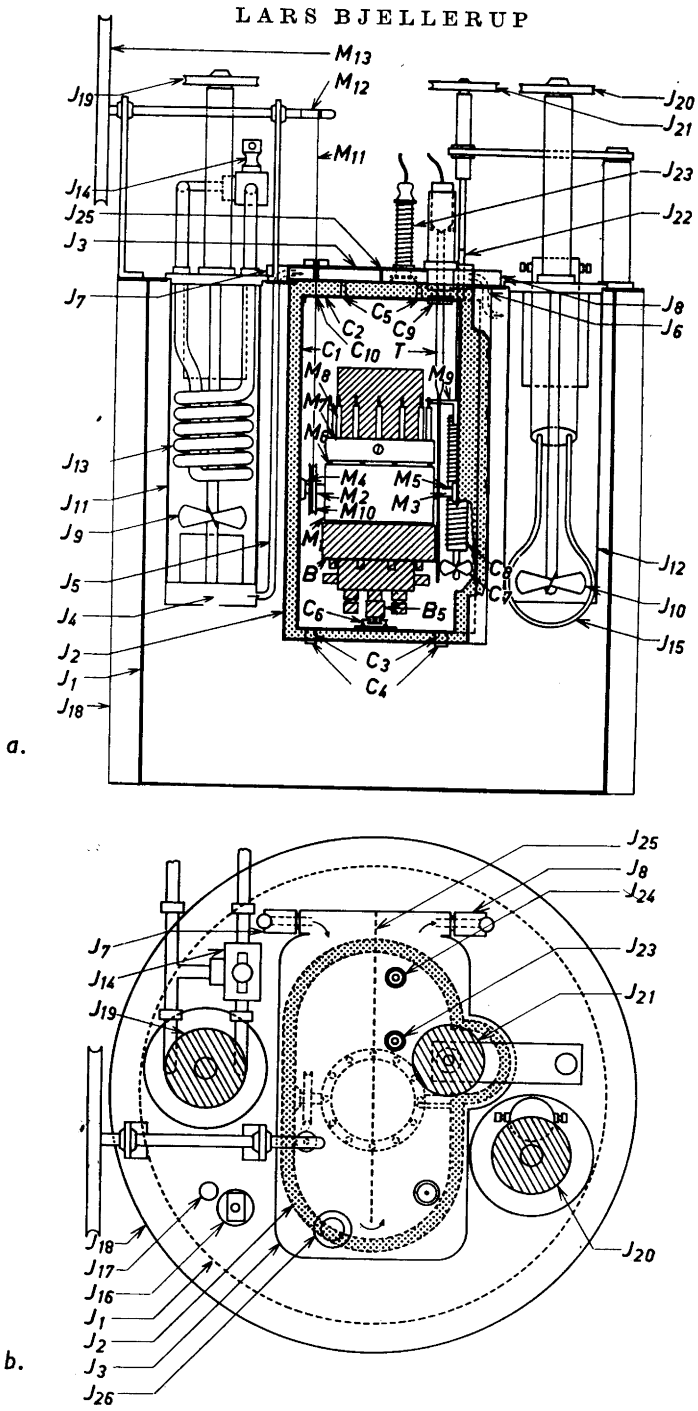

Fig. 1. Assembled calorimetric system: a. Sectional view. b. Top view.

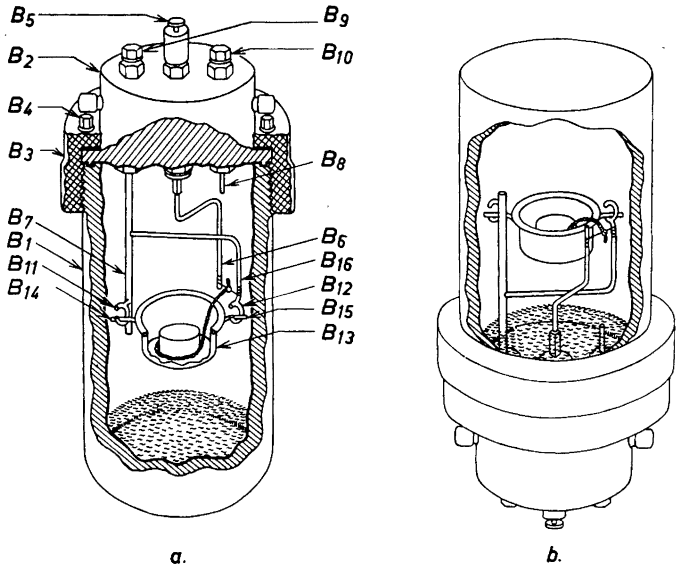

Fig. 2. Charged combustion bomb: a. In upright position. b. In inverted position.

Combustion bomb. The combustion bomb, shown in Fig. 2, was of a conventional three-part type consisting of body B_1, head B_2, and sleeve B_3. All three parts were made of stainless steel. The inner surface of the body, the bottom of the head and all internal fittings were lined with platinum of 0.20 mm thickness. A gas-tight seal between body and head was obtained through a gold gasket situated in a groove in the bottom of the flange of the head. The head was pressed against the body by the aid of eight set-screws B_4 in the sleeve and a chromium-plated, hard steel ring lying on top of the flange of the head below the set-screws. The design was very similar to that described in Ref.[34]

The head was equipped with a terminal B_5 for ignition, electrically insulated from the rest of the head, mainly through teflon washers, and ending with the platinum rod B_6. The head was also equipped with two platinum tubes, one B_7 for gas-inlet into the bomb and one B_8 for gas-outlet. The openings to the tubes could be closed by the two valves B_9 and B_{10} with gold packings.

To the gas-inlet tube were welded two open platinum rings B_{11} and B_{12} between which the platinum combustion crucible B_{13} could be suspended by the aid of a platinum ring having two short axles B_{14} and B_{15} as seen in Fig. 2. The design was similar to that described in Ref.[24] This device made it possible to charge the bomb in a conventional way, as described later, while it was in an ordinary upright position, place it in its suspension ring in the calorimeter vessel and then rotate the ring through 180 degrees about the axis M_2—M_3 so that the bomb could be temporarily fixed in an inverted position, as shown in Figs. 1 a and 2 b, while the crucible and its contents retained their original upright position. The charge was then ignited with the bomb in this position which directed the hot gases from the combustion blast towards the body of the bomb instead of towards the more sensitive head. When rotation of the bomb was started after completion of the combustion process the axles of the crucible suspension ring slipped out through the openings in the platinum rings B_{11} and B_{12} so that the crucible and suspension ring fell down into the bomb liquid and were thoroughly rinsed.

For ignition of the sample the two platinum rods B_6 and B_{16} were connected through a 0.05 mm platinum wire of approximately 10 mm length. One end of a fuse, consisting of a weighed piece of cotton string about 90 mm long, was attached to the mid-point of the thin platinum wire and the other end of the fuse was put in contact with the sample.

Application of a potential of 12 V to the ignition circuit caused such a rapid heating of the thin platinum wire to its melting point that only a small amount of energy (estimated to be less than 0.5 cal) was introduced into the calorimeter before the circuit was broken. During this process, however, the fuse was ignited and the fuse in turn ignited the sample. The variation in the electrical ignition energy from experiment to experiment was considered small enough to permit incorporation of this energy into the energy equivalent of the calorimeter. The internal volume of the bomb was 0.2670 liter.

Calorimeter vessel. The calorimeter vessel, consisting of can C_1 and lid C_2, had the shape shown in Fig. 1. The dotted space in Fig. 1 represents the air-gap between the calorimeter vessel and the constant-temperature-jacket. The distance between the outer surface of the calorimeter and the inner surface of the jacket was 10 mm at all points[32,p.168]. The can was supported on four cylindrical Bakelite pegs C_3 snugly fitting in four corresponding pits in the jacket well C_4. The three Lucite pegs C_5 in the calorimeter lid C_2 were just long enough to be slightly pressed against the under side of the jacket lid J_3 when this was placed in its closed position as shown in Fig. 1. Spring clip C_6, attached to the bottom of the can, could be lifted a few millimeters from the bottom and slid on to a knob on the electrical ignition terminal B_5. In this way, the bomb could be kept in the inverted position, shown in Fig. 1, during the fore period and the first part of the reaction period of the calorimetric experiments. Also, the spring clip served as an electrical lead to the ignition terminal.

The calorimeter lid was equipped with a calorimeter stirrer C_7, a 10 W calorimeter heater C_8, a rubber washer C_9 through which the thermometer T could be inserted and tightly positioned in the calorimeter, a small orifice C_{10} for the copper wire M_{11}, and two flat electrical contacts (not shown in the figure) leading to the heater C_8 and to the spring clip C_6, respectively.

Moving mechanism. The device used to effect appropriate agitation of the bomb contents during the reaction period consisted of the following parts shown in Fig. 1: the bomb supporting ring M_1 with axles M_2 and M_3 and bearings M_4 and M_5 attached to the wall of the calorimeter can; the flat ball bearing M_6; the bomb fastening ring M_7 with twelve evenly spaced rods M_8; the removable stud M_9 projecting from the wall of the calorimeter can; the pulley M_{10} on axle M_2 of the supporting ring; the 0.3 mm copper wire M_{11} wound on pulley M_{10}; the pulley M_{12} driven by a motor operating on pulley M_{13}.

Withdrawal of drive wire M_{11} from pulley M_{10} by rotation of pulley M_{12} gave the bomb a rotational motion about the horizontal axis M_2-M_3 perpendicular to the bomb axis. During this end-over-end rotation of the bomb, each passage through the inverted position shown in Fig. 1, brought one of the rods M_8 into contact with stud M_9, which pushed the rod, causing the bomb to rotate about the bomb axis (axial rotation) through one twelfth of a full revolution. Since the bomb in the inverted position was supported entirely by the ball bearing M_6, and did not fit too tightly in the supporting ring M_1, it was very easily axially rotated whilst in the inverted position. In all other positions during the end-over-end rotation, however, the bomb was more or less pressed directly against the supporting ring so that no axial rotation occurred with the bomb in these positions. Consequently, the moving mechanism, during the withdrawal of the drive wire, effected a compound rotation of the bomb about an axis perpendicular to the bomb axis and about the bomb axis at the same time. The speed of the axial rotation was one twelfth of the speed of the end-over-end rotation *.

In all experiments — calibration as well as combustion experiments — in the present work a length of 600.0 ± 0.5 cm of the 0.3 mm copper wire was wound around pulley M_{10} in 43 turns. The withdrawal of the wire was made at such a rate as to give the bomb an end-over-end rotation rate of 12 rpm and consequently an axial rotation rate of 1 rpm. Unwinding of all 43 turns of drive wire thus required a time of 215 sec. The agitation, due to this rotation, of the 30 ml of bomb solution used in all combustion experiments with bromine compounds, was found to be satisfactory for establishing a homogeneous and stable final liquid-gas system in the bomb.

The amount of frictional energy introduced into the calorimeter through the rotation was estimated, from a crude measurement of the force necessary to effect the rotation,

* The author's thanks are due to Dr. S. Sunner, Thermochemistry Laboratory, University of Lund, for cooperation in the construction of the moving mechanism.

at approximately 2.5 cal per combustion experiment. The variation in this rotation energy from one experiment to another was difficult to assess but since the rotation was performed exactly in the same way in all experiments the rotation energy was considered constant and was incorporated into the energy equivalent of the calorimeter.

Thermometric system. The thermometric system consisted of a flat, 25 ohm platinum resistance thermometer T (Leeds & Northrup Co., Catalog No. 8160) positioned in calorimeter and jacket lid as shown in Fig. 1 and a type G-2 Mueller bridge (L. & N., Catalog No. 8069) in conjunction with a type HS reflecting galvanometer (L. & N., Catalog No. 2284-d) and a telescope equipped with a 1 000 mm scale which had been properly curved *. The distance between scale and galvanometer mirror was 93 cm in all directions. Using a thermometer current of about 4 mA and taking the last figure from galvanometer deflections the resistance could be read to the nearest 0.00001 ohm which was equivalent to 0.0001°C in the corresponding temperature value.

Jacket. The constant-temperature-jacket consisted of a water-filled, 43 l, cylindrical tank J_1 enclosing the calorimeter well J_2, which had a volume of about 10 l. The well was covered by a double-walled lid J_3, through which was circulated water from the jacket tank by the aid of a centrifugal pump J_4 and tubes J_5 and J_6 in hinges J_7 and J_8 as described in Ref.[24] The water in the tank was stirred by two 750 rpm propeller-stirrers J_9 and J_{10} operating in stirrer wells J_{11} and J_{12} (so that water was forced from bottom to top in well J_{11} and in the opposite direction in well J_{12}). Through a coil of copper tubing J_{13}, positioned around the stirrer shaft in well J_{11}, a constant flow of 21°C water was passed at a rate of 50 ml/min. J_{14} was a by-pass switch for the water flow. Around stirrer J_{10} was mounted a 22 W immersion heater J_{15}. The temperature of the jacket water was kept constant within a temperature interval of 0.003°C at about 25.22°C by balancing the constant cooling effect from coil J_{13} against an intermittent energy input from heater J_{15}. The heater was operated by a mercury-in-glass thermoregulator J_{16} (shown only in Fig. 1 b) *via* an electronic relay. The temperature of the jacket water was checked after each experiment by placing the resistance thermometer in hole J_{17} and reading it continuously for some minutes. J_{18} was a plastic sheet surrounding the jacket tank. J_{19}, J_{20} and J_{21} were pulleys for the two jacket stirrers and the calorimeter stirrer, respectively. J_{22} was a Lucite stud for coupling stirrer C_7 with pulley J_{21}. In the jacket lid were mounted two electrical terminals J_{23} and J_{24} which could be pushed down into the calorimeter well to make connection with the two flat contacts (*cf.* above) in the calorimeter lid leading to the heater and to the ignition spring clip [23, p. 21]. J_{25} was an interior wall in the jacket lid and J_{26} a glass window for inspection of the flow of water in the lid.

The whole apparatus was kept in a thermostated room at a temperature of 23.0±0.2°C.

EXPERIMENTAL PROCEDURE

Calibration experiments

The calorimetric system was calibrated by combustion of NBS standard benzoic acid, under the conditions given in the NBS certificate [35]. The recommendations, also given in the certificate, for certain details of the procedure were followed except for the method of igniting the sample. The ignition was effected with the device described above (p. 1515) using the procedure given below for the heat of combustion experiments. In all other details (including for example rotation of the bomb) the procedure of the calibration experiments was, wherever possible, the same as that for the combustion experiments. From what will be said later it will be evident that the most important difference in procedure between calibration and combustion experiments was in the nature and amount of the liquid placed in the bomb before the experi-

* Thermometer and bridge had both been calibrated at the National Bureau of Standards, Washington, D. C.

ments. In the calibration experiments 0.810 ml (corresponding to 3 g per liter of bomb volume) of water was introduced into the bomb but in the combustion experiments with the bromine compound 30.05 ml of an arsenious oxide solution (corresponding to 112 g of water per liter of bomb volume) were placed in the bomb. The corresponding effect on the results obtained will be discussed later.

Heat of combustion experiments

Preparation and assembly of the initial system. A portion of the *p*-bromobenzoic acid sample was made into a pellet having a mass corresponding to an amount of 6.0 mg-atoms of bromine. The pellet was lightly polished with a soft brush to remove any loose fragments of substance from its surface. It was then placed in the pre-weighed platinum combustion crucible and the whole was weighed to the nearest 0.00001 g. Paraffin oil of known composition and heat of combustion was added to the pellet in the crucible in such an amount that the temperature rise obtained in the combustion experiment would be, within 1 %, the same as that obtained in the calibration experiments. The weight of paraffin oil added was obtained by weighing crucible with contents to the nearest 0.00001 g. The cotton string fuse was weighed and attached to the mid-point of the thin platinum ignition wire. The crucible with its contents was placed in the crucible support in the bomb head and the free end of the fuse was immersed in the oil in the crucible. In the bottom of the bomb body was placed 30.05 ml of 0.0627_9 M arsenious oxide (As_2O_3) solution and the bomb was assembled. The gas-inlet opening of the bomb was connected to a cylinder of oxygen containing 0.3 % of nitrogen as an impurity but no combustible impurities. To remove the air from the bomb the latter was flushed with oxygen for 3 min at a rate of flow of 800 ml/min (at 23°C and 1 atm). The gas-outlet valve was closed and the bomb filled with oxygen to a final pressure of 30.0 $\pm$ 0.05 atm at 25°C. The filling required a time of about 12 min. The bomb was tested for leaks by immersion in water for 2 min. The outer surface of the calorimeter can and lid and the inner side of the well were polished with chamois leather and the copper wire of the moving mechanism was wound around pulley M_{10} (Fig. 1). Fastening ring M_7 was placed on the bottom of the calorimeter can under the supporting ring M_1. Ball bearing M_6 was placed in its groove on the fastening ring and the bomb was lowered into the supporting ring, ball bearing and fastening ring. The fastening ring with the ball bearing was pressed against the supporting ring and locked in position by two set-screws in the fastening ring. Stud M_9 was put in place and the bomb was carefully rotated through 180° about axis M_2—M_3 and fastened in the inverted position, shown in Fig. 1, by spring clip C_6. Water, of 24.1°C temperature, was then added to the can until can and contents balanced, within 0.05 g, a counterpoise which remained unchanged throughout the work *. The mass of water added was about 5 000 g. Immedi-

* Thus the mass of water in the calorimeter can varied from experiment to experiment with the total mass of contents introduced into the bomb, all other masses in the calorimetric system being kept constant. The variations thus introduced into the energy equivalent of the calorimetric system were accounted for in the calculations of the experiments.

ately after weighing, the calorimeter can with contents was placed in the jacket, and the calorimeter lid was pressed into place after the drive wire had been fed through orifice C_{10} (Fig. 1). The wire was then fed through the corresponding orifice in the jacket lid and the latter was put in place over the well. The end of the drive wire was fastened to pulley M_{12} (Fig. 1) and the calorimeter stirrer was connected with pulley J_{21}. The resistance thermometer was put in place in the calorimeter and the calorimeter stirrer was started.

Calorimetric observations. The calorimeter was heated to a temperature of 24.057°C and left to reach thermal equilibrium. After about 20 min, when equilibrium had been established, the temperature of the calorimeter had reached the value 24.087°C. At this temperature, which in all experiments was taken as starting point for the calorimetric observations, the resistance-*versus*-time readings of the fore period were begun. The fore period had a duration of 20 min and the thermometer resistance was read every 2 min at the times 0, 2, 4, ..., 18 min. During these readings the bridge current was adjusted to give a bridge sensitivity corresponding to a galvanometer deflection of 1.0 mm of scale length per 0.0001 ohm of change in the bridge setting. After the 18th min reading the bridge sensitivity was reduced to give a galvanometer deflection of 400 mm. of scale length per 0.1000 ohm of change in the bridge setting * and the bridge was set at a preselected reading corresponding to about two thirds of the total temperature rise of the calorimeter during the reaction period **. At time 20 min the charge was ignited and the reaction period began. During the first 3 min of the reaction period, when the temperature rose very rapidly, resistances were read from the galvanometer deflections without changing the bridge setting from the preselected value mentioned above. For convenience the resistance was not observed at certain selected times, but instead the time was recorded on a chronograph when passing through certain selected resistance values. These values were so chosen as to give time-temperature data at small enough intervals to permit calculation of the energy exchange between calorimeter and surroundings with sufficient accuracy, *cf.* Ref.[32] and below. The intervals were in order, in °C, 0.004 (approx.), 0.05, 0.05, 0.1, 0.1, 0.1, 0.1, 0.1, 0.1, 0.05, 0.05, 0.025, 0.025, 0.0125. Immediately before time 23 min, when the temperature rise was becoming slow again, the bridge sensitivity was reset at the value it had during the fore period, and the rest of the calorimeteric observations were done by reading the resistance — operating the bridge in the conventional way — at selected times. From time 23 min to time 25 min the resistance was read every half minute and each minute from 25 min to 36 min. Thermal equilibrium had always reestablished not later than at time 36 min and therefore the reaction period was always taken to be 16 min long. During the after period, which began at time 36 min and had a duration of 20 min, the resistance was read every 2 min at the times 38, 40, ..., 56 min. Finally the jacket temperature was measured with the calorimeter thermometer.

* A change in resistance of 0.1000 ohm corresponded in this interval to a temperature change of 0.9950°C.

** The temperature rise obtained in all experiments in this work was 0.88 ± 0.01°C.

Chemical analysis of the final system. After disassembly of the apparatus the bomb gases were slowly let out and the liquid phase in the bomb was quantitatively transferred to a volumetric flask and diluted to 250 ml. In order to determine the chemical composition at the end of the reaction period of the liquid phase in the bomb, aliquot portions of the diluted bomb solution were withdrawn and used for determination of the concentrations of the following components: (i) nitric acid, (ii) bromoaurous acid, (iii) bromoplatinous acid, (iv) arsenious oxide, and (v) hydrobromic acid.

(i) Nitric acid was determined colorimetrically by a diphenylamine method [36] as follows. A 2 ml sample of the diluted bomb solution was mixed with 10 ml of conc. sulphuric acid in a glass-stoppered flask and the mixture was allowed to cool to room temperature. 1 ml of a diphenylamine solution was then added, consisting of 200 mg of diphenylamine dissolved in a mixture of 26 ml of water and conc. sulphuric acid to a volume of 250 ml. After a selected standard time-interval (usually 15 min) the absorbance of the solution was measured with a photoelectric colorimeter using a red filter. The nitric acid concentration was then read from a reference curve obtained with nitrate standards containing the same amounts of arsenious oxide, arsenic oxide and hydrobromic acid as the samples. The amount of nitric acid formed in each combustion experiment was about 0.1 mmole.

(ii) Bromoaurous acid was determined colorimetrically on a 2 ml sample by a rhodanine method [37,38]. The amount of bromoaurous acid formed in each combustion experiment was found to be about 0.005 mmole.

(iii) Bromoplatinous acid was determined on a 2 ml sample by oxidation with bromine to bromoplatinic acid which latter was determined colorimetrically by an iodide method [38,39]. The amount of bromoplatinous acid formed in each combustion experiment was found to be about 0.0015 mmole.

(iv) Arsenious oxide was determined by titration with potassium permanganate [40] using the following procedure. To a 50 ml sample of the diluted bomb solution was added 10 ml of 3 M sodium hydroxide, 15 ml of 6 M hydrochloric acid and one drop of 0.002 M potassium iodide. The mixture was titrated with 0.1 N potassium permanganate solution using a platinum electrode for indication of the end point, at which a change in potential of about 250 mV was obtained for an addition of 0.005 ml of the permanganate solution. The amount of hydrobromic acid present in the sample was found not to interfere with the determination of the arsenious oxide.

(v) Hydrobromic acid was determined by potentiometric titration of a 20 ml sample (to which had been added 30 ml of water and 6 ml of 5 M nitric acid) with 0.04 M silver nitrate solution. The amounts of arsenious oxide and arsenic oxide present in the sample were found not to interfere with the determination of hydrobromic acid.

CALCULATION OF RESULTS

The corrected temperature rise

The difference between the temperature of the calorimeter at the end of the reaction period (*i.e.* at time 36 min) t_f and the temperature of the calori-

meter at the beginning of the reaction period (*i.e.* at time 20 min) t_i constitutes "the observed temperature rise" of the calorimeter $t_f - t_i$. This quantity is conveniently considered as the sum of two terms Δt and Δt_{ex}, where Δt is "the corrected temperature rise", *i.e.* the temperature rise of the calorimeter during the reaction period due to the heat of the actual bomb process, and Δt_{ex} is "the heat exchange correction", *i.e.* the temperature rise of the calorimeter during the reaction period due to energy exchange between calorimeter and environment. The value of Δt, needed in the further calculations, was obtained from eqn. 1.

$$\Delta t = t_f - t_i - \Delta t_{ex} \tag{1}$$

Values of all three quantities on the right in this equation were calculated from the temperature-time ($t-\tau$) observations of the calorimetric experiment in the following way *.

The mean temperatures t_I and t_{II} (in ohms **) and the rates of temperature rise $R_I = \left(\frac{dt}{d\tau}\right)_I$ and $R_{II} = \left(\frac{dt}{d\tau}\right)_{II}$ (in ohm/min) of the calorimeter during the fore and after periods, respectively, were computed from the ten resistance readings of each period using eqns. 2—5.

$$t_I = \frac{1}{10}\,(t_o + t_2 + \ldots + t_{18}) \tag{2}$$

$$t_{II} = \frac{1}{10}\,(t_{38} + t_{40} + \ldots + t_{56}) \tag{3}$$

$$R_I = \frac{1}{330}\,[9(t_{18} - t_0) + 7(t_{16} - t_2) + \ldots + (t_{10} - t_8)] \tag{4}$$

$$R_{II} = \frac{1}{330}\,[9(t_{56} - t_{38}) + 7(t_{54} - t_{40}) + \ldots + (t_{48} - t_{46})] \tag{5}$$

The obtained values for t_I, t_{II}, R_I and R_{II} were inserted in eqns. 6 and 7 to give values for t_i and t_f.

$$t_i = t_I + 11\ R_I \tag{6}$$

$$t_f = t_{II} - 11\ R_{II} \tag{7}$$

The value of Δt_{ex} was calculated from eqn. 8 ***

$$\Delta t_{ex} = [R_{II} + K(t_{II} - \frac{1}{\tau_f - \tau_i}\int_{\tau_i}^{\tau_f} t\,d\tau)](\tau_f - \tau_i) \tag{8}$$

where K is the leakage modulus of the calorimeter system (in ohm/min ohm), τ is the time at which the temperature of the calorimeter is t, τ_i is the time

* The computation of "the heat exchange correction" has been discussed by several authors, see for example Refs. 2 (p. 743), 27 (p. 228), 28 (p. 37), 32, 33, 41—44, 45 (p. 94), 46 (p.136).

** Throughout the calculations for obtaining the value of Δt all temperature values were expressed in resistance (in ohms) of the given resistance thermometer, as measured with the given bridge.

*** This equation is identical with "the improved form of the Regnault-Pfaundler formula" given in Ref. 28 (p. 41, eqn. 13) and Ref. 2 (p. 746, eqn. 18).

at which the reaction period begins and τ_f the time where it ends. The term containing the integral should be physically interpreted as the mean temperature of the calorimeter during the reaction period. In all experiments τ_i and τ_f were 20 min and 36 min, respectively, the value of K was calculated from eqn. 9

$$K = -\frac{R_{II}-R_I}{t_{II}-t_I} \tag{9}$$

and the value of the integral was obtained from the temperature-time data of the reaction period by numerical integration using the trapezium method.

It should be mentioned that a necessary condition for using eqn. 8 in the computation of Δt_{ex} is that, within the temperature interval of the calorimetric observations, the rate of temperature rise of the calorimeter, due to energy exchange with the environment, should be a linear function of the calorimeter temperature, which could be represented for example by the following relation

$$R = \frac{dt}{d\tau} = K(t_j-t) + w \tag{10}$$

where t_j is the constant temperature of the jacket and w is the rate of temperature rise of the calorimeter, due to constant energy leakage from the environment to the calorimeter mainly through the stirring of the calorimeter water. The present apparatus was checked in respect of this requirement by measuring, as given in Refs.[32,47], R for various calorimeter temperatures t while the temperature of the jacket t_j was kept constant. The results are given in Table 1.

The energy equivalent of the calorimetric system

The energy equivalent of the calorimetric system varied with nature and amount of the contents introduced into the bomb. In addition, the experimental procedure used in this work required the amount of water in the calorimeter vessel to vary, as described on p. 1518, with the total mass of contents in the bomb, so that the total mass of bomb-contents plus water remained constant. For convenience in calculation of the results from calibration as well as heat of combustion experiments, the energy equivalent of the calorimetric system was divided into three parts: (i) the energy equivalent of a "standard calorimetric system" consisting of the whole system as assembled for a fictive experiment with no contents in the bomb ε°(Calor.)*, (ii) the energy equivalent of an amount of water equal in mass to the contents of the bomb $C_P(H_2O)m^i$(Cont.), where $C_P(H_2O)$ is the heat capacity of liquid water at temperature t_i and m^i(Cont.) is the total mass of the contents of the bomb, and (iii) the energy equivalent of the contents of the bomb ε(Cont.) **. The last quantity was different in the initial and final states of the experiment, *i.e.* the states in the bomb at the beginning and at the end of the reaction

* The notation used in this section is the same as that in Ref.[48]

** With "contents of the bomb" was understood all removable matter in the interior of the bomb, including the platinum combustion crucible and its suspension ring.

period. These two energy equivalents are denoted by ε^{i}(Cont.) and ε^{f}(Cont.), respectively. Let $-\Delta E_{\text{I.B.P.}}$ be "the heat of the isothermal bomb process", *i.e.* the amount of heat released in the actual bomb process if it occurred isothermally at a selected temperature t_h, let $\Delta E_{\text{ign.}}$ be the amount of electrical energy introduced into the calorimetric system to ignite the sample, and let $\Delta E_{\text{rot.}}$ be the amount of energy introduced into the calorimetric system by the rotation of the bomb in the reaction period: then the following relation holds

$$-\Delta E_{\text{I.B.P.}} + \Delta E_{\text{ign.}} + \Delta E_{\text{rot.}} =$$

$$\begin{aligned}&\ulcorner\varepsilon^{\circ}(\text{Calor.}) - C_P(H_2O)m^{i}(\text{Cont.}) + \varepsilon^{i}(\text{Cont.})](t_h - t_i) + [\varepsilon^{\circ}(\text{Calor.}) - \\ &C_P(H_2O)m_i(\text{Cont.}) + \varepsilon^{f}(\text{Cont.})](t_f - \Delta t_{ex} - t_h) = \\ &[\varepsilon^{\circ}(\text{Calor.}) - C_P(H_2O)m^{i}(\text{Cont.})](t_f - \Delta t_{ex} - t_i) + \varepsilon^{i}(\text{Cont.})(t_h - t_i) + \\ &+ \varepsilon^{f}(\text{Cont.})(t_f - \Delta t_{ex} - t_h) \qquad (11)\end{aligned}$$

In the present work t_h was taken as 25°C and all experiments were so arranged as to give $t_f - \Delta t_{ex}$ a value which was virtually 25.0°C. Without significant loss in accuracy the relation

$$t_h = t_f - \Delta t_{ex}$$

could therefore be inserted in eqn. 11 which together with eqn. 1 gave the following relation

$$\begin{aligned}&-\Delta E_{\text{I.B.P.}} + \Delta E_{\text{ign.}} + \Delta E_{\text{rot.}} = \\ &[\varepsilon^{\circ}(\text{Calor.}) - C_P(H_2O)m^{i}(\text{Cont.}) + \varepsilon^{i}(\text{Cont.})]\,\Delta t \qquad (12)\end{aligned}$$

which could be rearranged to give eqn. 13

$$\begin{aligned}&\varepsilon^{\circ}(\text{Calor.}) - (\Delta E_{\text{ign.}}/\Delta t) - (\Delta E_{\text{rot.}}/\Delta t) = \\ &-\Delta E_{\text{I.B.P.}}/\Delta t + C_P(H_2O)m^{i}(\text{Cont.}) - \varepsilon^{i}(\text{Cont.}) \qquad (13)\end{aligned}$$

In all calibration and heat of combustion experiments the quantities $\Delta E_{\text{ign.}}$, $\Delta E_{\text{rot.}}$ and Δt differred from certain fixed values by amounts small enough to permit considering the quantities $\Delta E_{\text{ign.}}/\Delta t$ and $\Delta E_{\text{rot.}}/\Delta t$ in eqn. 13 as being constant throughout the work and incorporating them into the constant value of ε°(Calor.). For simplicity this was done by removing the two terms from eqn. 13 which thereby changed to:

$$\varepsilon^{\circ}(\text{Calor.}) = -\Delta E_{\text{I.B.P.}}/\Delta t + C_P(H_2O)m^{i}(\text{Cont.}) - \varepsilon^{i}(\text{Cont.}) \qquad (14)$$

The values of m^{i}(Cont.) and ε^{i}(Cont.) in eqn. 14 could be computed, as given in detail in Ref.[48], from data obtained in each calibration experiment. The value of the term $-\Delta E_{\text{I.B.P.}}$ could also be computed from the data obtained in a calibration experiment by use of the relation

$$-\Delta E_{\text{I.B.P.}} = -m'\Delta Ec/M(\text{Benzoic acid}) - \Delta E(HNO_3) - m'''\Delta Ec/M(\text{Fuse}) \qquad (15)$$

where m' is the mass of benzoic acid burned, $-\Delta Ec/M$(Benzoic acid) is the quantity of heat evolved by combustion at t_h°C of one unit of mass of the standard benzoic acid under the actual bomb conditions of the calibration experiment, $-\Delta E(HNO_3)$ is the small quantity of heat evolved during the

combustion process by the formation from water, oxygen and nitrogen (present as impurity in the oxygen) of a certain amount of nitric acid, m''' is the mass of fuse burned to ignite the benzoic acid sample, and $-\Delta E_c/M$(Fuse) is the heat of combustion of the fuse under the actual bomb conditions of the calibration experiment.

From the data obtained in each calibration experiment a value of $\varepsilon°$(Calor.) could thus be computed by the aid of eqn. 14. A set of calibration experiments was made in all of which the initial contents of the bomb were within practical limits the same. Therefore the values of m^i(Cont.) and ε^i(Cont.) were within required limits the same for all experiments in the set. Therefore the values of $-\Delta E_{I.B.P.}/\Delta t$ computed from the individual experiments were averaged before eqn. 14 was used for calculation of the $\varepsilon°$(Calor.) value of the calorimetric system, *cf.* Table 2.

The heat of combustion of the sample

The most useful thermodynamic quantity that can be calculated from the experimental data obtained in a combustion experiment with an organic bromine compound is the standard heat of combustion of the compound, $-\Delta E_c°$(Compound), at the reference temperature, t_h, of the combustion experiment. This is the change in energy associated with the "idealized combustion reaction" represented by eqn. 16, in which all reactants and products are in their thermodynamic standard reference states [49]:

$$C_aH_bO_cBr_d(c \text{ or liq}) + (a + b/4 - c/2)\ O_2(g) \rightarrow \rightarrow a\ CO_2(g) + b/2\ H_2O(liq) + d/2\ Br_2(liq) \qquad (16)$$

The various steps in which the value of $-\Delta E_c°$(Compound) is computed from the experimental data will be treated in this section.

The heat of the isothermal bomb process, $-\Delta E_{I.B.P.}$, was calculated, using eqn. 14, directly from the experimental data obtained in a heat of combustion experiment and the $\varepsilon°$(Calor.) value determined in the calibration experiments. To assign the measured heat-quantity to the corresponding amount of chemical reaction, it was only necessary to define the initial and final states of the bomb contents with an accuracy equivalent to the precision in the calorimetric data. This required a chemical analysis of the final system as described previously (p. 1520). The description of the initial and final states is treated in full detail in Ref.[48] The chemical change of the contents of the bomb from the initial to the final state in the bomb process, which is usually called "the chemistry of the bomb process", is conveniently described through a set of arbitrary reactions consistent with the actual initial and final states. The various reactions are selected so that the associated energy changes shall be known with appropriate accuracy.

The chemistry of the bomb process. Through the present and previous work the chemistry of the bomb process in combustion experiments with organic bromine compounds is well established. The combustion of an organic bromine compound in a bomb in oxygen at 30 atm pressure results in the following transformations of the elements in the sample: the carbon is quantitatively transformed to carbon dioxide, part of the hydrogen is transformed to hydrogen

bromide and the rest to water, and part of the bromine is transformed to hydrogen bromide and the rest to elemental bromine. This part of the bomb process is conveniently represented by eqn. 17. Of the products formed in reaction 17 the elemental bromine is quantitatively reduced to hydrobromic acid by the arsenious oxide solution, as represented in eqn. 18, while the hydrogen bromide and the water are absorbed by the bomb solution forming hydrobromic acid as given in eqn. 19:

$$C_aH_bO_cBr_d(c \text{ or } liq) + \{a + [b-(1-x)d]/4-c/2\}\ O_2(g) \rightarrow$$
$$\rightarrow a\ CO_2(g) + xd/2\ Br_2(g) + (1-x)d\ HBr(g) + [b-(1-x)d]/2\ H_2O(liq) \quad (17)$$

$$Br_2(g) + 1/2\ As_2O_3(aq) + (2n + 1)\ H_2O(liq) \rightarrow$$
$$\rightarrow 2\ (HBr \cdot nH_2O)(liq) + 1/2\ As_2O_5(aq) \quad (18)$$

$$HBr(g) + n\ H_2O(liq) \rightarrow (HBr \cdot nH_2O)(liq) \quad (19)$$

The actual bomb process can thus be described as the sum of eqn. 17, xd/2 times eqn. 18 and (1—x)d times eqn. 19. For calculation purposes it is, however, useful to represent the actual bomb process not by the more realistic eqns. 17—19 but instead by the hypothetical eqns. 20 and 21:

$$C_aH_bO_cBr_d(c \text{ or } liq) + [a + (b-d)/4-c/2]\ O_2(g) +$$
$$+ [nd-(b-d)/2]\ H_2O(liq) \rightarrow a\ CO_2(g) + d\ (HBr \cdot nH_2O)(liq) \quad (20)$$

$$As_2O_3(aq) + O_2(g) \rightarrow As_2O_5(aq) \quad (21)$$

It is seen that the sum of eqn. 20 and xd/4 times eqn. 21 is identical with the aforementioned sum of eqn. 17, xd/2 times eqn. 18 and (1—x)d times eqn. 19. The bomb process was therefore considered to comprise one reaction in which all of the bromine compound reacted according to eqn. 20 and another reaction in which the amount of arsenious oxide consumed during the process reacted according to eqn. 21. Further reactions during the bomb process were the combustion of the auxiliary oil and of the fuse, respectively, according to the following equations:

$$C_aH_b(liq) + (a + b/4)\ O_2(g) \rightarrow a\ CO_2(g) + b/2\ H_2O(liq) \quad (22)$$

$$C_aH_bO_c(c) + (a + b/4-c/2)\ O_2(g) \rightarrow a\ CO_2(g) + b/2\ H_2O(liq) \quad (23)$$

Since a significant part of the gaseous carbon dioxide formed in reactions 20, 22 and 23 was dissolved in the bomb liquid the reaction given in eqn. 24 also contributed to the bomb process.

$$CO_2(g) \rightarrow CO_2(aq) \quad (24)$$

Finally, to account for the small amounts of nitric acid, bromoaurous acid and bromoplatinous acid present in the final bomb solution, side reactions according to eqns. 25—27 were also assumed to occur in the bomb process.

$$1/2\ N_2(g) + 5/4\ O_2(g) + 1/2\ H_2O(liq) \rightarrow HNO_3(aq) \quad (25)$$

$$Au(c) + 1/4\ O_2(g) + 2\ HBr(aq) \rightarrow HAuBr_2(aq) + 1/2\ H_2O(liq) \quad (26)$$

$$Pt(c) + 1/2\ O_2(g) + 4\ HBr(aq) \rightarrow H_2PtBr_4(aq) + H_2O(liq) \quad (27)$$

From this is evident that the isothermal bomb process could conveniently be described as the sum of the main combustion reaction 20 and the auxiliary combustion reactions 21—27.

The heat effect, $-\Delta E$(Compound), associated with the main combustion reaction 20 can be called the "heat of the combustion of the sample in the bomb process". This quantity was obtained from the observed "heat of the isothermal bomb process", $-\Delta E_{\text{I.B.P.}}$, by subtraction of the heat effects $-\Delta E$(As), $-\Delta E$(Oil), $-\Delta E$(Fuse), $-\Delta E(CO_2)$, $-\Delta E(HNO_3)$, $-\Delta E$(Au), and $-\Delta E$(Pt), these being the heats associated with the actual amounts of reaction according to eqns. 21—27, respectively. For computation of the latter quantities it was necessary to know (i) the amounts of reaction and (ii) the molar heats of reaction for the various auxiliary combustion reactions.

The amounts of reaction in the bomb process. The amounts of reactions 20, 22, and 23 were computed from composition and mass of the bromine compound, the paraffin oil, and the fuse, respectively, that were placed in the bomb. The amount of reaction 21 was determined from the amount of arsenious oxide consumed in the bomb process, obtained from the analytical determinations of arsenious oxide in the initial and final bomb solutions. The amount of reaction 24 was determined as given in Ref.[48] The amounts of reactions 25—27, finally, were obtained from the experimentally determined amounts of nitric acid, bromoaurous acid and bromoplatinous acid in the final bomb solution.

Heats of reaction for the auxiliary combustion reactions. The values used for the molar heats of reaction for the various auxiliary combustion reactions are summarized below. The data were either obtained directly as results from experimental thermochemical work or computed from data given in Ref.[49]

$-\Delta$E (reaction 21) = $(77.4 \pm 0.1) \times 10^3$ cal/mole at 25°C, Ref.[50]

$-\Delta$E°(reaction 22) = $-\Delta Ec°/M$(Oil) = 10 980.5 ± 1.2 cal/g at 25°C, this work

$-\Delta E°$(reaction 23) = $-\Delta Ec°/M$(Fuse) = 3 971 ± 4 cal/g at 25°C, this work

$-\Delta E$ (reaction 24) = $(3.89 \pm 0.14) \times 10^3$ cal/mole at 25°C, Ref.[48]

$-\Delta E°$(reaction 25) = 14.176×10^3 cal/mole at 25°C, Ref.[49]

$-\Delta E°$(reaction 26) = 8×10^3 cal/mole at 25°C, Ref.[49] *

$-\Delta E°$(reaction 27) = 43.4×10^3 cal/mole at 25°C, Ref.[49] **

---

* Since no value has been found for the standard heat of formation of $HAuBr_2$(aq) a guess, from related data given in Ref. [49] of −32 kcal/mole was used for this quantity in calculating $-\Delta E°$(reaction 26). As will be seen in the following the error resulting from use of this uncertain value for $-\Delta E°$(reaction 26) will be small.

** In calculating this heat of reaction the value −91.0 kcal/mole was used for the standard heat of formation of H_2PtBr_4(aq) at 25°C.

For rigorous calculation of the "heat of the combustion of the sample in the bomb process", $-\Delta E$(Compound), according to the scheme outlined above, the given auxiliary heat of reaction data should all be applicable to actual conditions of the bomb process instead of being standard heats of reaction as some of them are. This apparent inconsistency is explained and eliminated through the mode of calculation used for the reduction of the obtained heat of combustion in the bomb process to the standard heat of combustion [48].

Reduction to standard heat of combustion. Through the various steps of the calculation described above a value was obtained for the heat of the combustion of the sample in the bomb process, $-\Delta E$(Compound), at the temperature $t_h = 25°C$. This value referred to reaction according to eqn. 20, with reactants and products in their actual states in the bomb process. The thermodynamically more useful standard heat of combustion, $-\Delta Ec°$(Compound), according to eqn. 16 was finally computed from the obtained $-\Delta E$(Compound) value by application of the Washburn reduction as given in Ref.[48] The various terms of this reduction were conveniently expressed as the sum of two quantities: (i) $-\Delta E$(HBr), the amount of heat associated with oxidation of the hydrobromic acid, formed in reaction 20, to elemental bromine according to eqn. 28

$$(HBr \cdot nH_2O)(liq) + 1/4\ O_2(g) \rightarrow (n + 1/2)\ H_2O(liq) + 1/2\ Br_2(liq) \quad (28)$$

and, (ii) $-\Delta E_\Sigma$, the amount of heat corresponding to "the remaining Washburn corrections" (see Ref.[48]). The amount of reaction for reaction 28 was computed from the mass and composition of the combustion sample, and the molar heats of reaction for various values of n were calculated from data in Ref.[49] (*cf.* Ref.[48]).

All the various heat quantities discussed above were combined in the over-all eqn. 29 to give the resulting value for $-\Delta Ec°/M$(Compound), the standard heat of combustion per gram of compound according to eqn. 16.

$$-\Delta Ec°/M(\text{Compound}) = \frac{1}{m'}\{-\Delta E_{\text{I.B.P.}} - [-\Delta E(\text{As}) - E\Delta(\text{Oil}) - \Delta E(\text{Fuse}) - \\ -\Delta E(CO_2) - \Delta E(HNO_3) - \Delta E(\text{Au}) - \Delta E(\text{Pt})] - \Delta E(\text{HBr}) - \Delta E_\Sigma) \quad (29)$$

In eqn. 29, m' denotes the mass of the bromine compound placed in the bomb and all other symbols have been defined previously.

Final over-all precision. The estimation of the final over-all precision in the $-\Delta Ec°/M$(Compound) values obtained, will be discussed in a later paper [51].

RESULTS

The energy exchange between calorimeter and environment

The calorimetric system was checked for linearity in the relation between calorimeter temperature and rate of energy exchange between calorimeter and environment by the method given on p. 1522. The results given in Table 1 were obtained from a series of measurements of the rate of temperature rise of the calorimeter at various calorimeter temperatures, while the temperature

of the jacket was kept constant at 25.495 ± 0.001°C *. In the various columns of the table are listed: (i) t, the average temperature of the calorimeter during the time interval in which the corresponding rate of temperature rise was measured; (ii) $(dt/d\tau)_{obs.}$, the observed rate of temperature rise; (iii) $(dt/d\tau)_{calc.}$, the rate of temperature rise calculated from the equation

$$dt/d\tau = [13.67_8\ (25.4950 - t) + 1.00_6] \cdot 10^{-4}$$

which is a "least squares" fit of eqn. 10 to the measured values of t and $(dt/d\tau)_{obs.}$; and (iv) $(dt/d\tau)_{obs.} - (dt/d\tau)_{calc.}$, the difference between the observed and the calculated rate of temperature rise.

Table 1. Results from the checking of the calorimetric system for linearity in the relation between calorimeter temperature and rate of energy exchange between calorimeter and environment.

t°	$(dt/d\tau)_{obs.}$ 10^{-4}deg/min	$(dt/d\tau)_{calc.}$ 10^{-4}deg/min	$(dt/d\tau)_{obs.} - (dt/d\tau)_{calc.}$ 10^{-4}deg/min
24.2218	18.37	18.42	−0.05
24.2476	18.13	18.07	+0.06
24.6224	13.02	12.94	+0.08
24.8056	10.36	10.44	−0.08
24.8175	10.18	10.27	−0.09
24.9856	8.03	7.97	+0.06
25.2201	4.79	4.77	+0.02

Since the uncertainty in the measured $(dt/d\tau)_{obs.}$-values in the first column of Table 1 was about ± 0.04 × 10^{-4} deg/min it was evident from the values listed in the last column that the agreement between observed and calculated $dt/d\tau$-values was satisfactory and that therefore the calorimetric system was unctioning so as to permit calculation of the energy exchange between calorimeter and environment by eqn. 8.

Calibration experiments

The experimental procedure used in the calibration experiments and the method of calculation of results have already been described, p. 1517 and 1522.

The benzoic acid was National Bureau of Standards standard sample 39 g [35] and the fuse was a cotton string having a percentage composition corresponding to the empirical formula $CH_{1.85}O_{0.91}$.

For reduction of weight in air to mass and calculation of the energy equivalent of the initial contents of the bomb, the following values at 25°C of density, ϱ, and specific heat, c_p, were used: for benzoic acid, $\varrho = 1.320$ g/ml [35,52], $c_p = 0.287$ cal/g deg [53]; for fuse, $\varrho = 1.5$ g/ml [45 (p. 81)], $c_p = 0.4$ cal/g deg [45 (p. 93)].

* It should be observed that all other calorimetric experiments in the present work were performed with the jacket having a temperature of 25.22°C, *cf.* p. 1517.

The results obtained are presented in Table 2. The heading of the table gives the experimental conditions which were common to all the calibration experiments, and in the various columns are listed the data obtained for the individual experiments. The symbols denote:

t_h	the reference temperature to which the calorimetric experiments are ascribed
t_i	the initial temperature of the actual bomb process
P^i(gas.)	the initial pressure, at t_h, of the gaseous phase in the bomb
V(Bomb)	the volume of the bomb
V^i(H_2O tot.)	the volume of water introduced into the bomb
m(Pt)	the mass of removable platinum parts in the bomb (crucible and suspension ring)
m^i(Cont.)	the mass of the initial contents of the bomb (see p. 1522)
$-\Delta Ec/M$(Benzoic	acid NBS 39 g) heat of combustion (per gram mass) of standard benzoic acid NBS 39 g under the actual bomb conditions
$-\Delta Ec/M$(Fuse)	heat of combustion (per gram) of the fuse under the actual bomb conditions
$\varepsilon°$(Calor.)	the energy equivalent of the standard calorimetric system (see p. 1522)
ε^i(Cont.)	the energy equivalent of the initial contents of the bomb (see p. 1523)
m'	the mass of benzoic acid burned
m'''	the mass of fuse burned
Δt	the corrected temperature rise (see p. 1520)
$-\Delta E(HNO_3)$	the heat evolved through the formation of the nitric acid
$-\Delta E_{I.B.P.}$	the heat of the isothermal bomb process (see p. 1523)

The value given in Table 2 for the heat of combustion of the standard benzoic acid under the actual bomb conditions of the calibration experiments, $-\Delta Ec/M$(Benzoic acid NBS 39g), was computed from the certified value [35] (*cf.* Refs.[54,55,52]) of 26.4338 ± 0.0026 abs. kj/g mass (6317.83 ± 0.62 cal/g mass) under certificate conditions by multiplication with a factor obtained as given in the certificate [35], *cf.* Refs.[43 (p. 37), 54 (p. 261)]. The actual conditions adhered to certificate conditions so closely that the required factor did not differ from unity to any significant extent. The value given in Table 2 for the heat of combustion of the fuse under the actual bomb conditions, $-\Delta Ec/M$(Fuse), is in fact the standard heat of combustion of the fuse, $-\Delta Ec°/M$(Fuse), obtained from heat of combustion experiments with the fuse. The error introduced into the results of the calibration experiments by this approximation was not significant.

Heat of combustion experiments

Two sets of combustion experiments were performed, one with the sample of paraffin oil used as auxiliary material in the combustion experiments with the bromine compound, and one with a sample of *p*-bromobenzoic acid. The

Table 2. Results of calibration experiments.

				ε°(Calor.) = 5 821.54 ± 0.36 cal/deg

[a] At 25°C under the actual bomb conditions; see text for further comments.

experimental procedure used in the heat of combustion experiments and the method of calculation of results have been described previously, p. 1518 and 1524. It should, however, be noted that since no reducing agent was required in the combustion experiments with the paraffin oil, the initial bomb liquid used in the paraffin oil experiments was the same as that used in the calibration experiments, *i.e.* 0.810 ml of water.

Paraffin oil USBM-P3a. The oil was a sample of redistilled mineral oil obtained from the Thermodynamics Laboratory, Petroleum Experiment Station, Bureau of Mines, Bartlesville, Oklahoma, under the laboratory designation Paraffin oil USBM-P3a. The oil was found to have a percentage composition corresponding to the empirical formula $CH_{1.89}$ and a density, ϱ, of 0.8755_0 g/ml at 20.00°C and 0.8723_5 g/ml at 25.00°C. For use in calculation of the energy equivalent of the initial contents of the bomb and in reduction to standard states the following values at 25°C of specific heat, c_P, and energy of compression, $(\partial E/\partial P)_T$, were used: $c_P = 0.53$ cal/deg [45 (p. 93)], $(\partial E/\partial P)_T = -0.0060$ cal/g atm. The latter value was calculated from the density values given above using the approximate relation $(\partial E/\partial P)_T = -T(\partial V/\partial T)_P$ as discussed in Ref.[56 (p. 542–43)].

The results obtained in the combustion experiments with the paraffin oil are presented in Table 3. The denotation of the symbols is the same as in Table 2. The following additional symbols are used:

$-\Delta E_c^\circ/M$(Fuse)	the standard heat of combustion (per gram) of the fuse
ε(Calor.)	the energy equivalent of the actual calorimetric system minus the contents of the bomb (see p. 1522); this quantity is related to ε°(Calor.) through the equation ε(Calor.) = ε°(Calor.) − $c_P(H_2O)m^i$(Cont.)
$-\Delta E_\Sigma/m''$	the heat to be evolved, per gram of paraffin oil burned, through the reactions constituting the sum of the remaining Washburn corrections (p. 1527)
$-\Delta E(CO_2)/m''$	the heat evolved, per gram of paraffin oil burned, from the dissolution of carbon dioxide in the final bomb solution
m''	the mass of paraffin oil burned
$-\Delta E_B/M$	the heat of combustion per gram of the compound in the isothermal bomb process at the temperature t_h (see Ref.[48])
$-\Delta E_c^\circ/M$	the standard heat of combustion per gram of compound at the temperature t_h; as discussed in Ref.[48] the following relation holds: $-\Delta E_c^\circ/M = -\Delta E_B/M - \Delta E_\Sigma/m''$

p-*Bromobenzoic acid.* The *p*-bromobenzoic acid used in the combustion experiments was a highly purified sample *.

* The principal aim with the combustion experiments in the present work was to investigate the precision obtainable with the described bomb-calorimetric method and not to determine an accurate value for the heat of combustion of the sample used in the combustion experiments. For this reason it was necessary to have access to a suitable organic bromine compound sample of fairly high purity, but the detailed description of the purification process and of the determination of the purity of the sample was not of primary interest. It is intended to report on these details in a later paper dealing with the heats of combustion and formation of *p*-bromobenzoic acid and with the possible use of this compound as a test substance for bomb combustions of organic bromine compounds.

Table 3. Results of combustion experiments on paraffin oil USBM-P3a.

t_h = 25.0°C	V(Bomb) = 0.2670 liter	$\varepsilon°$(Calor.) = 5 821.54 ± 0.36 cal/deg	ε(Calor.) = 5 801.16 cal/deg	
t_i = 24.1°C	V^i(H_2O tot.) = 0.810 ml		ε^i(Cont.) = 3.21 cal/deg

			Standard deviation of mean	± 1.2
				$-\Delta Ec°/M$ = 10 980.5 ± 1.2 cal/g

For use in reducing weight in air to mass in the calculation of the energy equivalent of the initial contents of the bomb and in the reduction to standard states, the following values at 25°C of density, specific heat and energy of compression were used: $\varrho = 1.889$ g/ml, $c_p = 0.18$ cal/deg g, $(\partial E/\partial P)_T = -0.0029$ cal/g atm. These values were obtained as follows: the density value was calculated from the value $\varrho^{20} = 1.894$, given in Ref.[57], using a value for the temperature coefficient of the density of 0.00054 g/ml deg, which is the average of the two values given for benzoic acid in Ref.[52]; the specific heat value was obtained from the value given earlier in this paper for benzoic acid, by assuming the molar heat capacities for benzoic acid and *p*-bromobenzoic acid to be approximately the same; and the energy of compression value given above is that obtained for benzoic acid from data given in Ref.[52]

The results obtained in the combustion experiments with the *p*-bromobenzoic acid sample are presented in Table 4. The denotation of symbols is the same as in Tables 2 and 3 except for m', which see below. The following additional symbols denote:

V^i(soln.)	the volume of arsenious oxide solution introduced into the bomb
C^i(soln.)	the concentration of As_2O_3 in the initial bomb solution
$-\Delta Ec^\circ/M$(Oil)	the standard heat of combustion per gram of the auxiliary paraffin oil at the temperature t_h
m'	the mass of *p*-bromobenzoic acid burned
$n^f(As_2O_5)$	the number of moles of As_2O_5 in the final solution
$-\Delta E(CO_2)$	the heat evolved from the dissolution of carbon dioxide in the final bomb solution
$-\Delta E$(Au)	the heat evolved through the formation of the bromoaurous acid
$-\Delta E$(Pt)	the heat evolved through the formation of the bromoplatinous acid
$-\Delta E$(HBr)	the heat to be evolved through oxidation to elemental bromine of the hydrobromic acid in the final solution
$-\Delta E_\Sigma$	the heat to be evolved through the reactions constituting the sum of the remaining Washburn corrections (see p. 1527)

DISCUSSION OF METHOD AND RESULTS

The precision of the method

The over-all precision [1 (p. 430)] of heat of combustion data obtained with the present method will be discussed in a later paper [51]. The immediate precision [1 (p. 430)] of the results from the calibration and from the combustion experiments presented above can, however, be used for comparison of the precision of the present technique with that of other bomb-calorimetric techniques.

As is seen from Table 2 the precision obtained in the calibration experiments with benzoic acid was 0.006 % in terms of standard deviation of the mean of the six experimental values. This figure is comparable to the best

Table 4. Results of combustion experiments on *p*-bromobenzoic acid.

precision obtained in calibration experiments with other present-day combustion calorimetric systems of static-bomb as well as moving-bomb type. The combustion experiments with paraffin oil, presented in Table 3, were performed under the same experimental conditions as the calibration experiments. The precision obtained was 0.011 %, from a set of only four individual experiments (see table). In a later series of combustion experiments on paraffin oil [51] with the same apparatus the standard deviation of the mean of six experimental values was found to be 0.008 %. Although slightly high these figures are also satisfactory in comparison with results from other modern bomb-calorimetric work. Thus the results obtained in the experiments with benzoic acid and paraffin oil demonstrated that the reproducibility obtainable with the apparatus and technique was satisfactory. More specifically, the assumption made earlier in this paper was confirmed that for certain energy quantities, such as the ignition energy $\Delta E_{ign.}$ and the bomb-rotation energy $\Delta E_{rot.}$, the variation in value from one calorimetric experiment to another was small enough to accept them as constant in all the calorimetric experiments. Tables 2 and 3 also prove that the apparatus and technique gave satisfactory precision in the temperature—time measurements and in the calculation of heat exchange corrections Δt_{ex}.

The precision obtained in the heat of combustion experiments with *p*-bromobenzoic acid, presented in Table 4, was 0.005 % in terms of standard deviation of the mean of seven experimental values. This high precision was virtually the same as that obtained in the calibration experiments with benzoic acid, which showed that neither did the presence of bromine in the compound affect the reproducibility of the combustion process of a pelleted sample, nor was the reproducibility affected by the presence of a large amount of bomb liquid or by the additional uncertainty in the determination of the amount of heat associated with the oxidation of arsenious oxide to arsenic oxide.

The various experiments of the present work thus have shown that the precision of heat of combustion results obtained with the described moving-bomb method for organic bromine compounds is comparable to the precision obtained with the best modern combustion calorimetric systems for other groups of organic compounds.

The accuracy of the method

Although the precision obtainable with the present method has been found to be high, the presence of undetected systematic errors might render the accuracy of obtained heat of combustion data much lower than actually would be attainable with this high precision. Therefore the accuracy of the method has to be investigated, and there are several possible ways of doing this. Since the principal use for heat of combustion data is to derive corresponding heats of formation, a suitable approach would be to compare, for certain selected bromine compounds, heats of formation calculated both from heat of combustion data and from calorimetric data on heats of reactions other than combustion. Such a comparison has been made and the results will be reported in a later paper [51]. It will, however, be appropriate to include in the

present discussion of method and results an examination of certain details of the technique which could possibly cause systematic errors.

The calorimetric part of the measurement

The energy exchange between calorimeter and environment. It was experimentally demonstrated earlier that the functioning of the present calorimetric system allowed calculation of the energy exchange between calorimeter and environment during the reaction period of an experiment by eqn. 8 given on p. 1521. A necessary prerequisite for this is, however, that equilibrium has been reestablished in the bomb before the after period starts. The question about attainment of equilibrium in the bomb will be discussed later in this paper.

The energies of ignition and of rotation of the bomb. It was evident from the discussion on p. 1523 that, as long as both calibration and combustion experiments were so arranged that the obtained Δt-values were virtually the same in all experiments, it was only the *variation* in the energies of ignition and of rotation from one set of experiments to another that might give rise to systematic errors. As has already been pointed out, such variations would also affect the precision in the various sets of measurements. Since this precision, however, was found to be as high as could be expected, the variations in the two mentioned quantities could not be significant.

The heats of reaction for the auxiliary combustion reactions. Any uncertainties in the molar heat of reaction values for the auxiliary combustion reactions 21—27, given on p. 1525, will give rise to corresponding systematic errors in obtained heat of combustion values. As is seen from Table 4 the quantities $-\Delta E(HNO_3)$, $-\Delta E$(Au) and $-\Delta E$(Pt) associated with the actual amounts of reactions 25—27 are small enough to permit large uncertainties in the corresponding molar heats of reaction *. Therefore, although the molar heat of reaction 26 has a high degree of uncertainty (p. 1526), the systematic errors from reactions 25—27 are probably small enough to be neglected. The variation in value of the quantity $-\Delta E$(Fuse) in calibration as well as combustion experiments is small enough to give with the uncertainty in the $-\Delta E^\circ$ (reaction 23)-value satisfactory cancellation of errors from this quantity and therefore this error in the obtained heat of combustion values is also small enough to be neglected. The systematic errors associated with the uncertainties in the molar heats of reaction 21, 22 and 24 are, however, significant. These errors will be treated more fully in a later paper [51] dealing with the evalaution of the final over-all precision in the obtained heats of combustion. It may be pointed out that all these three molar heats of reaction were obtained, as specified on p. 1526, from recent experimental work directly in connection with the work presented in this paper.

Chemical part of the measurement

Homogeneity and equilibrium in the final state in the bomb. It has already been stressed that, as the method requires a large volume of bomb liquid, it is

* Since the quantity $-\Delta E(HNO_3)$ appears in calibration as well as combustion experiments the error from this quantity is partly cancelled through the procedure of the given method.

imperative that homogeneity in the final liquid phase and equilibrium between the gaseous and the liquid phase in the bomb should be achieved before the after period of a measurement has started. The presence of a large volume of bomb liquid and the mode and duration of the rotation of the bomb in the present work brought about a thorough rinsing of the whole interior surface of the bomb, except for certain parts of the platinum rod B_6 (Fig. 2), and the gas-inlet tube B_7. Homogeneity of the liquid phase was therefore rapidly obtained.

Considering equilibration of the bomb gases with the bomb solution, it was found (see below) that, at the end of the reaction period, no hydrogen bromide or elemental bromine could be detected in the gaseous phase and therefore these components must have been quantitatively transferred to the bomb solution during the reaction period. The carbon dioxide was a third component, the equilibration of which between the gaseous and the liquid phase was of primary importance for the present method. Recently, the influence of various experimental factors on the rate of absorption of carbon dioxide in the final bomb liquid and the time required for reaching equilibrium between the gaseous and the liquid phase has been experimentally studied for different moving-bomb techniques [26]. Since the results of this investigation were utilized in designing the moving mechanism used in the present work, it can be confidently assumed that in all experiments the distribution of carbon dioxide between the gaseous and the liquid phase in the bomb was complete within the reaction period.

Chemistry of the bomb process. The accuracy of the heat of combustion data can only compare with the over-all precision of the experimental results if the nature and amount of the various chemical reactions 21—27, constituting the bomb process, are known to a corresponding degree of accuracy.

The amounts of reactions 20, 22, and 23 were obtained, as described earlier, from the composition and mass of the bromine compound, the paraffin oil, and the fuse, respectively. A possible check on the completeness of the sum of these three reactions would be by an experimental determination of the total amount of carbon dioxide present in the bomb after the combustion. Due to the large amount of bomb liquid such a determination would be experimentally very difficult, and no such measurement has been attempted.

A check on the completeness of the transformation of the bromine in the combustion sample to hydrogen bromide according to eqn. 20 would be the analytical determination of the amount of bromide ion in the final bomb liquid *. This was done in the experiments presented in Table 4 by potentiometric titration of aliquot 20 ml samples of the diluted bomb solutions with silver nitrate solution and calculation of the total amount of hydrogen bromide present in the final bomb liquid. It was necessary to correct for the small amounts of hydrogen bromide consumed in reactions 26 and 27 and therefore present in the final bomb liquid as $HAuBr_2$ and H_2PtBr_4, respectively. From

* That no detectable amounts of bromine, in the form of hydrogen bromide or elemental bromine, were present in the final gas phase was demonstrated in separate combustion experiments by discharging the bomb gases, at the end of the reaction period, through a sodium hydroxide solution and analyzing the solution for bromide ion.

available stability constants [58] for these compounds it was estimated * that by the silver nitrate titration approximately one of the bromines in $HAuBr_2$ and none of the bromines in H_2PtBr_4 were titrated as bromide ion. Taking account of this in the calculation of the total amount of bromine present in the final bomb liquid the following figures were obtained for the recovery of the amount of bromine introduced into the bomb with the combustion sample: 99.3, 99.4, 99.6, 99.0, 99.5, 99.7, 99.8, and 99.8 %, respectively. Because of the uncertainties in the analytical method the deviation of these figures from the theoretical value 100.0 could not be considered significant and therefore the figures could be taken as an indication of the absence of gross "chemical" errors in this part of the method.

The actual oxidation state of the dissolved gold and platinum in the bomb liquid was difficult to assess. Combination of available data on oxidation potentials [59] with the concentrations of the various constituents in the final bomb solution implied that the gold should be present as Au(0) and the platinum as Pt(II). It was, however, experimentally found that the precipitation of metallic gold from the bomb solution was very slow and therefore it could be assumed that the oxidation state of the entire amount of gold, which had been dissolved during the combustion process was — at the end of the reaction period — Au(I) and that the precipitation of gold during the after period was completely negligible.

If arsenious oxide solution is not affected by gaseous oxygen under bomb conditions the amount of reaction 21 should be equivalent with the amount of elemental bromine formed in the actual combustion reaction 17. It is a principal requirement that no reaction between the arsenious oxide solution and the oxygen in the bomb should take place in either the initial or the final period of the calorimetric experiment. This question will be discussed next.

Stability of the arsenious oxide solution. For possible use as a reductant in combustion experiments with organic compounds containing chlorine the former I.U.C. Standing Commission for Thermochemistry discussed [60] three different reducing agents: arsenious oxide, hydrazine monohydrochloride and formic acid. Of these compounds only arsenious oxide has been further studied [61]. Instead of the monohydrochloride, hydrazine dihydrochloride has also been studied for such purposes [62]. A comparison has recently been made [63] of arsenious oxide and hydrazine dihydrochloride for use in static-bomb combustion calorimetry of organic chlorine compounds. Arsenious oxide was used as reductant in the introductory moving-bomb work on organic bromine compounds in this laboratory [17,18] and since a closer study (see below) showed that an arsenious oxide solution of the composition used in the present work was completely stable under the experimental bomb conditions of the present technique, this substance was chosen as a reductant for the further work.

The stability of the arsenious oxide solution and the accuracy of the analytical procedure were tested by treating 30.01 ml samples of the arsenious oxide solution in the following ways: (1) The sample was diluted in a volumetric flask to 250.0 ml, (2) The sample was placed in the bomb body and the bomb

* The author's thanks are due to Mr. Ragnar Larsson, Department of Inorganic and Physical Chemistry, University of Lund, for making the calculations required in this estimation.

was closed. It was shaken for a minute and then opened. The contents were carefully transferred to a volumetric flask by repeated rinsing with water and diluted to 250.0 ml, (3) The sample was placed in the bomb which was then closed and filled with oxygen to a pressure of 30 atm. After 24 h the oxygen was discharged and the liquid contents were transferred to a volumetric flask and diluted as above, (4) The sample was placed in the bomb and used for a combustion experiment with benzoic acid or paraffin oil. After the experiment the bomb liquid was transferred as above to a volumetric flask and diluted to 250.0 ml. Numerous experiments of this type were performed. From all the solutions obtained under items 1 to 4 aliquot samples of 50 ml were withdrawn and titrated with potassium permanganate solution according to the method described above (p. 1520). The volume of permanganate solution consumed was in all the experiments 15.05 ml within $\pm$ 0.1 % *. These results indicated that, within the precision of the analytical method, no oxidation of the arsenious oxide solution occurred during combustion experiments with compounds containing only carbon, hydrogen and oxygen. Therefore it could be confidently assumed that the stability of the reductant during the initial and final period of an experiment was satisfactory.

Amount of reaction. From what has been said above on the analytical determinations of the amounts of carbon dioxide and hydrogen bromide present in the final state in the bomb it was evident that the only feasible way of determining the amount of reaction for the main combustion reaction 20 was from the mass and composition of the organic bromine compound placed in the bomb. This makes the question of the purity of the combustion sample most important.

Purity of the sample. The use of the above method for determination of the amount of reaction 20 requires that the impurities in the combustion sample are known in nature and amount or, preferably, that the purity of the sample is high enough to give no significant contribution to the uncertainty of the over-all method. In the latter case the absence of inert impurities, such as water, is especially important.

Application of the principle of comparative measurements to the present method

The application of the method of comparative measurements to combustion-bomb calorimetric studies of organic sulfur, chlorine and bromine compounds, respectively, has been discussed recently by various authors [64–66]. Three different methods, which should be adaptable for use in studies of bromine compounds, were mentioned in Ref.[66] The technique described above constitutes a fourth possible method. On account of the nature of this work the discussion of the present technique from the method-of-comparative-measurements point of view will, however, be deferred to a later paper.

Acknowledgement. The author's thanks are due to the *Swedish Natural Science Research Council* for financial support of this investigation.

* For two solutions from combustion experiments with benzoic acid a slightly lower result was obtained.

Isolation of Five Myoglobins from Seal (*Phoca vitulina*)

NEVENKA M. RUMEN

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

1. Crystalline seal myoglobin contains 5 components. They have been separated by the aid of a cellulose ion-exchanger.
2. All five myoglobins have been crystallized from ammonium sulphate and their crystal shapes were found to be identical under the microscope.
3. The iron content was the same for all five.
4. Mb I is a basic protein, the others have IP values in the pH range 7.6—6.2.
5. Glycine is the terminal group in all five Mb's. Mb IV may contain serine as a second terminal residue.
6. The only differences found amongst the components is the isoelectric point and slight differences in the extinction coefficient of certain bands of the spectrum.

Already in 1934 Theorell [1] found an exceptionally high concentration of myoglobin in the seal, where the muscle press juice contains from 5 to 10 % of myoglobin. This is something like ten times the concentration normally found in mammals. Kendrew, Parrish and others [2] have also found that aquatic mammals, like whales, seals and penguins are particularly rich sources for myoglobin, so that their skeletal muscles are almost black in colour.

In this paper the isolation and some of the properties of seal myoglobin will be described.

ISOLATION

Seal myoglobin was prepared from the meat of the common seal, *Phoca vitulina*, by the method described for sperm-whale myoglobin by Kendrew and Parrish [3], and kindly given by Dr. Kendrew for this work. The crude preparation, which was sent as a thick paste in phosphate buffer, pH 6.8, was dissolved in a very small amount of water and dialyzed three times against distilled water in the cold, and four or five times against 0.01 M tris-buffer, pH 8.50 ± 0.02.

Carboxymethyl cellulose was prepared according to Peterson and Sober [4], and a column was packed with it and charged with tris buffer pH 8.5. The column dimensions were 1.9×23 cm. The load of the protein was 119 mg in a volume of 2.5 ml. The temperature was 4°C; no difference was noticed if the chromatograms were run at room temperature.

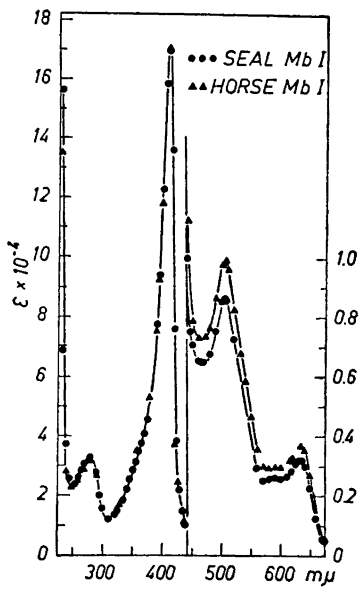

Fig. 1. Light absorption curves of seal ferri-Mb I and horse ferri-Mb I.

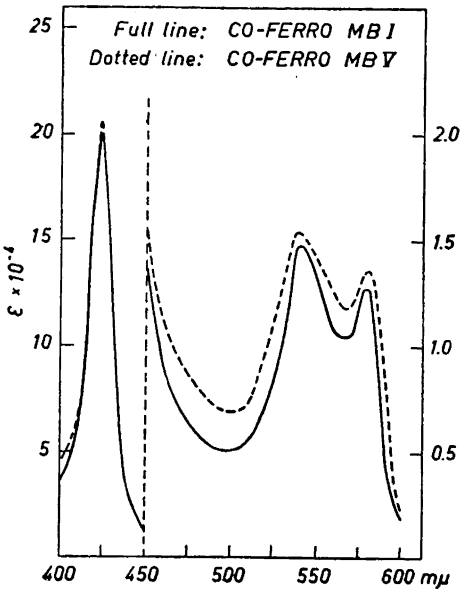

Fig. 2. Light absorption curves of seal CO-myoglobins I and V.

The chromatogram was eluated with the same buffer. On the column five distinct bands separated, moving with different speeds. The fastest component was named Mb V, and the slowest, which contained about 90 % of the total amount, was named Mb I. The distances between the bands were: Mb I 3 cm from the top, the distance between Mb I and II was 3.7 cm, between II and III 4.5 cm, between III and IV 2.5 cm, and Mb V came rather close to Mb IV. The yield of Mb I was about 90 % of the total; Mb II 2.5; Mb III 1.7; Mb IV 1.7 and Mb V 3.4 %. The high content of Mb I may be explained by the repeated crystallization from phosphate and ammonium sulphate, which followed after the extraction from the meat.

The five components were dialyzed over night in the cold against distilled water, and each component was put separately on a column, and eluated with tris buffer. In this way it was possible to concentrate the solutions, and at the same time to complete purification.

PROPERTIES

The *homogeneity* of the five myoglobins was demonstrated by moving boundary electrophoresis in phosphate buffer $\mu = 0.1$, at various pH in the range 6.1—9.0. The isoelectric point, determined by boundary electrophoresis, was found to be near pH 8.05 for myoglobin I and for myoglobin II at pH 7.6. The isoelectric points for Mb III, IV and V were not determined, because of lack of protein.

The *sedimentation constant* of Mb I determined in the Spinco centrifuge, was found to be $S_{20} = 1.95\ S$, a value which is similar to those obtained for horse myoglobin I by Theorell and Åkeson [5].

The *minimum molecular weight* deduced from the iron content (0.30 % for Mb I, 0.29 % for Mb II, 0.30 % for Mb III, 0.29 % for Mb IV, and 0.30 % for Mb V) is 18 600 for all five myoglobins. These values are comparable with those found by Theorell [5] for pure and homogeneous horse myoglobin.

The *spectrophotometric analysis* of the seal myoglobins showed that the five myoglobins have light adsorption maxima and minima exactly at the same wave lenghts as pure horse myoglobin I, but they differ in extinction coefficients. Seal myoglobin I and horse Mb I have the same molar light absorption at 280, 315 and 409 mμ, but they differ at the wave lenghts 465, 505, and 635 mμ, which can be seen from Fig. 1. The results for all five myoglobins are given in the Tables 1 and 2.

The *prosthetic group* of the seal myoglobin I is identical with that of horse Mb I; this was demostrated by resynthesis from seal apo-protein and protohematin. Resynthesized Mb I was crystallized and the crystals were identical with those of the native seal myoglobin. The yield of Mb I after resynthesis from apo-protein and protohematin was 93.5 %, determined from the optical density of the solution at 409 mμ. Myoglobin I was crystallized from ammonium sulfate (80 %) at pH 8. For Mb II the pH was adjusted to pH 7.5, and for the other components to 7. All five myoglobins crystallized in the same form.

Free amino group of the five myoglobins. For the determination of the N-terminal group of the seal myoglobins Sanger's method [6], slightly modified, was used.

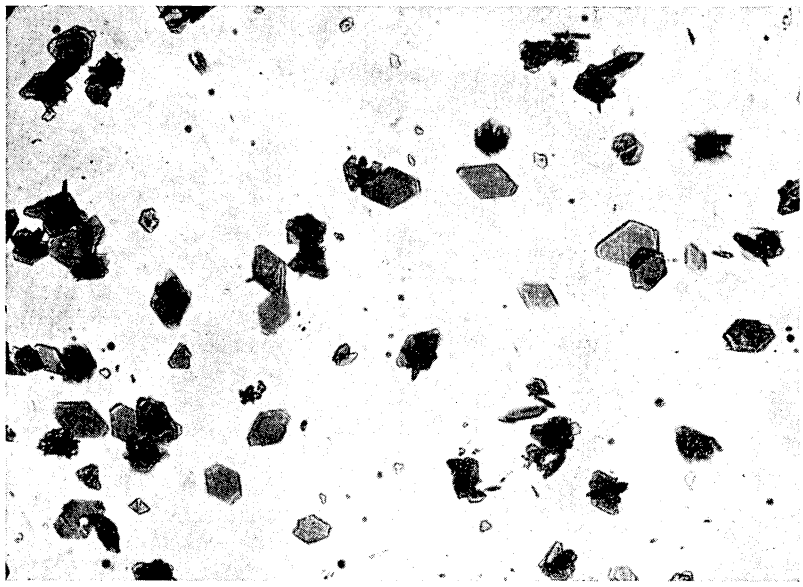

Fig. 3. Crystals of native seal Mb I from ammonium sulfate (× 83).

In each experiment 3 mg (0.25 ml) of pure salt-free myoglobin, denatured with 0.75 ml ethanol was used, and 0.5 ml of a 10 % solution of $NaHCO_3$ and 0.005 ml liquid 1,2,4-fluorodinitrobenzene were added. The mixture was then vigorously stirred for 2 h at room temperature. The precipitate formed was centrifuged off, washed with water, ethanol and finally with ether. The precipitate was hydrolyzed with 6 N HCl at 110°C for 4.6 and 8 h. After hydrolysis, the solution was cooled and evaporated to dryness, water added and dried. After dissolving in a small volume of water, the solution was extracted twice with ethyl acetate. The extracts were combined, evaporated under vacuum to a small volume, applied to a corner of a Whatman No. 1 paper and run by the ascending technique with butanol-ammonia [7] (*n*-butanol was equilibrated with the same volume of 5 % ammonia and the top phase used). After 24 h the paper was dried at 38°C for 4 h. The paper was then run in the second dimension using the descending technique and 1.5 M aqueous phosphate buffer, pH 6. The paper was dried and the R_F values were compared with those of known DNP-amino acids. In myoglobins I, II, III, and V only one spot was observed, which was found to be DNP-glycine. In Mb IV two spots were observed, with R_F values corresponding to ε-DNP-lysine or DNP-serine, and DNP-glycine.

To identify them, the DNP-amino acids were eluated from the paper after chromatographic separation and heated with concentrated ammonia [8] in a sealed capillary for 2 h at 108°C. The DNP-derivatives had been split, and the free amino acids could be run by one-dimensional paper chromatography, using phenol as solvent [9]. On the paper lysine could be identified, but whether serine

was present or not was difficult to see, because of the tailing of the spots. The experiment could not be repeated because of the shortage of fraction IV. The N-terminal group of unpurified seal myoglobin has been determined by Orláns [2], who found glycine as the terminal residue.

Acknowledgements. Grateful acknowledgement is made to Professor H. Theorell for his interest and advice during the course of this work. The author wishes to thank Dr. John C. Kendrew for kindly supplying the myoglobin mixture.

Hydrolysis of Carboxylic Acid Esters of Thiocholine and its Analogues

3. Hydrolysis Catalysed by Acetylcholine Esterase and Butyrylcholine Esterase

EDITH HEILBRONN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The hydrolysis of thiocholine esters, α-methylthiocholine esters and β-methylthiocholine esters, catalysed by the enzymes acetylcholine esterase and butyrylcholine esterase, was studied with an automatic recording titrator at pH 8.00 and 25°C. Michaelis-Menten constants, maximum velocities and reaction rates are given. It was shown that acetylthiocholine is easier split by butyrylcholine esterase than acetylcholine. Both are split at the same rate by acetylcholine esterase.

The influence of some reversible and irreversible inhibitors on the hydrolysis of acetylcholine and acetylthiocholine, catalysed by acetylcholine esterase and butyrylcholine esterase, was studied at pH 8.00 and 25°C. It was shown that the substrates are about equally good protectors for acetylcholine esterase, but that the thioester is the better protector for butyrylcholine esterase.

The hydrolytic effect of imidazole and cysteine on the hydrolysis of the thioesters was shown. Hydrolysis was enhanced about 4 times with imidazole and about 50 times with cysteine.

The bonds between the enzymes and the substrates are discussed on the basis of the results obtained.

Choline esters are known to be of interest *in vivo* for their potent pharmacodynamic effects and *in vitro* as substrates for choline esterases. Some of their thiocholine analogues have been prepared during the 1930's and were investigated for their pharmacodynamic actions [1]. Acetylthiocholine was used by Koelle [2] and others in histochemical methods for the determination of choline esterase activity, and by Zajiceck [3] and others in a diver technique method for determination of choline esterase activity in single cells. Thiocholine esters were also used in a few studies on the structure of choline esterases by, *e.g.*, Wilson [4] and Bergmann [5].

In two preceding papers the acid [6] and alkaline [7] hydrolysis of thiocholine esters and analogues has been described. This paper reports studies on the hydrolysis, catalysed by acetylcholine esterase (AChE) and butyrylcholine esterase (BuChE), of the thiocholine esters and their methylsubstituted analogues, acetylhomothiocholine and acetylcholine. The work was done in order to gain more knowledge about the reaction of this type of ester with choline esterases. Earlier studies [7] had demonstrated the catalytic effect of some buffer anions, e.g. phosphate, on the hydrolysis of the thioesters. To avoid this effect an automatic recording titrator [8], allowing fairly exact studies of hydrolysis, was used for the study of the enzymic hydrolysis. Besides the measurements on the enzymic hydrolysis a few experiments were carried out in order to show that the thiocholine esters and analogues interact with the same groups in the enzymes as the choline esters do. The protective effect of the thioesters against some reversible and irreversible inhibitors was studied, and the catalytic effect of some organic compounds, proposed in literature [9,10] to be related to the active centre in choline esterases, on the hydrolysis of acetyl-β-methylthiocholine and acetylthiocholine, was confirmed.

EXPERIMENTAL

Materials

Substrates. The same esters as described earlier [6,7] were used. Acetylhomothiocholine was prepared by Hansen according to the same method as was used for the other thiocholine esters [11,12].

Enzymes. The source for *AChE* was freeze-dried electric organs from *Torpedo oscellata*. *BuChE* was obtained from fraction IV-6-3, prepared from retroplacentar serum (AB Kabi, Stockholm).

Catalysts. Imidazole was from Schuchardt GMBH, L-cysteine hydrochloride and DL-serine were from Merck & Co. 2-Methyloxazoline was synthetized according to Wenker [13].

Inhibitors. Sarin was prepared by Fagerlind [14], eserine salicylate was from Smith Ltd, London, choline iodide and thiocholine iodide were prepared by Hansen.

Methods

pS-Activity curves. Reaction velocities were determined with an automatic recording titrator [8] at 25°C and pH 8.00. A 0.100 M solution of sodium hydroxide was added. For reasons explained later reaction velocities are expressed as recorder units, proportional to the amount of sodium hydroxide consumed by the hydrolysed ester, per unit of time (relative activities). The values used for calculations of reaction rates refer to hydrolysis from 1 to 10 min after addition of the substrate.

The activities of the enzyme solutions were checked each day with acetylthiocholine at 10^{-2} M substrate concentration. All activity values were corrected to the activity obtained the first day. The activity of BuChE solutions was constant during about 14 days when the solutions were kept in a refrigerator. The solutions of AChE were less stable.

Enzyme solutions. AChE: 500 mg of freeze-dried electric organs were homogenised in 100 ml of 0.10 M potassium chloride with a Potter-Elvehjem homogenizer. The solution was filtered through filter paper Munktell No. 3 and diluted 1:4 with 0.10 M potassium chloride. BuChE: 25 mg of serum fraction IV-6-3 were dissolved in 100 ml of 0.10 M potassium chloride.

Substrate solutions. The final concentration of the substrate was in all pS-activity experiments 0.100 M, 0.050 M, 0.010 M, 0.005 M, 0.001 M and 0.0005 M. The substrates were dissolved in 0.10 M potassium chloride.

Procedure and reaction mixture. The reaction mixture without enzyme was titrated to pH 8.00 with 0.100 M sodium hydroxide. The enzyme solution was added and the pH immediately again corrected to pH 8.00. The following reaction mixtures were used: enzyme solution 1 ml (AChE) or 3 ml (BuChE), substrate solution 30 ml, 0.10 M potassium chloride to make a total volume of 40 ml.

Rate of hydrolysis. In these experiments the automatic recording titrator [9] was used to keep pH constant at 8.00, and the amount of unhydrolysed ester was determined as iron-hydroxamate complex as described earlier [15]. The concentration of the esters was 0.001 M, enzyme concentration as described for pS-activity determinations. The temperature was 25°C.

Spontaneous hydrolysis and catalytic effects of some organic compounds. The spontaneous hydrolysis of each thioester was determined for 0.050 M and 0.010 M solutions. In these experiments the enzyme solution was replaced by 0.10 M potassium chloride. From the values obtained the spontaneous hydrolysis for the other substrate concentrations was calculated. Enzymic hydrolysis was calculated according to eqn (2) below. The spontaneous hydrolysis of acetylcholine was calculated from values found in this laboratory and published earlier [7]. The following equations were used for the corrections of the observed hydrolysis of acetylcholine:

$$k1_{\text{spont.}} \times C_S = k0_{\text{spont.}} \quad (1)$$

$$k0_{\text{obs.}} - k0_{\text{spont.}} = k0_{\text{enz.}} \quad (2)$$

All enzyme activity values were corrected for spontaneous hydrolysis.

In experiments with imidazole, 2-methyloxazoline, cysteine and serine the final concentration of the catalyst was the same as the concentration of the substrate, 0.001 M. The substance was dissolved in 0.10 M potassium chloride and pH adjusted to 8.00. The solution was then added to the reaction mixture. The total volume was 40 ml and the temperature 25°C.

Inhibition studies. An electrometric apparatus [16] was used for all experiments, except those where the substrate was used to protect the enzymes against inhibition by sarin. In these experiments the automatic recording titrator [8] was used.

Electrometric method. Enzyme solutions and procedure. AChE: 50 mg of freeze-dried electric organs were homogenised in 20 ml of Michels' buffer, run through filter-paper Munktell No. 3 and diluted 1:20 with Michels' buffer. BuChE: 50 mg of serum fraction IV-6-3 were dissolved in 200 ml of Michels' buffer. The reaction mixtures were incubated at 25°C. The final concentration of inhibitor was the same in all experiments, 10^{-7} M eserine (experiments with BuChE) or 10^{-2} M butyrylcholine (experiments with AChE). The concentration of the substrate was varied between 10^{-1} M and 10^{-3} M.

In experiments with sarin, thiocholine or choline the inhibitor concentration causing 50 % inhibition of enzyme activity was determined for the different pairs of substrates and inhibitors. The concentration of the substrates was 8.0×10^{-3} M. Incubation was allowed to proceed for 30 min before the addition of the substrate.

Automatic recording titrator. Procedure. Reaction velocities for inhibition with sarin after protection of the enzymes by substrate were determined with 3.9×10^{-7} M (BuChE) or 1.2×10^{-6} M (AChE) sarin and the substrates acetylcholine or acetylthiocholine, 4×10^{-3} (BuChE) or 5×10^{-3} M (AChE). The method and enzyme solutions were the same as described for pS-activity curves, but 2 ml of sarin were added after about 4 min. The concentrations refer to the reaction mixture. Calculations were done analogously to Guggenheim's [17] method in all cases where the spontaneous hydrolysis of substrates and inhibitors could be neglected, but otherwise as described by Tammelin [18].

Ionic Strength. Procedure and reaction mixture. Enzyme solutions were as described for pS-activity curves. By addition of the necessary amounts of potassium chloride the ionic strength was varied between 0.10 – 0.25 M. The following reaction mixture was used: 38 ml of 0.10 M potassium chloride + 1 ml of 0.40 M acetylthiocholine bromide + 1 ml of enzyme solution + varying amounts of solid potassium chloride.

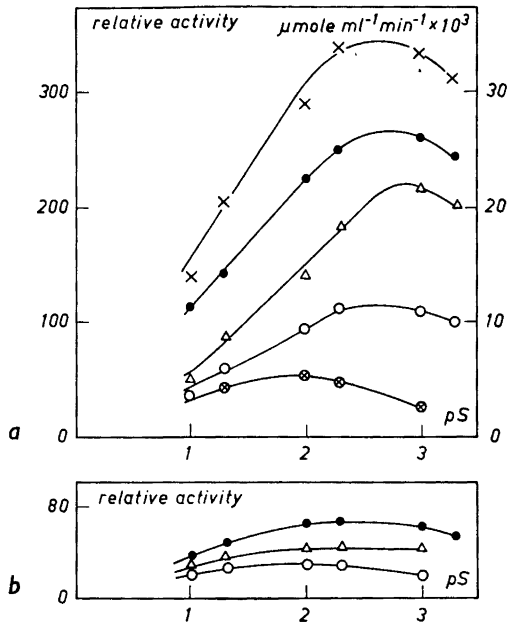

Fig. 1. Acetylcholine esterase: a. pS-Activity curves for the acetyl esters of thiocholine (●), α-methylthiocholine (○), β-methylthiocholine (△), homothiocholine (⊗) and choline (×) at pH 8.00 and 25°C. Only acetylcholine refers to the y-axis on the right hand side. b. pS-Activity curves for the propionyl esters of thiocholine (●), α-methylthiocholine (○) and β-methylthiocholine (△).

RESULTS

pS-Activity curves

Relative activities and values of maximum velocity given here are only comparable if the alcohol group in the esters is the same.

AChE. Fig. 1 shows the pS-activity curves for acetylcholine esterase and the acetyl and propionyl esters of thiocholine, α-methylthiocholine and β-methylthiocholine, and acetylcholine. Michaelis-Menten constants were not calculated, as the enzyme is inhibited by excess of substrate as seen by the decreasing activity at higher substrate concentrations. Only the right limb of each curve would have allowed calculations of the constants, and this was not obtained over a large enough substrate range. The activity values are expressed as relative activities, except for acetylcholine, as the pK_a-values for some of the products of hydrolysis, α-methylthiocholine and β-methylthiocholine, could not be determined, because these compounds were not available. Studies on the spontaneous hydrolysis of the thioesters [7] also show that secondary reactions occur with some of the products of hydrolysis. Therefore it was impossible to calculate the amount of sodium hydroxide equivalent to 1 mole of hydrolysed ester.

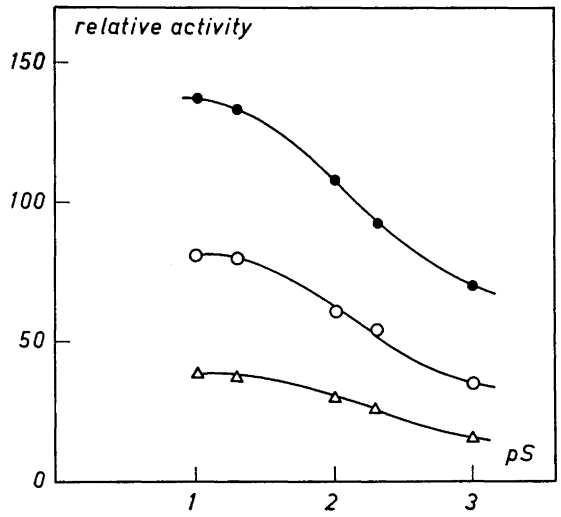

Fig. 2. Butyrylcholine esterase. pS-Activity curves for the acetyl esters of thiocholine (●), α-methylthiocholine (△) and β-methylthiocholine (○) at pH 8.00 and 25°C.

The experiments show that the catalytic effect of AChE resembles the one demonstrated for hydroxide ions [7], but decreases more rapidly with elongation of the acyl group in the ester. All acetyl esters are split easily but propionyl esters are split at a lower rate. The hydrolysis of *n*-butyryl, *iso*-butyryl, valeryl and benzoyl esters is extremely slow and not measurable with the method used. As in hydroxide-ion-catalysed hydrolysis the decreasing rate of hydrolysis with the length of the acyl group in the ester may be explained by combined steric and inductive effects of this group. The more rapid decrease in AChE-catalysed hydrolysis compared with hydroxide-ion-catalysed hydrolysis is probably caused by the importance of steric hindrance in enzyme-catalysed hydrolysis. The effect of the acyl group in the esters on the rate of AChE-catalysed hydrolysis is well known from choline esters [19]. The substrate maximum with thioesters was obtained at about the same concentration of ester as with acetylcholine, as seen in Fig. 1. The effect of substitution in the alcohol group in the esters upon the AChE-catalysed hydrolysis was also the same as observed with hydroxide ions as catalysts. All three types of esters are readily split and show the same type of curve. Homothiocholine shows a very slow hydrolysis and a somewhat different substrate curve.

BuChE: Fig. 2 shows curves obtained with butyrylcholine esterase and thioesters. When the enzyme velocity (v) is plotted against $v/[S]$ according to the Michaelis-Menten equation, expressed as

$$v = -\frac{v}{[S]} \cdot K_M + V_{max} \qquad (3)$$

the lines are not straight, just as has earlier been shown with the substrate butyrylcholine [20]. This deviation from straight lines in the Michaelis-Menten plot was explained as a sign of a possible existance of two enzymes able to split thiocholine esters as well as choline esters. One of the enzymes seems to have a fairly low substrate maximum [20] and to have reached its maximum velocity (V_{max_2}) below the substrate concentration of 10^{-3} M. Michaelis-Menten constants (K_M) and maximum velocities (V_{max}) for the BuChE-catalysed hydrolysis of the thioesters were therefore calculated from the determinations at the four highest substrate concentrations and are seen in Table 1. If there are two enzymes, then the values of the Michaelis-Menten constant are still correct for the enzyme with the highest V_{max} (V_{max_1}), because V_{max_1} is reached at the substrate concentrations used for the calculations. A subtraction of V_{max} with V_{max_2} would only cause a parallel shift of the curve obtained for the enzyme with V_{max_1}. The values of maximum velocity given in Table 1 would then be too high. It is seen from Table 1 that K_M

becomes smaller with elongation of the acyl group of the thioesters. Branching of the acyl group gives a larger constant. The benzoyl ester was not split to any measurable extent. V_{max} has its highest value for the butyryl esters and falls again before K_M becomes larger. The dependence of V_{max} from the length and shape of the carbon chain of the acyl group in the esters confirms the result obtained by, e.g., Whittaker[19] with choline esters. Elongation of the acyl group has thus the reverse effect in BuChE-catalysed hydrolysis from that in hydroxide-ion and AChE-catalysed hydrolysis, but the steric effect of the acyl group seems to be the same.

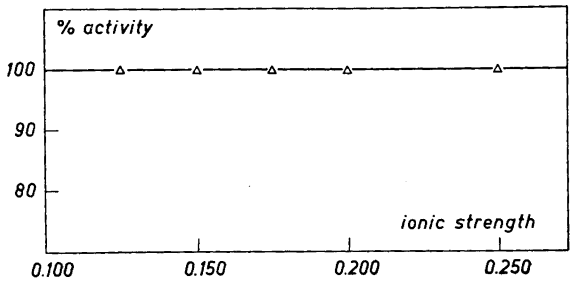

Fig. 3. Acetylcholine esterase. Dependence of enzyme activity at pH 8.00, 25°C and substrate concentration 10^{-3} M (acetylcholine) on ionic strength.

It has been observed [21] that the catalytic effect of BuChE on acetyl-β-methylthiocholine is different from its effect upon the analogous oxygen ester. It is shown here that this difference exists for all the esters examined. The K_M-values for thiocholine esters and β-methylthiocholine esters, seen in Table 1, are the same in contrast to those for the corresponding choline esters, where the β-methyl compound is known to be split at a nonmeasurable rate by BuChE. Catalysis by hydroxide ions was shown [7] to have the same effect. Only a few values for α-methylthiocholine esters are given because in the other cases it was difficult to reproduce the values. Acetylhomothiocholine was split at a nonmeasurable rate. The Michaelis-Menten constant for reaction with acetylcholine was measured for comparison and found to be $3{,}7 \times 10^{-3}$ moles $\times$ l^{-1}. The thiocholine ester is thus more easily split.

Influence of ionic strength. Varying the ionic strength between 0.10 and 0.25 M was shown to have no influence on AChE-catalysed reactions, see Fig. 3. The effect on the BuChE-catalysed hydrolysis has been demonstrated earlier [20].

Rate of hydrolysis

In a few experiments the rate of enzymic hydrolysis of the acetyl esters was measured at constant pH by determination of the amount of unhydro-

lysed ester. The curves obtained show a first order reaction with respect to ester concentration. The pseudo-first order rate constants are seen in Table 2. It is seen that AChE catalyses the hydrolysis of acetylcholine and acetylthiocholine at practically the same rate at the substrate concentration used, while BuChE is a better catalyst for acetylthiocholine.

Effect of inhibitors

Eserine and butyrylcholine. Fig. 4 shows the curve obtained with the system BuChE — acetyl-β-methylthiocholine in the presence of, or without, the inhibitor eserine, which is competitive with choline esters. These curves are representative for a competitive reaction. As expected the thioesters react with at least some of the same active groups in the enzyme as the inhibitor does. An experiment to demonstrate this with acetyl-β-methylcholine as inhibitor did not work. The affinity of this compound for BuChE was too low to show any inhibitory effect even at a high concentration (5×10^{-2} M). For AChE, butyrylcholine was used as inhibitor to demonstrate the competitive effect.

Choline and thiocholine. Table 3 shows the negative logarithm of the inhibitor concentration causing 50 % inhibition after incubation of the enzymes with choline for 30 min at 25°C and pH 8. Substrates were acetylcholine and acetylthiocholine, respectively. The higher concentration of choline necessary to inhibit the enzymes to 50 % when acetylthiocholine is used as substrate shows that thioesters have a greater affinity for BuChE than the oxygen analogues. In the case of AChE the difference in pI_{50} is very small. From the equations according to Briggs-Haldane [22] for the rate of enzyme reaction in the presence of, (eqn 4), or without, (eqn 5), a competitive reversible inhibitor

Table 3. pI_{50}- values for the inhibition of AChE and BuChE by choline or thiocholine in the presence of acetylcholine or acetylthiocholine and equilibrium constants for the inhibition of BuChE. Concentration of substrates 8×10^{-3} M. 25°C and pH 8. Incubation time 30 min.

	Enzyme

$$v = \frac{V}{1 + \frac{K_M}{[S]}\left(1 + \frac{[I]}{K_I}\right)} \quad (4)$$

$$v = \frac{V}{1 + \frac{K_M}{[S]}} \quad (5)$$

the values of the dissociation constants for the enzyme-inhibitor complex K_I could be calculated for the systems BuChE-acetylcholine-choline, BuChE-acetylthiocholine-choline and BuChE-acetylcholine-thiocholine. They are seen in Table 3.

Sarin. It was shown that after inhibition by an irreversible phosphorylating inhibitor, such as sarin, the active groups of the enzyme are blocked in such a way that no difference in the enzymic hydrolysis of oxygen esters and thioesters after inhibition can be demonstrated. This is seen from the values of pI_{50} in Table 4. When, however, the esters were used to protect the enzymes against inhibition, it could be demonstrated that the thioester was the better protector for BuChE. Acetylcholine and acetylthiocholine were found to be about equally good protectors for AChE. The results are seen in Table 5.

Effect of some organic compounds

The effect of imidazole, serine, cysteine and 2-methyloxazoline upon the hydrolysis of acetylcholine, acetyl-β-methylcholine, acetyl-β-methylthiocholine and acetylthiocholine was studied with the automatic recording titrator at pH 8.00 and 25°C. None of the compounds had any

Table 4. Concentration of sarin, expressed as the negative logarithm, causing a 50 % inhibition of the hydrolysis of the acetyl esters of choline, thiocholine, α-methylthiocholine, β-methylthiocholine and homothiocholine by the enzymes AChE and BuChE at pH 8, $t = 25°C$. Incubation time 30 min.

Substrate \ Enzyme	AChE	BuChE IV-6-3
Acetylcholine	8.80 ± 0.01	8.29 ± 0.01
Acetylthiocholine	8.93 ± 0.01	8.36 ± 0.01
Acetyl-α-methylthiocholine	8.92 ± 0.01	8.24 ± 0.005
Acetyl-β-methylthiocholine	8.92 ± 0.05	8.29 ± 0.01
Acetylhomothiocholine	8.85 ± 0.05	—

observable effect upon the hydrolysis of the choline esters, nor could any effect be noted on the hydrolysis of the thioesters by serine and methyloxazoline. Imidazole enhanced the hydrolysis of the thiocompounds about 4 times and cysteine about 50 times. The rate constants obtained with cysteine were found to be 0.144 min^{-1} for acetylthiocholine and 0.139 min^{-1} for acetyl-β-methylthiocholine. The effect of the above mentioned compounds seems to be related to the pK_a of the substances, the compound with the higher pK_a having the better hydrolytic effect. It has been pointed out by Larsson [23], that the basicity of a reagent seems to be a significant factor for its reactivity.

Table 5. Second order velocity constants for reaction of sarin with AChE and BuChE in the presence of acetylcholine iodide or acetylthiocholine iodide at pH 8.00 and 25°C.

	Enzyme			
	AChE		BuChE

DISCUSSION

The catalytic activity of esterases [24,25] is generally described as one of bifunctional type, a basic and an acid group taking part in the reaction. There are reasons to believe that the choline esterases have at least two sites in their active center [24,25], called the anionic and the esteratic sites. The anionic site seems to bind and direct substrates or inhibitors with quaternary nitrogen by means of an ionic bond. There is some evidence [24,25] that the anionic site is a carboxyl group. The hydrolytic activity of the enzyme seems to originate from the esteratic site, which seems to consist of a nucleophilic part, maybe a nitrogen atom in an imidazole ring (the basic group) and an electrophilic part, for instance the hydrogen atom in an amino group or a phenolic hydroxyl group (the acid group). The basic group in the enzyme is thought to form a covalent bond with the carbonyl carbon of a substrate, resulting in an addition complex. With the aid of the acid group in the esteratic site, which may form a hydrogen bond to the oxygen in the substrate, the combined acid-base attack upon the substrate results in the formation of an acylated enzyme.

There are several theories about the nature of the nucleophilic group. There are reasons to believe that it is an imidazole ring in histidine [10], but degradation experiments with choline esterases and other esterases show that, after inhibition with organophosphorus compounds, phosphorylated serine is always found, and no imidazole is found near the phosphorylated serine [25,26]. These findings caused a revival of a theory first suggested by M. Bergmann,

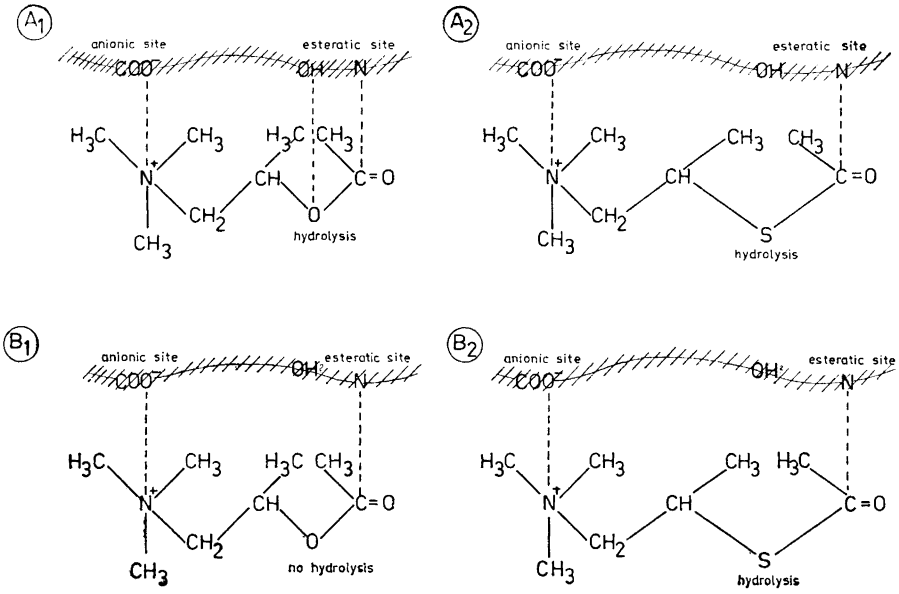

Fig. 5. Models showing attraction of choline esters (1) and thiocholine esters (2) to the surface of acetylcholine esterase (A) and butyrylcholine esterase (B). Dotted lines show points of attraction between enzymes and esters.

about the existence of an oxazoline ring formed from the aminoacid sequence aspargyl-serine [9]. However there is the possibility that the catalytically active imidazole is working near the phosphorylated serine, but situated in another part of the α-helix of the protein and therefore lost in degradation experiments.

The experiments here described confirm for *AChE* the picture of a combined acid-base attack at the enzyme and the picture of the esteratic and anionic sites and their importance and limiting effect in the orientation and binding of the substrate. The difference in radius of oxygen and sulphur and the difference in their influence upon the electrophilic properties of the carbonyl carbon seem not very important as seen from the small differences in the rates of hydrolysis and in the protection effects of the two types of esters.

Bergmann *et al.*[5] have published values for the rate of the AChE-catalysed hydrolysis of acetylcholine and acetylthiocholine at pH 7.5 and 28°C. They found that acetylthiocholine at the substrate concentration used (10^{-3} M) was split 5 times faster than acetylcholine. We were not able to confirm this result but obtained the same rate for the AChE-catalysed hydrolysis of acetylcholine and acetylthiocholine (Table 2). Our measurements were done at pH 8.0 and 25°C. To get the right value for the hydrolysis of acetylthiocholine we had to use the Hestrin method and to keep the pH constant with the automatic recording titrator, otherwise we would have obtained catalysis by buffer ions and difficulties in keeping the pH constant because of the acid properties of thiocholine ($pK_a \sim 7.7$) [7], one of the products of hydrolysis. Thiocholine would also have consumed sodium hydroxide, if the titration method had been used, or evolved CO_2, if the Warburg method had been used. Of course this latter effect would not have increased 5 times the value obtained for the rate of hydrolysis.

It may be worthwhile to discuss the shape of the pS-activity curves for AChE and substrates. The same type of curve was obtained with thioesters as substrate as with acetylcholine. The shape of the acetylcholine curve was found by some authors [5,27] to be a rather narrow bell showing maximum activity at pS around 2.25. These curves were mostly determined at pH 7.4 with the Warburg method. From our laboratory already in 1954 curves were published [28] showing a less narrow bell and an activity which still was near its maximum value at pS 3. Maximum activity was around pS 2.75 and this pS-value increased with the pH. It was observed that this type of curve was obtained as soon as the enzyme activity was measured from near the starting point of the reaction. It was clearly seen during the experiments that the activity in each determination decreased very soon if low substrate concentrations were used. The curves were at that time measured with the electrometric method at pH 8. In the meantime we have used the automatic recording titrator, which allows measurements of enzyme activity from the starting point of the reaction and the use of a second syringe [20,23] containing substrate solution to keep the concentration of the substrate constant. pS-Activity curves were measured at pH 7.5 [18] and now at 8.0 and showed the same shape as published earlier by us.

BuChE is known to be a less "specific" enzyme than AChE. The rate of hydrolysis of oxygen esters and thioesters increases, up to a certain limit,

with the length of the acyl group in the ester in spite of the inductive effects of the acyl group, when BuChE catalyses the reaction. The limit may depend on steric hindrance from the long acyl group in the formation of the enzyme-substrate addition complex. Furthermore the probably somewhat less electrophilic sulphur ester is more easily split than the oxygen analogue and is a better protector aginst inhibitors. Both hydroxide-ion- and BuChE-catalysed hydrolysis of thioesters was shown to be independent of a shielding methyl group near the ester sulphur, the hydrolysis possibly, therefore, taking place without an attack on the sulphur. It may be that BuChE is less ready to attack a substrate with the aid of an acid group than AChE and therefore able to split the thioester but not the oxygen ester. The shape of the pH-activity curve for the enzyme with acetylcholine gives no definite information concerning an acid group, because the decreasing activity at high pH [29] seems to be the result of more general protein denaturation as well as the dissociation of a functional acid group. The catalytic effect of imidazole on thioesters, but not on oxygen esters, demonstrated by Bergmann *et al.*[5] for acetylthiocholine and here for acetyl-β-methylthiocholine, demonstrates the ability of sulphur esters to split on attack of this nucleophilic group alone. That the thioesters are less susceptible to an attack by hydrogen ions than oxygen esters was demonstrated by their slower hydrolysis in acid medium.

The enzymes AChE and BuChE differ in some important way in the reaction with their substrates. Summarizing the results obtained in this and two preceding papers [6,7] the following points are found:

The thiocholine esters and their methylsubstituted analogues hydrolyse slower in acid medium than their oxygen ester analogues.

The hydrolysis of the thioesters is affected by some buffer ions, e.g. phosphate. Secondary reactions with the products of hydrolysis seem to occur in alkaline medium at least with the methylsubstituted thioesters.

The hydrolysis of the thioesters at pH 8.00 is catalysed by imidazole and enhanced by cysteine in contrast to their oxygen analogues.

The activation energies in hydroxide-ion-catalysed hydrolysis are about equal for acetylthiocholine, acetyl-β-methylthiocholine and acetylcholine, but about 33 % higher for acetyl-β-methylcholine.

Acetyl-β-methylthiocholine is split by BuChE in contrast to its oxygen analogues.

The reaction rates between AChE and acetylcholine or acetylthiocholine are about equal, but BuChE reacts faster with acetylthiocholine than with acetylcholine.

Choline and thiocholine are about equally good inhibitors for AChE, but thiocholine is a better inhibitor for BuChE.

Acetylcholine and acetylthiocholine protect AChE about equally well against sarin, but acetylthiocholine is the better protector for BuChE.

On the basis of these results one way to explain the difference between the two enzymes and their reaction with the substrates is shown in Fig. 6. A hydrogen bond is thought to exist between the enzyme and the ether oxygen to explain the shielding effect of the β-methyl group in hydroxide-ion- and enzyme-catalysed hydrolysis [7] of β-methylcholine esters. For perhaps steric reasons, BuChE is not able to create this hydrogen bond between its acid group and

the ether oxygen in β-methylcholine esters. Competition with water may occur and be unfortunate for the enzyme. The thioesters seem to be able to split without this hydrogen bond and are therefore split also by BuChE.

My sincere thanks are due to the Director of the Research Institute of National Defence, Dept. 1, Professor G. Ljunggren, to Professor A. Tiselius, Director of the Institute of Biochemistry, University of Uppsala, for their kind interest in this work, and to Docent B. Malmström, Institute of Biochemistry, University of Uppsala, for helpful discussions.

Acetate Carboxyl Oxygen (^{18}O) as Donor for Phenolic Hydroxy Groups of Orsellinic Acid Produced by Fungi

STEN GATENBECK and KLAUS MOSBACH

Institute of Biochemistry, University of Lund, Lund, Sweden

Oxygen-18 labelled sodium acetate was administered to the culture medium of the orsellinic acid producing fungus *Chaetomium cochliodes* Pall. The ^{18}O content in the carboxyl group and the hydroxy groups of orsellinic acid was determined. A high degree of incorporation was found, where the ^{18}O content of the carboxyl group was half that of each hydroxy group. These results confirm the hypothesis of a β-polyketoacid as an intermediate in the biosynthesis of orsellinic acid.

During the last five years it has been shown by several investigators [1-4] that the biogenesis of some aromatic substances proceeds by head to tail coupling of acetate units. However, from these results nothing can be said with any certainty about the intermediate steps in the course of the biosynthesis of the final aromatic substance from acetate.

Structural analysis of naturally occurring phenolic compounds proposes an intermediate of β-polyketo character [5,6]. The distribution of the oxygen atoms in for example orsellinic acid corresponds exactly to the sequence of the carbonyl groups in an unbranched β-polyketo acid (Fig. 1).

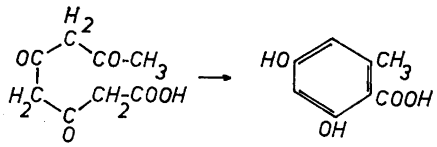

Fig. 1.

If there is a direct condensation of acetate units to the postulated β-polyketo acid, administration of ^{18}O labelled acetate to the orsellinic acid [7] producing fungus *Chaetomium cochliodes* should result in ^{18}O-labelling of the orsellinic acid.

EXPERIMENTAL

Preparation of $CH_3-{}^{14}CO^{18}ONa$. Oxygen-18 labelled water (344 mg) with 90 atom% of ^{18}O was slowly added to a slight excess of the equivalent amount of icecold acetyl chloride. The acetic acid and the hydrochloric acid formed were neutralized with 1 N NaOH by titration. To this solution 1 mC (17 mg) of ^{14}C-carboxyl labelled CH_3COONa was added. A representative sample of the mixture was evaporated to dryness and its isotope content measured.

Culture conditions. Four culture flasks, each containing 500 ml of Czapek-Dox medium, were inocculated with perithecia from *Chaetomium cochliodes* Pall. The culture medium was removed by suction after 20 days incubation at 28°C in the dark. Care was taken not to rupture the mycelium. Fresh Czapek-Dox medium and the labelled acetate were added after rinsing the mycelium twice with distilled water. The incubation was continued for further 8 days.

Isolation of orsellinic acid. The mycelium was filtered off. The culture medium after taking out a small volume for ^{18}O analysis, was acidified with HCl and extracted three times with ether. The residue (300 mg) of the evaporated ether extract was recrystallized from diluted acetic acid yielding orsellinic acid (150 mg), m.p. 176°C.

Determination of ^{14}C. A part of the dry sample of the sodium acetate mixture was combusted to CO_2 according to van Slyke and Folch [8]. The carbon dioxide was trapped in carbonate-free barium hydroxide solution. The barium carbonate formed was isolated and its radioactivity measured with a G.M.-counter. The found radioactivity was 52 600 cpm/mg C. Thus the radioactivity of the carboxyl group will be 2 × 52 600 cpm/mg C.

The same procedure was undertaken with orsellinic acid. The found radioactivity after the total combustion was 2 200 cpm/mg C. As orsellinic acid is built up by four acetate units, which has been shown by one of us (M)[9], the labelled C atoms in the molecule will contain 2 × 2 200 cpm/mg C.

Determination of ^{18}O. The analytical data of all the ^{18}O measurements are listed in Table 1.

The oxygen of the sodium acetate was isolated as carbon dioxide which was obtained after cracking the substance in the presence of heated (1 100°C) carbon and oxidation of the formed carbon monoxide with iodine pentoxide to carbon dioxide according to Unterzaucher [10]. One of the oxygen atoms in the resulting carbon dioxide will thus be derived from the test sample. The liberated iodine was fixed on a slightly heated silber gauze and the carbon dioxide flushed with nitrogen into a clear solution of octadecylamine in petroleum ether (b.p. 40–60°C). The precipitate of octadecyl carbamate was isolated by centrifugation and dried in vacuum over solid paraffine. The dry octadecyl carbamate was used directly for measurement in a masspectrometer whereby the carbon dioxide was released by heating the carbamate to about 100°C. The same procedure of isolating the oxygen as carbon dioxide has been applied throughout this work. The use of octadecylamine as absorbing agent for carbon dioxide has been introduced by Ehrensvärd [18]. This method has turned out to be most convenient for ^{18}O determinations.

The spared test sample of the culture medium was distilled. A few milligrams of the water were taken out, transformed to carbon dioxide in the same way as described above and the ^{18}O content measured.

The average ^{18}O content of orsellinic acid was determined from 5 mg of the substance.

For decarboxylation of the orsellinic acid, 30 mg were heated in a stream of nitrogen in a quartz tube at 180°C for 20 min. The formed carbon dioxide was driven over into a solution of octadecylamine in petroleum ether and its ^{18}O content measured.

The residue consisting of orcinol, shown to be pure by paper chromatography, was analyzed for the ^{18}O amount in the two remaining hydroxy groups.

RESULT AND DISCUSSION

The data in Table 1 show that the ^{18}O from the administered acetate has been incorporated to a high degree in orsellinic acid.

This confirms the hypothesis of direct condensation of activated acetate units to orsellinic acid. Furthermore, a condensation of the acetate *via* acetyl-

Table 1. ^{18}O and ^{14}C analysis.

Samples analyzed	Average ^{14}C- radio-activity	Radio-activity of labelled C-atoms	^{18}O-content	^{18}O-content	$^{18}O/^{14}C \times 10^4$	Dilution ^{18}O *versus* ^{14}C
	cpm/mg C	cpm/mg C	atom %	atom % excess		
Standard			0.20	0.00		
Sodium acetate	52 600	105 200	33.20	33.00	3.13	1
H_2O (culture medium)			0.20 (3)	0.00 (3)		
Orsellinic acid	2 200	4 400	0.72	0.52		
Carboxyl group		4 400	0.59	0.39	0.89	3.6
Orcinol		4 400	0.92	0.72	1.64	1.9

coenzyme A should end up in a hydrolysis of the terminal thiolester. The atom % excess of ^{18}O in the carboxyl group should then be half that of the hydroxy groups in the orsellinic acid. This is also confirmed by our experiment (COOH: 0.39 atom % excess; OH: 0.72 atom % excess ^{18}O).

By comparing the radioactivity in the carboxyl group of the original sodium acetate with that in orcinol a dilution of 24 times is observed whereas the ^{18}O excess of the carboxyl group is diluted 46 times. The ratio $^{14}C/^{18}O$ dilution is almost 1:2 giving place for speculations since the activation of the acetate through the adenosine triphosphate-coenzyme A system would not give rise to dilution of the acetyl oxygen unless there is hydrolysis of the intermediates. Of course there is the possibility of exchange of the oxygen with water before activation of the acetate. Nevertheless, the ratio 1:2 invites one to think of an organized exchange of the acetyl oxygen. It could be explained by a hydratization of one of the intermediates or there could be an hitherto unknown intermediate step in the course of acetate activation.

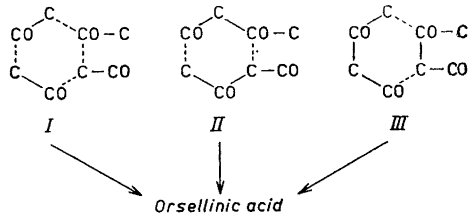

Fig. 2. Alternative pathways of the condensation of acetate to orsellinic acid. I. Successive condensation of acetyl-coenzyme A. II and III. Two different ways of formation of orsellinic acid from acetoacetyl-coenzyme A.

The condensation of the acetate units to orsellinic acid may proceed in one of two possible ways, either by successive condensation of four C-2 units presumably acetyl-coenzyme A or by coupling of two C-4 compounds like acetoacetyl-coenzyme A (Fig. 2). The alternative that a β-polyketo unit underlying the synthesis of orsellinic acid is formed by an oxidative mechanism acting upon a long chain fatty acid could be excluded, since in that case the oxygen atoms entering in successive β-positions should be nonlabelled in view of the very low ^{18}O content of the water in the culture medium (0.003 atom % excess).

It is reasonable to draw a parallel between orsellinic acid and fatty acid synthesis. In the first case the acetate condensation stops at the keto level whereas in the fatty acid synthesis the keto stage is further reduced *via* a DPN-system.

The high degree of incorporation of the ^{18}O from the acetate into the phenolic hydroxy groups of orsellinic acid seems to be promising for a further use of this procedure as a common method of distinguishing between oxidatively and non-oxidatively formed hydroxy groups in compounds derived from acetic acid.

The authors are much indebted to Prof. G. Ehrensvärd for valuable discussions and to Dr. C. Karrman for putting the resources of his analytical department at our disposal.

Amino Acid Studies. Part II.* Structure and Synthesis of Albizziine (L-2-Amino-3-ureidopropionic Acid), an Amino Acid from Higher Plants**

ANDERS KJÆR and P. OLESEN LARSEN

Organic Chemical Laboratory of the Royal Veterinary and Agricultural College, Copenhagen, Denmark

Albizziine is an amino acid, recently isolated from various species of the botanical family *Mimosaceae*. The suggested structure, L-2-amino-3-ureidopropionic acid (I), has now been unequivocally established by comparison of N-benzoylalbizziine methyl ester with a synthetic specimen of methyl L-2-benzamido-3-ureidopropionate (III).

A simple and satisfactory synthesis of L-albizziine from L-2,3-diaminopropionic acid has been developed, based on temporary masking with cupric ions of the 2-amino-grouping during carbamylation at the desired 3N-position. The same procedure has been applied in the preparation of DL-albizziine. L-2-Ureido-3-aminopropionic acid (II), the positional isomeride of L-albizziine, has been synthesized for comparison purposes.

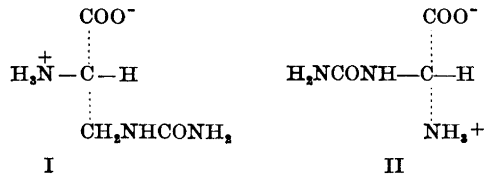
Various observations relating to the acid hydrolysis and biogenesis of albizziine are briefly discussed.

Albizziine constitutes a recent addition to the rapidly increasing class of free amino acids occurring in higher plants (for a summary *cf. e.g.* Ref.[1]). It was discovered in and isolated from seeds of the botanical species *Albizzia julibrissin* Durazz. by Gmelin *et al.*[2]. The same authors demonstrated commercially available seed material of the species *Albizzia lophantha* Benth. to be an alternative and satisfactory source of albizziine and provided paper-chromatographic evidence for the presence of the new amino acid in several other species of the same or related genera, all belonging to the family *Mimosaceae* [2]. Still more recently, Gmelin *et al.*[3] listed additional sources of albizziine and mentioned *Enterolobium cyclocarpum* as a particularly rich source. The elementary composition [2,3], positive reaction with ninhydrin and Ehrlich's reagent [2], and the products formed upon acid hydrolysis [3], suggested that

* The communication which appeared in *Experientia* 15 (1959) 253 should be regarded as Part I of this series.

** Presented in abstract before the 10th Meeting of Scandinavian Chemists in Stockholm, Sweden, August 1959.

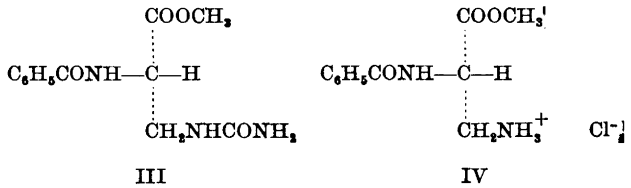
albizziine was L-2-amino-3-ureidopropionic acid (I), although the isomeric structure (II) was not incompatible with the available evidence [3].



I II

In a preliminary communication from this laboratory [4], (I) has been unequivocally established as the correct structure for albizziine. It is the purpose of the present paper to expand on the structure determination, as well as to describe a single-step synthesis of albizziine from L-2,3-diaminopropionic acid. Furthermore, various observations in connexion with the acid hydrolysis of the latter will be discussed.

Upon benzoylation in aqueous carbonate solution, albizziine yielded an oily derivative which, however, could be transformed into a crystalline methyl ester on treatment with diazomethane. The identity of the ester as methyl L-2-benzamido-3-ureidopropionate (III) was established upon critical comparison with an unambiguously synthesized specimen.



III IV

The latter was produced by interaction at pH 7 of potassium cyanate and *levo*rotatory methyl 2-benzamido-3-aminopropionate hydrochloride (IV). Synthesis of this was achieved essentially as described by Schneider [5] through a series of reactions departing from configurationally known L-asparagine and involving the preparation of L-2,3-diaminopropionic acid. Additional and independent corroboration of the L-configuration of (IV) was available through its experimentally established relationship with L-serine [5]. The above transformations unequivocally established the projection formula (I) as the correct expression for albizziine.

The formally simple structure of albizziine rendered the development of a synthesis of this lower homologue of L-citrulline a logic extension of the structure determination. L-2,3-Diaminopropionic acid offered itself as a suitable starting material, and attempts were consequently directed towards selective carbamylation of its terminal amino-grouping. From analogous cases it appeared natural to proceed *via* selective protection of the 2N-grouping, carbamylation at the 3N-position and, eventually, removal of the protecting group under mild conditions. Apart from its circumstantial character this approach, however, suffered from the disadvantage that no 2N-monoacylated derivatives of

diaminopropionic acid had ever been prepared by direct acylation *. From theoretical considerations this should, in principle, be possible by direct acylation under controlled conditions [6]; steric factors may, however, be responsible for the failure in effecting the process as desired.

An alternative approach, based on Hofmann-degradation of a suitable N-acyl-L-asparagine and introduction of the carbamido-grouping into the 3-amino-substituent of the 2N-acylated intermediate, ultimately followed by removal of the acyl-group, constitutes a variant of a method formerly employed in the synthesis of L-2,3-diaminopropionic acid [8,5]. Though this approach seemed promising in principle **, a route involving fewer steps still appeared desirable. Hence, attention was directed towards the possibility of introducing a carbamido-grouping into L-2,3-diaminopropionic acid selectively and in a single reaction step.

First, the diamino-acid was subjected to reaction with potassium cyanate in a series of experiments in which the relative amounts of reactants, as well as the pH-value of the solutions, were varied. As estimated from paper chromatography ***, mixtures of the isomerides, (I) and (II), were consistently obtained, accompanied by varying amounts of the 2,3-diureido-derivative; the latter appeared on the chromatograms as Ehrlich-positive, ninhydrin-negative spots possessing higher R_F-values than the monosubstituted products. Clearly, masking of the 2-amino-grouping was required to secure a homogeneous reaction product.

In the synthesis of ω-acylated derivatives of 2,ω-diaminocarboxylic acids, copper complexes have often proved very useful. Thus, Kurtz [10] prepared DL-citrulline from urea and the copper complex of ornithine, a procedure subsequently extended by the same author [11] to include syntheses of L-citrulline, DL- and L-2-amino-6-ureidohexanoic acid, as well as DL- and L-2-amino-4-ureidobutyric acid. More recently, Smith [12] modified the synthesis of L-2-amino-4-ureidobutyric acid, L-citrulline and L-2-amino-6-hexanoic acid from urea or cyanate and the appropriate 2,ω-diamino acids. In the 2,4-diaminobutyric acids, the two amino groupings are sufficiently close to form an alternative site of complex formation, as evident from the strong complexing action between cupric ions and 1,3-diaminopropane. Still, however, the 1,2-complex must be present, in view of the successful preparation of the 4-ureido-

* Several years ago, one of us (A.K.) demonstrated monocarbobenzoxylation of DL-diaminopropionic acid to take place exclusively at the 3N-position [6]. However, recent reinvestigation of the mono-derivative has revealed its content of a slight amount of the 2N-isomeride. The alternative course, leading predominantly to the latter and suggested as prevalent in a less alkaline environment, has not since been experimentally verified [6]. Lately, Poduška *et al.* [7] demonstrated that DL-diaminopropionic acid upon treatment with tosylglycyl chloride afforded the 3N-tosyl-glycyl-derivative.

** After the conclusion of the present work, we were privately informed that Dr. J. Rudinger, Institute of Chemistry, Czechoslovakian Academy of Science, Prague, has, in actuality, synthesized L-2-amino-3-ureidopropionic acid (I) along similar lines, utilizing the tosyl-derivative of L-asparagine. Specimens of his synthetic material, natural albizziine, and a sample synthesized in this laboratory as described below, were all found to possess coinciding infra-red spectra.

*** For the present purpose a general paperchromatographic method was devised [9], according to which 2-monoaminocarboxylic acids can be distinguished from other ninhydrin-positive compounds. Thus, the isomeric aminoureidopropionic acids, (I) and (II), can be individually recognized by this procedure.

derivatives. The copper complexes of 2,3-diaminopropionic acid have been studied by Ley and Hegge [13]. Visually these authors noticed a red-violet colour of the copper complex of this acid, deviating from that given by ordinary 2-amino-acids and hence attributed to participation of the 3-amino-grouping. On acidification, the colour changed to a bluish-purple, characteristic for the ordinary 2-amino-acids. From the comprehensive studies of Albert [14,15] on copper complexes of amino acids it can be inferred that the deviating properties exhibited by 2,3-diaminopropionic and 2,4-diaminobutyric acid must be ascribed to their contents of terminal amino-groups, in sufficient proximity to the other active site to permit additional complex formation of a different type. Calculations, based on the quantitative treatment of Albert (*l.c.*), suggested that in the pH-range 3—5, ionic species containing a positively charged amino group in 3-position should be predominant and, hence, selective carbamylation feasible. Explorative experiments indicated that this was, in fact, the case. The individual runs were controlled by paper chromatography in acid solvent systems, in which the copper complexes are sufficiently dissociated to permit the free amino acids to migrate (*cf.* Ref.[16]). Development of the chromatograms were performed with Ehrlich's reagent as well as with ninhydrin according to the modification devised in this laboratory [9]. Best results were obtained when a solution of L-2,3-diaminopropionic acid hydrochloride and half a molecular proportion of cupric sulphate was maintained at pH 5 and 58° during the slow addition of a large excess of potassium cyanate. The soluble copper complex of the reaction product was then decomposed by hydrogen sulphide, the resulting amino acids absorbed on an acid exchange resin, and finally isolated by elution with ammonia. On addition of ethanol, albizziine, uncontaminated with the isomeride (II), separated in about 50 % yield. The usual procedure for the preparation of copper complexes of 2-amino acids consists in boiling the latter with excess cupric oxide or carbonate. In the present case, however, it was observed that considerable quantities of the desired complex was lost by adherence to the excess of solid reagents, and it was found advantageous and convenient to form the complex simply by adding a soluble copper salt to the amino acid solution. Most likely, this modification could be employed also in other, analogous cases. On critical comparison, the pure, synthetic compound proved indistinguishable from natural albizziine. The infra-red spectrum is presented in Fig. 1.

The new plant amino acid possessed a surprisingly high *levo*rotation in water ($[\alpha]_D^{22} - 67°$), yet displaced towards more *dextro*rotatory values on acidification in accordance with the Lutz-Jirgenson rule for L-2-amino acids [17]. Table 1 presents a collection of rotatory values for the next higher homologues, measured under identical conditions. The numerically high rotation of albizziine probably reflects a strong vicinal influence from the carbamido-grouping.* The isomeride (II) is seen to deviate principally from the 2-amino-acid derivatives in its rotatory pattern.

* Through the courtesy of Dr. W. Klyne, Postgraduate Medical School, London, the rotatory dispersion curves of L-albizziine and the higher homologues of the same configurational series have been determined over the wave-length range 290—600 mμ. Whereas in aqueous solution the latter all possess similar, plain and positive curves, L-albizziine exhi-

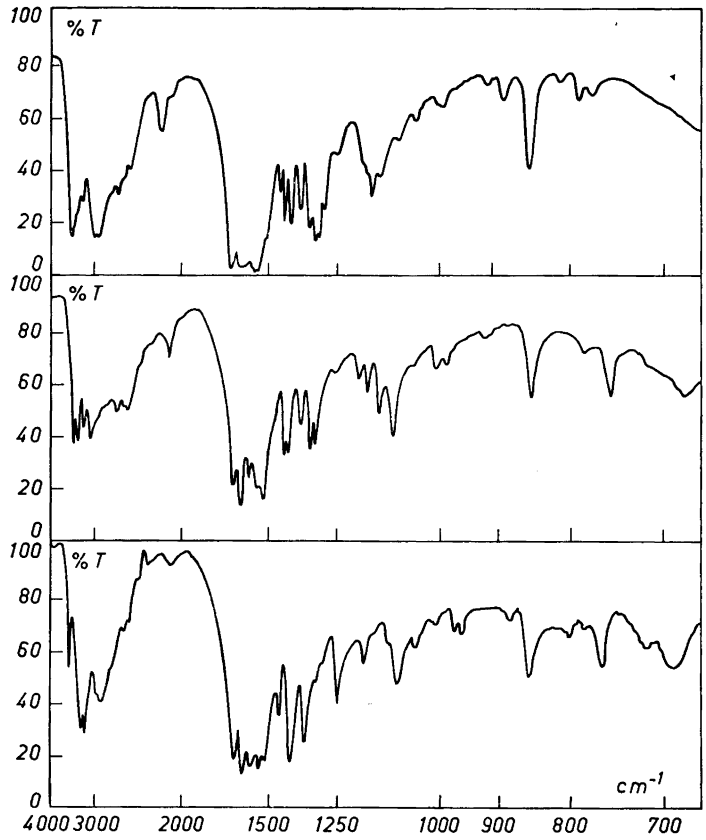


Fig. 1. Infra-red spectra, determined in potassium bromide discs. Upper curve: natural L-albizziine (I); middle curve: racemic albizziine; lower curve: the L-albizziine-isomeride (II) (L-2-ureido-3-aminopropionic acid).

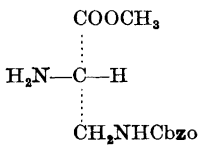
The synthesis of DL-2-amino-3-ureidopropionic acid (DL-albizziine) from DL-2,3-diaminopropionic acid hydrobromide was achieved as described above for the L-series, with the sole exception that the intermediate copper complex was slightly soluble and therefore separated during preparation. Again, racemic albizziine was considerably less soluble in water than the natural isomeride and possessed a distinctly different infra-red spectrum in the solid state (Fig. 1).

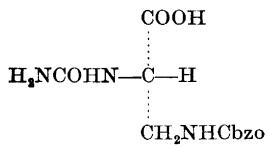
During the present studies it became of interest to synthesize L-2-ureido-3-aminopropionic acid (II), the positional isomeride of albizziine. Carbobenz-

bits an almost mirror image-formed, negative curve. This pattern is a telling illustration of the frequently observed, dramatic influence of chromophores in positions adjacent to an optically active centre and of the caution required in interpreting dispersion curves devoid of Cotton effect. In acid and alkali the deviations are less conspicuous.

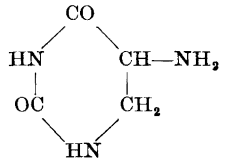
oxylation of the hydrochloride of L-2,3-diaminopropionic acid at pH 7 proceeded to give a homogeneous mono-derivative, transformed by diazomethane into an ester, which was proved to be methyl L-2-amino-3-benzyloxycarbamido-propionate (V, Cbzo = $C_6H_5CH_2OCO$) upon comparison with an authentic specimen, synthesized as described by Schneider [5]. Hence, the monocarbobenzoxylated L-diaminopropionic acid carried the acyl-grouping in 3N-position.



V



VI



VII

Reaction of the latter acid with potassium cyanate afforded crystalline L-2-ureido-3-benzyloxycarbamidopropionic acid (VI, Cbzo = $C_6H_5CH_2OCO$) which, on hydrogenolysis, yielded (II). On paper chromatograms, run in several solvent systems, this albizziine-isomeride migrated at virtually the same rate as albizziine but could be distinguished from the latter by its much weaker and slower ninhydrin-reaction or, still better, by its deviating behaviour when treated with copper salt and ninhydrin according to the method developed in this laboratory [9]. Both albizziine and (II) yielded, as expected, the same positive Ehrlich-reaction, but clearly deviated in their rotations (Table 1) and infra-red spectra (Fig. 1).

Table 1. Molecular rotation of L-albizziine and various homologues, determined in this laboratory.

[a] Gornall, A. G. and Hunter, A. *Biochem. J.* **33** (1939) 170. [b] In 0.1 N HCl.

In course of their degradation studies on albizziine, Gmelin *et al.*[3] isolated 2,3-diaminopropionic acid hydrohalides of lower specific rotation than previously recorded, subsequent to hydrolysis with strong mineral acid. The authors suggested acid-induced racemization of L-diaminopropionic acid as a likely explanation, an assumption which has now been confirmed in this laboratory. Upon heating at 125° the specific rotation of a solution of L-2,3-diaminopropionic acid hydrochloride in 48 % hydrobromic acid decreased from an initial value of 19.3° to 1.2° in the course of 6 h. Paper chromatography confirmed that no extensive decomposition was responsible for the loss in rotatory power. On the other hand, paperchromatographic analysis of an acid hydrolysis mixture of albizziine as a function of time suggested the concomitant or intermediate formation of a ninhydrin-positive product with higher R_F-values, possibly one of the unknown 5-aminodihydrouracils (VII). The obviously limited formation of this cyclized product is in marked contrast to the customary, and usually very facile cyclodehydration of 3-ureido-substituted carboxylic acids [18,19]. Possible explanations for this fact, supplemented by a detailed investigation of the albizziine hydrolysis, will be presented in a forthcoming communication.

A possible relationship between albizziine and a hydrouracil derivative merits further consideration in connexion with reflections on the biogenesis of the former. Formally, it recalls the well-established biosynthesis in animals and microorganisms of the uracil ring from ureidosuccinic acid *via* dihydroorotic and orotic acid. In lack of evidence to the contrary, however, albizziine may equally well, if at all, be on the pathway of reductive pyrimidine degradation [20]. A different biochemical perspective in connexion with the occurrence of albizziine is suggested by its formal similarity with citrulline, a key compound in the formation of arginine and urea, or decomposition products of the latter, in mammalian tissues and certain microorganisms. In this connexion, the recent establishment by Gmelin *et al.*[3] of the occurrence of free L-2,3-diaminopropionic acid, a formal analogue to L-ornithine, in seeds of *Mimosa Palmeri* and *M. hemiendyta* of the family *Mimosaceae*, appears particularly interesting. Botanically, these species are close allies of the known albizziine-producing plants and it may well be that the new amino acids within this family are results of a particular and interesting enzymic mechanism.

EXPERIMENTAL

Melting points are uncorrected and determined in an electrically heated block. Rotations are measured in a 1 dm tube at the D-line. Infra-red spectra of all the compounds described have been determined in potassium bromide pellets on a Perkin-Elmer "Infracord"-instrument.

N-Benzoylalbizziine methyl ester. To a cooled and stirred aqueous solution of albizziine* (149 mg) and anhydrous soda (285 mg), a total of 0.175 ml of benzoyl chloride was added in small portions. Extraction with ether, acidification, extraction with pentane, and treatment of the aqueous phase with Norite gave a solution from which the reaction product was removed by extraction with ethyl acetate. The colourless, glassy product was

* The specimen employed was isolated from seeds of *Albizzia lophantha* Benth. according to the procedure of Gmelin *et al.* [2] and had an $[\alpha]_D^{23}$ of —67.0° (*c* 2.1, H_2O).

dissolved in anhydrous methanol and treated with excess diazomethane. Evaporation of the solvent and trituration of the residue with pentane yielded the crystalline ester (78 mg) which was recrystallized twice from water before analysis (15 mg), m. p. 171—174° (decomp.). (Found: C 54.40; H 5.68; N 15.89. Calc. for $C_{12}H_{15}N_3O_4$: C 54.33; H 5.70; N 15.84.) A slightly impure specimen, isolated from the mother liqour, had the rotation value $[\alpha]_D^{21}$ −30° (*c* 1.0, CH_3OH). The infra-red spectrum of the pure product was indistinguishable from that of the synthetic specimen described in the sequel.

Synthetic methyl L-*2-benzamido-3-ureidopropionate* (III). A sample of methyl L-2-amino-3-benzyloxycarbamidopropionate hydrochloride * (488 mg) was benzoylated according to Schneider [5] to give *methyl* L-*2-benzamido-3-benzyloxycarbamidopropionate* (480 mg). An analytical specimen separated from chloroform as colourless needles, m. p. 98.5—99.5°, $[\alpha]_D^{28}$ −17.3° (*c* 1.2, CH_3OH). (Found: C 63.85; H 5.67; N 7.74. Calc. for $C_{19}H_{20}N_3O_5$: C 64.04; H 5.66, N 7.86.) Literature value [5]: m. p. 102°, (no rotation reported). Again, decarbobenzoxylation was performed with hydrogen and palladium black as described [5]. It was found advantageous, however, to run the reaction at 40°. *Methyl* L-*2-benzamido-3-aminopropionate hydrochloride* (IV) was obtained in 80 % yield as colourless crystals, m. p. 171—174° (decomp.), $[\alpha]_D^{30}$ −48.3° (*c* 1.0, CH_3OH). (Found: C 51.10; H 5.87; N 10.67. Calc. for $C_{11}H_{15}N_3O_3$, HCl: C 51.06; H 5.84; N 10.83.) Literature value [5]: m. p. 179° (decomp.), (no rotation reported).

A solution of (IV) (130 mg) and potassium cyanate (113 mg) in water (3 ml) deposited, in the course of 3 h, a crystalline product the amount of which was increased (to 92 mg) upon concentration. A pure specimen of *methyl* L-*2-benzamido-3-ureidopropionate* (III) (69 mg) separated from water as clusters of colourless needles, m. p. 172—173.5° (decomp.), alone or in admixture with the methyl ester of N-benzoylalbizziine described above. $[\alpha]_D^{28}$ −32.5° (*c* 1.2, CH_3OH). The infra-red spectra of the two specimens were identical and possessed all the bands expected.

Synthesis of L-*albizziine* (I). A solution of L-2,3-diaminopropionic acid hydrochloride ** (300 mg) and cupric sulphate (2.2 ml of a 0.5 M solution) in water (28 ml) was brought to pH 5 by addition of 2 N NaOH. The stirred solution was kept at 58° and placed in a pH-stat, preset to maintain a constant pH of 5 by automatic addition of 4 N HCl during the introduction of a solution of potassium cyanate (430 mg in 4.8 ml) in the course of 100 min. At the end of another 100 min, the colour had changed from an initial reddish-violet to a bluish-purple and the HCl-consumption was very slow. The solution was then treated with hydrogen sulphide and filtered. The combined filtrate and washings (200 ml) were percolated through a column containing a cation exchange resin (Zeokarb 215, packing volume: 100 ml) in the acid form. The column was washed with water, and the amino acids eluted by means of 2 % ammonia. Evaporation of the eluate afforded crystalline needles (255 mg), consisting of reasonably pure albizziine. Two recrystallizations from aqueous ethanol afforded pure L-albizziine (150 mg), m. p. 206—211° (decomp.), alone or when mixed with a natural specimen, $[\alpha]_D^{26}$ −66.0° (*c* 2.0, H_2O). The infra-red spectrum was identical with that of a natural sample of albizziine [3] (Fig. 1).

Synthesis of DL-*albizziine.* When a solution of DL-2,3-diaminopropionic acid hydrobromide (555 mg) was processed as described for the corresponding L-isomeride, the light-blue copper complex (273 mg) separated and was filtered off. After decomposition with hydrogen sulphide and evaporation of the resulting solution, a crystalline residue (239 mg) was obtained. It was recrystallized twice from aqueous ethanol to give prisms of pure DL-albizziine (138 mg), m. p. 210—216° (decomp.). (Found: C 32.30; H 6.29; N 28.28. Calc. for $C_4H_9N_3O_3$: C 32.65; H 6.17; N 28.56.) The infrared spectrum (Fig. 1) deviates distinctly from that of the optical isomeride.

L-*2-Amino-3-benzyloxycarbamidopropionic acid.* To a cooled and stirred solution of L-2,3 diaminopropionic acid hydrochloride (1.41 g) in a phosphate buffer of pH 7 (15 ml, 1/15 M) and water (10 ml), a toluene solution (1.9 ml) containing 11 mequiv. of carbo-

* The sample employed was prepared as formerly described [5] and had the rotation $[\alpha]_D^{21}$ —4.2° (*c* 2.0, H_2O); (no rotation was previously recorded).

** The diamino-acid employed was isolated from seeds of *Mimosa Palmeri* as described by Gmelin *et al.*[3] and had the rotation value $[\alpha]_D^{24}$ + 24.8° (*c* 4.7, 1 N HCl).

benzoxy chloride was gradually added in the course of 1 h. Intermittent addition of 1 N NaOH served to maintain the pH-value at 6.5—7. After standing for 2.5 h at room temperature the solution was cooled. The crystalline precipitate was filtered off and washed with ice-cold water and ether. The carbobenzoxy-derivative (1.85 g) separated from water in colourless needles, m. p. 227—229° (decomp.), $[\alpha]_D^{21}$ −18.7° (*c* 1.0, 1 N HCl); $[\alpha]_D^{18}$ −4° (*c* 1.1, 0.1 N NaOH). (Found: C 55.45; H 5.80; N 11.80. Calc. for $C_{11}H_{12}N_2O_4$: C 55.45; H 5.92; N 11.76.) The specimen proved to be uncontaminated with the 2N-acylated isomer when tested by our spot test technique [9].

That the carbobenzoxy-group had entered the L-2,3-diaminopropionic acid in 3N-position appeared from the transformation of the above carbobenzoxyacid into the corresponding methyl ester hydrochloride. The acid (96 mg) was suspended in anhydrous methanol (2 ml) and treated with an excess of ethereal diazomethane. After filtration and evaporation an oil was obtained which upon solution in methanol and addition of methanolic HCl yielded an ester hydrochloride (36 mg) which was recrystallized from methanol and ether; m. p. 161—162° (decomp.), alone or in admixture with a specimen of *methyl* L-*2-amino-3-benzyloxycarbamidopropionate hydrochloride* (V) prepared as described by Schneider [5], who reported the m. p. 164°. Furthermore, the infra-red spectra of the two preparations were completely identical.

L-*2-Ureido-3-benzyloxycarbamidopropionic acid* (VI). A solution of the above described L-2-amino-3-benzyloxycarbamidopropionic acid (875 mg) and potassium cyanate (1 440 mg) in water (100 ml) was boiled under reflux for 20 min. After concentration to 30 ml and ether extraction, acidification with conc. HCl to pH 3 and cooling caused the ureido-acid to separate in crystalline form (721 mg), m. p. 181—182° (decomp.), $[\alpha]_D^{17}$ −1.5° (*c* 1.0, 0.1 N NaOH). A specimen was recrystallized twice from water before analysis, m. p. 188—190° (decomp.). (Found: C 51.10; H 5.58; N 15.01. Calc. for $C_{12}H_{15}N_3O_5$: C 51.24; H 5.38; N 14.94.)

L-*2-Ureido-3-aminopropionic acid* (II). A suspension of palladium black (90 mg) in a solution of the carbobenzoxy-acid (VI) (500 mg) in 50 % methanol (50 ml) was kept at 50° while a stream of hydrogen was passed through, until the production of CO_2 ceased. After filtration and concentration of the filtrate, the latter was treated with Norite, and ethanol was cautiously added, resulting in separation of needles of the colourless ureido-acid (II) (225 mg). A sample for analysis was recrystallized twice from water by addition of ethanol, m. p. 204—210° (decomp.); $[\alpha]_D^{25}$ +3.2° (*c* 1.0, H_2O), $[\alpha]_D^{25}$ −43.0° (*c* 1.0, 0.1 N HCl), $[\alpha]_D^{27}$ +24.6° (*c* 1.0, 0.1 N NaOH). (Found: C 32.75; H 6.24; N 28.70. Calc. for $C_4H_9N_3O_3$: C 32.65; H 6.17; N 28.56.) The infra-red spectrum of this albizziine-isomeride is reproduced in Fig. 1.

Racemization of L-*2,3-diaminopropionic acid.* A solution in constantly boiling hydrobromic acid of L-2,3-diaminopropionic acid hydrochloride, with an initial rotation of $[\alpha]_D^{20}$ +19.3° (*c* 1.6), was heated at 125° in a closed vessel. After 4 h, the rotation had decreased to $[\alpha]_D^{23}$ +4.6° (*c* 1.6) and at the end of 6 h a rotation of $[\alpha]_D^{21}$ +2° (*c* 1.6) indicated almost complete racemization. Upon paper chromatography only one spot was observed, *viz.* that of 2,3-diaminopropionic acid.

The authors are grateful to their former research associate, Dr. R. Gmelin, for the gift of an albizziine specimen as well as various seed samples. Thanks are due also to Professor S. Bergström who provided us with useful reference samples of various citrulline-homologues and to Dr. J. Rudinger for advance information on his synthesis of albizziine. Microanalyses were performed by Mr. P. Hansen at the Chemical Laboratory of the University of Copenhagen.

Grants from *The Research Council of the Technical Sciences, (Det Teknisk-Videnskabelige Forskningsråd)* and *The Carlsberg Foundation Stipendium for the Royal Veterinary and Agricultural College (Carlsbergfondets Legat for Den Kgl. Veterinær- og Landbohøjskole)* for the acquisition of the employed infra-red and potentiometric equipment, respectively, are gratefully acknowledged.

*iso*Thiocyanates XXXVI. * (+)-4-Methyl-2-oxazolidinethione, the Enzymic Hydrolysis Product of a Glucoside (Glucosisymbrin) in Seeds of *Sisymbrium austriacum* Jacq.

ANDERS KJÆR and BO W. CHRISTENSEN

Organic Chemical Laboratory of the Royal Veterinary and Agricultural College, Copenhagen, Denmark

Previous reports on the presence of *iso*thiocyanates and their parent glucosides in various species of the cruciferous genus *Sisymbrium* are discussed.

Paperchromatographic evidence for the presence of three new *iso*thiocyanate glucosides (A, B and C) in seeds of *Sisymbrium austriacum* Jacq. is presented. Upon enzymic hydrolysis the glucosides A and B afford substituted 2-oxazolidinethiones, probably originating in initially formed and spontaneously cyclizing β-hydroxysubstituted *iso*thiocyanates, different from those formerly recognized. Glucoside C, the structure of which has yet to be established, appears to furnish a non-cyclizing mustard oil.

By synthesis of its antipode, the heterocyclic enzymic hydrolysis product produced from glucoside A is proved to be the hitherto unknown (+)-4-methyl-2-oxazolidinethione (V) of established absolute configuration. This represents the first example of a naturally derived 4-substituted 2-oxazolidinethione. The nature of glucoside B is being investigated at the present.

Certain configurational and biogenetical implications are briefly discussed.

The cruciferous genus *Sisymbrium* is of nearly cosmopolitan distribution and comprises about 80 individual species, a few of which have formerly been quoted as sources of *iso*thiocyanate glucosides. Thus, Lepage [1] in 1846 reported on the presence of a mustard oil-producing glucoside in seeds of *S. officinale* Scop.** A few years ago, Schultz and Gmelin [2] recorded paperchro-

* Presented in abstract before the 10th Meeting of Scandinavian Chemists, August 1959, in Stockholm, Sweden.

Part XXXV of this series: *Acta Chem. Scand.* **13** (1959) 851.

** Another species cited by the same author as a glucoside source, *S. cheiranthoides* Et. et W., is more commonly recognized as *Erysimum cheiranthoides* L.

Like several cruciferous genera that of *Sisymbrium* represents a far from well-defined collection of taxa. Numerous species, at one time regarded as belonging to the genus *Sisymbrium* have subsequently been transferred to other genera and *vice versa*, a fact which calls for attention in chemotaxonomic considerations.

matographic evidence for the presence of sinigrin in fresh plants of *S. officinale* and *S. Loeselii*, a finding which was later supplemented by data indicating the occurrence of the same glucoside also in seeds of the former species [3,4]. Paper chromatography of seed material of *S. strictissimum* revealed a content of two glucosides, tentatively interpreted [5] as glucoputranjivin * and glucocochlearin. In this laboratory the latter assignment was supported by independent studies of volatile mustard oils liberated from seed of *S. strictissimum* L., indicating their identity as *iso*propyl and *sec.*-butyl *iso*thiocyanate [6]. In seed material of the common weed, *Sisymbrium sophia* L.**, the presence of sinigrin was established by formation of paperchromatographically identified N-allylthiourea subsequent to enzymic hydrolysis and ammonia treatment of the liberated mustard oil. Fresh plants of *S. luteum* (Maxim) O. E. Schulz, on the other hand, were found to be devoid of volatile mustard oils [6].

In the course of systematic studies in this laboratory on the distribution of *iso*thiocyanate glucosides in a large number of plant species, the presence of three strong glucoside spots were noticed upon paper chromatography of a methanolic seed extract of *Sisymbrium austriacum* Jacq.*** Paperchromatographic experiments, conducted in various solvent systems and in the presence of several authentic reference glucosides, suggested that the three compounds (A, B and C) were different from all mustard oil glucosides previously encountered in Nature (*cf.* Refs. [7,8]). In butanol:ethanol:water (4:1:4), glucoside A migrated slowly, corresponding to an R_B-value [4] of 0.34, whereas compound B possessed an R_B-value of 0.59. The third glucoside (C) was much more lipophilic (R_B 1.67). Two additional, but weaker spots, located between compounds B and C, were possibly attributable to glucoputranjivin and glucocochlearin, two glucosides affording *iso*propyl and *sec.*-butyl *iso*thiocyanate on enzymic hydrolysis, respectively. Solutions of the individual glucosides, A, B and C, were obtained by elution of the appropriate horizontal zones from paper band chromatograms developed in the same solvent system and subjected to enzymic hydrolysis with a cell-free myrosinase preparation. It appeared that both glucoside A and B afforded Grote-positive hydrolysis products directly, whereas compound C underwent fission to a component which gave positive Grote-reaction only after treatment with ammonia. These observations, supplemented with characteristic UV-absorption patterns of the hydrolysis products derivable from A and B, suggested that the latter belonged to the group of 2-oxazolidinethiones, formerly recognized as cyclized products of initially produced β-hydroxy-substituted *iso*thiocyanates (*cf.* Refs.[7,8]). Glucoside C, in contrast, appeared to yield a reasonably stable mustard oil which was transformed into its thiourea derivative on treatment with ammonia. Upon paper chromatography, with the upper layer of the solvent system benzene:heptane:water (9:2:9) as the mobile phase, the supposable 2-oxazolidine-

* This glucoside was differently interpreted in Ref. [3], *viz.* as sinigrin.

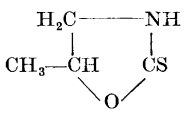
** This plant is now more commonly recognized as a species of the genus *Descurainia*, *viz.* *D. sophia* (L.) Webb; *cf.* foot note on p. 1575.

*** This species is indigeneous to the mountain areas of Middle Europe. The authenticity of the seed material employed in the present studies has been controlled through the courtesy of the *Botanical Garden of the University of Copenhagen* by sowing and subsequent botanical determination of the resulting plants.

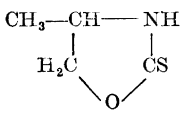
thiones derived from glucoside A and B ('THIOX A' and 'THIOX B') migrated at a rate corresponding to an R_{Ph}-value * of 0.27 and 0.62, respectively. These figures, as well as direct chromatography with various 2-oxazolidinethiones as reference substances, indicated that both compounds, and hence the glucosides A and B, were different from all previously encountered natural compounds. The present communication reports on the structural elucidation of 'THIOX A' and hence glucoside A for which the name *glucosisymbrin* is proposed. The chemical identity of the glucosides B and C will form the subject of forthcoming papers.

In a preliminary isolation experiment a small specimen of pure, crystalline 'THIOX A' was secured after a rather long and tedious series of purification steps (see Exptl. Part). The crystalline product proved very helpful as seeding material for a subsequently obtained portion of 'THIOX A', isolated from a larger sample (220 g) of seeds of *Sisymbrium austriacum* Jacq.** The seed material was finely ground, defatted with carbon tetrachloride and thoroughly extracted with 70 % methanol. After removal of impurities with lead acetate, the resulting solution was enzymically hydrolyzed with myrosinase, and the ether-extractable reaction products purified by means of alumina to give an almost colourless oil (1.6 g). After extraction with water and lyophilization of the aqueous solution an oil remained which on seeding with the previously obtained, crystalline specimen of 'THIOX A' yielded a portion of crystals (133 mg) which was repeatedly recrystallized from various solvents to yield an analytically pure sample of chromatographically homogeneous 'THIOX A', m.p. 64°, which proved to be *dextro*rotatory in ethanol solution.

The analytical composition, C_4H_7ONS, in conjunction with the ultra-violet and infra-red spectra, strongly suggested that 'THIOX A' was a methyl-substituted 2-oxazolidinethione. Of these, both the (±)-5-methyl-derivative (I) [9,10] (m.p. 72-73°[9], 74.5-75.0°[10]) and the racemic 4-methyl-2-oxazolidinethione [11]



I



II

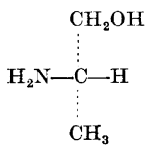
(II) (m.p. 75-76°) had been formerly described. Previous experience within this series has indicated that the racemic compounds often melt higher than the enantiomorphs and deviate considerably from the latter in their infra-red spectra. Careful paper chromatography in benzene:heptane:water (9:2:9), however, showed that 'THIOX A' travelled at a slightly, but consistently, higher rate than a specimen of racemic (I), prepared in this laboratory. Again, it was noticed that in the same solvent system (±)-4-vinyl-2-oxazolidinethione

* *i.e.* the ratio between the distances travelled by the said substance and (±)-5-phenyl-2-oxazolidinethione on the same chromatogram.

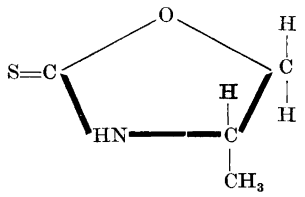
** The seed material employed was produced by cultivation on a larger scale through 1957—58 in the *Botanical Garden of the University of Copenhagen*. The authors are very grateful to the Garden for its valuable assistance.

migrated slightly faster than the (±)-5-isomeride *. This fact, in conjunction with the observation that 'THIOX A' compared with the 4-vinyl-isomeride, produced more blue and stable colours with Grote's reagent than the 5-methyl- and 5-vinyl-substituted ring compounds, supported the belief that 'THIOX A' was, in fact, one of the stereoisomeric 4-methyl-2-oxazolidinethiones (II). Accordingly, the correctness of this assumption was tested by the following synthetic approach.

The 2-amino-alcohol required for the synthesis of one of the optically active 4-methyl-2-oxazolidinethiones (II) is either (+)- or (−)-2-amino-1-propanol (alaninol). Consequently, natural L(+)-alanine was reduced with lithium aluminium hydride in tetrahydrofuran as described by Vogl and Pöhm [12] to give (+)-2-amino-1-propanol (III) in 78 % yield. The amino-alcohol was characterized as its acid oxalate [12,13], whereas a neutral oxalate with the reported m.p. [12–14] could not be obtained despite many attempts, possibly on account of the formation of unresolvable solid solutions of the acid and neutral salts.

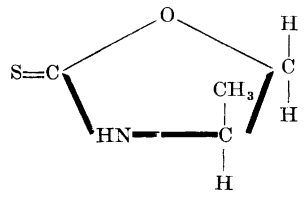


III



(−)

IV



(+)

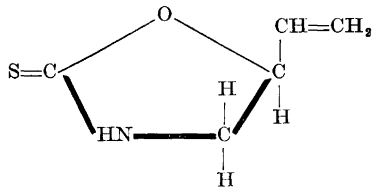
V

L-Alaninol (III) was then treated with thiocarbonyl chloride and triethylamine in chloroform solution to give an oil which was induced to crystallize only after seeding with 'THIOX A'. As shown below the synthetic compound constitutes, in actuality, the antipode of 'THIOX A'. Hence, the successful seeding should probably be attributed to a case of oriented overgrowth on crystals of intermediately formed traces of the racemic compound (*cf. e.g.* Ref.[15]). The synthetic preparation was indistinguishable from 'THIOX A' on paper chromatography and furthermore possessed the same elementary composition and melting point as well as ultra-violet and infra-red spectra as 'THIOX A'. Its optical rotation, however, was similar in magnitude *but opposite in sign* to that of the naturally derived, *dextro*rotatory 2-oxazolidinethione. The enantiomorphous relationship between the two compounds further appeared from the fact that a mixture of equal amounts of the two separated from methanol as the racemic 4-methyl-2-oxazolidinethione (II) possessing the m.p. 75—76°, in agreement with the value previously reported [11]. Not unanticipated, the infra-red spectrum of the latter deviated considerably from that of the enantiomers (Fig. 1).

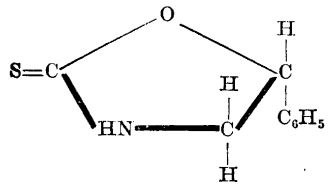
* Synthetic specimens of the vinyl-substituted 2-oxazolidinethiones were kindly supplied by Dr. M. G. Ettlinger of the Chemistry Department, Rice Institute, Houston, Texas, U.S.A.

The above synthetic route, departing from configurationally known (+)-alanine, immediately establishes the absolute configuration (IV) for the *levo*rotatory, synthetic product *. Consequently, (V) depicts the absolute configuration for the naturally derived, *dextro*rotatory 4-methyl-2-oxazolidinethione ** ('THIOX A').

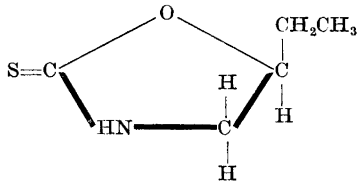
The new 2-oxazolidinethione represents the first example of a 4-substituted derivative of natural provenance. Previously reported compounds of this type include 5,5-dimethyl-[17], (−)-5-vinyl-[18] and (−)-5-phenyl-2-oxazolidinethione [19]. To the last two of these we have assigned the absolute configurations (VI)[20] and (VII)[21], respectively. Furthermore, it has been pointed out [20] that the synthetic, *levo*rotatory 5-ethyl-derivative possesses the absolute configuration (VIII).



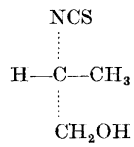
VI



VII



VIII



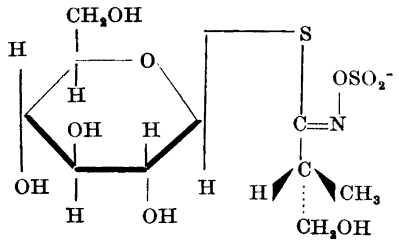
IX

It is of interest to note that exchange of a vinyl- or ethyl-grouping in 5-position with a methyl-substituent in 4-position on the same side of the ring plane, results in a change in sign of rotation, whereas no such alteration accompanies the exchange of the 5-phenyl- with the 4-methyl-substituent. It is expected that further insight into the relationship between configuration and optical rotation in the present class of substances will be obtained from rotatory dispersion studies at present under way.

On the very likely premises that *dextro*rotatory 4-methyl-2-oxazolidinethione (V) results from spontaneous intramolecular cyclization of an initially produced β-hydroxy*iso*propyl *iso*thiocyanate, the above determination of the absolute configuration of (V) immediately establishes the spatial arrangement (IX) around the asymmetric carbon atom of the latter.

* *(S)*-4-Methyl-2-oxazolidinethione in the specification system of Cahn *et al.*[16]

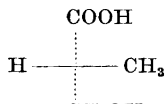
** *(R)*-4-Methyl-2-oxazolidinethione in the same system.



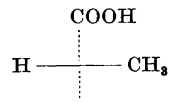
X

Although no experimental proof is available, it appears likely that the configuration depicted in (IX) is that prevailing also in the side-chain of the parent glucoside glucosisymbrin which, therefore, should be formulated as (X), in accordance with the revised general glucoside structure forwarded by Ettlinger and Lundeen [22]. In an analogous case, *viz.* that of glucocochlearin which on enzymic hydrolysis affords (+)-2-butyl *iso*thiocyanate, the same authors [22] suggested that the intramolecular rearrangement accompanying the enzymic reaction would probably proceed with retention of configuration as a consequence of the reaction mechanism involved.* This view has indirectly received some support from the establishment in this laboratory of the same absolute configuration of naturally derived (+)-2-butyl mustard oil as that prevailing around the β-carbon atom of natural *iso*leucine [23] which may be envisaged as biogenetically related with glucocochlearin.

The structural elucidation of glucosisymbrin raises the question as to its biogenetic relationship with glucoputranjivin, the glucoside producing *iso*propyl *iso*thiocyanate and present in *inter alia* several *Sisymbrium* species [24]. It appears likely that one may be derivable from the other by enzymic oxidation or reduction, a possibility which, however, needs further clarification. A reaction sequence analogous to the well-established valine catabolism in animal tissues, proceeding *via iso*butyryl-CoA and β-hydroxy*iso*butyric acid [25], may conceivably be operative also in higher plants. In this connexion attention should be drawn to the establishment by Suchý *et al.*[26] of one of the enantiomorphous β-hydroxy*iso*butyric acids as the acid moiety of the sesquiterpene lactone arctiopicrin.



XI



XII

* *Added in proof.* Provided this assumption proves tenable, acid hydrolysis of glucosisymbrin, analogous to that recorded for other *iso*thiocyanate glucosides by Ettlinger and Lundeen [22], should afford optically active β-hydroxy*iso*butyric acid possessing the absolute configuration (XI).

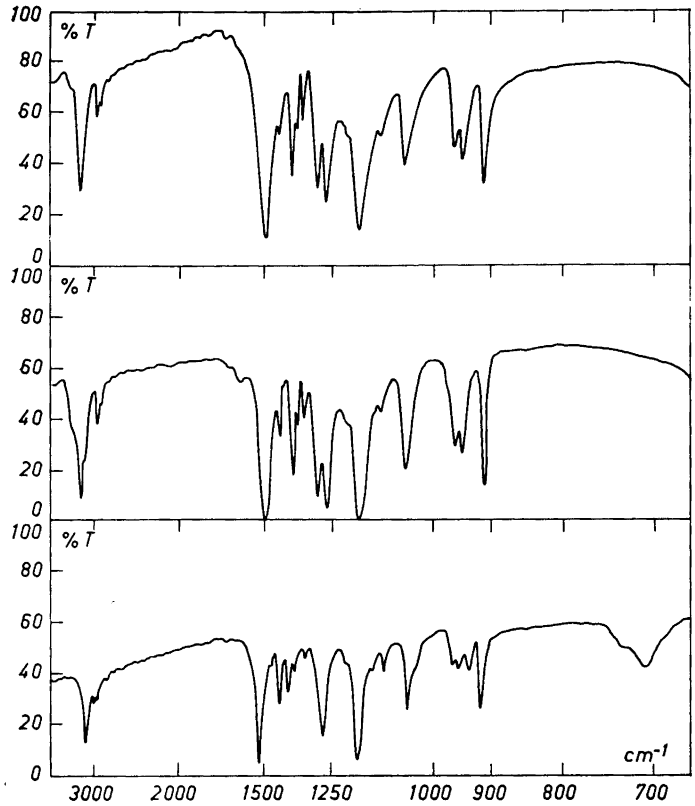


Fig. 1. Infra-red spectra, determined in KBr pellets. Upper curve: naturally derived, *dextro*rotatory 4-methyl-2-oxazolidinethione ('THIOX A'). Middle curve: synthetic, *levo*rotatory enantiomer of the same substance. Lower curve: racemic 4-methyl-2-oxazolidinethione.

Very recently, Asen *et al.*[27] isolated (−)-β-amino*iso*butyric acid from bulbs of *Iris tingitana*. The determination by Balenović and Bregant [28] of the absolute configuration (XII) for *levo*-rotatory β-amino*iso*butyric acid establishes identical configurations around the asymmetric β-carbon atom of (XI) and (XII), both derivable from plant sources. Again, it appears interesting that methylmalonic acid semialdehyde, a product on the catabolic pathway of β-hydroxy*iso*-butyric acid in mammalian tissues, has been shown to undergo a reversible transamination with glutamate to furnish β-amino*iso*butyric acid [25].

EXPERIMENTAL

All melting points reported are uncorrected and, if not otherwise stated, determined in capillary tubes in a slowly heated bath. Rotations are measured in a 1 dm tube. Infra-red spectra are determined in KBr pellets on a Perkin-Elmer "Infracord" instrument.

Exploratory paperchromatographic investigations. A glucoside solution, prepared by boiling a finely ground seed sample of *Sisymbrium austriacum* Jacq. (0.5 g) with 70 % methanol (5 ml), was chromatographed descendingly on Schleicher and Schüll paper

No. 2243b together with a reference sample of glucotropaeolin, with the upper layer of the solvent system *n*-butanol:ethanol:water (4:1:4) as the mobile phase. Three spots were easily distinguishable upon dipping the chromatogram through methanolic silver nitrate, and were attributed to the glucosides A, B and C with R_B-values [4] of 0.34, 0.59 and 1.67, respectively. In *n*-butanol:pyridine:water (6:4:3) the R_B-values were: 0.65, 0.80 and 1.19. That the three spots in this solvent system also represented the glucosides A, B and C in the same sequence was proved by chromatographing the individual compounds, obtained by elution with water of the appropriate zones from chromatograms run as bands in the neutral system, in the pyridine solvent.

To the individual aqueous eluates, each of a volume of 1 ml, were added a phosphate buffer (pH 6.7, 1/15 M, 0.25 ml) and 3 drops of a cellfree myrosinase solution. After 1 h at room temperature, the three solutions were extracted with chloroform. The extracts derivable from the glucosides A and B yielded a strong blue colour with Grote's reagent in contrast to that originating from compound C. The first two solutions, together with a reference solution of (±)-5-phenyl-2-oxazolidinethione [19], were subjected to descending chromatography on Whatman paper No. 1 with the upper layer of the solvent system benzene:heptane:water (9:2:9) as the mobile phase. On spraying with Grote's reagent two blue spots were observed, derivable from glucoside A and B and possessing R_{Ph}-values of 0.27 and 0.62, respectively. Neither of these spots could be assigned to any previously encountered product of natural origin but both exhibited the same characteristic UV-spectrum in ethanol (λ_{max} 243 mμ, λ_{min} 219 mμ), very similar to the pattern previously registered for 2-oxazolidinethiones. After treatment with a chloroform solution of dry ammonia the reaction product of glucoside C yielded a Grote-positive derivative, travelling near the solvent front in water-saturated chloroform.

Preliminary isolation experiment. Dry seeds (220 g) of *Sisymbrium austriacum* Jacq. were covered with carbon tetrachloride (500 ml) and finely ground in a Waring blendor without cooling. The process was repeated with fresh solvent (500 ml) and the suspension was finally refluxed for 1 h. The filtered, defatted seed powder (155 g) was then extracted with three 1 l portions of 70 % methanol. After filtration through Celite, the extract was concentrated *in vacuo* to a sticky brown mass, which was dissolved in the lower phase (200 ml) of the solvent system employed for paper chromatography (*n*-butanol:ethanol: water, 4:1:4). The solution was introduced into No. 1 of a total of 11 separatory funnels, all preloaded with the corresponding upper phase (200 ml in each funnel). The crude mixture was now distributed in a counter-current manner through all vessels. Troublesome emulsion formation was overcome by centrifugation before the next following transfer. Paper chromatography indicated that glucoside C was primarily concentrated in the separatory funnels No. 5—8, supplemented with the upper phase of funnel No. 9, whereas the lower layer of the latter plus the vessels No. 10 and 11 contained essentially a mixture of glucoside A and B, contaminated with considerable quantities of an almost black syrup. To a solution of the crude fraction containing A and B in water (400 ml), a 10 % solution of basic lead acetate was added until the separation of a yellow-brown precipitate ceased (a total of *ca.* 120 ml). The latter was removed by filtration through Celite, and hydrogen sulphide was introduced into the filtrate to precipitate excess lead ions. The filtered solution was concentrated *in vacuo* to an almost colourless syrup. This was redissolved in water (400 ml), equal volumes (20 ml) of 1/15 M solutions of primary and secondary potassium phosphate were added, followed by 25 ml of a myrosinase solution. After having been kept for 3 h at room temperature, the solution was extracted with four 300 ml portions of ether which were pooled and dried. The residual yellow oil (1.3 g) was dissolved in benzene (20 ml) and rapidly washed through a small column of alumina (4 × 0.8 cm) with additional benzene, until the Grote-reaction became negative. This procedure yielded an almost colourless oil (1.1 g) which was thereafter subjected to careful adsorption chromatography on neutral alumina (column diameter: 2.2 cm, height of packing: 25 cm) with 1 % of methanol in benzene as the eluant. Fractions of 5 ml were taken; the Grote-positive constituents were located in fractions No. 147—178. Paper chromatography revealed that the fractions No. 147—155 contained exclusively 'THIOX B', No. 170—181 solely 'THIOX A' and the intermediate fractions a mixture of the two.

The 'THIOX A'-fractions were taken to dryness, redissolved in pure benzene and a small insoluble residue discarded. The oily product (134 mg) was subjected to fractional sublimation at 0.2 mm Hg. At 40° (bath temperature) an oily fraction distilled and was discarded. The bath was slowly raised to 80° when a deposit of crystalline material

(34 mg) on the 'cold finger' was noticed. The somewhat oily preparation was recrystallized from anhydrous ether at low temperature to give thin colourless prisms, $[\alpha]_D^{24}$ +22.1° (*c* 0.85, MeOH). The recovered material from the rotation determination, supplemented by a fraction of crystalline material obtained directly from fraction No. 166–169 on seeding, was purified by repeated recrystallizations from a mixture of benzene and petroleum ether to give a pure specimen (16.8 mg) of 'THIOX A' as colourless prisms with m. p. 64–65°.

Isolation of (+)-4-methyl-2-oxazolidinethione. Another seed portion (220 g) was processed exactly as described above with the sole exception that the cumbersome countercurrent extraction was omitted. The lead-purified glucoside extract was enzymically hydrolyzed as described in the foregoing. Again, yellow contaminants were partially removed from the ethereal extract by means of a small alumina column. The residue was treated with water (80 ml) causing a considerable amount of a gummy product (polymerisation?) to separate. The latter was thoroughly washed and the aqueous solution lyophilized to give a colourless oil. This was taken up in ether (5 ml), the solution was cooled to 0° and seeded with previously obtained crystals of 'THIOX A' when the separation of crystalline, but slightly oily 'THIOX A' (133 mg) started. Two recrystallizations from a mixture of benzene and petroleum ether (1:1), followed by another two from anhydrous ether afforded a pure specimen of 'THIOX A' (17 mg), m. p. 63.5°–64.5°. (Found: C 41.06; H 6.15; N 11.81. Calc. for C_4H_7ONS: C 40.99; H 6.02; N 11.95.)

An additional 9.6 mg of the same purity was secured by repeated recrystallizations of the mother liquor preparation, m. p. 64°; $[\alpha]_D^{24}$ +21.1° (*c* 0.72, EtOH). The infra-red spectrum is reproduced in Fig. 1.

Synthesis of (−)-4-Methyl-2-oxazolidinethione. L-Alanine (8.01 g, $[\alpha]_D^{28}$ +14.7° (*c* 7.0, 1 N HCl)) was reduced by means of a solution of $LiAlH_4$ (10.5 g) in tetrahydrofuran (120 ml), according to the procedure described by Vogl and Pöhm [12]. Distillation *in vacuo* afforded L(+)-alaninol in 78 % yield as a colourless oil, b. p. 67°/8 mm, n_D^{25} 1.4487, $[\alpha]_D^{25}$ +22.0° (*c* 6.45, 96 % EtOH). Literature values: b. p. 78–80°/12 mm, $[\alpha]_D^{17}$ +20.1° (alcohol) [13]; b. p. 85°/10 mm, $[\alpha]_D^{17}$ +20.3° (EtOH) [12].

The amino-alcohol was characterized as its acid oxalate, produced by mixing hot solutions of the former and of oxalic acid dihydrate (20 % excess). The salt separated from ethanol in colourless needles, m. p. 151°, $[\alpha]_D^{26}$ +13.8° (*c* 2.5, H_2O). (Found: C 36.35; H 6.56; N 8.55. Calc. for C_3H_9ON, $C_2H_2O_4$: C 36.35; H 6.71; N 8.48). Literature values: m. p. 140–141°[13]; m. p. 141–142°[12]; (no rotation data reported). Repeated attempts to prepare the formerly described neutral oxalate proved unsuccessful, despite variations in the procedure and amounts of reactants employed. Beautiful, crystalline salts were obtained with the reported rotation value ($[\alpha]_D^{23}$ +18.0° (*c* 2.3, H_2O)) but invariably melting over a wide temperature range (*e. g.* 125–140°).

To a cooled and stirred solution of thiocarbonyl chloride (1.16 g) in chloroform (15 ml), another solution of L(+)-alaninol (0.65 g) and triethylamine (1.76 g) in chloroform (10 ml) was added in the course of 10 min. Shortly after the addition of the amino-alcohol was completed the thiophosgene smell disappeared, and the yellow solution was evaporated to dryness *in vacuo*. Repeated extractions with ether removed the Grote-positive product from triethylamine hydrochloride. The concentrated extract was decolourized with Norite, filtered and again concentrated to a final volume of 7 ml. Only after addition of seed crystals of 'THIOX A' a crystalline precipitate appeared. Next day, the product (346 mg) was recrystallized thrice from ether to give an analytical specimen (180 mg) of *(−)-4-methyl-2-oxazolidinethione*, m. p. 65°, $[\alpha]_D^{26}$ −22.9° (*c* 1.12, 96 % EtOH). (Found: N 11.77; S 27.42. Calc. for C_4H_7ONS: N 11.95; S 27.36.) The infra-red spectrum of the synthetic preparation was indistinguishable from that of 'THIOX A' (Fig. 1). The latter, therefore, is the antipodal (+)-4-methyl-2-oxazolidinethione.

Racemate formation. Synthetic material (2.36 mg) was mixed with 'THIOX A' (2.36 mg) and the solid dissolved in a few drops of methanol. The residual oil crystallized on scratching, and the racemate was recrystallized from two drops of water to give thin, colourless needles, m. p. 75.5–76.0° (microscope). Literature value: m. p. 75–76°[11].

The infra-red spectrum, which is conspicuously different from that of the optically active forms, is presented in Fig. 1.

Microanalyses were performed by Mr. P. Hansen at the Chemical Laboratory of the University of Copenhagen. Thanks are also due to Dr. R. Gmelin for valuable assistance in the preliminary phases of these studies.

The present work is part of investigations supported by *The Danish State Research Foundation (Statens Almindelige Videnskabsfond)* and *Kai Hansen's Fond.* One of us (A.K.) wishes to express his gratitude to *The Research Council of the Technical Sciences (Det Teknisk-Videnskabelige Forskningsråd)* for the appropriation of an infra-red spectrophotometer.

Studien über Lokalanästhetica

XVII. * Synthese von N-Diäthylaminoalkyl-substituierten 2,6-Dimethylbenzamiden und 2,6-Dimethylbenzylideniminen

NILS LÖFGREN und WILLY STOFFEL

Institut für organische Chemie und Biochemie der Universität, Stockholm, Schweden

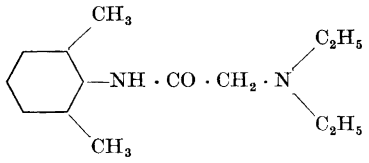
Es werden drei für die Synthese von N-Dialkylaminoalkyl-2,6-dimethylbenzamide geeignete Methoden, sowie die Synthesen von sechs Verbindungen dieser Reihe beschrieben. Die Reaktion von N-Halogenalkyl-2,6-dimethylbenzamiden mit sekundären Aminen führt ausser zur Bildung obiger Amide, durch Ringschluss zu heterocyclischen Verbindungen, von denen das 2-(2,6-Dimethylphenyl)-2-oxazolin und das 2-(2,6-Dimethylphenyl)-5,6-dihydro-1,3,4*H*-oxazin isoliert wurden. Die synthetisierten Amide sind äussert stabil gegen hydrolytische Einflüsse, was aus einem vergleichenden Hydrolyseversuch mit dem kernisomeren, sterisch nicht gehinderten N-(3-Diäthylaminopropyl)-3,5-dimethylbenzamid hervorgeht, das auch synthetisiert wurde. Für diese Stabilität wird eine elektronentheoretische Deutung gegeben. Ferner wurde das früher nicht beschriebene N,N-Dimethyl-2,6-dimethylbenzamid synthetisiert, und für die Darstellung des N-(2-Diäthylamino-1,2-dimethyläthyl)-2,6-dimethylbenzamids wurde das bisher nicht bekannte 2-Amino-3-(diäthylamino)butan präpariert. Über die Synthese zweier Schiff-Basen des bisher wenig untersuchten 2,6-Dimethylbenzaldehyds, nämlich das N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzylidenimin und das N-(3-Diäthylaminopropyl)-2,6-dimethylbenzylidenimin wird auch berichtet. Die neueren Methoden zur Synthese von Aldehyden von Plieninger und Werst [2], Grundmann [3], Weygand und Mitarbeitern [4], erwiesen sich für die Darstellung des 2,6-Dimethylbenzaldehyds, wegen der sterischen Hinderung, als nicht geeignet.

Es wird weiter über die lokalanästhetische Wirksamkeit und die Toxizität der synthetisierten *N*-Dialkylaminoalkyl-*eso*-dimethylbenzamide berichtet.

Auf Grund experimenteller Befunde sind die bemerkenswerten Eigenschaften des Xylocains® (α-Diäthylamino-2,6-dimethylacetanilid), vor allem im Vergleich mit den kernisomeren Verbindungen — sowohl in physikalisch-chemischer Hinsicht (U.V.-Spektrum [5,6] Dipolmoment [6], Molrefraktion [5], Dis-

* Mitteilung XVI dieser Reihe, siehe Löfgren, Tegnér und Takman [1].

soziationstant [5], Resistenz gegen Säuren und Basen [5]), als auch in pharmakologischer Hinsicht [5,7,8] — auf den durch die vicinale Gruppierung bedingten Ortho-Effekt zurückzufüren. Der Ortho-Effekt äussert sich in einer stark

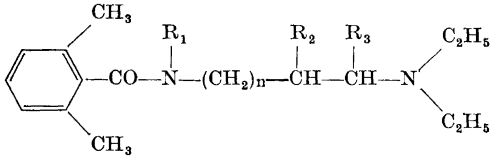


Xylocain ®

verminderten Resonanz zwischen Kern und Amidstickstoff [5].

Invertiert man im Xylocain die Amidgruppierung so kommt man zum N-(Diäthylaminomethyl)-2,6-dimethylbenzamid. Die Darstellung dieser Verbindung, die als Xylocainisomer von besonderem Interesse erschien, wurde über eine Mannich-Reaktion (vgl. S. 1594) versucht. Da aber die Substanz nicht befriedigend rein erhalten werden konnte, wird auf die Beschreibung der Syntheseversuche verzichtet *. Es werden hier sechs andere N-(Diäthylaminoalkyl)-2,6-dimethylbenzamide (I—VI) beschrieben, die zwei oder mehrere Kohlenstoffatome zwischen Amid- und Amin-Stickstoff enthalten (vgl. Tabelle

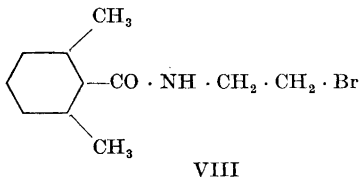
Tabelle 1. Synthetisierte Verbindungen vom Typus



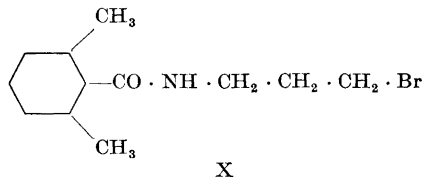
Verbdg.	n	R_1	R_2	R_3
I	0	H	H	H
II	0	CH_3	H	H
III	1	H	H	H
IV	0	H	H	CH_3
V	0	H	CH_3	H
VI	0	H	CH_3	CH_3

1). Sie sind — wie Xylocain — durch die ortho-ständigen Methylgruppen sterisch gehindert (vgl. S. 1593). Alle sechs Verbindungen wurden auf ihre lokalanästhetische Wirksamkeit geprüft.

Das N-(Diäthylaminoäthyl)-2,6-dimethylbenzamid (I) und das N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid (III) wurden über das früher nicht beschriebene N-(2-Bromäthyl)-2,6-dimethylbenzamid (VIII) und das N-(3-



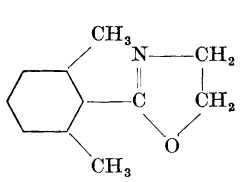
VIII



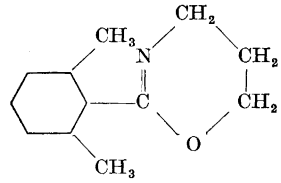
X

* Die Arbeiten mit der Substanz werden fortgesetzt.

Brompropyl)-2,6-dimethylbenzamid (X) dargestellt. Als Nebenprodukte bei der Darstellung von I und III über VIII bzw. X wurden das 2-(2,6-Dimet-



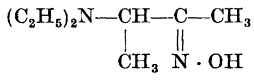
IX



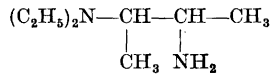
XI

hylphenyl)-2-oxazolin (IX) und das 2-(2,6-Dimethylphenyl)-5,6-dihydro-1,3,4*H*-oxazin (XI) isoliert.

Die Synthese von N-(2-Diäthylamino-1,2-dimethyläthyl)-2,6-dimethylbenzamid (VI) wurde über die Stufen 3-Brom-2-butanon, 3-Diäthylamino-2-butanon, 3-Diäthylamino-2-butanon-Oxim (XII) und 2-Amino-3-(diäthylamino)-butan (XIII) durchgeführt. XII und XIII sind früher nicht in der



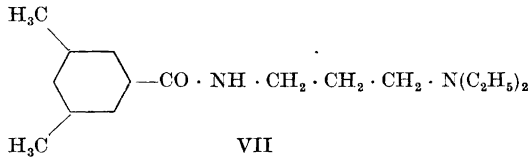
XII



XIII

Literatur beschrieben worden.

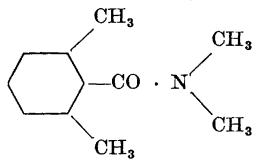
Um den Effekt von den in den 2,6-Stellungen sterisch hindernden Methylgruppen hinsichtlich der lokalanästhetischen Aktivität und hinsichtlich der Stabilität gegenüber hydrolytischen Einflüssen zu studieren, wurde die der Verbindung N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid (III) kernisomere, sterisch ungehinderte Verbindung N-(3-Diäthylaminopropyl)-3,5-dimet-



VII

hylbenzamid (VII) dargestellt. Die Verbindung VII wurde auf ihre lokalanästhetische Wirksamkeit geprüft und in einem Hydrolyseversuch mit III verglichen.

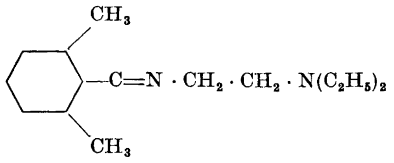
Das bisher noch nicht beschriebene N,N-Dimethyl-2,6-dimethylbenzamid



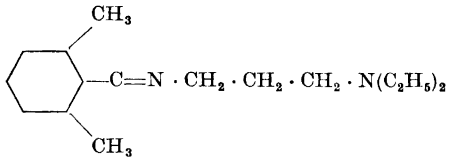
XIV

(XIV) wurde auch synthetisiert.

Von den Kondensationsprodukten des 2,6-Dimethylbenzaldehyds ist bisher nur das von Lock und Schmidt [9] beschriebene Semicarbazon bekannt. Offenbar verhinderte der Ortho-Effekt in den Versuchen letztgenannter Autoren die Bildung des Phenylhydrazons und die Reaktion nach Perkin. Hier gelang es, das N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzylidenimin (XV) und das N-(3-Diäthylaminopropyl)-2,6-dimethylbenzylidenimin (XVI) darzustellen. —



XV



XVI

Ferner wurde versucht, bei der Synthese des sterisch gehinderten 2,6-Dimethylbenzaldehyds neuere Methoden zur Darstellung von Aldehyden (Plieninger und Werst [2], Grundmann [3], Weygand und Mitarbeiter [4]) anzuwenden. Wegen der sterischen Hinderung erwiesen sich hier diese Methoden als nicht geeignet (vgl. S. 1595).

CHEMISCH-THEORETISCHER TEIL

Für die Synthese der N-Diäthylaminoalkyl-2,6-dimethylbenzamide wurden drei Methoden (A, B, C) ausgearbeitet. Die Ausgangssubstanz für die beiden ersten Methoden A und B war das 2,6-Dimethylbenzoylchlorid. Es wurde über die folgenden Stufen synthetisiert:

vic.-m-Xylidin $\xrightarrow[CuCN]{\text{Diazotierung}}$ 2,6-Dimethylbenzonitril $\xrightarrow[H_2SO_4(96\ \%)]{\text{Verseifung}}$

2,6-Dimethylbenzamid $\xrightarrow[H_3PO_4(100\ \%)]{\text{Verseifung}}$ 2,6-Dimethylbenzoesäure $\xrightarrow{SOCl_2}$

2,6-Dimethylbenzoylchlorid.

Analog dem Verfahren von Clarke und Read [10] zur Synthese des *o*-Tolunitrils wurde *vic.-m*-Xylidin in das Diazoniumsalz und weiter durch Sandmeyer-Reaktion mit CuCN in das 2,6-Dimethylbenzonitril mit 60 % Ausbeute überführt. Nach Berger und Oliver [11] wurde durch Verseifung des Nitrils mit konzentrierter Schwefelsäure bei konstant 80° in der ersten Stufe das 2,6-Dimethylbenzamid (50 % Ausbeute) erhalten. Mit 100 % Phophorsäure wurde die Verseifung bis zur Säure weiter geführt. Diese fiel hier in 60 % Ausbeute an. Die Darstellung des Säurechlorids mit Thionylchlorid verläuft fast quantitativ und wurde dem Verfahren von Lock und Schmidt [9], in dem Phosphorpentachlorid angewendet wird, vorgezogen.

Die erschwerte Verseifung des 2,6-Dimethylbenzonitrils beruht auf sterischen Faktoren, die durch die ortho-ständigen Methylgruppen bedingt sind.

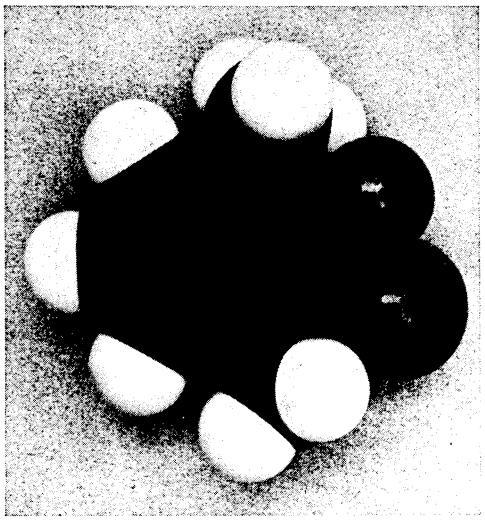


Fig. 1. Stuart-Modell des 2,6-Dimethylbenzoylchlorid-Moleküls.

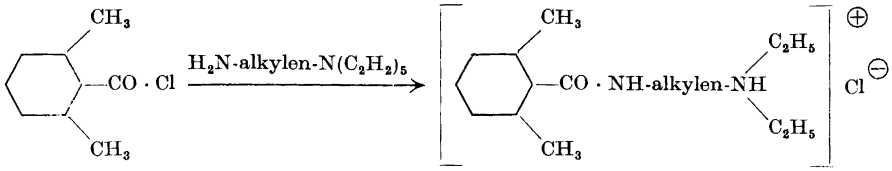
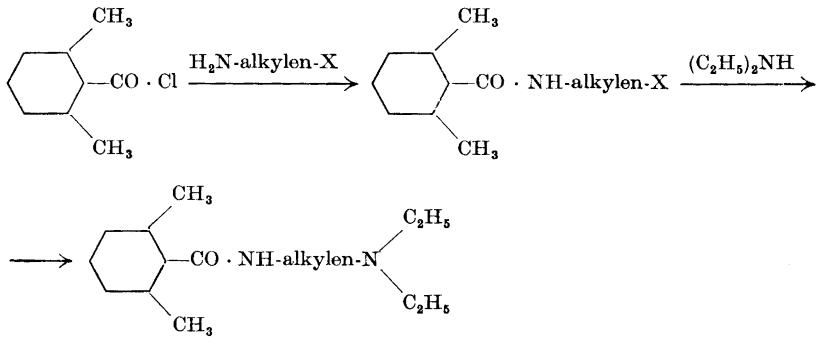
Aus Versuchen Hoffmanns [12], das Pentamethylbenzonitril zu verseifen, geht hervor, dass auch die kräftigsten Verseifungsmethoden erfolglos blieben und lediglich zum Pentamethylbenzol führten. Das dargestellte 2,6-Dimethylbenzoylchlorid wird ebenso wie das Mesitylencarbonsäurechlorid fast wie ein aliphatisches Säurechlorid durch Wasser stürmisch zersetzt. Das Stuart-Modell zeigt (vgl. Fig. 1), dass von den beiden Atomen Sauerstoff und Chlor das eine oberhalb und das andere unterhalb der Ebene des Benzolkerns liegt. Die Drehbarkeit der $-C\overset{O}{\diagdown\!\!\diagup}\underset{Cl}{}$ Gruppe um die C_{kern} — C-Achse wird dadurch auf Oszillationen um eine Mittellage beschränkt, die dadurch bestimmt ist, dass die durch $-C\overset{O}{\diagdown\!\!\diagup}\underset{Cl}{}$ gelegte Ebene senkrecht zur Ebene des Benzolkernes liegt. Dadurch wird eine Interferenz der p-Elektronen der Carbonylgruppe mit dem π-Bindungssystem des Kerns herabgesetzt. Die Ausbildung von mesomeren Grenzstrukturen ist somit stark zurückgedrängt, wodurch das reaktive Verhalten des Säurechlorids eine Erklärung findet.

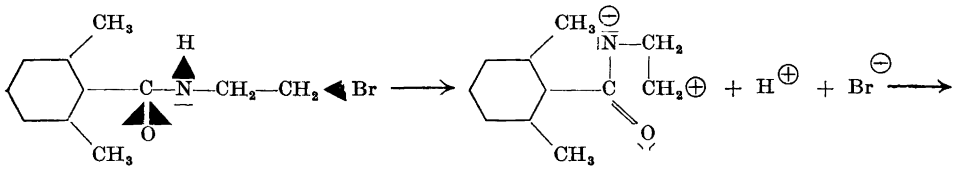
Nach *Methode A* wurde ohne Zusatz eines Protonenakzeptors das 2,6-Dimethylbenzoylchlorid mit dem entsprechenden Diäthylaminoalkylamin zur Reaktion gebracht. Die unter der Reaktion entstehende Base fungiert selbst als Protonenakzeptor:

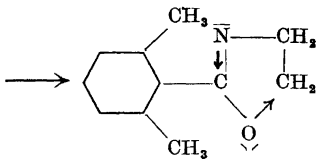


Nach der *Methode B* lassen sich N-Diäthylaminoalkyl-2,6-dimethylbenzamide stufenweise synthetisieren. Man bringt das Säurechlorid mit zwei Mol des betreffenden Halogenalkylamins zur Reaktion. Über das so gewonnene N-Halogenalkyl-2,6-dimethylbenzamid wird dann in der gewöhnlichen Weise die Diäthylaminobase dargestellt:



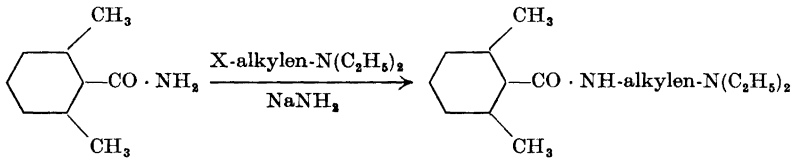
Nach Methode B wurden N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzamid (I) und N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid (III) über N-(2-Bromäthyl)-2,6-dimethylbenzamid (VIII) resp. N-(3-Brompropyl)-2,6-dimethylbenzamid (X) dargestellt. Nach der Umsetzung mit Diäthylamin fielen bei der fraktionierten Destillation des Reaktionsproduktes jeweils eine niedriger und eine höher siedende Fraktion an. Die niedriger siedende Fraktion konnte im ersten Falle als das 2-(2,6-Dimethylphenyl)-2-oxazolin (IX), im zweiten Falle als das 2-(2,6-Dimethylphenyl)-5,6-dihydro-1,3,4*H*-oxazin (XI) identifiziert werden. Gabriel und Heymann [13] sowie Gabriel und Elfeldt [14] stellten Oxazoline durch Behandeln von Halogenalkylbenzamiden mit Natronlauge dar. Der Ringschluss zu dem hier bei der Synthese als Nebenprodukt in 20 bzw. 30 % Ausbeute anfallenden Oxazolin bzw. „Pentoxazolin" erfolgte beim Erhitzen der entsprechenden N-Halogenalkyl-2,6-dimethylbenzamide mit Diäthylamin in benzolischer Lösung:





Durch die Schlüsselatome O und Br wird die Amidwasserstoff-Bindung stark polarisiert. Unter der Einwirkung von Diäthylamin kommt es zur Abspaltung des Wasserstoff- und Bromions und zur Bildung des fünfgliedrigen Oxazolin- bzw. sechsgliedrigen „Pentoxazolinringes". Mit Bromwasserstoffsäure gaben die beiden „Oxazoline" die erwartete Reaktion (vgl. Gabriel und Heymann [13]): Sie wurden unter Ringöffnung in die entsprechenden Ausgangsverbindungen (VIII, X) verwandelt. Die beiden N-Diäthylaminoalkyl-2,6-dimethylbenzamide (I und III) wurden in 50 % Ausbeute erhalten.

Die Ausgangssubstanzen in der *Methode C* sind das 2,6-Dimethylbenzamid und Diäthylaminoalkylhalogenide oder deren Salze. Als Protonenakzeptor dient das Natriumamid:



Es wurden zwei Mol Natriumamid eingesetzt, wenn das Hydrochlorid oder das Hydrobromid des Diäthylaminoalkylhalogenids angewandt wurde.

Durch den Ortho-Effekt wird die Hydrolyse von ortho-substituierten Benzoesäureestern verschwert. So konnten Hinshelwood und Newling [15] zeigen, dass die Verseifung des *o*-Nitrobenzoesäureäthylesters eine um rund 6 000 cal höher liegende Aktivierungsenergie erfordert als die des isomeren *p*-Nitrobenzoesäureäthylesters. Die über die Silbersalze mit Alkyljodid gewonnenen Mesitylencarbonsäureester lassen sich nicht wieder verseifen [16]. Da der Verlauf der Hydrolyse von Amiden in elektronentheoretischer Hinsicht dem der Ester sehr verwandt ist, wurde das Verhalten der ebenfalls dem Ortho-Effekt unterliegenden synthetisierten N-Diäthylaminoalkyl-2,6-dimethylbenzamide gegenüber hydrolytischen Einflüssen untersucht. Als Vergleichssubstanz wurde das N-(3-Diäthylaminopropyl)-3,5-dimethylbenzamid (VII) synthetisiert und unter den gleichen Bedingungen wie die entsprechende 2,6-Verbindung (III) der sauren Hydrolyse unterworfen. Der Versuch zeigte (siehe exp. Teil S. 1601), dass die 2,6-Verbindung unter diesen eingreifenden Bedingungen fast überhaupt nicht hydrolysiert wird. Sie konnte in 91 % Ausbeute unverändert zurückgewonnen werden. Dagegen wurde die dem Ortho-Effekt nich unterliegende 3,5-Verbindung (VII) nahezu vollständig hydrolysiert. Die 3,5-Dimethylbenzoesäure wurde in 86 % Ausbeute isoliert.

Die erschwerte Hydrolyse der 2,6-Dimethylbenzamide kann auf folgende Weise gedeutet werden: Die Stuart-Modelle des synthetisierten 2,6-Dimethyl-

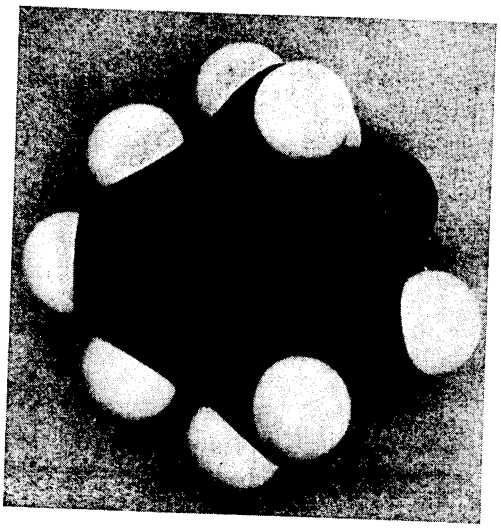


Fig. 2. Stuart-Modell des 2,6-Dimethylbenzamid-Moleküls.

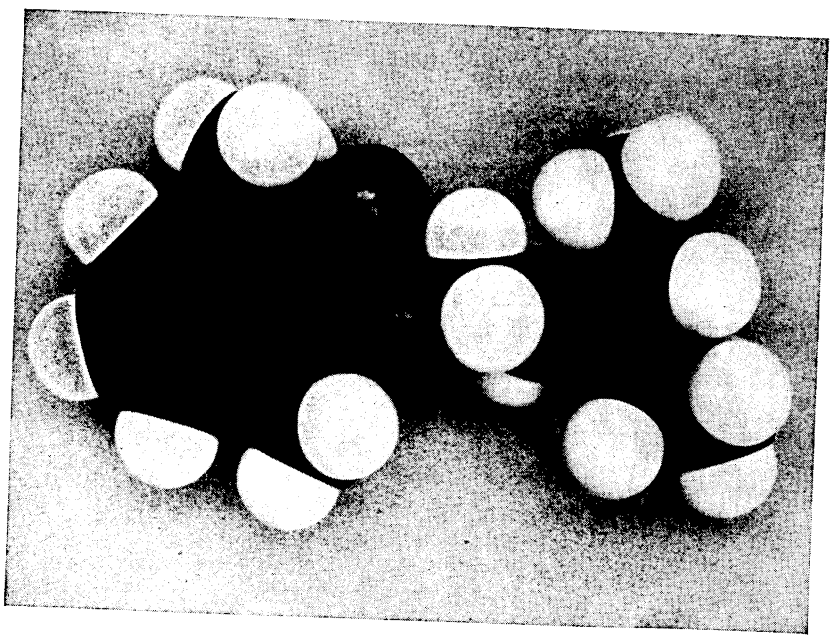

Fig. 3. Stuart-Modell des N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzamid-Moleküls.

benzamids und der N-Diäthylaminoalkyl-2,6-dimethylbenzamide zeigen deutlich (vgl. Fig. 2 und 3), dass eine sterische Hinderung zwischen den Wasserstoffatomen der ortho-ständigen Methylgruppen und sowohl dem Carbonylsauerstoff als auch dem Amidstickstoff besteht. In Wasserstoffbrücken beansprucht praktisch der Wasserstoff keinen Raum, vielmehr wird der Kernabstand der durch die H-Brücken verbundene Atome verringert. Wie aus einem Studium der sterischen Verhältnisse der hier aktuellen Verbindungen (vgl. Fig. 2 und 3) hervorgeht, so ist die Möglichkeit für die Bildung intramolekularer Wasserstoffbrückenbindungen (Chelatbindungen), einmal zwischen dem Carbonylsauerstoff- und einem Wasserstoffatom der einen *o*-Methylgruppe, zum anderen zwischen dem Amidstickstoff- und einem Wasserstoffatom der anderen *o*-Methylgruppe gegeben, d.h. die Repulsion der einander nahe kommenden Gruppen wäre aufgehoben und statt dessen gegen eine Attraktion durch Chelatbindungen vertauscht worden (vgl. Branch und Calvin [17]). Durch die Bildung dieser Wasserstoffbrücken entstehen — wie aus dem Stuart-Modell ersichtlich ist — zwei zum Benzolring *koplanar* liegende sechsgliedrige Chelatringe. Die durch die erwähnten H-Brücken gebildete koplanare Drei-Sechsring-Struktur, die also den Benzolring mit einbezieht, wird ferner durch Resonanz stabilisiert. Fig. 4 veranschaulicht das Wasserstoffbrücken-System, und unter den Formeln stellen *d* und *e* solche dar, die aus der durch die koplanare Lage bedingten Resonanz mit dem Benzolkern resultieren *.

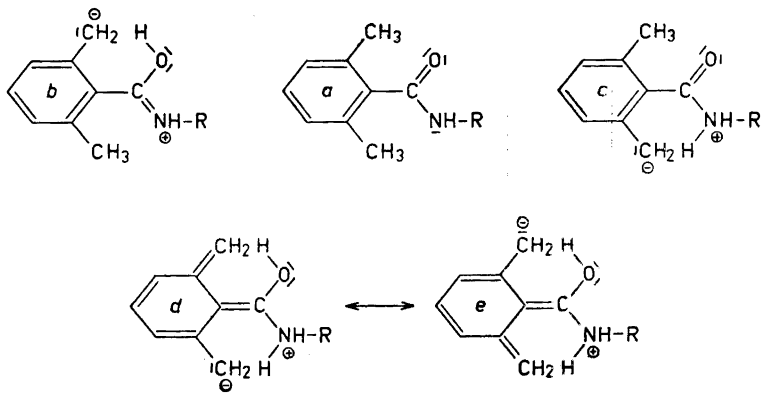

Fig. 4. Wasserstoffbrücken-System in 2,6-Dimethylbenzamiden.

Wasserstoffbrücken zwischen ortho-Methylgruppen und Aminostickstoff werden von Branch und Calvin [17] z.B. im Falle des *o*-Methylanilins beschrieben. Löfgren [5] (vgl. auch Lindström [18]) hat auf Grund experimenteller Befunde das Vorkommen eines solchen den Amid-Stickstoff und den *o*-Methyl-Wasserstoff mit einschliessenden fünfgliedrigen Chelatringes im *a*-Diäthylamino-2,6-

* Die hier angewandte Schreibweise für die Wasserstoffbrückenbindung schliesst sich der von Branch und Calvin [17] (siehe Beispiel *o*-Toluylsäure) an.

dimethylacetanilid (Xylocain) wahrscheinlich gemacht. Nach Watson [19] sowie Branch und Calvin [17] ist die Bildung sechsgliedriger Chelatringe — wie im vorliegenden Fall — am stärksten begünstigt. — Durch den oben beschriebenen Ortho-Effekt in den 2,6-Dimethylbenzamiden sollte die Amid-Gruppe weitgehend gegen Attacken von Reagentien, z.B. von Protonen, geschützt sein. — Somit ist eine Erklärung für die Hydrolyse-Resistenz gegeben.

Über eine Mannich-Reaktion wurde versucht, das N-(Diäthylaminomethyl)-2,6-dimethylbenzamid aus 2,6-Dimethylbenzamid, Formaldehyd und Diäthylammoniumchlorid zu synthetisieren. Da jedoch die Reindarstellung der Base durch Destillation wegen der schnellen Zersetzung unmöglich war, die dargestellten gewöhnlichen Salze unbefriedigende Analysenwerte gaben, und die Freisetzung der Base aus den Salzen zur Zersetzung führte, wurde vorläufig von dieser Synthese Abstand genommen.

Bei der Alkylierung des 2,6-Dimethylbenzamids mit 1-Diäthylamino-2-chlorpropan konnte erwartet werden, dass als hauptsächliches Reaktionsprodukt nicht das N-(2-Diäthylamino-1-methyläthyl)-2,6-dimethylbenzamid (V) entsteht, sondern das N-(2-Diäthylamino-2-methyläthyl)-2,6-dimethylbenzamid (IV). Schultz, Robb und Sprague [20] sowie andere Autoren [21-23] haben nämlich gefunden, dass bei der Alkylierung mit 1-Dialkylamino-2-chlorpropanen in alkalischem Medium eine solche Wanderung der Methylgruppe stattfindet. Der Reaktionsverlauf der Alkylierung des im alkalischen Milieu als

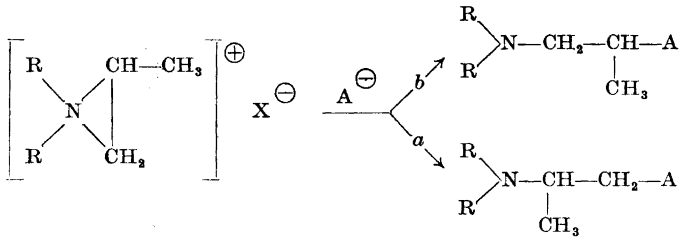

Fig. 5.

Anion vorliegenden Kupplungspartners (A^-) kann so gedeutet werden, dass aus dem 1-Dialkylamino-2-chlorpropan ein Äthylenimmoniumion als Zwischenprodukt ensteht; vgl. Fig. 5. In diesem Äthylenimmoniumion ist die Bindung zwischen Stickstoffatom und Methylengruppe leichter angreifbar, so dass der im Fig. 5 angegebene Reaktionsverlauf *a* begünstigt ist. — Bei der Alkylierung des 2,6-Dimethylbenzamids mit 1-Diäthylamino-2-chlorpropan nach Methode C trat diese oben beschriebene Umlagerung tatsächlich ein. Die sorgfältige Destillation des Reaktionsproduktes gab nur eine im Brechungsindex einheitliche Fraktion. Entsprechend obiger Hypothese sollte diese Fraktion das Umlagerungsprodukt N-(2-Diäthylamino-2-methyläthyl)-2,6-dimethylbenzamid (IV) sein. Zur Klärung dieser Frage wurde 2-Amino-1-(diäthylamino)-propan nach Breslow und Mitarbeitern [24] durch reduktive Aminierung von Diäthylaminoaceton synthetisiert. Das 1-Amino-2-(diäthylamino)propan wurde durch Reduktion des nach Luten [25] synthetisierten 2-Diäthylaminopropionitrils

erhalten. Die Diamine wurden mit dem 2,6-Dimethylbenzoylchlorid nach Methode A zur Reaktion gebracht. Wie im experimentellen Teil beschrieben, sind die physikalischen Eigenschaften (Kp., Fp., n_D^{20}) des Umlagerungsproduktes mit denen nach Methode A synthetisierten N-(2-Diäthylamino-2-methyläthyl)-2,6-dimethylbenzamids (IV) identisch. Die betreffenden Eigenschaften des Umlagerungsproduktes und des N-(2-Diäthylamino-1-methyläthyl)-2,6-dimethylbenzamids (V) unterscheiden sich hingegen eindeutig. Weiterhin zeigt die Mischschmelzpunktprobe des Umlagerungsproduktes mit dem N-(2-Diäthylamino-2-methyläthyl)-2,6-dimethylbenzamid (IV) keine Depression. — Die Wanderung der Methylgruppe hat im vorliegenden Fall offenbar quantitativ stattgefunden.

N-(2-Diäthylamino-1,2-dimethyläthyl)-2,6-dimethylbenzamid (VI) wurde durch Kupplung des 2,6-Dimethylbenzoylchlorids mit dem 2-Amino-3-(diäthylamino)butan (XIII) synthetisiert. Das Diamin erhielt man über die Stufen 3-Brom-2-butanon, 3-Diäthylamino-2-butanon und 3-Diäthylamino-2-butanon-Oxim (XII). Das 3-Diäthylamino-2-butanon ist früher von Rose und Weedon [26] durch Hydratisierung von 3-Diäthylamino-1-butin synthetisiert worden. Das dem Keton entsprechende Oxim (XII) sowie das durch die Reduktion des Oxims erhaltene 2-Amino-3-(diäthylamino)butan (XIII) sind bisher nicht in der Literatur beschrieben. Bei der Bromierung von Methyläthylketon wurde die von Catch und Mitarbeitern [27] angegebene Vorschrift befolgt. Bei der Reduktion des Ketoxims mit $LiAlH_4$ wurde eine Ausbeute von 50 %, mit Natrium und Äthanol von 60 % d.Th. erzielt. Auf eine Trennung des bei der Synthese entstehenden Gemisches von zwei Racematen musste wegen Mangel an Substanz verzichtet werden.

Analog dieser Derivate der 2,6-Dimethylbenzoesäure, waren die des 2,6-Dimethylbenzaldehyds, die Diäthylaminoalkyl-2,6-dimethylbenzylidenimine (Schiff-Basen) von Interesse. Der 2,6-Dimethylbenzaldehyd wurde nach Lock und Schmidt [9] durch Rosenmund-Reduktion [28] in rund 60 % Ausbeute erhalten. Bei der Darstellung dieses Aldehyds wurden weiterhin moderne Verfahren für die Synthese von Aldehyden geprüft. Es war nämlich von Interesse zu ermitteln, ob diese Methoden sich auch mit sterisch gehinderten Molekülen als erfolgreich erweisen würden. Nach der Aldehyd-Methode von Plieninger und Werst [2] hydriert man das betreffende Nitril katalytisch in Gegenwart von Semicarbazid und fängt den anfallanden Aldehyd als Semicarbazon ab. Diese Methode erwies sich hier als erfolglos: unter Berücksichtigung der angegebenen Versuchsbedingungen wurde kein Wasserstoff aufgenommen. — Nach Grundmann [3] gelangt man zum Benzaldehyd über die Stufen Benzoylchlorid, Diazoacetophenon, ω-Acetoxy-acetophenon und Phenylglykol (durch Reduktion nach Meerwein-Ponndorf), das durch Bleitetraacetat gespalten wird. Schon die Bildung des 2,6-Dimethyldiazoacetophenons war in wiederholten Versuchen nicht zu erreichen. Die Möglichkeit einer Hydrolyse des empfindlichen Säurechlorids, durch Spuren von Feuchtigkeit in der ätherischen Diazomethanlösung, wurde durch Einleiten von gasförmigen Diazomethan nach der Vorschrift von Arndt und Amende [29] ausgeschlossen. — Das von Weygand und Mitarbeitern [4] ausgearbeitete Verfahren, den Aldehyd aus dem entsprechenden N-Methylanilid durch Reduktion mit $LiAlH_4$ darzustellen, scheiterte ebenfalls an der Präparation des Ausgangsproduktes N-Methyl-2,6-dimethyl-

benzanilids. — Der durch Rosenmund-Reduktion des 2,6-Dimethylbenzoylchlorids in befriedigender Ausbeute dargestellte 2,6-Dimethylbenzaldehyd ist äusserst luftempfindlich und die Oxydation zur Säure ist nur eine Frage von Stunden. Daher wurden die beschriebenen Versuche unmittelbar im Anschluss an die Vacuumdestillation des Aldehyds durchgeführt. — Die Kondensation des 2,6-Dimethylbenzaldehyds mit dem 1-Amino-2-(diäthylamino)äthan und dem 1-Amino-3-(diäthylamino)propan zu den entsprechenden N-Diäthylaminoalkyl-2,6-dimethylbenzylideniminen XV und XVI war ohne Schwierigkeiten zu erzielen und verlief mit guter Ausbeute. Diese Verbindungen werden leicht durch verdünnte Säuren hydrolysiert.

CHEMISCH-EXPERIMENTELLER TEIL *

Die N-Diäthylaminoalkyl-2,6-dimethylbenzamide wurden, wie schon im theoretischen Teil (S. 1588) berichtet, nach den drei für die Synthese letztgenannter Amide allgemein anwendbaren Methoden A, B und C synthetisiert.

Methode A. In einen 250 ml Dreihalskolben, der mit einem durch Quecksilberverschluss abgedichteten Hershbergrührer, Rückflusskühler und Tropftrichter (beide mit $CaCl_2$-Rohren) versehen war, wurde eine Lösung von 0,030 Mol Diäthylaminoalkylamin in 50 ml trockenem Äther eingetragen. Unter Umrühren wurden 0,030 Mol 2,6-Dimethylbenzoylchlorid, in 25 ml Äther gelöst und unter Eiskühlung langsam eingetropft. Der Äther wurde vom Kristallbrei dekantiert und das Salz mit Äther gewaschen. Es wurde in 50 ml Wasser gelöst, die Base mit 30 % Natronlauge in Freiheit gesetzt und in Äther aufgenommen. Nach dem Trocknen über K_2CO_3 und Abdampfen des Lösungsmittels, wurde die Base durch fraktionierte Destillation als Öl erhalten. Einige Verbindungen gingen in den kristallinen Zustand über und konnten durch Umkristallisieren gereinigt werden.

Methode B. In der unter Methode A beschriebenen Apparatur wurden 0,050 Mol 2,6-Dimethylbenzoylchlorid, in 50 ml trockenem Äther gelöst und mit einer Lösung von 0,10 Mol Halogenalkylamin in 50 ml Äther zur Reaktion gebracht. Die ätherische Lösung des N-Halogenalkyl-2,6-dimethylbenzamids wurde vom ausgefallenen N-Halogenalkylammoniumchlorid abgesaugt und das Filtrat bis zur Trockenen eingeengt. Das N-Halogenalkyl-2,6-dimethylbenzamid, das bei den durchgeführten Synthesen kristallin war, wurde durch Umkristallisieren gerenigt. 0,030 Mol N-Halogenalkyl-2,6-dimethylbenzamid wurden in 50 ml über Natrium getrocknetem Benzol mit 0,10 Mol Diäthylamin fünf Stunden unter Rückfluss gekocht. Nach dem Erkalten der Lösung wurde vom abgeschiedenen Diäthylammoniumchlorid oder -bromid abgesaugt und das benzolische Filtrat erschöpfend mit verdünnter Salzsäure extrahiert. Die Base wurde dann mit 30 % Natronlauge freigesetzt und in Äther aufgenommen. Nach dem Trocknen über K_2CO_3 und Abdampfen des Äthers wurde der Rückstand wie unter Methode A beschrieben weiterbehandelt.

Methode C. Die für die Reaktion erforderliche Menge Natriumamid wurde nach der von Vaughen, Vogt und Nieuwland [30] aus metallischem Natrium und flüssigem Ammoniak mit einer Spur von Eisen (III)-nitrat als Katalysator frisch bereitet. In einem 500 ml Dreihalskolben, der mit einem durch Quecksilberverschluss abgedichteten Hershberg-Rührer und Rückflusskühler (mit $CaCl_2$-Rohr) versehen war, wurden 0,11 Mol Natriumamid in 100 ml trockenem Toluol suspendiert, 0,050 Mol 2,6-Dimethylbenzamid eingetragen und unter kräftigem Rühren eine Stunde unter Rückfluss gekocht. Dann wurde das Halogenalkyldiäthylammoniumchlorid oder -bromid zugesetzt und unter fortgesetztem Rühren weitere vier Stunden unter Rückfluss gekocht. Fand die Alkylierung des 2,6-

* Alle Schmelzpunkte sind korrigiert, alle Siedepunkte unkorrigiert. — Wenn nicht anders vermerkt, wurden die Äquivalentgewichts-Bestimmungen der synthetisierten Basen in 30 % äthanol mit 0,1 N HCl durchgeführt. Mischindikator: 1 Teil 0,1 % äthanolische Methylenblaulösung und 1 Teil 0,2 % äthanolische Methylrotlösung.

Dimethylbenzamids mit Diäthylaminoalkylhalogenid statt, so wurden 0,050 Mol Benzamid und 0,055 Mol Natriumamid angewandt. Nach dem Abkühlen auf Zimmertemperatur wurde vom ausgefallenen Natriumchlorid oder -bromid abgesaugt und die Base in verdünnter Salzsäure aufgenommen. Die saure wässerige Phase wurde stark alkalisch gemacht. Die in Freiheit gesetzte Base wurde in Äther aufgenommen und die Ätherlösung über K_2CO_3 getrocknet. Nach dem Abdampfen des Äthers wurde die Base wie unter A weiterbehandelt.

N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzamid (I), *N-(2-Bromäthyl)-2,6-dimethylbenzamid* (VIII) *und 2-(2,6-Dimethylphenyl)-2-oxazolin* (IX). 2-(Diäthylamino)äthylamin wurde nach der von Amundsen und Krantz [31] beschriebenen Methode synthetisiert, d.h. N-(2-Chloräthyl)diäthylammoniumchlorid wurde mit alkoholischer Ammoniaklösung behandelt. Das Diamin wurde als farbloses Öl vom Kp. 80°/85 mm erhalten (in Übereinstimmung mit dem von Amundsen und Krantz [31] angegebenen Kp.); $n_D^{20} = 1{,}4380$; Ausbeute 65 % d.Th. Nach der Methode A (S. 1596) wurden 4,9 g (0,030 Mol) 2-(Diäthylamino)-äthylamin und 5,0 g (0,030 Mol) 2,6-Dimethylbenzoylchlorid zur Reaktion gebracht und durch Destillation 4,2 g (0,017 Mol) Base, entspr. 57 % d.Th. als leicht gelbliches Öl vom Kp. 149—150°/0,5 mm erhalten. Durch chromatographische Reinigung einer *Cyclo*hexanlösung mittels Al_2O_3 (Brockmann) wurden die spurenhaften Verunreinigungen entfernt und das *N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzamid* (I) als farbloses Öl erhalten; $n_D^{20} = 1{,}5194$. (Gef.: Äquiv.-Gew. 249. Ber. für $C_{15}H_{24}N_2O$: 248.) N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzamid (I) wurde auch nach Methode B (S. 1596) synthetisiert, wobei als Nebenprodukt das 2-(2,6-Dimethylphenyl)-2-oxazolin (IX) isoliert wurde. — Nach der Vorschrift von Cortese [32] wurde Aminoäthanol durch Behandeln mit Bromwasserstoffsäure in N-(2-Bromäthyl)ammoniumbromid überführt. Die aus 29 g (0,11 Mol) des Salzes frisch bereitete Base wurde mit 8,4 g (0,050 Mol) 2,6-Dimethylbenzoylchlorid zur Reaktion gebracht. Nach dem Umkristallisieren des Rückstandes der ätherischen Lösung aus 96 % Äthanol wurde das *N-(2-Bromäthyl)-2,6-dimethylbenzamid* (VIII) in Form farbloser, blättchenförmiger Kristalle vom Fp. 126° erhalten. Ausbeute 12 g (0,047 Mol), entspr. 94 % d.Th. (Gef.: C 51,4; H 5,60; Br 31,4; N 5,57. Ber. für $C_{11}H_{14}BrNO$ (256,15): C 51,6; H 5,51; Br 31,2; N 5,47.) Die Diäthylaminobase wurde durch Behandeln von 8,0 g (0,031 Mol) N-(2-Bromäthyl)-2,6-dimethylbenzamid (VIII) mit 7,3 g (0,10 Mol) Diäthylamin dargestellt. Bei der fraktionierten Destillation des Reaktionsproduktes wurden zwei Hauptfraktionen erhalten: 1) Kp. 90—93°/0,5 mm; $n_D^{20} = 1{,}5355$; Ausbeute 2,0 g. 2) Kp. 149—150°/0,5 mm; $n_D^{20} = 1{,}5192$; Ausbeute 3,8 g.

Die niedriger siedende Fraktion 1 erwies sich als das *2-(2,6-Dimethylphenyl)-2-oxazolin* (IX). (Gef.: C 75,4; H 7,63; N 8,18. Ber. für $C_{11}H_{13}NO$ (175,2): C 75,4; H 7,48; N 8,00.) Die oben angegebene Ausbeute von 2,0 g entspricht demnach 0,013 Mol oder 42 % d.Th. — Typisch für die Oxazoline ist die Reaktion mit Halogenwasserstoffsäuren. Das Oxazolin wird dabei unter Ringöffnung in das entsprechende N-Halogenalkylbenzamid verwandelt. Mit Bromwasserstoffsäure sollte demnach IX die Ausgangsverbindung VIII geben. Um dies zu bestätigen wurde IX mit konzentrierter Bromwasserstoffsäure im Überschuss bis zur Sirupkonsistenz auf dem Wasserbad eingeengt. Auf Zugabe von Wasser ging nur ein geringer Teil in Lösung. Der körnige Rückstand hatte einen Schmelzpunkt von 123° und nach dem Umkristallisieren aus 96 % Äthanol von 126°. Der Mischschmelzpunkt mit N-(2-Bromäthyl)-2,6-dimethylbenzamid (VIII) zeigte keine Depression.

Die höher siedende Fraktion 2 war mit dem nach Methode A (S. 1596) synthetisierten N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzamid (I) identisch. (Gef.: Äquiv.-Gew. 249. Ber. für $C_{15}H_{24}N_2O$: 248.) Die oben angegebene Ausbeute von 3,8 g entspricht demnach 0,015 Mol oder 50 % d.Th.

N-(2-Diäthylaminoäthyl)-N-methyl-2,6-dimethylbenzamid (II). Das N-(2-Diäthylaminoäthyl)methylamin wurde früher von Kermack und Wight [33] aus N-(2-Bromäthyl)-diäthylammoniumbromid und alkoholischer Methylaminlösung synthetisiert. Die Versuchsbedingungen wurden von den Autoren nicht näher beschrieben. Das Diamin wurde hier auf folgende Weise synthetisiert: Im Autoclaven wurden 45 g (0,18 Mol) N-(2-Bromäthyl)diäthylammoniumbromid mit 90 g einer 33 % Lösung von Methylamin in absolutem Äthanol 20 Stunden bei 100° erhitzt. Nach dem Ansäuern mit Salzsäure wurde bis zur Sirupkonsistenz im Vacuum eingeengt, die Base mit Natronlauge in Freiheit gesetzt, in

Äther aufgenommen und die Lösung über K_2CO_3 getrocknet. Nach dem Abdampfen des Lösungsmittels wurde durch Destillation eine farblose Flüssigkeit vom Kp. 44°/10 mm (lt.Lit.[33]: 158°/760 mm) erhalten; n_D^{20} = 1,4340; Ausbeute 7,2 g (0,056 Mol), entspr. 32 % d.Th. — Nach der Methode A wurden 4,2 g (0,025 Mol) 2,6-Dimethylbenzoylchlorid und 3,6 g (0,028 Mol) N-(2-Diäthylaminoäthyl)methylamin zur Reaktion gebracht. Durch fraktionierte Destillation wurde die Base als farbloses Öl vom Kp. 135—137°/0,6—0,7 mm erhalten; n_D^{20} = 1,5145; Ausbeute 4,3 g (0,016 Mol), entspr. 64 % d.Th. (Gef.: Äquiv.-Gew. 262. Ber. für $C_{16}H_{26}N_2O$: 262.)

N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid (III), *N-(3-Brompropyl)-2,6-dimethylbenzamid* (X) *und 2-(2,6-Dimethylphenyl)-5,6-dihydro-1,3,4*H*-oxazin* (XI). 1-Amino-3-(diäthylamino)propan wurde durch Reduktion des nach Terent'ev und Kost [34] sowie Whitmore und Mitarbeiter [35] durch Addition von Diäthylamin und Acrylnitril dargestellten 3-Diäthylaminopropionitrils mit Natrium und Äthanol in 30 % Ausbeute erhalten. Die katalytische Hydrierung nach letzteren Autoren ergab eine Ausbeute von 45 %. Die Reduktion wurde auch mit Lithium-Aluminiumhydrid nach der von Nystrom und Brown [36] allgemein angegebenen Methode durchgeführt: Zu 300 ml über Natrium und Lithium-Aluminiumhydrid getrockneten Äther in einem Dreihalskolben, der mit einem durch Quecksilberverschluss abgedichteten Hershberg-Rührer, Rückflusskühler und Tropftrichter (beide mit $CaCl_2$-Rohren) versehen war, wurden 7,6 g (0,20 Mol) $LiAlH_4$ gegeben. 25 g (0,20 Mol) 3-Diäthylaminopropionitril, in 200 ml Äther gelöst, wurden unter Rühren so zugetropft, dass das Reaktionsgemisch in gelindes Sieden geriet. Nach einstündigem Sieden unter Rückfluss wurde das überschüssige $LiAlH_4$ mit 25 ml Äthylacetat und der graue Komplex mit 50 ml 10 N Natronlauge unter Eiskühlung zerlegt. Es wurde vom Salzrückstand abgesaugt, die ätherische Lösung über Na_2SO_4 getrocknet, das Lösungsmittel abgedampft und der Rückstand fraktioniert destilliert. Das Diamin ging als farblose Flüssigkeit bei 64°/22 mm über; n_D^{20} = 1,4445 (nach Shriner und Hickey [37]: n_D^{20} = 1,4437); Ausbeute 14 g (0,11 Mol), entspr. 50 % d.Th. Nach der Methode A wurde das *N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid* (III) synthetisiert und die Base durch Destillation und nachherige Reinigung einer *Cyclo*hexanlösung durch Schütteln mit Al_2O_3 (Brockmann) als farbloses Öl erhalten. Kp. 160—161°/0,6 mm; n_D^{20} = 1,5143. Das Öl erstarrte zu farblosen, nadelförmigen Kristallen, die nach dem Umkristallisieren aus Pentan einen Schmelzpunkt von 44° hatten. Ausbeute 75 % d.Th. (Gef.: Äquiv.-Gew. 263. Ber. für $C_{16}H_{26}N_2O$: 262.)

Die gleiche Verbindung wurde auch nach Methode B (S. 1596) synthetisiert, wobei als Nebenprodukt das 2-(2,6-Dimethylphenyl)-5,6-dihydro-1,3,4*H*-oxazin(XI) isoliert wurde. N-(3-Brompropyl)ammoniumbromid wurde durch Gabriel-Synthese aus Kaliumphthalimid und 1,3-Dibrompropan und anschliessende Hydrolyse des N-(3-Brompropyl) phthalimids mit Bromwasserstoffsäure in Eisessig nach Hamer und Rathbone [38] synthetisiert. Fp. 163° (lt.Lit.[38]: 161—163°). Das Amid wurde durch Kupplung von aus 6,4 g (0,028 Mol) N-(3-Brompropyl)ammoniumbromid frisch bereiteter Base und 4,5 g (0,028 Mol) 2,6-Dimethylbenzoylchlorid gewonnen. Nach dem Umkristallisieren aus einer Mischung Methylalkohol-Wasser 3:1 (V/V) wurde das *N-(3-Brompropyl)-2,6-dimethylbenzamid* (X) in Form farbloser, fettigglänzender, blättchenförmiger Kristalle vom Fp. 86° erhalten. Ausbeute 4,4 g (0,023 Mol), entspr. 83 % d.Th. (Gef.: C 53,4; H 5,74; Br 29,9; N 5,31. Ber. für $C_{12}H_{16}BrNO$ (270,2): C 53,3; H 5,97; Br 29,6; N 5,19.) 4,4 g (0,023 Mol) N-(3-Brompropyl)-2,6-dimethylbenzamid (X) wurden mit 5,1 g (0,070 Mol) Diäthylamin zur Reaktion gebracht. Bei der fraktionierten Destillation des Reaktionsproduktes fielen zwei distinkt siedende Fraktionen an: 1) Kp. 95—98°/0,5 mm; n_D^{20} = 1,5395; Ausbeute 0,96 g. 2) Kp. 160°/0,5 mm; n_D^{20} = 1,5143; Ausbeute 3,8 g.

Bei der ersten Fraktion handelt es sich um das *2-(2,6-Dimethylphenyl)-5,6-dihydro-1,3,4*H*-oxazin* (XI). (Gef.: C 75,7; H 8,10; N 7,41. Ber. für $C_{12}H_{15}NO$ (189,3): C 76,1; H 7,99; N 7,40.) Die oben angegebene Ausbeute von 0,96 g entspricht demnach 0,0051 Mol oder 23 % d.Th. Diese Substanz gab ebenfalls die für die Oxazoline charakteristische Reaktion (vgl. unter Subst. IX, S. 1597). Es wurde also durch Behandeln mit Bromwasserstoffsäure im Überschuss das N-(3-Brompropyl)-2,6-dimethylbenzamid (X) zurückerhalten.

Die zweite Fraktion entsprach dem *N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid* (III) (vgl. oben). (Gef.: Äquiv.-Gew. 261. Ber. für $C_{16}H_{26}N_2O$: 262.) Die oben angegebene Ausbeute von 3,8 g entspricht demnach 0,015 Mol oder 65 % d.Th.

N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid (III) wurde auch nach Methode C (S. 000) synthetisiert: N-(3-Brompropyl)diäthylammoniumbromid wurde früher von Marvel, Zartmann und Bluthardt [39] durch Spaltung des von Lohmann [40] synthetisierten 1-Diäthylamino-3-phenoxypropans mit Bromwasserstoffsäure dargestellt. Es wurde nun unter Modifizierung des von Cortese [32] zur Darstellung des N-(2-Bromäthyl)ammoniumbromids ausgearbeiteten Methode durch Behandeln des 3-Diäthylamino-1-propanols mit Bromwasserstoffsäure dargestellt. Das 3-Diäthylamino-1-propanol erhielt man durch Addition von Diäthylamin und Allylalkohol nach Gawron und Spoerri [41]. In einem 500 ml Rundkolben wurden 50 g (0,38 Mol) 3-Diäthylamino-1-propanol auf 0° gekühlt und unter kräftigem Rühren mit 350 ml (2,59 Mol) Bromwasserstoffsäure (d = 1,49) gemischt. Dann wurden über eine 45 cm hohe Widmer-Kolonne 90 ml Wasser abdestilliert und das Reaktionsgemisch anschliessend zwei Stunden bei gelindem Sieden unter Rückfluss gehalten. Weitere 35 ml, 30 ml und 20 ml Wasser wurden abdestilliert und zwischen den Destillationen zwei Stunden, am Ende der Reaktion noch drei Stunden unter Rückfluss gekocht. Nach Abdestillieren von 115 ml Bromwasserstoffsäure wurde der tiefbraune Rückstand mit Äther gewaschen und zur Entfärbung mit Aktivkohle (Norit) 15 Min. auf dem siedenden Wasserbad erhitzt. Das fast farblose Filtrat wurde im Vacuum bis zur Trockenen eingedampft. Der wachsartige, leicht gelbliche Rückstand wurde bei 40–45° in 100 ml Butanol gelöst und das Hydrobromid mit 300 ml Äther ausgefällt. Es wurde vom Lösungs- und Fällungsmittel abgesaugt und das fast farblose, stark hygroskopische Salz über P_2O_5 getrocknet. Fp. 91–92° (lt.Lit.[39]: 91–94°); Ausbeute 71 g (0,26 Mol), entspr. 68 % der Theorie. 7,5 g (0,050 Mol) 2,6-Dimethylbenzamid, 14,3 g (0,050 Mol) N-(3-Brompropyl)diäthylammoniumbromid und 4,4 g (0,11 Mol) Natriumamid wurden nach Methode C zur Reaktion gebracht. Die Base wurde durch fraktionierte Destillation und nachherige Reinigung einer *Cyclo*hexanlösung durch Schütteln mit Al_2O_3 (Brockmann) als farbloses Öl vom Kp. 158–160°/0,5 mm erhalten; n_D^{20} = 1,5145. Das Öl erstarrte bald und kristallisierte aus Pentan in Form nadelförmiger Kristalle vom Fp. 43–44°. Ausbeute 11,5 g (0,0438 Mol), entspr. 88 % d.Th. (Gef.: Äquiv.-Gew. 261. Ber. für $C_{16}H_{26}N_2O$: 262.)

N-(2-Diäthylamino-2-methyläthyl)-2,6-dimethylbenzamid (IV). Nach der von Goldfarb [42] abgeänderten Methode von Callsen und Hahl [43] wurde N-(2-Chlorpropyl)diäthylammoniumchlorid durch Addition von Diäthylamin an Propylenoxyd und anschliessende Behandlung des 1-Diäthylamino-2-propanols mit Thionylchlorid in 50 % Gesamtausbeute erhalten. Fp. 107° (lt.Lit.[42]: 107°). Nach der Methode C (S. 1596) wurden 7,5 g (0,050 Mol) 2,6-Dimethylbenzamid, aus 2,3 g (0,10 Mol) Natrium frisch bereitetes Natriumamid und 9,2 g (0,050 Mol) N-(2-Chlorpropyl)diäthylammoniumchlorid zur Reaktion gebracht. Die durch fraktionierte Destillation gewonnene Base ging als farbloses Öl vom Kp. 162°/0,5 mm über; n_D^{20} = 1,5165. Das Öl erstarrte bald zu einer Kristallmasse und wurde nach dem Umkristallisieren aus Pentan in Form weisser, blättchenförmiger Kristalle vom Fp. 56° erhalten. Ausbeute 6,3 g (0,024 Mol), entspr. 48 % d.Th. (Gef.: Äquiv.-Gew. 263. Ber. für $C_{16}H_{26}N_2O$: 262.) Die gleiche Verbindung wurde nach Methode A (S. 1596) erhalten: 1-Amino-2-(diäthylamino)propan wurde durch Reduktion des 2-Diäthylaminopropionitrils gewonnen. Das Nitril wurde nach der von Luten [25] angegebenen Methode durch Kondensation von Acetaldehyd, Diäthylamin und Kaliumcyanid synthetisiert. Bei der Reduktion mit Natrium und Äthanol wurde die von Magidson und Grigorowsky [44] für die Reduktion des 6-Diäthylaminocapronitrils angegebene Vorschrift befolgt. Das Diamin siedete bei 57°/16 mm; n_D^{20} = 1,4390; Ausbeute 55 % d.Th. (Die Verbindung ist früher [45] durch Behandeln von 1-Chlor-2-diäthylaminopropan mit methylalkoholischem Ammoniak dargestellt worden.) Das 1-Amino-2-(diäthylamino)propan und das 2,6-Dimethylbenzoylchlorid wurden dann nach Methode A zur Reaktion gebracht. Durch Destillation und darauffolgende Reinigung einer *Cyclo*hexanlösung durch Schütteln mit Al_2O_3 (Brockmann) wurde das *N-(2-Diäthylamino-2-methyläthyl)-2,6-dimethylbenzamid* (IV) als farbloses Öl vom Kp. 158–160°/0,4 mm erhalten; n_D^{20} = 1,5163. Das Öl erstarrte zu einem farblosen Kristallbrei. Nach dem Umkristallisieren aus Petroläther (Kp. 45–65°) wurden farblose, rhombische Kristalle vom Fp. 56–57° erhalten. Der Schmelzpunkt

stimmt also mit dem nach Methode C (S. 1596) synthetisierten Umlagerungsprodukt (IV) überein. Weiterhin zeigt der Mischschmelzpunkt mit beiden Substanzen keine Depression.

N-(2-Diäthylamino-1-methyläthyl)-2,6-dimethylbenzamid (V). Nach Breslow und Mitarbeitern [24] wurde 2-Amino-1-(Diäthylamino)propan durch reduktive Aminierung von Diäthylaminoaceton dargestellt. Aus diesem Diamin wurde nach Methode A (S. 1596) das *N-(2-Diäthylamino-1-methyläthyl)-2,6-dimethylbenzamid* (V) als farbloses Öl vom Kp. 152–153°/0,7 mm gewonnen; n_D^{20} = 1,5120; Ausbeute 67 % d.Th. Das Öl erstarrte zu farblosen Kristallen, die nach dem Umkristallisieren aus Pentan in Form weisser, blättchenförmiger Kristalle vom Fp. 50° erhalten wurden. (Gef.: Äquiv.-Gew. 262. Ber. für $C_{16}H_{26}N_2O$, 262.)

N-(2-Diäthylamino-1,2-dimethyläthyl)-2,6-dimethylbenzamid (VI), *3-Diäthylamino-2-butanon-Oxim* (XII) und *2-Amino-3-(diäthylamino)butan* (XIII). 3-Brom-2-butanon wurde nach der Vorschrift von Catch und Mitarbeitern [27] durch Bromierung von Methyläthylketon und anschliessende wiederholte fraktionierte Destillation dargestellt. 3-Diäthylamino-2-butanon wurde in der unterMethode B (S. 000) schon beschriebenen Weise durch Behandeln von 3-Brom-2-butanon mit Diäthylamin gewonnen. Es wurde als farblose Flüssigkeit vom Kp. 57–58°/12 mm erhalten; n_D^{20} = 1,4265; Ausbeute 83 % d.Th. (Gef.: Äquiv.-Gew. 145. Ber. für $C_8H_{17}NO$: 144.) Der hier gefundene Siedepunkt des Aminoketons stimmt mit denen von Rose und Weedon [26] angegebenen überein; sie erhielten die Verbindung durch Hydratisierung von 3-Diäthylamino-1-butin. Die Oximierung wurde in Anlehnung an eine Vorschrift von Shriner und Fuson [46] vorgenommen: Zu 15 g (0,11 Mol) Keton wurde unter Umschütteln und Eiskühlung eine Lösung von 10 g (0,15 Mol) Hydroxylaminhydrochlorid in 25 ml Wasser gegossen und über Nacht bei Zimmertemperatur stehen gelassen. Die Lösung wurde mit 50 ml Äther überschichtet und eine Lösung von 12 g Natriumhydroxyd in 12 ml Wasser und festes Kaliumkarbonat bis zur Sättigung zugefügt. Die wässerige Phase wurde dreimal mit je 50 ml Äther ausgeschüttelt und die vereinigten Ätherextrakte über K_2CO_3 getrocknet. Der Äther wurde abgedampft und das Oxim als farbloses Öl vom Kp. 113–114°/12 mm durch Destillation gewonnen; n_D^{20} = 1,4710. Das 3-Diäthylamino-2-butanon-Oxim (XII) kristallisierte bald in farblosen Nadeln vom Fp. 52°; Ausbeute 12 g (0,076 Mol), entspr. 69 % d.Th. (Gef.: Äquiv.-Gew. 158. Ber. für $C_8H_{18}N_2O$: 158.) In der gleichen Weise, wie unter Verbindung (III) (S. 000) beschrieben, wurden 11,5 g (0,073 Mol) Ketoxim mit 3,8 g (0,10 Mol) $LiAlH_4$ in Äther reduziert. Das *2-Amino-3-(diäthylamino)butan* (XIII) wurde als farblose Flüssigkeit vom Kp. 60°/12 mm erhalten; n_D^{20} = 1,4380; Ausbeute 5,5 g (0,038 Mol), entspr. 50 % d.Th. (Gef.: C 66,3; H 13,7; N 19,6. Ber. für $C_8H_{20}N_2$ (144,3): C 66,6; H 13,9; N 19,5.) Das Oxim wurde auch mit Natrium und Äthanol reduziert: In einem mit Quecksilberverschluss abgedichteten Hershberg-Rührer und mit Rückflusskühler versehenen Dreihalskolben wurden 46 g (2,0 Mol) Natrium in 100 ml trockenem Toluol fein verteilt und unter kräftigem Rühren eine Lösung von 28 g (0,18 Mol) Oxim in 250 ml absolutem Äthanol aus einem Tropftrichter unter Ausschluss der Luftfeuchtigkeit langsam zugetropft. Nach dem Eintragen des Oxims wurde das Reaktionsgemisch noch eine Stunde unter fortgesetzem Rühren in gelindem Sieden gehalten bis das Natrium vollständig in Lösung gegangen war. Es wurde unter Eiskühlung mit konzentrierter Salzsäure angesäuert, im Vacuum bis zur Sirupkonsistenz eingeengt und die Base, wieder unter Eiskühlung, mit festem Kaliumhydroxyd in Freiheit gesetzt. Sie wurde in Äther aufgenommen und in der gleichen Weise wie oben beschrieben behandelt. Ausbeute 16 g (0,11 Mol), entspr. 60 % d.Th. (Gef.*: Äquiv.-Gew. 72,6. Ber. für $C_8H_{20}N_2$ (144,3): 72,2.) 4,7 g (0,028 Mol) 2,6-Dimethylbenzoylchlorid und 5,5 g (0,036 Mol) 2-Amino-3-(diäthylamino)butan (XIII) wurden nach Methode A (S. 1596) zur Reaktion gebracht. Das *N-(2-Diäthylamino-1,2-dimethyläthyl)-2,6-dimethylbenzamid* (VI) wurde durch fraktionierte Destillation als leicht gelbliches Öl vom Kp. 162°/0,5 mm erhalten. Die spurenhaften Verunreinigungen wurden durch chromatographische Reinigung einer *Cyclo*hexanlösung mittels Al_2O_3 (Brockmann) entfernt und die Base als farb-

* Titration der Base in wasserfreiem Medium (Eisessig) mit 0,1 N Überchlorsäure, in wasserfreiem Eisessig gelöst, gegen den Indikator BZL-Blau (Ciba) nach der Methode von Riddick [47].

loses Öl, dass bald zu farblosen, prismenartigen Kristallen vom Fp. 39° erstarrte, fast quantitativ zurückerhalten. Aus Pentan kristallisierte die Verbindung in Form von Nadeln vom Fp. 40°. — Auf eine Trennung der beiden Racemate musste wegen Substanzmangel verzichtet werden. (Gef.: Äquiv.-Gew. 275. Ber. für $C_{17}H_{28}N_2O$: 276.)

N-(3-Diäthylaminopropyl)-3,5-dimethylbenzamid (VII). 3,5-Dimethylbenzoesäure wurde durch Oxydation von Mesitylen mit verdünnter Salpetersäure nach der von Snyder, Adams und McIntosh [48] beschriebenen Methode gewonnen. Fp. 165—166° (lt.Lit.[48]: 165—167°). Das 3,5-Dimethylbenzoylchlorid wurde in der üblichen Weise durch Behandeln mit Thionylchlorid erhalten. Kp. 116°/13 mm; n_D^{20} = 1,5465. (Kp. lt. Weiler [49]: 110°/10 mm) Nach der Methode A (S. 1596) wurden aus 6,7 g (0,040 Mol) 3,5-Dimethylbenzoylchlorid und 5,2 g (0,040 Mol) 1-Amino-3-(diäthylamino)propan 7,5 g (0,029 Mol) *N-(3-Diäthylaminopropyl)-3,5-dimethylbenzamid* (VII), entspr. 73 % d.Th., als farbloses Öl vom Kp. 174°/0,4 mm erhalten; n_D^{20} = 1,5200. (Gef.: Äquiv.-Gew. 261. Ber. für $C_{16}H_{26}N_2O$: 262.)

N,N-Dimethyl-2,6-dimethylbenzamid (XIV). In einem 250 ml Dreihalskolben, der mit einem durch Quecksilberverschluss abgedichteten Hershbergrührer, Rückflusskühler und Tropftrichter (beide mit $CaCl_2$-Rohren) versehen war, wurde eine Lösung von 4,5 g (0,062 Mol) Dimethylamin in 50 ml über Natrium getrocknetem Äther eingetragen. Unter kräftigem Rühren und Eiskühlung wurden 5,0 g (0,030 Mol) 2,6-Dimethylbenzoylchlorid, in 25 ml Äther gelöst, langsam zutropfen lassen. Es wurde vom Niederschlag des N,N-Dimethylammoniumchlorids abgesaugt und der Rückstand in 50 ml Wasser aufgenommen. Aus der mit Schwefelsäure schwach angesäuerten Lösung wurde das Amid im Perforator mit Äther extrahiert. Nach dem Trocknen der ätherischen Lösung über Na_2SO_4 und Abdampfen des Äthers wurde der zähflüssige, ölige Rückstand im Vacuum destilliert. Das leicht gelbliche Öl vom Kp. 118—119°/2,5 mm erstarrte bald. Es wurde in einer Mischung Petroläther (Kp. 50—60°)-Kohlenstofftetrachlorid 4:1 (V/V) aufgelöst und die Lösung dann auf eine Säule gegossen, die aus Al_2O_3 (Brockmann) und der Flüssigkeitsmischung bereitet war. Mittels dieser Mischung wurde dann das Chromatogramm entwickelt. Das N,N-Dimethyl-2,6-dimethylbenzamid lief ziemlich schnell durch, während die gelben Verunreinigungen sehr fest zurückgehalten wurden. Das Lösungsmittel wurde abgetrieben und der farblose Rückstand aus 96 % Äthanol umkristallisiert. Es wurden weisse, rhombische Kristalle erhalten. Fp. 62—63°; Ausbeute 4,3 g (0,024 Mol), entspr. 80 % d.Th. (Gef.: C 74,3; H 8,47; N 7,91. Ber. für $C_{11}H_{15}NO$: C 74,5; H 8,53; N 7,94.)

N-(2-Diäthylaminoäthyl)-2,6-dimethylbenzylidenimin (XV). In einem 15 ml Erlenmeyer-Kölbchen wurden 1,32 g (0,00985 Mol) 2,6-Dimethylbenzaldehyd mit 1,2 g (0,011 Mol) 2-(Diäthylamino)äthylamin 15 Min. auf siedendem Wasserbad erhitzt. Das Reaktionsgemisch trübte sich bald. Es wurde in Äther aufgenommen und über K_2CO_3 getrocknet. Nach dem Abdampfen des Lösungsmittels wurde die Schiff-Base durch Destillation als farblose Flüssigkeit vom Kp. 140—141°/0,5 mm erhalten; n_D^{20} = 1,5230; Ausbeute 1,28 g (0,00551 Mol), entspr. 50 % d.Th. (Gef.: C 77,9; H 10,5; N 12,2. Ber. für $C_{15}H_{24}N_2$ (232,3): C 77,6; H 10,4; N 12,1.)

N-(3-Diäthylaminopropyl)-2,6-dimethylbenzylidenimin (XVI). In der gleichen Weise wie unter Substanz (XV) beschrieben, wurden aus 0,65 g (0,0050 Mol) 1-Amino-3-(diäthylamino)propan und 0,65 g (0,0049 Mol) 2,6-Dimethylbenzaldehyd die Schiff-Base als farblose Flüssigkeit vom Kp. 129—130°/0,6 mm erhalten; n_D^{20} = 1,5200; Ausbeute 1,0 g (0,0039 Mol), entspr. 80 % d.Th. (Gef.: C 78,8; H 10,3; N 11,2. Ber. für $C_{17}H_{26}N_2$ (258,4): C 79,0; H 10,1; N 10,9.)

Vergleichender Hydrolyseversuch des N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamids (III) *und des N-(3-Diäthylaminopropyl)-3,5-dimethylbenzamids* (VII). Es wurden 0,60 g (0,0023 Mol) N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid (III) und 1,0 g (0,0038 Mol) N-(3-Diäthylaminopropyl)-3,5-dimethylbenzamid (VII) mit je 20 ml 10 % Schwefelsäure vier Stunden unter Rückfluss bei einer Ölbadtemperatur von 130° gekocht. Das Reaktionsgemisch, dass das N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamid (III) enthielt, war völlig klar. Die schwefelsaure Lösung wurde mit Äther ausgeschüttelt und der Äther abgedampft. Es hinterblieb nur ein spurenhafter Rückstand. Die wässerige Phase wurde stark alkalisch gemacht und die ausgefallene Base in Äther aufgenommen. Die ätherische Lösung wurde über K_2CO_3 getrocknet und das Lösungsmittel vollständig abgedampft. Der fast farblose ölige Rückstand hatte einen Brechungsindex n_D^{20} = 1,5140

(n_D^{20} des N-(3-Diäthylaminopropyl)-2,6-dimethylbenzamids (III) = 1,5144). Ausbeute 0,55 g (0,0021 Mol), entspr. 91 % d.Th. (Gef.: Äquiv.-Gew. 262. Ber. für $C_{16}H_{26}N_2O$: 262.)

Das im Rückflusskühler befindliche Sublimat und der im Kölbchen mit dem N-(3-Diäthylaminopropyl)-3,5-dimethylbenzamid (VII) befindliche Niederschlag wurden in Äther aufgenommen. Nach dem Trocknen der ätherischen Lösung über Na_2SO_4 konnten 0,49 g (0,0033 Mol), entspr. 85 % d.Th., 3,5-Dimethylbenzoesäure vom Fp. 164° erhalten werden. Der Mischschmelzpunkt mit der reinen 3,5-Dimethylbenzoesäure zeigte keine Depression.

PHARMAKOLOGISCHER TEIL

Die Verbindungen I—VII wurden auf ihre lokalanästhetische Wirksamkeit an der Kaninchencornea nach der Technik von Wiedling [50] geprüft und mit der Wirksamkeit des Xylocains verglichen. Um die Veränderung der in den Xylocainverbindungen vorkommenden Gruppierung Ar·NH·CO- (Anilid-Typus) in die in den hier aktuellen Verbindungen enthaltene Gruppierung Ar·CO·NH- (Benzamid-Typus) in ihrer pharmakologischen Auswirkung zu studieren, wurde auch das früher [5,8,51] beschriebene Xylocainanalog β-Diäthylamino-2,6-dimethylpropionanilid, $2,6\text{-}(CH_3)_2C_6H_3\cdot NH\cdot CO\cdot CH_2\cdot CH_2\cdot N(C_2H_5)_2$ mit untersucht. Diese Substanz unterscheidet sich von der Benzamid-Verbindung I, $2,6\text{-}(CH_3)_2C_6H_3\cdot CO\cdot NH\cdot CH_2\cdot CH_2\cdot N(C_2H_5)_2$, lediglich durch die Umkehrung der Gruppierung -NH·CO-.

Für die Prüfung wurden sämtliche Basen in Wasser mittels Salzsäure gelöst. Diese Lösungen bestimmter Konzentration wurden alle auf ein pH von 5,5 eingestellt und die physiologische Menge Kochsalz zugesetzt.

Bei der Testung einer Substanz wurde die Konzentration aufgesucht, bei der die Lösung dieselbe Duration wie eine 0,0738 molare Lösung von Xylocainhydrochlorid (2 %-ige Lösung von Xylocain·HCl) aufwies. Die Aktivität letzterer Lösung wurde gleich eins gesetzt. Die *relative Aktivität*, RA, einer Substanz wurde berechnet als der Quotient zwischen der Molarität der Standard-Lösung von Xylocain (= 0,0738 M) und der gefundenen Molarität der Testlösung. Die Auswertung einer Substanz wurde mit 10—20 Tieren ausgeführt und der Mittelwert berechnet. Falls eine Substanz bei der Applikation einer 0,0738 M Lösung keine messbare Anästhesie hervorrief, so wurde die Verbindung als *inaktiv* bezeichnet.

Die Toxizität der Substanzen wurde mittels subcutaner Injektionen an weissen Mäussen bestimmt. Für jede Substanz wurden ungefär 50 Tiere verwendet und der LD_{50}-Wert berechnet. Die LD_{50}-Werte werden hier in zwei verschiedenen Massen angegeben, nähmlich (a) in g per kg Körpergewicht und (b) in Mol per kg Körpergewicht („molarer" LD_{50}-Wert).

Den Quotient aus dem *molaren* LD_{50}-Wert von Xylocain und dem entsprechenden Wert einer der anderen Substanzen, bezeichnen wir als die *relative Toxizität*, RT, der Substanz. Für den Quotienten RA/RT führen wir die Bezeichung *anästhetischer Index*, Q, ein.

In der Tabelle 2 sind die Resultate der pharmakologischen Messungen zusammengestellt, Ein Vergleich zwischen dem Xylocainhomolog B (Anilid-Typus) und der isomeren Substanz I (Benzamid-Typus) zeigt, dass die Umkehr der Gruppierung -NH·CO- in die Gruppierung -CO·NH-, mit einer

Tabelle 2. Lokalanästhetische Aktivität (Kaninchencornea) und subcutane Toxizität (weisse Maus) von neun Verbindungen. Für die Begriffe *relative anästhetische Aktivität* (RA), *relative Toxizität* (RT) und *anästhetischer Index* (Q), siehe S. 1602.

	Verbindung	Relative anästhetische Aktivität (RA) Xylocain = 1	Toxizität, LD_{50}		Relative Toxizität (RT) Xylocain = 1	Q
			g Base/kg	Mol/kg · 10^3		
A	2,6-$(CH_3)_2C_6H_3$·NH·CO·CH_2·N$(C_2H_5)_2$ (=Xylocain)	1,0	0,34	1,4	1,0	1,0
B	2,6-$(CH_3)_2C_6H_3$·NH·CO·$(CH_2)_2$·N$(C_2H_5)_2$	1,3	0,30	1,2	1,2	1,1

VI	2,6-$(CH_3)_2C_6H_3$·CO·NH·CH(CH_3)·CH(CH_3)·N$(C_2H_5)_2$	3,4	0,075	0,27	5,2	0,65
VII	3,5-$(CH_3)_2C_6H_3$·CO·NH·$(CH_2)_3$·N$(C_2H_5)_2$	0,88	0,71	2,7	0,52	1,7

[a] Hinsichtlich des Begriffes inaktiv, siehe S. 1602.

Erniedrigung der Aktivität (RA) um etwa 60 % einhergeht. Gleichzeitig wird die Toxizität (RT) um etwa 50 % herabgesetzt, so dass der anästhetische Index (Q) ungefähr 25 % niedriger wird. Wenn in I der Amidwasserstoff gegen eine Methylgruppe ausgetauscht wird (I → II), so ist die resultierende Verbindung II „inaktiv" * und hat im Vergleich mit I eine um etwa 30 % niedrigere Toxizität. Dieselben Veränderungen sowohl an Aktivität als auch an Toxizität erhält man bei Verlängerung der zweigliedrigen Methylenkette in I zu einer dreigliedrigen in III. Verzweigt man in I die Seitenkette, —CO·NH·CH_2·CH_2·N$(C_2H_5)_2$, mit einer Methylgruppe an einer der beiden Methylengruppen, so steigt in beiden Fällen (I → IV, I → V) die Aktivität um das drei- bis vierfache, während gleichzeitig die Toxizität ungefähr dreimal erhöht wird. Man beachte in diesem Zusammenhang, dass unter den drei isomeren Verbindungen III, IV und V, die eine Trimethylenkette, -CH_2·CH_2·CH_2-, enthaltende Verbindung III „inaktiv" ist, während die beiden anderen Verbindungen, die statt dessen eine methylsubstituierte Äthylenkette, -CH_2-CH(CH_3)-

* Hinsichtlich des Begriffes inaktiv — siehe oben.

oder $-CH(CH_3)-CH_2-$, besitzen, beide ungefähr 100 % aktiver sind als Xylocain. Die „inaktive" Verbindung III hat eine Toxizität, die mindestens um 50 % niedriger ist als die des Xylocains, während IV und V Toxizitäten haben, die im Vergleich mit Xylocain mindestens um 50 % höher sind. Führt man in I Verzweigungen an beiden Methylengruppen ein (I → VI), so wird die Aktivität ungefähr siebenmal und die Toxizität acht- bis neunmal gesteigert.

Schliesslich mag erwähnt werden dass, wenn man in der Verbindung III, die — wie oben besprochen — „inaktiv" ist, die 2,6-Stellung der Kernmethylgruppen zur 3,5-Stellung verändert, eine Verbindung VII resultiert, die beinahe so aktiv ist wie Xylocain. Im Vergleich mit III hat VII ungefähr dieselbe Toxizität, und mit Xylocain verglichen ist die Verbindung um etwa 50 % weniger toxisch.

Zwei von den synthetisierten Verbindungen, nähmlich I und VII wurden auf ihre infiltrationsanästhetische Wirksamkeit beim Menschen geprüft und mit Xylocain verglichen. Um auch hier den Anilid-Typus mit dem Benzamid-Typus zu vergleichen, wurde in den Messungen das Xylocainhomolog B mituntersucht (Vergleich von B und I). — Von sämtlichen vier Substanzen wurden eine 0.0214 molare Lösung * des Hydrochlorids bereitet. Diese Lösungen enthielten die physiologische Menge Kochsaltz, eine Adrenalinkonzentration von 1:100 000 und hatten ein pH von 5,0. Bei der Testung wurden die Lösungen subcutan in Mengen von 1 ml appliziert (hinsichtlich Einzelheiten in der Methodik — siehe Löfgren, Tegnér und Takman [1]). Die Latenzzeit und die Duration wurden beobachtet und die auf Xylocain bezogenen Relativwerte berechnet. In Tabelle 3 ist die *relative Latenzzeit* mit RL und die *relative Duration* mit RD bezeichnet.

In Übereinstimmung mit den Messungen an der Cornea findet man auch hier, dass der Übergang vom Anilid-Typus zum Benzamid-Typus (B → I) von einer Aktivitätserniedrigung begleitet ist ($(RD)_B > (RD)_I$). An der Cornea fanden wir, dass VII merklich aktiver war als I, während dagegen in der subcutanen Technik, VII im Vergleich zu I eine merklich geringere Aktivi-

Tabelle 3. Testung der Duration, der Latenzzeit und der Irritation von vier Verbindungen durch subcutane Injektion am Menschen. Für die Begriffe RD (relative Duration) und RL (relative Latenzzeit), siehe oben.

	Verbindung	RD	RL	Irritation
A	$2,6\text{-}(CH_3)_2C_6H_3\cdot NH\cdot CO\cdot CH_2\cdot N(C_2H_5)_2$ (= Xylocain)	1	1	0
B	$2,6\text{-}(CH_3)_2C_6H_3\cdot NH\cdot CO\cdot(CH_2)_2\cdot N(C_2H_5)_2$	0,9	3	+
I	$2,6\text{-}(CH_3)_2C_6H_3\cdot CO\cdot NH\cdot(CH_2)_2\cdot N(C_2H_5)_2$	0,7	3	+
VII	$3,5\text{-}(CH_3)_2C_6H_3\cdot CO\cdot NH\cdot(CH_2)_3\cdot N(C_2H_5)_2$	0,4	4	0

* Eine 0,0214 molare Lösung von Xylocain ist 0,5 %-ig in Bezug auf die Basenmenge.

tät besitzt. Löfgren und Mitarbeiter haben früher [1,52,53] solche Diskrepanzen zwischen Oberflächen- und Infiltrationsanästhesie gefunden. Neuerdings ist auch von Koelzer und Wehr [54] hervorgehoben worden, dass „bei den Aminoacetaniliden die Fähigkeit zur Oberflächenanästhesie * fast nie mit der Wirkung als Injektionsanästheticum ** parallel geht". Bedenkt man, dass die physiologischen Verhältnisse — wie z.B. Durchblutung und Enzymaktivität — denen eine Substanz bei der oberflächlichen Applikation an der Cornea, und andererseits bei der Injektion unter die Haut begegnet sehr verschieden sind, so ist es nicht erstaunlich, dass Diskrepanzen von ohen erwähnter Art existieren. Unserer Ansicht nach sollte es für eine grössere Anzahl Substanzen verschiedener Konstitution überhaupt unmöglich sein, eine Korrelation zwischen der oberflächenanästhetischen Wirkung an der Cornea und der Infiltrationsanästhetischen Wirkung zu finden.

Bei den subcutanen Testungen wurden, wie oben erwähnt, auch die Latenzzeiten bestimmt. Die Fehler dieser Messungen sind relativ gross, so dass die in der Tabelle 3 angeführten RL-Werte (siehe oben) nur als Grössenordnungen aufzufassen sind. Man kann aber mit Sicherheit sagen, dass sämtliche drei Verbindungen (B, I und VII) als Infiltrationsanästhetica im Vergleich mit Xylocain wesentlich grössere Latenzzeiten aufweisen. — Es wurde weiter beobachtet, dass Xylocain und VII keine Irritation hervorriefen, während B und I eine schwach schmerzerregende Wirkung ausübten.

Herrn Dr. S. Wiedling danken wir für die Ausführung der Toxizitätsbestimmungen und für die Messung der lokalanästhetischen Wirkung an der Kaninchencornea.

Infrared and Raman Spectra of Some Systems Containing Thiocyanate Groups

PER-OLOF KINELL and BROR STRANDBERG

Institute of Physical Chemistry and Institute of Inorganic Chemistry, University of Uppsala, Uppsala, Sweden

Infrared spectra have been taken of solid silver thiocyanate and ammonium silver thiocyanate in the region 400–2 200 cm^{-1}. These spectra indicate that the latter compound is composed of silver thiocyanate and thiocyanate ions in agreement with X-ray data. The assignment of the fundamentals has not been possible because one of the fundamentals has evaded detection. A probable correspondence between the lines in the spectra of the thiocyanate ion, the silver thiocyanate and the ammonium silver thiocyanate has been given.

Raman spectra from solutions containing silver thiocyanate dissolved in ammonium and sodium thiocyanate have shown that these solutions do not contain spectroscopically detectable units having strong bonds between SCN groups and silver ions. The silver ion influences the CN stretching frequency. There is an increase in this frequency when going from the solutions to the solid compounds.

In the present paper some results from a study of systems containing silver and thiocyanate groups will be reported. The systems have been investigated by means of molecular spectroscopic methods. The principal aim of the work has been to compare the vibrational behaviour of the thiocyanate group in different environments. Therefore systems having a known crystal structure have been chosen, namely silver thiocyanate investigated by Lindqvist [1] and ammonium silver dithiocyanate studied by Lindqvist and Strandberg [2]. Furthermore, water solutions of sodium and silver thiocyanates (Leden and Nilsson [3]) and ammonium and silver thiocyanates (Nilsson [4]) were examined in order to elucidate possible differences between thiocyanate groups in a solid phase and in its corresponding mother liquid.

The vibrational behaviour of the thiocyanate ion, SCN^-, is characterized by three fundamental modes (*cf.* Herzberg [5]) either it is regarded as linear (point group $C_{\infty v}$) or bent (point group C_s). There has been some discussion about its proper structure (Saraf [6]), but for the sake of simplicity it will *pro tempore* be regarded as linear. Then the first of the normal vibrations, ν_1, corresponds to a stretching of the CN-bond. Being a triple bond it is strong

and, consequently, the vibrational frequency high, about 2 065 cm^{-1}. The second vibration, ν_2, is a bending of the molecule with a frequency of about 480 cm^{-1}. It is a doubly degenerate mode. The third vibration, ν_3, can essentially be looked upon as a stretching of the S—C-bond with a frequency of about 750 cm^{-1}. In the crystalline phase the vibrational state of the SCN^- ion corresponds in its main features to that in solution (Jones [7]). The degenerate mode, ν_2, is split.

In some previous works the change in the ν_1 mode frequency has been studied in order to elucidate the structure of various thiocyanate complexes. Thus Chatt *et al.*[8,9] have found a change in the infrared absorption in the region 2 100—2 170 cm^{-1} with the position of thiocyanate groups in platinum and palladium complexes containing tri-*n*-propyl phosphine or -arsine groups. They distinguish between terminal SCN groups having absorption in the range 2 100—2 120 cm^{-1} and bridging SCN groups giving rise to frequencies in the region 2 150—2 185 cm^{-1}. The difference has been attributed to increased bond order of the CN bond with increasing positive charge on the sulphur atom as a consequence of coordination to two metal atoms. However, the type of bridging is at present not definitely settled (*cf.* Ref.[9]).

Fujita, Nakamoto and Kobayashi [10] have explained the higher ν_1-stretching frequency in Cr^{3+} and Co^{3+} complexes as due to *sp* hybridization of the nitrogen atom compared to sp^2 hybridization in thio*iso*cyanic acid. The frequencies are 2 000—2 180 cm^{-1} and 1 963 cm^{-1}, respectively. The interaction between the sulphur atom and outer ions such as Hg^{2+} and Ag^+ shifts the CN stretching vibration to higher frequencies.

The crystal symmetry of the silver thiocyanate is according to Lindqvist's investigation [1] monoclinic with the space group $C2/c$ (C_{2h}^6). The unit cell contains eight silver thiocyanate molecules. The structure can best be described as built up by endless chains, with the composition $(AgSCN)_n$ formed by a covalent bond from a silver atom to the end sulphur of one thiocyanate group and a bond to the end nitrogen of another thiocyanate group. (The latter bond is not necessarily covalent.) The chains have a zig-zag shape and progress almost perpendicularly to the *bc* plane. There is a silver-sulphur interaction between different chains: the Ag-S distances are 2.997 ± 0.011 Å and 2.886 ± 0.012 Å compared to the Ag-S bond distance of 2.428 ± 0.001 Å and the Ag^+-S distance of 2.9—3.1 Å. No significant deviation from linearity in the SCN group has been found.

The symmetry of the ammonium silver dithiocyanate is monoclinic [2], belonging to space group $P2_1/n$ (C_{2h}^5). The unit cell contains four molecules. The crystal is built up by AgSCN molecules, NH_4^+ ions and SCN^- ions. The silver atom coordinates four sulphur atoms in a very distorted tetrahedron. The Ag-S distances are: 2.474 ± 0.020 Å within the AgSCN molecule, 2.654 ± 0.019 Å, 2.630 ± 0.027 Å and 2.742 ± 0.029 Å from one AgSCN molecule to the three surrounding SCN^- ions.

The state of the thiocyanate group in water solution at high contents of thiocyanate is, according to solubility and potentiometric data [3], characterized by a series of complexes of the type $Ag_m(SCN)_{2m+2}^{(m+2)-}$. The complex having $m = 1$ is the most abundant in solutions containing sodium thiocyanate.

From electron distribution functions [4] in ammonium silver thiocyanate systems it has been found that a model based on the $Ag_m(SCN)_{2m+2}^{(m+2)-}$ complexes gives one Ag-S distance, which does not correspond to a maximum of the distribution function. An idealized layer structure based upon the crystal structure of ammonium silver dithiocyanate gives Ag-S and Ag-Ag distances in agreement with the distribution curve.

EXPERIMENTAL

Material. The potassium, sodium and ammonium thiocyanates used in the present investigation were of analytical grade. The ammonium salt was recrystallized because it was slightly reddish, probably due to some iron impurities. All the solutions were prepared from distilled water and were carefully filtered. Silver thiocyanate was precipitated from silver nitrate and potassium thiocyanate solutions. It was always used just after preparation. Ammonium silver dithiocyanate was crystallized from mother liquid M I prepared from 100.0 g AgSCN, 98.8 g NH_4SCN and 102.5 g H_2O. The composition corresponds to a point in the phase diagram of $AgSCN-NH_4SCN-H_2O$ situated in the liquid area but quite near to the phase limit of $NH_4Ag(SCN)_2(s)$ (*cf.* Occleshaw [11]). The molarities of the different ions are approximately $M_{SCN^-} = 9.5$, $M_{Ag^+} = 3.0$ and $M_{NH_4^+} = 6.5$. (M means here total concentration.) After about 30 g of $NH_4Ag(SCN)_2$ had crystallized, the supernatant liquid was separated from the crystals as mother liquid M II, having the approximate composition $M_{SCN^-} = 9$, $M_{Ag^+} = 2.5$ and $M_{NH_4^+} = 6$. Mother liquid M III was prepared from 11.5 g of AgSCN, 48.5 g of NaSCN and 40 g of H_2O in order to get a saturated solution without solid phase (Occleshaw [11]). The approximate composition is $M_{SCN^-} = 10$, $M_{Ag^+} = 1$ and $M_{Na^+} = 9$.

Infrared measurements. Infrared spectra were taken from the solid compounds using either the technique with paraffin oil mulls or with potassium bromide pellets. Spectra were run both in a Perkin-Elmer model 21 spectrophotometer equipped with NaCl, KBr and CsBr prisms and in a Beckman spectrophotometer IR-2 in the NaCl region. Difficulties arouse with the KBr pellets, for even when very high pressures were used, the prisms were slightly opaque. The reason for this is believed to be the difference in compressibilities of the crystals. The softer thiocyanate material cannot be sintered with the harder potassium bromide. Nevertheless quite good spectra could be obtained in all regions of interest for the present investigation. The accuracy in the wave number determination is $\pm$ 2—3 cm^{-1}.

Jones [7] has reported the appearance of anomalous absorption bands from potassium thiocyanate in potassium chloride and bromide disks. The type of anomaly is not stated. Furthermore, Jones [12] has observed foreign peaks from disks containing potassium silver dicyanide. As pointed out by Jones and Chamberlain [13], this can depend upon an exchange of ions or ion complexes between the different lattices. Such an exchange between K^+ and NH_4^+ has been observed by Pliskin and Eischens [14]. In the present case the differences between spectra from mulls and pellets generally are small.

Raman measurements. The raman spectra of the soluble salts and of the mother liquids were obtained using a raman spectrograph arranged for both photographic and photoelectric recording (Kinell [15]). The sample volume was about 20 ml. A saturated sodium nitrite solution was used to filter away the 4 046 and 4 077 Å lines. The temperature in the raman tube was kept at 20°C. Depolarization measurements were made using the polaroid sheet technique. The accuracy in the wave number determinations varied with the shape of the lines and also with their intensity. Some of the lines obtained were fairly broad. The accuracy is $\pm$ 2—3 cm^{-1}, and the spectral band width used was 5 — 60 cm^{-1}. Under the influence of the exciting light, the solution of ammonium thiocyanate and the mother liquids M I and M II slowly became coloured reddish-brown. This was probably due to the presence of minute amounts of ferric ions and could be remedied by adding traces of a reducing agent (ascorbic acid) to the solutions. All the solutions were filtered through a Jena G4 sintered disk filter which had been thoroughly washed

Table 1. Infrared absorption frequencies (in cm^{-1}) of the thiocyanate ion in solid systems, observed with different prisms and in various preparations (vs = very strong, m = medium).

Assignments Jones [7]	KSCN				NH_4SCN					Values given by Jones [7]	Intensity

ν_{2b}	—	—	—	471	—	—	466	472	465	470	m

with distilled water. The solid ammonium thiocyanate and ammonium silver dithiocyanate were also run, but only the strong ν_1 vibration could be observed due to excessive scattering of mercury light. Also impurities in the mercury spectrum caused disturbances. In photographic recording, Ilford Zenith plates were used. They were processed in Kodak D-76 fine grain developer. For intensity comparisons the carbon tetrachloride line 459 cm^{-1} was used. The ratio of the heights of the actual line to the reference line was taken as a measure of the intensity (*cf.* Kinell [15]).

RESULTS

Infrared spectra. The absorption frequencies of the thiocyanate ion obtained from the potassium and ammonium salts in the solid state are collected in Table 1, together with the values of ν_1 and ν_2 from an acetone solution of the potassium salt. The assignments are those given by Jones [7]. His values

Table 2. Infrared absorption frequencies (in cm^{-1}) of silver thiocyanate in the solid state, observed with different prisms and in various preparations (vs = very strong, m = medium, w = weak). The assignments are only to be regarded as a classification.

Assignments	NaCl		KBr		CsBr	Intensity

	—	—	450.5	—	449.5	m
	—	—	443.5	442.5	442.5	m
?	—	—	420	419	420	w

are also given in the last column. The values from disks agree very well with Jones' values. The slightly changed frequencies in paraffin oil mulls of ammonium thiocyanate cannot at present be explained. The higher ν_3 value and lower ν_1 value in acetone solution correspond to similar results found for water solutions by Jones [7] and Gordy and Williams [16].

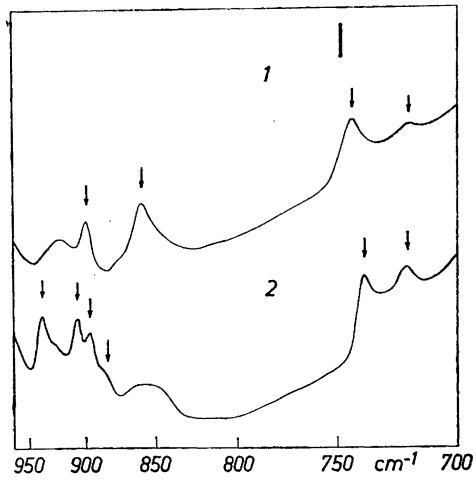

Fig. 1. Infrared spectra of silver thiocyanate (1) and ammonium silver dithiocyanate (2) showing the fundamentals in the region 700 – 750 cm^{-1} and the overtones in the region 850 – 950 cm^{-1}. All actual lines are indicated by arrows to distinguish them from the background. The position of the SCN^- ν_3 vibration frequency is shown by the dash in the upper part of the figure. Paraffin oil mulls were used. Prism: NaCl.

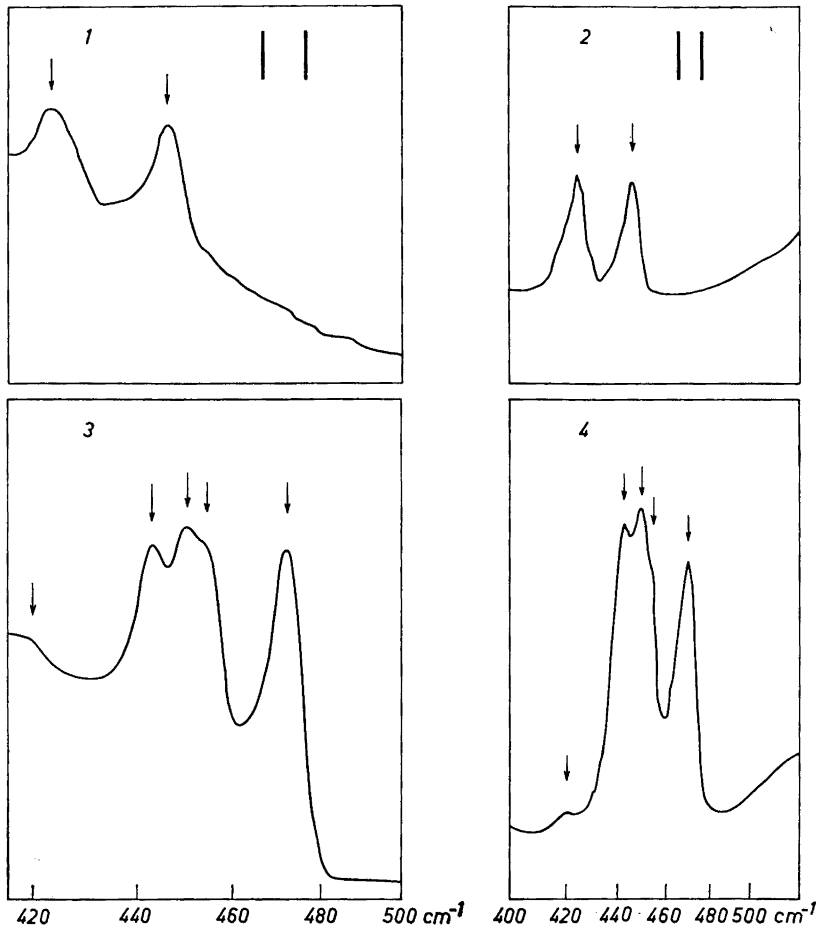

Fig. 2. Infrared spectra of thiocyanates: 1) AgSCN, KBr prism; 2) AgSCN, CsBr prism; 3) $NH_4Ag(SCN)_2$, KBr prism; 4) $NH_4Ag(SCN)_2$, CsBr prism. The actual lines are indicated by arrows. The positions of the ν_2 vibration frequencies of the SCN^- ion are shown by the dashes in the upper part of the figure. Paraffin oil mulls were used.

The absorption frequencies of solid silver thiocyanate are collected in Table 2. There are some disagreements between paraffin mull and potassium bromide disk values. The high frequency 2 160 cm^{-1} corresponds very well to the value 2 149 cm^{-1} reported by Chatt [9]. In potassium bromide disks a line at 455 cm^{-1} has been observed. It has a tendency to decrease with the age of the disks. As it does not appear in any of the other spectra, it has been discarded. No indications of any lines which could be associated with silver thiocyanate were found in the region 400—250 cm^{-1}.

Finally the absorption frequencies of solid ammonium silver dithiocyanate are given in Table 3. The ν_2 values at 450 and 455 cm^{-1} are from bands which

Table 4. Raman lines of the thiocyanate ion (in cm^{-1}) in water solutions of potassium and ammonium thiocyanate. The figures within parentheses under the wave numbers are the intensities of the lines compared to the 459 cm^{-1} carbon tetrachloride line as a reference.

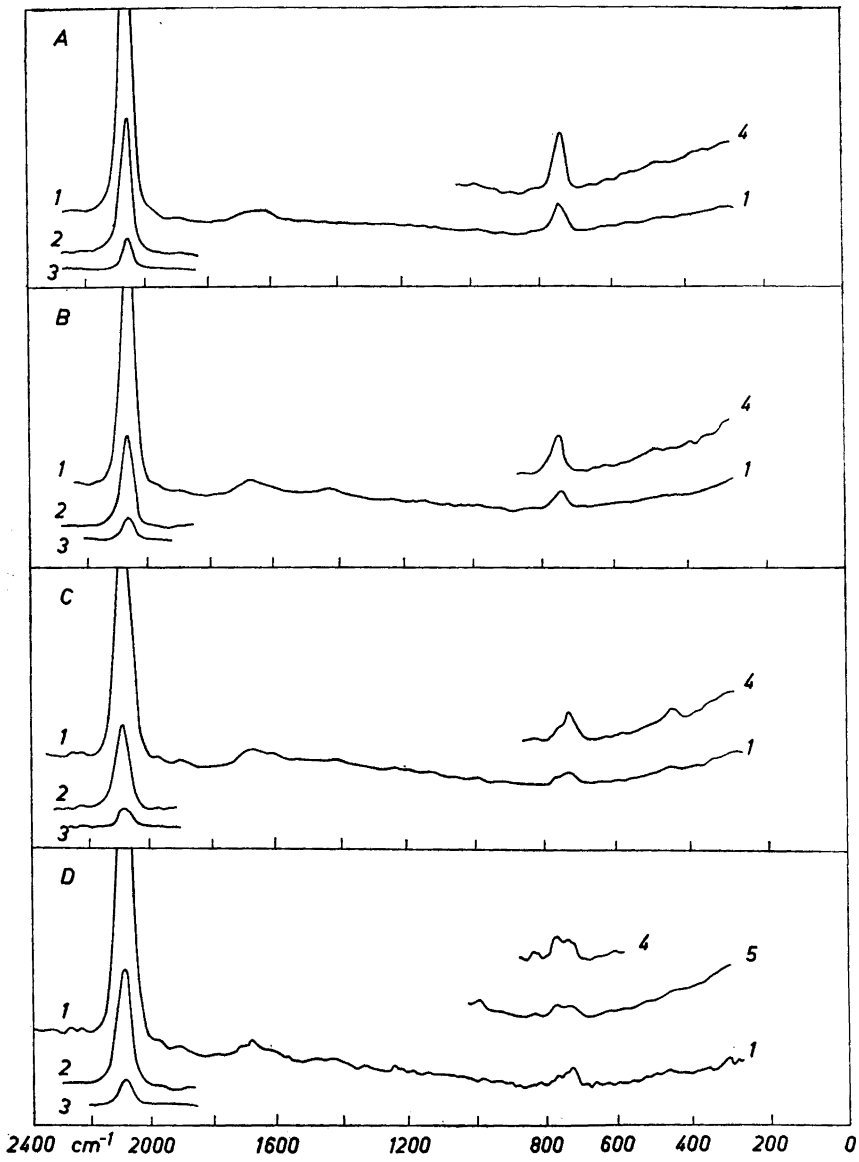

Fig. 3. Photoelectrically recorded raman spectra of A) water solution of KSCN; B) water solution of NH_4SCN; C) mother liquid M I and D) mother liquid M II. Spectra marked with the same figure are directly comparable.

are given in Fig. 2. In both figures the position of the corresponding bands of ammonium thiocyanate has been indicated.

For the present purpose the absorption bands due to the ammonium ion were not studied.

Raman spectra. The frequencies of the raman displacements observed in water solutions of the thiocyanate ion and in the mother liquids are given in Tables 4 and 5. A dash indicates that the line was observed but its frequency not estimated. The existence of the line 485 cm^{-1} as a fundamental mode excited from the Hg line 4 358 Å is dubious. The value is in agreement with the ν_1 mode excited by 4 077 Å. However, existence of a ν_2 mode is evident from the first harmonic at 940 cm^{-1}. Then the ν_2 frequency would be 470 cm^{-1}. This is in good agreement with the infrared data and with the value in water solution observed in the infrared by Jones [7]. The value given by Saraf [6], 499 cm^{-1}, seems too high. The corresponding line from the mother liquids is easily observed. The ν_1 mode excited from 4 077 Å would appear at about 500 cm^{-1}. In some of the spectra of the mother liquids a splitting of the ν_3 line was observed. In test runs (M I′, M II′) it could not be reproduced. No indications of a splitting of the other lines have been found in runs made and photographs taken at different slit widths. The ν_1 line is slightly skew towards shorter wave lengths.

The general appearance of the spectra is shown in Fig. 3. All the spectra No. 1 have been recorded under the same conditions. The bands between 1 400—1 800 cm^{-1} are due to the water molecules and to the ammonium ions. From spectra Nos. C:3 and D:3 the skewness of the ν_1 line can be seen. The results of the runs made on solid ammonium thiocyanate and ammonium silver dithiocyanate are given in Fig. 4. In the first case the existence of a line at about 2 065 cm^{-1} is quite clear from a comparison of the background spectrum (4) with the actual spectrum (5). In the last case both the background (1) and the actual curve (2) are reproducible in all essential details. The curve (3) representing the difference between (2) and (1) has two maxima indicating absorption at 2 085—2 090 cm^{-1} and at about 2 120 cm^{-1}. In Fig. 5 the ν_1 vibration of potassium thiocyanate is recorded at four different concentrations. No significant change in the position of the line can be found.

In order to find any possible differences between the state of polarization of the raman lines of the thiocyanate group in pure water solution and in the mother liquid, spectra with the incident light polarized in directions parallel and perpendicular to the direction of observation were taken. From these, the depolarization factors were found to be 0.58 and 0.65 for the ν_1 line in potassium thiocyanate solution and in mother liquid M III, respectively. The value 0.58 corresponds with the figure 0.55 given by Saraf [6]. Both of the values obtained here show that the ν_1 mode is polarized. There are no significant shifts in the position of the lines (*cf.* Tables 4 and 5), and thus it is not probable that the higher depolarization factor from M III should indicate the presence of a depolarized line quite near to a polarized one. The other lines were not measured, but the photographically obtained spectra showed that they are polarized. This is also the case with the $2\nu_2$ mode.

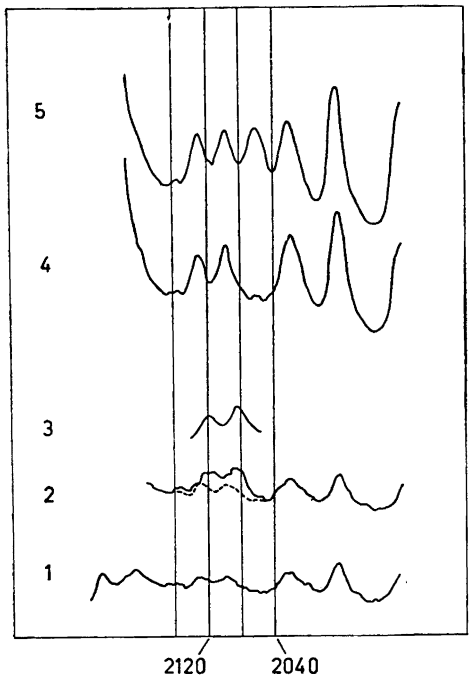

Fig. 4. Raman spectra of solid thiocyanates: 1) and 4) mercury lamp background; 2) background and superimposed spectrum of $NH_4Ag(SCN)_2$(s); 3) spectrum of $NH_4Ag(SCN)_2$(s); 5) background and spectrum of NH_4SCN(s).

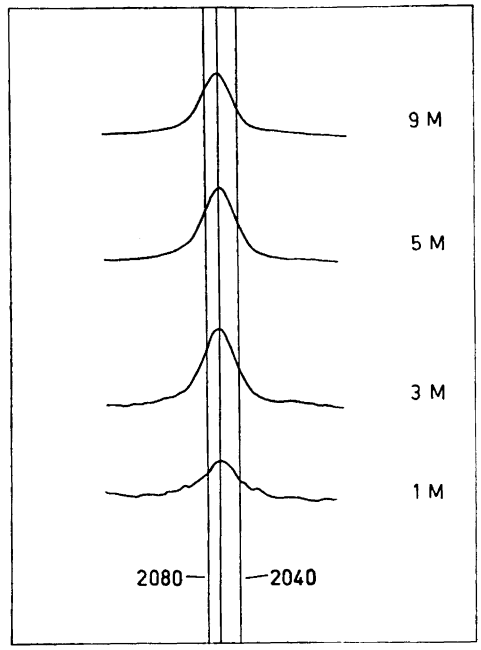

Fig. 5. The ν_1 line of SCN^- in water solutions of potassium thiocyanate of different concentrations.

DISCUSSION

Interpretation of spectra. In the following section some remarks concerning the interpretation of the spectra obtained will be made. The complete assignment of the frequencies must be postponed to a later occasion (Kinell, work in progress).

The only symmetry element of an isolated four atomic molecule of the type AgSCN is a plane of symmetry, *i.e.* the plane containing all the atoms. The number of normal modes is six. The molecule belongs to the point group C_s. This contains two species of normal vibrations; A', symmetric with respect to the plane of symmetry and, A'', antisymmetric with respect to this plane. Then, the representation which has the vibrational motions as its basis can be broken down into its irreducible components in the following way

$$\Gamma_{vib} = 5A' + A''.$$

All the vibrations belonging to A' must occur in the plane of symmetry and the only one of A'', at right angle to this plane. All six vibrations are active in both raman and infrared spectra.

In a crystal the field of force, in which the molecules are located, will cause a splitting of the internal vibrational modes. Furthermore, the classification and the selection rules of the modes will change because of the different symmetry properties of the molecule and the crystal. Applying the methods (*cf.* Bhagavantam and Venkatarayudu [17], Hornig [18], and Winston and Halford [19]) worked out for analysis of the normal vibrations of molecules in crystals, one finds for the silver thiocyanate that its factor group of the space group C_{2h}^6, having the invariant subgroup of the lattice translations as its identity element, is isomorphic to the point group C_{2h}. Then the following reduction of the representation which has the internal vibrational modes as its basis will be obtained

$$\Gamma_{vib} = 4A_g + 6B_g + 6A_u + 6B_u$$

Only the species symmetric with respect to inversion will be raman active, and the species antisymmetric with respect to the same operation infrared active. Thus, the six normal modes of the isolated AgSCN molecule will in the crystal be split into twelve vibrations.

In silver thiocyanate the crystal can be regarded as built up from AgSCN chains [1], and then the line group method of Tobin [20] can be used for the analysis of the normal modes. The chains are regarded as isolated and infinite. Their symmetry is described by a one dimensional space group, a line group. The symmetry of the repeating unit is characterized by the elements of the factor group of the line group, which has the invariant subgroup of the chain translations as its identity element. The repeating unit consists of two AgSCN molecules and the factor group is isomorphic to the point group C_s. Then we have for the internal vibrations

$$\Gamma_{vib} = 8A' + 8A''.$$

Both of the species A' and A'' are raman and infrared active. Thus even in this case more frequencies than for the isolated molecule will appear. Taking even lattice modes under consideration, one finds that each factor group mode of the line group corresponds to one infrared active and one raman active mode under the space group. The silver thiocyanate molecules are located on general points in the unit cell and thus no classifiction is obtained under the site group (*cf.* Hornig [18]).

The above analyses indicate that the silver thiocyanate in the solid state ought to have a rather complicated spectrum in the infrared. On the contrary, the observed spectrum contains only a few lines. If the 900 cm^{-1} lines are regarded as overtones, only five fundamental frequencies have been found. The silver atom is heavy compared to all the other atoms in the silver thiocyanate molecule, and therefore any frequency involving the stretching of the Ag-S bond or bending of the Ag-S-C angle will be low and probably evade observation with the instruments used. An investigation of the *iso*cyanic acid (Herzberg and Reid [21]) has shown that this molecule, which has the same geometrical shape as the silver thiocyanate molecule, has bending modes at 572, 670 and 797 cm^{-1}. The last value refers to the H-N-C angle. In addition, Eyster and Gillette [22] have shown that the frequency of the bending deforma-

tion of the angle in hydrazoic acid and methyl azide decreases from 1 153 cm^{-1} to 259 cm^{-1} when the methyl group is substituted for the hydrogen atom. Also in methyl *iso*cyanate and methyl *iso*cyanide the frequencies are low, 353 cm^{-1} and 290 cm^{-1}, respectively. A more thoroughgoing analysis of possible overtones and combination lines in the spectrum of AgSCN (except those already given here) has been started. It is hoped that the new data can give information about possible low frequencies.

The spectrum of the ammonium silver dithiocyanate is also fairly simple. In the case of completely free AgSCN and SCN^- units it should consist of nine fundamental frequencies, all of which are allowed in both the raman and infrared spectrum. The factor group analysis (the space group C_{2h}^5 of the crystal has a factor group having the invariant subgroup of the lattice translations as its identity element, which is isomorphic to the point group C_{2h}) gives for the internal vibrational modes

$$\Gamma_{vib} = 9A_g + 9B_g + 9A_u + 9B_u.$$

The gerade species are raman active, the ungerade infrared active. The observed spectrum may contain nine lines (the 900 cm^{-1} bands are tentatively regar-

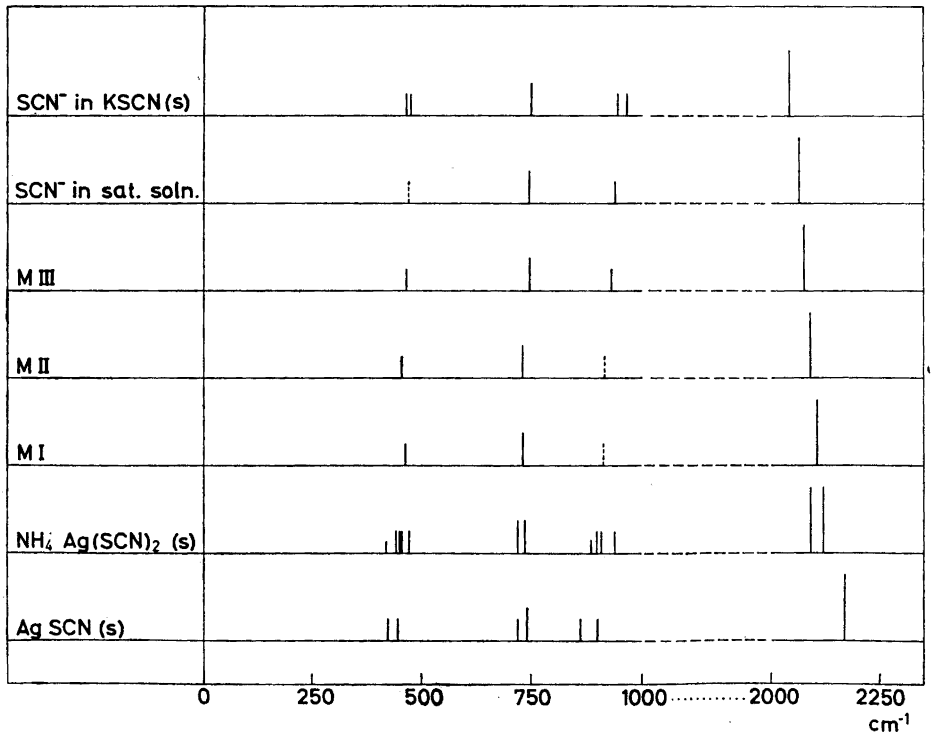

Fig. 6. Schematic raman and infrared spectra of systems containing thiocyanate groups. The intensities are only approximate.

ded as overtones), but only a more thorough study of possible overtones and combination bands in other regions will give a definite answer.

From Fig. 6, where all the spectra have been collected in a schematic diagram, it follows that the spectrum of ammonium silver dithiocyanate seems to be a superposition of the spectra of the SCN^- ion and the AgSCN molecule. This is in agreement with the structure given by Lindqvist and Strandberg [2]. If the lines 2 090 cm^{-1}, 738 cm^{-1}, 472 cm^{-1} and 454.5 cm^{-1} (Table 3) are assumed to belong to the thiocyanate ion, then the remaining lines 2 120 cm^{-1}, 722 cm^{-1}, 450.5 cm^{-1}, 443.5 cm^{-1} and 420 cm^{-1} should correspond to the silver thiocyanate lines (Table 2) except for one missing ν_3 line and one extra ν_2 line. The ν_3 line may not be resolved from the SCN^- line. The interpretation of the 420 cm^{-1} line as a fundamental may be somewhat doubtful because of its very low intensity. It could be an overtone of a low frequency vibration at about 200 cm^{-1}, which would evade detection by the equipment used. The 423 cm^{-1} of silver thiocyanate is most probably a fundamental. Then the following coordination between the spectral lines can be done on the basis of the present data:

	SCN^-	$NH_4Ag(SCN)_2$	AgSCN
Fundamentals	2 053	2 120	2 169
		2 090	
Overtones	968	940	
	951	909	
		899	901
		887	861
Fundamentals	749	738	743
		722	723
	484	472	
	470	454.5	
		450.5	446.5
		443.5	423
Overtone?		420	?

The raman spectra of the mother liquids are very similar to the spectrum of the SCN^- ion in water solution. Therefore it seems quite reasonable to make the same assignments of the lines in both cases. Due to the weakness of the 460 cm^{-1} band, no detailed study of its structure can be made. The broadening of the energy levels on account of the strong interaction in the solution may have smoothed out a possible splitting. On the other hand, bending modes are not very sensitive to changes in the symmetry of the local field (Bauer and Magat [23]). This has clearly been demonstrated in the case of the nitrate ion in water solutions, where at higher concentrations only one of the two doubly degenerate vibrations is split, the other one is not because it should approach a pure bending of the ion (Mathieu and Lounsbury [24]).

As a summary of this discussion, one could say (*cf.* Fig. 6) that irrespective of the environmental conditions, the vibrational frequencies of the SCN

unit fall into four groups, which are well separated from each other. The environmental circumstances influence the position of the lines in each group. Especially the displacement of the 2 050 cm^{-1} band to higher frequencies is noticeable. There may be a fifth group of frequencies, however, this one has most certainly to do with vibrations involving the silver atom.

The state of the SCN group in solution. From the foregoing discussion it is evident that the behaviour of the SCN group in the different environments can approximately be described by the three vibrational modes of the free SCN^- ion. The dependence of the ν_2 and ν_3 vibrations on the conditions of the solution is noticeable but not very pronounced and no conclusions of general value con be drawn.

The vibration of the CN group seems to be the most sensitive to differences in the composition of the solution. The spectra taken at various slit widths show that a splitting of the line is very unlikely. The polarization measurements indicate the improbability of the presence of different symmetry types of SCN groups having very nearly equal frequencies. The existence of complexes of the type $Ag(SCN)_4^{3-}$ (Leden and Nilsson [3]) with a strong bond between the silver and sulphur atoms should at the concentrations and exposure times used certainly have revealed new raman lines separated from those of the thiocyanate ion. Assuming I_d symmetry of the complex ion one gets the following reduction of the normal mode representation

$$\Gamma_{vib} = 3A_1 + 3E + 2F_1 + 6F_2$$

The totally symmetric A_1 species, the doubly degenerate E species and the triply degenerate F_2 species are raman active. The last species is the only one active in infrared. Of these the three totally symmetric lines can be expected to have rather high intensities. Complexes of the type $Ag_2(SCN)_6^{4-}$ have on the assumption of D_{2h} symmetry,

$$\Gamma_{vib} = 10A_g + 6B_{1g} + 5B_{2g} + 6B_{3g} + 3A_u + 9B_{1u} + 9B_{2u} + 6B_{3u}.$$

The gerade species are raman active and the ten totally symmetric modes are expected to have the highest intensity. However, Leden and Nilsson [3] have found that the concentration of this complex is much lower than that of the mononuclear complex, and therefore it is doubtful if any of its lines could have been found under the actual recording conditions.

The frequency of the CN stretching mode as a function of the molar ratio of Ag/SCN is given in Fig. 7. Evidently the displacement of the line is dependent upon the amount of silver present in the system. Furthermore, there is an increase of the frequency going from the various solutions to the solid compounds. The displacement cannot be an effect of the SCN^- concentration. This follows from the frequencies in the M I and M III solutions, which have almost the same SCN^- molarity, and also from the results given in Fig. 5 on the ν_1 frequency in potassium thiocyanate at different concentrations. It can also be concluded that the effect cannot be a first order electrostatic phenomenon because M I, M III and the KSCN solution have each the same molarity of positive ions. The differences in ionic radii of Ag^+ (1.26 Å),

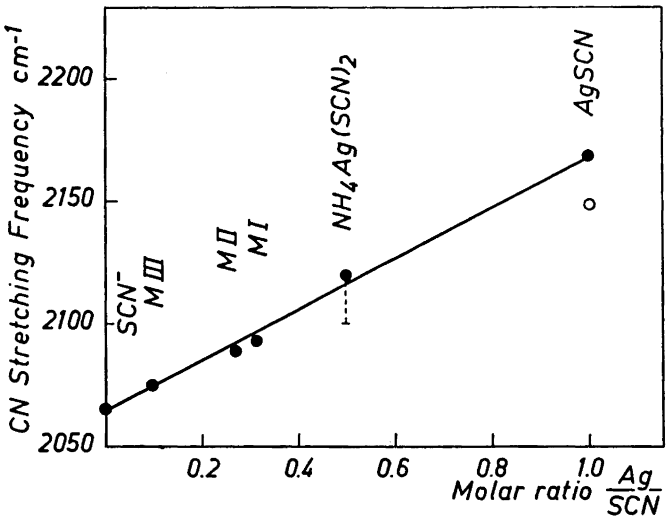

Fig. 7. The frequency of the CN stretching mode as a function of the molar ratio Ag/SCN. O at Ag/SCN = 1 is the value taken from Chatt's *et al.* work [9]. The dotted line at Ag/SCN = 0.5 corresponds to the frequencies given by Chatt *et al.*[8] for platinum and palladium complexes having terminal SCN groups.

Na^+ (0.95 Å), K^+ (1.33 Å) and NH_4^+ (1.48 Å) indicate that sodium could approach the SCN^- ion more closely than the ammonium ion, and consequently in the case of a pure electrostatic attraction, the M III solution would expect to give a higher displacement than the M I solution.

It is of interest to note that the platinum and palladium complexes studied by Chatt *et al.*[8], and having terminal SCN groups, fit into the pattern. The frequencies of complexes having molar ratios of Pt/SCN and Pd/SCN equal to unity and containing bridging SCN groups fall in the region 2 154—2 169 cm^{-1}. Thus they correspond to the behaviour of silver thiocyanate.

The possibility that the ν_1 line should consist of two unresolvable lines, one from the free SCN^- ion and the other from a SCN group bound to the silver ion, is not probable because the half intensity width of the line in M I (53 cm^{-1}) is only slightly higher than in a solution of potassium thiocyanate (47 cm^{-1}). The peak distance of such lines would be at least 50 cm^{-1} and thus the half intensity width of the sum line would be expected to be at least about twice this value.

The evidences given here indicate that the presence of the silver ions in the solutions influences all the thiocyanate groups to approximately the same amount. The displacements observed in the CN stretching vibration are directly dependent upon the amount of silver present per thiocyanate group. The binding of the sulphur atoms to the silver nucleus is not strong enough to give the complexes a character of independent units, which can be detected by spectroscopic means. The data also show that there is a difference between the structure of the solid ammonium silver thiocyanate and its mother liquid.

Acknowledgements. The authors are indebted to Professor Stig Claesson and Professor Gunnar Hägg for their interest in this work and for the ways in which they have facilitated its completion.

We thank Professor Arne Tiselius for his kindness to place an infrared spectrograph at our disposal.

We are very thankful to Dr. Ingvar Lindqvist for his interest in this study and for many stimulating discussions.

Grants from the *Swedish Natural Science Research Council* and from the *Knut and Alice Wallenberg Foundation* are gratefully acknowledged.

Studies on Local Anesthetics XVIII *

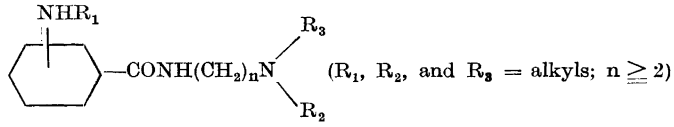
Synthesis of N-(Dialkylaminoalkyl)benzamides

BJÖRN LÜNING

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden

Benzamides of the general structure $Ar-CO-NH-R_1-N(R_2)_2$, in which Ar is a methyl substituted benzene nucleus, have been synthesized. Ar contains 1–3 methyl groups in all possible positions. R_1 represents $-CH_2CH_2-$, $-CH_2CH_2CH_2-$, $-CH(CH_3)CH_2-$, $-CH_2CH(CH_3)-$, $-CH(CH_3)CH(CH_3)-$, or $-CH_2C(CH_3)_2CH_2-$, and R_2 is a methyl or ethyl group. The number of new compounds which have been synthesized is 63. In one case a compound containing two asymmetric carbon atoms was separated into two racemates. The physical constants of 8 unknown benzoyl chlorides are also reported.

A well known local anesthetic is Nupercaine, *i.e.* N-(2-diethylaminoethyl)2-butoxycinchoninamide [1,2]. This compound was the first local anesthetic belonging to the amide type, that was introduced into the market. The discovery of nupercaine led to further research on amides as local anesthetics. Thus Eisleb [3] in a patent describes benzamides of the general structure:

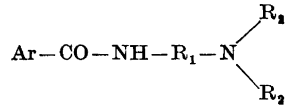


(R_1, R_2, and R_3 = alkyls; $n \geq 2$)

An amide of the anilide type is Xylocaine®, *i.e.* α-(diethylamino)-2,6-dimethylacetanilide which was introduced clinically in 1948 [4,5a]. Since then an extensive research work on anilides as local anesthetics has been carried out, and in the last few years anesthetics of the benzamide type have been subjected to much interest. Thus Hazard *et al.*[6,7], Hach *et al.*[8], Koelzer and Wehr [9], Moore [10], as well as Löfgren and Stoffel [11] have investigated benzamides in which the aryl group consists of a hydrocarbon residue.

* For paper XVII of this series, see Löfgren and Stoffel [11].

In the present work sixtythree new compounds of the benzamide type have been synthesized, and these will later be investigated for their local anesthetic action; all of these compounds are represented by the formula:



Ar is a methyl substituted benzene nucleus. The number of methyl groups in Ar is one, two, or three — all possible combinations, *viz.* fifteen, being included. R_1 is an alkylene radical presented in Table 1 ; R_2 is methyl or ethyl. Chemical data of the bases synthesized are given in Table 2.

To synthesize N-(dialkylaminoalkyl)benzamides, one mole of acid chloride and 1.6 mole of dialkylaminoalkylamine were mixed in ether, the excess of amine being used as a proton acceptor. If only one mole of amine per mole of acid chloride was used, the yield was considerably lower (*c.f.* p. 1631).

Most of the methyl substituted benzoic acids used in this investigation have recently been described by Smith and Stanfield [12]. The methods of synthesis reported by these investigators were not followed in all cases but the melting points of the acids are in agreement with the reported ones [12].

2,3,5-Trimethylbenzoic acid and 3,4,5-trimethylbenzoic acid were prepared in two different ways. The conventional route, which was first followed, involves the oxidation of *iso*durene with dilute nitric acid [13,14]. However, this process gives a mixture of three monobasic acids, four dibasic acids, nitro

Table 1. Alkylene radicals R_1 (*cf.* above).

Ethylene	$-CH_2-CH_2-$
Trimethylene	$-CH_2-CH_2-CH_2-$
1-Methylethylene	$-CH(CH_3)-CH_2-$
2-Methylethylene	$-CH_2-CH(CH_3)-$
1,2-Dimethylethylene	$-CH(CH_3)-CH(CH_3)-$
2,2-Dimethyl-1,3-propylene	$-CH_2-C(CH_3)_2-CH_2-$

acids, and an appreciable amount of nonacidic nitro compounds [14]. Only about 10 % of this mixture consists of monobasic acids. 3,4,5-Trimethylbenzoic acid and 2,3,5-trimethylbenzoic acid were isolated from this mixture according to a method described under 3,4,5-trimethylbenzoic acid (*cf.* p.1628). This process differs in several ways from that given by Jannasch and Weiler [14]. Because of the small yield (1 % of each acid) and since the 2,3,5-trimethylbenzoic acid prepared in this way is also very difficult to purify, other routes of synthesis of the two acids were devised. 2,3,5-Trimethylbenzoic acid was prepared by carbonation [15] of the Grignard reagent of 6-bromopseudocumene, which was obtained by a four step procedure from pseudocumene [16]. 3,4,5-Trimethylbenzoic acid was made from 5-bromohemimellitene *via* the Grignard reagent. The bromo compound was prepared by a Sandmeyer reaction [17] from 3,4,5-trimethylaniline, which was obtained by a nuclear methylation of 3,5-dimethylaniline according to a recently published method [18].

Some of the acid chlorides required for the synthesis of the amides have not been hitherto reported in literature; their data are found in Table 3.

Most of the amines used in this investigation have been described by Löfgren and Stoffel [11]. 1-Amino-3-diethylamino-2,2-dimethylpropane was obtained by $LiAlH_4$ reduction [19] of the oxime of diethylaminopivalaldehyde [20].

2-Amino-3-diethylaminobutane contains two asymmetric carbon atoms, and consequently each of the corresponding amides forms two racemates having different chemical properties. In fact, these amides appear as mixtures of crystals and oil. The values given in Table 2 refer to these mixtures. The two racemates were separated completely and collected only in one case, *viz.* the *o*-toluamide. Of the other racemates, only the solid forms were collected. They were obtained as crystalline substances after treating the semi-solids on porous plate. The melting points of these substances are given in brackets in Table 2.

Pharmacological data, ultraviolet spectra, and ionization constants will be published elsewhere, together with a discussion of the results.

EXPERIMENTAL *

o-, m-, and p-*Toluic acids* were all available commercially. *2,3-Dimethylbenzoic acid* **, *2,4-dimethylbenzoic acid*, *2,5-dimethylbenzoic acid*, and *3,4-dimethylbenzoic acid* were synthesized from the corresponding amino compounds by diazotization followed by treatment of the diazonium salt with potassium cyanocuprate(I) [21]: The nitriles formed were saponified by treatment with 50 % (vol/vol) sulfuric acid [22].

3,4-Dimethylbenzoic acid was also prepared in the following way: *o*-xylene was brominated [23] to form 3,4-dimethylbromobenzene, which was then converted to the acid by carbonation [15] of the corresponding Grignard reagent.

2,6-Dimethylbenzoic acid. To obtain this acid 2,6-dimethylbromobenzene was prepared by means of a Sandmeyer reaction [17] and then transformed to the acid *via* the Grignard compound [15].

3,5-Dimethylbenzoic acid was made from mesitylene by partial oxidation with dilute nitric acid [24].

* All melting points are corrected unless otherwise stated.

** The melting points of the acids were all in accordance with those given by Smith and Stanfield [12].

[a] Titration of the base in 30 % ethanol with 0.1 N HCl; mixed indicator methylene blue — methyl red.
[b] Supercooled.
[c] Purified *via* the hydrochloride, see Table 3.

2,3,4-Trimethylbenzoic acid was synthesized from 2,6-dimethylaniline, which was first converted to 2,6-dimethyliodobenzene by means of a Sandmeyer reaction [25]. 2,6-Dimethyliodobenzene was converted to hemimellitene by treatment of the corresponding Grignard reagent with dimethyl sulfate according to a general method [26]. The hemimellitene was brominated to form 4-bromohemimellitene [27] from which the acid was obtained by carbonation [15] of the Grignard reagent.

2,3,5-Trimethylbenzoic acid was synthesized by oxidation of *iso*durene as is described under *3,4,5-trimethylbenzoic acid (cf.* below). The 2,3,5-trimethylbenzoic acid was also made by nitration of pseudocumene, and the 5-nitropseudocumene thus formed was then reduced with iron and acetic acid [5b] to pseudocumidine. This was brominated in concentrated hydrochloric acid [16,27] giving 2-bromo-3,4,6-trimethylanilinium chloride, which was then de-aminated by treatment with ethyl nitrite and concentrated sulfuric acid in ethanol solution [28]. The acid was obtained from the bromo compound by carbonation [15] of the corresponding Grignard reagent; yield 33 %; m. p. 126°—127°. (Jannasch and Weiler [14] state m. p. 127° for this acid.)

2,3,6-Trimethylbenzoic acid was made in a good yield from pseudocumene according to Smith and Stanfield [12].

2,4,5-Trimethylbenzoic acid was obtained by partial oxidation of durene with dilute nitric acid [30].

2,4,6-Trimethylbenzoic acid was prepared from mesitylene by bromination [23] and subsequent carbonation [15] of the corresponding Grignard reagent.

*3,4,5-Trimethylbenzoic acid. Iso*durene, 50 g (0.37 mole), was added to 225 ml of water and 75 ml of nitric acid (d = 1.40; 1.15 mole) and the mixture was refluxed for 6 h. After cooling, the reaction products were taken up in ether, which was then extracted with potassium carbonate solution. The oily residue remaining after evaporation of the ether was subjected to another oxidation with nitric acid. The potassium carbonate solutions obtained from the two runs were combined and acidified. After cooling to 0°, the aqueous layer was decanted off and rejected. The residue was dissolved in 100 ml of glacial acetic acid, 5 g of zinc powder were added, and the mixture boiled for 30 min. Water, 700 ml, was added and the aqueous solution containing acetic acid was decanted off from the sticky yellow residue, which was dissolved in 375 ml of ethanol. To this solution, dry hydrogen chloride was introduced at a "fairly rapid rate" [31] for 30 min. A large excess of water was added and the esters formed were taken up in ether, which was then washed three times with dilute sodium carbonate solution. The ether was evaporated, and the residual esters were saponified on the steam bath with 5 % potassium hydroxide in

[d] During the course of this work compound LVIII was synthesized by Hach *et al.*[8] and studied pharmacologically by Koelzer and Wehr [9]. Hach *et al.*[8] describe the compound as melting at 64°. Moreover, they did not succeed in preparing the hydrochloride of LVIII. (*cf.* Table 3.)

[e] *cf.* p. 1632.

ethanol. After precipitation of the "*iso*durylic" acids with dilute hydrochloric acid, they were dissolved in thionyl chloride. The solution was refluxed for 5 h, and after removing excess thionyl chloride the residue was distilled at 10 mm Hg. A fraction boiling at 120°—135° was collected and hydrolyzed at room temperature with 30 % sodium hydroxide. The mixture of acids was precipitated and dissolved in an equivalent amount of 10 % sodium hydroxide. The solution was washed with ether, and an excess of saturated barium chloride solution added. A voluminous precipitate separated from the solution, and was collected. The acid, liberated from this slightly soluble barium salt, is 3,4,5-trimethylbenzoic acid; m. p. 215°; yield (based on 450 g, *i. e.* 3.36 mole of *iso*durene): 7.3 g (0.044 mole, 1.3 %); recorded m. p. [13,14] 215°. The filtrate which was separated from the barium salt precipitate (*cf.* above) gave another acid, which after several recrystallizations from different solvents (*e. g.* ethanol, light petroleum) melted at 108°. This must be impure 2,3,5-trimethylbenzoic acid since dry distillation with soda lime gave an oil, which after sulfonation yielded a sulfonamide of m. p. 172°—174°. Very probably this compound was identical with pseudocumenesulfonamide with a recorded m. p. at 174° [13,32] *.

The yield of acid was 4.8 g (0.030 mole, 0.9 %). (Melting point of pure 2,3,5-trimethylbenzoic acid, *cf.* above.) (Found: equiv. wt.** 161. Calc. for $C_{10}H_{12}O_2$: 164.)

3,4,5-Trimethylbenzoic acid was also obtained by carbonation of the Grignard reagent of 5-bromohemimellitene, this compound being prepared from 3,4,5-trimethylaniline.

3,4,5-Trimethylaniline ***. 3,5-Dimethylaniline, 47 g (0.39 mole), was dissolved in 30 ml of 37 % HCl (0.36 mole) and 200 ml of water. After cooling to 0°, 75 ml of 37 % (1.0 mole) formaldehyde solution was added under stirring. The temperature was kept at 0° for 60 min and was then allowed to reach 20°. After adding a large excess of sodium carbonate solution, the orange coloured sludge was filtered and the collected solid was dried at 80°. The resulting yellow powder, after mixing with 60 g (0.81 mole) of calcium hydroxide, was dry distilled in a wide necked distillation apparatus, heated by means of a metal bath which was kept at 500°. A semi-solid distillate formed which was taken up in a mixture of ether and 20 % hydrochloric acid. Following removal of the ether phase,

* No mixed melting point could be determined because of lack of substance.

** Titration of the acid with NaOH, using phenolphtalein as an indicator.

*** This compound has been obtained previously but in a very low yield [33,34]. The method applied here is a modification of one described by Barclay *et al.* [18], and has given a relatively good yield.

Table 3. Data of acid chlorides synthesized in this investigation.

[a] Measurement made on supercooled compound.

the base was liberated from the aqueous acid solution and distilled. Yield of 3,4,5-trimethylaniline boiling at 238°–248° was 11.3 g (0.084 mole, 22 %); m. p. 68°–72°. Acetyl derivative recrystallized from methanol; m. p. 163°–164°. (Recorded melting point [33,34] of base is 76°, and of acetyl derivative 164°.)

5-Bromohemimellitene. 3,4,5-Trimethylaniline was converted to 5-bromohemimellitene by a Sandmeyer reaction [17]. This compound appeared as an orange coloured oil; b. p. 109°–114°/12 mm Hg; n_D^{25} 1.5560; yield 34 % (*cf.* Ref.[35]). The low yield is probably due to instability, even at 0°, of the diazonium salt. 3,4,5-Trimethylbenzoic acid was obtained from the bromo compound by carbonation [15] of the corresponding Grignard reagent; yield 64 %; m. p. 214° (*cf.* above).

Acid chlorides. The acids were converted to the corresponding acid chlorides by treatment with thionyl chloride and subsequent distillation [36]. In Table 3 the physical constants, yields, and analyses are given for those acid chlorides which have not been described previously.

1-Amino-2-dimethylaminoethane was prepared by a Mannich reaction between dimethylammonium chloride, paraformaldehyde, and cyanide ion [37] and subsequent reduction of the condensation product according to a general method with $LiAlH_4$ [19]: b. p. 103°–108°; yield 36 % (*cf.* Ref.[37]).

1-Amino-2-diethylaminoethane was available commercially.

1-Amino-3-diethylaminopropane has been obtained by cyanoethylation of diethylamine [38], and subsequent reduction of the cyano group with $LiAlH_4$ [19] (*cf.* Refs.[11,38]).

2-Amino-1-diethylaminopropane. From diethylaminoacetone the oxime was prepared, the general method given by Vogel [39] being followed; yield 80 %; b. p. 98°–100°/10 mm Hg; m. p. 40°. (Found: equiv. wt.* 143. Calc. for $C_7H_{16}N_2O$: 144.2.) The desired amine was obtained from the oxime in accordance with a method given for the reduction of nitriles with $LiAlH_4$ [19]; yield 53 % (*cf.* Ref.[11]).

1-Amino-2-diethylaminopropane was prepared *via* the nitrile [40] (Mannich reaction), reduction being carried out with $LiAlH_4$ [19] (*cf.* Ref.[11]).

2-Amino-3-diethylaminobutane was made [11] by bromination of ethyl methyl ketone, and subsequent separation of the isomeric bromo ketones [41]. The resulting 3-bromo-2-butanone was treated with diethylamine to form 3-diethylamino-2-butanone; this was converted to the corresponding oxime which was then reduced with $LiAlH_4$ [19]; yield 58 % (*cf.* Ref.[11]).

*1-Amino-3-diethylamino-2,2-dimethylpropane. Iso*butyraldehyde, paraformaldehyde, and diethylammonium chloride were condensed by a Mannich reaction to diethylamino-

* Titration with 0.1 N HCl in 30 % ethanol; mixed indicator methylene blue — methyl red.

[a] For the preparation of these bases see Löfgren and Stoffel [11].

pivalaldehyde [20]. From this aldehyde the oxime was prepared [39]; yield 89 %; b. p. 132°—133°/22 mm Hg; n_D^{20} 1.4649. Without further characterization this compound was reduced according to general methods by (a) sodium in ethanol [42] (b) $LiAlH_4$ [19]. The desired amine was obtained in a yield of 42 % and 45 %, respectively; b. p. 105°/52 mm Hg; n_D^{20} 1.4442. (Found: equiv. wt.* 78.8. Calc. for $C_9H_{22}N_2$: 79.1.)

Preparation of dialkylaminoalkylamides of methyl substituted benzoic acids. The appropriate dialkylaminoalkylamine (0.040 mole) was dissolved in 50 ml of highly purified ether in a 300 ml three necked round bottomed flask, equipped with a sealed Hershberg stirrer, funnel, and a condenser ($CaCl_2$). The desired acid chloride (0.025 mole) was dissolved in 50 ml of ether. Stirring was started, and the acid chloride solution was added to the amine solution during a period of 30 min, agitation being maintained for another 2 h. Then 100 ml of 2 N NaOH were added. The ethereal layer was separated off and washed twice with water. After drying (Na_2SO_4), the ether was driven off and the base was recrystallized or distilled. Characterization of the compounds is found in Table 2.

In order to study the same reaction but with the reactants in another proportion an experiment was carried out using 3,5-dimethylbenzoyl chloride and 1-amino-2-diethyl-

* Titration with $HClO_4$ in glacial acetic acid; indicator BZL-BLUE (Ciba) [43].

aminoethane in the ratio 1:1.1; the yield of N-(2-diethylaminoethyl)3,5-dimethylbenzoyl chloride was 53 %. When using the molar proportion 1:1.6 as is described in the general method above the yield of the same product was 90 %.

Hydrochlorides were prepared from the bases by dissolving them in dry ether and adding an appropriate amount of dry hydrogen chloride in dry ether. The colourless microcrystalline precipitates were recrystallized from suitable solvents. Melting points, solvents for recrystallization, and analytical data are found in Table 4.

Separation of the racemates of N-(2-diethylamino-1,2-dimethylethyl)2-methylbenzamide (V). From the oily crude base which remained after evaporation of the ether, crystals slowly deposited, at room temperature resulting in a semi-solid mass. The two phases were separated from each other according to the excellent method described by Morton [44] and Hicks [45]. The solid component was recrystallized twice from *iso*propyl ether containing light petroleum. The separated oil was then distilled. The oil is called V*a* and the solid V*b*. For further characterization *the picrate of V*a was made, and after two recrystallizations from *iso*propanol and one from dioxane, yellow rhombic plates of m. p. 146° were obtained. (Found: C 54.0; H 6.22; N 14.24; O 26.06. Calc. for $C_{22}H_{29}N_5O_8$: C 53.8; H 5.95; N 14.25; O 26.04.) The salt (2 g) was dispersed in 50 ml of ethanol and 175 ml of water. To the suspension thus formed, 150 ml * of moist Amberlite IRA 400 anion exchanger (chloride form) was added, the mixture being stirred for 6 h. From the colourless solution the base was liberated and taken up in ether. The solvent was evaporated leaving V*a* as a crystalline solid which was recrystallized once from light petroleum. Characterizations of the bases are found in Table 2.

*Di-picrate of V*b; needles from *iso*propanol of m. p. 126°. (Found: C 47.0; H 4.47; N 15.75; O 32.60. Calc. for $C_{28}H_{32}N_8O_{15}$: C 46.7; H 4.48; N 15.55; O 33.30.)

N-(2-Diethylamino-1,2-dimethylethyl)3-methylbenzamide (XI), N-(2-diethylamino-1,3-dimethylethyl)4-methylbenzamide (XVII), and N-(2-diethylamino-1,2-dimethylethyl)-3,5-dimethylbenzamide (XXXIX). After distillation of these bases, all of them appeared as semi-solid mixtures of crystals and oil. The refractive indices of these bases, given in Table 2, refer to the super-cooled mixtures. A small portion of each of the three bases was left on porous plate for three days. The crystals were scraped off and the melting points determined. These melting points are given in brackets in Table 2 (concerning theory see Morton [44]).

I wish to express my sincere gratitute to *Aktiebolaget Astra*, Södertälje for financial support during the course of this work.

An Initiating Mechanism of Color Formation and Decomposition in Polyvinyl Chloride

SVEN SÖNNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

The thermal instability of polyvinyl chloride, prepared in emulsion systems, is related to the presence of peroxides, formed during the polymerization process, or later, by autoxidation. The rate of color formation and decomposition is preferably studied in pyridine below 100°C. Redox systems, where the polymer takes part as an active component, are effective inhibitors of discoloration and degradation. Graft copolymers can be prepared by a seeding technique, based upon the same principle.

Polymerization of vinyl chloride is usually carried out in emulsion systems. The reaction takes place in water, containing ammonium or sodium salts of higher, saturated fatty acids. The aqueous phase is saturated with monomer under pressure at moderate temperatures (40—50°C). Persulphate ions are the preferred initiators. Sulphate ion radicals are generated by thermal dissociation, followed by diffusion into soap micelles, where solubilized monomer enters into reaction. The general picture of the kinetic scheme at steady state conditions is well-known from the fundamental work of Smith and Ewart [1,2].

The degree of conversion of monomer into polymer may be varied by release of pressure at different times of reaction. This is actually used in practice as a versatile method influencing upon the solubility characteristics of the final polymer; other working variables, such as added amounts of initiator, soap and modifiers being unconsidered.

A critical state arises in the polymerising system when remaining monomer is suddenly removed. Growing polymer radicals have to find a way of deactivation or propagation. Traces of molecular oxygen may act as comonomer: *

$$R\cdot + O_2 = R{-}O{-}O\cdot$$

* The occurrence of an induction period in vinyl chloride polymerization indicates formation of peroxide radicals at this early stage of the process, but this does not exclude the presence of oxygen at high degrees of conversion, as monomer is preferably added continually to the reacting system.

especially when the concentration of vinyl chloride is low. Radicals, trapped in the polymer particle, will react in the same way, when exposed to air at (spray) drying or grinding operations. Deactivation occurs by hydrogen abstraction from the surrounding medium. The net result is a polymeric hydroperoxide. High degree of stability and bad accessibility may cooperate to render its detection difficult by standard reagents.

The dry, purified polymer is soluble in pyridine at room temperature, or slightly above, at moderate degrees of polymerization. Such a solution remains colorless at 0—5°C in the absence of light, but discoloration rapidly takes place in sunlight or merely by heating, even in an inert atmosphere. The following changes of color are observed at 100°C (Table 1).

Table 1. Color formation in a solution of polyvinyl chloride in pyridine at 100°C. Concentration of solute: 10^{-2} g · ml^{-1}.

Time of heating, min	Color
0	Water white
10	Pale brown
25	Pale red brown
145	Red brown
300	Deeply red
330	Dusky brown
Blank of solvent after 330 min : water white	

The color changes indicated above are accompanied by a gradually decreased solubility, easily seen by cooling back to room temperature, when a gel is obtained from deeply colored solutions. This sol-gel transformation is reversible within the period of heating, found in Table 1. At continued thermolysis, approximately during 10—12 h, the hot solution shows increasingly viscoelastic properties, apparently due to formation of an infinite network. The dusky brown color is further enhanced.

It deserves to be noticed that similar results are obtained when the polymer is purified by reprecipitation from dioxane or separated into two fractions by soaking in acetone. The instability in pyridine seems to be a property inherently related to molecular structure.

Identical changes of color are observed when polyvinyl chloride is milled with plasticizers at elevated temperature in the absence of stabilizers. Extensive trial and error has been a requisite of finding adequate structures of such additives. The work has partly been guided by the current opinion that stabilizers principally act as scavengers for hydrogen chloride [3–6]. This is an oversimplification, as recently pointed out [7,8], as hydrogen chloride is a secondary product from a transfer reaction between a chlorine atom and a macromolecule:

$$\sim\sim\sim CH_2-CHCl-CH_2-CHCl\sim\sim + Cl\cdot = HCl + \sim\sim CH_2-CHCl-\dot{C}H-CHCl\sim\sim$$

leaving the question open in what way elementary chlorine is liberated. Earlier studies on dehydrochlorination of polyvinyl chloride [7-9] suggest the existence of thermolabile chlorine-carbon bonds in special chain sections of the macromolecules, for instance at branching units (chlorine bonded to a tertiary carbon atom) or in the vicinity of unsaturated end groups. These groups would be formed when termination occurs by disproportionation or by chain transfer to monomer. Many explanations merely rest on the incidental presence of initiator residues in the primary polymer particles. Such impurities dissociate on heating into free radicals and initiate degradation and decomposition by a chain reaction.

In the opinion of the writer no imperfections of these kinds are indispensable to explain the thermal instability of polyvinyl chloride, prepared in emulsion systems, as the presence of (hydro) peroxides can be varified experimentally in a very simple manner. Even a peroxide of unusual stability would be decomposed in a basic medium as pyridine by the formation of a redox system with said peroxide as active component. This can be done in many ways, but it is exceedingly important to find such coreactants that deactivate the released radicals without generation of a new population attacking the polymer. It also deserves to be noticed that free radicals and elementary chlorine mostly show identical type reactions, why a distinction between primary and secondary steps would be solely obtained at such a low reaction temperature, where thermal dissociation of C—Cl bonds is insignificant. Fortunately many redox systems are worked out with a view of acting at room temperature or below. Table 2 shows some reduction activators, inhibiting color formation in solu-

Table 2. Inhibitors of color formation in solutions of polyvinyl chloride in pyridine.

Coreactant(s)	Added amount to 1 g polymer	Suggested type reactions
$H_2N-OH \cdot HCl$	0.01—0.1 g	$ROOH \rightarrow RO\cdot + HO\cdot$ $HO\cdot + H_2N-OH \rightarrow H_2O + \dot{H}N-OH$ $RO\cdot + H_2N-OH \rightarrow ROH + \dot{H}N-OH$ $2\ \dot{H}N-OH \rightarrow N_2 + 2\ H_2O$
H_2N-NH_2 + $FeCl_2$	0.01—0.1 g 10 mg	$ROOH \rightarrow RO\cdot + HO\cdot$ $Fe^{2+} + HO\cdot \rightarrow Fe^{3+} + HO:^-$ $RO\cdot + H_2N-NH_2 \rightarrow ROH + \dot{H}N-NH_2$ $Fe^{3+} + H_2N-NH_2 \rightarrow Fe^{2+} + \dot{H}^+ + \dot{H}N-NH_2$ $H^+ + HO:^- \rightarrow H_2O$ $2\ \dot{H}N-NH_2 \rightarrow 2\ NH_3 + N_2$
$H_2N-NH_2 \cdot H_2O$	0.1 g	$N_2H_4 \cdot H_2O \rightleftharpoons H_2N-NH_3^+ + HO:^-$ $ROOH \xrightarrow{(HO:^-)} RO\cdot + HO\cdot$ $RO\cdot + N_2H_4 \rightarrow ROH + \dot{N}_2H_3$ $HO\cdot + N_2H_4 \rightarrow H_2O + \dot{N}_2H_3$ $2\ \dot{N}_2H_3 \rightarrow 2\ NH_3 + N_2$

tions of polyvinyl chloride in pyridine below 100°C. Inhibition has been considered as satisfactory when no color formation is visible during the schedule of observation, used in Table 1.

Several reducing agents behave as strong retarders of color formation and gelation. Paraformaldehyde, hydroquinone and *p*-hydroxybenzoic acid are a few of them. Classical inhibitors of vinyl polymerization, nitrobenzene and picric acid, show a similar effect. Unsaturated compounds, known to polymerize in a neutral aqueous medium by initiation of radicals, inhibit the later steps of the color formation cycle (red and dusky brown). This is especially valid for N,N′-methylene-bis(acrylamide).

The prehistory of the polymer is rather important, quite apart from the very method of preparation. It has been repeatedly observed that technical grades of polyvinyl chloride with a very low particle size are able to oxidise *p*-aminophenol, metol and pyrogallol at room temperature in the absence of air (suspension in methanol-water-reagent). A reprecipation from pyridine reduces the rate of oxidation, — indicated by the brown/black color in the liquid — but this improvement is gradually lost by repeated drying in air. Hydroperoxydation of polyvinyl chlroide would seem to be partly reversible.

Present experience on the properties of polyvinyl chloride (emulsion type) supports the idea that it might serve as an initiator of vinyl polymerization, provided the reaction medium is selected with care. This was proved by making a graft copolymer with acrylonitrile according to a "seeding" technique. The reacting mixture consisted of:

Polyvinyl chloride (5 g), dispersed in 500 g water,
Antarox G 100 (a nonionic detergent, 1 g)
Sodium pyrosulphite (1 g) and ferrous chloride (0.1 g)
Acrylonitrile (25 g)
Temp. of reaction: 32°C, time of reaction: 240 min, rate of stirring: 50 rpm.

Yield of pure, dry copolymer: 22 g.

It was easily verified that a true graft copolymer had been produced. Contrary to homopolymers of acrylonitrile dissolution can be carried out at 15—20°C, using only pyridine as solvent. Such a solution shows a very low viscosity and phase separation takes place on heating. Stable solutions are found in dimethyl formamide and dimethyl sulfoxide.

The high reactivity of polyvinyl chloride in the presence of reduction activators and a comonomer emphasises its character of peroxide or polymer radical. The inherent thermal instability of technically produced material is self-evident from this point of view. It also explains why a minor amount of (elementary) chlorine is stripped from the polymer already during its synthesis. After a long induction period due to oxygen, polymerization sets in at a rate far exceeding that working at standard conditions in an inert atmosphere. Polymeric peroxides at arbitrary degrees of polymerization are apparently decomposed into free radicals. Their primary constitution may be written

$$\sim\sim\sim\sim CH_2-\underset{\displaystyle Cl}{\underset{|}{CH}}-O\cdot \rightarrow \sim\sim\sim CH_2-\underset{\displaystyle \cdot}{CH}-O\cdot + Cl\cdot$$

Such a radical would be easily deactivated, if its reactivity is too low to initiate propagation, as the chlorine atom is in a labile position, compared to a regular sequence. Final polymer would show the presence of carbonyl groups in its infrared spectrum. This has been confirmed [9].

Addition Compounds of Olefins with Metal Salts

II. The Reaction of Ethylene with Silver Ions in Aqueous Solution

PAUL BRANDT

Chemistry Department A, Technical University, Copenhagen, Denmark

The reaction between silver ions and ethylene is bimolecular. The reaction is reversible, but the equilibrium is not as strongly displaced towards the reaction product as that of the equilibrium of mercuric ions and ethylene. The former process takes place as a simple addition of ethylene without formation of hydrogen ions.

The equilibrium formation constants were determined at seven temperatures between 17.5°C and 32.5°C. The dependence of the equilibrium constant upon the temperature was determined in 1 M trifluoracetate solution as:

$$\log_{10} K_1 = -3.42 + \frac{7.37}{2.3 \cdot RT}$$

The relation between the rate constant (time in sec.) and the absolute temperature for the reaction between the aquo silver ion and ethylene in 1 M trifluoracetate solution was found to be:

$$\log_{10} k_{+1} = 14.88 - \frac{20.36}{2.3 \cdot RT}$$

from determination of the rate constant at five temperatures between 15.0°C and 25.0°C.

In solutions containing triethanolamine(Am) the constants of the following equilibria were determined at 25.0°C:

$AgAm^+ + C_2H_4 \rightleftharpoons AgAm,C_2H_4^+$, $K_3 = 57.0 \pm 0.5$ and

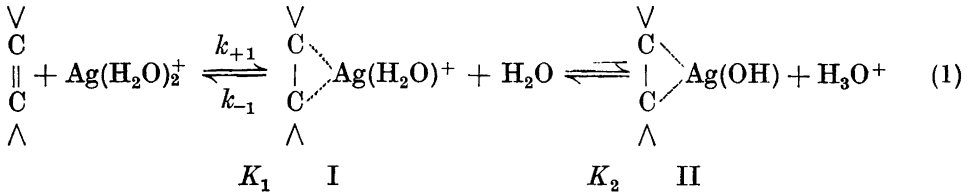
$AgAm_2^+ + C_2H_4 \rightleftharpoons AgAm,C_2H_4^+ + Am$, $K_4 = 2.65 \pm 0.15$.

In contrast to the addition product of ethylene and mercuric ion the corresponding ethylene silver ion was found to be a weak acid (pK about 8.5).

In the present work the reaction between silver ions and ethylene has been studied. The reaction is fast and an equilibrium is established in about 20 min. The equilibrium is obtainable from both sides.

The only silver salt which could be used was the trifluoroacetate. The nitrate and perchlorate ethylene salts turned out to be unsoluble. In all experiments a constant salt medium of 1 M sodium trifluoroacetate was used.

Trueblood and Lucas [2] have shown that only one ethylene molecule combines with the silver ion. In the present work it has been shown manometrically that the reaction is bimolecular with respect to the diaquo silver ion and to ethylene. The following equilibria are assumed:



(1)

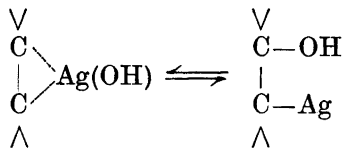
The equilibrium constants are,

$$K_1 = \frac{[\mathrm{I}]}{[\mathrm{Ag^+}][\mathrm{C_2H_4}]} \tag{2}$$

and

$$K_2 = \frac{[\mathrm{II}][\mathrm{H^+}]}{[\mathrm{I}]} \tag{3}$$

It has not been possible to prove the existence of an organic form of the ion II:



(4)

The results deviate in some respects from those of the corresponding reaction between ethylene and mercuric ions investigated by Brandt and Plum [1]. The time of establishing this equilibrium is about 10 h. However, the equilibrium is much more displaced towards the reaction product than that of the silver ion-ethylene reaction.

It is assumed that no measurable amounts of the organic form are formed with silver, while the main product formed with mercury is assumed to be the corresponding organic form. It has been shown that the complex ion I is a weak acid ($pK = 8.5$), while that of the corresponding mercuric ion is a strong acid ($pK = -0.5$), but this is understandable as the acidity constants of the corresponding aquo ions differ about 10^8 times.

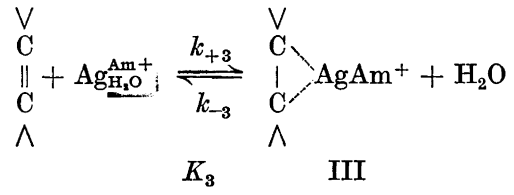
The equilibrium constant K_1 was determined at seven temperatures in the range from 17.5°C to 32.5°C. The solution was 0.025 M with respect to free hydrogen ions. The dependence of K_1 upon temperature was found to be:

$$\log_{10} K_1 = -3.42 + \frac{7.37}{2.3 \cdot RT} \tag{5}$$

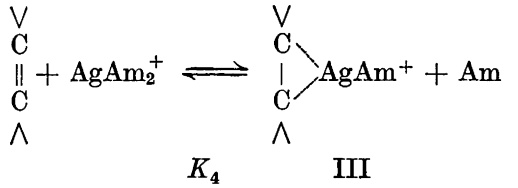
where T is the absolute temperature.

At 25°C, K_1 is 94.0 ± 0.5. Trueblood and Lucas [2] have determined the same equilibrium constant by measuring the partition coefficient of ethylene between silver nitrate solution and carbon tetrachloride, and found the value 85.3.

The acid dissociation constant K_2 of the complex ion I has been determined in solutions containing triethanolamine. In these solutions the following equilibria are assumed together with (1):



(6)



(7)

where Am stands for triethanolamine. The equilibrium pressure of ethylene was measured together with pH. From these measurements, from the previously found value of K_1 and from the known stoichiometry of the solutions the concentrations of all species of the equilibria could be calculated using the equilibrium constants determined by Bjerrum and Refn [3] for the silver-triethanolamine system.

The values of K_2 and K_3 together with the corresponding values of the concentrations of the ions II and III were calculated by successive approximations. The results are, $K_2 = 2.2 \times 10^{-9}$ and $K_3 = 57.0$ at 25°C.

Finally the value of K_4 was calculated to 2.65 ± 0.15 at 25°C.

The rate constant, k_{+1}, depends upon temperature as,

$$\log_{10} k_{+1} = 14.88 - \frac{20.36}{2.3 \cdot RT} \tag{8}$$

where k_{+1} is measured in mole per liter per sec. and T is the absolute temperature. k_{+1} was determined at five temperatures in the range from 15°C to 25°C. The value at 25°C was found to be, 0.875 mole per liter per sec.

The rate constant, k_{+3}, was determined at one temperature only, 25°C, and found to be, 0.355 mole per liter per sec.

The heat of formation of the ethylene-silver complex was determined as −7.37 kcal/mole as expressed in (5).

The activation energy of + 1 was found to be 20.36 kcal/mole as shown in (8).

Consequently the energy of activation of −1 is 27.73 kcal/mole.

EXPERIMENTAL

Apparatus. All the experiments were carried out in a Brønsted shaking apparatus similar to that described by Hofman-Bang [4] and Brandt & Plum [1] with the following alteration: Somewhat larger flasks were used as the consumption of ethylene was much less than obtained with mercuric salts. The total volume of the reaction vessel was usually 175—250 ml.

Materials and solutions. The triethanolamine was of pure grade and was distilled once (bp. 277—279°C at 150 mm Hg). All other chemicals were of analytical grade.

The ethylene was taken from a steel cylinder and purified before being transferred to the apparatus by passing it through six Friedrichs washing bottles, three of which contained concentrated sulphuric acid and three others alkaline pyrogallol solution.

The pure silver perchlorate and trifluoroacetate solutions (only used in preliminary experiments) were prepared by dissolving a known amount of freshly prepared silver oxide in a known amount of free acid in a volumetric flask and diluting with water containing suffient sodium hydroxide to obtain a total anion concentration of 1.000 mole per liter and a hydrogen ion concentration of 0.025 mole per liter.

In most of the experiments the solutions used were prepared by weighing a known amount of silver nitrate and a known amount of trifluoroacetic acid and diluting with water containing suffient sodium hydroxide as above. The stoichiometric concentrations of the solutions were: 0.100 silver nitrate; 0.900 trifluoroacetic acid and 0.975 sodium hydroxide which, for the ion concentrations, corresponds to: 0.100 silver ions; 0.025 hydrogen ions and 1.000 for the anions.

The alkaline solutions containing triethanolamine were prepared by weighing the silver nitrate, triethanolamine, trifluoroacetic acid and sodium hydroxide, dissolving each of them in a little water in a volumetric flask; thereafter diluting with water. A survey of these solutions is given in Table 2.

The exact concentration of silver ion was determined by a Volhard titration in the acid solutions, whereas for the alkaline solutions it was calculated from the known amount of silver nitrate weighed.

In the present work, square brackets are used to denote true concentrations, while C indicates total concentrations. All the concentrations are in mole per liter, and all pressures are in mm Hg.

The constants given here are therefore not the 'activity constants' but 'concentration constants', valid only under these specific conditions. In the calculation of the constants only concentration in mole per liter are used.

The hydrogen ion concentration, $[H^+]$, was measured with an ordinary glass electrode connected with a 'Radiometer' valve potentiometer, model PHM 3i. $[H^+]$ was determined in every case by standardizing against solutions of well-defined hydrogen ion concentrations having as nearly as possible the same values as the solutions investigated.

Preliminary experiments. Some preliminary experiments were carried out using pure silver nitrate solution, but the solution became opaque within a few minutes and it was impossible to obtain reproducible results. The following values were found for K_1: 64.7; 67.2; 43.6; 64.2; 77.0 and 84.3.

Other experiments were carried out with a solution of pure silver perchlorate, but the same difficulties occurred again, as a white precipitate was formed within a few minutes. The following values for the equilibrium constant were ascertained: 94.0; 92.1 and 94.2. The average value 92.9 agrees very well with the results obtained in the main experiments (see Table 1), whereas they differ a little from the value found by Trueblood and Lucas [2].

A few experiments were carried out with other cations, *i. e.*, K^+ and NH_4^+ instead of Na^+, but in every case a white precipitate occurred within a few minutes.

No precipitation occurs either with pure silver trifluoroacetate solution or with a solution containing 20 % nitrate ions and 80 % trifluoroacetate ions.

The experiments mentioned above were carried out in neutral solution or a solution with a hydrogen ion concentration of 0.025.

Some experiments were carried out in weakly alkaline solutions containing ammonia and ammonium nitrate, ammonium perchlorate or ammonium trifluoroacetate, but a white precipitate occurred in each case. With triethanolamine no precipitation was observed.

Table 1. Results of experiments at various temperatures for determination of the equilibrium constant K_1 in 1 M sodium trifluoroacetate solution. The stoichiometric concentration of the solutions used were:

$C_{AgNO_3} = 0.1000$, $C_{CF_3COOH} = 0.025$ and $C_{CF_3COONa} = 0.875$ mole per liter.

When employing a great excess of triethanolamine (solution F in Table 2), the uptake of ethylene after 24 h corresponded only to the ethylene dissolved in water. In this solution the concentrations of the monoamine ion and the free silver ion are negligible compared to the concentration of $AgAm_2^+$. Thus it is evident that the equilibrium constant K_4 for the reaction between ethylene and the diamine ion, can not be determined directly.

DETERMINATION OF THE EQUILIBRIUM CONSTANTS

The experimental results for the determination of the equilibrium constant K_1 are shown in Table 1. The results are summarized in eqn. (5). Graphical methods were used to obtain the numerical data of the equation.

The concentration of the silver ethylene ion is calculated, using the assumption that the concentration of the ion II is negligible, as being equal to the uptake of ethylene,

$$[\mathrm{I}] = \beta(P_0 - P_\infty) - \alpha \cdot P_\infty \tag{9}$$

where P_0 is the initial pressure, P_∞ the pressure of ethylene when equilibrium is established (both expressed in mm Hg), α the molar solubility of ethylene in water at 1 mm Hg pressure, and β an apparatus constant.

As the solubility of ethylene is slight, it may be assumed that Henry's law is valid, and the concentration of free ethylene may therefore be calculated from the equation,

$$[\mathrm{C_2H_4}] = \alpha \cdot P \tag{10}$$

where the value of α is 6.34×10^{-6} at 25°C when P is expressed in mm Hg.

Experiment No. 22 in Table 1 may be taken as an example. The volume V of the reaction vessel was 226.4 ml and the volume v of the solution was 100 ml. The value of β is 0.681×10^{-4}. By Volhard titration the initial concentration of the silver ion was found to be 0.0992. The initial pressure P_0 was 258.4 mm Hg and the equilibrium pressure P_∞ was 135.4 mm Hg. From eqn. (12) the value of [I] is calculated to be 0.00752 and the concentration of the free silver ions is thus, $[\mathrm{Ag^+}] = 0.0992 - 0.0075 = 0.0917$. The equilibrium constant, K_1, is,

$$K_1 = \frac{0.00752}{0.0917 \times 6.34 \times 10^{-6} \times 135.4} = 94.4$$

The constancy of the expression of K_1 shows that the assumptions made are resonable. Perturbations of equilibrium mixtures caused by changes of ethylene pressure lead to reestablishments of equilibrium, independently of the sign of the perturbation.

In order to determine the second equilibrium constant K_2 experiments were carried out in weakly alkaline solutions containing triethanolamine. In Table 2 the compositions of these solutions are stated, and Table 4 gives the results of the absorbtion of ethylene in these solutions.

From the pH measurements the figures of Table 2 were calculated in the following way. The total amount of triethanolamine, Am, is distributed over the following four species: Am, $\mathrm{AmH^+}$, $\mathrm{AgAm^+}$, and $\mathrm{AgAm_2^+}$ each of which can be calculated by means of the following euqations,

$$C_{\mathrm{Am}} = [\mathrm{Am}] + [\mathrm{AmH^+}] + [\mathrm{AgAm^+}] + 2[\mathrm{AgAm_2^+}] \tag{11}$$

$$\bar{n} \cdot C_{\mathrm{Ag}^+} = [\mathrm{AgAm^+}] + 2[\mathrm{AgAm_2^+}] \tag{12}$$

$$[\mathrm{AmH^+}] = \frac{[\mathrm{Am}][\mathrm{H^+}]}{K} \tag{13}$$

Table 2. Solutions containing triethanolamine. The stoichiometric concentrations of the solutions were: $C_{AgNO_3} = 0.2000$ and $C_{CF_3COOH} = 0.800$. In solutions A, B, D and F: $C_{NaOH} = 0.700$. In solutions C and E: $C_{NaOH} = 0.780$.

Solution	A	B_1	B_2	C	D_1	D_2	E_1	E_2	F
pH (measured)	7.10	8.18	8.40	8.90	7.69	7.83	8.45	8.78	9.20
$\bar{n}$	0.85	1.76	1.79	1.75	1.37	1.41	1.62	1.65	2.00

[Am]	0.0096	0.1625	0.1844	0.1533	0.0403	0.0434	0.0912	0.0966	1.81
$[AmH^+]$	0.0626	0.0851	0.0579	0.0153	0.0640	0.0509	0.0263	0.0127	0.09
$\bar{n} \cdot C_{Ag^+}$	0.1602	0.3524	0.3576	0.3506	0.2740	0.2810	0.3240	0.3304	0.40
$C_{Am}^{calc.}$	0.2375	0.6000	0.5998	0.5192	0.3783	0.3753	0.4415	0.4397	2.30
$C_{Am}^{weighed}$	0.2380	0.6000	0.6000	0.5200	0.3760	0.3760	0.4400	0.4400	2.30

Bjerrum and Refn [3] determined corresponding values of pAm and $\bar{n}$ (the average number of Am molecules bound to one silver ion) in 0.5 M $NaClO_4$ solution. It is permissable to use these values in our solutions (1 M medium) as the dependence of the equilibrium constants upon the concentration of the inert salt is small as shown by Bjerrum [6]. The value of $\bar{n}$ was found by trial and error.

As an example of the calculations solution D_1 may be used. For the values 1.3 and 1.4 of $\bar{n}$, the C_{Am} is calculated to be 0.3401 and 0.3918, respectively. As it should be 0.3760, the correct value of $\bar{n}$ must be close to 1.4. Using the value 1.37 for $\bar{n}$ we get 0.3783 for the total Am concentration, which is less than 1 % from the correct value.

Ethylene reacts with the silver diaquo ion and with the silver monoamine ion, whereas no measurable reaction takes place between ethylene and the diamine silver ion as proved by the experiments with solution F. The experiments in alkaline solution were carried out at one temperature only, *i.e.*, 25°C.

From the total uptake of ethylene the sum of concentrations of the complex ions I, II, and III can be calculated by means of eqn. (9),

$$C_x = [\mathrm{I}] + [\mathrm{II}] + [\overline{\mathrm{III}}] \tag{14}$$

The concentration of the ion I is calculated from the expression of K_1 (2). The concentration of the free silver ion is estimated in the following way,

$$C_{Ag^+} = [Ag^+] + [AgAm^+] + [AgAm_2^+] + C_x \tag{15}$$

denoting $C_{Ag^+} - C_x = a$ we obtain

$$a = [Ag^+] + [AgAm^+] + [AgAm_2^+] \tag{16}$$

$$[Ag^+] = \alpha_0 \cdot a \; ; \; [AgAm^+] = \alpha_1 \cdot a \; ; \; [AgAm_2^+] = \alpha_2 \cdot a \tag{17}$$

where

$$\alpha_0 + \alpha_1 + \alpha_2 = 1 \tag{18}$$

The equilibrium constants for the mono- and diamine silver ions are

$$K_1' = \frac{[AgAm^+]}{[Ag^+]\cdot[Am]} = 10^{2.30} \text{ and } K_{12}' = \frac{[AgAm_2^+]}{[Ag^+][Am]^2} = 10^{3.64} \quad (19)$$

From eqns. (16), (17), (18), and (19) we obtain,

$$\alpha_0 = \frac{1}{1 + K_1'[Am] + K_{12}'[Am]^2}, \quad \alpha_1 = \frac{K_1'[Am]}{1 + K_1'[Am] + K_{12}'[Am]^2},$$

$$\alpha_2 = \frac{K_{12}'[Am]^2}{1 + K_1'[Am] + K_{12}'[Am]^2} \quad (20)$$

C_x is always a small fraction of the total silver concentration. The ratio C_x/C_{Ag^+} varies between 2 % and 6 %. In the first approximation we can therefore assume that the change of [Am] caused by uptake of ethylene is negligible. Consequently, approximate values of α_0, α_1 and α_2 can be evaluated, and knowing $[Ag^+]$, $[C_2H_4]$ and K_1 an approximate value of [I] is obtained. $K_2 = \frac{[II][H^+]}{[I]}$ and $K_3 = \frac{[III]}{[AgAm^+][C_2H_4]}$ are determined by successive approximations. It is assumed that [II] is small compared to [III] in solu-

tions B and D. This gives a rough determination of K_3. From this value of the constant, [III] is calculated for solutions C and E and estimate is obtained for the concentration [II] and the constant K_2. Using this value of K_2, [II] is calculated in solution B and D and the assumption that [II] is small compared to [III] is seen to be justified. The concentration [III] and K_3 are now adjusted by aid of the correction, and new values of [II] and K_2 are obtained. After a few iterations K_2 and K_3 became really constant.

In Table 3 examples of the iteration procedure are given. From K_3 and the equilibrium constants of Bjerrum and Refn [3] (19) K_4 could be calculated. The values for K_4 are shown in Table 4. The small calculated value, 2.65, is in agreement with the experimental fact that solutions in which the ion $AgAm_2^+$ is predominating do not take up ethylene.

MEASUREMENT OF THE RATE OF REACTION WITH THE SILVER AQUEOUS ION

In Table 6 a representative run is shown. It is seen that it takes about one minute before stationarity is established between the rate of solution of ethylene and the velocity of the reaction with silver ions. In this first minute, there is not enough ethylene in the solution (even though the solubility rate

is very high), as the rate of reaction is very great. Then for about 2 min the reaction takes place at a rate that permits of measuring the pressure exactly at the desired time. The rate constant in this interval is almost a true constant. In the first minute nearly 70 % of the complex is formed, and in the following 2 min about 26 %. After about 20 min the equilibrium is established, and in this last interval the remaining 4 % of the complex is formed.

The calculation of the rate constant, on the basis of the assumption that the reaction is bimolecular, is made by means of the equation:

$$-\frac{d[C_2H_4]}{dt} = k_{+1}[Ag^+][C_2H_4] - k_{-1}[Ag(C_2H_4)^+] \quad (26)$$

The integrated form of this equation is:

$$\frac{K \cdot P_\infty}{P_0 - 2P_\infty - K\alpha^2 P_\infty^2 \log e} \log \frac{K\alpha P_\infty(P_0 - P) - (P_0 - P_\infty)}{K\alpha P_\infty(P_0 - 2P_\infty) + P_\infty} = k_{+1} \cdot t \quad (27)$$

where
$$K = \frac{\alpha \cdot P_\infty - \beta(P_0 - P_\infty)}{\alpha \cdot P_\infty(\alpha \cdot P_\infty + \beta(P_0 - P_\infty) - C_{Ag^+})} \quad (28)$$

As a rule the rate constant was determined from the slope of the straight line plot of logarithmic expression (27) against t, usually simplified to:

$$\frac{K}{\sqrt{q} \cdot \log e} \log \frac{x + A}{x + B} = k_{+1} \cdot t \quad (29)$$

where: $a = K \cdot \alpha \cdot P_0 \cdot C_{Ag^+}$; $b = -1 - c \cdot C_{Ag^+} - \frac{a}{C_{Ag^+}}$;

$$c = \frac{K\alpha(P_0 - P_\infty)}{C_x} \; ; \quad q = b^2 - 4ac \; ; \quad A = \frac{b - \sqrt{q}}{2c} \; ;$$

$$B = \frac{b + \sqrt{q}}{2c} \text{ and } x = \frac{C_x(P_0 - P)}{P_0 - P_\infty}$$

(x is the concentration of the complex ion at the time t).

In all the tables in this paper the rate constants are given in mole per liter per min.

As small amounts of atmospheric air are always present in ethylene, the concentration of the air was determined by reaction with a mercuric salt solution and a deficit of ethylene. The value of the pressure when equilibrium had been established was used to calculate how much atmospheric nitrogen was mixed with the ethylene (the oxygen was absorbed in the basic pyrogallol before the ethylene was transferred into the reaction chamber). Usually the nitrogen content was about 3—5 %.

Some experiments were carried out in the opposite direction, by starting with a solution in equilibrium with ethylene at high pressure. By decreasing the pressure with about 200 mm Hg, a reaction occurs in the reverse direction, as ethylene is now given off. In Table 7 the calculation of one of these

Table 5. Results of experiments for determination at various temperatures of the rate constant in 1 M trifluoroacetate solution of the reaction between silver diaqueous ions and ethylene. The stoichiometric concentrations of the solution are the same as described in Table 1.

experiments is shown, and it is seen that the pressure increases about 50 mm Hg in the first 3 min, and only 2 mm Hg in the following 20 min, thereafter the equilibrium is again established.

The calculation is carried out by means of the same equation as above (26), but as the initial concentration of the complex ion is not at zero, the integrated expression differs slightly from eqn (27):

$$\frac{K}{\sqrt{q} \cdot \log e} \left(\log \frac{y + A}{y + B} - \log \frac{y_0 + A}{y_0 + B} \right) = k_{+1} \cdot t \qquad (30)$$

reciprocal reaction). Employing Arrhenius' equation in 1 M trifluoroacetate solution all the results are expressed as follows:

$$\log_{10}k_{+1} = \log_{10}A - \frac{E_A}{2.2 \cdot RT} = 14.88 - \frac{20.36}{2.3 \cdot RT} \quad (31)$$

The value of the energy of activation (expressed in kcal) and the value of the frequency exponent are in good agreement with other values found in rapid complex reactions [5]. The value of the rate constant given in the last column is calculated from this equation and is in very good conformity with the experimental average value.

The value of the rate constant in dilute aqueous solution must be of the same order of magnitude as the one found in 1 M salt solution, because the reaction occurs between an ion and a neutral molecule. From the equation:

$$\log K_1 = \log \frac{k_{+1}}{k_{-1}} \quad (32)$$

the dissociation velocity constant k_{-1} for the mono ethylene complex silver ion can be calculated, and from the equation:

$$Q = E_A - E_{-A} \quad (33)$$

the energy of activation for the dissociation reaction of the complex ion can also be calculated; the value of E_{-A} is found to be 27.73 kcal.

MEASUREMENT OF THE RATE OF REACTION WITH SILVER TRIETHANOLAMINE ION

In Table 8 a survey is given of the results for determination of the rate constant for the reaction between the silver triethanolamine ion and ethylene (5). The value found is about half of that found for the aquo ion, *i.e.*, it is of the same order of magnitude as for the aqueous ion.

As previously mentioned the hydrogen ion concentration is the same before and after reaction with ethylene. As not more than about 2 % of the total

Table 8. Results of experiments for determination of the rate constant at 25°C for the reaction between the silver mono triethanolamine ion and ethylene.

Expt.No.	Solution	k_{+1}	k_{+1}(average)
81	B_1	21.3

84	B_1	22.1	
85	C	20.5	

amount of silver ions reacts with ethylene, the calculation of these experiments can be made using the assumption that the free silver ion concentration as well as the concentration of the mono triethanolamine silver ion are both

constant, *i.e.*, $\bar{n}$ is constant. As the concentration of the ion I is only about 5 % of the total amount of the complex ions formed, the calculation can be made under the assumption that a reaction with ethylene occurs only with the mono triethanolamine silver ion. Eqn. (27) can therefore be simplified to:

$$\frac{\beta(P_0-P_\infty) - a \cdot P_\infty}{a \cdot a \cdot P_0 \cdot \log e} \log \frac{P_0-P}{P_0-P_\infty} = k_{+1} \cdot t \qquad (34)$$

where 'a' is the concentration of the silver mono triethanolamine ion.

The author takes the opportunity to thank Professor J. Bjerrum for his interest, advice and helpful discussions during the course of this work, as well as *Statens almindelige Videnskabsfond* for financial support.

The Acid Soluble Nucleotides of *Vicia Faba*

M. F. ABDEL-WAHAB and S. A. EL-KINAWI

From the Isotope Centre, A.E.E., Cairo, Egypt and Institute of Biological Chemistry, University of Copenhagen, Denmark

The use of small doses of ^{32}P has been found to stimulate the synthesis of the acid soluble nucleotides of *Vicia Faba*. A suitable incorporated activity has been found to be 0.1 μC per seed in a 48 h period, while higher and lower doses seemed to be less effective.

The acid soluble nucleotides of *Vicia Faba* were extracted with 10 % perchloric acid, and fractionated by ion exchange chromatography. They were shown to include the 5′-triphosphates of adenosine, guanosine, cytidine and uridine as well as mono- and diphosphate.

The identification of ten nucleotides was mainly based on the ultraviolet absorption measurements on the extract and pure nucleotides, radioactivity measurements together with chemical and enzymatic analyses. The extraction was carried out on plants exposed to ^{32}P before sowing.

While heavy radiation is damaging to plant life, some authors have claimed that moderate exposure would stimulate plant growth and accelerate the metabolic processes [1]. Bean plants were grown in solutions in which the ^{32}P concentration was varied. The plants were later radiographed, (that is, laid over sheets of X-ray film) showing that the ^{32}P uptake increased within but not beyond a very low concentration range of phosphorus in the soil [1].

Small doses of ^{32}P have been shown to increase the production of nucleoproteins in plants [2].

In the last few years many reports have appeared concerning the metabolism of the acid soluble nucleotides, in yeast [3–5], wheat, oats and barley [6]. As a further continuation of the study of the metabolism of acid soluble nucleotides in different plants, we present here the first results of experiments carried out on *Vicia Faba*.

The main difficulties encountered in the demonstration of these compounds in plants have centred on the problem of their separation from interfering substances and their isolation in pure form. Methods developed primarily for the isolation of the nucleotides from animal tissues have proved to be unsatisfactory for the isolation of these compounds from plants [7].

Cohn was one of the pioneers in using the chromatographic methods for the estimation of the acid soluble nucleotides in yeast [7]. Potter and coworkers [8]

have improved the method of separation on the column and shortened the time for the estimation of the acid soluble nucleotides by the so called gradient elution method.

An improved method for the isolation of the acid soluble nucleotides from plant tissues has been described by Bergkvist [6]. The application of this method to *Vicia Faba* established the occurrence of all the four ribonucleotides, *viz.* the adenosine, guanosine, cytidine and uridine derivatives. Such nucleotides exist in the form of acid soluble 5-ribonucleotides at different levels of phosphorylation. Of great interest is the occurrence of uridine, besides adenosine derivatives in *Vicia Faba*, in contrast to the dominating role of the latter in animal tissues.

In the present paper we have tried to give a complete picture of the acid soluble nucleotides obtained by cold 10 % perchloric acid (PCA) extraction of 250 g of *Vicia Faba* plant, just before fruiting. The yield was found to be low; however, the nucleotides isolated were similar to those which have previously been obtained from yeast under anaerobic conditions [5]. The results given are the average of ten experiments. The seeds of the plants used for the extraction were first exposed to the beta-radiation emitted from small doses of ^{32}P. In a previous paper we have estimated the suitable dose for irradiation to produce no harmful effect on the plant. The morphological appearance of the plant and the analyses of total nitrogen, soluble nitrogen, and protein nitrogen were taken as criteria for the estimation of the suitable dose (Abdel-Wahab and El-Kinawi, unpublished work). A suitable incorporated activity has been found to be 0.1 μC per seed and a 48 h period of exposure.

Both radioactivity and ultraviolet adsorption were measured on the extract. The results obtained for the acid soluble extract of the *Vicia Faba* nucleotides from ultraviolet absorption spectrum, and from radioactivity measurements, were found similar (see Figs. 1 and 2).

Autoradiogaphic experiments have shown that the ^{32}P-uptake is more pronounced in leaves than in shoot or root systems. They have shown also that plants grown in pots afford better material than those grown in the field. In our experiments we have used pot plants four weeks after sowing. At the end of such a period the plant has begun to fruit.

The acid soluble nucleotides were isolated by homogenising the plant material in ice-cold 10 % PCA and freed from other phosphorus-containing or ultraviolet-absorbing substances according to the method described by Bergkvist [6]. After adsorption on a strong base anion exchanger in the formate form, the individual nucleotides were eluted with formic acid solutions containing increasing concentration of sodium formate. Elution of the nucleotides was followed by the change in optical density of the effluent fractions at 260 mμ and 270 mμ. The optical densities of the effluent fractions at 260 mμ were plotted against the effluent volume to obtain the chromatograph shown in Fig. 1. The elution positions as well as the absorbance ratios gave a preliminary identification of the individual fractions. Resolution of the elution position was achieved by plotting the radioactivity against the tube number. The activity was measured in counts per min and gave rise to the results shown in Fig. 2. Figs. 1 and 2 are nearly similar. From these figures one can conclude also that no reduced nucleotides are detected under our

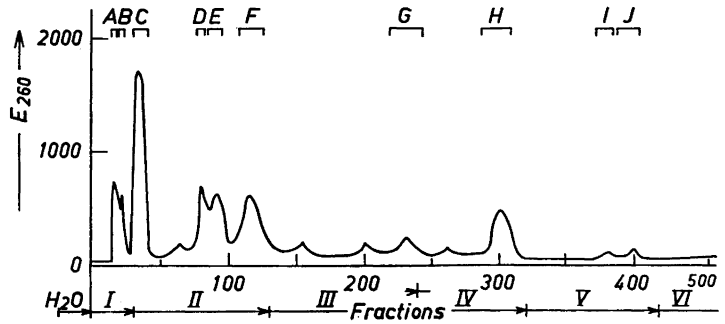

Fig. 1.

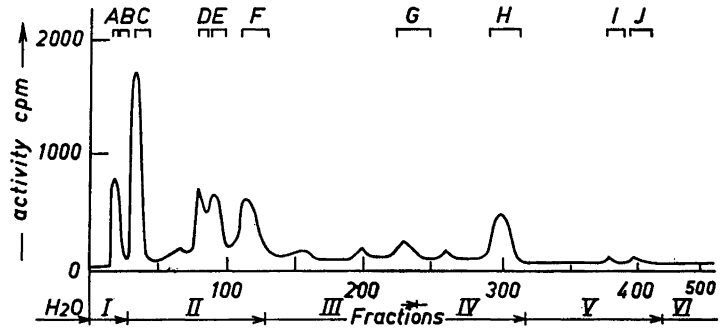

Fig. 2.

experimental conditions in *Vicia Faba*. An attempt to demonstrate such reduced nucleotides in yeast under anaerobic conditions has been carried out by us [5], and proved also their absence in yeast. In case such nucleotides are present in *Vicia Faba* they should only appear in Fig. 2 (radioactivity), but not in Fig. 1 (ultraviolet-absorption), because of the fact that such reduced nucleotides have no absorption in the ultraviolet spectrum.

The R_F values obtained from the paper chromatograms in different solvent systems and the density curves of the free nucleotides eluted from the paper chromatograms were also studied and compared to standard pure nucleotides. Since the nucleotides obtained from the column were dissolved in large volumes of formate buffer, it was desirable to concentrate them and to get rid of the excess salts. In order to remove the excess of salts, the individual peaks were separated, readsorbed on norite and then eluted with ammoniacal ethanol. The solutions thus obtained were used to identify the nucleotides and establish the purity of the peaks by comparison of their chromatographic behaviour with those of the corresponding authentic samples.

Further characterization of the nucleotides was obtained by the following procedures:

a. Ultraviolet absorption spectra in 0.1 N HCl and 0.1 N NaOH.
b. Determination of the total phosphorus content and of the phosphorus liberated after hydrolysis for 10 min in 1 N HCl.
c. Determination of the sugar content in each sample.
d. Paper chromatographic identification of the nucleotides and comparing their R_F values in different solvents with authentic samples.
e. Comparing the optical density curves of the nucleotides with standard curves over a range, 220—320 mμ, in intervals of 5 mμ.
f. The position of the phosphate group on the different nucleotides was confirmed by oxidation with periodate and the action of rattle snake venom [6].

Fig. 1 shows the ultraviolet extinction of 260 mμ of the fractions collected by an automatic fraction collector against the tube number. The results are obtained from 250 g *Vicia Faba* (whole plant), extracted by means of ice cold 10 % PCA and chromatographed on Dowex 1, formate form. The extinction values were obtained by the use of a Beckman spectrophotometer. The formate system used gave rise to peaks up to buffer solution V (*cf.* Experimental). Buffer solutions VI, VII, and VIII did not give rise to new peaks. Each tube represents 5 ml effluent. The diagram indicated the presence of ten distinct peaks as described at the bottom of Table 1 and are arranged in order of appearance.

In Fig. 2 the radioactivity is plotted against the tube number. The activity was measured as counts per min. Solutions used for measurements are those used in Fig. 1. The absence of extra peaks in Fig. 2 denotes that no reduced nucleotides are detected.

Table 1. R_F values of the ten peaks obtained from Fig. 1, compared with the R_F values of the standard pure nucleotides.

	R_F for the peaks appearing in Figs. 1 and 2. / R_F for the pure standard nucleotides

Identified nucleotides	A CMP	B DPN	C AMP	D GMP	E UMP	F ADP	G UDPX*	H ATP	I UTP	J GTP

* UDPX is a sugar derivative of uridine diphospate.

Comparison of the R_F values obtained showed the existence of ten nucleotides identified in Table 1. The density curves obtained for the peaks in acid and alkaline medium and those of the ten pure standard nucleotides, together with the extinction ratios E_{250}/E_{260} and E_{270}/E_{250}, confirmed the presence of ten nucleotides.

EXPERIMENTAL

Irradiation of seeds. 250 g = 400 seeds of *Vicia Faba*, variety Rebaia 34, kindly supplied by the Egyptian Botanical Adminstration, were soaked in 2 l of tap water containing 40 μC ^{32}P. After 48 h, the seeds were removed from the soaking medium washed twice with tap water and used for sowing.

Sowing. Seeds were sowed in pots (3 per pot) and left to grow out of doors. The soil used for sowing was that used for sowing beans and other plants in Egypt. The plants were irrigated daily and after the first week the seedlings began to appear. At the end of four weeks the plants began to fruit. A control experiment was carried out using the same procedure but without using ^{32}P in the soaking medium.

Separation of the acid soluble nucleotides. The whole mature plant, which had begun to fruit, was ready for the extraction at the end of four weeks. 250 g of fresh whole plant were homogenised in 1 000 ml ice-cold 10 % PCA in a Waring Blender and reextracted with 250 ml 5 % PCA. The nucleotides were isolated from the PCA extract by ether extraction. The etherial layer containing the nucleotides was separated and left to evaporate by passing a stream of air through it. The oily residue left after aeration was dissolved in 500 ml CO_2-free redistilled water and brought to pH 8 by dilute ammonium hydroxide.

Fractionation of the nucleotides. Dowex 1 in the formate form was used as fractionating system. The individual nucleotides were eluted with increasing concentrations of formic acid or a mixture of formic acid and sodium formate. The following eluting system and the type of column described, were used.

Eluting Buffers	Formic acid, M		Sodium formate, M
I	0.02		—
II	0.10		—
III	0.10	+	0.05
IV	0.10	+	0.30
V	0.10	+	0.40
VI	0.10	+	0.60
VII	0.20	+	0.80
VIII	0.50	+	1.00

Exchanger. Dowex 1—X 10, 200—400 mesh, strong base anion exchanger, 1.2 × 20 cm formate column, effluent rate 1 ml per min.

The nucleotides were recovered from the pooled fractions by norite adsorption. For each peak the paper chromatographic procedure was carried out as is explained elsewhere.

Ultraviolet absorption. The chromatographic fractions were analysed by measuring their extinction at 250, 260 and 270 mμ in a spectrophotometer, Beckman Model DU with photomultiplier. The extinctions at 260 mμ were plotted against tube number as shown in Fig. 1. Each peak was also further studied by determining its optical density over a range of 220 to 320 mμ in intervals of 5 mμ, in 0.1 N HCl and 0.1 N NaOH solutions. The absorption ratios E_{250}/E_{260} and E_{270}/E_{260} were determined as well and used as criteria for the identification of the different nucleotides.

Phosphorus determination. Each sample was evaporated to a very small volume to remove the solvent used for elution. The samples were then heated with perchloric acid in 25 ml micro-Kjeldahl flasks till they turned colourless. The samples were left to cool and phosphorus was determined by the method of Allen [9], adapted to a total volume of 5 ml, and the acid labile phosphorus was determined after 10 min hydrolysis in 1 N HCl at 100°C.

Pentose estimation. Both samples from *Vicia Faba* extract and standard pure nucleotides were subjected to pentose estimation using the orcinol method of Albrum and Umbereit [10]. The results were calculated by comparison with the standards.

Periodic oxidation. Oxidation with periodate was performed according to Dixon and Lipkin [11], to confirm the position of the phosphate group in the nucleotides present.

Action of snake venom. The action of rattle snake venom was studied according to the method of Bergkvist [6].

Paper chromatography. Schleicher and Schüll, No. 204, 3b, filter paper was used. The Markham and Smith method [12], for localisation of the spots on the paper chromatogam was used. Identification of the R_F of nucleotides present, was achieved by using pure nucleotides and comparing the R_F values obtained (see Table 1).

Both the descending and ascending methods for paper chromatography were used to resolve the nucleotides.

Descending systems.

1. *Iso*butyric acid/NH_3/H_2O (60/1/33).
2. Ethanol/M ammonium acetate (aqueous) (70/30).
3. 0.1 M phosphate buffer (pH 6.8)/saturated ammonium sulphate/*n*-propanol (1/60/40).
4. Butanol/glacial acetic acid/water (40/11/50).

Ascending system.

5. *Iso*amylalcohol/water/citric acid (10/50/0.3 g).

The sample tubes belonging to one peak in the extinction curve (Fig. 1) were collected, shaken with 2 g norite for 20 min, then centrifuged and the supernatent fluid was discarded. The adsorbed nucleotides were then eluted successively with 10 and 5 ml of the ammoniacal ethanol (50 % aqueous ethanol containing 0.5 % ammonium hydroxide, *d* 0.91). The eluent was separated by centrifugation and lyophilised. The dry residues, dissolved in a minimum amount of distilled water (40—80 μl), were used to spot the chromatograms.

Acknowledgment. One of the authors (Abdel-Wahab) is most grateful to prof. Dr. Phil. Hans H. Ussing for his continuous interest and helpful criticism; he wishes also to thank the IAEA in Vienna for the maintenance award which enabled him to visit the Institute of Biological Chemistry in Copenhagen where he continued his work in this field.

Characterization of Intestinal Invertase as a Glucosido-Invertase

II. Studies on Transglycosylation by Intestinal Invertase

ARNE DAHLQVIST and BENGT BORGSTRÖM

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Purified hog intestinal invertase produced a number of oligosaccharides in a concentrated sucrose solution. Since no oligosaccharides were produced from a mixture of glucose and fructose under the same conditions, the mechanism for oligosaccharide formation is a transglycosylation.

At the initial stage of the reaction more fructose than glucose was liberated. Intestinal invertase therefore transfers *glucose*, which also appears from the structure of the oligosaccharides produced. This is in accordance with the classification of intestinal invertase as a glucosido-invertase (α-D-glucopyranosidase).

The origin and structure of some of the oligosaccharides produced were studied. The product by transfer of glucose to sucrose was identified as α-D-glucopyranosyl (1 → 4) α-D-glucopyranosyl (1 → 2) β-D-fructofuranoside. The name *maltosucrose* is proposed for this trisaccharide.

Maltosucrose was rapidly hydrolyzed by intestinal invertase. During this hydrolysis, sucrose was formed as an intermediate product. The maltose linkage of the trisaccharide is therefore hydrolyzed before the sucrose linkage.

No resynthesis of sucrose could be demonstrated during the hydrolysis of sucrose in the presence of ^{14}C-labelled glucose or fructose. The ^{14}C-hexoses were, however, incorporated into other oligosaccharides.

It is generally assumed that two different kinds of invertases exist, namely, fructosido-invertases (β-D-fructofuranosidases) and glucosido-invertases (α-D-glucopyranosidases). It has been suggested that intestinal invertase is a glucosido-invertase. The experimental evidence for this theory is, however, incomplete [1]. For this reason, a study of the transglycosylation by intestinal invertase was performed, the results of which are reported in the present paper.

During the action of glycosidases upon a *concentrated* substrate solution, a number of oligosaccharides are usually * formed by a process called transglycosylation [3]. Since this phenomenon occurs with highly purified glycosidase preparations as well, it is assumed that hydrolysis and transglycosylation are catalyzed by the same enzyme [3].

With invertases two different kinds of transglycosylation have been observed, namely *transfructosylation* and *transglucosylation* **. It has been demonstrated that yeast invertase [3] and invertase from *Penicillium spinulosum* [3,4], which undoubtedly are *fructosido*-invertases, have trans-*fructosyl*ase activity. Honey invertase [3,5,6] on the other hand, which is a *glucosido*-invertase, has trans*glucosyl*ase activity. The hypothesis that these enzymes are fructosido- and glucosido-invertases is therefore supported by the transglycosylase activities, which seem to provide a valuable basis for the classification of invertases.

MATERIALS AND METHODS

Purified intestinal invertase (from pig) was obtained by mutual displacement chromatography on TEAE-cellulose [2]. The preparation used had a maltase/invertase activity quotient of 0.6 and an invertase activity of 250 units per mg of protein [8]. It contained no trehalase or maltase III activity [7].

Sucrose, glucose and fructose had analytical grade purity. Sucrose and glucose were obtained from J. T. Baker Co., fructose from Pfanstiehl Chemical Inc.

^{14}C-Labelled glucose and fructose (uniformly labelled) were obtained from The Radiochemical Centre (England).

Paper chromatography of sugars was performed by the descending technique on Whatman No. 1 paper. The lower end of the paper was serrated so as to allow the solvent to drip off (Fig. 1). 2—5 μl spots of the solution to be analyzed were applied to the paper, and after drying the chromatogram was equilibrated and run with ethyl acetate:acetic acid:water 9:2:2 (v/v). For separation of the oligosaccharides produced by transglycosylation, the chromatogram was run for 3 days. Under these conditions the sucrose spot travelled about 15 cm.

As *general reagent* for the detection of the sugar spots, the *periodate* reagent described by Movery [9], was used. This reagent had the great advantage over the more commonly used aniline phthalate reagent that it had the same sensitivity to non-reducing oligosaccharides as to reducing sugars.

For detection of free *reducing groups* in oligosaccharides ammoniacal silver nitrate [10] was used. This reagent reacted with glucose, fructose and maltose, but did not produce any colour even with great amounts of non-reducing oligosaccharides such as sucrose, raffinose, melezitose or trehalose.

Fructose-containing oligosaccharides were detected with the modified Seliwanoff reagent described by Hattori and Shiroya [11]. This reagent is specific for ketoses. Fructose, sucrose, raffinose and melezitose produced brilliantly red spots with this reagent, while glucose, maltose and trehalose did not produce any colour at all.

For the chromatography of ^{14}C-labelled sugars papers were used which had previously been cut into 1.5 cm broad strips, 1 cm apart, held together by intact paper [12]. The lower end of these papers, too, was serrated. One sugar spot was applied to each strip. After the run, the distribution of the radioactivity was measured for each strip with a Geiger-Müller counter. The paper strip automatically moved in front of the tube, and the time for 100 counts was recorded for each cm length of the strip. No back-ground correction was made (Figs 2 and 3). After counting, the sugar spots were localized with the periodate reagent.

* No transglycosylation could be demonstrated with intestinal trehalase [2].

** Trans*glycos*ylation is the name for the transfer of any sugar residue while trans*glucos*ylation means the transfer of *glucose*.

For the *quantitative determination* of glucose and fructose, papers were used which had been cut in the same way as in the case of ^{14}C-labelled sugars. The chromatograms were run for 20 h only. The sugar spots were localized by marker sugars run on parallel strips. 3 cm long pieces of the paper containing the sugars to be determined were eluted in small beakers with 5 ml of water at room temperature for 20 min with occasional shaking. A sample of the eluate, containing 1 – 9 μg of glucose or fructose, was used for quantitative determination with the highly sensitive method of Park and Johnson [13]. The colour produced was measured at 690 mμ with a Beckman B spectrophotometer.

Chromatography of sugars on carbon-celite columns was performed as described by Whistler and Durso [14]. 300 g each of Darco G-60 and celite were mixed and packed to a column 9 × 25 cm. The column was washed with 1 l of 0.1 N HCl, 3 – 4 l of 50 % (by vol.) ethyl alcohol in water and finally with water. After adsorption of the sugar mixture to the column, the monosaccharides were eluted with 0 – 2.5 %, the disaccharides with 5 – 7.5 % and the trisaccharides with 10 – 15 % ethyl alcohol. The amount of sugar in the effluent was measured with the anthrone method, performed as described by Scott and Melvin [15], but with heating for 7.5 min at 100°C instead of for 16 min at 90°C. The column had a capacity of 10 g of sugar (determined with maltose). 10 – 15 l of solvent was used for the elution of each class of sugar.

Raybin's diazouracil test [16]. 10 mg of the sugar to be tested was dissolved in 0.5 ml of 0.1 N NaOH. 0.5 ml of a freshly prepared 0.4 % solution of diazouracil in water was added. If the reaction was positive, a *green colour* developed in a few minutes at room temperature. After 10 min 1 drop of 0.1 M $MgCl_2$ was added. When the reaction was positive, a stable *blue precipitate* was formed. If the reaction was negative, no colour developed, and after addition of $MgCl_2$ a red precipitate was formed.

Sucrose and raffinose gave positive Raybin's test, while glucose, fructose, maltose and melezitose gave negative reaction, in accordance with earlier findings [16,17]. The reaction is specific for the sucrose structure [17].

Determination of reducing sugars produced from oligosaccharide A. The enzymatic digestion of oligosaccharide A was performed in 0.1388 M (7 %) solution with 0.05 M maleate buffer pH 6.5. The reducing sugars produced were determined with the method of Somogyi and Nelson [18,19], after precipitation of the proteins with the Zn-Ba-reagent of Somogyi [20].

RESULTS AND DISCUSSION

Demonstration of oligosaccharide formation. In a solution containing 30 %* sucrose, 0.05 M maleate buffer pH 6.5 and 38 units of purified intestinal invertase per ml, glucose and fructose were rapidly formed at 37°C. During the course of the reaction, however, a number of oligosaccharides were formed, too, all of which moved slower than sucrose on the paper chromatogram with the solvent used.

One of these, oligosaccharide A, was formed very early in the reaction (Fig. 1). It has the R_s value (*i.e.* mobility/mobility of sucrose) 0.38. Later in the reaction two oligosaccharides were formed with mobility intermediate between oligosaccharide A and sucrose, namely, oligosaccharides B_1 and B_2 with R_s values 0.83 and 0.70, respectively. In addition one oligosaccharide with low mobility, oligosaccharide C with R_s 0.17, was formed.

When a 30 % solution of invert sugar was incubated during the same conditions, only glucose and fructose were found on the paper chromatogram. Intestinal invertase therefore has no demonstrable synthetic action. The oligosaccharides formed from sucrose must therefore be formed by *transglycosylation.*

* Per cent means g of solute per 100 ml of solution.

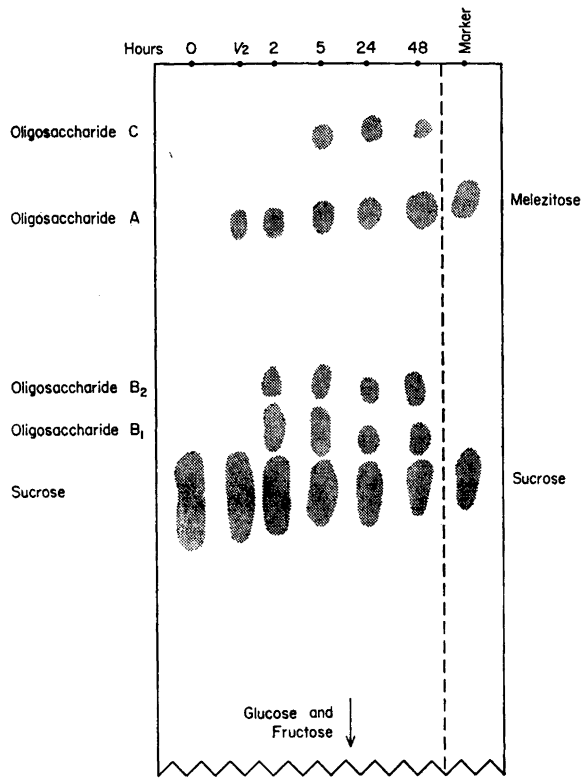

Fig. 1. Formation of oligosaccharides by transglycosylation. Purified intestinal invertase (38 units/ml) in 30 % sucrose with 0.05 M maleate buffer pH 6.5 at 37°C. Chromatogram developed during 3 days.

Oligosaccharides formed by transglycosylation are usually hydrolyzed when the reaction has been in progress for a sufficiently long time. In the present case, the reaction was followed for 14 days. Although the oligosaccharide spots had become smaller after this time, they were still clearly visible. This fact may be explained by inhibition of the enzyme brought about by the great amounts of monohexoses present. Pure oligosaccharide A was found to be rapidly hydrolyzed by intestinal invertase.

Amounts of glucose and fructose produced. The relative amounts of glucose and fructose produced by an invertase preparation during the action on a concentrated sucrose solution are dependent upon the nature of the transglycosylation. For each fructosyl group transferred one glucose molecule is liberated, and for each glucosyl group transferred, one fructose molecule is liberated.

During the action of intestinal invertase on a 30 % sucrose solution, the amount of fructose liberated at the initial stage of the reaction (5—10 %

Table 1. Properties of sugars produced by action of intestinal invertase in 30 % sucrose solution at pH 6.5 and 37°C.

hydrolysis) was 1.5 times the amount of glucose liberated, determined by quantitative paper chromatography. The transglycosylation by intestinal invertase must therefore be a transfer of *glucose*. Since it has earlier been found that fructosido-invertases transfer fructose, while glucosido-invertases transfer glucose [3], this fact affords strong evidence that intestinal invertase is a glucosido-invertase. This conclusion implies, of course, that hydrolysis and transglycosylation are catalyzed by the same enzyme. This, however, seems probable since purified intestinal invertase (with 250 times increased specific activity) was found to produce the same oligosaccharide spots as a crude preparation of intestinal glycosidases.

Properties of the oligosaccharides produced. Some information about the properties of the different sugars formed may be obtained on the paper chromatogram by use of specific spray reagents. In the present case ammoniacal silver nitrate was used for the demonstration of reducing end groups, and a modified Seliwanoff reagent for the demonstration of fructose in oligosaccharides. The results with these reagents are listed in Table 1.

Oligosaccharide A is non-reducing and contains fructose. This may be expected if oligosaccharide A is formed by transfer of a glucosyl radical to sucrose. This is the probable way for the formation of oligosaccharide A, since it appears very early in the reaction. The isolation of oligosaccharide A and the determination of its structure are described below.

Oligosaccharide C is also non-reducing and contains fructose. Since this sugar has a low chromatographic mobility, it is probably a tetrasaccharide, possibly formed by transglycosylation to oligosaccharide A. This theory is supported by the fact that a sugar with the same mobility as oligosaccharide C is produced when intestinal invertase acts upon a solution of pure oligosaccharide A.

Oligosaccharides B_1 and B_2 are reducing sugars. Their relatively high chromatographic mobility indicates that they may be disaccharides. This theory is supported by the fact that they were eluted (together with sucrose) by 5 % ethyl alcohol from a carbon-celite solumn. The slowest moving one, oligosaccharide B_2, contains no fructose, and has the same chromatographic mobility as maltose. It may be identical with this sugar.

If oligosaccharides B_1 and B_2 are disaccharides, they may be formed either by transfer of glucose to free fructose and glucose, or by partial hydrolysis of a trisaccharide. By the use of ^{14}C-labelled fructose and glucose it was possible to identify oligosaccharides B_1 and B_2 as the products of transglucosylation to free fructose and glucose, respectively (see below).

Isolation and structure of oligosaccharide A. 60 g of sucrose were dissolved in 0.05 M maleate buffer pH 6.5 to a final volume of 200 ml and 1 ml of a purified invertase preparation, containing 600 units of invertase and 3 mg of protein, was added. As preservative, 5 ml of toluene was added. After 7 days at 37°C the solution had a reducing power corresponding to 25 % hydrolysis of the sucrose. The reaction was then interrupted by boiling for 5 min.

By paper chromatography the digest was found to contain fructose, glucose, sucrose and the series of oligosaccharides described above. The whole solution was filtrated through a 9 × 25 cm carbon-celite column. The amount of sugar was about 6 times the capacity of the column. Because greater molecules are adsorbed with greater force, however, the solution passing through the column contained only monosaccharides, sucrose and oligosaccharide B_1 and B_2, while all the oligosaccharide A was adsorbed to the column. The disaccharides adsorbed to the column were eluted with 15 l of 7.5 % ethyl alcohol. Oligosaccharide A was then eluted with 8 l of 12.5 % ethyl alcohol. This fraction was evaporated *in vacuo*, lyophilized and dried *in vacuo* at 50°C over P_2O_5. In this way 1.66 g of chromatographically pure oligosaccharide A was obtained (when 1 mg of the preparation was chromatographed it formed only one spot, which had the same mobility as oligosaccharide A).

The preparation did not reduce Somogyi's copper reagent. During total acid hydrolysis (boiling with 1 N HCl for 15 min) a mixture of glucose and fructose was obtained. With the aid of quantitative paper chromatography the mixture was found to contain two parts glucose and one part fructose. By cryoscopy (in water) the molecular weight of oligosaccharide A was determined at 470 (calculated for a trisaccharide 504.4). The sugar is therefore a non-reducing trisaccharide, composed of one fructose and two glucose molecules.

Raybin's diazouracil test was positive for oligosaccharide A, which demonstrates that fructose and one of the glucose molecules are joined by a sucrose link. This was later supported by the observation of a non-reducing, fructose-containing sugar, with the same mobility as sucrose, as intermediate product during the hydrolysis of oligosaccharide A by intestinal invertase.

Since the fructofuranoside link of sucrose is very easily split by acids, it was thought possible to split this link by mild acid hydrolysis while preserving the other link of the trisaccharide. When the trisaccharide was boiled with 0.05 N HCl for 15 min only fructose and a reducing disaccharide, which did not contain fructose, and which had the same chromatographic mobility as maltose, were found. 500 mg of oligosaccharide A were partially hydrolyzed by 0.05 N HCl and applied to a 3.5 × 20 cm carbon-celite column. The fructose was eluted with 2 l of 2.5 % ethyl alcohol and discarded. The disaccharide was eluted with 2 l of 7.5 % ethyl alcohol, evaporated *in vacuo* and lyophilized. The yield was 193 mg of chromatographically pure sugar.

This sugar was identified as maltose. It had the same chromatographic mobility as maltose, $[\alpha]_D^{20}$ + 130.0° (5 % in water) after slight downwards mutarotation (maltose $[\alpha]_D^{20}$ + 130.4° [17]). It gave a phenylosazone which (crystallized from ethyl alcohol) had the same crystal form as maltosazone. Acetylation with sodium acetate as catalyst yielded a β-octaacetate with m.p. 156—159°C (first crystallization from ethyl alcohol) maltose α-octaacetate 157—159°, mixed m.p. 156—158°).

Oligosaccharide A is therefore α-D-glucopyranosyl (1→ 4) α-D-glucopyranosyl (1→ 2) β-D-fructofuranoside. A sugar with this structure has earlier ben isolated from the oligosaccharides produced from sucrose by honey invertase [6]. The properties of our preparation agreed well with those reported for this trisaccharide. $[\alpha]_D^{20}$ + 122.1° (2.7 % in water) (reported $[\alpha]_D^{25}$ + 121.8°) [6] Acetylation with pyridine as catalyst [6,21] yielded a hendecaacetate with $[\alpha]_D^{20}$ + 83° (amorphous, 1.18 % in $CHCl_3$) (reported $[\alpha]_D^{25}$ + 86.0°) [6]. A suitable name for α-D-glucopyranosyl (1→ 4) α-D-glucopyranosyl (1→ 2) β-D-fructofuranoside should be *maltosucrose*.

Enzymatic hydrolysis of oligosaccharide A. In a 0.1388 M (7 %) solution of oligosaccharide A (maltosucrose), containing 0.05 M maleate buffer pH 6.5 and 600 units of purified intestinal invertase per ml, the oligosaccharide was rapidly hydrolyzed. After 30 min at 37°C, glucose, fructose and one intermediate disaccharide with the same chromatographic mobility as sucrose, were formed. The disaccharide was non-reducing and contained fructose, which supports the hypothesis that it is sucrose, formed by partial hydrolysis of oligosaccharide A.

A faint spot with the same chromatographic mobility as oligosaccharide C was also observed after 30 min. This supports the belief that oligosaccharide C is formed by transglycosylation to oligosaccharide A.

After 5 h at 37°C, only glucose and fructose were found on the paper chromatogram. The hydrolysis of oligosaccharide A therefore goes on until completed.

The *rate* of hydrolysis of oligosaccharide A in 0.1388 M solution was studied with more dilute enzyme solutions. The amount of reducing sugars produced from oligosaccharide A was 0.24 times the amount produced from sucrose during the same conditions. Calculated as the number of glycosyl linkages hydrolyzed per time unit, the rate for hydrolysis of oligosaccharide A is 0.48 times the rate for sucrose hydrolysis when calculated as hydrolysis to glucose and sucrose, or 0.32 times when calculated as complete hydrolysis into glucose and fructose.

Transglycosylation to free hexoses. The reaction mixture contained 30 % sucrose, ^{14}C-labelled fructose or glucose (about 1 mg/ml) which gave 1 250 000 cpm/ml with the counter used, 0.05 M maleate buffer pH 6.5 and 50 units/ml of purified intestinal invertase. After different times of reaction at 37°C, 5 μl samples were applied to a paper chromatogram. Each spot thus contained 6 250 cpm of ^{14}C-labelled sugar.

As is seen in Figs. 2—3 fructose and glucose are incorporated into oligosaccharides B_1 and B_2, respectively. This reaction is very rapid during the first hour, but then proceeds much slower since the ^{14}C-labelled monohexoses

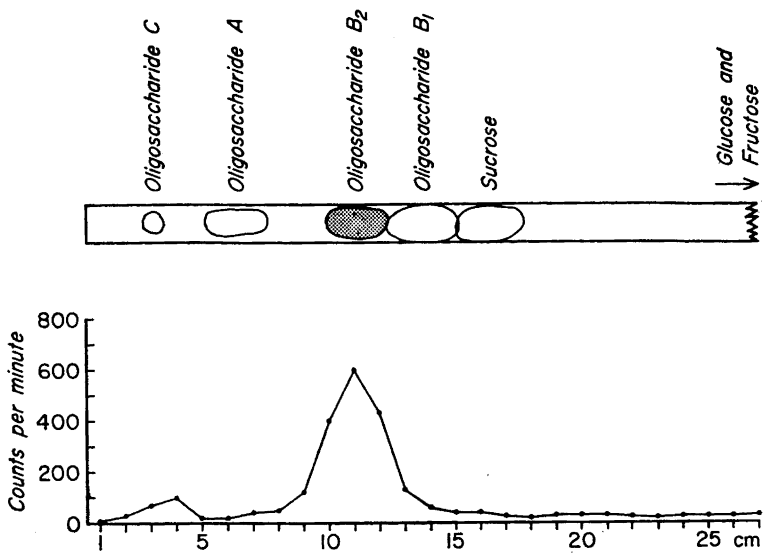

Fig. 2. Transglycosylation by intestinal invertase with ^{14}C-glucose as receptor. Incubated at 37°C for 23 h. For experimental conditions, see text. Glucose is incorporated into oligosaccharide B_2. The spot applied to the chromatogram contained 6 250 cpm of ^{14}C-labeled sugar. 25 % of the activity is localised in the oligosaccharide B_2 spot.

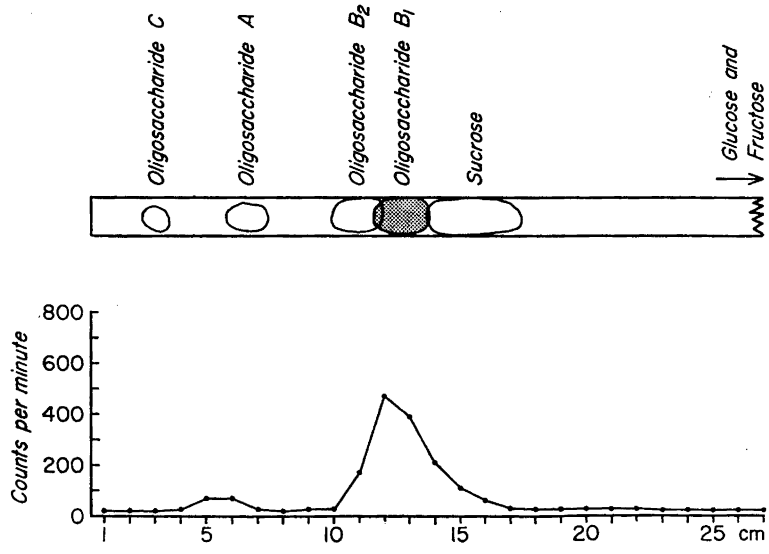

Fig. 3. Transglycosylation by intestinal invertase with ^{14}C-fructose as receptor. Incubated at 37°C for 5 h. For experimental conditions, see text. Fructose is incorporated into oligosaccharide B_1. The spot applied to the chromatogram contained 6 250 cpm of ^{14}C-labeled sugar. 20 % of the activity is localised in the oligosaccharide B_1 spot.

are diluted with inactive hexoses produced by hydrolysis. In both cases a very small peak of activity is also found, with chromatographic mobility intermediate between oligosaccharides A and C. Since no sugar spot could be detected in this place, these peaks must be caused by sugars which are formed only in very small amounts.

The incorporation of fructose and glucose into oligosaccharides B_1 and B_2, respectively, is in accordance with the fact that oligosaccharide B_1 contains fructose while oligosaccharide B_2 does not (see above), since intestinal invertase transfers *glucose*. The results show that oligosaccharides B_1 and B_2 are formed by transfer of glucose to free fructose and glucose respectively.

No resynthesis of sucrose by transglycosylation could be demonstrated. Resynthesis of sucrose (with glucose as receptor) has been observed with mold invertase, but could not be demonstrated with yeast invertase [3].

The Synthesis of 1-Phenyl-3-methyl-4-acyl-pyrazolones-5

BROR SKYTTE JENSEN

Danish Atomic Energy Commission, RISØ, Denmark

A new synthesis of 4-acyl-1-phenyl-3-methyl-pyrazolones-5 is presented. Condensations of acid chlorides or anhydrides with 1-phenyl-3-methyl-pyrazolone-5 in dioxane, catalyzed by suspended calcium hydroxide, have been found to produce the 4-acylated derivatives directly and in good yields.

The following new compounds have been prepared: 4-propionyl-, 4-butyryl-, 4-trifluoroacetyl-, 4-chloroacetyl,- 4-ethoxycarbonyl-, 4-*p*-bromobenzoyl-, 4-*p*-nitrobenzoyl-1-phenyl-3- methyl-pyrazolone-5 and 4-benzoyl-1-*p*-nitrophenyl-3-methyl-pyrazolone-5.

The compounds thus prepared are promising chelating agents for the extraction of metal ions.

During a search for new chelating agents for the extraction of metal ions it was found [1] that 1-phenyl-3-methyl-4-acetyl-pyrazolone-5 possessed valuable properties as such. Hence the syntheses of other 4-acyl substituted pyrazolones were planned for an investigation of their properties.

Previously the 4-acetyl-, 4-benzoyl- and 4-oxalyl-1-phenyl-3-methyl-pyrazolones [2–4] have been synthetisized by conventional Claisen condensations of esters with the pyrazolone, the reaction being catalysed by the sodium salt of the acid or sodium ethoxide. The yield was not reported for the acetyl derivative, it was low for the benzoyl derivative and was exellent for the oxalyl derivative.

A new method of synthesis of these compounds has been evaluated. Recognizing the phenolic character of the rather acid 1-phenyl-3-methyl-pyrazolone-5 a Fries rearrangement of the 5—O acylated derivative to the 4—C acylated derivative by anhydrous zink chloride was tried. The 5—O acylated pyrazolones were easily prepared by a Schotten-Baumann acylation reaction. In fact the expected product was obtained by the reaction, however, accompanied by large amounts of coloured by-products. Further experiments showed that a suspension of calcium hydroxide in dioxane, with a small amount of water added, served equally well or better as a catalyst for the acyl migration from position 5 to position 4. Finally it was found that a direct one step synthesis was effected by treating a solution of 1-phenyl-3-methyl-pyrazolone-5 in dioxane containing suspended calcium hydroxide as a catalyst

with an acid chloride or anhydride. A rapid reaction led directly to the calcium complex of the 4-acylpyrazolone which is stable under the alkaline conditions, and which is expected to protect the wanted derivative from further reactions.

This method was successfully used to prepare the acetyl-, propionyl-, butyryl-, valeryl-, chloroacetyl-, benzoyl-, *p*-bromobenzoyl-, *p*-nitrobenzoyl- and ethoxycarbonyl derivatives of 1-phenyl-3-methyl-pyrazolone-5 and to prepare the benzoyl derivative of 1-*p*-nitrophenyl-3-methyl-pyrazolone-5. It failed to give a product capable of metal extraction with pivalyl chloride. An oily product was isolated which was not further characterized.

When an attempt was made to prepare the 5-trifluoroacetate of the pyrazolone by reacting trifluoroacetic anhydride with the pyrazolone in dry pyridine, a vigorous reaction led directly to the 4-trifluoroacetyl-pyrazolone. It was not tried to prepare this compound by the present method.

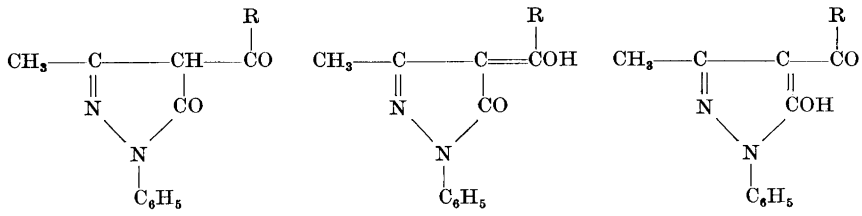

Fig. 1.

The 4-acyl-pyrazolones are good crystallizing compounds often obtainable both in the keto form (Fig. 1 a) by recrystallization from polar solvents as alcohol-water or dioxane-water mixtures, and in the enol form (Fig. 1 b, c) by recrystallization from nonpolar solvents as ligroin, chloroform *etc.* The enol forms are yellowish coloured solids, whereas the keto forms are colourless. Michaelis and Engelhardt also reported the isolation of both the keto and enol forms of 1-phenyl-3-methyl-4-benzoyl-pyrazolone-5.

The Schotten-Baumann 5—O acylation was found to be endothermic indicating a large heat absorption in the enolization of the 5-keto group. This indicates that in the unsubstituted pyrazolone, the keto form is much more stable than the enol form and that the resonance energy of the pyrazole nucleus is small. The enolization of the 4-acylated pyrazolones is believed to occur in the side chain. In this way energy is gained due to the extended conjugation which arises (Fig. 1 b). If the 5-keto group enolizes, the gain in energy will be smaller as the system becomes cross-conjugated (Fig. 1 c). This is because the pyrazole nucleus as indicated above is best represented as a cyclic unsaturated hydrazone.

The acid strength of the 4-acyl-pyrazolones is of the same magnitude as that of carboxylic acids, *i.e.* their pK values vary from 3—5. Their molecular-weights were obtained by titration in water-alcohol mixtures with phenolphtalein as indicator [5].

EXPERIMENTAL

The procedure for the preparation of the different compounds is the same. One typical synthesis is described in detail. For the other compounds prepared, only the solvent for recrystallization is noted together with the constants of the compounds.

1-Phenyl-3-methyl-4-benzoyl-pyrazolone-5. 15 g of 1-phenyl-3-methyl-pyrazolone were placed in a flask equipped with a stirrer, separatory funnel and a reflux condenser and dissolved in 60–80 ml dioxane (Merck reagent grade) by application of heat. Twelve g of calcium hydroxide were added, and 9.9 ml of benzoylchloride were added dropwise within 1 min. The reaction mixture became a thick paste and the temperature increased during the first few minutes. The mixture was heated to reflux for 30 min. The calcium complex in the flask was decomposed by pouring the mixture into dilute hydrochloric acid (200 ml, 2 N) which caused cream coloured crystals to separate. The crystals were collected on a Büchner funnel. They were recrystallized from methanol-water slightly acidified to destroy any undecomposed calcium-complex. Yield of pure product 70 %. m. p. keto 122°C, enol 92°C. Literature [3] m. p. 120°C.

1-Phenyl-3-methyl-4-acetyl-pyrazolone-5. Recryst. MeOH–H_2O. Yield 56 %, m. p. keto 58°C, Lit. 58°C. $C_{12}H_{12}N_2O_2$ (216.2), found 218.

1-Phenyl-3-methyl-4-propionyl-pyrazolone-5. Recryst. MeOH–H_2O. Yield 50 %, m. p. keto 62°C. $C_{13}H_{14}N_2O_2$ (230.3), found 236. (Found: C 67.80; H 6.14. Calc.: C 67.7; H 6.14.)

1-Phenyl-3-methyl-4-butyryl-pyrazolone-5. Recryst. MeOH–H_2O. Yield 57 %, m. p. keto 80°C. (Found: C 68.75; H 6.58. Calc.: C 68.8; H 6.60.) $C_{14}H_{16}N_2O_2$ (244.3), found 245.

1-Phenyl-3-methyl-4-chloroacetyl-pyrazolone-5. Recryst. MeOH–H_2O. Yield 73 %, m. p. keto 88°C, enol 140°C. $C_{12}H_{11}N_2O_2Cl$, H_2O (268.7), found 267. (Found: C 53.75; H 5.01. Calc.: C 53.8; H 4.87.)

1-Phenyl-3-methyl-4-ethoxycarbonyl-pyrazolone-5. Recryst. MeOH–H_2O. Yield 46 %, m. p. keto 122°C, enol 72°C. $C_{13}H_{14}N_2O_3$, H_2O (245.3), found 248. (Found: C 63.08; H 5.92. Calc.: C 62.9; H 6.48.)

1-Phenyl-3-methyl-4-p-bromobenzoyl-pyrazolone-5. Recryst. Dioxane-water. Yield 82 %, m. p. keto 167 C, enol 122°C. $C_{17}H_{13}N_2O_2Br$ (357.3), found 357. (Found: C 57.03; H 3.57. Calc.: C 57.1; H 3.67.)

1-Phenyl-3-methyl-4-p-nitrobenzoyl-pyrazolone-5. Recryst. Dioxane-water. Yield 79 %, m. p. keto 200°C, enol 192°C. $C_{17}H_{13}N_3O_4$ (323.3), found 324. (Found: C 63.37; H 4.49. Calc.: C 63.1; H 4.05.)

1-p-Nitrophenyl-3-methyl-4-benzoyl-pyrazolone-5. Recryst. Dioxane-water. Yield 50 %, m. p. keto 174°C, enol 224°C. $C_{17}H_{13}N_3O_4$ (323.3), found 323. (Found: C 63.17; H 4.13. Calc.: C 63.1; H 4.05.)

1-Phenyl-3-methyl-4-trifluoroacetyl-pyrazolone-5. To a solution of 8.5 g 1-phenyl-3-methyl-pyrazolone in 50 ml anhydrous pyridine 10 g trifluoroacetic anhydride were added dropwise. Heat was evolved and the flask was cooled under tap water. The reaction mixture became red brown. After one hour at room temperature the contents of the flask were poured into 200 ml of water whereby no precipitate was formed. After acidification the compound crystallized. Recrystallization from ethanol-water mixture gave 78 % yield of pure product, m. p. keto 144°C, enol 132°C. $C_{12}H_9N_2O_2F_3$ (273.3), found 273. (Found: C 53.27; H 3.47. Calc.: C 53.3; H 3.36.)

All melting points were measured on a Kofler hot bench. Microanalyses have been performed by Mr. P. Hansen at the Chemical Laboratory of the University of Copenhagen, and the syntheses by Mr. O. Jørgensen at the Chemical Laboratory of the Danish Atomic Energy Research Establishment, Risø.

The Influence of Nitrocatechol and Sulphate Ions on Ox Liver Arylsulphatase A at 40° C

S. O. ANDERSEN*

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

Experiments are reported which show that when ox liver arylsulphatase A hydrolyses nitrocatechol sulphate at pH 5.0 and 40°C there is a distinct fall in the reaction velocity during the first 10–15 min. Later the reaction velocity increases and, eventually, it reaches a constant value. It is shown that this increase in velocity is due to the liberated nitrocatechol, whereas the liberated sulphate ions tend to inhibit the reaction, if they are not precipitated. A reaction scheme is proposed and an expression is derived which can describe the reaction progress under the condition of the experiments.

In 1953 Roy[1] observed that the kinetics of the enzymatic hydrolysis of the potassium salt of nitrocatechol sulphate (2-hydroxy-5-nitrophenyl sulphate) by partially purified preparations of ox liver arylsulphatase A are of an anomalous type. Since then the kinetics of this system have been investigated by several groups,[2-6] but the problem cannot be considered as solved.

Both Roy [2] and Baum, Dodgson and Spencer [4] found that when the reaction takes place at 37°C and pH 5.0, the reaction progress can be divided in three stages. In stage I and stage III the velocity is rather high, but is low in stage II; the duration of the stages depends on substrate and enzyme concentrations. In contrast to this the present author has reported some experiments performed at pH 5.0 and 20°C, in which only stage I and II were found.[6] The cause of this discrepancy was not found. Experiments have now been performed at 40°C in an attempt to clarify this problem, and they are reported here together with a proposed mechanism, which explains the kinetics found at this temperature.

* Present address: Universitetets Zoofysiologiske Laboratorium B, Copenhagen, Denmark.

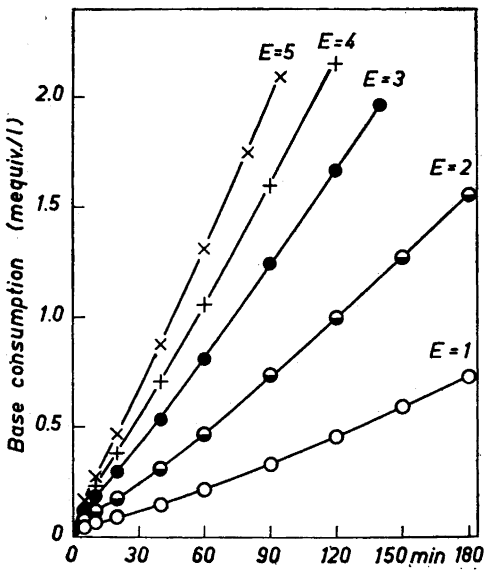

Fig. 1. Reaction progress of the enzymatic hydrolysis of nitrocatechol sulphate at pH 5.0 and 40°C. Substrate concentration was kept constant at 0.003 M in 30 ml 0.05 M $SrCl_2$. The relative enzyme concentrations are indicated on the figure.

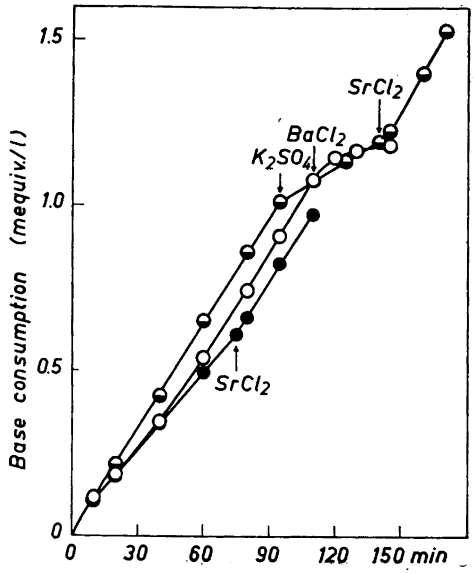

Fig. 2. Reaction progress of the enzymatic hydrolysis of nitrocatechol sulphate at pH 5.0 and 40°C. Substrate concentration was kept constant at 0.003 M in 30 ml 0.10 M KCl. ◒—◒—◒: 0.002 M nitrocatechol added before start of experiment, 1.0 ml M K_2SO_4 added at 95 min, 3 ml 0.5 M $SrCl_2$ added at 140 min. ●—●—●: 0.002 M K_2SO_4 added before start of experiment, 3 ml 0.5 M $SrCl_2$ added at 75 min. O—O—O: no addition before experiment, 20 mg $BaCl_2$ added at 110 min.

EXPERIMENTAL

The enzyme and the nitrocatechol sulphate were prepared as described earlier [6]. Nitrocatechol was prepared from its sulphate ester by acid hydrolysis.

The enzymatic hydrolysis of the sulphate ester was followed by continued automatic titration in a pH-stat, as already described [6]. The substrate concentration was kept constant during the experiments and the liberated sulphate was precipitated as $SrSO_4$ instead of as $BaSO_4$, since it has been found that excess Ba++ has a pronounced effect on the enzyme activity [7].

The experiments were performed at 40.0°C and at pH 5.0 in a medium, which consisted of 0.05 M solution of $SrCl_2$. A small amount of $SrSO_4$ was added to prevent supersaturation of this substance during the experiments. When the influence of sulphate ions was investigated 0.10 M KCl was used instead of 0.05 M $SrCl_2$.

RESULTS

The experiments in Fig. 1 were all performed at the same substrate concentration and at different enzyme concentrations. In contrast to the experiments at 20°C the three stages described by Roy and Dodgson are clearly seen

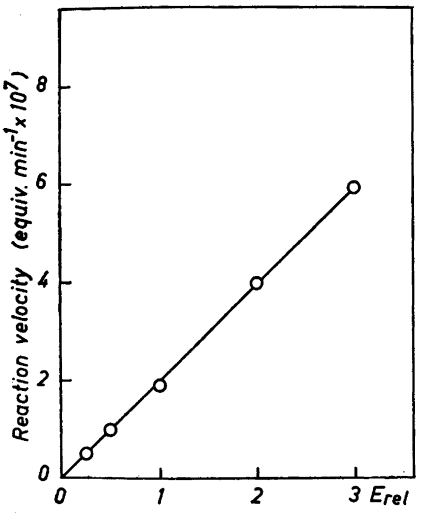

Fig. 3. Reaction velocity in stage III *versus* the relative enzyme concentration. Experiments with added nitrocatechol (0.002 M) and constant substrate concentration (0.003 M).

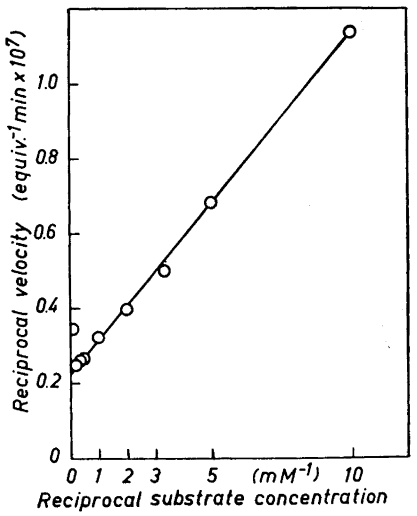

Fig. 4. Reciprocal reaction velocity in stage III *versus* reciprocal substrate concentration. Experiments with added nitrocatechol (0.002 M).

at 40°C. As the substrate concentration was kept constant during the experiments and the sulphate formed during the reaction was precipitated, the only factor known to change during the experiments is the liberated nitrocatechol. So nitrocatechol was added to the reaction mixture, before an experiment was started, in order to see, if it would have any influence on the reaction progress. The result was that stage II disappeared completely, so that stage I went directly into stage III. (◒—◒—◒ of Fig. 2). It made no difference to the reaction progress whether the enzyme was incubated for some hours with nitrocatechol, or it was added just at the beginning of the experiment.

Experiments with different enzyme concentrations and with 0.002 M nitrocatechol added were then performed and the reaction velocity in stage III determined. This velocity is plotted against the enzyme concentration in Fig. 3, and it is seen that under these circumstances the velocity is proportional to the enzyme concentration. Experiments with the same enzyme concentration but different substrate concentrations and added nitrocatechol were also performed. In Fig. 4 the reciprocal of the velocity in stage III is plotted against the reciprocal substrate concentration, according to Lineweaver and Burk [8]. This shows that below a substrate concentration of 0.005 M the kinetics of the reaction are in accordance with the Henry-Michaelis scheme with K_m equal to 0.0004 M. Inhibition occurred at the highest substrate concentration. The influence of sulphate ions can be seen in Fig. 2. 0.002 M nitrocatechol was added to one of the experiments and 0.002 M K_2SO_4 to another. The

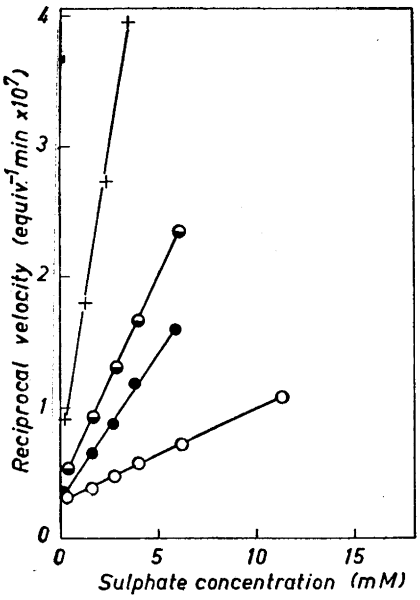

Fig. 5. Effect of sulphate ions on the reaction velocity in stage III in experiments with added nitrocatechol (0.002 M) and constant substrate concentration. O—O—O: 3 mM nitrocatechol sulphate, ●—●—●: 1 mM nitrocatechol sulphate, ◒—◒—◒: 0.5 mM nitrocatechol sulphate, +—+—+: 0.3 mM nitrocatechol sulphate.

reaction progress was followed for some time, whereafter it was tried, if addition of K_2SO_4, $SrCl_2$ or $BaCl_2$ would have any effects. It is seen that sulphate ions inhibit the reaction and that strontium ions can release the enzyme from this inhibition. Barium ions inhibit the reaction too. To investigate the influence of sulphate ions experiments were performed with excess of nitrocatechol and addition of varying amounts of K_2SO_4. The rate of the reaction was determined, and the concentration of SO_4^{--} was calculated as the sum of the sulphate added and the sulphate liberated during the reaction. The reciprocal velocity is plotted against the sulphate concentration for four different substrate concentrations in Fig. 5, which shows that the inhibition is of the competitive type.

REACTION MECHANISM

These experiments show that the kinetics of the enzyme at 40°C follow a simple scheme, when the reaction has reached a steady state, but that this is only the case when there is excess of nitrocatechol present, and when the liberated sulphate ions are removed. It has been shown previously that the kinetics at 20°C, where no reactivation was found, could be explained by supposing the following scheme:

$$A + X_1 \rightleftharpoons X_2 \qquad (\pm 1)$$
$$X_2 \rightarrow X_1 + P_1 + P_2 \qquad (+2)$$
$$X_2 \rightleftharpoons X_3 \qquad (\pm 3)$$

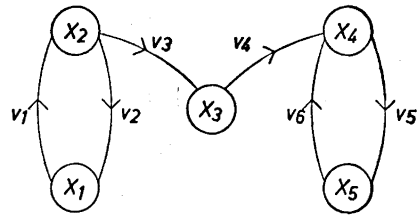

Fig. 6.

where X_1, X_2 and X_3 are different forms of the enzyme. A is the substrate, and P_1 and P_2 are the reaction products, nitrocatechol and sulphate ion respectively. The formation of X_3 is supposed to be rather slow.

To explain the reactivation found at 40°C the following reactions must be added to the scheme:

$$P_1 + X_3 \rightleftharpoons X_4 \qquad (\pm 4)$$
$$X_4 \rightarrow X_5 + P_1 + P_2 \qquad (+5)$$
$$A + X_5 \rightleftharpoons X_4 \qquad (\pm 6)$$

Nitrocatechol reacts in some way with the inactive form of the enzyme, X_3, and converts it to a new active form, X_4. The whole scheme is essentially two Henry-Michaelis schemes connected through the X_3-form. In the manner of Christiansen [9,10] it can be expressed as in Fig. 6.

If we make the simplifying assumption that reaction (3) only goes from the left to the right, so that there is no reverse reaction, then it is possible to derive from this scheme an expression for the reaction progress, which can be tested on the experiments. This assumption is not quite unjustified, as the equilibrium of the reaction must be far to the right. This follows from the results of experiments with very low enzyme concentration, where the velocity in stage II is less than a tenth of the initial velocity.

It is further assumed that the formation of X_3 is rather slow in comparison with all the other reactions in the scheme, so we have:

$$x_1 = (K_1/a)x_2 \qquad (7)$$
$$x_5 = (K_2/a)x_4 \qquad (8)$$
$$-\mathrm{d}(x_1 + x_2)/\mathrm{d}t = k_3 x_2 \qquad (9)$$

x_i is used for the concentration of the enzyme form X_i, and a and p_1 for the concentration of A and P_1, k_i is the velocity constant of reaction (i) and K_1 and K_2 are the Michaelis constants, $(k_{-1} + k_2)/k_1$ and $(k_{-6} + k_5)/k_6$, of the first and second cycle in the reaction scheme.

Further we have

$$E = x_1 + x_2 + x_3 + x_4 + x_5 \qquad (10)$$
$$x_3 p_1 = K_3 x_4 \qquad (11)$$

and

$$\mathrm{d}\xi/\mathrm{d}t = k_2 x_2 + k_5 x_4 \qquad (12)$$

where ξ is the amount of substrate split at time t. When no nitrocatechol has been added to the reaction mixture ξ will be equal to p_1. From (7), (8), (10), and (11) we get

$$E = (K_1/a + 1)x_2 + (K_3/\xi + K_2/a + 1)x_4 \tag{13}$$

and from (7) and (9) we get

$$x_2 = \frac{E}{(K_1/a + 1)} e^{-t/(K_1/a + 1)}$$

or setting $1/(K_1/a + 1) = \lambda$

$$x_2 = E\lambda e^{-\lambda t} \tag{14}$$

From (13) and (14) we can now get an expression for x_4

$$x_4 = E(1-e^{-\lambda t})/(K_3/\xi + K_2/a + 1) \tag{15}$$

Substitution of the values of x_2 and x_4 in (12) gives

$$d\xi/dt = Ek_2\lambda e^{-\lambda t} + Ek_5(1-e^{-\lambda t})/(K_3/\xi + K_2/a + 1) \tag{16}$$

This equation can be rewritten as

$$\left(\frac{K_3}{\xi} + \frac{K_2}{a} + 1\right) d\xi = \frac{Ek_2K_3\lambda e^{-\lambda t}}{\xi} dt + Ek_2\left(\frac{K_2}{a} + 1\right)\lambda e^{-\lambda t}dt + Ek_5(1-e^{-\lambda t})dt \tag{17}$$

This equation can be integrated directly apart from the term

$$Ek_2K_3\lambda(1/\xi)e^{-\lambda t}dt \tag{18}$$

but if we consider that this term will be insignificant in the later parts of the reaction when we no longer have small values of ξ and t, then we can transform it to an integrable form. We have for the first part of the reaction, before considerable amounts of x_4 have been formed:

$$\begin{aligned} d\xi/dt &= k_2x_2 = k_2E\lambda e^{-\lambda t} \\ \xi &= k_2E(1-e^{-\lambda t}) \end{aligned} \tag{19}$$

Substitution of ξ in (18) transforms it to

$$\frac{K_3\lambda e^{-\lambda t}}{1-e^{-\lambda t}} dt, \text{ or in integrated form } K_3\ln(1-e^{-\lambda t}) \tag{20}$$

Eqn. (17) can now be integrated:

$$K_3\ln\frac{\xi}{\xi_0} + \left(\frac{K_2}{a} + 1\right)\xi = K_3\ln\frac{1-e^{-\lambda t}}{1-e^{-\lambda t_0}} + E\left(\left(\frac{K_2}{a} + 1\right)k_2 - \frac{k_5}{\lambda}\right)(1-e^{-\lambda t}) + Ek_5t \tag{21}$$

As ξ_0 and t_0, the values of ξ and t at zero time, both are zero, ln ξ_0 and $\ln(1-e^{-\lambda t_0})$ become $-\infty$, but their difference has a finite value. From (19) we get

$$\begin{aligned}(1-e^{-\lambda t})/\xi &= k_2E \\ \ln(1-e^{-\lambda t_0}) - \ln\ \xi_0 &= \ln\ (k_2E)\end{aligned} \qquad (22)$$

Eqn. (21) can now be written

$$t + A(1-e^{-\lambda t}) + B\ln(1-e^{-\lambda t}) = C\xi + B\ln\ \xi - D \qquad (23)$$

where $A = (K_2/a + 1)k_2/k_5 - (K_1/a + 1)$
$B = K_3/Ek_5$
$C = (K_2/a + 1)/Ek_5$
$D = \dfrac{K_3\ln(k_2E)}{k_5E}$

That this expression is in close agreement with the experiments is shown in Table 1. The values of A, B, C, D, and λ which were used in the calculations are given in Table 2.

Table 1. The table indicates the amount of substrate, ξ, hydrolysed at the time t for different enzyme concentrations (E). The experimental conditions are given in the text. t is in min and ξ in mequiv/l. Δ is the difference between corresponding values of the terms $t + A(1-10^{-\lambda t}) + B\log(1-10^{-\lambda t})$ and $C\xi + B\log\xi - D$. These terms have been calculated from the values of A, B, C, D, and λ given in Table 2.

Table 2. The values of the parameters A, B, C, D, and λ used to calculate the results in Table 1.

E_{rel}	A min	B min	C min/mM	D min	λ min^{-1}
1	8.6	40.7	194.0	54.2	0.12
2	3.4	22.6	100.8	23.0	0.12
3	4.0	15.8	63.8	13.8	0.12
4	3.6	11.5	51.5	9.0	0.12
5	3.8	9.36	42.5	7.1	0.12

A and λ are independent of the enzyme concentration, and B and C are inversely proportional to it as shown in Fig. 7. From Fig. 8 it can be seen that DE is linearly related to log E, which is in accordance with the derived expression.

DISCUSSION

The results presented in this paper show that when the reaction is performed at 40°C the reaction progress can be divided into three stages with different velocities in accordance with the results of Roy [2] and Baum, Dodgson and Spencer [4]. In contrast to these authors it is found that sulphate ions do not have any activating effect, but inhibit the enzyme at all concentrations investigated. This means that the activation from stage II to stage III is due only to the liberated nitrocatechol. Apart from this difference the scheme proposed

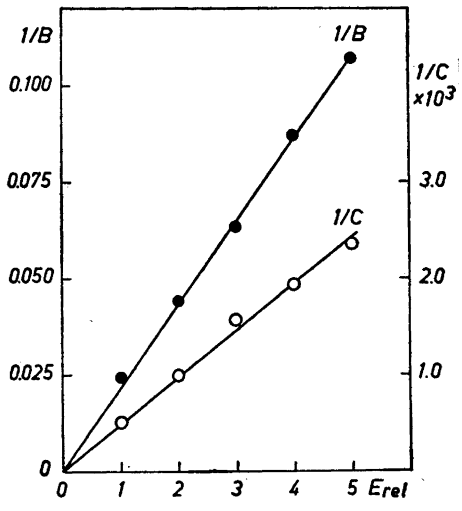

Fig. 7. Variation of the calculated values of 1/B and 1/C with the relative enzyme concentration.

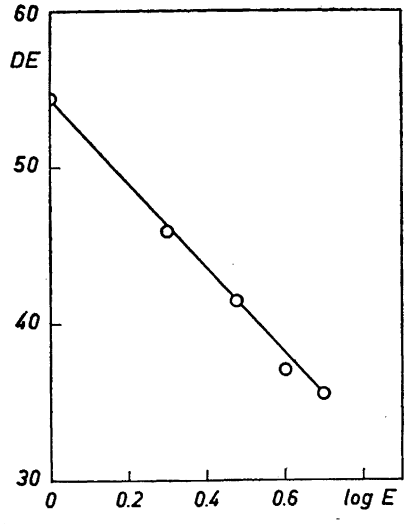

Fig. 8. Variation of the calculated value of DE with the logarithm of the relative enzyme concentration.

in this paper corresponds closely to the scheme proposed by Baum and Dodgson [5]. It is planned to investigate whether this difference could be due to acetate in the medium as used by the other groups, in contrast to chloride in this work.

The reaction scheme here proposed must only be regarded as tentative, though it is in accordance with the experiments. Minor variations in the reaction scheme are possible without the form of the final expression being effected. It is possible that reaction (3) should be $X_2 \rightleftharpoons X_3 + P_1 + P_2$, so that the inactive X_3-form of the enzyme does not contain substrate.
Then we should get further

$$X_3 + P_1 \rightleftharpoons X_4 \qquad (4a)$$
$$X_4 + A \rightleftharpoons X_5 \qquad (5a)$$
$$X_5 \rightarrow X_4 + P_1 + P_2 \qquad (6a)$$

This will give an expression for the reaction progress which will have the same form as (23), apart from the slight contribution to the reaction products from $X_2 \rightleftharpoons X_3 + P_1 + P_2$. But this contribution will be stoichiometrically equal to the enzyme concentration and far smaller than what can be measured.

The Kinetics of Crystal Growth in Barium Sulfate Precipitation

III. Mixed Surface Reaction and Diffusion Controlled Rate of Growth

ARNE E. NIELSEN

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

The chronometric integrals for precipitation processes where the crystal growth velocity is controlled simultaneously by fourth-order surface reaction and diffusion are calculated numerically and found to agree with the experiments.

The method reported constitutes a new experimental method for obtaining rate-constants and diffusion coefficients.

In a previous article [1] the chronometric integrals for the pure cases of diffusion or p-th order surface reaction rate control of crystal growth in precipitation processes were expressed in terms of known functions and tabulated (for $p = 1, 2, 3$ and 4), and the general differential equation between the degree of advancement α and time t was derived also for the case where both types of rate control were effective at once. This equation has previously [2] been solved in terms of known functions for $p = 1$ only.

In the following we restrict the treatment to cases where the solubility of the substance is so small that it can be neglected ($s/c_0 < 0.05$). The crystals are assumed spherical. Only in cases of very flat or long crystals this will give errors larger than 10–20 %. We may write the solution to the "pure cases" thus

1. Diffusional rate control:

$$t = K_D \int_0^\alpha \frac{\mathrm{d}\alpha}{\alpha^{1/3}(1-\alpha)} = K_D I_D(\alpha)$$

2. p-th order surface reaction:

$$t = K_p \int_0^\alpha \frac{\mathrm{d}\alpha}{\alpha^{2/3}(1-\alpha)^p} = K_p I_p(\alpha)$$

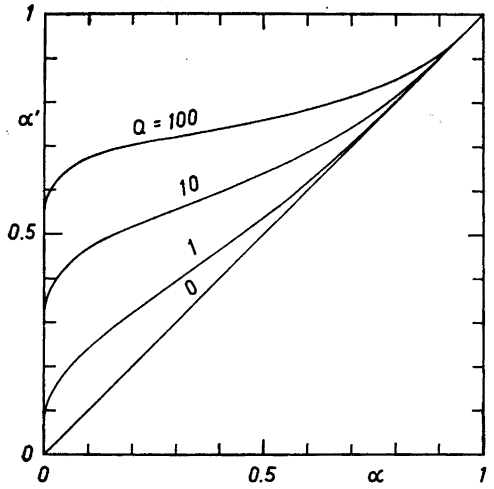

Fig. 1. The relation between the "effective" degree of advancement at the crystal surface α', and α, for different values of Q. The difference between α and α' is caused by the slowdown of the reaction by diffusion. Q is a measure of this influence; Q is a constant during the reaction.

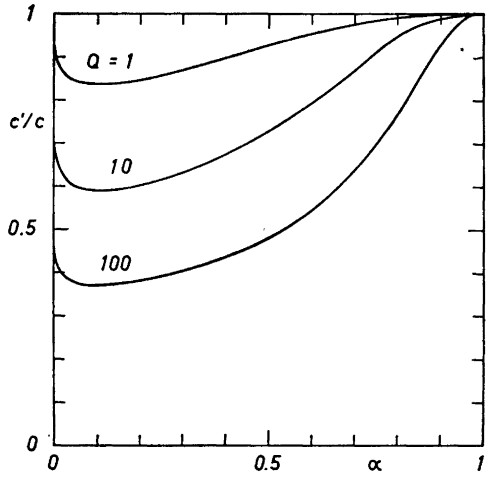

Fig. 2. The ratio between the concentration at the surface and in the bulk solution, when both diffusion and fourth-order surface reaction are rate determining.

where $K_D = r_1^2/3vDc_0$, $K_p = r_1/3vk_pc_0^p$, r_1 = particle radius when $\alpha = 1$, v = molar volume of precipitate, D = diffusion coefficient, c_0 = concentration when $t = 0$ (and $\alpha = 0$), k_p = p-th order surface reaction rate constant.

For $p = 1$ the solution to the "mixed case" is simply [2]

$$t = K_D I_D(\alpha) + K_1 I_1(\alpha)$$

For $p > 1$ the solution has not been found explicitely. In order to get a numerical solution we use the equation derived in the previous paper [1]

$$\frac{dr}{dt} = \frac{vD(c-c')}{r} = vk_p(c')^p$$

where c' is the concentration at the surface of the crystal. We define α' by $c' = c_0(1-\alpha')$ and derive

$$\alpha' - \alpha = (K_D/K_p)(1-\alpha')^p\alpha^{1/3}$$

The dimensionless quantity $Q \equiv K_D/K_p = r_1k_pc_0^{p-1}/D$ is constant during each single experiment (when the number of crystals is constant and they are all alike), and if we solve, for fixed p and Q, the equation

$$\alpha' - \alpha = Q(1-\alpha')^p\alpha^{1/3}$$

with respect to α' for a series of values of α, (see Figs. 1 and 2), we can calculate the following integrals

$$t = K_D \int_0^\alpha \frac{d\alpha}{\alpha^{1/3}(\alpha' - \alpha)} = K_p \int_0^\alpha \frac{d\alpha}{\alpha^{2/3}(1-\alpha')^p}$$

$$= K_D I_{DpQ}(\alpha) = K_p I_{pDQ}(\alpha)$$

The result of this procedure is given in Table 1 for $p = 4$ and for several values of Q. Since

$$I_{pDQ}/I_{DpQ} = K_D/K_p = Q = \text{a constant}$$

it is not necessary to tabulate both the integrals.

In order to compare experimental results with these integrals it is probably best to plot α as a function of log t on transparent paper and slide this over a plot of α as a function og log I_{pDQ} or I_{DpQ} (see Fig. 3).

If the kinetics is of the kind discussed here, one may find Q and for instance the value $t_{0.5}$ of t for $\alpha = 0.5$. This has been done for experiments on $BaSO_4$[1] and from the results Fig. 4 was drawn, to show a typical exemple of how Q varies with c_0.

In case of very exact measurements it may be necessary to use Q-values corresponding to curves not given in Fig. 3. For this purpose another method is suggested. The shape of the experimental curve may be expressed by the ratio

$$\Theta = t_{0.75}/t_{0.25}$$

From Fig. 5 the corresponding Q is found.

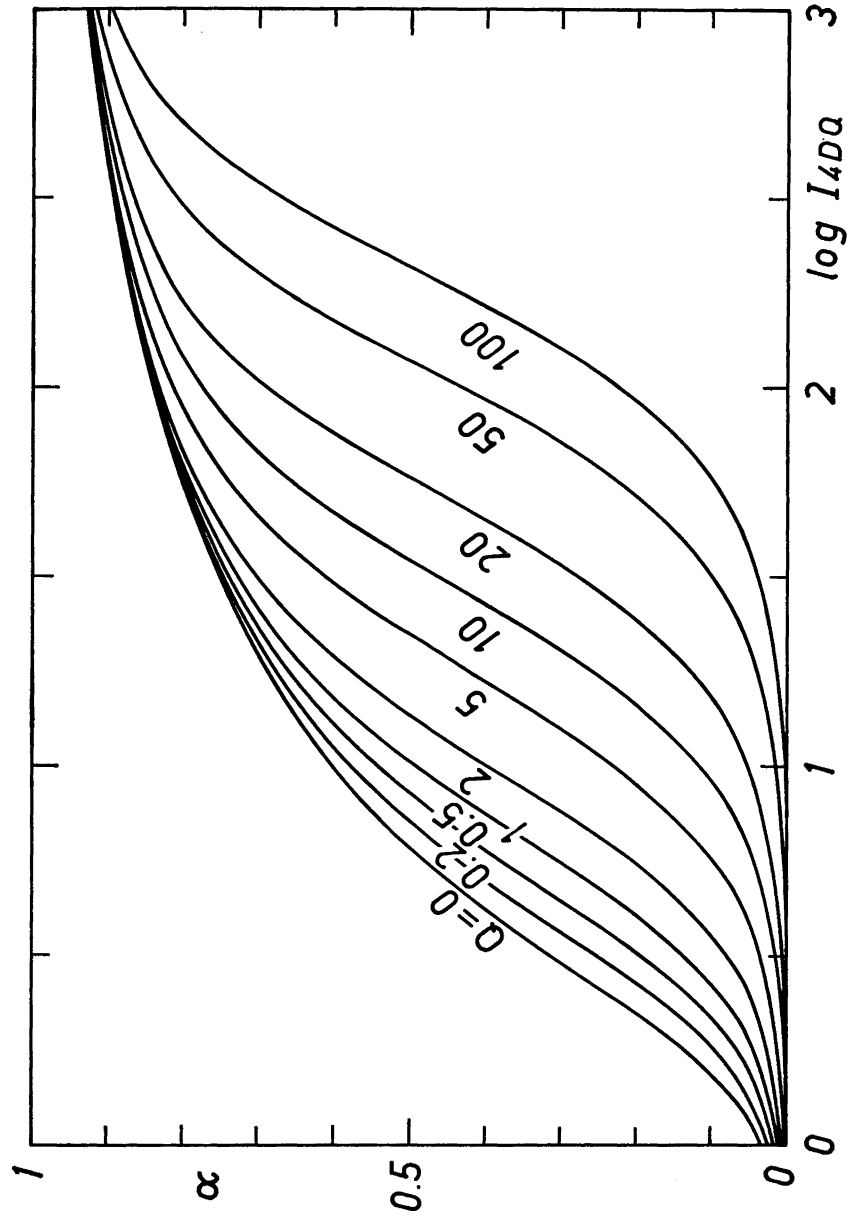

Fig. 3. A semi-logarithmic plot of α *versus* the chronomals I_{4DQ}. For check of kinetics and determination of Q: plot α *versus* log t on transparent paper and slide over this figure.

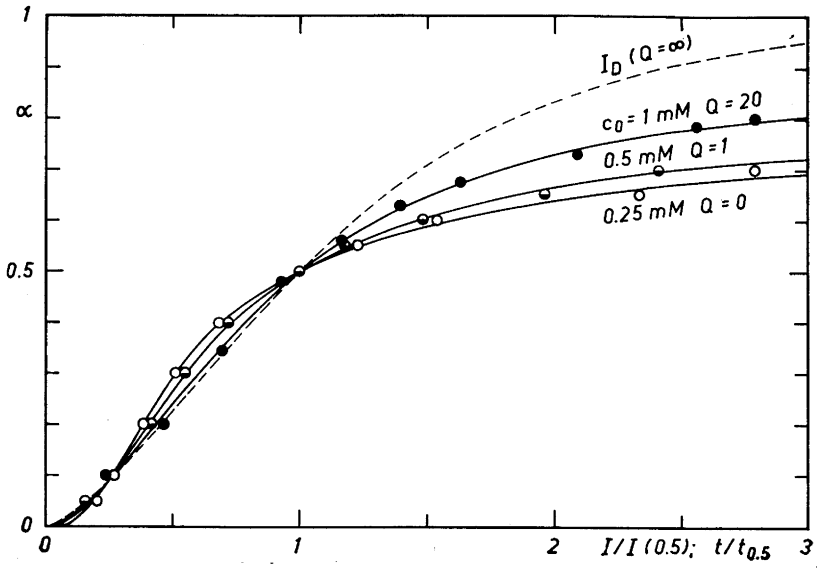

Fig. 4. Experimental values from $BaSO_4$-precipitations with different initial concentration c_0, and theoretical I_{4DQ}-curves. All t- and I-values are divided by the corresponding value at $\alpha = 0.5$ in order to make it easier to see the characteristic differences in shape of the curves with different values of Q. Large c_0 corresponds to large Q, *i. e.* diffusional slow-down is more important at high than at small c_0.

In Fig. 6 is shown how the concentration c' at the surface varies with time and how its deviation from c influences the kinetics.

If r_1 or N (the number of particles per unit volume) is known one may derive D and k_p from Q and $t_{0.5}$ by means of

$$\begin{aligned} K_p &= t_{0.5}/I_{pDQ}(0.5) \\ K_D &= t_{0.5}/I_{DpQ}(0.5) = QK_p \\ r_1 &= (3vc_0/4\pi N)^{1/3} \\ k_p &= r_1/3vc_0^pK_p = 1/(36\pi v^2N)^{1/3}c_0^{p-1/3}K_p \\ D &= r_1^2/3vc_0K_D = 1/(48\pi^2vN^2c_0)^{1/3}K_D \end{aligned}$$

$I_{pDQ}(0.5)$ may be found from Fig. 5 also for values of Q not given in Table 1.

In the previous paper D was found for $BaSO_4$ from the initial slope of a plot of I_D against t, and k_4 was found as the final slope ($0.70 < \alpha < 0.80$) of I_4 against t. In this way the diffusion coefficient of $BaSO_4$ at 25°C was found to be 3.0×10^{-6} cm^2/s.

If we plot α as a function of log t and determine Q and $t_{0.5}$ from Fig. 3 as described above, we get the values for D and k shown in Fig. 7. At 25°C, $D = 1.7 \times 10^{-5}$ cm^2/s.

The diffusion coefficient of $BaSO_4$ in aqueous solution has never been measured before (as far I know) because of the low solubility of this substance,

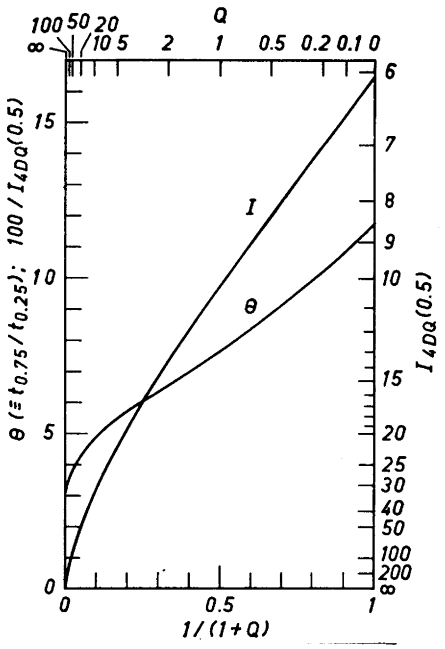

Fig. 5. Diagram for finding Q and I_{4DQ} (0.5) from the ratio $\Theta \equiv t_{0.75}/t_{0.25}$.

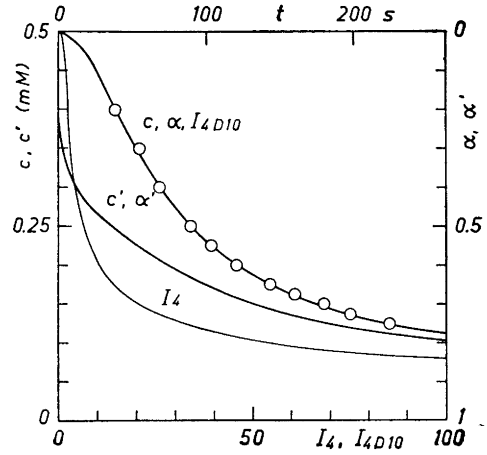

Fig. 6. The circles are experimental points and I_{4D10} is the corresponding theoretical curve. c' is the concentration at the surface, calculated for the actual experiment. I_4 is the hypothetic curve obtained if diffusion did not slow down the reaction (*i. e.* $D = \infty$), for the same value of k_4.

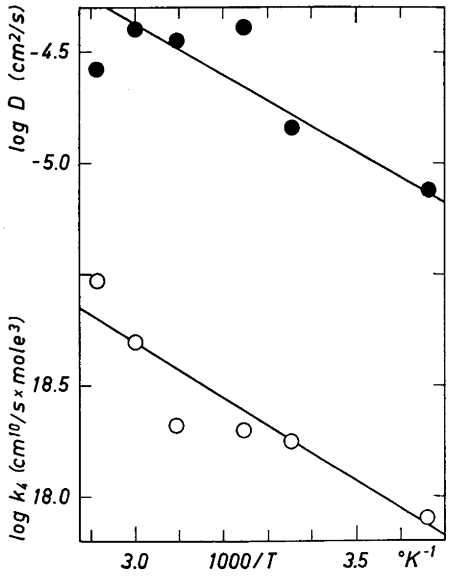

Fig. 7. The fourth-order rate constant of the crystal growth surface reaction and the diffusion coefficient plotted logarithmically as functions of the reciprocal temperature. The slopes give the heats (or energies) of activation, $-2.30\ R\mathrm{d}\log k_4/\mathrm{d}(1/T) = 5\,000$ cal/mole for each of the curves.

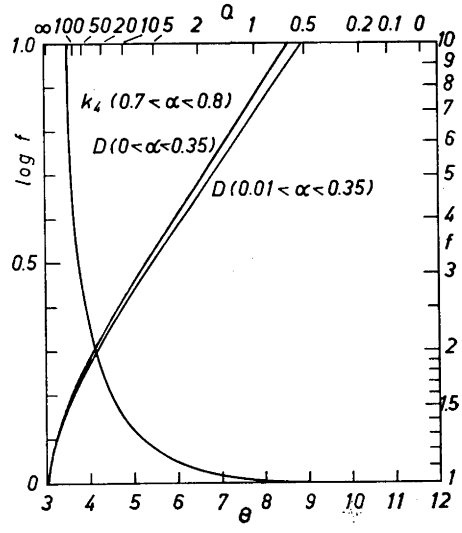

Fig. 8. The correction factors to be applied to the approximate values of D and k_4 obtained from the initial and final slopes on plots of t *versus* I_D and I_4, respectively. The two curves for D correspond to drawing the straight line through origo and to approximating the points around the point of inflexion (practically all of the points with $0.01 < a < 0.35$).

but it may be estimated rather accurately from the electric mobilities [3], which gives $D = 9.4 \times 10^{-6}$ cm^2/s. The value found by means of I_{pDQ} is seen to be better than the one obtained in the previous paper from I_D.

In Fig. 8 are given the correction factors to be applied to the (approximate) values determined by the method of the previous paper in order to get the correct ones. We observe that the correction factors are both equal to 2 for $Q = ca.$ 30, and when one of them is smaller than 2 the other one is larger.

The error introduced by treating the crystals geometrically as spheres is not serious compared with the uncertainty of the experiments reported. When the measuring technique has been improved it may be necessary to correct for this shape-error through solving the Laplace equation of diffusion in the space around the crystal.

Proton Magnetic Resonance of Thiophenes

III. Splittings of Side-chain Resonance Peaks

SALO GRONOWITZ and RAGNAR A. HOFFMAN

Institute of Chemistry and Institute of Physics, University of Uppsala, Uppsala, Sweden

Splittings of the aldehydic hydrogen resonance lines of the order of 1 c/s have been observed in certain thiophenealdehydes and oximes. This has been shown to be due to spin-spin coupling with the 5-hydrogen. No splittings have been observed when this position is blocked.

In connection with our work on the NMR-spectra of thiophenes [1,2], we have studied the splitting of side-chain hydrogens in methylthiophenes, thiophenealdehydes and thiophenealdoximes.

In the present paper we wish to communicate some of our results. These findings may provide a foundation for a discussion of some remarkable features in the NMR spectra of these compounds.

In an earlier communication [1] we discussed the NMR spectra of the ring hydrogens in several monosubstituted thiophenes. In this connection we observed the splittings ($\sim$ 1 c/s) of the resonance lines of the aldehydic hydrogens in 2- and 3-thiophenealdehyde.

These splittings could possibly be due to restricted rotation of the aldehyde group; conjugation between the aldehyde group and the thiophene ring giving rise to C—C double bond character [3] *. The aldehydic hydrogen might have different chemical shifts in the two possible rotational isomers thus giving rise to two hydrogen lines. The splittings then should be field as well as temperature dependent. Such chemical shifts due to hindered rotation have been observed, *e.g.* in amides and nitroso compounds [5].

Another possible explanation of the splittings is that they are caused by spin-spin coupling of the aldehyde proton to one or more of the ring protons. In 2-thiophenealdehyde the ring hydrogen spectrum was not well enough

* We obtained no splittings of the aldehyde resonance line in benzaldehyde or 1-naphthaldehyde, but this fact might be explained by the greater conjugation in the thiophene compounds as compared to the benzene analogues [4].

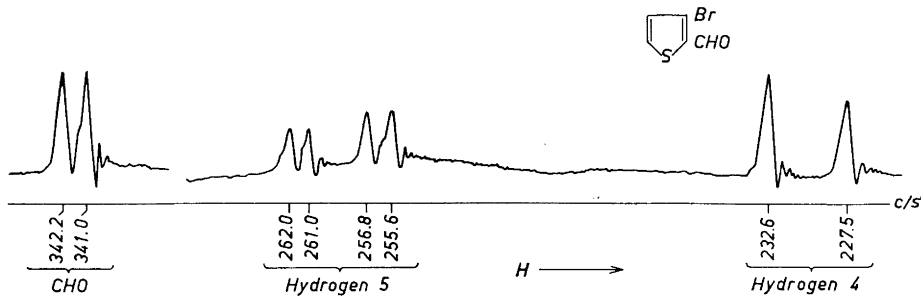

Fig. 1. NMR-spectrum of 3-bromo-2-thiophenealdehyde in *cyclo*hexane (internal reference) at 40 Mc/s.

resolved to make a definite choice between the two alternative explanations possible. However, some preliminary experiments indicated that the splittings were temperature independent. In disubstituted thiophenes the ring hydrogen spectra are simpler, and therefore such spin-spin splittings should be observed in the ring hydrogen resonance band as well.

This was the case in 3-bromo-2-thiophenealdehyde. The spectrum of this compound with *cyclo*hexane as the internal reference (Fig. 1) has the aldehydic hydrogen resonance at 342 c/s. This consists of a doublet with a splitting of 1.2 c/s. The two ring hydrogens give rise to a quartet and a doublet. The splittings in the quartet are 5.3 c/s and 1.1 c/s and in the doublet 5.1 c/s. This latter is the known J_{45} coupling constant for thiophenes [1,2]. The lower field quartet lies in the same region as the 5-hydrogen resonance in 2-thiophenealdehyde and the doublet has a shift similar to that of the 4-hydrogen of 2-thiophenealdehyde [1]. These results thus show that coupling occurs between the 5-hydrogen and the aldehydic hydrogen of this compound. Splittings of the aldehydic hydrogen in doublets were also observed in 4-substituted 2-thiophenealdehydes such as 4-bromo-2-thiophenealdehyde (0.9 c/s) and 4-methyl-2-thiophenealdehyde (1.3 c/s). In the first mentioned compound, however, the chemical shift between the 3- and 5-hydrogens is so small, (*cf.* 2-thiophenealdehyde[1]), that splittings due to coupling with the aldehydic hydrogen could not be observed in the ring spectrum. In the second compound the spectrum was complicated through additional coupling of the ring hydrogens with the methyl group.

No splitting of the aldehydic hydrogen resonance was however observed in 5-substituted 2-thiophenealdehydes such as 5-bromo-2-thiophenealdehyde and 5-methoxy-2-thiophenealdehyde.

These facts show that the splitting of the aldehydic hydrogen resonance line is caused by a coupling with the 5-hydrogen. These observations are quite remarkable since the coupling hydrogens are separated by as much as five bond distances, but consistent with Leane and Richards' interpretation [6] of the spectrum of furfural at 30 Mc/s. We have obtained a well resolved spectrum of furfural at 40 Mc/s and obtained a splitting of the aldehydic hydrogen equal to 0.8 c/s. Since they obtained a splitting of 0.9 c/s it is clear that these

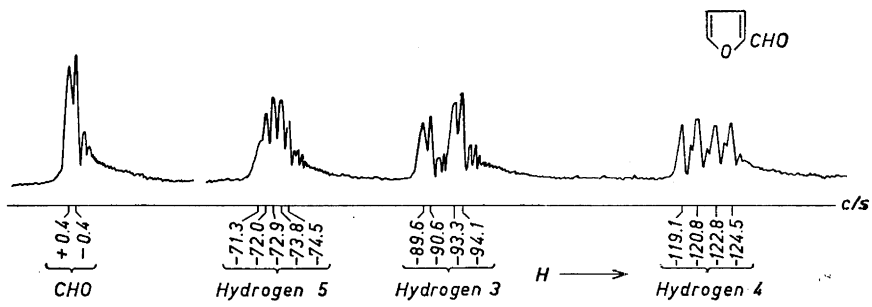

Fig. 2. NMR-spectrum of furfural at 40 Mc/s. The shifts are given relative to the aldehyde proton resonance line. The assignments are those of Refs.[6,7]

splittings are caused by spin-spin interactions. A chemical shift should have given a splitting at 30 Mc/s equal to 3/4 of that at 40 Mc/s.

The spectrum of the ring proton, which occurs at the lowest magnetic field (Fig. 2), consists of a quintet. This could be interpreted as a superposition of the patterns arising from three spin-spin couplings, two of which are nearly equal, and about half the magnitude of the third. This additional splitting of the lowest field ring proton resonance was also observed by Leane and Richards. They assign this multiplet to the five hydrogen as did Corey *et al.*[7] Apparently these assignments were based solely on the observed chemical shifts. If correct, it should then be pointed out that the relative magnitudes of J_{45} and J_{34} in furans are opposite to those in thiophenes. (In furans $J_{34} > J_{45}$ in thiophenes $J_{34} < J_{45}$ [1,8]). Leane and Richards [6] assumed that $J_{34} > J_{45}$ for thiophenes. Their interpretations of the spectra of 2-nitrothiophene and 2-thiophenecarboxylic acid thus would seem to be incorrect. This difference in relative magnitudes of the coupling constants in thiophenes and furans, if correct, is of considerable theoretical interest. It should be of great value therefore to obtain spectra of 2,3-disubstituted and 2,5-asymmetrically

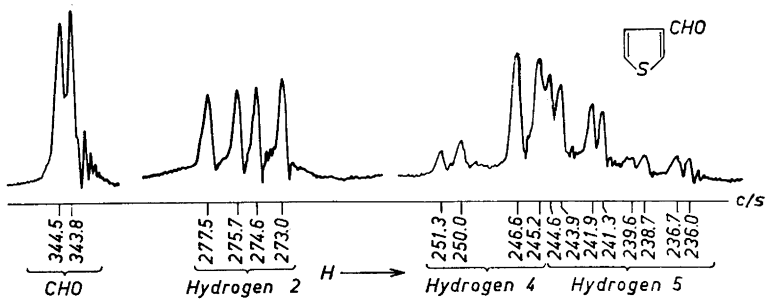

Fig. 3. NMR-spectrum of 3-thiophenealdehyde in *cyclo*hexane (internal reference) at 40 Mc/s.

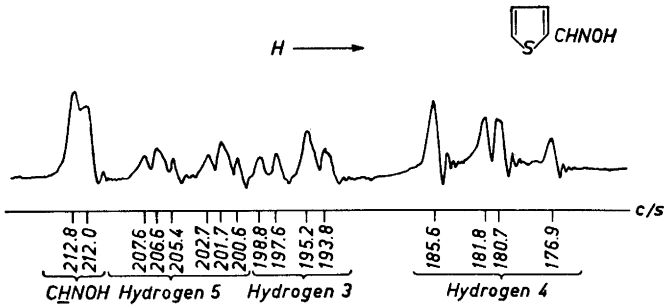

Fig. 4. NMR-spectrum of 2-thiophenealdoxime in dimethyl sulphoxide (internal reference) at 40 Mc/s.

disubstituted furans in order to confirm the assignments of coupling constants in furans.*

The observed splitting of the aldehydic hydrogen resonance in 3-thiophenealdehyde (Fig. 3) may be caused by spin-spin interaction with the five hydrogen since the resonance lines in the 2 × 2 × 2 multiplet have splittings equal to 2.7, 5.2 and 0.7 c/s, respectively [1]. We intend to confirm this interpretation by studying the spectra of substituted 3-thiophenealdehydes. We have shown through a study of several substituted 3-methylthiophenes [9] that the splitting of the methyl resonance in 3-methylthiophene is caused by coupling with the 2-hydrogen. This indicates that the mechanism of the spin-spin coupling between side-chain protons and protons of the ring is different in thiophenealdehydes and methylthiophenes.**

An investigation of the aldoxime hydrogen splitting in aromatic aldoximes is complicated by the fact that those compounds exist in *syn* and *anti* isomers. We have investigated a sample of 2-thiophenealdeoxime, m.p. 130—131°, which was predominantly the anti form [10]. Its spectrum in dimethyl sulphoxide (Fig. 4) showed a doublet at 212 c/s from the solvent peak with a splitting of 0.8 c/s. Because of its shift [5] and because it is absent in the spectrum of 2-acetothienone oxime, this doublet is assigned to the aldoxime hydrogen. The spectrum of its ring hydrogens is well resolved; consisting of one sextet and two quartets. The hydrogen causing the high field quartet has couplings to the other ring hydrogens equal to 3.8 and 4.9 c/s and is thus [1] hydrogen 4. The next quartet has splittings equal to 1.3 and 3.7 c/s and is therefore assigned [1] to hydrogen 3. The band from the 5-hydrogen at the lowest field consists of two triplets. This can be interpreted as arising from a proton coupled to three other hydrogens with two couplings being nearly equal and much smaller than the third. Thus the aldoxime hydrogen in 2-thiophenealdoxime

* The NMR spectrum of 5-chloromethyl furfural has been obtained by R. J. Abraham and H. J. Bernstein. *Canad. J. Chem.* **37** (1959) 1056.

** Smaller spin couplings (≈ 0.4 c/s) between the methyl group and the 4- and 5-hydrogens in 3-methylthiophene have been observed by P. L. Corio and I. Weinberg. *J. Chem. Phys.* **31** (1959) 569.

is coupled to the 5-hydrogen as is the aldehydic hydrogen in 2-thiophenealdehyde. The aldoxime hydrogen as well as the ring hydrogens in 3-thiophenealdoxime gave complex spectra probably due to small relative shifts of the ring hydrogens. The splittings of the aldehyde and oxime hydrogen resonances are listed in Table 1.

Table 1. Observed splittings of aldehyde and oxime hydrogen resonance lines.

Compound	B.p./M.p.	Ref.	Splitting c/s
Furfural	63— 64° (20 mm)		0.8
2-Thiophenealdehyde	85° (20 mm)	11	0.9
3-Thiophenealdehyde	86— 87° (20 mm)	12	0.7
5-Bromo-2-thiophenealdehyde	105—107° (11 mm)	13	≈0
5-Methoxy-2-thiophenealdehyde	79— 81° (0.9 mm)	14	≈0
3-Bromo-2-thiophenealdehyde	109—110° (10 mm)	9	1.2
4-Bromo-2-thiophenealdehyde	114—115° (11 mm)	9	0.9
	44— 45° (m. p.)		
4-Methyl-2-thiophenealdehyde	95— 96° (11 mm)	15	1.3
2-Thiophenealdoxime	130—131° (m. p.)	16	0.8

We note that long-range splittings of aldehydic hydrogen resonance lines have not as yet been observed in either the benzene or the α,β-unsaturated aldehyde series [9]. It is suggested that there might be a connection between the magnitude of the splittings and the degree of conjugation in the aldehydes. This would, however, require some interaction between the extended π-orbitals and the σ type C—H bond in the aldehyde group which is rather unexpected. We are continuing our studies in this field.*

EXPERIMENTAL

The spectra were obtained with a Varian Associates Model V-4300 B high resolution Spectrometer and a flux-stabilized 12″ magnet model V-4012-HR from the same company. The magnet sweep was calibrated by the familiar modulation side-band technique and the shifts from the internal standard were obtained by interpolation on the recorder chart. The modulation frequency obtained from the power line was 50 c/s.

References to the methods of preparation of the compounds investigated are given in Table 1. 4-Bromo-2-thiophenealdehyde and 3-bromo-2-thiophenealdehyde have been obtained from 4-bromo-2-lithiothiophene and 3-bromo-2-lithiothiophene, respectively, through the reaction with N,N-dimethyl formamide. Details of the preparation of these new compounds will be given later.

Acknowledgements. The authors wish to express their thanks to professor Arne Fredga and to professor Kai Siegbahn for their interest in this work and for all facilities put at the authors' disposal. We are indebted to professor J. Sicé (Chicago) for a generous gift of 5-methoxy-2-thiophenealdehyde. One of us (R.A.H.) thanks the *State Technical Research Council* (of Sweden) for a grant.

* Splittings of the aldehyde peak in ortho-substituted benzaldehydes (~ 0.5 c/s) have recently been observed in these laboratories by Drs. D. and V. J. Kowalewsky (private communication).

Uptake of Orthophosphate by the Pea Plant (*Pisum sativum*)

II.* Identification of the Organic Phosphate Esters Formed

JORMA K. MIETTINEN and TOIVO SAVIOJA

Biochemical Institute, Helsinki, Finland

The main phosphate esters formed in assimilation of orthophosphate in the pea plant are identified by two-dimensional paper chromatography using co-chromatography and radioautography. They are ** ATP, UTP, GTP, ADP, UDP, AMP, F6P, G6P, F1,6P, and an unknown compound marked No. 10. In the root several additional unidentified esters are formed, which are not found in the shoot extracts.

The general pattern of esterification of orthophosphate is similar in intact and detached pea root. No noticeable qualitative differences are found in the esterification pattern between pea, rye, oat, and barley plants, but some difference between these and the yeast *Torulopsis utilis* is noticeable.

In the first part [1] of this research project it was established that assimilation of orthophosphate by intact pea roots is a very rapid process. After 10 sec of assimilation, 2 organic phosphates — ATP and a diphosphate, probably ADP — showed labelling, and after 2 min, labelling was found in 4 triphosphates — ATP, GTP, UTP and an unidentified compound — and in 3 spots in the diphosphate area and 2 spots in the monophosphate area of the two-dimensional chromatogram. A dynamic equilibrium was reached in 5 min, after which time chromatograms from both roots and shoots were qualitatively very similar. The results with phosphorus-deficient pea plants (total P 30—50 % of normal) were not essentially different. The labelling obtained in the

* The first paper in this series is Ref.[1]

** The following abbreviations are used: AMP, ADP, ATP = adenosine-5'-mono-, -di- and -triphosphate, resp.; CMP, CDP, CTP = cytidine-5'-mono-, di- and -triphosphate, resp.; GMP, GDP, GTP = guanosine-5'-mono-, di- and -triphosphate, resp., and UMP, UDP, UTP = uridine-5'-mono-, di- and triphosphate, resp. 2-PGA = 2-phosphoglyceric acid, 3-PGA = 3-phosphoglyceric acid, PCHO = phosphorylcholine, G1P = glucose-1-phosphate, G6P = glucose-6-phosphate, F6P = fructose-6-phosphate, F1,6P = fructose-1,6-diphosphate, UDPG = uridine-diphosphoglucose, TCA = trichloroacetic acid.

short reaction times was relatively weak. Therefore identification of most of the spots was not achieved in the above study.

The main goal of the present study was the identification of the labelled phosphates formed. For this purpose somewhat longer assimilation times were used than in the above study to get stronger labelling in the spots. By the application of a new solvent combination [2] satisfactory two-dimensional paper chromatograms are obtained from the original extracts after removal of TCA, without any further purification, and this has made possible chromatographic identification of 10 of the labelled compounds formed. Though the time scale of the present experiment (1—30 min) extends far beyond the most interesting biokinetical interval of the primary phases of assimilation (1—60 sec), the activity of the separated spots was determined to give an idea of the quantitative changes taking place in longer times in the relative activities of the compounds formed. Stringent conclusions can hardly be drawn from figures like these, but the scale on which the experiment was carried out was too small to make determinations of specific activities possible. This will be tried later on and will require working on a larger scale and using different techniques, probably ion exchange columns, which may also provide conclusive identification of the isolated compounds. The present identifications by co-chromatography are only preliminary, although the probability that they are correct is relatively high, since a total of about one hundred two-dimensional co-chromatograms were made.

METHODS

Plant material. The pea plants *(Pisum sativum, var.* Torsdag) were grown in a sterilized nutrient solution inoculated with an efficient strain of *Rhizobium*, the bottles being closed with cotton wool. The green parts were free in the greenhouse air. The nutrient solution was similar to that used in the previous study [1] for "high-phosphorus" plants. The plants were 23 days old when the experiments were made.

Extraction and chromatography were also made as mentioned previously [1] except for the first solvent in paper chromatography. All extracts were diluted with water to 12 ml after removal of the TCA and 0.5 ml of the diluted extract was used for each chromatogram. The solvent used in the present study for the first dimension was *t*-butanol:formic acid (98 %): water, 8:3:4 (Miettinen [1]). In the second dimension the mixture of Hanes, *n*-propanol:NH_4OH (25 % NH_3):water, 6:3:1, was used.

Performance of the experiment. About 10 mC of carrier-free orthophosphate (PBS 1, Radiochemical Centre, Amersham, England), neutralized to pH 7.0, was added to 150 ml of phosphate-free but otherwise complete nutrient solution [1].

This solution was then evenly divided into 5 small beakers. Each sample consisted of a bunch of 5 plants, the roots of which were dipped into the isotope solution for the proper time (1, 5, 15 or 30 min), at the end of which the roots were rapidly washed in cold water, separated from the shoot and crushed in 8 % TCA. A fifth sample (30 min) was taken to study the effect of detachment (of the roots from the shoot) on the uptake rate of the phosphate ion. The detachment was made just before dipping. Of the roots all except the cutting place was dipped, of the shoot about 1 cm of the lower end only. The detached roots were dipped into the same solution as the 1 min sample of the intact plants. The detached shoots were dipped into a separate solution.

During the experiment the plants were, in addition to diffuse daylight, illuminated with one "Photolita" SM lamp at 70 cm distance.

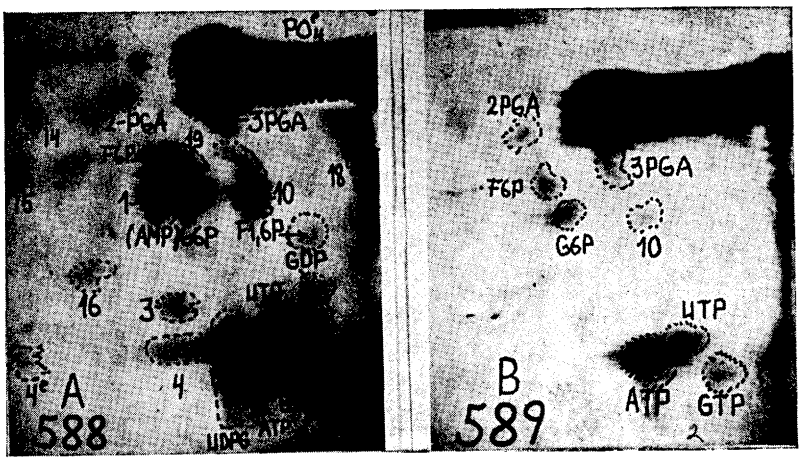

Fig. 1. Radioautograms of two-dimensional paper chromatograms of soluble phosphates present in intact (A) and detached (B) pea roots after 1 min uptake of radioactive orthophosphate.

RESULTS

The following compounds were found to be labelled *in the roots of intact plants* after 1 min assimilation: ATP, UTP, GTP, UDPG, AMP(?), G6P (?), F6P, 2-PGA, 3-PGA, unknowns Nos 1, 3, 4, 10, 13—16, 18, 19, and traces of F1,6P and GDP (Fig. 1, A). The unknown No. 1 may be identical with G1P, but this is still uncertain because the coloured spot of added authentic compound did not exactly match the radioactive spot in one case. In the *roots detached from the shoot* (Fig. 1, B) only weak labelling was found in ATP, UTP and GTP and in traces of extremely faint spots of the other compounds. Total activity of the root extracts was: intact roots 2.0×10^7, detached roots 0.77×10^7 c.p.m. Because of their low activity the individual spots of these chromatograms were not counted.

In the 5 — 30 min samples PCHO and the nucleotide diphosphates ADP, UDP and GDP became labelled in addition to the compounds mentioned above. Chromatograms of the root (A) and shoot (B) extracts of the 15 min sample are presented in Fig. 2. The same spots are found labelled in both cases except for Nos 1, 3, 4, 18 and 19, which do not appear in the shoot (Fig. 2, B). The total activities of the extracts and relative activities of some individual compounds are reported in Table 1. The total activity of the shoots is *ca.* 2—3 % of the activity of the roots, but the relative activity of the organic phosphates, compared with the inorganic spot, is much higher in the shoot.

The composition of the extracts of the intact and the detached shoots after 30 min assimilation is illustrated in Fig. 3. Again, both extracts are qualitatively similar but the labelling of all compounds is very much stronger in the detached shoot which was able to absorb radioactive nutrient solution without the "sieving" effect of the roots. As the only unknowns in both of

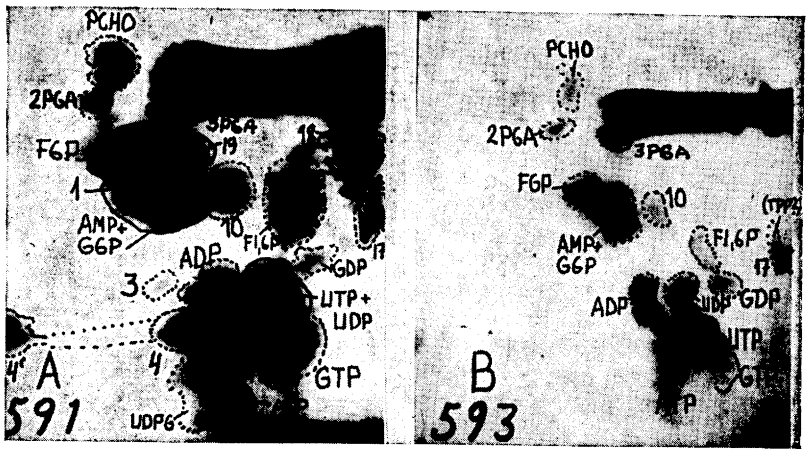

Fig. 2. Radioautograms of two-dimensional paper chromatograms of soluble phosphates present in the root (A) and the shoot (B) of intact pea plants after 15 min uptake of radioactive orthophosphate.

these extracts, spots Nos 10, 17 and 18 show labelling, of which the two latter ones well match with inorganic pyrophosphate (P_2O_7) and thiamine pyrophosphate (TPP). The identity of these two spots is not yet fully established, however.

DISCUSSION

The main purpose of this study was the identification of the acid-soluble phosphates formed during phosphorus assimilation in the pea plant. A number of acid soluble phosphates have been chromatographically identified by earlier workers in the pea and in other higher plants. Rowan [3] identified in pea seed-

lings ATP, ADP, UTP, UDP, UMP and a dinucleotide containing both adenosine and guanosine. In another paper [4] he identified G1P, G6P and F1,6P. Loughman and Scott Russell [5] found in barley roots 5 nucleotides, of which they identified ATP and ADP. Of sugar phosphates they mention G6P, F6P and F1,6P. Ginsburg, Stumpf and Hassid [6] isolated UDPG from mung bean seedlings. According to Burma and Mortimer [7] UDPG is synthetized in the leaves of sugar beet from G1P and UTP. Maizel, Benson and Tolbert [8] have found PCHO to be the main organic transport form of phosphate in higher plants. Lindeman [9] identified in *Chlorella* ATP, ADP, UTP, UDPG, AMP, F6P, G6P, F1,6P and 3PGA. We have found these same compounds among several other ones labelled in the pea plant in the present study.

Aronoff [10], when studing phosphate assimilation in the roots of soybean, concluded that the first compound to become labelled was F1,6P. Mitsui, Aso and Ishizuka [11], on the other hand, consider G6P and F6P to be the primary labelled phosphate esters in wheat seedlings. From these the labelling is transferred to nucleotides. Contrary to the above results we found in one of our earlier investigations [1] labelling earliest in nucleotides, primarily in ATP. Nearly simultaneously a weaker labelling appears, however, in three sugar phosphates, G6P, F6P, and F1,6P [12]. ATP is without doubt a primary assimilation product, but any of the other ones mentioned above may also be formed independently of and simultaneously with ATP [12].

All identifications in the present study are based on several tests by cochromatography. The nucleotide nature of spots so identified was further confirmed in an unpublished experiment in which the acid soluble phosphates were fractionated by means of Norite active charcoal. All spots identified as nucleotides and the unknowns 3 and 4 were adsorbed by the charcoal (and re-

eluted by pyridine), whereas the spots identified as sugar phosphates passed through the column unabsorbed.

In another unpublished experiment we compared acid soluble phosphates of pea, rye, oat and barley plants after 10 min's orthophosphate assimilation. The same and only the same labelled compounds were found in all these plants. However, comparison of pea and yeast [2] shows slight differences, *i.e.* first, the yeast does not show labelling in 2-PGA and second, two compounds in yeast, which have been preliminarily identified as phosphoserine and phosphothreonine, do not show labelling in the roots of higher plants.

In yeast extracts one of the strongest labelled phosphates is the unknown No. 3, which is absorbed by Norite like a nucleotide and is located on the two-dimensional chromatograms in the region of nucleotide triphosphates. It becoms faintly labelled after about 1 min's assimilation, but after 10—30 min it becomes one of the strongest spots. We are presently working on the identification of this compound.

An interesting difference between the root and shoot of the pea plant is, that the root extracts contain several unidentified phosphate esters which are not found in the shoot.

Acknowledgements. This study has been performed under the tenure of the *FAO André Mayer Fellowship* by one of the authors (JKM). A grant from *Suomen Luonnonvarain Tutkimussäätiö* is also gratefully acknowledged. We are greatly indebted to Prof. A. I Virtanen for his interest and encouragement and for the working facilities he has generously made available to us.

An Electron Diffraction Investigation of the Molecular Structure of Allene

A. ALMENNINGEN, O. BASTIANSEN and M. TRÆTTEBERG

Universitetets kjemiske institutt, Blindern-Oslo;
Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The electron diffraction sector method was used to determine the structure of allene vapour. The observed molecular parameters are the following: C—H: 1.081_6 Å (u = 0.0795 Å), C=C: 1.311_6 Å (u = 0.0390 Å), C_1C_3: 2.617_3 Å (u = 0.0519 Å) and <H—C=C: 120.8°. The C_1C_3 distance was found to be shorter than twice the C=C distance. This can be explained by out-of-linearity vibrations.

The molecular structure of allene was determined by the electron diffraction sector method, using a modified s^3 sector. The electron diffraction diagrams were taken at three different distances between the scattering point and the photographic plate (approximately 48, 19 and 12 cm). The photometer curves were read off and the usual corrections were carried out.

The subtraction of the background, *viz.* atomic and incoherent scattering, was carried out by fitting a theoretical background to the intensity curve by means of a least square treatment giving the intensity zero line and the intensity scale. An example of the correspondence between the background and the intensity curve is demonstrated in Fig. 1 for the average of the 48 cm plates. The correspondence is good except for the innermost part. As a general rule, the middle parts of the intensity curves fit well with the theoretical background. At the innermost and outermost parts corrections generally have to be made. The short distance curves (12 cm) were all treated separately. Because of the low intensity values the correspondence is less satisfactory. A small error in the readings gives raise to a relatively large error in the amplitudes. The background was fitted to each of the experimental curves and the difference curves were averaged. The curves from the various distances were normalized, and after the averaging of the overlapping regions the first total molecular intensity curve was obtained extending from s = 1.25 to s = 65 Å^{-1}.

By Fourier transformation of the damped molecular intensity curve (damping factor $e^{-0.0009\ s^2}$) the corresponding radial distribution (R.D) curve was obtained. In this curve the Gaussian shaped peaks corresponding to the interatomic distances were completely resolved except for some unavoidable overlap of the C—H and C=C double bond peaks.

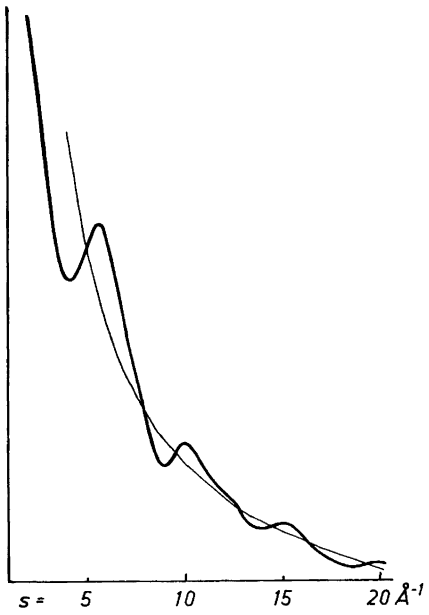

Fig. 1. Allene. Intensity curve from the 48 cm photographic plates with the theoretical background fitted in.

From this first R.D. curve, the most probable model of the molecule was determined and a theoretical intensity curve corresponding to this model computed. By means of the theoretical intensity curve it is possible to correct for the most serious errors in the background. In this case only small corrections were necessary for obtaining the final molecular intensity curve (Fig. 2) upon which the final conclusions were based.

A series of R.D. curves was calculated from the final intensity curve using different damping constants ($k = 0$, 0.0009 and 0.0015) and Δs values of 1/2 and 1/4 Å^{-1}. Three of these curves are presented in Fig. 3.

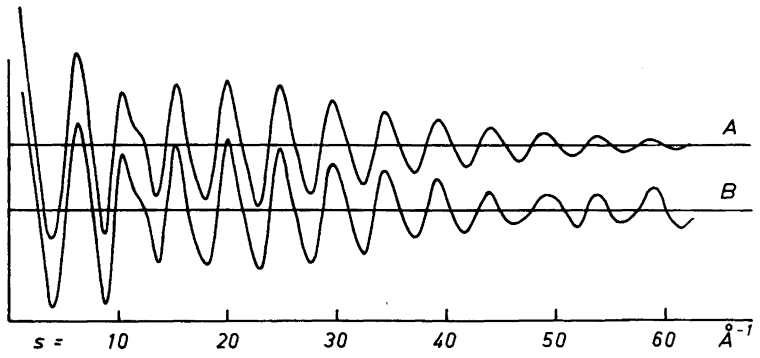

Fig. 2. Allene. Theoretical (A) and experimental (B) intensity curves.

Table 1. Allene. Internuclear distances and mean amplitudes of vibrations.

Distances	Observed r values	Observed u values	u values calculated from spectroscopic data
C—H	1.0816	0.0795	0.0772
C=C	1.3116	0.0390	0.0401
C_2H_1	2.0840	0.1046	0.1015
C_1C_3	2.6173	0.0519	0.0451
C_3H_1	3.2963	0.1272	0.1144
<H—C=C: 120.8°			

These R.D. curves were also resolved into Gaussian peaks. The internuclear distances and mean amplitudes of vibration ($u = \sqrt{\overline{(r - r_0)^2}}$) are presented in Table 1. If a linear carbon skeleton is assumed the structure is determined from three parameters. (The question of the relative position of the HCH planes has been ignored).* The R.D. curves give altogether five distances, and the best set of parameters was calculated using the method of least squares. The parameters thus obtained are: C—H: 1.083 Å, C=C: 1.308 Å and H—C=C angle 120.6°.

It is worth noting that the C=C value obtained by this procedure is 0.003 Å smaller than that computed directly from the C=C peak of the R.D. curves. This of course corresponds to the fact that the C_1C_3 distance as found from the R.C. curves is about 0.006 Å smaller than twice the C=C distance obtained in the same way. Even if this effect is very small we are inclined to believe that it is real. The effect can easily be explained by an out-of-linearity vibration. If this argument holds the best C=C distance should be 1.312 Å instead of 1.308 Å.

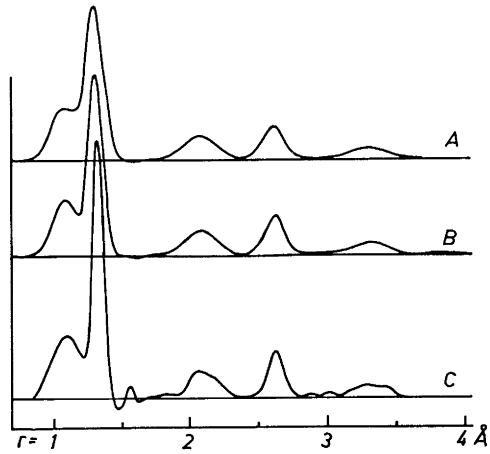

Fig. 3. Allene. Radial distribution curves with different damping constants (A: $k = 0.0015$, B: $k = 0.0009$, and C: $k = 0$).

* *Added in proof:* A closer examination of the R. D. curves reveals the presence of HH distance peaks beyond the largest CH peaks, corresponding to an angle of 90° between the two HCH planes.

Table 2. Allene. Theoretical and experimental values for areas under the peaks in the radial distribution curves.

Distances	Theoretical areas	Experimental areas
C—H C=C	54.80	54.5
C_2H_1	9.54	9.6
C_1C_3	9.12	9.1
C_3H_1	6.03	4.7

A similar effect which can also be interpreted by the assumption of out-of-linearity vibrations was observed for dimethyldiacetylene [1].

The structure parameters obtained for allene are in accordance with the values obtained by Stoicheff from high resultion Raman spectroscopy [2]. Using both allene and allene-d_4 the C=C distance of 1.309 Å is obtained. Assuming a C—H distance of 1.07 ± 0.01 Å as found in an earlier work on ethylene [3], he obtains an HCH angle of 117° (H—C=C angle equal to 121.5°). We feel that Stoicheff's assumed C—H distance is a trifle too small.

It is of interest to compare our parameters with the recently obtained values for ethylene [4-6]. The data obtained from three indepentent methods are: C—H: 1.086 ± 0.003 Å, C=C: 1.337 ± 0.003 Å and <H—C=C: 121.5° ± 1°. This shows that the CH_2 group in ethylene, within rather narrow error limits, has the same structure as in allene. However, the C=C distance is, as pointed out by Overend and Thompson [7] and by Stoicheff [3], no doubt larger in ethylene than in allene.

In the last column of Table 1 the u values calculated from spectroscopic data by Cyvin [8] have been presented. The correspondence is satisfactory except for the C_1C_3 distance where a significant discrepancy seems to be present. This discrepancy can be satisfactorily explained by the mentioned out-of-linearity vibration. The spectroscopic calculations were based upon the assumption of a linear model. The out-of-linearity vibrations should not only lead to a decrease in the C_1C_3 distance but should also lead to an increase in the mean amplitude of vibration for this distance.

As a control of the reliability of the R.D. curves the measured areas have been compared with the theoretical ones on a relative scale. The values are given in Table 2.

This investigation has been sponsored by the *United States Air Force Development Command* under contract AF 61(052)—72.

Phase Relations in the System Ag-Sb-S at 400° C

JAN BARSTAD*

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.

The coexisting phases in the three-phase fields of the system Ag—Sb—S at 400°C within the region Ag_2S—Sb_2S_3—Sb—Ag have been determined by means of X-ray identification in samples annealed at 400°C and quenched to room temperature. In addition, the reactions between pellets of silver-antimony alloys and silver-antimony sulfides at 400°C have been investigated. The results are in agreement with the isothermal section of the ternary phase diagram deduced from X-ray investigations.

In conjunction with kinetic investigations on solid state reactions in the quasi-binary system Ag_2S—Sb_2S_3, it was found desirable to reexamine the isothermal section of the phase diagram of the ternary system Ag—Sb—S at 400°C. Previously this ternary system was investigated by Schenck, Hoffmann, Knepper and Vögler [1] with the help of measurements of the H_2S/H_2 ratio during the reduction of sulfides of the quasi-binary system Ag_2S—Sb_2S_3 with H_2 at 400°C. From the obtained staircase curves the boundaries of two-phase and three-phase fields were deduced. As the H_2S/H_2 ratios for some of the steps of the staircase curves were close together, the reality of some steps may be questioned. The composition of the silver-antimony sulfide phases was given as $Ag_2S{\cdot}Sb_2S_3$, $4Ag_2S{\cdot}Sb_2S_3$, and $2Ag_2S{\cdot}Sb_2S_3$. This is in disagreement with thermal studies by Jaeger and van Klooster [2] and by Jensen [3] where only the phases $Ag_2S{\cdot}Sb_2S_3$ and $3Ag_2S{\cdot}Sb_2S_3$ were observed. The work was confined to the region Ag—Sb—Ag_2S—Sb_2S_3 of the system Ag—Sb—S. The nature of the coexisting phases was ascertained by the following methods.

1) Samples whose compositions were presumably in three-phase fields were prepared from the elements, annealed at 400°C, and quenched. In addition, two samples in two-phase fields were investigated. The phases present were identified by means of X-ray powder diagrams with the help of a General Electric diffraction unit with Cu-radiation and Ni-filter.

2) Pressed and sintered pellets of Ag_2S, Ag_3SbS_3, $AgSbS_2$ and Sb_2S_3 and pellets of Ag, Ag_3Sb, and Sb solidified from melts were prepared. Two pellets

* Present address: Forsvarets Forskningsinstitutt, Kjeller pr. Lillestrøm, Norway.

of different composition 2—3 mm thick were pressed together and heated at 400°C for several days in a N_2 atmosphere. Observation of a reaction zone involving new phases indicates that the phases initially present do not coexist under equilibrium conditions.

The following informations on the crystal structures and homogeneity ranges of the phases in the binary systems were used.

1) The binary system Ag—Sb

By means of metallographic examination and X-ray diffraction identification, Weibke and Effinger [4] studied the system Ag—Sb in detail. Their results agree in principle with previous X-ray diffraction investigations by Broderick and Ehret [5] and by Westgren, Hägg, and Eriksson [6]. At 400°C, the following phases exist:

α-Phase. Homogeneity range 0—6.2 atom % Sb[4]. Face-centered cubic structure with a lattice constant increasing from $a = 4.086$ Å for pure silver to $a = 4.121$ Å[6]. Lattice constant for pure silver is given on the ASTM data card [7] as $a = 4.0862$ Å at 27°C.

ζ-Phase. Homogeneity range 9.4—14.9 atom % Sb[4]. Hexagonal close-packed structure with lattice constants increasing from $a = 2.927$ Å, $c = 4.784$ Å, $c/a = 1.634$[6] to $a = 2.961$ Å, $c = 4.797$ Å, $c/a = 1.620$ [4].

ε-Phase. Homogeneity range 21.3—26.2 atom % Sb [4]. Orthorhombic structure which can be considered as a slightly distorted ζ-phase structure. The change in lattice constants within the homogeneity range for alloys annealed at 400°C is from $a = 2.986$ Å, $b = 5.180$ Å, $c = 4.774$ Å to $a = 2.996$ Å, $b = 5.246$ Å, $c = 4.854$ Å [6].

The lattice constants given by Westgren, Hägg, and Eriksson [6] for the lower limit of the homogeneity range of the ε-phase are considerably higher than those given by Weibke and Effinger [4]. Only the latter authors give the annealing temperature of the alloys and report differences in lattice constants for alloys annealed at 400°C and 500°C and thus their values are considered to be more accurate.

Sb-Phase. The dimensions of the hexagonal unit cell of pure Sb are given on the ASTM data card [8] as $a = 4.307$ Å, $c = 11.273$ Å. The solubility of Ag in Sb and its effect on the lattice constants are not yet known.

2) The binary system Sb—S

As shown already by Jaeger and van Klooster [2], Sb_2S_3 is the only stable compound in the system Sb—S. The compound Sb_2S_5 has been obtained only by precipitation from aqueous solutions. The ASTM data card [9] gives the following dimensions of the orthorhombic unit cell of Sb_2S_3: $a = 11.229$ Å, $b = 11.310$ Å, $c = 3.839$ Å.

The homogeneity ranges of the Sb phase and the Sb_2S_3 phase must be considered as very limited, but actual data are missing.

3) The binary system Ag—S

There is only one compound Ag_2S, which has a cubic structure at 400°C [10], called α Ag_2S or argentite. Transformation to the low temperature modification, called β Ag_2S or acanthite, takes place spontaneously near 178°C even on rapid quenching. According to Ramsdell [11] acanthite is monoclinic, $a = 9.47$ Å, $b = 6.92$ Å, $c = 8.28$ Å, $\beta = 124°$. The homogeneity range of α

Ag_2S was deduced by Wagner [12] at 200° and 300°C from electrochemical measurements and can be given as $Ag_{2.000}S$ to $Ag_{2.002}S$.

The solubility of S in Ag is negligible.

4) The quasi-binary system $Ag_2S-Sb_2S_3$

A thermal study of the system $Ag_2S-Sb_2S_3$ was first made by Jaeger and van Klooster [2]. The most detailed investigation has been made by Jensen [3]. Two intermediate compounds with a narrow homogeneity range are reported, $AgSbS_2$ and Ag_3SbS_3.

$\alpha AgSbS_2$. This modification is stable above 380°C. The crystal structure is cubic with a lattice constant $a = 5.653$ Å according to Graham [13]. The transformation to the low temperature modification β $AgSbS_2$, miargyrite, takes place on slow cooling whereas α $AgSbS_2$ is preserved on quenching.

Ag_3SbS_3, pyrargyrite. The structure of this phase was determined by Harker [14]. The dimensions of the hexagonal unit cell are $a = 11.06$ Å, $c = 8.74$ Å.

In addition, there have been reported the minerals polyargyrite, 11 $Ag_2S{\cdot}Sb_2S_3$, polybasite, $8Ag_2S{\cdot}Sb_2S_3$, pyrostilpnite, $3Ag_2S{\cdot}Sb_2S_3$, and stephanite, $5Ag_2S{\cdot}Sb_2S_3$. Polybasite and pyrostilpnite were prepared by Weil and Hoeart [15] by heating the components in glycerol.

IDENTIFICATION OF PHASES BY X-RAY DIFFRACTION

In Fig. 1 the compositions of the samples in the ternary system are indicated in the phase diagram. The exact composition and the phases identified in each sample are given in Table 1.

The interpretation of the X-ray diffraction diagrams was complicated because overlapping of diffraction lines from different phases often occurred. The β Ag_2S, Sb_2S_3 and Ag_3SbS_3 phases give very complex patterns. The complex β Ag_2S pattern could have been avoided by using a high temperature camera where the specimen was kept at a temperature above 178°C, but in the present investigation a high temperature camera was not used.

The accuracy of the lattice constants is estimated to be 0.2 % unless otherwise stated.

The lattice constants of the individual phases found in the various samples were compared with values available in the literature with the following results.

Sb_2S_3-Phase. Within the limits of error, complete agreement was found between the Sb_2S_3 phase in sample G and pure Sb_2S_3 [9].

Sb-Phase. Within the limits of error the lattice constants of Sb in the samples G, A, and B agreed with those of pure Sb[8].

α $AgSbS_2$-Phase. The samples G, A, B, K, and C contain α $AgSbS_2$ with a lattice constant equal to the value given for pure α $AgSbS_2$ [13].

ε-Phase. The calculated lattice constants in samples B and K are $a = 2.992$ Å, $b = 5.244$ Å, $c = 4.852$ Å. In sample C considerable overlapping from Ag_3SbS_3 interferes with an accurate evaluation of the lattice constants, but they are within a limit of error of $\pm$ 0.4 % the same as in samples B and K. Upon comparing these values with the lattice constants of the ε-phase in the system Ag—Sb[6] within the homogeneity range, nearly complete agreement with the values for the Sb-rich limit of the ε-phase is found. In sample L where

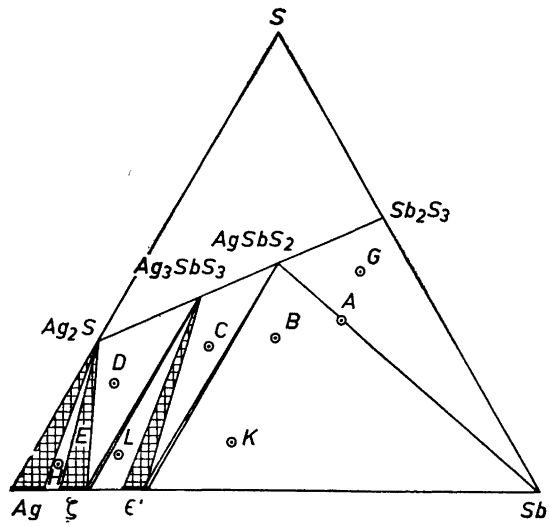

Fig. 1. Isothermal section of the phase diagram of the system Ag—Sb—S at 400°C for the region Ag—Sb—Ag_2S-Sb_2S_3.

both the ε-phase and the ζ-phase are present, nearly complete overlapping of the reflections from these phases is observed.

Ag_3SbS_3. Within an estimated error of ± 0.4 %, agreement of the lattice dimensions of the Ag_3SbS_3 phase in the samples C, L, D with synthetic Ag_3SbS_3 prepared from Ag_2S and Sb_2S_3 was obtained.

ζ-Phase. The following lattice constants were obtained:

Sample L: $a = 2.965$ Å, $c = 4.783$ Å
Sample D: $a = 2.963$ Å, $c = 4.780$ Å
Sample E: $a = 2.940$ Å, $c = 4.792$ Å
Sample H: $a = 2.924$ Å, $c = 4.763$ Å

Table 1.

Alloy	Atom % Ag	Sb	S	Phases present
G	9.4	41.9	48.7	Sb_2S_3, Sb, α $AgSbS_2$

E	79.0	5.3	15.7	ζ, Ag_2S
H	87.7	7.4	4.9	ζ, Ag_2S, Ag

α Ag_2S. The diffraction lines of Ag_2S in the alloys D, E, and H were identified by a comparison with those of pure Ag_2S. Due to the transformation to β Ag_2S on cooling, the lattice constant of α Ag_2S has not been obtained.

Ag-Phase. The lattice constant of the silver-phase in alloy H was found to be $a = 4.112$ Å compared with the value $a = 4.121$ Å given as the upper limit for the a phase in the system Ag—Sb.

The following conclusions can be drawn:

There is no indication of more than very limited homogeneity ranges of the phases Sb_2S_3, Sb, $AgSbS_2$, and Ag_3SbS_3 as deviations from the lattice dimensions of the pure stoichiometric phases have not been observed.

No significant solubility of sulfur in α Ag, ζ and ε seems to occur as the three-phase samples have lattice constants which do not differ from the lattice constants at the phase boundaries in the corresponding binary system Ag—Sb.

As sample D contains ζ-phase with lattice constants nearly equal to the lattice constants at the Sb-rich end of the ζ-phase in the system Ag—Sb, the tie lines from nearly the whole phase area must be directed towards the Ag_2S phase. The tie lines from the α Ag phase area are also directed towards the Ag_2S phase.

Sample C contains ε-phase with lattice constants nearly equal to the lattice constants at the Sb-rich end of the ε-phase in the system Ag—Sb. The tie lines from nearly the whole ε-phase area are thus directed towards the Ag_3SbS_3 phase.

There is no indication of a phase with the approximate composition $31\ Ag{\cdot}2Ag_2S{\cdot}Sb_2S_3$ as reported in the paper by Schenk *et al.*[1]

The experimental data given by Schenck *et al.*[1] are not in obvious conflict with the phase diagram in Fig. 1 although they have been interpreted differently. It must be recalled, however, that some of the reported steps of the H_2S/H_2 *vs.* composition plots are not very distinct and, therefore, do not permit a definite construction of the phase fields.

REACTION BETWEEN PELLETS OF DIFFERENT COMPOSITION

The pellet combinations Sb—$AgSbS_2$, Ag_3Sb—$AgSbS_2$, Ag_3Sb—Ag_3SbS_3 and Ag_3Sb—Ag_2S gave no indication of a reaction after heating 170 h at 400°C. Except for the combination Ag_3Sb—Ag_2S, the phases involved are connected by tie lines in the Fig. 1 and thus coexist at 400°C.

After 170 h at 400°, the pellets of the combinations Sb—Ag_3SbS_3 and Sb—Ag_2S were easily separated, but a thin reaction layer could be observed at the contact surfaces. The pellet combination Ag_3Sb—Sb_2S_3 showed a more pronounced reaction; the pellets stuck together. Reactions between the phases Ag and Ag_3SbS_3, Ag and $AgSbS_2$, and Ag and Sb_2S_3 take place very rapidly. After 100 h virtually only the reaction products could be observed on staining polished cross sections according to Gaudin and McGlashan [16].

In all the pellet combinations where a reaction was observed, the two initial phases do not coexist according to the phase diagram in Fig. 1.

Short Communications

Lower Homologues of Thioctic Acid

GÖRAN CLAESON

Chemical Institute, University of Uppsala, Uppsala, Sweden

A few years ago I prepared 1,2-dithiolane-3-carboxylic acid[1], the lowest homologue of 6,8-thioctic acid [2-4]. It was my intention to prepare other homologues with side chains more like the biologically important acid. In 1956, however, Thomas and Reed prepared the nearest lower and higher homologues of 6,8-thioctic acid, 1,2-dithiolane-3-butyric acid and 1,2-dithiolane-3-caproic acid [5]. These homologues exhibited much lower biological activity than DL-6,8-thioctic acid in the acetate-replacing factor assay [6,7].

Preparation of the homologues between 1,2-dithiolane-3-carboxylic acid and 6,8-thioctic acid has thereby lost part of its biological interest. The acids with a carboxyl group in a position α to sulphur in the 1,2-dithiolane or 1,2-dithiane ring, however, show some interesting properties, which are not observed in the homologues where the carboxyl is screened by a side chain. This is a preliminary report of the syntheses and UV spectra of some carboxyl substituted cyclic disulphides.

The UV spectrum of 1,2-dithiane contains a characteristic absorption maximum at 290 mμ and that of 1,2-dithiolane a maximum at 330 mμ[8]. When a carboxylic group is substituted in a position α to the disulphide group, it causes a withdrawal of electrons from the disulphide group, resulting in a shift of the absorption band towards shorter wavelengths. This is observed for 1,2-dithiolane-3-carboxylic acid, which has an absorption peak at 280 mμ (Fig. 1) that is, a hypsochromic shift of 50 mμ. A still greater hypsochromic shift was observed by Schotte[9] for 1,2-dithiolane-3,5-dicarboxylic

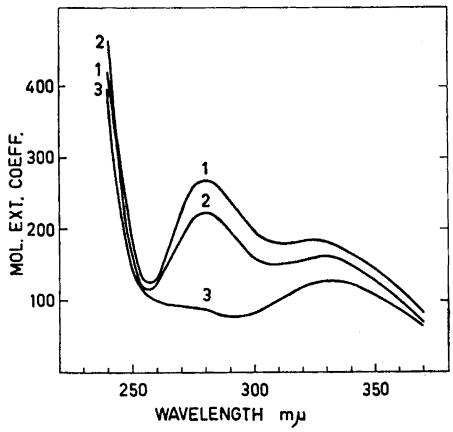

Fig. 1. UV absorption spectra of 1,2-dithiolane-3-carboxylic acid: (1) in 0.6 M HCl (solvent: alcohol); (2) in alcohol; (3) in 0.01 M NaOH (solvent: alcohol).

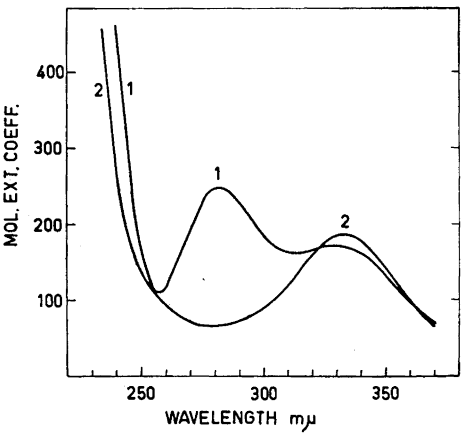

Fig. 2. UV absorption spectra of: (1) 5-methyl-1,2-dithiolane-3-carboxylic acid; (2) 5-methyl-1,2-dithiolane-3-acetic acid. Solvent: alcohol.

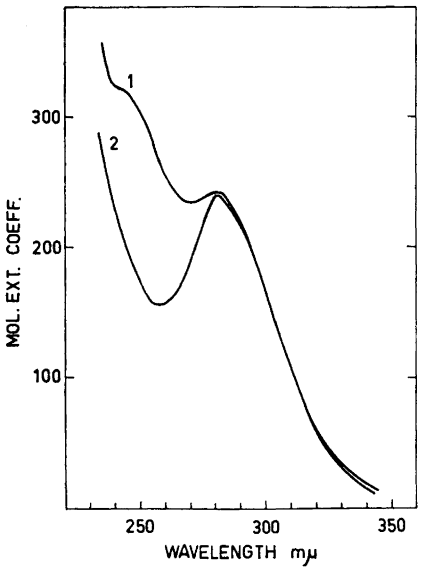

Fig. 3. UV absorption spectra of 1,2-dithiane-3-carboxylic acid: (1) in alcohol; (2) in 0.025 M KOH (solvent: alcohol).

acid (λ_{max} = 250 mμ). The spectrum of 5-methyl-1,2-dithiolane-3-carboxylic acid shows an absorption peak at 283 mμ (Fig. 2). The small bathochromic shift caused by methyl group in the latter acid will be discussed.[10]

In 6,8-thioctic acid the carboxylic group is too far away to have any influence on the -S-S-group, and the side chain therefore acts upon the disulphide group as an alkyl group, λ_{max} = 333 mμ[8]. Even if a carboxylic group is substituted in the β-position, it does not affect the disulphide group seriously. The spectrum of 5-methyl-1,2-dithiolane-3-acetic acid with an absorption maximum at 334 mμ, makes this clear (Fig. 2). The recently prepared 1,2-dithiolane-3-acetic acid also has an absorption maximum at the same wavelengths as 6,8-thioctic acid[11]. Schotte has shown that a carboxylic group in the 4-position, as well as other groups situated there, has no effect on the characteristic absorption peak of the five-membered ring[12,13]; *cf.* also Schotte.[14]

Fredga has prepared 1,2-dithiane-3,6-dicarboxylic acid[15,16], and Schotte has recorded its UV spectrum[9]. The carboxylic group shifts the absorption maximum to shorter wavelengths, but because the disulphide peak is so close to the absorption band at about 200 mμ the spectrum becomes nearly continuous above 200 mμ where the readings were made. 1,2-Dithiane-3-carboxylic acid has now been prepared. As could be expected, the hypsochromic shift of λ_{max} was here smaller. The spectrum is shown in Fig. 3. The inflexion at about 245 mμ corresponds to the 280 mμ maximum of 1,2-dithiolane-3-carboxylic acid, and the peak at 282 mμ corresponds to the absorption at 333 mμ in the dithiolane analogue. On the other hand, 1,2-dithiane-4-carboxylic acid gives nearly the same absorption band as the unsubstituted ring and 1,2-dithiane-3-butyric acid (5,8-thioctic acid)[17].

Figs. 1 and 2 show that the alkali salts of the two acids have absorption curves which are quite different in character from those of the free acids. The peaks attributed to the usual disulphide band have disappeared, but the lower intensity bands at longer wavelengths remain.

Thus it is clear from the spectra that 1,2-dithiolane-3-carboxylic acid and 1,2-dithiane-3-carboxylic acid show two maxima in the actual region for the disulphide absorption, and one of these maxima disappears when the acid is converted to its ionized form. Schotte has found that the absorption curves for 1,2-dithiolane-3,5-dicarboxylic acid and some other acids changed character in alkaline solution[9], but he did not obtain the pronounced maxima seen in Figs. 1 and 3. Such a split of the disulphide absorption band has not been previously reported in the literature. These double absorption bands may be explained by the assumption that the two sulphur atoms in the disulphide group need not be regarded as

Acid	M.p.	*Found* S	*Found* Eq.wt.	*Calc.* S	*Calc.* Eq.wt.
1,2-Dithiolane-3-carboxylic	81—82° *	42.61	150.6	42.69	150.2
5-Methyl-1,2-dithiolane-3-carboxylic	77—79°	39.14	164.7	39.05	164.3
5-Methyl-1,2-dithiolane-3-acetic	83—86.5°	35.67	177.8	35.97	178.3
1,2-Dithiane-3-carboxylic	75—76°	39.09	165.0	39.05	164.3

* This acid polymerizes easily and the polymer melts at about 147°.

a unit. In ultraviolet absorption the exited electron may originate from either of the two sulphur atoms, and in an electrically asymmetrical disulphide there must be two separate exitation energies for electrons from the two different sulphur atoms, resulting in two UV absorption bands.

Experimental. A Beckman model DU photoelectric quartz spectrophotometer equipped with a hydrogen discharge lamp was used for the ultraviolet absorption measurements.

The synthetic methods for the acids (*cf.* p. 1710) will be published later.

I wish to express my gratitude to Professor Arne Fredga for his great interest in this work and for many valuable discussions. I am also indebted to Dr. Lennart Schotte for interesting discussions.

On the Effect of Ionizing Radiations on Cyanocobalamin

MONICA SJÖSTEDT and L.-E. ERICSON

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The destruction of cyanocobalamin (vitamin B_{12}) by ionizing radiations has generally been estimated spectrophotometrically or microbiologically [1-4]. Smith [4] mentions in his recent article on the instability of radioactive vitamin B_{12} that absorption spectroscopy gives a moderately accurate measure of the residual vitamin B_{12}. He also states that a microbiological assay can be used as there is no evidence of a significant breakdown to other microbiologically active compounds. In our preliminary studies of the effect of γ-rays on cyanocobalamin we have been unable to correlate the changes in the absorption spectra with the microbiological activity of irradiated solutions of vitamin B_{12}. Moreover, evidence has been obtained for the formation of microbiologically active breakdown products.

Solutions of cyanocobalamin containing 5 mg per ml in a phosphate buffer of pH 5 were irradiated under aerobic conditions with γ-rays from a ^{60}Co source. The doses given were 2, 5 and 10 Mrad. The spectra of the irradiated and nonirradiated solutions of vitamin B_{12} were measured in a Beckman Model DU spectrophotometer. A tube assay with *Escherichia coli* 113—3 [5] was used for the microbiological tests. The assay media were those of Diding [6] and of Burkholder [7], to which 1.5 mg of KCN per l had been added. Growth was measured turbidimetrically after incubation of the tubes for 20 h at 37°C.

The spectra of the non-irradiated and of the irradiated solutions of cyanocobalamin are shown in Fig. 1. Concomitant with the decrease in the absorption maxima following irradiation, there was also a tendency for the peaks in the 360 and 550 mμ regions to shift towards lower wavelengths. Calculation of the degree of destruction by comparing the absorption at 361 mμ of irradiated and non-irradiated solutions indicated that 60 % of the vitamin originally present had been destroyed by a dose of 2 Mrad. According to the microbiological assay approximately 85 % was inactivated by this dose.

On the Effect of Ionizing Radiations on Cyanocobalamin

MONICA SJÖSTEDT and L.-E. ERICSON

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The destruction of cyanocobalamin (vitamin B_{12}) by ionizing radiations has generally been estimated spectrophotometrically or microbiologically [1-4]. Smith [4] mentions in his recent article on the instability of radioactive vitamin B_{12} that absorption spectroscopy gives a moderately accurate measure of the residual vitamin B_{12}. He also states that a microbiological assay can be used as there is no evidence of a significant breakdown to other microbiologically active compounds. In our preliminary studies of the effect of γ-rays on cyanocobalamin we have been unable to correlate the changes in the absorption spectra with the microbiological activity of irradiated solutions of vitamin B_{12}. Moreover, evidence has been obtained for the formation of microbiologically active breakdown products.

Solutions of cyanocobalamin containing 5 mg per ml in a phosphate buffer of pH 5 were irradiated under aerobic conditions with γ-rays from a ^{60}Co source. The doses given were 2, 5 and 10 Mrad. The spectra of the irradiated and nonirradiated solutions of vitamin B_{12} were measured in a Beckman Model DU spectrophotometer. A tube assay with *Escherichia coli* 113—3 [5] was used for the microbiological tests. The assay media were those of Diding [6] and of Burkholder [7], to which 1.5 mg of KCN per l had been added. Growth was measured turbidimetrically after incubation of the tubes for 20 h at 37°C.

The spectra of the non-irradiated and of the irradiated solutions of cyanocobalamin are shown in Fig. 1. Concomitant with the decrease in the absorption maxima following irradiation, there was also a tendency for the peaks in the 360 and 550 mμ regions to shift towards lower wavelengths. Calculation of the degree of destruction by comparing the absorption at 361 mμ of irradiated and non-irradiated solutions indicated that 60 % of the vitamin originally present had been destroyed by a dose of 2 Mrad. According to the microbiological assay approximately 85 % was inactivated by this dose.

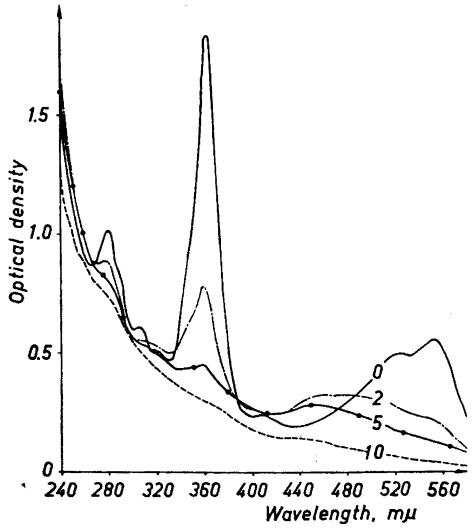

Fig. 1. Absorption spectra for solutions of non-irradiated cyanocobalamin (0), and for solutions irradiated with 2, 5 and 10 Mrad.

For the microbiological assays, series of dilutions were made of the irradiated cyanocobalamin solutions. In Fig. 2 the turbidity (optical density) of the tubes to which the solutions of irradiated vitamin B_{12} were added has been plotted against the degree of dilution. In the same figure

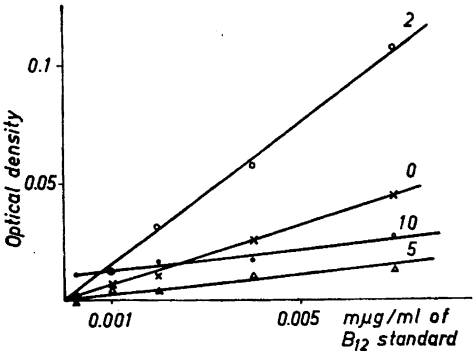

Fig. 2. The response of *E. coli* 113—3 to varying concentrations of non-irradiated cyanocobalamin (0) and to dilutions of cyanocobalamin solutions irradiated with 2, 5 and 10 Mrad.

the turbidity of the B_{12}-standards has been plotted against the concentration of the vitamin in mμg per ml. The slope of the line of the B_{12}-solution irradiated with 2 Mrad was twice as steep as that of the standard curve. The solution irradiated with 10 Mrad, however, gave a line with a slope that was less than that of the non-irradiated cyanocobalamin. As the retention of the vitamin was very low after irradiation with 10 Mrad, the latter line was obtained by adding increasing amounts of non-irradiated cyanocobalamin to the irradiated solution diluted $1:3.5 \times 10^6$. Vitamin B_{12}-solutions that had received a dose of 5 Mrad gave varying results but the dose-response line had in most cases (as in Fig. 2) a slope that was less than that for the non-irradiated vitamin. The same results were obtained irrespective of whether the simple medium of Diding or the more complex medium of Burkholder was used. If cyanocobalamin were the only microbiologically active compound remaining after irradiation one would expect the slopes of the lines to be identical.

The factor(s) responsible for the increased relative activity of the sample that had received a dose of 2 Mrad appears to be more heat labile than vitamin B_{12}.

Paper electrophoresis has revealed the presence of at least four compounds in the irradiated solutions which can support the growth of *E. coli* 113-3.

The authors would like to express their sincere thanks to Drs. P. Vidal and L. Brunelet, Conservatome, Lyon, France, for the irradiations of the solutions of cyanocobalamin. The financial support of the *Swedish Atomic Energy Commission*, the *Swedish Technical Research Council* and the *Swedish Agricultural Research Council* is also acknowledged.

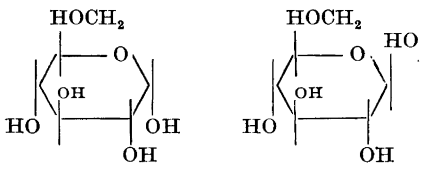
The Structure of α- and β-Glucose

ANDERS KJÆR
Den kgl. Veterinær- og Landbohøjskoles organisk-kemiske laboratorium, Copenhagen, Denmark

BENGT LINDBERG
Institutionen för träkemi, Kungl. Tekniska Högskolan, and Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

The structures (I) and (II) are generally accepted for α- and β-D-glucose, respectively, on basis of chemical evidence (*cf. e.g.* Ref.[1]). In the energetically favoured chair form the hydroxyl group at $C_{(1)}$ assumes an axial orientation in (I), and an equatorial position in (II). This picture has been conclusively confirmed by complete X-ray structure determination of α-D-glucose [2]. A similar approach places the generally accepted structure of sucrose, representative of the α-D-glucopyranosides, beyond dispute [3]. Furthermore, the studies by Lemieux *et al.*[4] of proton magnetic resonance spectra of various pyranosides are entirely consistent with the commonly accepted structures.



I II

It hence appears surprising that Blom, in a recent communication to this journal [5], maintains the opposite view, that in the stable chair conformation the anomeric hydroxyl group assumes an equatorial orientation in α-D-glucose and α-D-galactose, and axial positions in the β-anomers. Without invalidating the evidence for the generally accepted structures, Blom presents four arguments in support of his revised formulation with its far-reaching consequences.

It is the purpose of the present communication to redress these arguments as either irrelevant or erroneous.

1. *Melting points.* Regarding a possible relationship between melting points and molecular structures in the penta- and hexa-substituted *cyclo*hexane series, Blom [5] states: "eine Verbindung mit einer höheren Anzahl von *para-trans*-Substituenten hat einen höheren Schmelzpunkt als die isomere Verbindung mit einer geringeren Anzahl".* This is definitely not the case. For example, *cis*-inositol, the sole stereoisomeride with no 1,4-*trans*-pair, melts higher (390° (corr.)) than any other inositol [6].

Blom extends the above "rule" to include the tetrahydropyran ring system and concludes, on basis of m. p. data for anomeric methyl and ethyl pyranosides of D-glucose and D-galactose, that the α-anomers contain an equatorial and the β-anomers an axial hydroxyl-group at $C_{(1)}$, contrary to the generally accepted structures. Unfortunately, crystalline preparations of both anomers of the methyl (and ethyl) D-aldohexopyranosides have, thus far, been recorded for only three (glucose, galactose and mannose) of the eight isomeric D-aldohexoses. However, closely analogous examples may serve to discredit Blom's suggestions. Thus, methyl β-D-xylopyranoside melts at 156—157°, the α-anomer at 91—92°, whereas the closely related methyl α-D-glucopyranoside melts at 166°, *i. e.* higher than the β-anomer (m. p. 105°).

Melting points are of course dependent upon crystal properties which are again complicated functions of molecular structure. Hence, the utmost caution is urged in all attempts to attribute structural significance to melting point data, not least where strongly hydrogen-bonded molecules are involved as in the present case.

2. *Molecular rotations.* As support for his structural revision, Blom [5] quotes certain observed regularities between the molecular rotations of various cyclitols and formally similar glycosides. For the sake of clarity, some of Blom's examples are presented in Table 1, together with additional data pertinent for the following discussion.

On basis of the molecular rotations of the first three pairs of compounds, Blom concludes that introduction at $C_{(2)}$, in a $C_{(2)}$-

* This "rule" is presented as an extension of melting point regularities within the series of acyclic, unsaturated *cis-trans*-isomerides. It should be pointed out, however, that several examples are known of *cis*-compounds melting higher than the corresponding *trans*-isomerides within this class of compounds.

Table 1[a].

Cyclitol	Structure	Classification of substituents	M_D	Methyl Glycoside	Structure	Classification of substituents	M_D
Myo-inositol		*aeeeee*	0	α-D-Gluco-side		*aeeee*0	+309
L-Inositol		*aaeeee*	−117	α-D-Manno-side		*aaeee*0	+154
Myo-2-deoxy-inositol		*aCeeee*	−81	α-2-Deoxy-D-glucoside		*aCeee*O	+246
Myo-6-deoxy-inositol [b]		*aeeee*C	+81	α-D-Gluco-side		*aeeee*O	+309
Deoxy-scyllitol		*eeeee*C	0	β-D-Gluco-side		*eeeee*O	− 66

[a] Blom's nomenclature is employed but the generally accepted structures for the α- and β-glycosides are retained. In the schematic formulae no distinction is made between OH-, CH_2OH- and OCH_3-groupings.

[b] This compound is the antipode of myo-2-deoxy-inositol.

deoxy ring compound, of an equatorial hydroxyl group results in a shift to more positive values, whereas introduction of an axial substituent in the same position is accompanied by a change in rotation to more negative values. This rule is then extended to the anomeric $C_{(1)}$-carbon and used as an argument for reversing the generally accepted formulae for α- and β-glucose.

It should be borne in mind, however, that contributions from individual asymmetric centers to the total optical rotations are not additive. Accordingly, the $C_{(2)}$-rule may very well fail when the configuration of one of the asymmetric carbon atoms is changed. Extrapolation of the rule to include $C_{(1)}$-substituents is definitely impermissible. For example, the two last examples in Table 1 indicate that, by analogous reasoning, axial substitution at $C_{(1)}$ results in more positive rotations than introduction of the same substituent in an equatorial orientation, opposite to Blom's claim. It should be emphasized, however, that the last example is not regarded as support for the accepted structures of anomeric D-glucoses, but merely as a means of disproving the validity of Blom's argumentation.

3. *Oxidation.* It is generally agreed that, within the cyclitol series, axially located hydroxyl groups are preferentially oxidized. Again, it appears a well-established fact that β-glucose is oxidized at a higher rate than the anomeric α-glucose. Blom [5] seeks support for the proposed structural revision in these facts, apparently disregarding the semiacetalic character of the anomeric hydroxyl group in the pyranose system which may conceivably render the validity of such comparions more than questionable. Thus, both anomers of galactose, possessing an axial group at $C_{(4)}$, are oxidized more readily at $C_{(1)}$ than at $C_{(4)}$. A completely satisfactory interpretation of the different oxidation rates of pyranose anomers, as well as the structur-

ally analogous cyclitols, has yet to be given, but there is evidence to indicate that different reaction mechanisms may be involved in the two ring systems (*cf. e. g.* Ref.[7]).

The frequently observed enzymic catalysis of reactions different from those favoured in non-enzymic systems renders Blom's reference to the biological glucose oxidation irrelevant in the present context.

4. *1,2-Anhydro-sugars.* Blom's argumentation on basis of the ring-opening reactions of Briegl's anhydride reflects a fatal negligence of the current, well-established stereochemical course of such reactions (*cf. e. g.* Ref.[8]) and, therefore, requires no further discussion here. In fact, the conversion of such epoxides into glycosides affords about the best chemical evidence for the correctness of the generally accepted structures.

In conclusion, the character and validity of the argumentation by Blom, balanced against the bulk of evidence in favour of the commonly accepted structures for α- and β-glucose, is insufficient to warrant any revision of the latter.

The Synthesis of 4,4,7,7-Tetrabenzyl-1,2,3,5,6-pentathiepane

BENGT MAGNUSSON

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

In connection with work on duplodithioketones [1,2], attempts have been made to prepare these by oxidation of *gem.*dithiols. These attempts were not successful. Methanedithiol gave only polymers even when the oxidation was carried out with air in high dilution at low temperature and in the presence of ferric chloride [3].

The products obtained by oxidation of *gem.*dithiols with iodine do not seem to be duplodithioketones [4].

The synthesis of a crystalline *gem.*dithiol, 1,3-diphenyl-2,2-dimercaptopropane, has recently been reported [5]. Attempts to oxidize it to a duplodithioketone was carried out by the autor, but the appropriate conditions have not yet been found. When the dithiol was treated with ammonium-polysulphide, 4,4,7,7-tetrabenzyl-1,2,3,5,6-pentathiepane (I) was obtained in 49 % yield. m.p. 130–131.5°C. (Found: C 65.52, 66.01; H 5.12, 4,96; S 29.09, 29.08; Mol.wt. 542, 550. Calc. for $C_{30}H_{28}S_5$: C 65.65; H 5.14; S 29.21; Mol.wt. 548.8.)

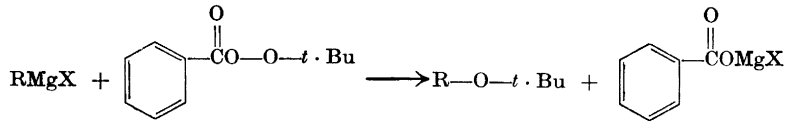
Studies of Peroxycompounds II. * The Preparation of Diethyl-*t*-butoxy-malonate and Ethyl-*t*-butoxy-acetoacetate

SVEN-OLOV LAWESSON and CURT BERGLUND

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

In the first paper of this series [1] a new method of preparing *t*-butylethers was described:



(1)

The reaction is very smooth and gives excellent yields in general, and seems further, at least in the laboratory scale, to be the best method to prepare aromatic *t*-butylethers.

It was then felt that a perester might react with sodium compounds of diethylmalonate or ethyl acetoacetate for instance. Earlier, Milas *et al.*[2] reacted *t*-butylperbenzoate with sodium methoxide in excess of methanol and obtained methylbenzoate and the sodium salt of *t*-butylhydroperoxide. In analogy with eqn. 1. the —O—O- bond could be split by certain types of organosodium compounds in inert solvents and an ether group introduced. We have now managed to introduce the *t*-butoxygroup into diethyl malonate and ethyl acetoacetate *via* the corresponding sodium compound. The perester used was *t*-butylperacetate, as the perbenzoate was difficult to separate from the new alkoxy-compound.

Experimentally the sodium compound was made in benzene from sodium hydride and the corresponding ester and to the preheated mixture *t*-butylperacetate was added dropwise. The reaction was exothermic but after the heat evolution ceased, the reaction flask was heated for some time. Diethyl-*t*-butoxy-malonate was isolated in a yield of 27 % (C 56.93; H 8.78. Calc. C 56.88; H 8.68) and the corresponding barbituric acid, m. p. 187—189°C, was also prepared (C 47,96; H 6.04. Calc. C 47,99; H 6.04). The sedative effect of the barbiturate was tested and found to be negligible. Compare the similar neopentylbarbituric acid prepared by Brändström [3]. Ethyl-*t*-butoxy-acetoacetate (C 59.47; H 8.85. Calc. C 59.38; H 8.97) was prepared in a similar way in a yield of 31 %.

Further research is planned in this field especially with peresters derived from stronger acids. Acknowledgement is expressed to *The Swedish Natural Science Research Council* for a grant and to Dr. R. Dahlbom *(AB Astra)* for the physiological test.

Studies of Peroxycompounds III. The Introduction of the Benzoyloxygroup into Diethylmalonate

SVEN-OLOV LAWESSON and TAMARA BUSCH

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

In the reaction between *t*-butylperbenzoate and a Grignard reagent the O—O-bond is easily split and the corresponding *t*-butylether is formed [1]. Also in the case of benzoylperoxide [1] the O—O-bond is first attacked by a Grignard reagent but here the mechanism is probably not yet quite understood. When a *t*-butyl perester was treated with the sodium compound of diethylmalonate or ethyl acetoacetate [2] a very sluggish reaction took place and the *t*-butoxygroup was introduced into the corresponding esters, although in low yields. It was then quite natural to investigate the reaction between benzoyl-

peroxide and sodium salts of malonic ester derivatives. In that case it was found that in inert solvents the O—O-bond was split with ease and the benzoyloxy group introduced into the malonic ester derivatives in good yields. The new products were then also characterized by hydrolyzing them to tartronic acids.

As a full paper will soon be submitted for publication in this Journal we include here only one experiment. Additional work is under way to test more fully this reaction especially with derivatives of ethyl cyanoacetate [3], malononitrile [3], β-diketones [4], β-ketoesters [5] and other active methylene compounds.

Experimental. The sodium compound of diethyl ethylmalonate was prepared from 2.4 g of NaH and 18.8 g of diethyl ethylmalonate in 150 ml of dry benzene. Then 18 g of benzoylperoxide in 150—200 ml of dry benzene was added to the sodium compound, cooled in an ice-water bath. After standing over night the reaction mixture was worked up in the usual way. Distillation gave diethyl O-benzoylethyltartronate with b. p. 137°/0.15 mm Hg. Yield 75 % n_D^{20} 1.4890. (Found: C 62.23; H 6.50. Calc for $C_{16}H_{20}O_6$: C 62.32; H 6.54.)

The investigation has been partly supported by a grant from *The Swedish Natural Science Research Council*, which is gratefully acknowledged.

Tetrahydrofuran as a New Solvent in Condensation Reactions

SVEN-OLOV LAWESSON and TAMARA BUSCH

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

Inspired by the work of H. Normant *et al.*[1,2] who succeded in preparing Grignard reagents from aryl chlorides and vinyl halides by running the reaction in tetrahydrofuran (THF) we have just began to study the usefulness of this solvent in certain condensation reactions. We now want to report very shortly some of our preliminary results. A full paper will be published at a later date.

It is known that potassium or sodium salts (enolates) of active methylene compounds in general are insoluble in such inert solvents as benzene, toluene, xylene, *etc.* Under these conditions further reactions are often very sluggish because of the inhomogeneous system. As magnesium ethoxide is soluble in inert solvents Lund's well-known method [3] offers some advantage in this case. An excellent review [4] has recently been published on this subject concerning these matters.

We have found that diethyl malonate reacts very vigorously with sodium hydride in THF and the corresponding sodium compound formed is completely soluble. Reactive halogen compounds as benzoylchloride, acetylchloride and ethylchloroformate react instantaneously and give diethyl benzoylmalonate, diethyl acetylmalonate and tricarbetoxymethane, respectively, in excellent yields. In the same way ethyl acetoacetate whose sodium compound is also soluble in THF, gives ethyl 2-benzoylacetoacetate and diethyl acetylsuccinate when treated with benzoylchloride and ethyl bromoacetate, respectively. The yields were in all cases higher than 70 % although we have not attempted to work out the conditions for maximum yields.

Experimental. All experiments were carried out in nitrogen atmosphere and in the usual type of apparatus. Preparation of diethyl benzoylmalonate may be taken as a typical example.

To sodium hydride (0.2 mole) covered with 200 ml of THF, was added 0.21 mole of diethylmalonate. In less than one hour the evolution of hydrogen had ceased and a clear solution was formed. The flask was cooled in ice-water and then 0.2 mole of redistilled benzoyl chloride was added all at once. Stirring was continued for another 5—10 min and then the mixture was poured into water and acidified. The aqueous solution was separated and extracted twice with ether. The organic layers were combined and washed with sodium bicarbonate solution and then with water, and finally dried over sodium sulphate. Distillation gave the main fraction at a b.p. of 137°C/0.5 mm Hg. Yield 72 %.

Preparation and Properties of Glucoconringiin, the Precursor of the Thyreostatic 5,5-Dimethyl-2-Oxazolidinethione

ROLF GMELIN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The mustard oil glucoside glucoconringiin is present according to Kjær *et al.*[1] in several *Cochlearia* spec. which are rather common in the Finnish flora. In the course of investigations with goitrogens in plants it seemed therefore of interest to isolate this glucosidic precursor of the thyreostatic and probably also goitrogenic 5,5-dimethyl-2-oxazolidinethione.

Some years ago Kjær *et al.*[1] and Schultz and Wagner [2] prepared and characterized glucoconringiin as its tetraacetyl derivative from seeds of *Conringia orientalis* (L.) Andrz. and showed that the deacetylated glucoside which they obtained in amorphous form is split by myrosinase into sulphate, glucose and 5,5-dimethyl-2-oxazolidinethione. This heterocyclic compound, isolated and identified by Hopkins [3] twenty years ago from *C. orientalis* seeds, is formed by spontaneous cyclization from an intermediate 2-hydroxy-2-methylpropyl *iso*thiocyanate. Its thyreostatic effect was established by Astwood *et al.*[4] and was found comparable to that of (−)-5-vinyl-2-oxazolidinethione (goitrin).

The purpose of this paper is to report briefly the method for preparation and some properties of crystalline glucoconringiin, which unlike its tetraacetyl derivative has the advantage of being split readily by myrosinase and is therefore more suitable for physiological investigations.

Glucoconringiin was prepared by ion exchange on Dowex 2-X 4 of an extract from seeds of *Conringia orientalis* (L.) Andrz. Upon elution with K_2SO_4 solution it was obtained as a colourless syrup which crystallized upon long standing in the refrigerator. Two recrystallizations from 90 % ethanol yielded pure glucoconringiin as anhydrous potassium salt in white, short needles. Elementary analysis agreed with the composition $C_{11}H_{20}NO_{10}S_2K$. F 168°C (decomp., uncorr.), $[\alpha]_D^{21}$ −10.87° in H_2O). In agreement with earlier results [1,2] the formation of glucose, sulfate and 5,5-dimethyl-2-oxazolidinethione could be observed during enzymatic cleavage. The enzymatic process could be followed by UV spectroscopy: with increasing cleavage the maximum absorbance shifts from 230.5 mμ to 240 mμ (ε = 15 400), the maximum of 5,5-dimethyl-2-oxazolidinethione.

Spectrophotometric assay of the enzymatic cleavage of glucoconringiin: 0.0155 g of glucoconringiin was dissolved in 2 ml of a mixture of equal parts of myrosinase solution and phosphate buffer pH 6.8. In certain intervals 0.1 ml portions were taken off, diluted to 50 ml with water and the UV absorption measured between 220 mμ and 260 mμ against an equal blank dilution of myrosinase solution and phosphate buffer solution.

Preparation and Properties of Glucoconringiin, the Precursor of the Thyreostatic 5,5-Dimethyl-2-Oxazolidinethione

ROLF GMELIN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The mustard oil glucoside glucoconringiin is present according to Kjær *et al.*[1] in several *Cochlearia* spec. which are rather common in the Finnish flora. In the course of investigations with goitrogens in plants it seemed therefore of interest to isolate this glucosidic precursor of the thyreostatic and probably also goitrogenic 5,5-dimethyl-2-oxazolidinethione.

Some years ago Kjær *et al.*[1] and Schultz and Wagner [2] prepared and characterized glucoconringiin as its tetraacetyl derivative from seeds of *Conringia orientalis* (L.) Andrz. and showed that the deacetylated glucoside which they obtained in amorphous form is split by myrosinase into sulphate, glucose and 5,5-dimethyl-2-oxazolidinethione. This heterocyclic compound, isolated and identified by Hopkins [3] twenty years ago from *C. orientalis* seeds, is formed by spontaneous cyclization from an intermediate 2-hydroxy-2-methylpropyl *iso*thiocyanate. Its thyreostatic effect was established by Astwood *et al.*[4] and was found comparable to that of (−)-5-vinyl-2-oxazolidinethione (goitrin).

The purpose of this paper is to report briefly the method for preparation and some properties of crystalline glucoconringiin, which unlike its tetraacetyl derivative has the advantage of being split readily by myrosinase and is therefore more suitable for physiological investigations.

Glucoconringiin was prepared by ion exchange on Dowex 2-X 4 of an extract from seeds of *Conringia orientalis* (L.) Andrz. Upon elution with K_2SO_4 solution it was obtained as a colourless syrup which crystallized upon long standing in the refrigerator. Two recrystallizations from 90 % ethanol yielded pure glucoconringiin as anhydrous potassium salt in white, short needles. Elementary analysis agreed with the composition $C_{11}H_{20}NO_{10}S_2K$. F 168°C (decomp., uncorr.), $[\alpha]_D^{21}$ −10.87° in H_2O). In agreement with earlier results [1,2] the formation of glucose, sulfate and 5,5-dimethyl-2-oxazolidinethione could be observed during enzymatic cleavage. The enzymatic process could be followed by UV spectroscopy: with increasing cleavage the maximum absorbance shifts from 230.5 mμ to 240 mμ (ε = 15 400), the maximum of 5,5-dimethyl-2-oxazolidinethione.

Spectrophotometric assay of the enzymatic cleavage of glucoconringiin: 0.0155 g of glucoconringiin was dissolved in 2 ml of a mixture of equal parts of myrosinase solution and phosphate buffer pH 6.8. In certain intervals 0.1 ml portions were taken off, diluted to 50 ml with water and the UV absorption measured between 220 mμ and 260 mμ against an equal blank dilution of myrosinase solution and phosphate buffer solution.

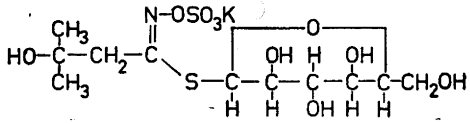
* based on the initial substrate concentration.

By treatment of glucoconringiin with hydrochloric acid hydroxylamine was formed which was detected by the method of Blom [5]. These results indicate that glucoconringiin is of the same structural type as the other known mustard oil glucosides [6], and has the following structure (p. 1719).

85 g of finely ground seeds of *Conringia orientalis* (L.) Andrz. were defatted by petro-



leum ether and extracted with two 1 l portions of 70 % methanol. The combined extracts were concentrated *in vacuo* to 300 ml and treated with a solution of lead acetate in order to precipitate undesired plant material. After separation of Pb-ions by H_2S the straw yellow filtrate was shortly boiled *in vacuo* until all H_2S had disappeared. The solution was filtered through a short column with 5 g of Al_2O_3 Merck and was then passed slowly through a column containing 10 ml Dowex 2-X 4 (chloride-form, 200 mesh). The effluent was free of glucoside and was discarded. After washing the resin with 200 ml of water the glucoside was eluted by 0.1 N K_2SO_4 solution. Fractions of 20 ml each were collected. The fractions 3—18 containing glucoconringiin as determined by the anthrone method and myrosinase test were brought to dryness *in vacuo*. The white residue was triturated with 3 portions of 30 ml CH_3OH at 40—50°C. The filtered methanolic solution left after evaporation *in vacuo* a colourless syrup which was dissolved in a small volume of hot 90 % ethanol. After cooling the glucoside separated partly as a viscous oil which crystallized after standing several weeks in the refrigerator. Two recrystallizations from 90 % ethanol yielded 585 mg glucoconringiin in short, white needles. F 168°C (decomp., uncorr.) $[\alpha]_D^{21}$ −10.87° (c = 3.68; in water). UV-maximum in H_2O 230.5 mμ (ε = 6 720), minimum 208 mμ (ε = 3 750). (Found: C 30.81; H 4.55; N 3.52; S 14.93. Calc. for $C_{11}H_{20}NO_{10}S_2K$ (429.51): C 30.75; H 4.69; N 3.27; S 14.93.)

The identification of the products formed by enzymatic cleavage was performed in the same way as described by Kjær *et al.*[1] for the crude glucoconringiin obtained from tetraacetylglucoconringiin. From 300 ml of glucoconringiin 82 mg of crude 5,5-dimethyl-2-oxazolidinethione were obtained which gave after two recrystallizations from benzene 32 mg of pure 5,5-dimethyl-2-oxazolidinethione, melting at 107°C alone or in mixture with a synthetic sample. Glucose was determined by paper chromatography in three solvent systems; sulfate was determined as $BaSO_4$.

For the detection of hydroxylamine as a product of hydrolysis with strong acids 10 mg of glucoconringiin were dissolved in 1 ml conc. hydrochloric acid and the solution was brought to dryness on the waterbath. The residue was taken up in 2 ml of water. After addition of about 200 mg of Na acetate the solution was further treated according to the procedure described by Blom [5].

This investigation is a part of a research project under U.S. Public Law No. 480, 83rd Congress.

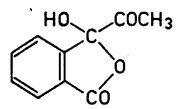
2′,5′-Dihydroxyterphenyl-2,2″-dicarboxylic Acid Dilactone

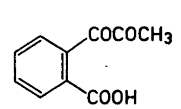
ERLING BERNATEK

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Ozonolysis of 2-methylnaphthoquinone yields methylphenylglyoxal-*o*-carboxylic acid which has a cyclic lactol structure (I) rather than the free carboxyl structure (II) [1].



I



II

By briefly heating an alkaline solution of the acid a condensation product $C_{20}H_{10}O_4$ was formed in low yield. This product was sparingly soluble in most organic solvents and the melting point was very high (420—422°) without noticeable decomposition. Dissolution could be effected by ethanolic but not aqueous sodium hydroxide and

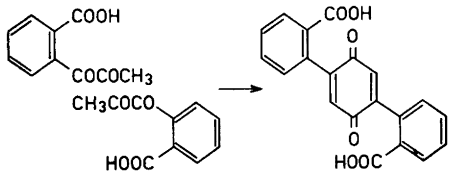
$C_{20}H_{10}O_4$ was precipitated unchanged after acidification. In concentrated sulphuric acid the substance dissolved easily with an intense light blue fluorescence.

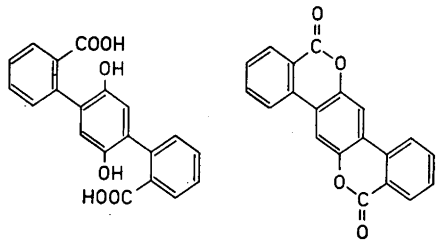
It is believed that $C_{20}H_{10}O_4$ is formed by condensation of two molecules of methylphenylglyoxal-*o*-carboxylic acid in the following way (writing the reactant in the open form for the sake of simplicity):



III

This is in close analogy to the condensation of methylphenylglyoxal in alkaline medium to 2,5-diphenylbenzoquinone [2].

In the hot alkaline medium some of the quinone III probably disproportionates giving the corresponding quinol (IV): 2′, 5′ - dihydroxyterphenyl - 2,2″ - dicarboxylic acid. On acidification this hydroxyacid is not stable, but lactonises immediately to $C_{20}H_{10}O_4$ (V).



IV *V*

The highly symmetrical structure for the condensation product is in accord with the high melting point and the low solubility of the substance. Further support comes from the spectroscopic data: A strong carbonyl band appears at 1 735 cm^{-1} which is in the lower part of the region for δ-lactones and consistent with the conjugation of the carbonyl groups with an aromatic nucleus. Aromatic absorption occurs strongly at 1 607 cm^{-1} and weakly at 1 582 cm^{-1}. The latter band must be due to the conjugated rings and is recognisable because of intensification by conjugation with carbonyl groups. Absorptions at 866 cm^{-1} and 767 cm^{-1} are probably caused by 1,2,4,5-tetrasubstitution and 1,2-disubstitution, respectively.

Our conclusion regarding the structure of $C_{20}H_{10}O_4$ is excellently borne out by X-ray crystallographic investigations [3].

Experimental. In the first experiments methylphenylglyoxal-*o*-carboxylic acid was isolated and purified before the alkali treatment. Later it was found more convenient to use directly the product from the ozonolysis in the following way:

2-Methylnaphthoquinone (5 g) in chloroform (150 ml) was ozonised at −5° until the solution became colourless. The ozonised solution was shaken with water (50 ml) and left overnight. Next day the chloroform was evaporated on a water-bath and the resulting aqueous solution filtered. To this was added aqueous sodium hydroxide (50 ml, 2 N) and the mixture boiled for a couple of minutes. In order to avoid deposition of tarry matter the alkaline solution was diluted with an equal volume of ethanol and thereafter acidified with 2 N hydrochloric acid. The dark red solution became yellow and a silky precipitate of fine needles separated (230 mg). The filtrate was made alkaline again (appr. 2 N) by the addition of solid sodium hydroxide and heated on the waterbath for 30 min. After addition of more ethanol and acidification an additional crop of needles (84 mg) was obtained. Recrystallisation was achieved with relatively large amounts of boiling glacial acetic acid. M. p. 420—422°, no decomp., crystallising again and giving the same m. p. (Found: C 76.4; H 3.3. Calc. for $C_{20}H_{10}O_4$: C 76.4; H 3.2.) The density was determined by the flotation method in mixtures of carbon tetrachloride and chloroform: $1.54 > d_{20} > 1.52$. Crystals large enough for this determination were obtained by recrystallisation from nitrobenzene.

The infrared solid-state spectra were recorded in Nujol-mull and KBr-discs with a Perkin-Elmer double beam spectrograph.

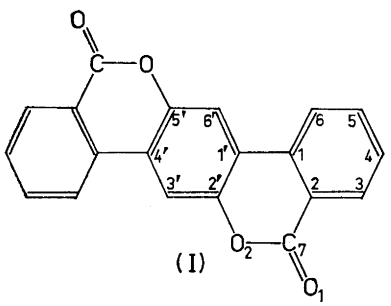
The Crystal and Molecular Structure of 2′,5′-Dihydroxyterphenyl-2,2″-dicarboxylic Acid Dilactone

BJÖRN PEDERSEN

Kjemisk institutt, Universitetet i Oslo, Blindern, Norway

As shown by Bernatek [1] the compound, $C_{18}H_{10}O_4$, formed by briefly heating an alkaline solution of methylphenylglyoxal-*o*-carboxylic acid probably is 2′,5′-dihydroxyterphenyl-2,2″-dicarboxylic acid dilactone (I).



(I)

To get further support for the assumed formula an X-ray crystallographic study of the compound was undertaken. The crystals, recrystallised from nitrobenzene, were long, very thin needles. Oscillation and Weissenberg photographs taken with Cu*K*-radiation (λ = 1.540 Å) showed the crystals to be monoclinic with

$$a = 3.82 \text{ Å} \quad b = 14.11 \text{ Å} \quad c = 12.54 \text{ Å}$$
$$\beta = 94.0°$$

The needle axis of the crystals is parallel to the *a*-axis. Systematic absences. *h0l* when *l* is odd, *0k0* when *k* is odd. This unambiguously determines the space group as No. 14, $P2_1/c$. The observed density [1], 1.53 g/cm³, indicates the presence of two formula units in the unit cell (d_{calc} = 1.55 g/cm³). The space group symmetry requires that the molecule possesses a centre of symmetry. Furthermore the short *a*-axis shows that the molecule is nearly planar (van der Waals thickness of an aromatic nucleus is 3.70 Å [2]). All this fully supports the formula (I).

The molecule must consequently lie in the unit cell nearly parallel to the *a* plane with its centre of symmetry in the origin. The only parameter left to determine before the molecule is located completely in the unit cell is therefore the angle the molecule is turned out from the *b* or *c*-axis. Due to these simplifying features of the crystal structure a quantitative investigation of the [100]-projection could be carried out. The intensities of the *0kl*-reflexions (109 out of 258 theoretically accessible) were measured with a photometer from integrated Weissenberg photographs taken with Cu*K*-radiation. The intensities were corrected for Lorentz and polarisation effects but not for absorption and extinction. On the basis of the corrected $F(0kl)$ [2]-values a Patterson map was worked out. The map showed a marked peak near the origin, at $v = 0.131$, $w = 0.123$, which probably is due to the intramolecular vector between O_1 and O_2 and coinciding O—C and C—C vectors. This reduces the possible ways of placing the molecule in the projection to two: the benzene ring 1—6 may either be placed near the *b*- or the *c*′-axis. But as $|F(021)|$ is very large and almost twice $|F(012)|$ the benzene ring must be placed near the *c*′-axis. A set of signs were calculated on the basis of a planar molecule analogous to (I) with all atoms equal and all nearest neighbour distances

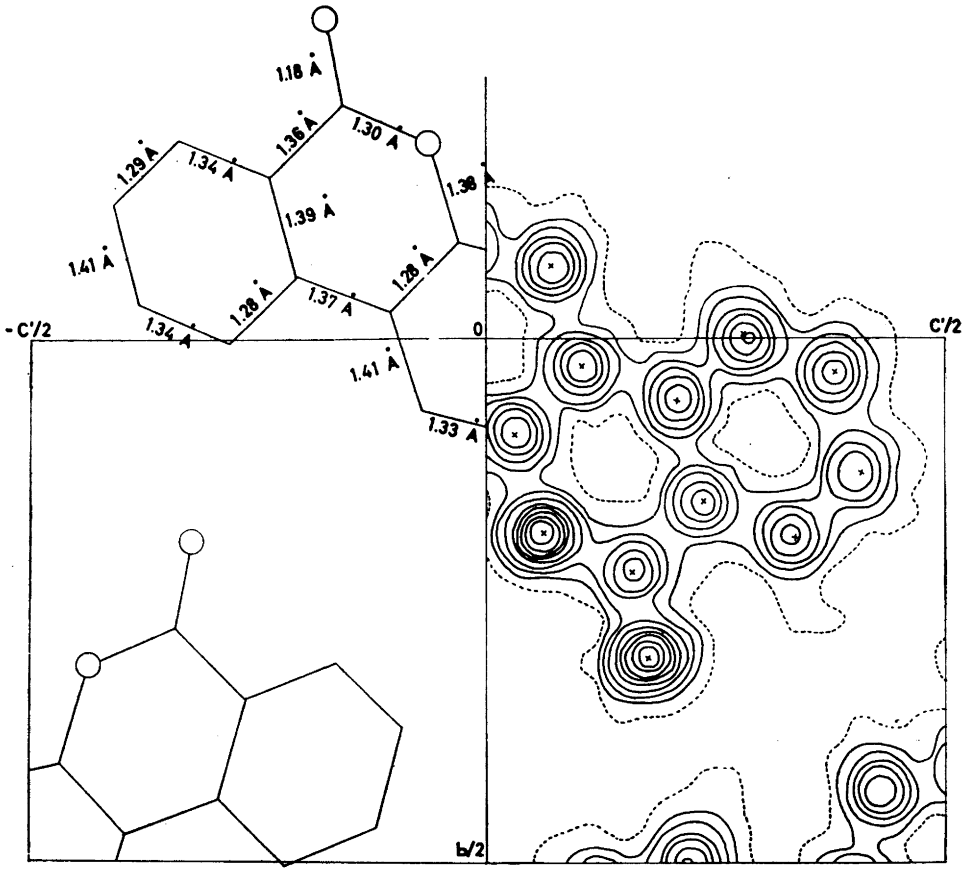

Fig. 1. *a*-Axis Fourier projection of $C_{20}H_{10}O_4$ with the found interatomic distances in the projection. Contours at intervals of 1 eÅ^{-2} with the 1 eÅ^{-2}-line broken.

equal to 1.40 Å in this position. A Fourier projection was evaluated, and this clearly showed all the atoms well resolved with the electron density in the oxygen positions distinctly higher than in the rest of the atomic positions. The atomic coordinates which were derived from the Fourier projection, were refined by the method of least squares on the Ferranti Mercury computer "Fredric" at the Norwegian Defence Research Establishment. The refinement was terminated after five cycles. The final coordinates and individual temperature factors, B, are given in Table 1. The reliability index, R, is 0.092 (unobserved reflexions not included).

The found interatomic distances in the projection are given in Fig. 1 together with the final Fourier map. The figure shows that the molecule is tilted somewhat out of the [100]-projection plane. The found projected bond distances indicate that the terphenyl part of the molecule is planar or nearly so with the carbonyl oxygen and lactone oxygen a little twisted out on each side of this plane. From such a model of the molecule and an assumed C—C distance in the terphenyl part of 1.40 Å the true C_2-C_7 and $C_1-C_{1'}$ distance are calculated as 1.48 Å and 1.43 Å, respectively. The former of these is in good agreement with what is found [3] for the corre-

sponding distance in benzoic acid, 1.48 Å. The Fourier map in Fig. 1 shows that the electron density in the carbon positions decreases with the distance from the origin, *i. e.* the centre of symmetry of the molecule. The temperature factors, B, increase in the same order. This is in accordance with what is found in other planar centrosymmetric molecules as naphthalene [4] and anthracene [5] and is due to the rigid-body vibrations of the molecules [6]. — The molecular packing is similar to the arrangement found in 1,2,5,6-dibenzanthracene [7].

The Fatty Acid Composition of Shea Butter and Olive Kernel Oil

AAGE JART

Danish Fat Research Institute, Copenhagen, Denmark

Shea butter. Shea butter (or karite butter) comes from the seeds of *Butyrospermum Parkii* of the family *Sapotaceae*. After the second world war shea nuts have been imported into Europe on a relatively small scale, but in Denmark the oil is used in appreciable quantities for certain types of margarines. It would therefore be of interest to know the composition of the fatty acids of this oil and especially the content of essential fatty acids.

For the present investigation shea nuts from West Africa were used. The fat in the nuts was isolated and analyzed, *i. a.* by alkali isomerization [1] and — in the form of methyl esters — by quantitative gas-liquid chromatography [2]. The chromatograph used was supplied by Griffin & George and had a 0.9 m column (25 % silicone grease on 40—60 mesh Firebrick). The temperature of the column was 215°C, the outlet pressure 1 atm, the katharometer current 100 mA, and the carrier gas used was helium (1.0 l/h). Using a speed of the recorder paper of 6 inches/h, the quantity M (in μl) of the individual components of the methyl ester mixture could be determined from the area A (in cm²) lying under the corresponding peaks in the chromatogram by applying the following formula (which has been derived by calibrating the apparatus by means of pure fatty acid methyl esters):

$$M_i = \log_{10}^{-1} (0.889 \times \log_{10} (A_i) - 0.058)$$

The calculated fatty acid composition (in weight per cent of the fatty acid mixture) and other results obtained from the analyses of the shea butter appear from Table 1; the content of oleic acid is found by determining the iodine value, while the stearic acid percentage is obtained as a difference. The results are in good agreement with those published in earlier works [3,4].

Olive kernel oil. Olive oil is obtained from the fruits of *Olea europea* which belongs to the family *Oleaceae*. The olive kernel contains about 1 % of the total amount of oil in the olive. Olive oil usually contains the kernel oil, as the olive stones are generally crushed during the milling procedure to which the olives are subjected in the factories. As adequate information concerning the linoleic acid content of olive kernel oil was not available from the literature, an investigation of this oil has been carried out.

The fatty acid composition *etc.* was determined in oil isolated from the kernels of olives obtained from Morocco. The investigation was made in the same manner as in the case of shea butter, and the results are summarized in the last column of Table 1. The oil examined showed a higher degree of unsaturation than a Portuguese olive kernel oil examined previously [5]. The composition ascertained is in fairly good agreement with that given for an olive kernel oil from the U.S.A. [6]

sponding distance in benzoic acid, 1.48 Å. The Fourier map in Fig. 1 shows that the electron density in the carbon positions decreases with the distance from the origin, *i. e.* the centre of symmetry of the molecule. The temperature factors, B, increase in the same order. This is in accordance with what is found in other planar centrosymmetric molecules as naphthalene [4] and anthracene [5] and is due to the rigid-body vibrations of the molecules [6]. — The molecular packing is similar to the arrangement found in 1,2,5,6-dibenzanthracene [7].

The Fatty Acid Composition of Shea Butter and Olive Kernel Oil

AAGE JART

Danish Fat Research Institute, Copenhagen, Denmark

Shea butter. Shea butter (or karite butter) comes from the seeds of *Butyrospermum Parkii* of the family *Sapotaceae*. After the second world war shea nuts have been imported into Europe on a relatively small scale, but in Denmark the oil is used in appreciable quantities for certain types of margarines. It would therefore be of interest to know the composition of the fatty acids of this oil and especially the content of essential fatty acids.

For the present investigation shea nuts from West Africa were used. The fat in the nuts was isolated and analyzed, *i. a.* by alkali isomerization [1] and — in the form of methyl esters — by quantitative gas-liquid chromatography [2]. The chromatograph used was supplied by Griffin & George and had a 0.9 m column (25 % silicone grease on 40—60 mesh Firebrick). The temperature of the column was 215°C, the outlet pressure 1 atm, the katharometer current 100 mA, and the carrier gas used was helium (1.0 l/h). Using a speed of the recorder paper of 6 inches/h, the quantity M (in μl) of the individual components of the methyl ester mixture could be determined from the area A (in cm²) lying under the corresponding peaks in the chromatogram by applying the following formula (which has been derived by calibrating the apparatus by means of pure fatty acid methyl esters):

$$M_i = \log_{10}^{-1} (0.889 \times \log_{10} (A_i) - 0.058)$$

The calculated fatty acid composition (in weight per cent of the fatty acid mixture) and other results obtained from the analyses of the shea butter appear from Table 1; the content of oleic acid is found by determining the iodine value, while the stearic acid percentage is obtained as a difference. The results are in good agreement with those published in earlier works [3,4].

Olive kernel oil. Olive oil is obtained from the fruits of *Olea europea* which belongs to the family *Oleaceae*. The olive kernel contains about 1 % of the total amount of oil in the olive. Olive oil usually contains the kernel oil, as the olive stones are generally crushed during the milling procedure to which the olives are subjected in the factories. As adequate information concerning the linoleic acid content of olive kernel oil was not available from the literature, an investigation of this oil has been carried out.

The fatty acid composition *etc.* was determined in oil isolated from the kernels of olives obtained from Morocco. The investigation was made in the same manner as in the case of shea butter, and the results are summarized in the last column of Table 1. The oil examined showed a higher degree of unsaturation than a Portuguese olive kernel oil examined previously [5]. The composition ascertained is in fairly good agreement with that given for an olive kernel oil from the U.S.A. [6]

Table 1. Fats of shea nuts and olive kernels.

	Butyrospermum Parkii	*Olea europea* (kernels)
Oil, % in nuts and kernels	46	41
Unsaponifiable matter, %	7.3	2.8
Free fatty acids, as % of oleic acid	3.4	3.9
Fatty acid composition, weight % of total fatty acids		
Palmitic acid	5.1	11.3
Stearic acid	43.5	1.2
Oleic acid	45.3	68.9
Linoleic acid	5.8	18.1
Linolenic acid	0.3	0.5

Experimental. Shea butter. The shea nuts were crushed in a hydraulic press and extracted with light petroleum (b.p. 50—70°C) in a large Soxhlet apparatus; after extraction for a couple of hours, the residue was ground and again extracted until all oil contained in the nuts had been isolated. The oil was saponified by means of ethanolic potassium hydroxide, and the unsaponifiable matter was extracted from an ethanolic/aqueous (50 % v/v) soap solution with several portions of ethyl ether. The fatty acids were isolated from the soap solution by dropwise addition of a 50 % solution of sulphuric acid and were converted into methyl esters by means of diazomethane.

Olive kernel oil. Air-dried olive stones from which the fruit coat had been removed almost completely were cracked carefully, and the individual kernels were removed by means of a pair of tweezers to avoid admixture of fruit coat oil. From 470 g of olive stones 40.0 g of kernels were obtained, and after crushing in an agate mortar and treatment with solvent naphtha in a Soxhlet apparatus these yielded 16.4 g of straw-coloured, crude olive kernel oil. A part of this oil was saponified, and the fatty acids obtained were converted into methyl esters by refluxing with excess of methanol and a little sulphuric acid to act as catalyst.

Isolation of an Anti-*Fusarium* Substance Present in Intact Rye Seedlings

ÖRN WAHLROOS and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

After it was shown in this laboratory that 6-methoxybenzoxazolinone is formed in wheat and maize plants and benzoxazolinone in rye plants from precursors through enzymatic reactions and ensuing chemical changes [1], a glucoside $C_{14}H_{17}O_9N$ (m. p. 186–187°C) could be isolated from rye seedlings. From this glucoside the aglucone $C_8H_7O_4N$ (m. p. 152°C) is formed when the seedlings are crushed [2]. The aglucone is converted into benzoxazolinone $C_7H_5O_2N$ under liberation of formic acid [2]. In young wheat and maize plants the corresponding methoxy derivative, the glucoside $C_{15}H_{19}O_{10}N$ (m. p. 168–170°C) was found as an original compound from which the aglucone $C_9H_9O_5N$ (m. p. 156–157°C) was enzymatically formed [3]. 6-Methoxybenzoxazolinone $C_8H_7O_3N$ is a reaction product of the latter. The glucosides have only a very weak anti-*Fusarium* activity, whereas the aglucones inhibit the growth of *Fusarium nivale* in an oatmeal-glycerol nutrient medium already at a concentration of 0.1 % and benzoxazolinone at a concentration of 0.06 % [3].

Because the extract of rye seedlings, after the enzyme activity had been destroyed by boiling intact seedlings with 70 % ethanol, inhibits the growth of *Fusarium nivale* at concentrations corresponding to 1 to 1.5 g of fresh weight per ml substrate, the seedlings have to contain antimicrobial substances which as such are present in the seedlings and not formed only after the seedlings are crushed. The rye seedlings used in this work were of the varieties Pekka, Ensi, and Kungsråg. They were collected in November and December on the field.

On dividing the 70 % alcohol extract of the seedlings into ether-soluble neutral material, ether-soluble weakly acidic material (soluble in 1 N NaOH), ether-soluble acids (soluble in sodium bicarbonate), and water-soluble material (not extractable with ether from acidified water solution), about half of the total activity of the alcohol extract is found in the ether-soluble weakly acidic material, and the other half in the water-soluble material.

In the water-soluble material, part of the activity was extractable with *n*-butanol. On attempts to fractionate the water-soluble material by paper chromatography, the activity could not be recovered. Also on standing in the refrigerator for two months the activity was lost.

The ether-soluble weakly acidic material was shown to contain an active component moving with an R_F-value of 0.86 in *n*-propanol:ammonia (7:3) on Whatman No. 4 paper (desc.). This component was purified at first by cellulose-column chromatography in the *n*-propanol-ammonia solvent, and then by adsorption chromatography on a silica-gel column. The silica-gel was previously equilibrated against water-vapour of the pressure 5.6 mm Hg at 20°C, and the active material was eluted with ethanol-free chloroform containing rising amounts (2–50 %) of ether. Because the material was found to be subject to autoxidation the following steps were carried out in a CO_2 atmosphere, and illumination of the samples was avoided. The chloroform-ether fractions were evaporated to dryness *in vacuo* and dissolved in methanol. After addition of 20 % of water the solution was cooled and the inactive material crystallizing was filtered off. The filtrate was again evaporated to dryness *in vacuo* and the residue was chromatographed on a cellulose column in a solvent consisting of water-saturated benzene containing 0.2 % of methanol. The R_F-value of the active component in this solvent on Whatman No. 4 paper was 0.87 (asc.). The active fractions were evaporated to dryness *in vacuo*. The resulting slightly yellow-green oil was found to solidify at −14 to −15°C, and it melted at −12.5 to −11°C. The oil was crystallized from methanol at −40 to −50°C using an apparatus described by Kajanne [4]. After separation of the crystals they were allowed to melt, and the resulting oil was filtered at −10 to −5°C through a micro filter. After drying over P_2O_5 at +20°C and 0.01 mm Hg pressure, the oil solidified at −14°C and melted at −12 to −11°C. The yield was 68 mg oil from 255 g fresh weight of seedlings. Considering the amount of oil in the mother liquor after crystallization the total amount of oil in

the plants was calculated to be about 1.5 mg per g fresh weight.

Some of the properties of the substance are listed below:

Boiling point: At a pressure of 0.01 mm Hg signs of boiling were observed at about 170°C, with simultaneous darkening of the sample.

Empirical formula: Found: C 76.16; H 10.61; O 12.96. Calc. for $C_8H_{14}O$: C 76.2; H 11.1; O 12.7. Calc. for $C_8H_{13}O$: C 76.8; H 10.4; O 12.8.

Molecular formula: For the molecular weight, determined by the camphor method, the value 270–290 was found. Accordingly, the molecular formula is $C_{16}H_{28}O_2$ or $C_{16}H_{26}O_2$ with the calculated molecular weight of 252 or 250.

UV-absorption: In *cyclo*hexane the substance exhibits one maximum, at 236 mμ, $\varepsilon = 3020$.

Acidic properties: The substance dissolves in aqueous sodium carbonate solution and in sodium hydroxide, being precipitated on acidifying.

Hydroxyl content: The substance is esterified by acetylchloride. The product of catalytic hydrogenation reacts with one mole of acetyl chloride per mole substance.

Catalytic hydrogenation at room temperature with PtO_2: Two moles of hydrogen per mole substance are rapidly consumed.

Reducing properties: The substance decolorizes permanganate rapidly in sodium carbonate solution. One of the products from permanganate oxidation was identified as azelaic acid, $HOOC-(CH_2)_7-COOH$, by isolation and mixed melting point determination. The substance is also oxidized by periodic acid at room temperature within a few minutes. It exhibits a reducing action upon 2,6-dichlorophenolindophenol and reduces Hg(I)-nitrate and bromine slowly. It is autoxidized in the air, the reaction is light-catalyzed. The products of autoxidation seem to contain peroxides (liberation of iodine from iodide).

Other reactions: With silver ions the substance seems to form a complex. No colour formation with ferric chloride was observed. With diazotized *p*-nitroaniline a yellow colour appeared on making the solution alkaline. With 2,4-dinitrophenylhydrazine the substance is reacting, as shown by chromatography and spectrometry of the reaction mixtures, though no crystalline product could be obtained. No carboxylic acid-, lactone-, or ester-reaction could be obtained with the substance.

On the basis of the oxidation products the isolated substance contains a straight saturated chain of nine C-atoms. The other properties listed above suggest that the substance contains: two aliphatic double bonds, one C–OH group, and one C=O group.

The substance isolated inhibits the growth of *Fusarium nivale* to 50 % at a concentration of 0.5 to 0.7 mg per ml of an oat-meal-glycerol medium. On increasing the concentration to 2.4 mg/ml the inhibition increases to 85 %. Above this concentration the inhibition *vs.* concentration curve becomes parallel to the concentration axis, depending on the poor solubility of the substance in aqueous medium.

The support given by the *Rockefeller Foundation* is gratefully acknowledged.

Amino Acid Composition of the Fibrinopeptides A and B

JOHN SJÖQUIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

During the transformation of bovine fibrinogen to fibrin by bovine thrombin at least two peptides (A and B) are released [1,2]. The qualitative amino acid composition of the peptides has been given by Bettelheim [1] after isolation of the peptides by means of electrophoresis and reversed phase partition chromatography. We have published preliminary amino acid analyses, which were performed in connection with structural studies of the peptides [3]. Recently, Gladner *et al.*[4] have analyzed Peptides A and B for their amino acid composition. Differing from our preliminary report, they found Peptide B to contain threonine. However, the presence of threonine was later confirmed in our studies of the amino acid sequence of the peptides [5].

This report deals with the amino acid composition of highly purified fibrinopeptides isolated by the technique of Blombäck and Vestermark [6]. Samples of the peptides (0.5—1 mg) were hydrolyzed in 5.7 N HCl for 22 h at 110°C. The amino acids of the hydrolysates were converted to phenyl thiohydantoin derivatives [7] and quantitatively estimated after separation on paper chromatograms [8].

Table 1 gives the results of these analyses. The figures refer to air-dried samples. The data agree well with those of Bettelheim [1] and Gladner *et al.*[5] Our analyses on performic acid oxidized fibrinopeptides have revealed no cysteine or cystine. Measurements of the tryptophan absorbtion in ultra violet indicate that none is present. No analyses have been performed to determine the amide-N.

The minimum number of amino acid residues in Peptide A is nineteen and that of Peptide B is twentyone. Therefore, the calculated minimum molecular weights of Peptides A and B are 1 890 and 2 460, respectively.

This work was supported by grants from *Statens Medicinska Forskningsråd.*

Absorption Spectra of Some Vanadium(III) Fluorides

C. J. BALLHAUSEN and FLEMMING WINTHER

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

A number of vanadium(III) fluorides having the general formula $[VF_n(H_2O)_{6-n}]^{+(3-n)}$ were prepared and their reflection spectra measured. An identification of the various absorption bands observed is proposed based on a crystal field level scheme with spin-orbit interaction included. The presence of lower crystalline fields than O_h is deduced from the position of the first spin-forbidden band.

It is the purpose of this note briefly to study the application of the theoretical ($3d^2$) crystalline field level scheme recently given by Liehr and Ballhausen [1] to the absorption spectra of vanadium(III) complexes. To achieve this goal we have chosen the series $[VF_n(H_2O)_{6-n}]^{+(3-n)}$, the reason for our choice being the fact that going down this series from n = 6 to n = 3 some small "spin-forbidden" bands may be seen, some of which are not easily detected otherwise. It may of course be argued that the theory as outlined by Liehr and Ballhausen [1] is not at all applicable to non-cubic complexes. While this is perfectly true in a formal way, we must nevertheless remember that F^- and H_2O stand very close together in the spectro-chemical series. Thus we would not expect great deviations from "cubic" behaviour for these mixed complexes. Most important, we shall not find any kind of significant splittings of the "cubic" bands, due to the actual presence of lower symmetry. On the other hand we would expect the spin-forbidden bands to be easier to detect by comparing the spectra of the different complexes.

Furthermore, there are experimental and theoretical reasons to expect that all "cubic" V(III) complexes are distorted along the trigonal axis due to to a Jahn-Teller effect [2,3], and especially the excited states possessing E_g electronic states may be very strongly coupled to the various molecular vibrations. While this fact makes an *a priori* "exact" analysis nearly impossible, it seems nevertheless possible to understand the general features of the d^2 system assuming a pure cubic crystalline field [4–7]. For special systems it is further necessary to throw in a trigonal field component [8,9] in the Hamiltonian in order to account for specific features. This procedure was found to be necessary in the present work in order to explain the position of the first spin-forbidden band.

As the complexes in question are rather insoluble, the absorption spectra were recorded as reflection spectra taken upon the crystalline powder. This method gives quite accurate results in so far as the location of the various absorption bands are concerned, but it is completely out of the question to estimate band intensities in this way. We shall accordingly refrain from interpreting the oscillator strengths of the bands [10].

EXPERIMENTAL

The various complexes $[VF_3(H_2O)_3]$, $NH_4[VF_4(H_2O)_2]$, $(NH_4)_2[VF_5H_2O]$ and $(NH_4)_3[VF_6]$ were made according to Petersen [11,12]. $K_2[VF_5H_2O]$ was made according to Palmer [13]. An unsuccessful attempt was made to prepare the mixed complexes containing 1 and 2 fluorine atoms.

When pure all of the complexes mentioned above are quite stable in the atmosphere, the hexa- and pentafluorides being the most stable. Both the hexafluoride and the hexahydrate can be washed with alcohol without apparent structural changes, whereas this is not the case with the "mixed" complexes.

As all of the compounds mentioned have been well characterized and analyzed before [11,12], we have only analyzed the prepared complexes for the ratio between the vanadium and fluorine contents. The analyses were carried out in a semimicro scale.

The vanadium content was found by means of potentiometry using MnO_4^- as titrating agent. This was carried out in two steps: V(III) → V(IV) and V(IV) → V(V). As the titration took place in the presence of F^-, no glass apparatus was used.

The fluorine content was found after the method of Willard and Winter [14].

The reflection spectra were recorded on a Beckman DU spectrophotometer with MgO powder used as standard.

CONCLUSIONS

The spectra recorded all show broad maxima at ~15 000 cm^{-1} and ~23 000 cm^{-1}. These we attributed to the assignments [7]

15 000 cm^{-1} due to $^3T_{1g} \rightarrow {}^3T_{2g}$ and
23 000 cm^{-1} due to $^3T_{1g} \rightarrow {}^3T_{1g}$.

More exactly for $VF_6^{\equiv\equiv}$ we get $^3T_{1g} \rightarrow {}^3T_{2g}$ 14 800 cm^{-1}, from which we calculate [1,7] $Dq = 1\,585$ cm^{-1} taking $F_2 = 14\ F_4$ with $F_4 = 70$ cm^{-1} as in Liehr and Ballhausen [1].

Table 1. Calculated [1] and observed band maxima for V(III) complexes.

Calculated wavenumbers for d^2 cubic configuration $F_4 = 70$ cm^{-1} and $F_2 = 14\ F_4$ $Dq = 1\,585$ cm^{-1} and $\lambda = 65$ cm^{-1} Transitions from $^3T_{1g}$ to:		Observed wavenumbers			
		$VF_6^{\equiv\equiv}$	$VF_5(H_2O)^{=}$	$VF_4(H_2O)_2^{-}$	$VF_3(H_2O)_3$
^1E_g, $^1T_{2g}$	9 200 cm^{-1}	10 200	10 500	12 000	11 500
$^3T_{2g}$	14 800 cm^{-1}	14 800	15 500	16 000	16 200
$^1A_{1g}$	19 600 cm^{-1}				
$^3T_{1g}$	23 200 cm^{-1}	23 000	23 500	23 800	24 500
$^1T_{2g}$	25 200 cm^{-1}				
$^1T_{1g}$	27 300 cm^{-1}			28 200	
$^3A_{2g}$	31 200 cm^{-1}				

The calculated and the experimental absorption peaks are collected in Table 1.

The agreement between the calculated and observed absorption bands is seen to be fairly good with the single exception of the first "spin-forbidden" band $^3T_{1g} \rightarrow {}^1E_g, {}^1T_{2g}$. Assuming a pure cubic crystallinen field, the two levels ^1E_g and $^1T_{2g}$ are nearly degenerate. However, by superimposing a trigonal field upon the octahedral field the $^1T_{2g}$ level will split into a ^1E_g and $^1A_{1g}$ level, whereas ^1E_g is not split. Thus we would expect a strong repulsion to take place between the two ^1E_g levels by going down in symmetry, and this fact can explain why the "first" spin-forbidden band is pushed upwards about 1 000 cm^{-1}. For details see the appendix.

All in all it may thus be concluded that a slightly modified theoretical level scheme [1] is sufficient to explain the experimental facts.

Acknowledgement. We want to thank Dr. Claus E. Schäffer for valuable assistence in checking the results for the $VF_6^{\equiv}$ compound.

APPENDIX

The d-electrons in a cubic field are usually quantized along the four-fold axis, and are described as $t_{2g} = (xz)$, (yz) and (xy) and $e_g = (z^2)$ and (x^2-y^2). If instead we quantize along the three-fold axis of the octahedron, the following linear combinations of d-orbitals transform correctly as zero-order wavefunctions

$$t_{2g}^{+} = \sqrt{\tfrac{2}{3}}\,(x^2-y^2) - \sqrt{\tfrac{1}{3}}\,(xz)$$
$$t_{2g}^{-} = \sqrt{\tfrac{2}{3}}\,(xy) + \sqrt{\tfrac{1}{3}}\,(yz)$$
$$t_{2g}^{0} = (z^2) \qquad \text{and}$$
$$e_g^{+} = \sqrt{\tfrac{1}{3}}\,(x^2-y^2) + \sqrt{\tfrac{2}{3}}\,(xz)$$
$$e_g^{-} = \sqrt{\tfrac{1}{3}}\,(xy) - \sqrt{\tfrac{2}{3}}\,(yz)$$

Now choosing the most general trigonal perturbation as

$V_\tau = A_2^0 Y_2^0 + A_4^0 Y_4^0 + A_4^3 (Y_4^3 - Y_4^{-3})$, we obtain by taking a suitable reference energy

$$(t_{2g}^{\pm} \mid V_\tau \mid t_{2g}^{\pm}) = D\tau$$
$$(t_{2g}^{0} \mid V_\tau \mid t_{2g}^{0}) = -2\ D\tau.$$

By descending in symmetry from O_h to C_{3v} we get $^1T_{2g} \rightarrow {}^1E_g + {}^1A_{1g}$ and $^1E_g \rightarrow {}^1E_g$. Writing down zero-order determinental single-electronic wavefunctions which transform correctly both under O_h and C_{3v}, we obtain

$$^1E_g[^1E_g^{-}(t_{2g})^2] = -\sqrt{\tfrac{1}{6}}\,|\,\overset{+}{t_{2g}}\,\overset{-}{t_{2g}}\,| + \sqrt{\tfrac{1}{6}}\,|\,\overset{-}{t_{2g}}\,\overset{+}{t_{2g}}\,| + \sqrt{\tfrac{2}{6}}\,|\,\overset{+}{t_{2g}}\,\overset{-}{t_{2g}^{0}}\,| - \sqrt{\tfrac{2}{6}}\,|\,\overset{-}{t_{2g}}\,\overset{+}{t_{2g}^{0}}\,|$$
$$^1T_{2g}[^1E_g^{-}(t_{2g})^2] = \sqrt{\tfrac{2}{6}}\,|\,\overset{+}{t_{2g}}\,\overset{-}{t_{2g}}\,| - \sqrt{\tfrac{2}{6}}\,|\,\overset{-}{t_{2g}}\,\overset{+}{t_{2g}}\,| + \sqrt{\tfrac{1}{6}}\,|\,\overset{+}{t_{2g}}\,\overset{-}{t_{2g}^{0}}\,| - \sqrt{\tfrac{1}{6}}\,|\,\overset{-}{t_{2g}}\,\overset{+}{t_{2g}^{0}}\,|$$

where $|\cdots|$ designates an antisymmetrized, normalized wavefunction and the plus or minus sign above the single orbitals means α or β spin.

For the interaction of the two ^1E_g levels in C_{3v} we get:

$$\begin{vmatrix} -E & -\sqrt{2}\,D\tau \\ -\sqrt{2}\,D\tau & D\tau - E \end{vmatrix} = 0$$

with $E = 2D\tau$ and $-D\tau$.

Taking $D\tau$ to be 500 cm^{-1}, we find that the accidental degeneracy in O_h of ^1E_g and $^1T_{2g}$ at 9 200 cm^{-1} is done away with, and that instead we have three levels located at 10 200 cm^{-1}, 9 200 cm^{-1} and 8 700 cm^{-1}. This value of $D\tau$ is in close agreement with the results of Pryce and Runciman [9]. Due to experimental difficulties the two expected bands at $\sim$ 9 000 cm^{-1} have not yet been found.

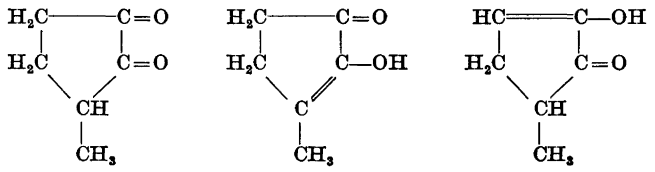
The Enol Structure of 3-Methyl*cyclo*pentane-1,2-dione

JOHAN B-SON BREDENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland

Nuclear magnetic resonance investigations show that 3-methyl*cyclo*pentane-1,2-dione occurs as the enol 3-methyl*cyclo*pent-2-en-2-ol-1-one.

The α-diketone 3-methyl*cyclo*pentane-1,2-dione (I), a compound which has been found in soluble wood tar [1] and tall light oil [2] and which is formed by alkaline digestion of spruce wood or galactose [3], has been shown to occur as a monoenol in the crystalline form as well as in solution [4,5].



I II III

Two different enol structures (II, III) can be written for the compound. Both structures have been previously used [4,6,7]. Hesse and Breig [8] have recently tried to solve the problem of the direction of the enolisation by chemical methods. Halogenation and oxidation studies led them to advance structure III. The evidences are not, however, convincing, since the structures of the most important products were not unambiguously proven. In addition, it has to be remarked that substitution in the 5-ring has an influence that is not easily anticipated. The solution to the problem has therefore to be found in such physical methods as do not influence the tautomerism. An excellent method for this purpose is nuclear magnetic resonance spectrometry. The nmr spectrum of the compound in $CDCl_3$ with tetramethylsilane as an internal reference is given in Fig. 1 a. This spectrum shows conclusively that the compound has the structure II. The methyl resonance appears as a single peak at a τ value [9] of 7.97. The methylene groups are apparently nearly equivalent and give the resonance at τ 7.57. In view of the known influence of a keto

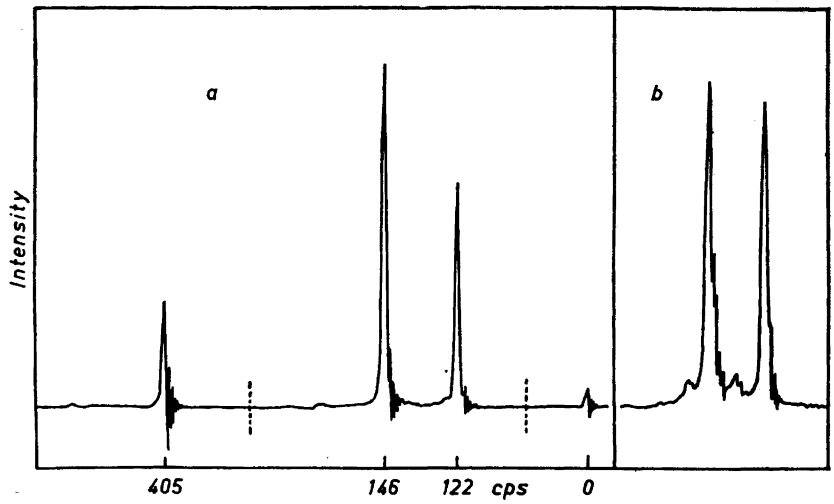


Fig. 1. Nuclear magnetic resonance spectra of 3-methyl-*cyclo*pent-2-en-2-ol-1-one in *a*. $CDCl_3$ solution, internal reference tetramethylsilane (parts of the base line are omitted at the broken lines), *b*. pyridine solution.

group and a double bond, respectively, in α-position to the methylene groups [10] the equivalence of the groups seems to be quite natural. The position at a τ value of 3.25 confirms the enol nature of the single proton peak. The areas appear to be in the ratio 3:4:1 which also tallies with structure II. Structure III would have given a much more complicated spectrum, *inter alia* a doublet for the methyl resonance. The nmr spectrum in pyridine did not reveal any shift in the enol equilibrium. However, the solvent effect had made the two methylene groups slightly non-equivalent and the spin-coupling between them was beginning to appear as a number of weak satellites (Fig. 1 b). The temperature was varied from the freezing to the boiling point of $CDCl_3$ with no evidence of anything but the enol form. These results, as well as infrared and ultraviolet investigations, show that the compound does not occur as an equilibrium mixture between the different tautomeric forms. Hesse and Breig [8] arrived at the same conclusion. Structure II finds further support from the absence of bands in the olefinic C-H stretching region of the infrared spectrum in CCl_4 (Fig. 2 b).

The enol structure II is the sterically favoured form since the C-methyl bond is staggered in relation to the C—H bonds on the adjacent atom in contrast to structure III where the C-methyl bond is opposed to one C—H bond. Hyperconjugation also favours structure II. The inductive effect of the methyl group which Hesse and Böckmann [7] thought to be operative in the tautomery can be observed in the ionisation of the enol. For the unsubstituted compound, *cyclo*pent-2-en-2-ol-1-one, the pK value is 9.14, and for compound II it is 9.60 [5]. This can be accounted for by structure II (compare phenol, pK 9.94, and *o*-cresol, pK 10.28 [11]). It is not possible, however, that the methyl group

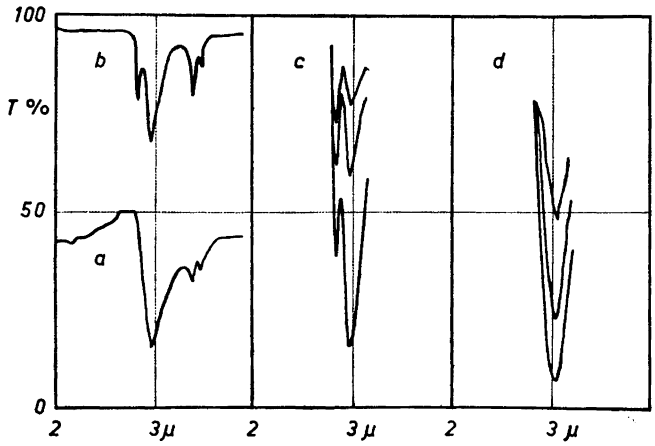

Fig. 2. Infrared spectra in the 2—4 μ region of 3-methyl-*cyclo*pent-2-en-2-ol-1-one, *a.* pellet, 2 mg in 300 mg KBr, *b.* saturated solution in carbon tetrachloride, *c.* solutions in chloroform, 1 g in 10, 30, and 50 ml, *d.* solutions in dioxan, 1 g in 10, 30, and 50 ml. All solutions in 0.1 mm cell.

in structure III should have had such a strong influence on the ionisation constant. A similar difference in the pK values is found in *cyclo*hex-2-en-2-ol-1-one and its 3-methyl homologue, the respective values being 10.30 and 11.23 [5]. This also confirms the enol structure for the last-mentioned compound advanced by Wallach [12] in connection with his investigations of the structure of diosphenol.

Methyl *cyclo*pentenolone is intermolecularly associated in the crystalline form, the OH stretching band absorbing at 3 350 cm^{-1} (Fig. 2 a). This band is also found in the carbon tetrachloride and chloroform solutions (Fig. 2 b, c). In these solutions there appears an additional band at 3 530 cm^{-1} which is strengthened upon dilution, the band at 3 350 cm^{-1} at the same time being weakened. The band at 3 530 cm^{-1} therefore corresponds to a chelate which, as a 5-ring hydrogen bridge, is rather weak. In dioxan the compound shows only one band at 3 280 cm^{-1} (Fig. 2 d).

EXPERIMENTAL

3-Methyl*cyclo*pent-2-en-2-ol-1-one, purum, Fluka A.-G., m. p. 106.5°, was used without further purification.

The nmr spectra were taken at Varian Associates, Palo Alto, California, with a 60 Mc High Resolution NMR Spectrometer. The infrared spectra were taken with a Beckman IR-5 spectrophotometer and the ultraviolet spectra with a Beckman DK-2 spectrophotometer.

Infrared maxima. Keto band, cm^{-1}, cryst. 1 710, in $CHCl_3$ 1 715, in CCl_4 1 715; double bond, cm^{-1}, cryst. 1 650, in $CHCl_3$ 1 667, in CCl_4 1 670.

Ultraviolet maxima. Water, λ_{max} 256 mμ (logε 4.14); ethanol, λ_{max} 258—259 mμ (logε 4.15); *cyclo*hexane, λ_{max} 251 mμ (logε 4.15).

The author wishes to express his thanks to Varian Associates, Palo Alto, California for taking the nmr spectra and to Dr. J. N. Shoolery for his comments on them.

Electron Diffraction Conformational Analyses of *Trans*-1,4-Dichloro- and Dibromo*cyclo*hexane

V. A. ATKINSON and O. HASSEL

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Electron diffraction studies have been carried out on two *trans*-1,4-dihalogen*cyclo*hexanes with chlorine and bromine as substituents. The results show that in the gas phase both compounds contain nearly equal amounts of the two possible conformations (*aa* and *ee*). The energy difference between the two conformations must be less than 170 cal/mole. Structural parameters of both conformations are given in Tables 1 and 2 for the dichloro and the dibromo compounds, respectively.

The fundamental principles of the stereochemistry of *cyclo*hexane and its derivatives have been set out several years ago [1]. It is now generally accepted that the two inter-convertable forms of a particular *cyclo*hexane derivative, both showing the "staircase" six-membered carbon ring, should in general possess different internal energies and therefore, according to statistical mechanics, be present in different concentrations in an equilibrium mixture. The energy difference will depend on the kind and number of substituents and on their positions in the molecule. The first attempt at a "conformational analysis" of a *cyclo*hexane derivative was made in 1943 [2] and the substance investigated was monochloro-*cyclo*hexane in the vapour state. The electron diffraction sector method was employed, but both the apparatus and the treatment of the experimental intensity curves used at that time were less satisfactory than those in use to-day in this laboratory. From differential radial distribution curves (*i.e.* the monochloroderivative minus *cyclo*hexane itself) the conclusion was drawn that the number of molecules in the equilibrium mixture with chlorine in the equatorial positions considerably larger than the number of molecules with axial chlorine atoms. A quantitative measurement of the equilibrium constant was not attempted at that time. Some attempts have more recently been undertaken both in this laboratory and elsewhere, to determine more quantitatively the conformational equilibrium of *cyclo*hexane derivatives using infrared spectroscopy or other experimental methods, but only in the liquid state or in the semi-liquid state of crystals containing "rotating" molecules [3]. The intermolecular forces can change the ratio of the con-

formations in condensed systems and we have therefore thought it worth while to try to determine equilibrium ratios in gaseous systems using modern electron diffraction technique. Considerable improvements have indeed been introduced since 1943 both in experimental technique and in the methods of treating the experimental data.

We have chosen *trans*-1,4-dichloro-*cyclo*hexane and the corresponding dibromo compound for our experiments. X-Ray crystallographic investigations have shown that these two substances are both diequatorial in the solid state. Infrared absorption spectra seem to indicate, however, that both conformations are present in liquid systems [4].

The measurements were carried out using the new Oslo electron diffraction apparatus [5] with distances of 19 and 48 cm between the nozzle and the photographic plate. The intensity data extended from $s = 1.25$ to $s = 45$. The data were treated in the manner described in a series of papers from this institute published after 1955. The radial distribution curves thus obtained are shown in Figs. 1(a) and 2(a).

RESULTS

Trans-1,4-dichlorocyclohexane

The radial distribution curve shown in Fig. 1(a) was obtained using a damping factor of 0.0015. The full arrows show where the C(3)-Cl, C(4)-Cl and Cl—Cl distances of the *ee* form would be expected and the broken arrows show where the same distances of the *aa* form would cause peaks. These distances are calculated on the basis of strictly tetrahedrally-directed carbon valences with bond distances: C—C = 1.53, C—Cl = 1.81 and C—H = 1.10 Å obtained from the positions of the first three peaks. The Cl—Cl peaks at 5.236 and 6.318 Å show that both conformations must be present in similar proportions.

Theoretical radial distribution curves were constructed from Gauss curves for both the *ee* and *aa* conformations. It then became apparent that structures based on the strictly tetrahedral carbon atom would not give a composite theoretical radial distribution curve which would agree satisfactorily with the experimental curve. At this time parallel work in our department [6] dealing with *cyclo*hexane itself showed that the carbon ring in the parent hydrocarbon is more "flat" than would be expected if the C—C—C angle were strictly tetrahedral (109° 28′). The value actually obtained from *cyclo*hexane (111.5°), was used to calculate revised theoretical radial distribution curves for the two conformations of *trans*-1-4-dichloro*cyclo*hexane.

In the case of the *ee* conformation the new curve appeared to agree with the experimental result, but a certain distortion of the *aa* model was necessary in order to obtain a close agreement with the experimental curve. This distortion was a tilting of the C—Cl bond away from the chief axis of the carbon ring. An angle of 6.3° between the C—Cl bonds and the axis turned out to give the best agreement with the experimentally observed maxima for which the *aa* conformation must be responsible. This tilting of the bonds of axial chlorine atoms agrees closely with earlier results from electron diffraction measurements of the *cyclo*hexane derivatives [7].

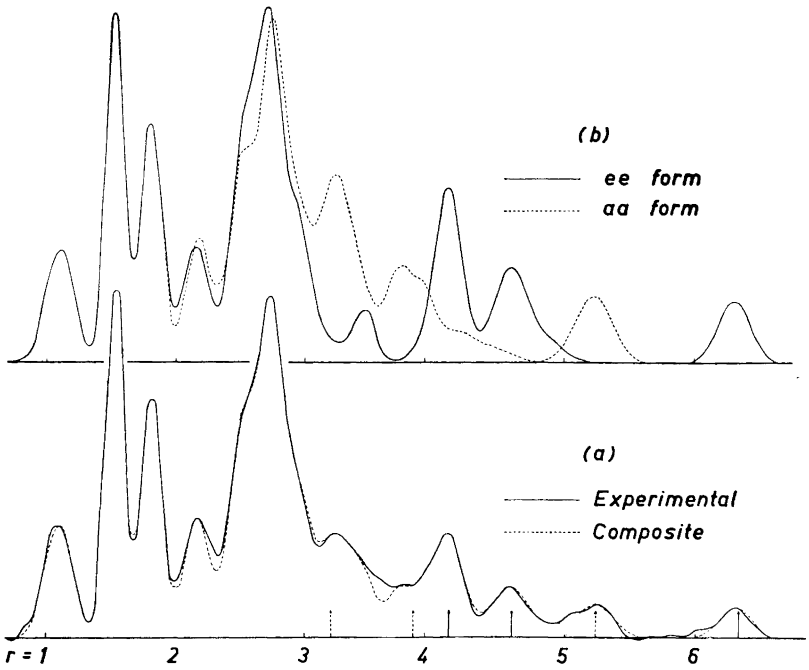

Fig. 1. Theoretical and experimental $\sigma(r)/r$ curves for *trans*-1,4-dichloro*cyclo*hexane.

Fig. 1(b) shows the theoretical radial distribution curves for both conformations based on the structural parameters in Table 1.

Least squares computations lead to the conclusion that the composite theoretical radial distribution curve giving best agreement with the experimental curve should be constructed on the basis of 49 % of the *ee* form and 51 % of the *aa* form. In Fig. 1(a) this composite radial distribution curve is compared with the experimental curve. The standard deviation is $\pm$ 6, *i.e.* 1.5 % of the vertical scale used.

Trans-1,4-dibromo*cyclo*hexane

Fig. 2(a) shows the experimental radial distribution curve obtained for this compound using a damping factor of 0.0036. The shape is similar to that of Fig. 1(a) showing that both conformations are again present in similar proportions.

The peak at 1.12 Å due to the C—H bond distance is lower than expected on theoretical grounds. This is probably due to some error in the selection of the experimental background to the intensity curve. However, this discrepancy, in a region where the *aa* and *ee* radial distribution curves are identical should not affect the conclusions, drawn from the other ends of the curves, about the proportions in which the two forms are present.

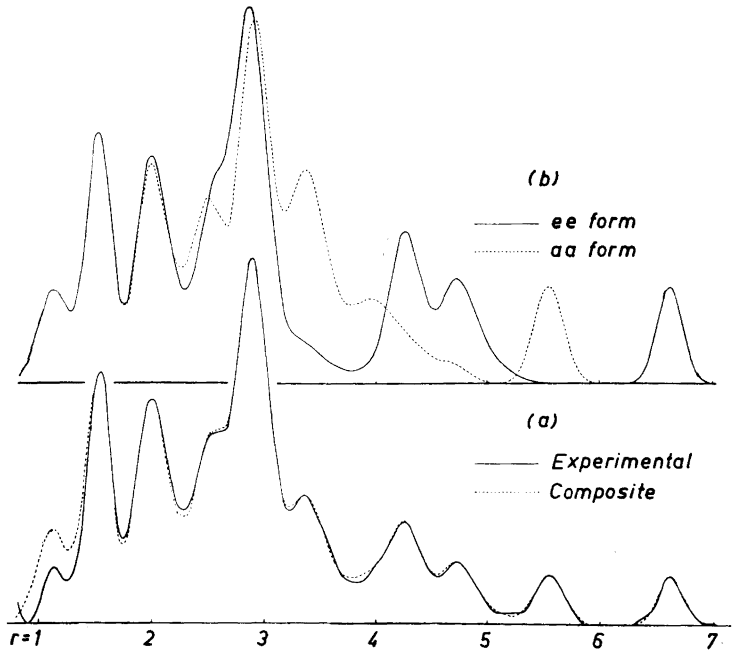

Fig. 2. Theoretical and experimental $\sigma(r)/r$ curves for *trans*-1,4-dibromo*cyclo*hexane.

Fig. 2(b) shows the theoretical radial distribution curves for the two conformations (*ee* and *aa*), based on the structural parameters given in Table 2. These parameters correspond to the same "flat" ring as was used for the chloro-compound. In the case of the *aa* form, there is again an extra distortion which tilts the bonds of the axial bromine atoms away from the main axis by an angle of 7.7°.

Least squares procedure showed that the composite radial distribution curve giving the best agreement with the experimental curve should have 51 % *ee* form and 49 % *aa* form. In Fig. 2(a) this composite theoretical curve is compared with the experimental curve. The standard deviation for the latter part of the curve (where $r > 1.5$) is $\pm$ 4.

DISCUSSION

The present conformational analyses clearly show that the amounts of the two forms present in the vapour state must be nearly equal. This result is contrary to that expected in the light of the old work on monochloro*cyclo*hexane [2].

The accuracy of the figures obtained clearly depends on the parameters chosen for the computation of the theoretical radial distribution curves for the *ee* and *aa* conformations. It appears very probable that small changes of the

Table 1. Structural parameters used for *trans*-1,4-dichloro*cyclo*hexane.

Bond distances used for both conformations		Bond angles	*ee* form	*aa* form
C—H	1.102 Å	C—C—C	111.5°	111.5°
C—C	1.530 Å	C—C—Cl = C—C—H	108.6°	110.6°
C—Cl	1.810 Å	H—C—Cl = H—C—H	111.5°	107.6°

Table 2. Structural parameters used for *trans*-1,4-dibromo*cyclo*hexane.

Bond distances used for both conformations		Bond angles	*ee* form	*aa* form
C—H	1.12 Å	C—C—C	111.5°	111.5°
C—C	1.530 Å	C—C—Br = C—C—H	108.6°	111.2°
C—Br	1.968 Å	H—C—Br = H—C—H	111.5°	100.1°

models would give slightly different theoretical radial distribution curves, which might have been combined in a slightly different proportion to give a composite curve which would have agreed equally well with the experimental curve. For this reason we assess our possible error in the ratio of the two conformations as high as ± 5 %. Even allowing for this error, the maximum energy difference between the two conformations obtained from Boltzmann's relation, is only 170 cal/mole.

The structural parameters employed when calculating the radial distribution curves are based on identical bond lengths in the two interconvertible conformations. There appears to be no reason to expect a difference in bond distances which could be of any significance for the present investigation. The distances recorded are taken from individual peaks whose positions can be assessed with an accuracy of ± 0.5 %. The value of the C—H bond distance for the bromine compound is associated with the major discrepancy between the theoretical and experimental curves and its error is estimated as ± 2 %.

The accuracy of the bond angles recorded in Tables 1 and 2 is more difficult to assess. The angles were chosen so that the theoretical and experimental radial distribution curves should show the best possible agreement. The influence of the bond distances involving hydrogen atoms on these curves is much less than that of the other distances. Therefore, only the C—C—C, C—C—Cl and C—C—Br angles recorded have real significance for our problem. Their accuracy is put at ± 0.5 %.

In both compounds it was necessary to assume that the axial bonds to halogen atoms were tilted away from the chief axis of the ring. The value of 6.3° for this deviation in the case of the dichloro compound agrees well with the 7° deviation assessed for 1*a*,2*a*,4*e*,5*e*-tetrachloro*cyclo*hexane [7], and for "*trans*"-1,2-dichloro*cyclo*hexane [8].

This tilting is ascribed to steric hindrance between the axial halogen and the axial hydrogens attached to C(3) and C(5). It is significant that, in both

trans-1,4-dihalogeno-*cyclo*hexanes, the effect of this deformation is to increase the H(3*a*)—Hal(*a*) and H(2*e*)—Hal(*a*) distances to approximately the same value. The actual distances were:

H(3*a*)—Cl(*a*) = 2.88 Å	H(2*e*)—Cl(*a*) = 2.86 Å
H(3*a*)—Br(*a*) = 3.00 Å	H(2*e*)—Br(*a*) = 3.05 Å

These are just within the limits expected from consideration of the van der Waal's radii (H = 1.2; Cl = 1.8 ; Br = 1.95 ± 0.1 Å)[9].

We wish to express our sincere gratitude to Mr. Arne Almenningen who was so kind as to take the electron diffraction pictures. We also wish to thank mag. scient. K. Lunde for letting us have pure samples of the compounds. Finally, thanks are due to *Norges Teknisk-Naturvitenskapelige Forskningsråd* for a postdoctorate fellowship (V.A.A.).

Studies in the Determination of Silica

II. The Separation of Phosphomolybdate from α-Silicomolybdate

LARS HENRIK ANDERSSON

Dept. of Analytical Chemistry, Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Experiments described in this paper show that it is possible to separate quantitatively phosphomolybdate from α-silicomolybdate by extracting water phases with *n*-butanol or *n*-butanol-benzene mixtures under certain specified conditions.

When silica is determined spectrophotometrically as α-silicomolybdate, phosphorus in the form of orthophosphate ion interferes seriously. Among the methods used to separate the heteropolymolybdic acids of silicon and phosphorus, extraction of water phases with different organic solvents has repeatedly been investigated [1–4]. Probably because the authors cited have worked with solutions in which equilibrium between α- and β-silicomolybdates has not been reached, definite conclusions cannot always be drawn from their data.

King *et al.*[5] precipitated phosphate as ferric phosphate by the "basic ferric acetate method" prior to the determination of silica as silicomolybdate.

In this paper some experiments with the extraction of heteropolymolybdic acids of phosphorus and silicon are described. An elementary theoretical account of the extraction is also presented. Experimental data on the formation and some properties of phosphomolybdate are given as are also some experiments on the determination of phosphorus as phosphomolybdic acid extracted into organic phases.

1. EXPERIMENTAL DETAILS

For an account of some of the experimental methods and instruments the reader is referred to the first paper [6] in this series. The chemicals used were of analytical grade; the solvents, however, were also in general distilled once using a small Vigreux column.

pH measurements in solutions, in which the concentration of perchlorate ion is not low enough, can not be performed using saturated calomel electrodes with asbestos or sintered glass plugs, dipping into the solution to be measured, since $KClO_4$ will precipitate in the plug causing a drift of potential. Instead a calomel electrode with a bent-up

open tip at the end of the tube dipping into the solution was used in the case of perchloric acid solutions.

The extinction measurements were carried out in 1 cm cells of fused silica, fitted with ground in stoppers.

If not otherwise stated the experiments have been performed at 20.0°C.

2. SOME EXPERIMENTS ON THE FORMATION OF PHOSPHOMOLYBDATE IN AQUEOUS SOLUTIONS

The reaction between orthophosphate and molybdate ions to form phosphomolybdate seems to be too complex to be useful as a basis for a method for phosphorus determination. It has earlier been studied by, *e. g.*, Nydahl [7].

The following experiment shows the complex nature of the system orthophosphate-sodium molybdate-hydrochloric acid.

To two solutions, each containing 3×10^{-5} moles Na_2HPO_4, equal amounts of a Na_2MoO_4 solution was added followed by concentrated hydrochloric acid until the pH in one solution was 3.5 and in the other 0.5; they were then diluted to 50 ml in calibrated measuring flasks. By mixing suitable amounts of these two solutions a series of pH-values in the interval $0.5 \leqq pH \leqq 3.5$ could be obtained. Now varying the amount of Na_2MoO_4 taken and measuring the extinction of the solutions against suitable blanks at 400 mμ the extinction as a function of pH with Na_2MoO_4 as a variable was recorded.

The results are shown in Fig. 1, where the extinction is plotted against pH. Nowhere in the range of molybdate concentration studied is the extinction independent of that variable. Also pH plays an important role.

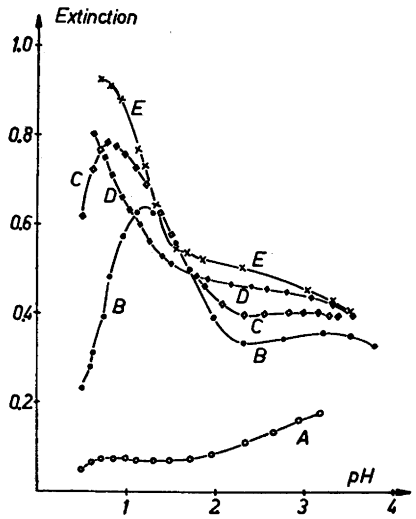

Fig. 1. Extinction of water solutions o f phosphomolybdate at 400 mμ.

3. A SIMPLIFIED THEORETICAL TREATMENT OF A CERTAIN TYPE OF EXTRACTION PROCESS

3.1. Notations and simplifying assumptions

The following notations will be used:

Concentrations in the water phase	[ ]
» » » organic »	[ ]'
The i:th acid dissociation constant of H_nA	k_i
Distribution constant for H_nA	γ

To begin with it will be assumed that the acid H_nA dissolves in the organic phase only as such (no polymerisation), dissociation taking place only in the water phase giving the ultimate product A^{-n} In this treatment also activity effects, mutual solubilities of the two phases and the influence of temperature are not taken into consideration.

3.2. The distribution of H_nA as a function of pH

By definition we have

$$k_i = \frac{[H^+]\,[H_{n-i}A^{-i}]}{[H_{n-i+1}A^{-i+1}]} \tag{1}$$

$$\gamma = \frac{[H_nA]'}{[H_nA]} \tag{2}$$

We also define an apparent distribution constant γ_a by

$$\gamma_a = \frac{[H_nA]'}{\sum_{i=0}^{n} [H_{n-i}A^{-i}]} \tag{3}$$

Putting $i = p$ in (1) and solving for $[H_{n-p}A^{-p}]$ we get, using (2)

$$[H_{n-p}A^{-p}] = \frac{1}{\gamma} \frac{\prod_{i=1}^{p} k_i}{[H^+]^p} [H_nA]' \tag{4}$$

Substituting eqn. (4) in (3) we arrive at the following expression for γ_a as a function of $[H^+]$:

$$\gamma_a = \frac{\gamma}{1 + \sum_{p=1}^{n} \frac{\prod_{i=1}^{p} k_i}{[H^+]^p}} \tag{5}$$

With fixed k_i, γ_a is therefore only a function of $[H^+]$. With the aid of eqn. (5) the function

$$\log \gamma_a = f(\mathrm{pH}) \tag{6}$$

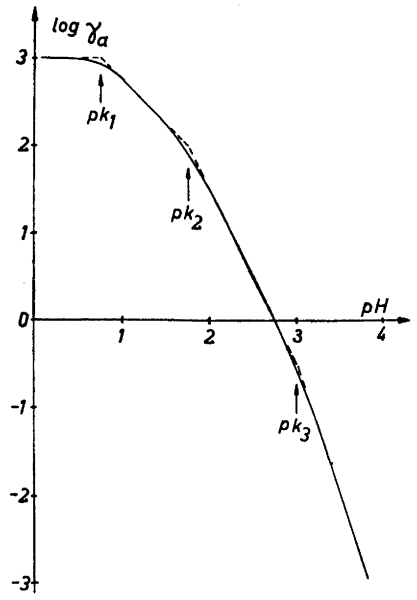

Fig. 2. Logarithm of apparent distribution constant as a function of pH.

can easily be constructed plotting log γ_a along the vertical and pH along the horizontal axis. Such a construction is shown in Fig. 2 for the hypothetical case H_3A with $pk_1 = 0.74$, $pk_2 = 1.75$, $pk_3 = 3$ and $\gamma = 10^3$. When pH$\rangle\rangle pk_3$ or when pH $\langle\langle$ pk_1 the curve approximates to straight lines; if the differences $pk_2 - pk_1$ and $pk_3 - pk_2$ are large enough, the form of the curve in the middle parts of the corresponding intervals will also be approximately straight lines with slopes -1 and $-1/2$, respectively. When pH $\rangle\rangle$ pk_3 the slope of the line is in the limit $-1/3$ and when pH $\langle\langle$ pk_1 the line is horizontal. These successive straight lines cut when pH = pk_1, pH = pk_2 and pH = pk_3, respectively.

3.3. Limits of applicability of foregoing treatment

The limits of applicability of the foregoing treatment can be summarised as follows:

a) the mass action law is strictly applicable only when activity is introduced instead of concentration.

b) the value of the distribution constant γ depends on the composition of the phases; this composition changes, *e. g.*, with the mutual solubilities of the two solvents, which depend on their salt contents.

c) polymerisation or other reactions can take place in one or both of the phases.

d) the "constants" k_i and γ are functions of temperature. In spite of these and other restrictions, experiments show that the treatment in 3.2 can to some extent be used to describe the behavior of extraction systems referred to later.

4. QUANTITATIVE EXTRACTION EXPERIMENTS

4.1. Description of experiments

The water phase containing α-silico- or phosphomolybdate, sodium molybdate, acid and when necessary additional salts was mixed in a beaker with the organic solvent using a magnetic stirrer to effect intimate phase contacts. A glass and a calomel electrode were dipped into the mixture being stirred; a reproducible pH-value could then after some stirring be read off the instrument. (pH-values measured in the way just described on solutions containing comparatively large amounts of organic compounds dissolved must only be regarded as relative, since the solvent is no longer water but a mixture of water and organic solvent.) If necessary concentrated acids were added to adjust pH to a desired value; when this was reached, the contents of the beaker were transferred to a graduated cylinder fitted with a ground glass stopper. This cylinder was placed in a thermostate and shaken now and then until equilibrium was reached. The volumes were read when the phases had separated completely; their contents of silicon and phosphorus were determined spectrophotometrically, silicon by the method described in the first paper in this series [6], phosphorus in the way described later in this paper (section 6). Finally the pH of the water phase was checked once more.

In the case of *n*-butanol-benzene mixtures a certain amount of care must be exercised if the original composition of the organic phase is to be maintained during the extraction process, since *n*-butanol and to a smaller extent benzene dissolve in the water phase. A large water phase is therefore first repeatedly shaken with new, small volumes of organic phase at a rather high pH (about = 4) until the water phase is in equilibrium with an organic phase, the composition of which is practically the same as the original organic mixture. The pH is then lowered to the desired value and the intended extractions carried out. This procedure is necessary when the water phase is more than about three times as large as the organic phase.

4.2. Extractions with *n*-butanol

4.2.1. *Preliminary notes.* The paper by Mellon and Wadelin [2] contains much information on the suitability of a number of organic solvents for the purpose of extracting heteropolymolybdic acids of phosphorus, arsenic and silicon. Some of these solvents have been tested and *n*-butanol was selected for more detailed experiments.

4.2.2. *Results of experiments.* The curves in Fig. 3 give the results obtained with water phases containing hydrochloric acid-sodium chloride. 15 ml water solution was extracted with 10 ml *n*-butanol. The water phase was 0.24×10^{-3} M in Si or P; curves B and D refer to water phases, which were also 0.6 M in NaCl. In Fig. 4 are given the extinctions of extracts from blank solutions as a function of pH.

The system nitric acid-sodium nitrate gives results which within experimental error are identical with those in Fig. 3. In the case of perchloric acid-sodium perchlorate corresponding curves are displaced about 0.2 pH units in

the direction of decreasing pH. In all three cases the slopes of the lines are $-1/2$ in the case of silicomolybdic acid; phosphomolybdic acid seems to split off two protons of about the same strength in the neighbourhood of pH 3 if no extra salt has been added; below that pH-value only one proton seems to have been split off. However, all conclusions regarding the basicity of these acids, drawn from experiments such as these, must be regarded with some uncertainty.

The effect of salt additions is important. At high pH values the displacement of the phosphomolybdic acid line is greater than that of the silicomolybdic acid line for a given increase in salt concentration. This implies that when separation is to take place at say pH 2.5, it is necessary to keep the amounts of salts present to a minimum. On the other hand, when extractions are made at pH-values around 2, salt additions have about the same effect on both systems.

Another effect of adding salts is to lower the extinctions of extracts from blank solutions. This should be born in mind if phosphorus is to be determined in the organic phase. When silica is determined in the water phase the blanks

» C, » = 0.4 M.

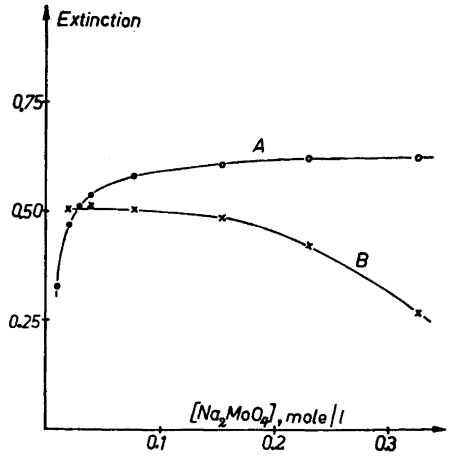

Fig. 6. Extinctions of water solutions (curve A) and extracts (curve B) of phosphomolybdic acid as functions of $[Na_2MoO_4]$.

are very low, being hardly affected if some molybdic acid has been extracted into the organic phase.

The system sulphuric acid-sodium sulphate exhibits a peculiar behaviour when silicomolybdic acid is extracted from these water phases, Fig. 5. The curves change direction when the pH has about the same value as the pK_s for HSO_4^- (2.0), the apparent distribution constants being much larger than expected. This implies that only small amounts of sulphate ions must be present if no silicomolybdic acid is to be extracted.

The results obtained in section 2 seem to show that the formation of phosphomolybdate in the experiments just described is not complete; in spite of this, however, straight lines are obtained in accordance with the simple theory in section 3. In this connection it must be pointed out that increasing the sodium molybdate concentration in the water phase has the effect of lowering the apparent distribution constant in the same way as when e.g. sodium chloride is added. This is demonstrated in the following experiment.

Water solutions, which were 0.8×10^{-3} M in Na_2HPO_4 and had a pH-value of 2.5, contained different amounts of Na_2MoO_4; 20 ml were extracted with 10 ml *n*-butanol in a beaker as described in section 4.1. The extinction of the extracts and of the original water solution were measured at 400 mμ. The results are shown in Fig. 6. Curve A demonstrates a rise in extinction, that could be predicted from the curves in Fig. 1, while on the other hand the decrease of extinction of the organic phase is evident from curve B.

4.3. Extractions with *n*-butanol — benzene mixtures

4.3.1. *Preliminaries.* To see if there was a composition of the organic mixture in question that was particularly suitable for extracting phosphomolybdic acid, the following experiment was performed.

15 ml water solution, 0.2×10^{-3} M in silicon or phosphorus, 0.02 M in Na_2MoO_4 and with the pH adjusted to 1.25 with HCl, was shaken with organic mixture (10 ml) until equilibrium was reached; by varying the composition of this organic mixture, organic phases with different extracting properties could be obtained. Extinctions of the extracts were measured at 400 mμ. Finally the pH of the water phase was checked once to see that it did not differ from the chosen value, 1.25.

In Fig. 7 the extinctions obtained are plotted along the vertical axis and the mole fraction of *n*-butanol in the organic mixture along the horisontal axis. A maximum extinction value is obtained, when the mole fraction is 0.5. The curves for silicomolybdic acid and for the blanks show that also at a mole fraction of 0.5 a separation between phosphomolybdic and silicomolybdic acids

is possible; at the same time a low blank is assured for the organic phase, if phosphorus is to be determined spectrophotometrically in that phase.

4.3.2. *Results of experiments.* In Fig. 8 the results of extraction experiments with water phases of the same composition as in 4.2.2 are shown. The systems with hydrochloric acid — sodium chloride and nitric acid — sodium nitrate behave in almost the same way. No extractions with perchloric acid — sodium perchlorate have been made, because at these low pH values and with organic phases containing only small amounts of water there are some risks of explosion. In the case of sulphuric acid — sodium sulphate, phosphomolybdic acid behaves in almost the same way as with hydrochloric acid — sodium chloride but silicomolybdic acid is more easily extracted: here too therefore only small amounts of sulphate should be present.

5. INFLUENCE OF TEMPERATURE

Extraction experiments with *n*-butanol and *n*-butanol — benzene mixtures showed that between 18° and 24°C only very small variations in apparent distribution constants with temperature were obtained, causing practically no changes in the curves of Figs. 3, 5 and 8.

Table 1.

No.	pH of water phase	Initial volume (ml) of water phase	org. phase	Final volume (ml) org phase	mmole P in initial 15 ml water phase	Extinction of final org. phase
			Extractions with *n*-butanol			
1	2.25	15	10	25	0.72×10^{-3}	0.050
2	2.25	15	10	25	1.20×10^{-3}	0.084
3	2.25	15	10	25	2.40×10^{-3}	0.170
4	2.25	15	10	25	3.60×10^{-3}	0.255
	Extractions with *n*-butanol-benzene mixture, mole fraction *n*-butanol = 0.5					
5	1.25	15	10	25	0.72×10^{-3}	0.060
6	1.25	15	10	25	1.20×10^{-3}	0.098
7	1.25	15	10	25	2.40×10^{-3}	0.196
8	1.25	15	10	25	3.60×10^{-3}	0.301

6. NOTE ON THE DETERMINATION OF PHOSPHORUS AS PHOSPHOMOLYBDIC ACID EXTRACTED INTO ORGANIC SOLVENTS

In connection with the determination of distribution constants for phosphomolybdic acid some experiments with the spectrophotometric determination of phosphorus were made. They are best discussed at this point.

The extractions were here carried out in separatory funnels after the pH-value of the water phase had been adjusted in the way described in section 4.1. When the phases had separated, the water phase (lower layer) was transferred to another funnel and the organic phase to a calibrated measuring flask; the water phase was once more extracted with a new portion of organic solvent. The combined extracts were diluted in the measuring flask to the mark with the corresponding solvent or solvent mixture. The extinctions were measured at 400 mμ; however, especially in the case of the 0.5 mole fraction mixture, a shorter wavelength (310 mμ, the maximum value of the extinction as a function of wavelength) can be chosen.

The results of these experiments can be found in Table 1; in Fig. 9 is also shown the extinctions as functions of wavelength for some typical extracts.

I wish to thank Dr. F. Nydahl, Head of the Department of Analytical Chemistry, for his continued interest in this investigation and for the facilities put at my disposal.

Addition Compounds of Phosphine Oxides

INGVAR LINDQVIST and GERD OLOFSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The formation of addition compounds with phosphine oxides as donor molecules has been studied. The following new compounds have been prepared: $SbCl_5 \cdot PO(C_6H_5)_3$, $SbCl_5 \cdot PO(CH_3)_3$, $SbCl_3 \cdot PO(CH_3)_3$, $SbCl_3 \cdot 2PO(CH_3)_3$, $AsCl_3 \cdot PO(CH_3)_3$, $AsCl_5 \cdot PO(CH_3)_3$, (stabilization of $AsCl_5$), $SeOCl_2 \cdot PO(CH_3)_3$, $HgCl_2 \cdot PO(C_6H_5)_3$, $HgCl_2 \cdot PO(CH_3)_3$, $5HgCl_2 \cdot 2PO(CH_3)_3$ and $SO_3 \cdot PO(C_6H_5)_3$.

The weak interaction between $HgCl_2$ and $PO(C_6H_5)_3$ has been revealed by a study of the infrared spectra of the compounds $HgCl_2 \cdot PO(C_6H_5)_3$ and $HgCl_2 \cdot PO(C_6H_5)_3$.

Addition compounds with phosphine oxides were described as early as 1861 by Hofmann [1] who prepared $ZnI_2 \cdot 2PO(C_2H_5)_3$. Sheldon and Tyree [2] have recently studied $SnCl_4 \cdot 2PO(C_6H_5)_3$ and $TiCl_4 \cdot 2PO(C_6H_5)_3$, and have shown that the phosphoryl stretching frequency in the infrared decreases 50—55 cm^{-1} as expected for adduct formation with the oxygen atom in $PO(C_6H_5)_3$ functioning as donor atom. The donor strength of $PO(CH_3)_3$ has been proved to be greater than that of $POCl_3$ with $SbCl_5$ as acceptor molecule [3]. In this connection we have found it interesting to investigate further the addition compounds of phosphine oxides in order to compare them with the $POCl_3$ adducts.

EXPERIMENTAL

Chemicals used. $PO(C_6H_5)_3$ was prepared according to Pickard and Kenyon [4]. Yield: 50 % calculated on $POCl_3$. Melting point +152—154°C.

$PO(CH_3)_3$ was prepared following McKee and Burg [5] but with use of $Mg(CH_3)Br$ instead of $Mg(CH_3)Cl$. Yield 75 % calculated on $POCl_3$. The colorless crystals melt at +137—139°C.

$SbCl_5$ and $SeOCl_2$ were purified by vacuum distillation.

$SbCl_3$ was sublimed directly onto a cool glass bulb placed 3 cm above the bulk of impure solid.

$AsCl_3$ and $POCl_3$ were purified by distillation and collected at +129° and 105°C.

$HgCl_2$, Merck *pro analysi*, was not further purified.

$Hg(C_6H_5)_2$ was prepared according to Pfeiffer and Truskier [6] and recrystallized from benzene. Yield 45 % calculated on $HgCl_2$. Melting point +124—125°C.

$Hg(C_6H_5)Cl$ was prepared following Nesmejanow [7]. Melting point +249—250°C.

Phase diagrams. The liquidus curves were studied by the same methods as described earlier [8]. In many cases the sublimation of $PO(CH_3)_3$ or the decomposition of the adduct compounds prevented the study of the liquidus curves in this way.

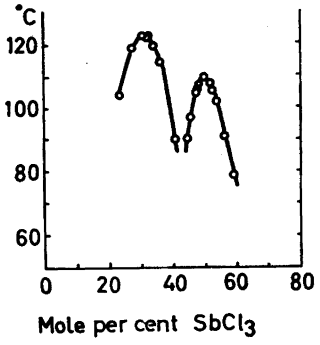

Fig. 1a. The system $SbCl_3$-$PO(CH_3)_3$.

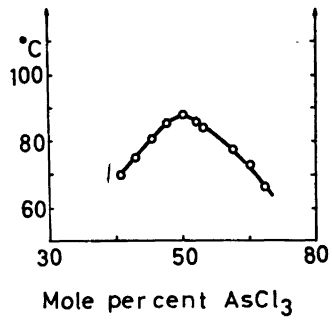

Fig. 1b. The system $AsCl_3$-$PO(CH_3)_3$.

Preparation of addition compounds. $SbCl_5 \cdot PO(C_6H_5)_3$ was precipitated from cool, dilute solutions of $SbCl_5$ and $PO(C_6H_5)_3$ in CCl_4 (mole ratio 1:1) and was recrystallized from $CHCl_3$ as almost colorless needle-shaped crystals. It is stable in air and can be melted carefully without decomposition at +196—197°C. The crystals are soluble in benzene (colorless solution), ether, chloroform or ethylene chloride. Preparation directly from $SbCl_5$ and $PO(C_6H_5)_3$ gives HCl evolution and darkly colored decomposition products (Found: Cl 31.0. Calc. 30.7.)

$SbCl_5 \cdot PO(CH_3)_3$ was precipitated as colorless crystals from a supersaturated solution in ethylene chloride. It is stable in air, melts without decomposition at +176—177°C, and can be dissolved in benzene (no color change). The thermal decomposition with evolution of HCl starts at +260°C (Found: Cl 44.7. Calc. 45.3.)

$SbCl_3 \cdot PO(CH_3)_3$ and $SbCl_3 \cdot 2PO(CH_3)_3$ were found in the phase diagram (Fig. 1a). The melting points are +110° and +124°C. Supercooling prevented the study of the system near the eutectic point. Crystals of both compounds prepared directly from the components are stable in air but we could not prepare them from CCl_4 solutions; only oil drops dispersed in the solution were obtained.

$AsCl_3 \cdot PO(CH_3)_3$ was found in the phase diagram (Fig. 1b). The melting point is +88°C. The system cannot be studied at higher phosphine oxide contents because of sublimation. The crystals can also be prepared from CCl_4 solutions. They are hygroscopic and decompose in air within a few minutes.

$AsCl_5 \cdot PO(CH_3)_3$ is formed when dry chlorine gas is led at 25°C through a liquid mixture of $AsCl_3$ and $PO(CH_3)_3$ (mole ratio 3:1). The color of the solution changes to orange, and orange crystals form upon cooling. They decompose near +50°C with loss of color. They also decompose in air with color disappearance. A rapid analysis of four different samples gave an average Cl content of 51.1 % (Calc. 51.5 %).

$SeOCl_2 \cdot PO(CH_3)_3$ was found in the phase diagram (Fig. 2a). Its melting point is +90°C.

$HgCl_2 \cdot 2PO(C_6H_5)_3$ was found in the phase diagram (Fig. 2b). The existence of the $HgCl_2 \cdot PO(C_6H_5)_3$ 1:1 compound was confirmed by powder photographs. The 1:2 compound can be precipitated from ethylene chloride solution and has been described earlier [4]. Both compounds are stable in air. The melting points are +110° and +126°C. The latter was measured with precipitated 1:2 crystals; the value +128°C found in the liquidus curve is less accurate.

$HgCl_2 \cdot PO(CH_3)_3$ and $5HgCl_2 \cdot 2PO(CH_3)_3$ were precipitated from acetone or alcohol solutions with excess of $PO(CH_3)_3$ and $HgCl_2$, respectively. They can be recrystallized with unchanged compositions. Their melting points are +137°C and +187°C. Phase diagrams cannot be studied because of the sublimation of $PO(CH_3)_3$. (Found: Hg 55.2. Calc. for $HgCl_2 \cdot PO(CH_3)_3$: 55.1.) (Found: Hg 64.9. Calc. for $5HgCl_2 \cdot 2PO(CH_3)_3$: 65.0.)

$HgCl_2$ does not give any addition compounds with $POCl_3$ as checked by us in a series of preparations.

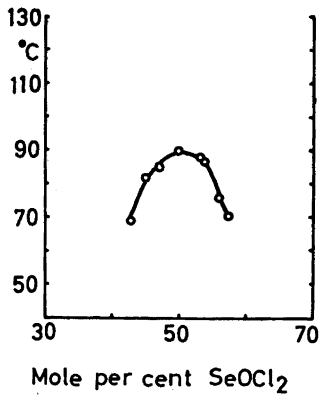

Fig. 2a. The system $SeOCl_2$-$PO(CH_3)_3$.

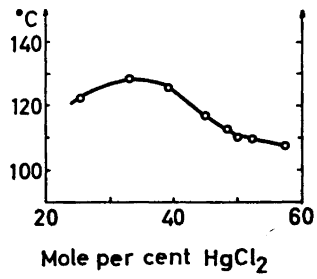

Fig. 2b. The system $HgCl_2$-$PO(C_6H_5)_3$.

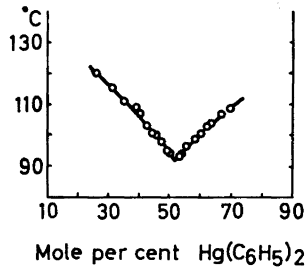

Fig. 2c. The system $Hg(C_6H_5)_2$-$PO(CH_3)$.

$Hg(C_6H_5)_2$ and $Hg(C_6H_5)Cl$ do not give any addition compounds as shown by the phase diagram for $Hg(C_6H_5)_2$ (Fig. 2c) and by repeated melting and precipitation experiments for $Hg(C_6H_5)Cl$.

$SO_3 \cdot PO(C_6H_5)_3$ was prepared by leading SO_3 through a U-tube filled with $PO(C_6H_5)_3$ dissolved in ethylene chloride. A white precipitate formed which dissolved in an excess of SO_3. It melts with decomposition at +102°C. (Found: S 8.63. Calc. 8.94.)

$SO_3 \cdot PO(CH_3)_3$ which has earlier been described by McKee and Burg [5] was also prepared and found to dissolve in an excess of SO_3.

Infrared spectra. The infrared spectra of $HgCl_2 \cdot PO(C_6H_5)_3$ and $HgCl_2 \cdot 2PO(C_6H_5)_3$ were recorded on a Perkin-Elmer Model 21 Spectrophotometer equipped with NaCl and CsBr prisms (in the Institute of Biochemistry). The crystals were dispersed in Nujol and studied between KBr and TlBr-TlI plates. The phosphoryl stretching frequency was found at 1 149 and 1 161 cm^{-1} and the antisymmetrical Hg-Cl bond stretching frequency at 352 and 345 cm^{-1} respectively. The corresponding values for pure $PO(C_6H_5)_3$ and $HgCl_2$ were 1 186 and 371 cm^{-1}.

DISCUSSION

1. In a paper on the addition compounds of sulfoxides and sulfones [9], a qualitative discussion of the cohesion energies in the solid state was attempted. The results were successful in so far as the principal predictions about the structures of the adduct molecules between $SbCl_5$ and sulfoxides or sulfones have later been confirmed by X-ray crystallography [10]. Spectroscopic investiga-

tions [11] indicate, however, that the conditions of interaction are quite complicated and that the reasonable results obtained in the paper on the sulfoxides and sulfones are rather fortuitous. This suggestion is strongly supported by the results presented here. The melting points of the compounds $SbCl_5 \cdot POCl_3$, $SbCl_5 \cdot PO(CH_3)_3$, and $SbCl_5 \cdot PO(C_6H_5)_3$ are 115, 40, and 43°C higher than the melting points of the pure donor molecules $POCl_3$, $PO(CH_3)_3$, and $PO(C_6H_5)_3$. The same argument as the one applied to $SbCl_5 \cdot SOCl_2$, $SbCl_5 \cdot SO(CH_3)_2$, *etc.* would here lead to the conclusion that the structures of $SbCl_5 \cdot POCl_3$ and $SbCl_5 \cdot PO(CH_3)_3$ have quite different bond angles at the donor atom oxygen (*cf.* Fig. 3 of Ref.[9]). We have, however, been able to show [12] that the structure of $SbCl_5 \cdot PO(CH_3)_3$ is very similar to the structure of $SbCl_5 \cdot POCl_3$[13]. The discussions of the resulting dipole moments and the melting point relations which were proposed [9] tentatively should therefore now be considered as too crude simplifications to permit any safe predictions.

2. It is difficult to express any opinion about the structures of $SbCl_3$ and $AsCl_3$ adducts. Structure determinations would be of great interest because of the labelling of the similar reactions of $SbCl_3$ or $AsCl_3$ with $POCl_3$ as weak electrostatic interaction, on the basis of the spectroscopic data [11].

3. The stabilization of $AsCl_5$ by complex formation with the strong donor molecule $PO(CH_3)_3$ was successful and can probably be achieved with other similar donors. The non-existence of free $AsCl_5$ thus seems to depend upon unfavorable energy conditions in the trigonal bipyramid $AsCl_5$, while the octahedral co-ordination is more favorable. The same difference is found with the very strong Lewis acid $SbCl_5$ but in that case the free $SbCl_5$ is also stable.

4. The importance of 1:2 adducts of $SbCl_3$ is confirmed by the existence of the compound $SbCl_3 \cdot 2PO(CH_3)_3$ in analogy with $SbCl_3 \cdot 2POCl_3$ and $SbCl_3 \cdot 2SO(CH_3)_2$[9].

5. $SeOCl_2$ on the other hand is here exceptional as an acceptor molecule in giving a 1:1 compound $SeOCl_2 \cdot PO(CH_3)_3$. The adducts with $POCl_3$ and sulfoxides cannot be prepared because of metathetical processes [8] but many 1:2 compounds are known, and the crystal structure of $SeOCl_2 \cdot 2NC_5H_5$ has recently been determined [14]. A comparative study of $SeOCl_2 \cdot PO(CH_3)_3$ would be of great interest.

6. The differences between the reactions of $PO(CH_3)_3$, $PO(C_6H_5)_3$, and $POCl_3$ with $HgCl_2$ are obvious. We have without success tried to isolate a 1:2 compound with $PO(CH_3)_3$ and a 5:2 compound with $PO(C_6H_5)_3$.

7. The interaction between $HgCl_2$ and $PO(C_6H_5)_3$ is of the same weak type as between $AsCl_3$ and $POCl_3$[11]. The spectra of $HgCl_2$ and $PO(C_6H_5)_3$ are both preserved and only slightly perturbed in the spectra of the adduct molecules. The band shifts are in the predicted direction and magnitude. The P-O bonds would thus be most perturbed for the highest mole ratio of $HgCl_2$, and the 1:1 adduct actually shows the largest decrease in the phosphoryl band position. The Hg-Cl bond on the other hand must be most perturbed in the 1:2 compound which has the highest $PO(CH_3)_3$ content, and the corresponding stretching frequency is accordingly shifted furthest in that compound.

8. The structure of $HgCl_2 \cdot 2PO(C_6H_5)$ can thus probably not be characterized by simple tetrahedral co-ordination around Hg but rather by a distorted square

co-ordination of the same type as in $HgCl_2 \cdot C_4H_8O_2$[15]. The structures of the 1:1 and 5:2 adducts are difficult to predict. They will be investigated by Mr. Brändén of this Institute as part of an extensive study on the crystal chemistry of $HgCl_2$ adduct molecules.

9. The negative results of the experiments with $Hg(C_6H_5)_2$ and $Hg(C_6H_5)Cl$ confirm earlier suggestions about the negligible or very weak acceptor properties of these compounds [16]. Strohmeier has, however, proved that $Hg(C_2H_5)_2$ has some acceptor character [17].

This work has been sponsored by the *Air Force Office of Scientific Research of the Air Research and Development Command, United States Air Forces*, through its European Office under contract No. AF 61(052)-43. This support is gratefully acknowledged. The Hg analyses were made by Dr. Lilly Gustafsson in the Analytical Department and the infrared spectrograph was put at our disposal by Professor Tiselius. We wish to thank them and Professor Hägg, Head of the Department of Inorganic Chemistry, for friendly help.

Addition Compounds of Diphosphorus Trioxide Tetrachloride

INGVAR LINDQVIST, MARGARETA ZACKRISSON and SIGVARD ERIKSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The formation of addition compounds with diphosphorus trioxide tetrachloride as donor molecule has been studied. The following new compounds have been prepared: $2SbCl_5 \cdot P_2O_3Cl_4$ and $SnCl_4 \cdot P_2O_3Cl_4$, and their infrared spectra have been recorded.

It has been established by a series of X-ray crystallographic structure determinations [1,2] that in phosphoryl chloride $POCl_3$, the oxygen atom functions as the donor in adduct formation. We have been interested in finding out how the related diphosphorus trioxide tetrachloride, $P_2O_3Cl_4$, reacts with typical acceptor molecules (Lewis acids) such as $SbCl_5$ and $SnCl_4$. The molecular structure of $P_2O_3Cl_4$ is not known, but it can safely be predicted to contain an oxygen bridge between the two phosphorus atoms. The bridge oxygen cannot be expected to function as a donor atom as efficiently as the oxygen atoms of the two phosphoryl groups. A study of the compositions of the addition compounds formed was supposed to give some information about this problem.

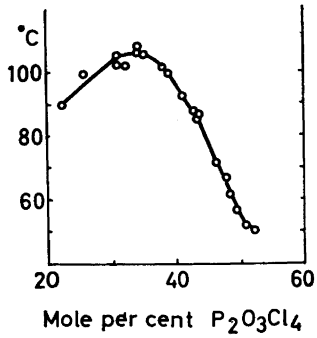

Fig. 1a. The system $SbCl_5-P_2O_3Cl_4$.

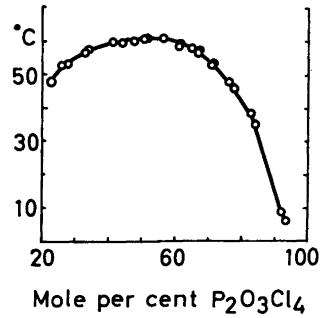

Fig. 1b. The system $SnCl_4-P_2O_3Cl_4$.

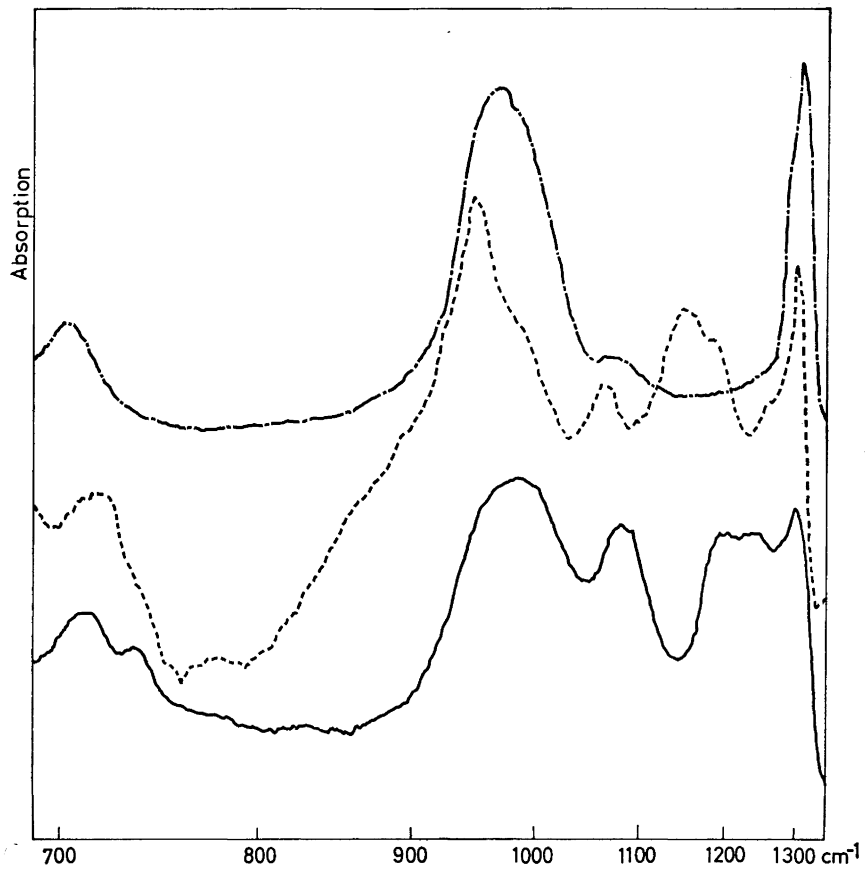

Fig. 2. The IR spectra of $P_2O_3Cl_4$ (broken line), $2SbCl_5 \cdot P_2O_3Cl_4$ (dashed line) and $SnCl_4 \cdot P_2O_3Cl_4$ (full line). In order to obtain a clearer picture the spectra have been arbitrarily displaced along the absorption axis.

EXPERIMENTAL

$P_2O_3Cl_4$ was prepared according to Grunze [3]. $SbCl_5$ and $SnCl_4$ were purified by vacuum distillation. Liquidus curves were studied by a method described earlier [4]. Infrared spectra were recorded on a Perkin-Elmer Model 21 Spectrophotometer equipped with a NaCl prism (in the Institute of Biochemistry). The spectrum of $P_2O_3Cl_4$ was run with the liquid in a thin layer between two NaCl plates. The spectra of the addition compounds were run in Nujol between NaCl plates.

RESULTS

1. The liquidus curve of the system $SbCl_5$-$P_2O_3Cl_4$ (Fig. 1*a*) shows a maximum at the composition $2SbCl_5 \cdot P_2O_3Cl_4$ where the entire liquid phase solidifies. The melting point is $+107-109°C$. At higher mole ratios of $P_2O_3Cl_4$ the study is prevented by strong super-cooling.

2. The liquidus curve of the system $SnCl_4$-$P_2O_3Cl_4$ (Fig. 1*b*) has one rather flat maximum at the composition $SnCl_4 \cdot P_2O_3Cl_4$. The melting point is +72°C.

3. The infrared spectra (in the region 7.5—14.5 μ) are shown in Fig. 2.

DISCUSSION

1. The existence of the compounds $2SbCl_5 \cdot P_2O_3Cl_4$ (*cf.* $SbCl_5 \cdot POCl_3$) and $SnCl_4 \cdot P_2O_3Cl_4$ (*cf.* $SnCl_4 \cdot 2POCl_3$) clearly indicates that in $P_2O_3Cl_4$ the oxygen atoms of both phosphoryl groups but not the bridge oxygen can function as donor atoms. In $2SbCl_5 \cdot P_2O_3Cl_4$ two molecules of $SbCl_5$ would thus be attached to the same molecule of $P_2O_3Cl_4$. In $SnCl_4 \cdot P_2O_3Cl_4$ two alternatives are possible. One possibility is that the two oxygen donor atoms in $P_2O_3Cl_4$ are bonded to the same molecule of $SnCl_4$ in *cis*-position (*cf.* the *cis*-structure of $SnCl_4 \cdot 2POCl_3$[2]). Another possibility is that two different $SnCl_4$ molecules interact with the same molecule of $P_2O_3Cl_4$. The structure would then not contain discrete molecular units of the addition compound.

2. The analysis of the spectrum of $P_2O_3Cl_4$ is very complicated, but we had hoped to be able to identify at least the phosphoryl bond stretching frequency by comparison with the spectra of the addition compounds. We do not feel competent, however, to attempt a correlation. Splitting and decrease of the phosphoryl frequency have probably both taken place as earlier found with $POCl_3$[5], but in this case the complex nature of the pure $P_2O_3Cl_4$ spectrum makes the interpretation more difficult.

This work has been sponsored by the *Air Force Office of Scientific Research of the Air Research and Development Command, United States Air Forces,* through its European Office under contract No. AF 61(052)-43. This support is gratefully acknowledged. The infrared spectrograph was put at our disposal by Professor Tiselius. We wish to thank him and Professor Hägg, Head of the Department of Inorganic Chemistry for friendly help.

On the Mechanism of the Formation of Hyodeoxycholic Acid in the Pig

Bile Acids and Steroids 89

SUNE BERGSTRÖM, ÅKE GÖRANSSON and BENGT SAMUELSSON

Department of Chemistry, Karolinska Institutet, Stockholm, and Djursjukhuset, Hälsingborg, Sweden

The mechanism of the formation of hyodeoxycholic acid has been studied in the pig with chenodeoxycholic acid-7β-^{3}H, 24-^{14}C. This acid was injected intraperitoneally into pigs and a bile fistula was prepared three days later. By this procedure the administered acid is hydroxylated in the liver to hyocholic acid (3α,6α,7α-trihydroxycholanic acid), which is then dehydroxylated to hyodeoxycholic acid (3α,6α-dihydroxycholanic acid) by the microorganisms in the intestine. Determination of the ^{3}H and ^{14}C content of chenodeoxycholic, hyocholic and hyodeoxycholic acids, isolated from the bile, showed that the ^{3}H-label is retained during the hyodeoxycholic acid formation. The mechanism of the elimination of the 7α-hydroxyl group is discussed.

The main bile acids in the normal pig bile are chenodeoxycholic, hyocholic and hyodeoxycholic acids, which occur conjugated mainly with glycine but also to a small extent with taurine [1]. The metabolism of the above mentioned bile acids in the pig has recently been investigated in our laboratories [2]. It was found that chenodeoxycholic acid (3α,7α-dihydroxycholanic acid) is 6α-hydroxylated to hyocholic acid (3α,6α,7α-trihydroxycholanic acid) in the liver, and the latter acid is then dehydroxylated to hyodeoxycholic acid (3α,6α-dihydroxycholanic acid) during the enterohepatic circulation. Hyodeoxycholic acid is not rehydroxylated in the liver. Immediately after the preparation of a bile fistula all three acids are present in the bile. However, hyodeoxycholic acid gradually vanishes and after two days only chenodeoxycholic and hyocholic acids are present [2]. Furthermore, after administration of cholesterol-4-^{14}C to a bile fistula pig the only labelled acidic products excreted in the bile are chenodeoxycholic and hyocholic acids [3]. All these experiments demonstrate

that hyodeoxycholic acid is formed secondarily from hyocholic acid in the intestine and exclude that it may be synthesized primarily in the liver.

The aim of the present investigation was to study the mechanism of hyodeoxycholic acid formation with the aid of chenodeoxycholic acid-7β-^{3}H, 24-^{14}C.

MATERIAL AND METHODS

Labelled acids: Chenodeoxycholic acid 7β-^{3}H was prepared by reducing 7-ketolithocholic acid with tritium-labelled sodium borohydride as described previously [4]. Specific activity: 0.5 μC/mg.

Chenodeoxycholic acid-24-^{14}C was prepared according to the method of Bergström *et al.*[5] Specific activity: 10 μC/mg.

A stock solution of chenodeoxycholic acid-7-β-^{3}H, 24-^{14}C was prepared by dissolving 21.0 mg of chenodeoxycholic acid-7-β-^{3}H and 0.5 mg of chenodeoxycholic acid-24-^{14}C in acetone. The ratio between tritium and ^{14}C of this acid was 1.13, when determined by the gas phase counting procedure.

Animal experiments. 10 mg of doubly labelled chenodeoxycholic acid was injected intraperitoneally as the sodium salt in 0.9 % aqueous sodium chloride into each of two young female pigs weighing about 20 kg. The bile fistulas were prepared three days after the injection of the labelled bile acid, according to the technique described earlier [3], and bile collection in ethanol immediately started.

Fractionation of the bile. The bile from 5 h collection periods was filtered, evaporated to dryness and hydrolyzed with 150 ml of 2 N KOH at 120° for 6 h in a sealed flask. The free bile acids were extracted from the acidified solution with ether.

Chromatographic separations. Reversed phase partition chromatography as described by Bergström, Norman and Sjövall [6,7] was used for separation of the free bile acids. The following solvent systems were used:

System	Moving phase	ml	Stationary phase	ml
C[6]	Methanol:water	150:150	Chloroform:*iso*octanol	15:15
F[7]	Methanol:water	165:135	Chloroform:heptane	45:5

3 ml of the stationary phase was supported on 4.5 g of Hostalene (Farbwerke Hoechst G.m.b., West Germany) [8]. Hostalene was purified before use by extraction with 95 % ethanol for 48 h in a Soxhlet extractor and then dried at 75°. All the chromatograms were run at a constant temperature of +23°.

Isotope analyses. The administered and isolated bile acids were combusted to CO_2 and water. The water was converted to butane with butyl magnesium bromide and the ^{14}C and ^{3}H of the CO_2 and butane was determined by gas phase counting as described by Glascock [6]. Two determinations were made on each bile acid sample.

RESULTS

Chenodeoxycholic acid 7β-^{3}H, 24-^{14}C was injected intraperitoneally into two pigs and bile fistulas were prepared three days after the injection. It has previously been demonstrated that chenodeoxycholic acid is hydroxylated at the 6α-position to hyocholic acid (3α,6α,7α-trihydroxycholanic acid) in the liver. The latter acid is dehydroxylated to hyodeoxycholic acid (3α,6α-dihydroxycholanic acid) by the intestinal microorganisms during the enterohepatic circulation. By the above-mentioned procedure it was thus expected that the injected doubly labelled chenodeoxycholic acid would be converted into both hyocholic and hyodeoxycholic acids.

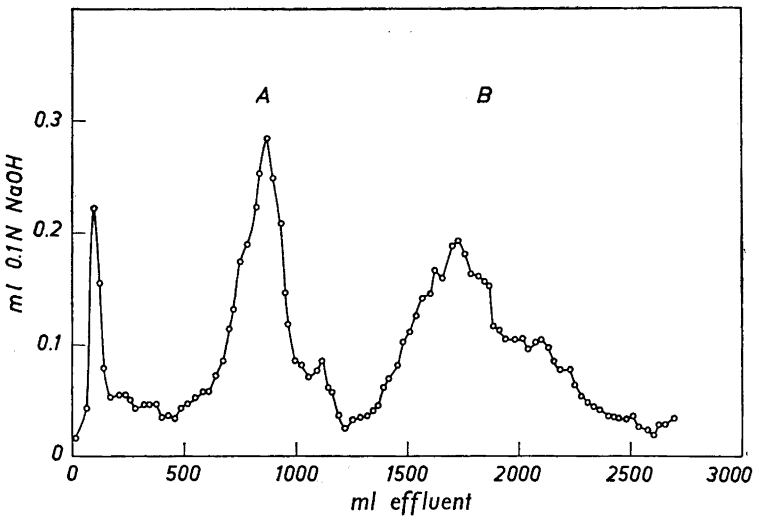

Fig. 1. Chromatographic separation of acids from hydrolyzed pig bile, excreted during 5h following the preparation of the bile fistula. Chenodeoxycholic acid-7β-^{3}H,24-^{14}C was administered 3 days before the operation. Column: 45 g Hostalene. Solvent system: Type C.

The hydrolyzed bile was chromatographed with solvent system C. In Fig. 1 is shown a chromatogram of the bile acids excreted during 5 h immediately following the operation (Pig I).

The material in the fractions of the peak (A. 650—1 000 ml effluent) which has the elution volume characteristic of hyocholic acid, was crystallized from aqueous acetic acid and aqueous acetone. Yield: 141.6 mg of hyocholic acid, m. p. 184—185°. (Lit.[10] m. p. 188—189°.) The second peak of the chromatogram shown in Fig. 1 (B. 1 350—2 400 ml effluent) was rechromatographed with solvent system F (Fig. 2), which is suitable for separation of dihydroxycholanic acids. Two major peaks appear, of which the first one (150—290 ml effluent) is eluted with the elution volume of hyodeoxycholic acid and the second one (300—410 ml effluent) with that of chenodeoxycholic acid. The material in these peaks was crystallized from ethyl acetate and ethylacetate/light petroleum, respectively, yielding 135.7 mg of hyodeoxycholic acid m. p. 198—199°, (Lit.[10] m. p. 197—198°) and 95.8 mg of chenodeoxycholic acid, m. p. 140—141° (Lit.[11] m. p. 140—142°).

The ^{3}H and ^{14}C content of the administered chenodeoxycholic acid 7β-^{3}H, 24-^{14}C and the isolated chenodeoxycholic, hyocholic and hyodeoxycholic acids from two pigs was determined. From the results of these determinations (Table 1) it is obvious that the original ^{3}H-labelling in chenodeoxycholic acid is retained both in hyocholic acid and in hyodeoxycholic acid.

Hyodeoxycholic acid, isolated from the bile, was oxidized with chromic acid in aqueous acetic acid at 2—3° to 3α-hydroxy-6-ketocholanic acid (m.p. 156—160°) [12] which had the same ^{3}H content as the starting material (Table 1).

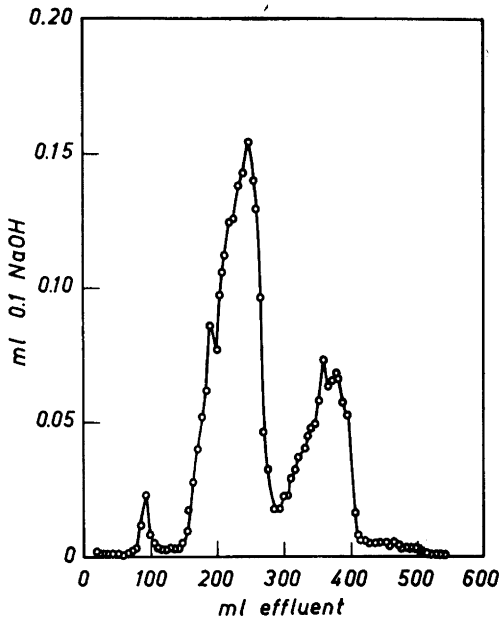

Fig. 2. Chromatographic separation of peak B of the chromatogram, shown in Fig. 1. Column: 22.5 g Hostalene. Solvent system: Type F.

The keto acid (200 mg) was dissolved in 15 ml 2 N KOH and refluxed for 24 h. The product was crystallized from ethylacetate yielding 112 mg of 3α-hydroxy-6-keto allocholanic acid (m. p. 187—188°) [12]. This acid contained only 5 % of the original ^3H labelling.

DISCUSSION

The formation of hyodeoxycholic acid in the pig involves elimination of the 7α-hydroxyl group from hyocholic acid, which is formed in the liver through 6α-hydroxylation of the primarily synthesized chenodeoxycholic acid.

This type of elimination reaction was originally demonstrated in the rabbit [13], in which the main bile acid, deoxycholic acid, is formed by dehydroxylation of cholic acid during the enterohepatic circulation. The same reaction has also been found in man [14] and in the rat [15]. The elimination of the hydroxyl group in hyocholic acid as well as in cholic acid is carried out by the microorganisms in the intestine. The mechanism of the elimination of the 7α-hydroxyl group has been studied in the rabbit with the aid of 7β-tritio-cholic acid [16]. The fact that the tritium label was retained in the deoxycholic acid excluded that an intermediate ketone formation occurs, although 7-keto-deoxycholic acid was rapidly converted into deoxycholic acid. This makes it probable that the dehydroxylation consists of a dehydration-reduction reaction sequence or a direct elimination. As 7α-hydroxylation of the formed deoxycholic acid in the rat liver resulted in complete elimination of the tritium label it appears probable that it had been moved into the 7α-position. In the present investigation the formation of hyodeoxycholic acid through an analogous reaction was studied with chenodeoxycholic acid-7β-^3H, 24-^{14}C. Determination of ^3H and ^{14}C in the administered and isolated chenodeoxycholic acid and isolated hyocholic and hyodeoxycholic acids showed that the ^3H-label is retained in the molecule during these transformations, *i. e.* hydroxylation at C6 and dehydroxylation at C7. The ^3H-label was still present in 3α-hydroxy-6-ketocholanic acid, formed by chromic acid oxidation of hyodeoxycholic acid, but could be eliminated by a base-catalyzed exchange of the keto-derivative, indicating that the ^3H-label was retained at C7 in hyodeoxycholic acid. The available data do not indicate if the label was in the 7α- or 7β-position (*cf.* above).

The most probable mechanisms for the elimination reaction, which are consistent with the isotopic experiments, are summarized below.

1) Direct elimination of the hydroxyl group at C7.
2) a) Dehydration with the formation of a Δ^6 or Δ^7-double bond.
   b) Reduction of this double bond.
3) a) Dehydration to the Δ^6-unsaturated derivative.
   b) Enol-ketone-rearrangement to 3α-hydroxy-6-ketocholanic acid.
   c) Reduction of the 6-ketoderivative to hyodeoxycholic acid.

The first two mechanisms have been discussed previously for the elimination of the 7α-hydroxyl group from cholic acid. Nor is it possible to differentiate between these two possibilities by the experiments reported in this paper.

In the hyodeoxycholic acid formation, however, a third mechanism cannot be excluded. Dehydration of hyocholic acid to the Δ^6-unsaturated derivative entails the formation of a compound with an enol configuration that might very easily rearrange to the ketone. Further work is in progress to clarify the above-mentioned questions.

High Temperature X-Ray Study of the Thermal Expansion of PtS_2, $PtSe_2$, $PtTe_2$ and $PdTe_2$

ARNE KJEKSHUS and FREDRIK GRØNVOLD

Kjemisk Institutt A, Universitetet i Oslo, Blindern, Norway

PtS_2, $PtSe_2$, $PtTe_2$ and $PdTe_2$, all with structures of the $Cd(OH)_2$-type and $c/a < 1.633$, have been studied by the X-ray powder method at temperatures in the range from 20 to 950°C. The thermal expansion is considerably anisotropic for all four compounds. For the a-axis it is almost linear over the whole temperature range, with linear thermal expansion coefficient, β_a, equal to 2.3×10^{-6} °C^{-1} for PtS_2 (20–562°C), 5.7×10^{-6} °C^{-1} for $PtSe_2$ (20–946°C), 5.8×10^{-6} °C^{-1} for $PtTe_2$ (20–870°C) and 12.0×10^{-6} °C^{-1} for $PdTe_2$ (20–574°C). For the c-axis the thermal expansion is approximately linear at lower temperatures only, and the expansion coefficient, β_c, equal to 37×10^{-6} °C^{-1} for PtS_2 (20–250°C), 20×10^{-6} °C^{-1} for $PtSe_2$ (20–283°C), 27×10^{-6} °C^{-1} for $PtTe_2$ (20–591°C) and 30×10^{-6} °C^{-1} for $PdTe_2$ (20–284°C). At higher temperatures the c-axis of PtS_2, $PtSe_2$ and $PtTe_2$ increases more slowly than at lower temperatures, while the c-axis of $PdTe_2$ increases more rapidly. For all compounds the volume expansion has a temperature dependence similar to that of the c-axis. The average thermal volume expansion coefficient, α, is 40×10^{-6} °C^{-1} for PtS_2 (20–250°C), 31×10^{-6} °C^{-1} for $PtSe_2$ (20–283°C), 39×10^{-6} °C^{-1} for $PtTe_2$ (20–591°C) and 57×10^{-6} °C^{-1} for $PdTe_2$ (20–284°C). The interatomic distances between metal and metalloid atoms, and between the metalloid atoms, have been calculated for the various temperatures.

Although detailed investigations are necessary for a complete description of the thermal movement of the atoms or molecules forming a crystal, some information might, in simple cases, be obtained from the thermal expansion of the crystal. Because of anharmonic vibrations in the crystals the expansion is generally not isotropic [1]. For layer structures the anisotropic expansion in favor of the direction normal to the layers is explainable on the basis of weak bonds between the atoms in different layers.

The present paper concerns the thermal expansion of PtS_2, $PtSe_2$ and $PtTe_2$[2] and $PdTe_2$[3], all of which have structures of the $Cd(OH)_2$-type. A drawing of four unit cells of the $Cd(OH)_2$-type structure is shown in Fig. 1. Filled circles represent metal atoms in (0 0 0), while open circles represent metalloid atoms

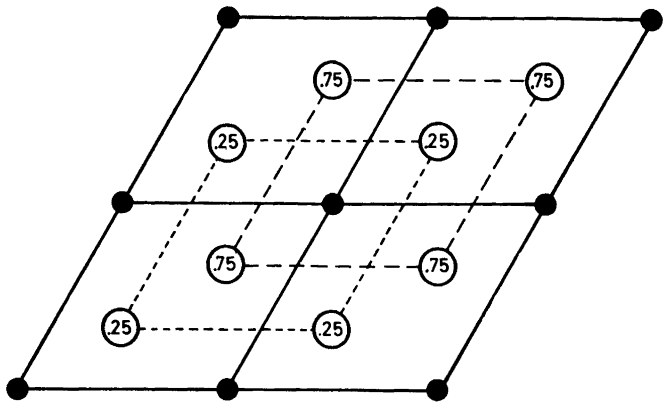

Fig. 1. Projection of four unit cells of the $Cd(OH)_2$-type structure on (001).

in ($\frac{2}{3}$ $\frac{1}{3}$ z) and ($\frac{1}{3}$ $\frac{2}{3}$ $\bar{z}$), with $z = 0.250$. From Fig. 1 it is seen that both metal and metalloid atoms form hexagonal nets, but at different heights. In the projection they are repeated at every 1/3 face diagonal.

Only a few compounds with this type of structure have been examined at temperatures other than room temperature. Megaw [4] studied the thermal expansion of single crystals of $Ca(OH)_2$ and $Mg(OH)_2$ by X-ray methods from 0 to 100°C. For these compounds the coefficient of expansion normal to the hexagonal layers was found to be 3 to 4 times larger than parallel to the layers.

Bredig [5] examined CdI_2, which forms polytypic structures based upon the $Cd(OH)_2$-structure [6], and found that this compound also exhibits relatively large thermal expansion normal to the hexagonal layers. (From 25 to 325°C β_c is approximately 4×10^{-5} °C^{-1}, while β_a is 1×10^{-5} °C^{-1}).

$NiTe_2$, with $Cd(OH)_2$-type structure, has been studied at several temperatures up to 800°C by Schneider and Imhagen [7]. They also determined the lattice constants of different samples in the composition range from NiTe (NiAs-type structure) to $NiTe_2$ as function of temperature.

Other compounds with layer structures, *e.g.* graphite [8], and boron nitride [9], show contraction in the hexagonal layers with increasing temperature, and large expansion perpendicular to the layers.

EXPERIMENTAL

The platinum chalcogenides were prepared from stoichiometric amounts of the elements heated in evacuated, sealed silica tubes at 825°C and slowly cooled to room temperature. The palladium ditelluride was prepared at 600°C.

Information about the purity of the elements is given elsewhere [2,3].

X-Ray powder photographs of the compounds were taken in a 190 mm Unicam high-temperature camera, with the samples sealed in thin-walled quartz capillaries. The samples were studied at temperatures between 20 and 950°C. PtS_2 and $PdTe_2$ could not, however, be examined at the very highest temperatures, PtS_2 because of its great dissociation pressure [10] which made the thin-walled quartz capillaries burst, and $PdTe_2$ because of its relatively low melting point of about 700°C.

By means of a voltage regulator, the registered temperature of the furnace surrounding the specimen was kept constant within $\pm 5°C$. The Pt/Pt-Rh thermocouples of the furnace had been calibrated with a standard couple located at the position of the specimen. Lattice constants are given in Ångström units ($\lambda CuK_{\alpha_1} = 1.54050$ Å). Only the high-angle reflections of the diffraction pattern were used in the calculation of the lattice constants. The probable error in the lattice constant determinations at temperatures above room temperature is estimated to be about 0.02 %. This includes a possible error due to variation in the composition of the sample with temperature.

RESULTS

The results of the lattice constant measurements are listed in Table 1. Here is also listed the c/a ratio, the unit cell volumes, the shortest interatomic distances between metal and metalloid atoms [(000)(2/3 1/3 0.250)] and between the metalloid atoms [(2/3 1/3 0.250) (1/3 2/3 $\overline{0.250}$)]. For every measured or

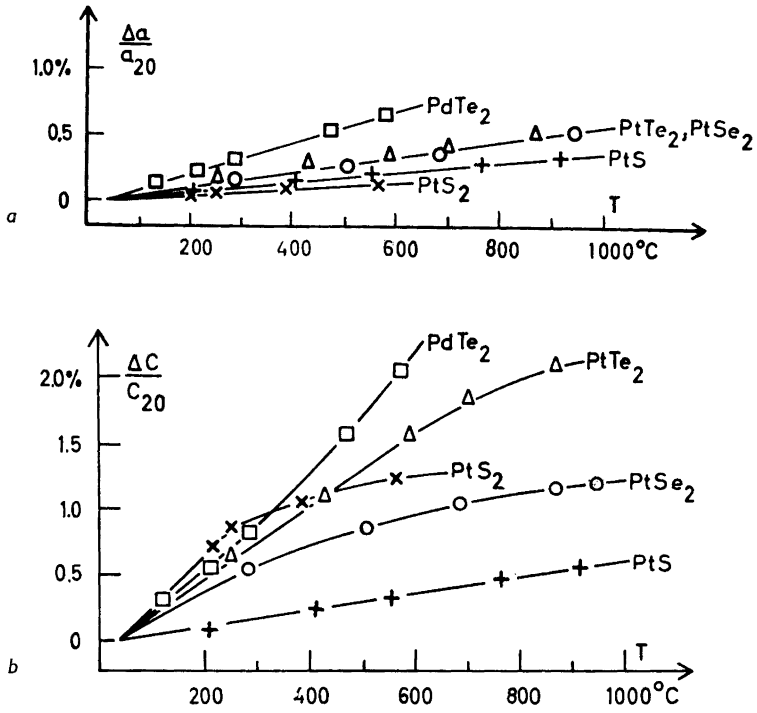

Figs. 2a, b. Relative lattice constant variations as function of temperature.

calculated property x_T, the ratio $\frac{x_T - x_{20}}{x_{20}} = \frac{\Delta x}{x_{20}}$ is calculated and plotted as $\frac{\Delta x}{x_{20}}$ *versus* T. The calculations of the expansion coefficients were based upon these data.

The change in length of the cell edges with temperature is rather different along the different axes. As shown in Fig. 2a, the a-axis of all four compounds increases linearily with increasing temperature. The expansion coefficient β_a is equal to 2.3×10^{-6} °C^{-1} for PtS_2 (20—562°C), 5.7×10^{-6} °C^{-1} for $PtSe_2$ (20—946°C), 5.8×10^{-6} °C^{-1} for $PtTe_2$ (20-870°C) and 12.0×10^{-6} °C^{-1} for $PdTe_2$ (20—574°C). The corresponding curves for the c-axis are shown in Fig. 2b. Those for PtS_2, $PtSe_2$ and $PtTe_2$ are of similar shape, while that for $PdTe_2$ is different. At lower temperatures the thermal expansion of the c-axis is linear, with expansion coefficient β_c equal to 37×10^{-6} °C^{-1} for PtS_2 (20—250°C), 20×10^{-6} °C^{-1} for $PtSe_2$ (20—283°C), 27×10^{-6} °C^{-1} for $PtTe_2$ (20—591°C) and 30×10^{-6} °C^{-1} for $PdTe_2$ (20—284°C). At higher temperatures the c-axis of PtS_2, $PtSe_2$ and $PtTe_2$ increases more slowly than at lower temperatures. The curve for the c-axis of $PdTe_2$ has the opposite curvature, and rises more sharply than at lower temperatures. In the temperature region just

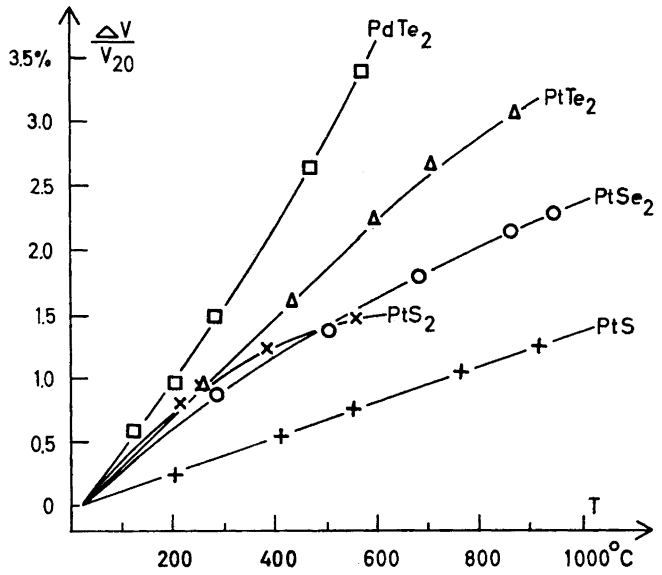

Fig. 3. Relative volume expansions as function of temperature.

below melting a fairly large increase in the coefficient of thermal expansion for the *c*-axis of $PdTe_2$ seems to occur.

The volume expansion is plotted as function of temperature in Fig. 3. For all compounds the volume expansion has a similar temperature dependence as the *c*-axis. The first part of the curves is approximately linear. The average thermal volume expansion coefficient α is 40×10^{-6} °C^{-1} for PtS_2 (20—250°C), 31×10^{-6} °C^{-1} for $PtSe_2$ (20—283°C), 39×10^{-6} °C^{-1} for $PtTe_2$ (20—591°C) and 57×10^{-6} °C^{-1} for $PdTe_2$ (20—284°C).

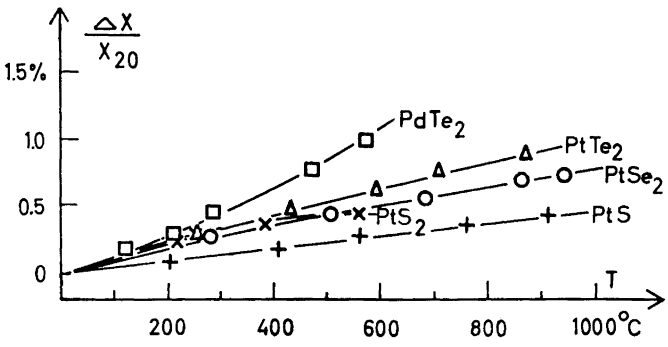

Fig. 4. Relative changes in interatomic bond distance between metal and metalloid atoms with temperature.

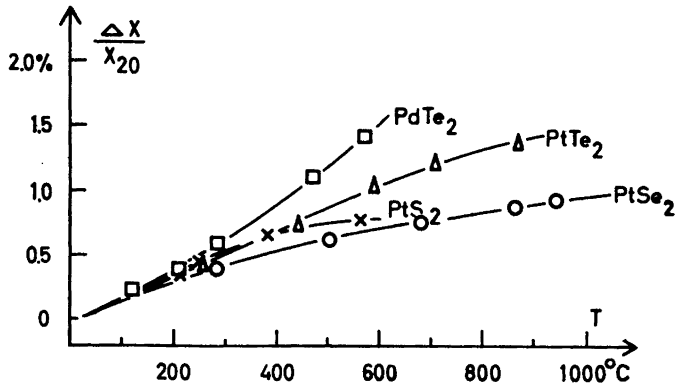

Fig. 5. Relative changes in the shortest metalloid-metalloid distance with temperature.

As seen from Fig. 4, the changes in bond distance are of the same order of magnitude as the average linear expansion. The expansion curves have a linear region with expansion coefficients 11×10^{-6} °C^{-1} for PtS_2 (20—250°C), 10×10^{-6} °C^{-1} for $PtSe_2$ (20—283°C), 11×10^{-6} °C^{-1} for $PtTe_2$ (20—591°C), and 16×10^{-6} °C^{-1} for $PdTe_2$ (20—284°C). The shortest metalloid-metalloid distances (*cf.* Fig. 5) change similarly, while the shortest metal-metal distances vary as the *a*-axis. The expansion coefficient over the linear region in Fig. 5 is 17×10^{-6} °C^{-1} for PtS_2 (20—250°C), 15×10^{-6} °C^{-1} for $PtSe_2$ (20—283°C), 17×10^{-6} °C^{-1} for $PtTe_2$ (20—591°C), and 23×10^{-6} °C^{-1} for $PdTe_2$ (20—284°C). The changes in the metal-metalloid and the metalloid-metalloid distances are calculated on the assumption that the parameter z has the same value $z = 0.250$ at all temperatures.

DISCUSSION

The present results show agreement with the expansion measurements [4] of $Mg(OH)_2$ and $Ca(OH)_2$ with regard to linearity and strong anisotropy of the expansion coefficients in the lower temperature range. The measurements were, however, only carried to about 100°C and deviations from linearity of the expansion coefficient might well take place at higher temperatures. From the results of Schneider and Imhagen [7] on $NiTe_2$ the curvature of the lattice constant variation could not be obtained with certainty.

Comparison with results from thermal expansion of compounds with other than $Cd(OH)_2$-type structures will here be limited to compounds with supposedly similar chemical bond type. Results for MnTe [11] and CrSb [12], both with NiAs-type structure, are similar in the temperature range below the antiferromagnetic transition temperature to those found for $PdTe_2$. In the range from −100 to + 50°C the thermal expansion coefficient of the *a*-axis of MnTe is almost zero, while for the *c*-axis it increases with temperature. In the range from 0 to 450°C the *a*-axis of CrSb increases linearly, while the *c*-axis increases more rapidly than at lower temperatures. FeS and $FeS_{1.09}$ also with NiAs-like

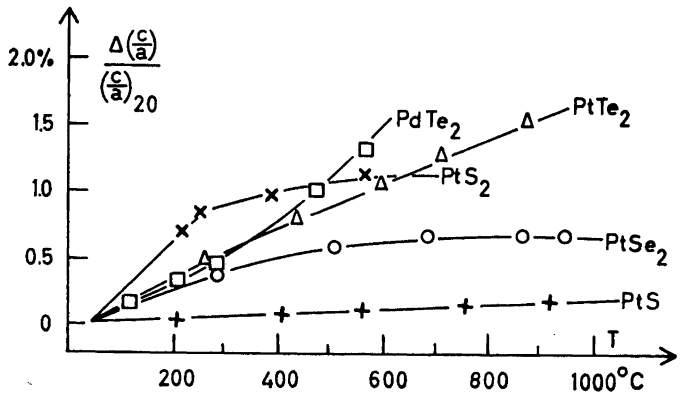

Fig. 6. Relative changes in the c/a ratio with temperature.

structures have been examined [13] in the temperature range from 20 to 385°C. Both a-axis and c-axis are found to increase with temperature. The expansion in the hexagonal plane is larger than perpendicular to it. For FeS $\beta_a \approx 1.5 \times 10^{-5}$ °C^{-1}, $\beta_c \approx 0$ (20 — 138°C) and $\beta_a \approx 1.7 \times 10^{-4}$ °C^{-1}, $\beta_c \approx 4 \times 10^{-5}$ °C^{-1} (138 — 325°C), and for $FeS_{1.09}$ $\beta_a \approx 5 \times 10^{-5}$ °C^{-1}, $\beta_c \approx 8 \times 10^{-6}$ °C^{-1} (75 — 325°C).

The present authors have examined the thermal expansion of PtS with B17-type structure. This compound has linear expansion both in the a- and c-directions, with $\beta_a \approx 3.9 \times 10^{-6}$ °C^{-1} (20—915°C) and $\beta_c \approx 5.8 \times 10^{-6}$ °C^{-1} (20—915°C) (*cf.* Figs. 2a, b). As apparent from Fig. 6 the expansion is approximately isotropic. The volume expansion (*cf.* Fig. 3) is linear with coefficient (α) 13.7×10^{-6} °C^{-1} in the temperature range studied. The platinum-sulfur bond distance shows a linear change in the examined temperature range with expansion coefficient 4.7×10^{-6} °C^{-1}, (*cf.* Fig. 4). The shortest metal-metal distance is also here equal to the length of the a-axis and shows the same variation with temperature (*cf.* Fig. 2a). There are two different short sulfur-sulfur distances which have the same relative variation as the a-axis and c-axis, respectively (*cf.* Figs. 2a, b).

Starting from absolute zero, the first part of a thermal expansion curve should be of sigmoidal type similar to the heat capacity curve. The reasons for the increase in volume at higher temperatures are not fully explained by the existing theories for the perfect lattice. On approaching melting, the curve is expected to show a rapid increase caused by an increasing number of lattice defects [14]. Fletcher [15] has attempted to show that the theories might account for the enhanced expansion without assuming lattice defects.

Of the compounds studied here only $PdTe_2$ shows an increase of the relative volume expansion at higher temperatures. This compound also has the lowest melting point. The relative expansions of PtS_2, $PtSe_2$ and $PtTe_2$ are still on the upper part of the sigmoidal curve.

Fajans [16] has found that in chemical compounds there is usually an increase in the thermal expansion with decreasing electronegativity difference between the elements. This rule applies to the two compounds $PtSe_2$ and $PtTe_2$ with α equal to $31 \times 10^{-6}\,°C^{-1}$ and $39 \times 10^{-6}\,°C^{-1}$, respectively, but not to PtS_2 and $PtSe_2$ or $PtTe_2$ since the expansion coefficient of PtS_2, $40 \times 10^{-6}\,°C^{-1}$, is greater than for the two others. The possibility that this might have been caused by PtS_2 loosing sulfur due to dissociation at higher temperatures cannot be excluded. If one, however, considers the a-axes, the expansion coefficient β_a increases from the sulfide to the telluride.

Acknowledgement. The authors wish to thank Professor Haakon Haraldsen for his interest in this study and for placing laboratory facilities at their disposal.

Crystal Structure of the Addition Compound 1,4-Dioxan-Chlorine

O. HASSEL and KNUT O. STRØMME

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

An X-ray analysis of the 1:1 compound 1,4-dioxan chlorine carried out at temperatures between −30° and −90°C shows that the crystals are isomorphous with those of the corresponding bromine compound [1]. The monoclinic unit cell has the dimension a = 9.36 Å, b = 8.83 Å, c = 4.13 Å and β = 91.5°. The observed O—Cl and Cl—Cl distances associated with the chlorine molecule bridges are 2.67 and 2.02 Å, respectively.

During the last years a series of addition compounds formed by molecules containing a donor atom (A) and halogen molecules have been studied in the solid state by X-ray crystallographic methods. One of the most striking features observed in these compounds is the existence of linear atomic arrangements A-halogen-halogen. So far, the halogen molecules chosen have been those of iodine or bromine, in some cases also iodo monochloride. In no case have addition compounds in which chlorine is directly attached to the donor atom been studied. From our earlier experience it would in fact seem probable that a charge transfer bond between, *e.g.*, an oxygen atom and a chlorine atom should be even weaker than the bond to a bromine atom which is in turn certainly weaker than an oxygen-iodine bond.

Results, recently obtained, tend to confirm this view but show that a series of donor molecules actually form addition compounds with chlorine which are isomorphous with the bromine and even the iodine compounds. This might perhaps appear a little surprising when we consider the difference in atomic radii of the different halogen atoms. The A-halogen bond distance, however, is determined both by the size of the halogen atom and by the strength of the bond established by electron transfer between the two atoms. Although the smaller radius of the chlorine atom will tend to shorten this bond distance a certain compensation results from the fact that the bond is weaker in the case of chlorine than in the case of bromine. The analogy between crystals containing a donor molecule and chlorine and those containing the same donor molecule and bromine, even suggests the formation of »chlorine molecule bridges» in chlorine addition compounds.

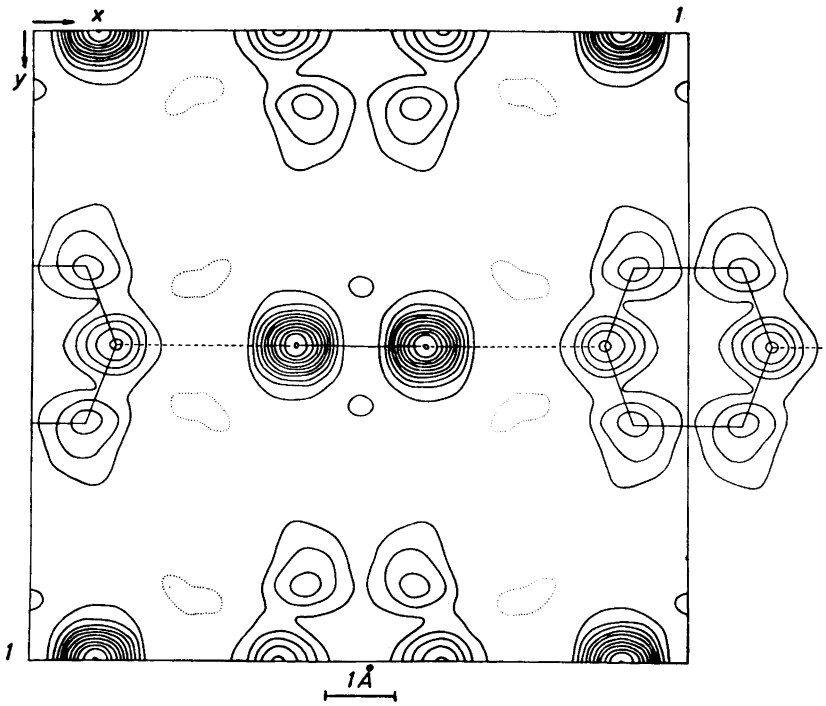

Fig. 1. Projection along [001]. Contour intervals $2\sum e$. Å^{-2}. Zero contour dotted.

Choosing first the 1:1 compound between 1,4-dioxan and chlorine, a report on the determination of the crystal structure of this compound will be given here.

Single crystals were obtained by cooling an equimolecular mixture of the two substances in a capillary tube mounted in a Weissenberg camera equipped with a cooling system. The melting point of the addition compound is approximately −5°C. Zero layer line Weissenberg photographs were taken at temperatures below −30°C, mostly at −90°C, and with rotation about the directions [001], [110] and [101] of the monoclinic cell.

The lattice parameters obtained from the diagrams are:

$$a = 9.36 \text{ Å} \qquad b = 8.83 \text{ Å} \qquad c = 4.13 \text{ Å} \qquad \beta = 91.5°$$

and the number of molecules in the unit cell *two* (density about 1.55). These figures and the following analysis confirmed the suggestion that the compound is actually isomorphous with the corresponding bromine compound and belongs to the space group $C2/m$. It was found difficult, however, to obtain good single crystals, particularily if the crystals had their c-axis approximately parallel to the axis of the capillary tube. It was observed that the crystals

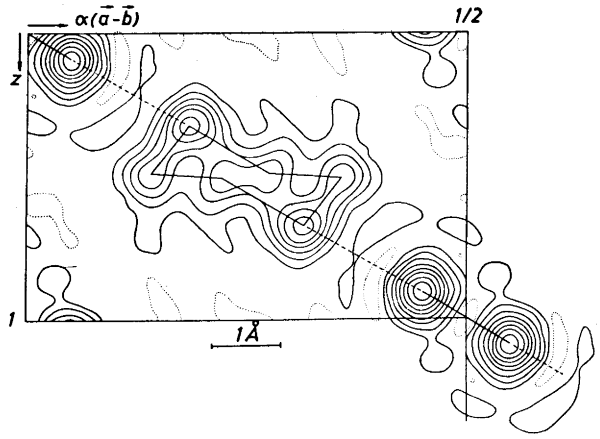

Fig. 2. Projection along [110]. Contours: 0, 2, 4, 8, 12, 16, — for chlorine and 0, 2, 4, 6, 8, 10 — for light atoms. Zero contour dotted.

have a marked tendency to grow along directions which are approximately parallel to the directions of the endless molecular chains of which the entire structure is found to be built up.

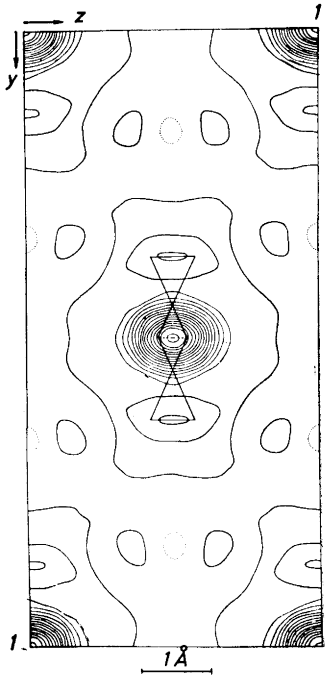

Fig. 3. Projection along [101]. Contours: 0, 2, 6, 10, 14 —. Zero contour dotted.

Table 1. Atomic coordinates in fractions of the cell-edges. Origin at a center of symmetry.

	x	*y*	*z*
O	0.371	0.000	0.322
Cl	0.101	0.000	0.094
C	0.419	0.134	0.492

Table 2. Bond distances and bond angles in the dioxan molecule.

C—C	1.52 Å (1.529);	C—O	1.44 Å (1.421)
∠ C—O—C	111° (112.5);	∠C—C—O	109° (109.0)

The suggestion that the dioxan-chlorine structure is very similar to the dioxan-bromine structure [1] made it appear reasonable to carry out the first Fourier synthesis along [001] inserting chlorine parameters almost identical with the bromine parameters found for the dioxan-bromine compound. The intensity material obtained from zero layer line photographs with rotation about the *c*-axis appeared, however, to be less satisfactory than intensity data obtained from other diagrams. For this reason the intensity material was partly supplemented by intensity data obtained from diagrams with rotation about other crystallographic directions.

The final electron density maps are reproduced in Figs. 1—3. The atomic coordinates computed using these maps are given in Table 1.

In the projection along [101] serious overlapping of atoms occurs. This is not the case in the two other projections, but the intensity material on which the [110] projection is based was considered more reliable than that leading to the [001] projection. Table 1 is mainly based on the coordinates obtained from this projection.

From the coordinates given in Table 1 the bond distances and bond angles within the dioxan molecule listed in Table 2 have been computed.

The values in parantheses are those recently obtained in this laboratory by Michael Davis from an electron diffraction study of dioxan vapour.

The Cl—Cl bond distance is 2.02 Å and thus only slightly longer than the spectroscopic value for the free molecule (1.988). The Cl—O distance obtained is 2.67 Å. The standard deviation in the Cl—Cl distance is 0.013 Å, in the *Cl*—O distance 0.026 Å and in the C—C distance 0.045 Å. It appears probable that the conclusion is legitimate that the chlorine-oxygen distance in the dioxan chlorine compound is actually slightly smaller than the bromine-oxygen distance in the corresponding bromine compound. The angle O—Cl—Cl is found equal to 178°. It appears doubtful whether or not the deviation from 180° is real. The deviation of the O—Cl bond from the direction of an equatorial bond is about 19° and in the same direction as that obtained in the bromine and iodine compounds.

The relatively small values of the temperature factor *B* ranging from 2.0 for exposures at the lowest temperature to 2.8 for the high temperature, indicate a relatively rigid structure.

Table 3. Observed and calculated structure factors. The figures represent one half of the absolute values.

Crystal Structure of the Addition Compound Benzene-Chlorine (1:1)

O. HASSEL and KNUT O. STRØMME

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The crystal structure of an equimolecular addition compound benzene-chlorine has been determined using single crystal Weissenberg technique and working at low temperatures, mainly about −90°C. The crystals are *monoclinic* (space group $C2/m$) and isomorphous with those of the corresponding benzene-bromine compound [2]. Chains of alternating benzene and chlorine molecules are present in the crystal, the Cl—Cl distance is 1.99 Å and the distance from one particular chlorine atom to the nearest benzene plane (3.28 Å), a little shorter than the corresponding distance in the bromine compound.

A considerable amount of experimental material has been gathered during the last few years concerning crystal structures of charge transfer compounds in which molecules of the heavier halogens and iodo monochloride are the electron acceptors. The most conspicuous results of these investigations are the facts that in all compounds so far investigated the arrangement, donor atom-halogen-halogen, is *linear*, and that both atoms of a particular halogen molecule may be capable of forming bonds to donor atoms.

Recently X-ray work has been started on addition compounds formed by *chlorine*. The first crystal structure to be studied was that of the 1:1 compound formed by 1,4-dioxan and chlorine [1]. It could be shown that this compound is isomorphous with the corresponding bromine compound and a proof of the existence of chlorine molecule bridges between oxygen atoms was thereby given. The next step in our research programme was to look for a possible solid compound between benzene and chlorine. We actually succeeded in growing crystals of a 1:1 compound and in determining its crystal structure.

The procedure followed was very similar to that briefly described for the benzene-bromine compound [2]. By cooling an equimolecular mixture of benzene and chlorine in a capillary tube to temperatures below −50°C (m.p. −40°C) single crystals of the 1:1 compound could be grown which were suitable for X-ray analyses in a Weissenberg camera. Photographs with CuK-radiation

Table 1. Atomic coordinates in fractions of the cell-edges. Origin at a center of symmetry.

Atom	x	y	z
Cl	0.116_5	0.000	0.116_5
C_1	0.575	0.080	0.342
C_2	0.500	0.161	0.500

and rotation about three different crystallographic directions were obtained at temperatures mainly at about −90°C.

The crystals turned out to be monoclinic, space group $C2/m$ with lattice parameters: $a = 7.41$ Å, $b = 8.61$ Å, $c = 5.65$ Å, $\beta = 99.5°$. With these parameters and assuming the unit cell to contain two molecules of either kind a density of 1.40 g/cm^3 is computed. This conforms to the expected density of a compound containing equal numbers of the two kinds of molecules. These findings make it appear extremely probable that the crystalline chlorine-benzene compound is isomorphous with the bromine-benzene compound previously investigated.

From zero layer line Weissenberg diagrams with rotation about [001], [100] and [10$\bar{1}$] intensity data were derived which could be used for the computation of electron density projections. It was assumed that the structure is indeed closely similar to that of the benzene-bromine compound [2]. The final Fourier maps with projections along [001], [100], and [10$\bar{1}$] are reproduced in Figs. 1—3. The number of reflexions observed in the ($hk0$) zone is 28 (theor. 48), in the ($0kl$) zone 26 (theor. 39) and in the (hkh) zone 19 (theor. 27). The atom form factors were taken from McWeeney [3] (hydrogen), Berghuis *et al.*[4] (carbon) and International Tables [5] (chlorine).

In Table 1 the atomic coordinates derived from the Fourier projections are listed. On computing the reliability factors it was found that the agreement between observed and calculated F-values improved on including the contribution from the hydrogen atoms, the coordinates of which were taken from a model. The R-values obtained were:

[001] 11.0 %; [100] 7.3 %; [10$\bar{1}$] 11.3 %

When calculationg the R-values a few strong reflexions which are suffering from extinction effects were omitted. Calculated and observed F-values are listed in Table 2. The following (anisotropic) temperature factors were introduced:

$$B_{100} = 3.2 \; ; \quad B_{010} = 7.8 \; ; \quad B_{001} = 5.2$$

The experimental results thus indicate anisotropic vibrations of the chlorine atoms, the vibrations being more pronounced perpendicular to [101] (the Cl—Cl direction) than along this direction. It appears justified, however, to assume that the thermal vibrations are independent of the direction within planes perpendicular to [101] (parallel to the benzene rings). This assumption actually conforms very well to the experimentally observed damping of the X-ray reflections.

Table 2. Observed and calculated structure factors. The figures represent one half of the absolute values. F—'s suffering from extinction are marked with an asterisk.

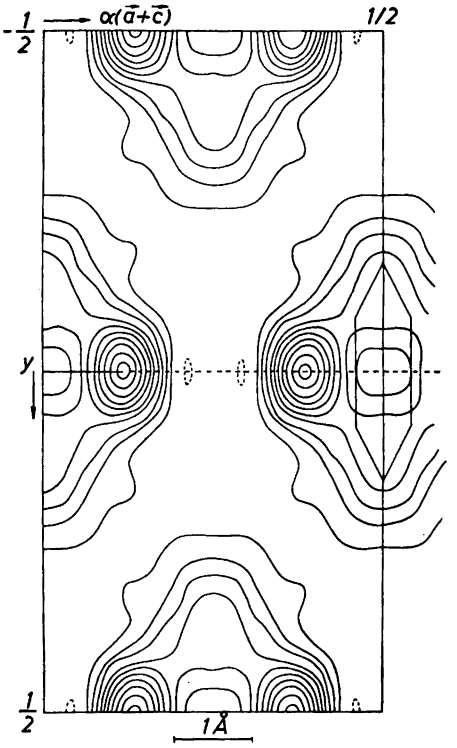

Fig. 3. Fourier projection along [10$\bar{1}$]. Contours as in Fig. 1.

All our findings thus confirm the expected close analogy between the structures of the benzene compounds of chlorine and bromine. In both cases the thermal movement of the atoms takes place preferably parallel to the benzene planes. The Cl—Cl bond direction is at least very nearly perpendicular to the benzene rings. The distance from a particular chlorine atom to the nearest benzene ring is 3.28 Å and thus 0.08 Å shorter than the corresponding distance in the bromine compound [2]. The observed Cl—Cl distance is 1.99 Å and thus identical with the spectroscopical value for the free molecule. In Table 3 the angles and interatomic distances in the benzene ring have been listed. The standard deviations of the reported distances are the following:

Cl—Cl 0.013 Å; C—Cl 0.026 Å; C—C 0.034 Å.

Table 3. Interatomic distances and angles within the benzene ring.

Bond	Bond length (Å)	Angle	
C_1-C_1	1.38	$C_1-C_1-C_2$	120.7°
C_1-C_2	1.37	$C_1-C_2-C_1$	118.6°

The present structure thus affords a second example of a chlorine molecule bridge in an addition compound, and of isomorphism between addition compounds in which chlorine and bromine are the electron acceptors. It is to be expected that many new examples will be found in the future. The reason for this isomorphism is no doubt, that the lengthening of the bond between donor molecule and chlorine is compensated by the smaller atomic radius of the chlorine atom.

This investigation has been sponsored by the *United States Air Force Development Command* under contract AF 61 (052)—71.

Separation of some O-Phosphorylated Amino Acids and Peptides on Anion Exchange Resin

LARS STRID

Department of Medical Biochemistry, University of Göteborg, Göteborg, Sweden

A chromatographic procedure for the separation of O-phosphorylated amino acids and peptides on the anion exchange resin Dowex 1-X2, is described. The following synthetic compounds have been separated: SerP *, ThrP, Gly-SerP-Gly, Gly-SerP, SerP-Gly, Leu-SerP, SerP-Leu, SerP-Asp, SerP-Glu and SerP-SerP.

Investigations of phosphoproteins in this laboratory [1-4] involve degradation of such proteins by enzymes and by acid, whereby a mixture of phosphorylated amino acids and phosphopeptides are obtained. In the synthesis of phosphopeptides [5-7], using diphenylphosphoryl chloride as the phosphorylating reagent, a mixture of phosphopeptide and by-products are obtained. Consequently, it was found necessary to work out a simple preparative separation method.

Ion exchange chromatography of phosphopeptides from partial acid hydrolysed phosphoproteins has earlier been used by several researchers. Most of them have used cation exchange resin [8,9] and in some cases rechromatography on anion exchange resin [10-13].

Using a cation exchange resin Österberg [3] obtained a pure phosphopeptide, containing three phosphate groups, from an enzymic digest of casein.

With anion exchange resin Kennedy and Smith [14] reported complete separation of the phosphates of the following amino acids: hydroxyproline, threonine, serine and tyrosine.

EXPERIMENTAL

Materials

All reagents used were of analytical grade.

2 M sodium formate was prepared by mixing equal volumes of 4 M sodium hydroxide and 4 M formic acid. The pH was adjusted to 5.5 with 4 M formic acid.

* The following abbreviations are used in this paper: SerP is O-phosphorylserine and ThrP is O-phosphorylthreonin. Peptides are abbreviated as commonly done in literature; thus Gly-SerP-Gly equals glycyl-(O-phosphoryl)-serylglycine (*cf.* also Table 1).

0.1 M formic acid.

2 M pyridine formate. 511 g 90 % formic acid and 790 g pyridine were mixed and diluted with water to 5 l. Resulting pH was 4.5. From this stock solution, 0.25, 0.50, and 1.00 M solutions were obtained by dilution with water.

Model compounds used in the chromatography are listed in Table 1.

Dowex 1-X2 (Cl^-) 200—400 mesh. 500 ml resin was washed on a Büchner funnel with 2 litres of 2 N HCl, followed by 2 litres of water. The resin was suspended in water and after the resin had settled for 10 min, the supernatant was decanted to remove the finest particles. Coarse particles were removed by wet screening through a 50 DIN sieve. The resin was then poured into a column and converted to the formate form by allowing 2 M sodium formate pH 5.5 to flow slowly through the column, until the effluent gave a negativ test for chloride. It was then washed with distilled water on a Büchner funnel and stored in moist form.

Method

Column. About 150 ml of the resin was washed with 700 ml 0.1 M formic acid and then suspended in 200 ml of the same acid and freed from air by evacuation. The suspended resin was poured into a column 1.6 × 50 cm to a height of 43 cm at a pressure of 15 cm Hg. The top of the column was connected to a mixing chamber of 550 ml, furnished with a magnetic stirrer. The mixing chamber was connected to a separatory funnel. The top of the column, mixing chamber and separatory funnel were all filled with 0.1 M formic acid, and after 100 ml acid had passed, the column was ready for use.

Chromatography. 0.5—2 mg of each component (Table 1) in 0.1—0.2 ml H_2O or 0.1 M formic acid was applied to the column and washed into it by washing twice with 0.2 ml of 0.1 M formic acid. The gradient system was connected, and elution started. The following elution schedule was used with the gradient given as limit concentration:

I 0.1 M formic acid (165 ml)
II Gradient to 0.25 M pyridine formate, pH 4.5 (725 ml)
III Gradient to 0.50 M pyridine formate, pH 4.5 (310 ml)
IV Gradient to 1.00 M pyridine formate, pH 4.5 (320 ml)

Fractions of 3.5 ml were collected. For the sake of convenience the flow rate in the experiment described here was 20 ml/h but can be increased considerably. The chromatographic run was performed at room temperature.

Analysis and identification of the eluate. 1 ml of each fraction was mixed with 1 ml of 0.2 M citrate buffer pH 5.0. 1 ml of ninhydrin solution was added [16] and the sample heated for 15 min in boiling water. After dilution with 10 ml of ethanol:water (1:1), the optical density was read at 570 mμ.

Table 1. Model compounds.

Compound *	Abbreviation
O-Phosphorylserine	SerP
Glycyl-(O-phosphoryl)-serine	Gly-SerP
O-Phosphorylserylglycine	SerP-Gly
Glycyl-(O-phosphoryl)-serylglycine	Gly-SerP-Gly
Leucyl-(O-phosphoryl)-serine	Leu-SerP
O-Phosphorylseryl-leucine	SerP-Leu
O-Phosphorylserylglutamic acid	SerP-Glu
O-Phosphorylserylaspartic acid	SerP-Asp
O-Phosphorylseryl-(O-phosphoryl)-serine	SerP-SerP
O-Phosphorylthreonine	ThrP
Aspartic acid	Asp
Serine	Ser

* The three last mentioned compounds were obtained from Mann Research Lab., N.Y. All other compounds were synthesized in this laboratory [5,6,15].

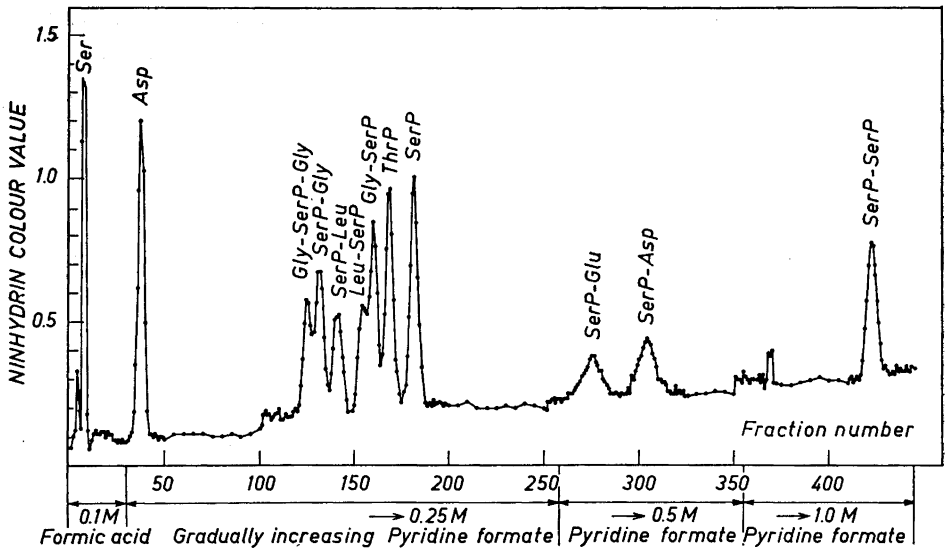

Fig. 1. Chromatogram obtained by separation of a synthetic mixture of phosphorylated amino acids and peptides. Dimensions of the column 1.6 × 43 cm. Volume of each fraction 3.5 ml. 1 ml of each fraction was used for the colour reaction.

The fractions from each peak were combined. Wherever overlapping occurred the intermediate fractions were discarded. The solutions were evaporated to dryness at 40° *in vacuo*. A small amount of water was added and the evaporation repeated until no smell of pyridine could be detected. As it was sometimes difficult to free the product from pyridine [6], particularly the slower fractions in the chromatography, it was found convenient to remove the pyridine on a small Dowex 50(H^+) column and to elute the peptide with water or weak acid.

Identification of the peaks was made from runnings where certain compounds were omitted, and by comparison between the applied and recovered ninhydrin colour.

The peaks were also identified by paper chromatography with the solvent system ButOH:HAc:H_2O(4:1:5). Each fraction gave only one spot. R_F-values and colours were compared with references (Table 1).

RESULTS AND DISCUSSION

It is evident that chromatography on anion exchange resin is useful for the separation of acidic substances such as phosphorylated peptides. These compounds are often so acidic that they are difficult to adsorb on cation exchange resins. On strong anion exchange resins on the other hand they are strongly retained. The resin Dowex 1-X2, being a strong anion exchanger, was used in this investigation. The low cross-linking was chosen to allow separation also of larger peptides.

Concerning elution medium the requirements were firstly that it should be easy to evaporate at temperatures where phosphopeptides are stable, and secondly that it should not produce colour reaction with ninhydrin. Pyridine formate meets these requirements and was therefore selected.

Synthetic phosphorylated amino acids and peptides [5,6,15] were used for working out the method. Serine and aspartic acid have been included to show where a neutral and acidic amino acid is eluted.

Fig. 1 shows a typical chromatogram. It can be seen that the more acidic the compounds, the more difficult they are to elute from the column. SerP-SerP, containing two phosphate groups per two amino acid residues, is the most acidic of the applied compounds, and is not eluted until the concentration of pyridine formate in the solvent is about 0.8 M. The phosphopeptides containing acidic amino acids are somewhat less acidic. They also show a strong binding to the column and are eluted in the order expected.

Phosphorylated amino acids and phosphopeptides containing neutral amino acids are eluted within a rather narrow region. Gly-SerP-Gly contains one phosphate group per three amino acid residues and is, as expected, eluted first. The phosphorylated derivatives of threonine and serine, having one phosphate group per amino acid residue, are eluted after the phosphopeptides containing neutral amino acids. The order of elution between the compounds agrees fairly well with the order of the pK values for their carboxyl groups, reported [17] by Fölsch and Österberg as being: Gly-SerP-Gly 3.29, SerP-Gly 3.13, SerP-Leu 3.11, Gly-SerP 2.90 and SerP 2.07.

As the method has been worked out for preparative use, no exact determinations of the recovery have been performed. The ninhydrin colour of each compound indicates a yield of between 85—107 %.

With slight modifications the present method has been used for isolation of phosphorylated peptides from products obtained by hydrogenation of O-diphenylphosphorylated peptide derivatives [6,7].

Studies on the Hydrolysis of Metal Ions

23. The Hydrolysis of the Ion $Bi_6(OH)_{12}^{6+}$ in Perchlorate Medium

ÅKE OLIN

Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of the ion $Bi_6(OH)_{12}^{6+}$ has been studied at 25°C in 0.1 M sodium perchlorate medium by means of the cells

$$\begin{array}{l} - \text{ Bi—Hg / S / ref. } + \\ - \text{ glass \quad / S / ref. } + \end{array}$$

where S had the general composition

B M Bi(III), H M H^+, $(0.1-3B-H)$ M Na^+, 0.1 M ClO_4^-.

The small solubility of the hydrolysis products necessitated the low concentration of the neutral salt. To keep the activity factors constant, the total metal ion concentration had to be diminished accordingly. B was varied between 4 and 0.5 mM. The data may be explained by the equilibria

$$\begin{array}{lll} 1.5\ Bi_6(OH)_{12}^{6+} + 2H_2O \rightleftharpoons Bi_9(OH)_{20}^{7+} + 2H^+ & \log K = -3.5 & \pm 0.1 \\ Bi_9(OH)_{20}^{7+} + H_2O \rightleftharpoons Bi_9(OH)_{21}^{6+} + H^+ & \log K_1 = -3.2 & \pm 0.2 \\ Bi_9(OH)_{21}^{6+} + H_2O \rightleftharpoons Bi_9(OH)_{22}^{5+} + H^+ & \log K_2 = -2.6 & \pm 0.2 \end{array}$$

The hydrolysis of Bi(III) in perchlorate medium can, for ease in description, be arbitrarily divided into two parts. The first part may be called the hydrolysis of the bismuth ion (Bi^{3+}) and the second part the hydrolysis of the $Bi_6(OH)_{12}^{6+}$ ion.

The hydrolysis of the bismuth ion has been studied a number of times [1,2]. The explanations of the experimental data, though divergent in details, give as main hydrolysis products polynuclear complexes with the ratio Bi:O equal or close to one. Recent studies [2,2a] strongly indicate $Bi_6(OH)_{12}^{6+}$ (or $Bi_6O_6^{6+}$ *etc.*) as the predominating species.

Holmqvist [3] found that solutions of the analytical composition $BiOClO_4$ are acid, which shows that the hydrolysis proceeds beyond the "bismuthyl" stage. He suggested the formation of the complex $Bi_2(OH)_5^+$. In 1954 Faucherre [4] published log h measurements on bismuth perchlorate solutions which had a composition varying between $BiOClO_4$ and $Bi_2(OH)_5ClO_4$. From the

measurements he concluded that the complex $Bi_8(OH)_{20}^{4+}$ is formed in this region. Faucherre states, however, that the result is quite uncertain. The present investigation is an extension to lower log h values of a previous study by the present author [2] on the hydrolysis of bismuth perchlorate solutions using electrometric methods.

Some of the symbols frequently encountered in the text are defined below:

B	total bismuth(III) concentration
b	concentration of Bi^{3+}
C	total bismuth(III) concentration, calculated as $Bi_6(OH)_{12}^{6+}$; $C = B/6$
c	concentration of $Bi_6(OH)_{12}^{6+}$
H	analytical hydrogen ion concentration
h	actual hydrogen ion concentration
Z	average number of hydrogen ions split off by one Bi^{3+}
Z'	average number of hydrogen ions split off by one $Bi_6(OH)_{12}^{6+}$. $Z' = 6(Z-2)$
$\eta =$	log B/b
$\eta' =$	η + (unknown) constant defined by eqn. (7)
$\delta =$	concentration of basic impurity in $NaClO_4$
$\varkappa_{P,Q}$	formation constant for $Bi_Q(OH)_P$ from $Bi_6(OH)_{12}^{6+}$ and H_2O
$y(x)_v$	y as a function of x at constant v

Other symbols used are defined when they first appear. All concentrations in the tables and figures are expressed in M (mole/l) and equilibrium constants are given on the M scale. In the text, however, the more convenient unit mM will be used frequently.

Method of investigation and choice of experimental conditions

The hydrogen ion concentration and the variation of free $[Bi^{3+}]$ with log h have been measured electrometrically for a large number of bismuth perchlorate solutions at equilibrium. As usual the measurements were carried out as potentiometric titrations keeping the total bismuth concentration constant in each run and varying log h by adding acid or base.

Because of the fairly low solubility [11] (*ca.* 25 mmoles/l) of the salt described as $Bi_2(OH)_3OClO_4$ it was found necessary to use a total ClO_4^- concentration as low as 0.1 M in order to keep the bismuth in solution in the log h range between -3 and -5. To minimize variations in the activity factors, the metal ion concentration has to be diminished accordingly. In 3 M $(Na)ClO_4$ it appears possible to use solutions containing at least 0.1 M of the metal ion investigated without causing serious variations in the activity factors; since little is known about these factors in solutions of low neutal salt concentration, the highest bismuth(III) concentration was now chosen by proportionality as 4 mM. In this way one is likely to be on the safe side [5].

The solutions measured had the general composition

$$[Bi(III)] = B \text{ M}; \quad [H^+] = H \text{ M}; \quad [Na^+] = (0.1-3B-H) \text{ M}; \quad [ClO_4^-] = 0.1 \text{ M}$$

where B denotes the total bismuth(III) concentration, and H the analytical hydrogen ion concentration defined by

$$H = [ClO_4^-] - 3B$$

In the present study H is always a negative number.

The following cells were used to measure the hydrogen ion concentration, h, and unhydrolysed Bi^{3+}, b.

$$- \text{ glass } /H^+/ \text{ ref } + \qquad \text{(I)}$$

$$E_g = E_g^\circ - 59.15 \log h - E_j \qquad (1)$$

$$- \text{ Bi—Hg } /Bi^{3+}/ \text{ ref } + \qquad \text{(II)}$$

$$E_{am} = E_{am}^\circ - 19.72 \log b - E_j \qquad (2)$$

As reference half-cell

$$0.1 \text{ M } NaClO_4/0.1 \text{ M } ClO_4^-, 0.095 \text{ M } Na^+, 0.005 \text{ M } Ag^+/AgCl, Ag \qquad \text{(III)}$$

was used, and the salt bridge was of the "Wilhelm" type [6].

To study the effect of a change in the nature of the neutral salt a few titrations were carried out in 0.1 M$(Ba)ClO_4$. In addition the direction of titration was reversed and $Ba(OH)_2$ was added to an acid solution. The use of this base ensures the absence of interfering carbonate. In general, acid was added to a hydrolysed solution. The experiments were carried out at 25°C.

Determination of the liquid junction potential in 0.1 M $NaClO_4$ and free acid or base in neutral salt solutions

The liquid junction potential in 0.1 M $(Na)ClO_4$ was determined between 0 and 15 mM H^+ by means of the cell

$$Ag, AgCl/0.005 \text{ M } Ag^+, H \text{ M } H^+, (0.095 - H) \text{ M } Na^+, 0.1 \ ClO_4^-/\text{ref.} \qquad \text{(IV)}$$

$$E = E^\circ - 59.15 \log[Ag^+] - E_j = E^{\circ\prime} - E_j \qquad (3)$$

since $[Ag^+]$ was kept constant. The liquid junction potential so defined contains any variation in the activity factors. The procedure to obtain E_j from the measurements has been described by Biedermann and Sillén [7] The above-mentioned cell has the advantage, over those containing log h sensitive electrodes, that small errors in the hydrogen ion concentration do not influence the result at low concentrations. Moreover the extrapolation involved in the determination can be carried out with greater confidence since the extrapolated value ($E^{\circ\prime}$), *i.e.* the potential of the cell with no acid added, can also be measured as a check.

The results fit the simple Henderson equation [8] with

$$E_j = -59.15 \log(1 + 26.7\ h) \qquad 0 < h < 0.015 \text{ M} \qquad (4)$$

The formula reproduces the experimental data to better than 0.05 mV.

When using the cell

$$\log h \text{ sensitive electrode } / h \text{ M } H^+, I - h \text{ M } Na^+, I \text{ M } ClO_4^-/ \text{ ref.} \qquad \text{(V)}$$

$$E = E^\circ - 59.15 \log h - E_j \qquad (5)$$

to determine E_j, it is often found that the points lying close to the origin ($H'<3$ mM) are off the straight line $E + 59.15 \log H'$ (H'). This is due to small acidic or basic impurities in the neutral salt, which cause the calculated hydrogen ion concentration, H', and actual hydrogen ion concentration, h, to be different.

The amount of impurity, $\delta = H'-h$, can be found by the following procedure. Let us assume, to be specific, that we want to know the concentration of small amounts of acid or alkali suspected to be present in a I M $NaClO_4$ solution at 25°C. To a known volume of this solution is added gradually a standardized $HClO_4$ solution, also containing $NaClO_4$ to make $[ClO_4^-] = I$ M, and the emf of the above cell (V) is measured. $E + 59.15 \log H'$ is then plotted as a function of H', where H' is the hydrogen ion concentration calculated from the volume of acid added. At higher acidities, where the impurity is small compared to H', the plot is linear and can be extrapolated to $H' = 0$ to give $E°$. Once $E°$ is known, h can be found for the first few points. The difference between h and H' for each point is then used to find the concentration of the impurity. It seems possible to determine this impurity to $\pm$ 0.01 mM.

The liquid junction potentials determined with the quinhydrone electrode agreed within $\pm$ 0.1 mV with those obtained with the silver-silverchloride electrode, which is to be expected if the activity factors stay constant (or change in the same manner with log h), since the basicity of quinone [9] does not show up if h <15 mM.

MATERIALS AND ANALYSIS

Sodium perchlorate was prepared from recrystallized Na_2CO_3 (Merck p.a.) and $HClO_4$ (Kebo p.a.). The product was recrystallized once from distilled water. The stock solution of $NaClO_4$ was analysed by evaporating a known volume to dryness and weighing the residue as $NaClO_4$. The determination of acidic or basic impurities was made as described above. After a preliminary determination of this impurity, a calculated amount of acid or base was added to make the solution neutral. The final product was reanalysed and found to be neutral to within $\pm$ 0.01 mM H^+ or OH^-.

Barium perchlorate was prepared from $Ba(OH)_2$ (Merck p.a.) and $HClO_4$. The product was recrystallized twice to reduce the chloride content to the order of 10^{-6} M in a 0.05 M solution. The stock solution was analyzed by evaporating a known volume to dryness and weighing the residue as $Ba(ClO_4)_2$. $Ba(ClO_4)_2$ is known to be a very hygroscopic substance, therefore the result was checked by passing known volumes through a cation-exchange resin and titrating with standard base. The two methods gave results identical to 0.1 %.

Perchloric acid solutions were prepared by diluting $HClO_4$ (Kebo p.a. 70—72 %) and were standardized against $KHCO_3$.

Barium hydroxide solutions were prepared by dilution of a filtered stock solution of $Ba(OH)_2$. All solutions containing this base were handled under nitrogen.

Bismuth (III) perchlorate solutions were prepared from Bi_2O_3 and $HClO_4$. Two stock solutions were made. The first solution, which had the analytical composition $BiOClO_4$, was prepared from known amounts of the oxide and the acid. As a check it was analysed for bismuth according to Winkler [10] and for perchlorate by cation exchange. Calculated and found values agreed to 0.1 %. The second solution was prepared by dissolving the oxide in hot acid but now choosing the molar proportion Bi_2O_3 : $HClO_4$ = 1:1.2. On cooling the solution crystals separated. These crystals gave the same X-ray powder photographs as crystals prepared by adding a concentrated $NaClO_4$ solution to $BiOClO_4$, or NaOH to mixtures of $NaClO_4$ and $Bi(ClO_4)_3$ solutions as described by Holmqvist[3] and Prytz and Nagel [11]. These authors found from the analysis a salt of composition $Bi_2(OH)_5OClO_4$. In addition to this salt Prytz and Nagel found a yellow salt, which precipitated when a large amount of $NaClO_4$ was added to a bismuthyl perchlorate solution. Its composition was given as $Bi_3(OH)_3O_2(ClO_4)_2$. This salt was not obtained in the present investigation.

The crystals were dissolved by adding water. On standing overnight, however, the solution became turbid. After filtration and standing the turbidity developed again. Since no impurities were found in the distilled water used, carbon dioxide from the air was suspected as interfering. This was confirmed by passing in CO_2. The formation of the insoluble carbonate is a slow process, and a pronounced turbidity appears only after one

or two h. The final stock solution was filtered through a bacteria filter (Jena G 5), and some acid added. The solution was analyzed and thereafter stored and handled under nitrogen. When stored under nitrogen the solution remained clear.

The Bi_2O_3 used was obtained by igniting twice recrystallized $Bi(NO_3)_3$ (Baker p.a.).

Bismuth amalgam was prepared and handled as described previously [2]. The bismuth concentration in the amalgam was 0.5 % (weight).

The emf measurements

The log h measurements were made with a Radiometer glass electrode, which had been checked against the quinhydrone electrode in an acetate buffer also containing 0.1 M $NaClO_4$. The potential between the two electrodes remained constant throughout the log h range -2 to -6. Thus the glass electrode behaved as a perfect hydrogen electrode. The bismuth amalgam electrode consisted of a pool on the bottom of the titration vessel.

Since E°_{am} could not be determined we could find only relative concentrations of unhydrolysed bismuth from the potentials. In order to compare titrations made at different times, a certain titration was repeated at regular intervals, and the average potential change (at most 0.4 mV) from the first of these standard titrations, for identical points, was taken as the shift in E°_{am} and used as a correction to the measured E.

All potentials were recorded with a Radiometer valve potentiometer (PHM 3) with the exception of the liquid junction potential measurements, where a Cambridge potentiometer was used.

The equilibria were rapidly attained. No time effects were present. This was established by comparing titrations for the same total bismuth concentration but starting from different analytical hydrogen ion concentrations. The Z and η' curves for the two titrations, in the log h region where they overlapped, were identical within the limits of the experimental error.

The glass electrode measurements showed, between identical titrations, a reproducibility which in general lay within the accuracy of the instrument (± 0.2 mV). The agreement between titrations on solutions made up from the two stock solutions was better than 0.01 Z units in most of the range studied. In the most acidic region, the spread in the glass electrode measurements, however, caused a somewhat larger uncertainty in Z.

The behavior of the amalgam electrode changed remarkably during the titration. As log h decreased the electrode became more and more sensitive to shakings and vibrations. The time required to attain a stable potential increased and finally no constant potentials were obtained. The last few potentials recorded were uncertain to at least 0.5 mV since the potential fluctuated by this amount. A swirling motion of the amalgam changed the potential by more than 20 mV and it regained the previous value after 1—2 h. This may be contrasted with the behavior at log $h = -2$ and higher. In this region the cell attained the equilibrium value immediately and shaking did not affect the potential at all.

RESULTS AND CALCULATIONS

Owing to the pronounced hydrolysis of Bi^{3+} it is not possible, when working with 0.1 M $(Na)ClO_4$ medium, to add enough acid to repress this reaction. Thus E° values could not be obtained by inserting analytical concentrations in eqns. (1) and (2). Instead, E°_g had to be determined in $HClO_4$—$NaClO_4$ mixtures, whereas E°_{am} remains unknown. Therefore only changes in the concentration of Bi^{3+} can be determined and not absolute values.

From eqn. (2) we find $\log b = \frac{E^\circ_{am}}{19.72} - \frac{(E_{am} + E_j)}{19.72}$ and from the definition of η;

$$\eta = \log B - \log b = \log B + \frac{(E_{am} + E_j)}{19.72} - \frac{E^\circ_{am}}{19.72} \qquad (6)$$

The measured E_{am} ranged between 500 and 400 mV. In the following calculations E°_{am} was arbitrarily replaced by 360.6 mV, which gave a convenient quantity η' defined as (∇ = unknown constant)

$$\eta' = \log B + \frac{(E_{am} + E_j)}{19.72} - \frac{360.6}{19.72} = \eta + \frac{(E^{\circ}_{am} - 360.6)}{19.72} = \eta + \nabla \qquad (7)$$

In order to be able to find possible reactions giving rise to Z values above 2 it is necessary to make some assumptions as to what species are formed

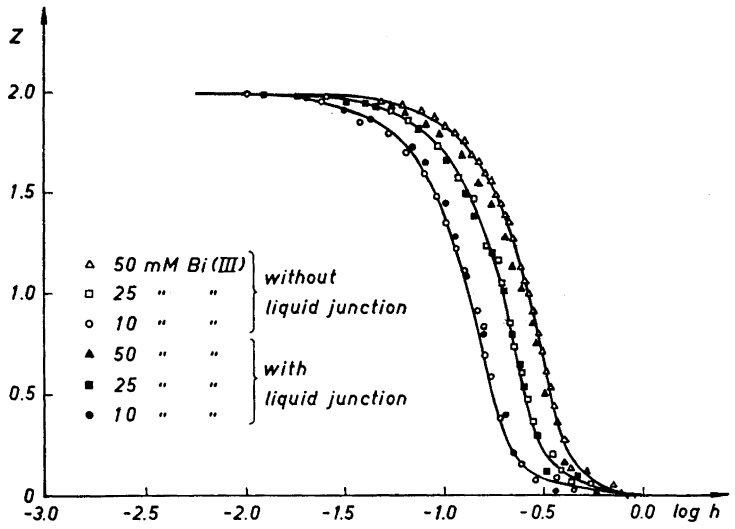

Fig. 3. Average number, Z, of protons split off by one Bi^{3+} in 3 M $(Na)ClO_4$ as a function of log h. The lines are calculated with $\log \beta_{12,6} = 0.33$ and $\log \beta_{11} = -1.58$.

in earlier stages of the hydrolysis. Previous measurents of η with 3 M$(Na)ClO_4$ medium[2] have indicated that the main complex formed is $Bi_6(OH)_{12}^{6+}$, and that in addition some $BiOH^{2+}$ is formed. Assuming only these two complexes it was possible to explain quantitatively the data over a wide range of concentrations. This hypothesis has been the basis for the present calculations.

The experimental results are shown graphically in Figs. 1 and 2 and numerically in Table 1.

With 0.05 M $Ba(ClO_4)_2$ — to be strict, 0.1 M $(Ba)ClO_4$ — as medium only log h measurements with $[Bi(III)_{tot}] = 4$ and 2 mM were made. The data obtained in general agreed to 0.005 Z units with those found with 0.1 M $(Na)ClO_4$ as medium. Therefore only a few data in the low log h region not covered by the measurements with the latter medium are given.

The η' values in the most acid region are characterized by parallel curves for the various B values, a slope $(\Delta\eta'/\Delta \log h)_B$ close to -2, and $(\Delta \log B/\Delta \log h)_{\eta'} = 2.4$ to 2.5. Thus the curves have the same properties as found with 3 M $(Na)ClO_4$, which makes it likely that the same complex, $Bi_6(OH)_{12}^{6+}$, predominates also at lower ionic strengths. With decreasing log h, $(\Delta\eta'/\Delta \log h)_B$ decreases, and the curves tend to become closer together, as seen along the log h axis.

The Z curves clearly indicate that $Bi_6(OH)_{12}^{6+}$ is in equilibrium with *larger* complexes, since the curves are separate and do not cross. The curves do not show a pronounced shelf at $Z = 2$ but turn fairly sharply downwards after having passed this value. Unfortunately it is not possible to follow the hydrolysis in 0.1 M $(Na)ClO_4$ for much smaller values than $Z = 2$, for the experimental

accuracy declines rapidly as the acidity increases. That there is a short separation between the reactions occuring above and below $Z = 2$ is evident from Fig. 3, which shows some Z curves from measurements with 3 $M(Na)ClO_4$. They exhibit a pronounced bending off towards $Z = 2$. These measurements are described in an appendix to the present paper. Holmberg, Kraus and Johnson [12] also found $Z_{lim} = 2.0$ from log h measurements.

An upper limit seems to exist for Z around 2.44. The solutions had a very low buffer capacity in this region. A small change in analytical composition led to a large log h change and finally precipitation started. It is remarkable that this limiting value is different from 2.5 which is the ratio OH:Bi in the solid phase [3,11]. The divergence of the limiting value from 2.5 is not likely to be due to an experimental error, since it was obtained with two independent stock solutions both in $NaClO_4$ and $Ba(ClO_4)_2$. Moreover protons were set free when the precipitate was formed, as is expected if the ratio OH:Bi = 2.5 in the solid phase and < 2.5 in the solution.

Elucidation of possible hydrolysis products. The formulas of the products formed by the hydrolysis of the $Bi_6(OH)_{12}^{6+}$ ion are difficult to find with certainty mainly for two reasons. Firstly, only low total metal ion concentrations could be measured, which causes the Z values in general to be uncertain to 0.01 unit. When we have polynuclear complexes present the spacing between the Z curves is very important in finding possible species to explain the data. With a small concentration range considerable uncertainty is introduced. Secondly high powers are present in the expression for the law of mass action for the complexes formed. This leads to a scatter of the experimental points used in the calculations.

It is convenient to consider the complexes as built up from $Bi_6(OH)_{12}^{6+}$ (C) and $OH^-(-H^+)$ and not from Bi^{3+} and OH^-. The complex $Bi_q(OH)_p$ is therefore written as

$$Bi_q(OH)_p = C_q(OH)_{p'} \text{ with } q = 6q' \text{ and } p = 12q' + p' \tag{8}$$

where p' and $6q'$ are whole numbers.

$\varkappa_{p',q'}$ denotes the equilibrium constant for the reaction

$$q'C + p'H_2O \rightleftharpoons C_{q'}(OH)_{p'} + p'H^+ \tag{9}$$

The expression (9) is so general that it includes all conceivable species, also Bi^{3+} ($q' = 1/6$, $p' = -2$) and $BiOH^{2+}$ ($q' = 1/6$, $p' = -1$) known to exist in small amounts.

The law of mass action gives

$$C = c + \Sigma q' \varkappa_{p'q'} c^{q'} h^{-p'} \tag{10}$$

$$CZ' = \Sigma p' \varkappa_{p'q'} c^{q'} h^{-p'} \tag{11}$$

The concentration of $Bi_6(OH)_{12}^{6+}$, c, is found from the amalgam data. We start with the equation

$$\frac{[Bi_6(OH)_{12}^{6+}] \cdot h^{12}}{[Bi^{3+}]^6} = \beta_{12,6} \text{ or } \log c = \log \beta_{12,6} + 6 \log b - 12 \log h \tag{12}$$

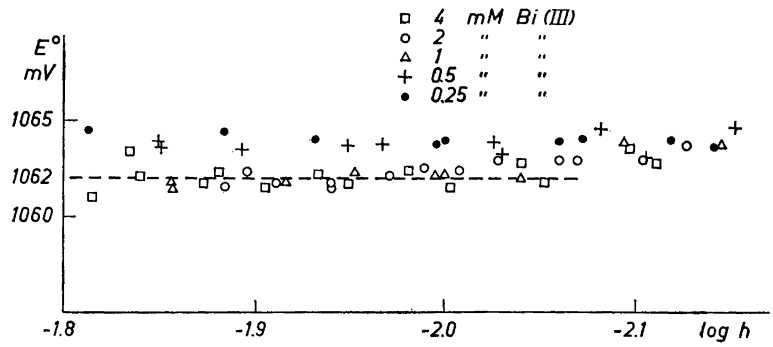

Fig. 4. The values of E° found from eqn. (13) as a function of log h.

Inserting log b and log h from eqns. (1) and (2) we get

$$19.72 \log c = 19.72 \log \beta_{12,6} + 6E^{\circ}_{am} - 4E^{\circ}_{g} + 4E_{g} - 6E_{am} - 2E_{j} = \\ = E^{\circ} + 4E_{g} - 6E_{am} - 2E_{j} \quad (13)$$

In this equation both $\beta_{12,6}$ and E°_{am} are unknown but by inserting $B/6$ for c, $E^{\circ} = 19.72 \log \beta_{12,6} + 6E^{\circ}_{am} - 4E^{\circ}_{g}$ can be found from the potentials in the most acid region where $Bi_6(OH)_{12}^{6+}$ is the predominating species. Since the amalgam data are presented as η', an equation from which c can be calculated using η' will be given.

$$\eta' = \log B - \log b + \nabla \text{ or } \log b = \log B - \eta' + \nabla \quad (14)$$

Inserting this expression for log b in (12)

$$\log c = \log \beta_{12,6} + 6\nabla + 6 \log B - 6\eta' - 12 \log h \quad (15)$$

is obtained. Log $\beta_{12,6} + 6\nabla$ is found by inserting $B/6$ for c as indicated above.

Fig. 4 shows the values of E° obtained from eqn. (13) in the region where $Bi_6(OH)_{12}^{6+}$ may be expected to predominate. It is seen that for the three highest concentrations E° comes out quite constant $= 1\,062 \pm 0.5$ mV, which is almost better than could be expected, considering the factors 4 and 6 in eqn. (13). The lower concentrations yield an E° *ca.* 2 mV higher. This is not unexpected since $Bi_6(OH)_{12}^{6+}$ is certainly not the sole species present. If for example the equilibrium constants were the same as given in Ref.[2] for 3 M $(Na)ClO_4$, we may estimate that for $B = 0.25$ mM, 5—7 % of the bismuth(III) is present as Bi^{3+} and $BiOH^{2+}$ at log $h = -2$. For the highest values of B we may also have disturbances from species more hydrolysed than $Bi_6(OH)_{12}^{6+}$ as indicated by the $(\Delta\eta'/\Delta \log h)_B$ values which are smaller than -2. In the calculations on the 0.5 mM titrations we have used the value of E° found for the higher concentrations, but only used the data in the low log h region where an error in E° is not so serious. No calculations have been performed on the 0.25 mM titrations and the reason for this is, that beside the uncertainty

in $E°$, these data must be subject to large errors since $(\Delta\eta'/\Delta \log h)_B$ does not decrease regularly with decreasing $\log h$ values. This contradicts the law of mass action.

When we know c, the quantity $CZ'/(C-c)$, which is the average number of OH^- per $Bi_6(OH)_{12}^{6+}$ unit in the complexes, can be calculated. The $CZ'/(C-c)$ ($\log h$) curves for the 4 and 2 mM titrations coincided or very nearly so, whereas the 1 and 0.5 mM titrations were slightly off the curve. However, if the $NaClO_4$ contained a basic impurity, δ, of the order of 0.01 mM, the $CZ'/(C-c)$ ($\log h$) curves for the different B coincide.

If only one complex had been formed, $CZ'/(C-c)$ should have come out as a constant equal to p'/q'. The hypothesis that only one complex is formed is ruled out, since $CZ'/(C-c)$ is found to be variable.

The same conclusion is reached from consideration of Z data alone [13]. Eqns. (10) and (11) give

$$C = c + q'\varkappa_{p'q'}c^{q'}h^{-p'} \tag{10a}$$

$$CZ' = p'\varkappa_{p'q'}c^{q'}h^{-p'} \tag{11a}$$

and after elimination of c

$$\log X = \log h - \frac{1}{p'}\log(p'\varkappa_{p'q'}C^{q'-1}) = \frac{1}{p'}\log\frac{(p'-Z'q')^{q'}}{p'^{q'}Z'} \tag{16}$$

Comparison with $Z'(\log X)$ curves calculated for different q' and choosing p' to give a $Z_{\lim} \approx 2.4$, showed no fit. The theoretical curves are steeper than the experimental ones, which means that intermediate complexes must be present.

The fact that the $CZ'/(C-c)$ ($\log h$) curves are independent of C, suggests that the complexes formed are homonuclear. The hydrolysis can then be represented by the reactions

$$Q'C + P'H_2O \rightleftharpoons C_{Q'}(OH)_{P'} + P'H^+ \tag{17}$$

$$C_{Q'}(OH)_{P'} + n\ H_2O \rightleftharpoons C_{Q'}(OH)_{P'+n} + n\ H^+ \quad (n = 1,2,3,\ ---N) \tag{18}$$

where Q', P' and N are unknown. With $\varkappa_{\overline{P',\ Q'}} = \varkappa$ and $\varkappa_{P'_i+n,\ Q'} = \alpha_n\varkappa$ the law of mass action gives

$$C = c + Q'\varkappa c^{Q'}h^{-P'}(1 + \alpha_1h^{-1} + \alpha_2h^{-2} + - - -) \tag{19}$$

$$CZ' = \varkappa c^{Q'}h^{-P'}(P' + (P'+1)\alpha_1h^{-1} + (P'+2)\alpha_2h^{-2} + - - -) \tag{20}$$

For the complex of highest Z, $C_{Q'}(OH)_{P'+N}$ or $Bi_Q(OH)_{P+N}$, the following relations must be fulfilled

$$(P+N)/Q = 2.44 \pm 0.02 \text{ or } (P'+N)/6Q' = 0.44 \pm 0.02;\ Q > 6;\ P,Q,N,P',$$

and $6Q'$ whole numbers.

A tentative value for Q' is found from eqn. (19). If homonuclear complexes are formed and the correct value of Q' is chosen $\log(C-c) - Q'\log c = f(h)$ when plotted as a function of $\log h$ should give one curve independent of C. Different Q' values were tested starting from $Q' = 7/6$. This test excluded all values of Q' except 7/6 and 9/6. $Q' = 8/6$ is ruled out since there is no corre-

sponding P' that gives a Z_{lim} in agreement with experiment. For $Q' > 9/6$ the experimental data fall less and less satisfactorily on a single curve.

With the help of the Q' values 7/6 and 9/6 a tentative value for N can be found. The experimental $CZ'/(C-c)$ (log h) curve ranges between 2.7 $\pm$0.1 and 1.3 $\pm$0.2, with these limits as asymptotes. These limiting values should be equal to $(P' + N)/Q'$ and P'/Q'. For $Q' = 7/6$ we should have $P' = 1.5 \pm 0.2$ and $P' + N = 3.15 \pm 0.1$. For $Q' = 9/6$ we find $P' = 1.95 \pm 0.3$ and $P' + N = 4.05 \pm 0.15$. We may thus conclude $N = 2$.

Determination of α_1 and α_2. Eqns. (19, 20) with $N = 2$ give after elimination of c

$$Q'\left(\frac{CZ'}{C-c}\right) - P' = \frac{\alpha_1 h^{-1} + 2\alpha_2 h^{-2}}{1 + \alpha_1 h^{-1} + \alpha_2 h^{-2}} = n \qquad (22)$$

Experimental $\bar{n}$(log h) were compared with normalized curves for the right hand side of the equation according to Sillén [14]. The sets tested were $P' = 1$, $Q' = 7/6$ (or $P = 15$, $Q = 7$) and $P' = 2$, $Q' = 9/6$ (or $P = 20$, $Q = 9$). Both combinations reasonably fitted the normalized curves, and α_1 and α_2 were determined for each set.

Determination of $\varkappa$. To determine $\varkappa$ and to make possible a choice of best values for P and Q the following equations were developed. Replacing $1 + \alpha_1 h^{-1} + \alpha_2 h^{-2}$ by φ (h) in eqn. (19) and $P' + (P' + 1)\alpha_1 h^{-1} + (P' + 2)\alpha_2 h^{-2}$ by $\omega(h)$ in eqn. (20) for simplification, eliminating c and introducing the new variables y and x defined by

$$y = Z' \frac{\varphi(h)}{\omega(h)}, \quad x = \log h - \frac{1}{P'} \log \varphi(h) - \frac{(Q'-1)}{P'} \log C \qquad (23, 24)$$

we get

$$X = x - \frac{1}{P'} \log \varkappa = \frac{1}{P'} \log \frac{(1-Q'\,y)^{Q'}}{y} \qquad (25)$$

Experimental $y(x)$ curves calculated with eqns (23, 24) and the previously determined constants α_1 and α_2 may be compared with normalized $y(X)$ curves from eqn. (25). If a fit is obtained, $P'^{-1} \log \varkappa$ is the difference between the coordinates on the x and X axes in this position. This comparison ruled out the set $P' = 1$, $Q' = 7/6$ but gave a good fit for the set $P' = 2$, $Q' = 9/6$ if we allow for a $\delta = 0.01$ mM OH^-.

The same calculations were carried out for complexes $Bi_{11}(OH)_{25+n}$ for $N = 2$. A fairly good fit was obtained if δ is assumed to be 0.02 mM OH^-, which is, however, larger than the estimated error in the experimental value for $\delta = 0.00 \pm 0.01$ mM OH^- or H^+.

Sillén's "core and links" approach [15,16] to the explanation of polynuclear complex formation will be briefly discussed since it has been successfully applied to the hydrolysis of many metal ions. If this assumption is valid it should be possible to represent the complexes by the formula $Bi_6(OH)_{12}[Bi_6(OH)_{12}(OH)_t]_n$, where t is a constant and n varies. nt and $6n$ must, of course, be whole numbers. This hypothesis requires that the $Z(\log h)_B$ curves should be parallel, and that $(\Delta \log B/\Delta \log h)_Z = t$ is constant. These characteristics

are not shown by the present data especially at high Z values. It may still be instructive to apply this hypothesis to the data, since the curves are sufficiently close together that a fairly small experimental error can distort the curves. In these calculations $t = 6$ was used in order to conform with a limiting value 2.5 for Z, and n arbitrarily assumed to take the values 0, 1/6, 2/6...1. The t value used is greater than the experimental average value which is closer to 5. The calculations indicated that the complexes with the smallest n predominate, but no satisfactory explanation of the data was afforded by this approach using simple assumptions about how the equilibrium constants vary with n. It is, however, not unlikely that a number of complexes with different values of q, as for instance in a "core + links" series, could also be made to fit the data, if no relation is assumed to exist between the equilibrium constants.

The determination of the equilibrium constants for the final choice of complexes, $Bi_9(OH)_{20}^{7+}$, $Bi_9(OH)_{21}^{6+}$, and $Bi_9(OH)_{22}^{5+}$, will be given in some detail using the methods indicated in the general discussion. We start with the determination of α_1 and α_2 which are the equilibrium constants for the reactions

$$Bi_9(OH)_{20}^{7+} + H_2O \rightleftharpoons Bi_9(OH)_{21}^{6+} + H^+$$
$$Bi_9(OH)_{20}^{7+} + 2H_2O \rightleftharpoons Bi_9(OH)_{22}^{5+} + 2H^+$$

This was accomplished by a combination of the η' and Z' data. We plotted the left hand side of eqn. (22), $1.5\,CZ'/(C-c)$-2, as a function of log h and compared the plot with normalized curves for the right hand side of the same equation. The normalization is brought about by the following substitutions

$$v^2 = \alpha_2 h^{-2} \text{ and } k = \alpha_1 \alpha_2^{-1/2} \qquad (26, 27)$$

which give

$$\bar{n} = \frac{\alpha_1 h^{-1} + 2\alpha_2 h^{-2}}{1 + \alpha_1 h^{-1} + \alpha_2 h^{-2}} = \frac{kv + 2v^2}{1 + kv + v^2} \qquad (28)$$

Curves $\bar{n}$ (—log v) were calculated for different values of k to find the value which gave the best agreement between the experimental and normalized curve. When this value was found, log α_2 was determined as twice the difference between the coordinates on the log h and —log v axes when the two curves overlapped and log α_1 was determined from eqn. (27). The best value of k was found to be 0.5. This value is, however, not very accurate owing to the scatter among the experimental points (Fig. 5).

The values found for log α_1 and log α_2 were

$$\log \alpha_1 = -3.2 \pm 0.2$$
$$\log \alpha_2 = -5.8 \pm 0.1$$

Knowing α_1 and α_2 we proceeded to determine $\varkappa_{20,9}$ from eqns. (23, 24 and 25). For each experimental point $\varphi(h)$ and $w(h)$ were first computed and then y and x. The plot $y(x)$ was compared with the theoretical $y(X)$ curve calculated from eqn. (25) with $Q' = 9/6$ and $P' = 2$, and examined for a fit. In this position twice the difference between the x and X coordinates gives log $\varkappa_{20,9}$ (Fig. 6).

$$\log \varkappa_{20,9} = -3.5 \pm 0.1$$

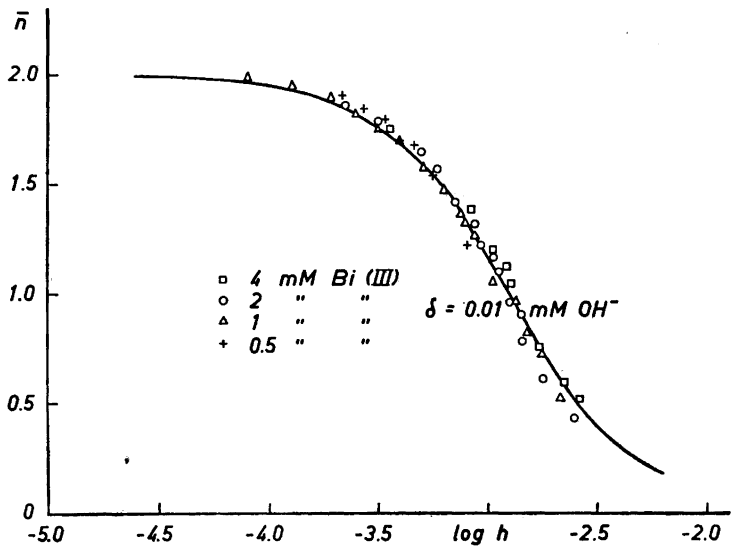

Fig. 5. Determination of α_1 and α_2 by curve fitting according to eqn. (28). The line represents the normalized curve in position of best fit.

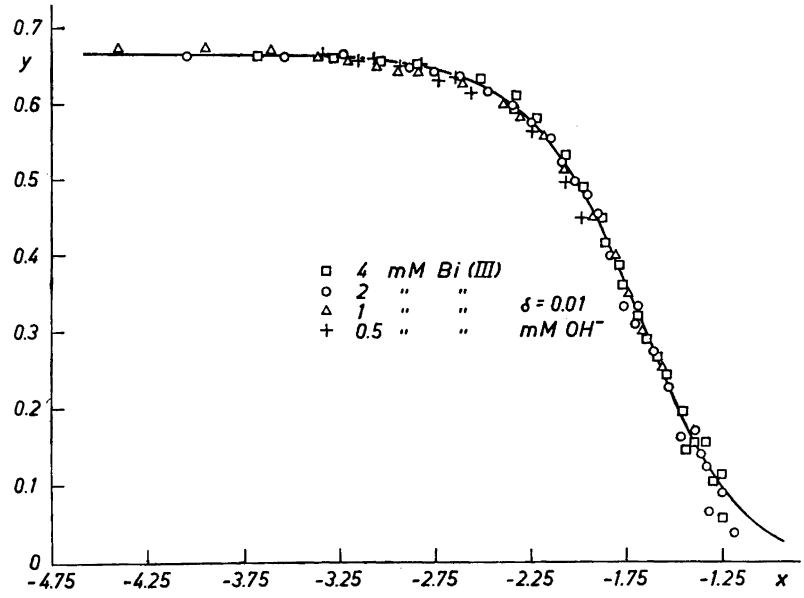

Fig. 6. Determination of $\varkappa_{20,9}$ by curve fitting according to eqn. (25). The line represents the normalized curve in position of best fit.

Log $\varkappa_{20,9}$ was also calculated from the amalgam data using eqn. (19) from which we find

$$\log \varkappa_{20,9} = \log(C-c) - 1.5 \log c + 2 \log h - \log \varphi(h) - \log 1.5 \qquad (19a).$$

$\varphi(h)$ was computed with the values for α_1 and α_2 already determined. The mean value obtained for log $\varkappa_{20,9}$ was

$$\log \varkappa_{20,9} = -3.45 \pm 0.1$$

When taking the mean value a few values from the most hydrolysed solutions were excluded. It is not suprising that the log $\varkappa_{20,9}$ values calculated from these points are erroneous. The estimated uncertainty in the amalgam potentials of at least 0.5 mV leads to an uncertainty in log $\varkappa_{20,9}$ of 0.23.

The data may also be represented by log $\varkappa_{20,9}$ and the two acidity constants (K_1 and K_2) of $Bi_9(OH)_{20}^{7+}$. We find that log K_1 = log α_1 and log K_2 = log α_2 − log α_1.

The numerical values are

$$\log K_1 = -3.2 \pm 0.2$$
$$\log K_2 = -2.6 \pm 0.2$$

Finally the experimental $Z(\log h)_B$ and $\eta'(\log h)_B$ curves were compared with the theoretical ones calculated with the equilibrium constants given (Figs 1 and 2).

Comparison with Faucherre's measurements

The only previous work on the hydrolysis of the "bismuthyl ion", which contains enough data to warrant a calculation of the species formed, is that by Faucherre. With some hesitation he gives $Bi_8(OH)_{20}^{4+}$ as a possible complex. To make a comparison with the present data easier, Faucherre's data were converted to give Z as a function of log h. This cannot be accomplished very accurately, since he presents only a small graph showing log h as a function of the analytical composition of the solutions. The most notable difference between the two sets of data is the disagreement between the limiting values for Z. Whereas in the present work Z values larger than 2.44 to 2.45 were not obtained and the form of the curves indicates that this is a limiting value, he found Z values at least larger than 2.46 before precipitation started. In this region his curves are still bending quite steeply upwards so that the limiting value 2.5 for Z proposed by him is reasonable. Some doubt may be raised concerning the complex $Bi_8(OH)_{20}^{4+}$. If we accept $Bi_4O_4^{4+}$ as the "mother complex", as was done by Faucherre, and calculate a theoretical curve for the combination $Bi_4O_4^{4+}$ and $Bi_8O_{10}^{4+}$, it is found that the agreement is poor between Faucherre's experimental data and the calculated curve even if we consider the previously mentioned uncertainty in the Z values. The theoretical curve is too steep for this explanation of the data. This was the situation met with when the present data were tested for the hypothesis that only one complex is formed.

DISCUSSION

It is not easy to discuss the plausibility of the proposed hydrolysis mechanism. On hydrolysis, the metal ions seem to be quite individualistic in their behavior so we have little or no help from analogies with other cations. The mechanism proposed shows some parallelism with that found for the VO_2^+ ion by Rossotti and Rossotti [17] but is widely different from what has been found for other ions. The VO_2^+ ion hydrolyses to the decavanadate $H_2V_{10}O_{28}^{4-}$, which splits off two hydrogen ions.

One intriguing feature of the mechanism proposed is the discrepancy between the number of OH^- groups bound per Bi(III) in the aqueous complexes and in the solid phase. However, the relationship between the solid phase described as $Bi_2(OH)_3OClO_4$ and the complexes in solution may not be simple, since protons were set free when the salt started to precipitate. It would be desirable to know the crystal structure of this salt. It may contain structural units that could give hints as to what is happening in the solution.

APPENDIX

In this appendix some log h measurements on bismuth(III) in 3 M $(Na)ClO_4$ will be described briefly. They were carried out with the cell — glass/0.01 M Ag^+, B M Bi(III), H M H^+,(2.99—3B—H)M Na^+, 3 M ClO_4^-/Ag, AgCl +

$$E_g = E_g^\circ - 59.15 \log h + \varepsilon$$

where ε is a correction term for the deviation of the glass electrode from ideality. The electrode used had the slope 59.15 up to H^+ = 350 mM. After 350 mM H^+, deviations from this slope became apparent. At 750 mM H^+, which was the highest acidity used, ε reached —0.4 mV.

The above cell was used in an effort to reduce the uncertainty in the measured potentials by elimination of the liquid junction. Since Bi^{3+} starts to hydrolyse in fairly acid solutions small differences in the measured emf cause large differences in Z.

The results are shown in Fig. 3. When the new data were compared with older ones, obtained from cells with liquid junctions, discrepancies were observed. These discrepancies were found to be caused by the E_g° chosen. When 59.15 log h was plotted as a function of H it was found that the plots for the two cells were perfectly superposable but slightly displaced from each other. The difference was 0.2 mV for the 10 and 25 mM Bi(III) and 0.5 mV for 50 mM. The rather large difference in the latter case merely reflects the difficulty of obtaining good E_g° values in very acid solutions where the liquid junction potential is large and corrections have to be applied to the glass electrode.

In Fig. 3 the drawn curves have been calculated with the equilibrium constants previously found from η data [2]

$$6Bi^{3+} + 12H_2O \rightleftharpoons Bi_6(OH)_{12}^{6+} + 12H^+ \quad \log \beta_{12,6} = 0.33$$
$$Bi^{3+} + H_2O \rightleftharpoons BiOH^{2+} + H^+ \quad \log \beta_{1,1} = -1.58$$

we thus find that the number of protons set free by the hydrolysis of Bi(III) in 3 M $(Na)ClO_4$ can be satisfactorily accounted for by the formation of $Bi_6(OH)_{12}^{6+}$ and $BiOH^{2+}$.

Note added in proof. After the completion of this work I was told by Dr. R.S. Tobias (private communication; results to be published in *J.Am.Chem.Soc.*) that from log h measurements in 1 M $(Na)ClO_4$ he had suggested the formation of $Bi_6O_6^{6+}$ and $Bi_6O_6(OH)_3^{3+}$. The agreement is good on $Bi_6O_6^{6+}$ (which is equivalent to $Bi_6(OH)_{12}^{6+}$ but the present data cannot be explained on the assumption that $Bi_6O_6(OH)_3^{3+}$ is formed as a main species in the latter stages of the hydrolysis of the Bi^{3+} ion.

Acknowledgements. The author wishes to thank sincerely Professor Lars Gunnar Sillén for his continual interest in this work. The author also wishes to thank Professor Robert E. Connick, Univ. of Calif., for helpful comments on the manuscript and Dr. George Biedermann for discussions during the work. Dr. Helen S. Dunsmore and Mr. David L. Martin have corrected the English of this paper. Mr. Frans Ericson has been helpful in constructing and maintaining the apparatus. This work has been supported by *Statens Tekniska Forskningsråd (Swedish Technical Research Council)*.

Vibrational Mean-Square Amplitude Matrices

VI. Planar Symmetrical XY_3 Molecules

S. J. CYVIN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The mean-square amplitude quantities for the planar symmetrical XY_3 molecular model are treated theoretically. The L matrix elements ($S = LQ$), and the symmetrized mean-square amplitude matrix elements at the temperatures $T = 0$ and 298 °K, are given numerically for the four boron trihalides.

The vibrations of planar symmetrical XY_3 molecules have been subjected to several investigations. For publications containing theoretical considerations on this problem, and involving force constant determinations, references are made to [1–7]. For the computations of mean amplitudes of vibration from spectroscopic data, it is referred to [7–9]. To the knowledge of the author, no determinations of mean amplitudes of vibration have so far been performed from electron-diffraction, for any molecule of the structure here considered. In the present paper, the mean-square amplitude quantities of planar symmetrical XY_3 molecules are treated, and numerical values for boron trihalides are reported.

THEORETICAL TREATMENT

For the in-plane vibrations of the considered molecular model there exist four independent harmonic vibrational constants. The following set of constants consists of mean-square amplitude quantities, based on a set of valence force coordinates.

$$\sigma = \langle r_1^2 \rangle = \langle r_2^2 \rangle = \langle r_3^2 \rangle \quad (1)$$

$$\sigma' = \langle r_1 r_2 \rangle = \langle r_2 r_3 \rangle = \langle r_3 r_1 \rangle \quad (2)$$

$$\tau = R^2\langle \alpha_1^2 \rangle = R^2\langle \alpha_2^2 \rangle = R^2\langle \alpha_3^2 \rangle \quad (3)$$

$$\tau' = R^2\langle \alpha_1\alpha_2 \rangle = R^2\langle \alpha_2\alpha_3 \rangle = R^2\langle \alpha_3\alpha_1 \rangle \quad (4)$$

$$\varrho = R\langle r_1\alpha_1 \rangle = R\langle r_2\alpha_2 \rangle = R\langle r_3\alpha_3 \rangle \quad (5)$$

$$\varrho' = R\langle r_1\alpha_2 \rangle = R\langle r_1\alpha_3 \rangle = R\langle r_2\alpha_3 \rangle = R\langle r_2\alpha_1 \rangle = R\langle r_3\alpha_1 \rangle = R\langle r_3\alpha_2 \rangle \quad (6)$$

In these equations, R is the equilibrium X—Y bond length, r representing the deviations of the interatomic X—Y distances, and α the inter-bond angle deviations, from their equilibrium values. The numbering of the coordinates is the same as that used in previous papers [7,9]. From the redundant condition $\alpha_1 + \alpha_2 + \alpha_3 = 0$ it is found

$$\tau + 2\tau' = 0, \qquad \varrho + 2\varrho' = 0 \tag{7}$$

for the quantities defined by eqns (3)—(6).

The interatomic distance deviations between the non-bonded atom pairs may be taken into account instead of the angle displacements, and designated r_1^*, r_2^* and r_3^*. Then the following mean-square amplitude quantities are to be introduced.

$$\tau^* = \langle (r_1^*)^2 \rangle = \langle (r_2^*)^2 \rangle = \langle (r_3^*)^2 \rangle \tag{8}$$

$$\varrho^* = \langle r_1 r_1^* \rangle = \langle r_2 r_2^* \rangle = \langle r_3 r_3^* \rangle \tag{9}$$

$$\varrho'^* = \langle r_1 r_2^* \rangle = \langle r_1 r_3^* \rangle = \langle r_2 r_3^* \rangle = \langle r_2 r_1^* \rangle = \langle r_3 r_1^* \rangle = \langle r_3 r_2^* \rangle \tag{10}$$

These quantities may be expressed in terms of the quantities from eqns. (1)—(6) by the following linear combinations.

$$\tau^* = \frac{3}{2}(\sigma + \sigma') + \frac{1}{6}(\tau - \tau') - 3^{-\frac{1}{2}}(\varrho - \varrho') \tag{11}$$

$$\varrho^* = 3^{\frac{1}{2}}\,\sigma' + \frac{1}{3}(\varrho - \varrho') \tag{12}$$

$$\varrho'^* = \frac{1}{2}\,3^{\frac{1}{2}}\,(\sigma + \sigma') - \frac{1}{6}(\varrho - \varrho') \tag{13}$$

The vibrational analysis is facilitated by introducing symmetry coordinates. The elements of the symmetrized mean-square amplitude matrix are given by

$$\Sigma_1 = \langle S_1^2 \rangle = \sigma + 2\sigma' \tag{14}$$

$$\Sigma_3 = \langle S_{3a}^2 \rangle = \langle S_{3b}^2 \rangle = \sigma - \sigma' \tag{15}$$

$$\Sigma_4 = \langle S_{4a}^2 \rangle = \langle S_{4b}^2 \rangle = \tau - \tau' \tag{16}$$

$$\Sigma_{34} = \langle S_{3a} S_{4a} \rangle = \langle S_{3b} S_{4b} \rangle = \varrho - \varrho' \tag{17}$$

Table 1. Symmetry coordinates for the planar symmetrical XY_3 molecular model.

Species	No.	Coordinate
A_1'	1	$3^{-\frac{1}{2}}\,(r_1 + r_2 + r_3)$
E'_a	3a	$6^{-\frac{1}{2}}\,(2r_1 - r_2 - r_3)$
	4a	$6^{-\frac{1}{2}}\,R\,(2\alpha_1 - \alpha_2 - \alpha_3)$
E'_b	3b	$2^{-\frac{1}{2}}\,(r_2 - r_3)$
	4b	$2^{-\frac{1}{2}}\,R(\alpha_2 - \alpha_3)$

The symmetry coordinates (S) are formed as normalized linear combinations of the valence force coordinates, and specified in Table 1. For the mean-square amplitude quantities of eqns. (14)—(17) one has the relations

$$\Delta_1 = \Sigma_1 \mu_Y^{-1} \tag{18}$$

$$\Delta_3 + \Delta_4 = [\tfrac{1}{2}(\Sigma_3 + \tfrac{1}{3}\Sigma_4)(3\mu_X + 2\mu_Y) - 3^{\frac{1}{2}}\,\Sigma_{34}\mu_X]\,(3\mu_X + \mu_Y)^{-1}\mu_Y^{-1} \tag{19}$$

$$\Delta_3\Delta_4 = \tfrac{1}{3}(\Sigma_3\Sigma_4 - \Sigma_{34}^2)(3\mu_X + \mu_Y)^{-1}\mu_Y^{-1} \tag{20}$$

Here μ_X and μ_Y denote the inverse masses of the X and Y atoms, respectively, and the values of Δ are connected with the vibrational normal frequencies (ν) through

$$\Delta_k = (h/8\pi^2\nu_k)\,\coth(h\nu_k/2kT) \tag{21}$$

where h is Planck's constant, k Boltzmann's constant, and T the absolute temperature. Another set of relations, involving the force constants, is given below.

$$\varepsilon_1 = K_1\Sigma_1 \tag{22}$$

$$\varepsilon_3 + \varepsilon_4 = K_2\Sigma_3 + \Phi\Sigma_4 + 2\Gamma\Sigma_{34} \tag{23}$$

$$\varepsilon_3\varepsilon_4 = (K_2\Phi - \Gamma^2)(\Sigma_3\Sigma_4 - \Sigma_{34}^2) \tag{24}$$

The force constants, *viz.* K_1, K_2, Φ and Γ, are based on the chosen symmetry coordinates (Table 1), and given in terms of usual valence force coordinates in Ref.[9] The values of ε are given by

$$\varepsilon_k = \tfrac{1}{2}h\nu_k\,\coth\,(h\nu_k/2kT) \tag{25}$$

If the coefficients of the transformation connecting the symmetry coordinates (S) with the normal coordinates (Q), *viz.*

$$S_i = \sum_k L_{ik}\,Q_k \tag{26}$$

are known, the symmetrized mean-square amplitude matrix elements are simply obtained by the following expressions.

$$\Sigma_1 = L_{11}^2\,\Delta_1 \tag{27}$$

$$\Sigma_3 = L_{33}^2\Delta_3 + L_{34}^2\Delta_4 \tag{28}$$

$$\Sigma_4 = L_{43}^2\Delta_3 + L_{44}^2\Delta_4 \tag{29}$$

$$\Sigma_{34} = L_{33}L_{43}\Delta_3 + L_{34}L_{44}\Delta_{44} \tag{30}$$

The most important ones of the mean-square amplitude quantities here concerned, are the two designated σ and τ^*, and defined by eqns. (1) and (8), respectively. They are given in terms of the symmetrized mean-square amplitude matrix elements by the expressions

$$\sigma = \tfrac{1}{3}(\Sigma_1 + 2\Sigma_3) \tag{31}$$

$$\tau^* = \Sigma_1 + \tfrac{1}{2}(\Sigma_3 + \tfrac{1}{3}\Sigma_4) - 3^{-\frac{1}{2}}\Sigma_{34} \tag{32}$$

These quantities represent the mean-square amplitudes of vibration for the bonded and non-bonded interatomic distances, respectively, and would also be obtainable from electron-diffraction. See, *e.g.* Refs.[10–15]

NUMERICAL COMPUTATIONS

In the numerical computations reported in the following, the three vibrational frequencies for $^{11}BY_3$ (Y = F,Cl,Br,I) together with ν_3 for $^{10}BY_3$ were used to determine the vibrational constants. The experimental data for BF_3 and BCl_3 have been taken from Ref.[4], those for BBr_3 and BI_3 from Ref.[5], and are quoted in a previous paper [7]. This paper [7] also contains the calculated force constants.

The coefficients L_{ik} defined by eqn. (26), for the trihalides of the ^{11}B isotope, are given numerically in Table 2. The resulting mean-square amplitude quantities Σ_1, Σ_3, Σ_4 and Σ_{34} at the absolute zero point and the temperature 298 °K, are given in Table 3.

Table 3. Mean-square amplitude quantities in Å² units for boron trihalides.

The Distribution of some Dialkylfluorophosphates in the Liquid Systems Carbon Tetrachloride/Water and Oil/Water

SVERRE ÖKSNE

Norwegian Defence Research Establishment, Toxicological Group, Lilleström, Norway

The distribution of four dialkylfluorophosphates (I–IV) has been investigated in the systems carbon tetrachloride/water and whale-oil/water, and that of III also in the system peanut oil/water. In the systems whale-oil/water and carbon tetrachloride/water the following sequence for the distribution coefficient (K) was found: I < III < II < IV.

In connection with investigations on the inhibition of cholinesterase, it was desirable to determine the distribution of some dialkylfluorophosphates (I–IV) between an organic solvent and water, and an oil and water. The compounds investigated had the formula $(RO)_2P(O)F$. R = ethyl (I), R = propyl (II), R = *iso*propyl (III), R = butyl (IV).

The distribution of III between peanut oil and water has been investigated by Augustinsson [1] who used the cholinesterase inhibiting effect of the water phase as a measure of the amount of III present.

In the work described herein two different methods were used for the quantitative determination of the dialkylfluorophosphates. The one is a *o*-tolidine perborate method for colorimetric estimation of dialkylfluorophosphates. The other is a method based upon analysis of fluoride. The values of the distribution coefficients found all refer to room temperature (20–24°C).

The results of a typical experiment, *viz.* the determination of the distribution coefficient (K) of III in the liquid systems whale-oil/water and carbon tetrachloride/water are given in Table 1.

A summary of the distribution coefficients (K) obtained is given in Table 2, which also includes the number of experiments made for each determination and the standard deviation.

The values of K vary widely with the length of the alkyl group. In the systems carbon tetrachloride/water and whale-oil/water the value of K varies in the following way with the alkyl group, ethyl < *iso*propyl < propyl < butyl.

Table 1. Data for the determination of the distribution of III between carbon tetrachloride and water and between whale-oil and water.

Solvent	Expt.	Total III mg	Vol.ratio solvent / water	mg of dialkylfluorophosphate recovered		Recovery %	*K*
				Solvent	Water		
Carbon tetrachloride	1	18.80	1 : 5	17.44	2.23	104.6	39.2
	2	18.37	1 : 3	17.41	1.39	102.1	37.5
	3	13.78	1 : 7	11.86	2.17	101.8	38.2
Whale-oil	1	111.6	1 : 8.87	55.8 [a]	55.8		8.87

	5	54.3	1 : 8.41	26.3 [a]	28.0		7.90

[a] Calculated by difference.

EXPERIMENTAL

Syntheses of dialkylfluorophosphates. The dialkylfluorophosphates were prepared by a one stage method [2]. Benzene was used as solvent. The products were redistilled until constant refractive index was obtained. No other test for purity was made. The refractive index was measured with a Hilger-Abbe refractometer, and the following values for n_D^{20} and boiling point respectively were found: I: 1.3722, 57°/11 mm; II: 1.3891, 80°/11.5 mm; III: 1.3817, 71°/14 mm; IV: 1.4013, 54°/0.02 mm.

Distribution coefficients of I—IV between carbon tetrachloride and water. The method used is a modification of the *o*-tolidine perborate method for estimation of phosphonofluoridates [3,4]. The following reagents and organic solvents were used:

Acetone *pro analysi*, purified with potassium permanganate and distilled.

Carbon tetrachloride *pro analysi* (Merck).

o-Tolidine reagent. *o*-Tolidine dihydrochloride (B.D.H.) was purified by treatment with stannous chloride and active carbon until a concentrated aqueous solution was colourless. A 1 % solution in water was used (prepared daily).

Phosphate buffer 0.05 M, pH = 11.5, prepared by dissolving 8.7 g of K_2HPO_4 in 1 litre of distilled water, and adjusted to pH 11.5 with saturated NaOH solution.

Table 2. Distribution coefficients of dialkylfluorophosphates in the liquid systems carbon tetrachloride/water, whale-oil/water and peanut oil/water.

Dialkylfluorophosphate	Distribution carbon tetrachloride/water			Distribution whale-oil/water			Distribution peanut oil/water	
	No. of expts.	*K*	Stand. dev.	No. of expts.	*K*	Stand. dev.	No. of expts.	*K*
I	5	3.46	0.16	5	2.7	1.11		
II	4	60.2	1.02	6	15.0	2.04		
III	3	38.3	0.86	5	8.6	0.63	4	7 6
IV	3	102	10.74	9	62	7.52		

Sodium perborate reagent. 1.25 % aqueous solution of sodium perborate (prepared daily).

For estimation of the calibration curve a known solution of dialkylfluorophosphate in carbon tetrachloride was prepared, and the reagents mixed in the following quantities and sequence. Acetone (20 ml), phosphate buffer (2.0 ml), sodium perborate reagent (1.5 ml), *o*-tolidine reagent (1.0 ml), water saturated with carbon tetrachloride (6.5 ml), carbon tetrachloride saturated with water (1—n) ml and a solution of dialkylfluorophosphate in carbon tetrachloride (n ml).

The intensity of colour was measured after 20 min in a Fisher Electrophotometer (model AC) with a blue filter, and the colorimetric readings, corrected for blanks, were plotted against mg of dialkylfluorophosphate.

For the determination of the distribution coefficient a measured volume of a known solution of dialkylfluorophosphate in carbon tetrachloride was shaken vigorously for 1 min with a known volume of distilled water. The phases were allowed to separate and samples of both of them were with-drawn and analyzed for dialkylfluorophosphate as described for the calibration. In analyzing the water phase (6.5—n) ml of water, n ml of water phase and 1 ml of carbon tetrachloride were used. The concentration in each phase was determined by comparison of the net colorimetric readings with the calibration curve.

Distribution coefficients of I—IV between whale-oil and water. The amount of dialkylfluorophosphate in the water phase was determined by colorimetric estimation of fluoride by interaction with a thorium lake [5]. The following reagents were used:

Refined whale-oil from De-No-Fa, Fredrikstad, Norway.

Thorium reagent, 0.001 M with respect to thorium nitrate and 1.0 M with respect to sodium sulphate, formic acid and sodium formate.

Alizarin indicator 0.00025 M. 0.0855 g of alizarin monosodium sulphonate was dissolved in 1 litre of distilled water.

For estimation of the calibration curve 20—40 mg of dialkylfluorophosphate was dissolved in 100 ml of distilled water. Samples of not more than 25 ml were boiled with reflux for 90 min with 10 ml of 0.1 M NaOH solution. The samples were filtered through paper filter and quantitatively transfered to 100 ml flasks. 20 ml of alizarin indicator was added, and the samples were titrated with 0.6 M nitric acid until a pure yellow colour was obtained. Then 20 ml of thorium reagent was added and the solution diluted to 100 ml with distilled water. The intensity of colour was measured after 30 min in a Fisher Electrophotometer (model AC) with a green filter, and the colorimetric readings, corrected for blanks, were plotted against mg of dialkylfluorophosphate.

For estimation of the distribution coefficient the density of a 3 % solution of dialkylfluorophosphate in oil was determined. A calculated volume (about 5 ml) of a known solution of dialkylfluorophosphate, about 3 % in oil, was shaken cautiously with 50 ml of distilled water for 5 min. The two phases were allowed to separate and samples of 5 ml of the water phase were withdrawn for analyses. The analyses were performed as described for the calibration, and the concentration of dialkylfluorophosphate in the water phase was determined by comparison of the net colorimetric readings with the calibration curve.

We did not succeed in analyzing the oil phase. The amount of dialkylfluorophosphate in the oil phase therefore was calculated by difference.

Distribution coefficient of III between peanut oil and water. The first part of the procedure was as described for the system whale-oil/water. The second part, the analyzing of the water phase, was performed by the *o*-tolidine perborate method as described before.

The Separation of Intestinal Invertase and Three Different Intestinal Maltases on TEAE-cellulose by Gradient Elution, Frontal Analysis, and Mutual Displacement Chromatography

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The separation of intestinal invertase and maltase activities on ion exchange columns was further studied by use of a modified ion exchange cellulose, TEAE-cellulose.

The gradient elution, frontal analysis, and mutual displacement techniques were applied to the separation of intestinal invertase and maltase activities on these columns.

The results with these separation methods supported the theory that intestinal maltase activity consists of three components, only one of which is associated with invertase activity.

The intestinal invertase activity behaved as one single enzyme. The homogeneity of intestinal invertase activity also appears from the K_s values for the invertase activity in different fractions of a chromatogram.

The method for the separation of intestinal maltase activities by partial heat inactivation was improved.

By combining the methods of heat inactivation and ion exchange chromatography, the three components of intestinal maltase activity were purified. The three maltase fractions had different K_s values, which supports the theory that they are different enzymes.

In a previous paper the separation of intestinal maltase activity in one heat-stable component (amounting to 1/3 of the total maltase activity) and one heat-labile component, was described [1]. The heat-stable maltase was without invertase activity. The heat-labile maltase, too, was partially separated from the invertase activity. In a preparation containing heat-labile maltase and invertase activity with a maltase/invertase activity quotient of 0.6, these activities could not, however, be further separated. In this preparation the invertase and maltase activities may therefore possibly be caused by the same enzyme.

As a working hypothesis, the possible existence of three different maltases in intestinal mucosa was therefore assumed. For the further study of these enzymes, however, improved separation methods were required.

In the present paper further separation experiments with intestinal invertase and maltase activities are described. Use was made of a modified ion exchange cellulose (TEAE-cellulose) and, in addition to *gradient elution*, two other techniques for chromatography, namely *frontal analysis* and *mutual displacement chromatography*. The separation by partial heat inactivation was improved, too. The enzyme fractions obtained were characterized by their K_s values.

MATERIALS AND METHODS

Solubilized glycosidases were prepared from pig intestinal mucosa as previously described [2].

Substrates. Sucrose of analytical grade purity was obtained from J. T. Baker Co. Maltose of analytical grade purity was obtained from Merck A. G. (Germany) and Pfanstiehl Chemical Co. The maltose preparations were found to contain oligosaccharides with a lower mobility than maltose on the paper chromatogram. For maltase determinations the preparations were used without further purification, but for K_s determinations chromatographically pure maltose was used, which was obtained by carbon column chromatography [3].

Determination of invertase and maltase activity was performed under the same conditions as used earlier, *i. e.* at 0.1388 M substrate concentration, in 0.05 M maleate buffer pH 6.5 and with toluene as preservative [1,2]. One unit of glycosidase activity produces 1 mg of monohexoses (*i. e.* 1 % of hydrolysis in 2.0 ml of reaction mixture) in 1 h at 37°C under these conditions. When the degree of hydrolysis did not exceed 10 %, the amount of monohexoses produced was proportional to the amount of enzyme present.

Determination of invertase activity. 1.0 ml of substrate solution (9.5 % sucrose *, 0.1 M maleate buffer pH 6.5 and a few ml of toluene per lit.) and 1.0 ml of enzyme solution with 0.5 – 3 units of invertase were mixed in a test-tube in a water-bath at 37°C. After 60 min the reaction was interrupted by the addition of 2.0 ml of the 3,5-dinitrosalicylic acid reagent of Sumner [4]. A blank was prepared with the same composition, in which, however, the 3,5-dinitrosalicylic acid reagent was added *before* the enzyme solution. The samples were heated in a boiling water-bath for 10 min, chilled with tap water, and diluted with 20.0 ml of distilled water. After mixing, the red colour was determined with a Beckman B spectrophotometer at 530 mμ. The colour was stable for at least 20 h. The amount of monohexoses produced was calculated from a standard curve with known amounts of glucose. Glucose and fructose have the same extinction coefficient with the 3,5-dinitrosalicylic acid reagent.

Determination of total maltase activity. Equal volumes of substrate solution (10.0 % maltose monohydrate, 0.1 M maleate buffer pH 6.5 and a few ml of toluene per lit.) and enzyme solution with 5 – 10 units of maltase per ml were mixed in a test-tube in a water-bath at 37°C. At zero time and after 60 min, 0.10 ml samples were withdrawn from the reaction mixture and immediately precipitated [5] with 1.0 ml of 5 % $ZnSO_4$ and 1.0 ml of 0.3 N $Ba(OH)_2$, diluted with water to 4.0 ml and centrifugated. 2.0 ml of the supernatant was transferred to a Folin's tube for sugar determination, 2.0 ml of the acid copper reagent of Tauber and Kleiner [6] was added, and the tube was boiled for 8 min in a water-bath. After chilling with tap water for 2 min, 2.0 ml of Benedicts molybdate reagent [6] was added, and after mixing the solution was diluted to the 25 ml mark with distilled water. After 3 – 30 min the blue colour was determined with a Beckman B spectrophotometer at 600 mμ. With each set of determinations, a series of tubes were boiled containing known amounts of maltose and glucose in mixture, corresponding to 0, 5, 10, and 15 % hydrolysis.

* Per cent means g of solute per 100 ml of solution.

Determination of heat-stable maltase activity. To the enzyme solution was added water or phosphate buffer (depending on the buffer content of the enzyme solution) until reaching a final concentration of 0.01 M phosphate buffer pH 6.0. The solution was then heated in a water-bath at 60°C for 45 min, which completely inactivated the heat-labile maltase activity, while the heat-stable maltase was unaffected [1]. The heat-stable maltase activity was determined with the procedure described above.

The heat-labile maltase activity was calculated as the difference between the total maltase activity and the heat-stable maltase activity.

K_s *for invertase activity* was determined as described earlier [7].

K_s *for maltase activity* was determined with 0.030—0.002 M maltose solutions. The degree of hydrolysis was not allowed to exceed 20 %. With these dilute substrate solutions it was necessary to use a larger volume of the reaction mixture for the quantitative determination of the glucose produced. Since amounts greater than 5 μmoles of the maleate buffer interfered with the reagents of Tauber and Kleiner, the modified reagents described by Caputto, Leloir and Trucco [8] were used for these determinations. Amounts as large as 50 μmoles of maleate buffer pH 6.5 did not interfere with these reagents.

Protein was determined with the method of Lowry *et al.*[9] by use of human serum albumin (kindly supplied by A.B. Kabi) as a standard.

Conductivity measurements (for determining the concentration of phosphate buffer in chromatography fractions) were made with a Philips conductometer, type PR 9500.

Diethylaminoethyl cellulose (DEAE-cellulose) was prepared from Solkafloc cellulose powder SW 40 A with the method of Peterson and Sober [10]. The product contained 0.75—0.85 mequiv. of titrable hydroxyl groups per g dry weight. The titrations were performed in 0.5 M NaCl [10].

Triethylaminoethyl cellulose (TEAE-cellulose) was prepared from DEAE-cellulose by ethylation as described by Porath [11]. The ethylation process increased the pK value of the ion exchanger from 9.5 (DEAE-cellulose) to 10.0 (TEAE-cellulose). Since the free base of TEAE-cellulose was found unstable even at room temperature, TEAE-cellulose was stored and used in its bromide form.

Before use, the TEAE-cellulose was stirred for 30—60 min with the buffer to be used as starting buffer in the chromatography. After packing the column, it was washed with several column volumes of the same buffer.

RESULTS AND DISCUSSION

Gradient elution from TEAE-cellulose. During gradient elution chromatography on DEAE-cellulose, intestinal maltase and invertase activties formed one single peak, which, however, was not homogeneous [2]. Porath [11] has reported the preparation of a modified anion exchange cellulose, TEAE-cellulose, with somewhat different adsorption properties. The chromatography of the intestinal glycosidases on TEAE-cellulose was therefore studied.

To a 1 × 11 cm column of TEAE-cellulose, which had been equilibrated with 0.010 M phosphate buffer pH 6.0, a solubilized intestinal glycosidase preparation containing 12.2 mg of protein, 180 units of invertase and 360 units of maltase in 0.010 M phosphate buffer pH 6.0 was applied. The enzymes were eluted with phosphate buffer pH 6.0 with continuously increasing concentration (Fig. 1). The experiment was performed at room temperature with a flow rate of 0.5 ml/min. Each fraction collected had a volume of 3.0 ml.

Also with TEAE-cellulose the invertase and maltase activities formed one common peak. The resolution within this peak seemed better, however, than that with DEAE-cellulose (*cf.* Fig. 1 in this publication with Fig. 3 in Ref.[2]). The first half of the invertase activity peak had a low maltase/invertase activity quotient (0.6) and is apparently identical with the fraction obtained earlier [1], which had the same maltase/invertase activity quotient, and in which the invertase

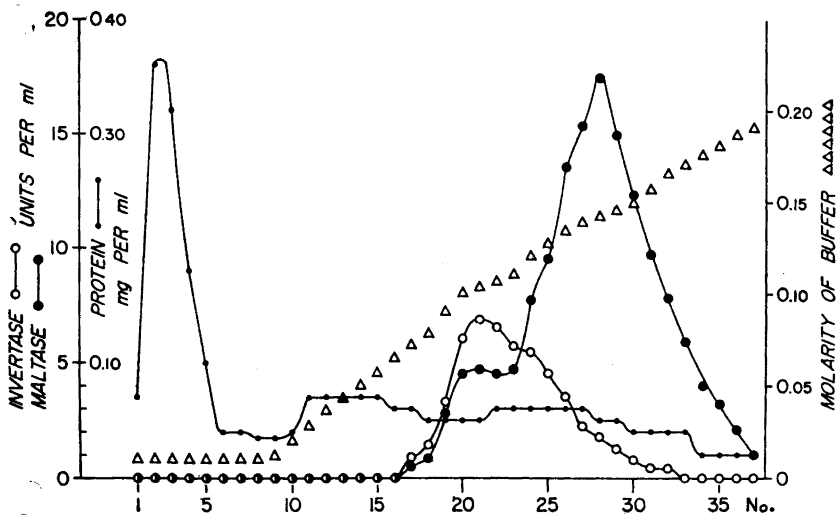

Fig. 1. Gradient elution of intestinal glycosidases on TEAE-cellulose at pH 6.0. For experimental conditions, see text. The molarity of the buffer in the effluent was determined by conductometry.

and maltase activities could not be further separated by rechromatography or by heat inactivation at varying pH. With TEAE-cellulose, too, the heat-stable maltase activity was the main component of the descending branch of the maltase peak.

Attempts to improve the separation by use of longer columns, lower flow rate, or step-wise elution, were not successful.

Frontal analysis. In frontal analysis the column is first washed with pure solvent. Then a relatively large volume of a solution of the substance to be analyzed is filtered through the column. Since the substance is adsorbed to the column, the filtrate is at first pure solvent. While more solution is filtered through the column, however, an increasing part of the column becomes saturated with the substance, and at last the substance appears in the effluent. If the flow rate is not too high, the concentration of the substance in the effluent rises rapidly from zero to the same concentration as in the influent. If there are more than one substance present in the solution, these substances may from separate fronts, depending on their concentration and the capacity of the column for each substance, and also on the competition of the different substances for the adsorbent (mutual displacement).

The frontal analysis principle was introduced by Tiselius [12], and its application to the separation of sugars and fatty acids on charcoal columns has been thoroughly studied by Claesson [13]. The frontal analysis principle has also been applied to the separation of inorganic ions on ion exchange column, which has been studied by Samuelsson [14]. As far as the present author is aware, however, frontal analysis has not been applied to the separation of proteins.

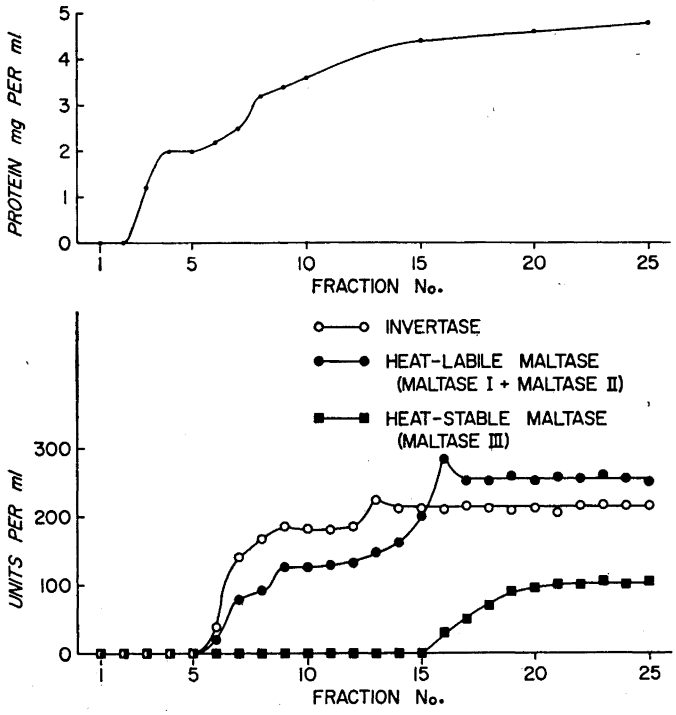

Fig. 2. Frontal analysis of intestinal glycosidases on TEAE-cellulose. 0.070 M phosphate buffer pH 6.0 was used as solvent. For experimental conditions, see text.

The frontal analysis of a solubilized intestinal glycosidase preparation on TEAE-cellulose was studied by use of phosphate buffer pH 6.0, and with varying molarity, as solvent. The experiments were performed on 1 × 6 cm columns containing 0.5 g (dry weight) of TEAE-cellulose, previously equilibrated with the same buffer as was used as solvent for the glycosidase preparation.

It was found necessary to use a relatively low flow rate, 2—3 drops (< 0.2 ml) per min, because otherwise very flat fronts were obtained. The experiments were always performed at room temperature (at lower temperature, a still lower flow rate would have been required).

The buffer concentration was found essential for the results. At low buffer concentration (0.010 M) all the glycosidases appeared as one common front. At higher concentrations (0.060—0.080 M) separate fronts were obtained. At still higher buffer concentration the glycosidases were not adsorbed to the column, but appeared in the effluent together with the solvent front. Since an important factor in frontal analysis seems to be the mutual displacement effect, these observations on the importance of the buffer concentration are in accordance with the findings of Boman [15,16].

A frontal analysis experiment is demonstrated in Fig. 2. The enzyme solution used contained 220 units/ml of invertase, 360 units/ml of maltase

and 4.8 mg/ml of protein in 0.070 M phosphate buffer pH 6.0. The flow rate was 3 drops/min and each fraction collected had a volume of 1.8 ml. The first glycosidase front was formed by invertase activity, accompanied by a heat-labile maltase activity with maltase/invertase activity quotient 0.6. This front corresponds to the maltase fraction I (invertase fraction) postulated earlier [1]. The appearance of these activities as one single, homogeneous front, strongly supports the theory that these activities are caused by one single enzyme. The fact that a second front of heat-labile maltase later appeared, is also in favour of the theory that two different heat-labile intestinal maltases exist.

The second front of heat-labile maltase activity (maltase II [1]) and the front of the heat-stable maltase activity (maltase III [1]) appeared in the same tubes. This front is, however, not homogeneous, since the increase in heat-labile maltase activity is more rapid than the increase in heat-stable maltase activity. This indicates an incomplete mutual displacement of these two activities, which was also found in mutual displacement technique chromatography.

Mutual displacement chromatography. In mutual displacement cromatography the substances to be separated are adsorbed to the upper end of an adsorbent column. The substances are then eluted by the addition of another substance to the influent, which is adsorbed to the column with greater force than any of the substances to be separated. The developer should have a sufficiently high concentration to elute the substances to be separated completely. These substances therefore travel down the column as one band, just in front of the developer. During the passage down the column, the different components of the band compete with each other for the adsorbent, which makes them form separate zones of increasing adsorbability. If sufficiently small fractions are collected, the components may therefore be obtained in different fractions.

This principle for chromatography was introduced by Tiselius [17], and was first applied to the separation of sugars on charcoal columns. It has also been applied to the separation of proteins, but only in a few cases and not always under clear-cut experimental conditions [16]. That one protein may displace another from an ion exchange column has been demonstrated by Boman [15,16]. He found, however, that protein-protein displacement is ineffective at low buffer concentration, *i.e.* when the protein to be displaced is strongly adsorbed.

The mutual displacement chromatography of intestinal glycosidases was performed on TEAE-cellulose columns, which had been equilibrated with phosphate buffer pH 6.0 with varying molarity. After adsorption of the glycosidase solution to the column, this was first eluted with the starting buffer to remove some inactive protein which was not adsorbed to the column [2]. The molarity of the influent buffer then at once was increased to 0.200 M, which eluted all the glycosidases. The enzymes appeared in the effluent as one single protein peak, which was, however, composed of zones with different enzymatic activity (Fig. 3).

The experiments were always performed at room temperature. To obtain good separation, it was necessary to use so low a flow rate as 1 drop/min (0.04 ml). In accordance with the experiences of Boman, the molarity of the starting buffer was of great importance for the separation. With 0.010 M

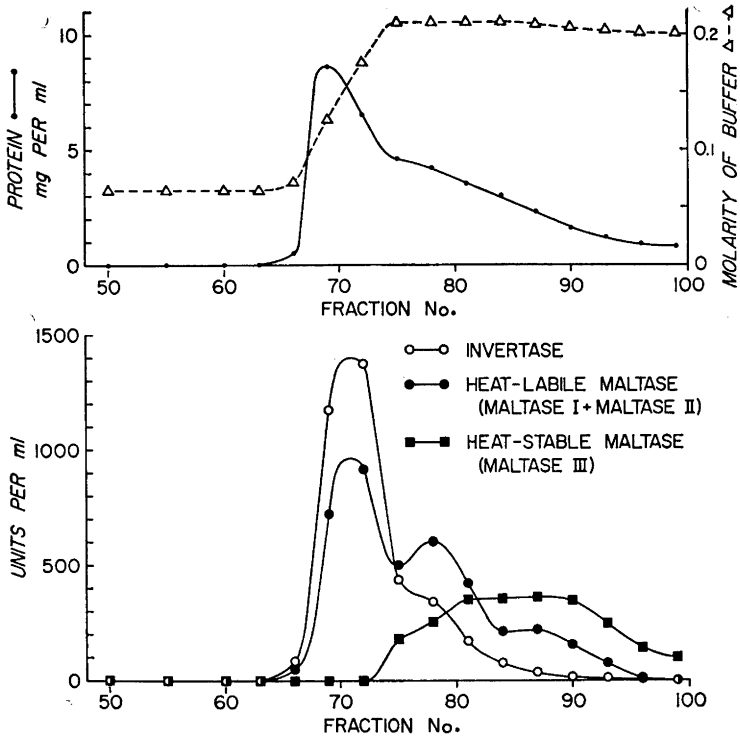

Fig. 3. Mutual displacement chromatography of intestinal glycosidases on TEAE-cellulose with 0.065 M phosphate buffer pH 6.0 as starting buffer. For experimental conditions, see text.

buffer practically no separation was obtained. The most effective separation was found with 0.065—0.080 M buffer. With 0.090 M buffer the separation was again poor, although the glycosidases were adsorbed to the column with this buffer.

The length of the column also had an influence on the separation, since better separation was obtained with a 1 × 100 cm column than with a 1 × 50 cm column. This is in contrast to the gradient elution technique, in which the length of the column was found to be of practically no importance.

These facts seem to prove that the separation obtained is really caused by mutual displacement, and that the experiments cannot be described as a gradient elution with a very steep gradient [16].

One mutual displacement chromatography of intestinal glycosidases is demonstrated in Fig. 3. A 1 × 100 cm column containing 9 g (dry weight) of TEAE-cellulose was equilibrated with 0.065 M phosphate buffer pH 6.0. 48.5 ml of an intestinal glycosidase preparation containing 313 units/ml of invertase, 430 units/ml of maltase, and 5.75 mg/ml of protein in 0.065 M phosphate buffer pH 6.0 was applied to the column with a flow rate of 3 drops

(0.12 ml)/min. The column was first eluted with 230 ml of 0.065 M phosphate buffer pH 6.0, which eluted 37 % of the protein applied to the column, but no invertase or maltase activity. The influent buffer was then shifted to 0.200 M phosphate pH 6.0, and at the same time the flow rate was lowered to 1 drop (0.04 ml)/min. Each fraction collected contained 20 drops (0.8 ml). The number of the fractions in Fig. 3 refers to the number of fractions collected from the moment the influent buffer was shifted to 0.200 M.

As is seen from the figure, the enzymes appear in the effluent as one single protein peak. The first part of this peak (fractions Nos. 66—72) contains the main part of the invertase activity and has a maltase/invertase activity quotient of 0.6. This part of the peak apparently corresponds to maltase fraction I (invertase fraction) described earlier [1]. The tailing of the invertase activity peak was reduced by the mutual displacement technique (*cf.* Fig. 1) but it was not completely abolished. K_s determinations for the invertase activity in fraction Nos. 69 and 85 gave the same values, 2.6×10^{-2}, in good accordance with the value obtained for a crude intestinal glycosidase preparation [7]. This shows that the intestinal invertase activity is caused by one single enzyme. As was found in the frontal analysis experiments, the mutual displacement between maltase II (invertase-free heat-labile maltase activity)[1] and maltase III (heat-stable maltase activity) [1] was much less effective, although a certain mutual displacement took place between these two enzymes also. The heat-stable maltase activity may be purified simply by heating the solution at 70°C [1], but the invertase-free heat-labile maltase fraction seems more difficult to separate. Rechromatography of fractions Nos. 75—84 did not appreciably increase the separation of this activity.

Heat inactivation of intestinal glycosidases. The frontal analysis experiments supported the theory that the heat-labile intestinal maltase is made up of two components. These two activities are rapidly inactivated at 60°C in 0.01 M phosphate buffer pH 6.0. At 50°C in the same buffer, the invertase activity was inactivated by 90 % in one hour. During the same time, however, the maltase activity was diminished only by 30 % (see Fig. 2 in Ref.[1]). If intestinal invertase and maltase I are supposed to be identical, this must mean that maltase II is not measurably inactivated under these conditions. Consequently, there must be a small difference in heat lability between maltases I and II as well.

At pH 7.0 this difference was found to be increased. A solubilized glycosidase preparation was used, which had been dialyzed against distilled water. The solution had a conductivity corresponding to about 0.005 M phosphate and contained 167 units/ml of invertase, 280 units/ml of maltase and 3.6 mg/ml of protein. The pH of the solution was 6.95, as measured with a glass electrode. When this solution was heated at 50°C, the invertase and maltase I activities were inactivated in 30 min, while the maltase II and III activities were not affected even after heating at 50°C for 60 min (Fig. 4). That the difference was caused by the shift in pH, was found by heating another sample of the solution in the presence of 0.010 M phosphate buffer pH 7.0 with the same results.

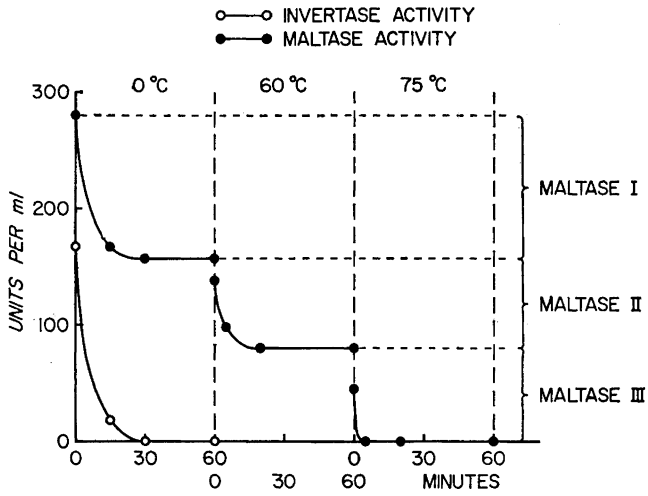

Fig. 4. Heat inactivation of intestinal maltase activity in three steps. Inactivation at 50°C was performed without buffer present (pH of the solution was 6.95). Inactivation at 60°C and 75°C was performed in 0.010 M phosphate buffer pH 6.0. The volume change by addition of the buffer is corrected for in the figure. Preheating was performed as described earlier [1]. The enzyme solution contained 167 units/ml of invertase, 280 units/ml of (total) maltase, and 3.6 mg/ml of protein.

When phosphate buffer pH 6.0 was added to a final concentration of 0.010 M (the change of volume has been corrected for in the figure) and the temperature increased to 60°C, the maltase II was rapidly inactivated while the maltase III was unaffected (Fig. 4).

In this way it was found possible to inactivate the invertase and maltase I activities with preservation of the maltase II and III activities. An attempt

Table 1. Change in adsorbability of the protein denaturated at 50°C at pH 7.0. The table shows the distribution of the protein in two corresponding mutual displacement chromatograms on TEAE-cellulose of the same enzyme solution, before and after heating to 50°C at pH 7.0 for 1 h. The amount of protein *not* eluted from the column was calculated from the amount of protein applied to the column.

	Protein as per cent of total	
	Enzyme solution not heated	Enzyme solution heated at 50°C at pH 7.0 for 1 h
Eluted with 0.080 M phosphate buffer pH 6.0	38	39
Eluted with 0.200 M phosphate buffer pH 6.0	32	18
Not eluted from the column	30	43

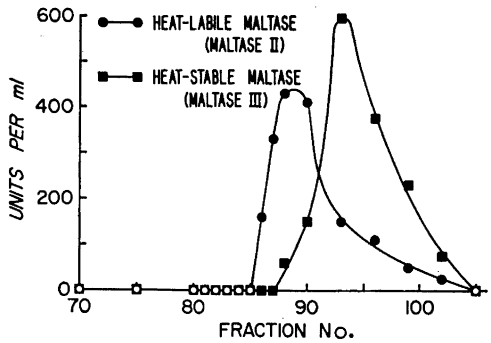

Fig. 5. Mutual displacement chromatography of intestinal maltase activities II and III on TEAE-cellulose with 0.080 M phosphate buffer pH 6.0 as starting buffer. For experimental conditions, see text.

was made to remove the inactivated protein by centrifugation, but it could not be sedimented even at 50 000 *g* (in a Spinco preparative ultracentrifuge). The adsorption properties of the inactivated protein were, however, found to be changed. The distribution of the protein in two corresponding chromatograms of the same glycosidase solution, one before and the other after heating at 50°C for 1 h, is shown in Table 1. It is seen that the heat-inactivated protein is not eluted from TEAE-cellulose by 0.200 M phosphate pH 6.0.

Mutual displacement chromatography of maltase II and III. A 1 × 100 cm column of TEAE-cellulose was equilibrated with 0.080 M phosphate buffer pH 6.0. 50 ml of an intestinal glycosidase preparation, in which the invertase and maltase I activities had been inactivated by heating for 1 h at 50°C, was used for the experiment. The solution contained 160 units/ml of maltase (II + III) and 3.6 mg/ml of protein. After addition of phosphate buffer pH 6.0 to a final concentration of 0.080 M, the solution was applied to the column, which was first eluted with 100 ml of 0.080 M phosphate buffer pH 6.0, and then with 0.200 M phosphate buffer of the same pH. The flow rate was 1 drop (0.04 ml)/min and each fraction collected contained 20 drops (0.8 ml).

The results of the chromatography is seen in Fig. 5. The mutual displacement between maltase II and maltase III was very incomplete. Only the two first fractions (Nos. 86 and 87) of the enzyme peak were free from heat-stable maltase activity.

Table 2. K_s values for three different intestinal maltases.

	K_s
Maltase I (invertase fraction)	1.1×10^{-2}
Maltase II (invertase-free heat-labile maltase activity)	2.2×10^{-3}
Maltase III (heat-stable maltase activity)	4.2×10^{-3}

K_s-values for the different maltase activities. For K_s determinations the following fractions were used:

Maltase I: Heat-labile maltase activity with maltase/invertase activity quotient 0.6, obtained by mutual displacement chromatography (fractions Nos. 66—72 of the chromatogram shown in Fig. 3).

Maltase II: Heat-labile maltase activity without invertase activity, obtained by mutual displacement chromatography of enzyme solutions which has been heated at 50°C at pH 7.0 for 1 h (fractions Nos. 86—87 of the chromatogram shown in Fig. 5 and corresponding fractions from similar chromatograms).

Maltase III: Heat-stable maltase activity, obtained from fractions Nos. 86—99 of the chromatogram shown in Fig. 3, fractions Nos. 93—102 of the chromatogram shown in Fig. 5, and the corresponding fractions from similar chromatograms. Traces of heat-labile maltase and invertase activity were inactivated by heating at 60°C for 1 h.

The K_s values for the different maltase activities are shown in Table 2. The figures reported are the mean of several separate determinations, with good agreement between them. The divergent K_s values demonstrate that the different maltase fractions are really different enzymes.

Studies on the Hydrolysis of Metal Ions

24. Hydrolysis of the Uranyl Ion, UO_2^{2+}, in Perchlorate Self-Medium

SIRKKA HIETANEN and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of UO_2^{2+} has been studied in perchlorate self-medium at 25°C, using quinhydrone or glass electrodes, which gave concordant results. The data indicate the two main reactions: $2UO_2^{2+} + H_2O \rightleftharpoons (UO_2)_2OH^{3+} + H^+$ (equilibrium constant β_{12}) and $2UO_2^{2+} + 2H_2O \rightleftharpoons (UO_2)_2(OH)_2^{2+} + 2\,H^+$ (equilibrium constant β_{22}). Small deviations at low acidities could be explained assuming the reaction $3UO_2^{2+} + 4H_2O \rightleftharpoons (UO_2)_3(OH)_4^{2+} + 4H^+$ (equilibrium constant β_{43}). The values obtained were: in the medium 0.4 UO_2^{2+}, 1.0 $(Na)ClO_4$, $\log \beta_{12} = -3.66 \pm 0.20$, $\log \beta_{22} = -6.02 \pm 0.03$. In 1.4 UO_2^{2+}, 3.0 $(Na)ClO_4$, $\log \beta_{12} = -3.68 \pm 0.20$, $\log \beta_{22} = -6.31 \pm 0.03$, $\log \beta_{43} \approx -12.6$ (quinh.), -12.9? (glass). The values for β_{22} and β_{43} are of the same order as obtained in an inert medium. The concentration of $(UO_2)_2OH^{3+}$ is appreciable only at high UO_2^{2+} concentration.

In an earlier paper [1] in this series, it was suggested that added information on the complex formation between two reagents, A and B, can be gained by equilibrium studies in what was termed as "self-medium". This means that one of the reagents, say B, which is charged, is kept at a high and constant total concentration and forms the major part of the ions of this sign of charge; the inert ions of opposite charge are kept at constant concentration. Self-medium measurements should especially give information on complexes A_pB_q with a higher ratio q/p than may be studied with the usual "inert medium" method.

The principle was applied to the hydrolysis of the thorium ion, Th^{4+}, in chloride self-medium. The data could be explained assuming the two complexes $Th_2(OH)_2^{6+}$ and Th_2OH^{7+}; for the first, a formation constant was found which agreed well with inert-medium data, the second complex was discovered by the self-medium work [1].

In the present work, the self-medium method has been applied to the hydrolysis of the uranyl ion in perchlorate self-medium. Denoting as usual the total concentration of B by B, and the "analytical" excess concentration of H^+ by H, which was negative in the majority of our solutions, the equilibrium solutions were composed as follows:

Medium	B	H	$[Na^+]$	$[ClO_4^-]=I$
0.4 UO_2^{2+}, 1.0 (Na)ClO_4	0.4	H	$0.2 - H$	1.0
1.4 UO_2^{2+}, 3.0 (Na)ClO_4	1.4	H	$0.2 - H$	3.0

The experiments were performed as titrations, starting with a certain solution S and adding from a buret measured amounts of another solution T. The compositions of the various solutions S and T followed the scheme above; Table 1 gives the values for H in S, T, and the final solution in the various experiments.

Table 1. Survey of titrations.

B	I	H S	H T	Final H quinh.	Final H glass	Corr mV quinh.	Corr mV glass	Symbol quinh.	Symbol glass
0.4	1.0	0.20	−0.30	0.08	−0.06	—	—	+	○
		−0.14	0.20	0.09	0.09	0.5	—	×	□
1.4	3.0	−0.20	0.20	0.05	0.05	0.5	−1.8	+	□
		0.20	−0.20	0.04	0.04	0.5	−1.8	+	□
		0.22	−0.18	0.02	0.02	—	—	×	●
		−0.18	0.22	0.02	0.02	−0.7	—	×	●
		0.20	−0.20		0.00		+50		○
		−0.20	0.20		0.04		+49.5		○

Rounded values are given for H. The two last titrations were made with a different type of glass electrode. In each solution, $[UO_2]_{total} = B$, $[ClO_4^-] = I$, $[Na^+] = 0.2 - H$.

After each addition of T, the hydrogen ion concentration, h, was measured with one of the cells

$$- \text{ glass electrode}|\text{equilibrium solution}||\text{SE}+ \quad \text{(I)}$$
$$-\text{Pt}|\text{Q,QH}_2\text{, equilibrium solution}||\text{SE}+ \quad \text{(II)}$$

Separate experiments were made with cells I and II. The reference electrode was

$$\text{SE} = B \text{ M } UO_2^{2+},\ 0.20 \text{ M } Na^+,\ I \text{ M } ClO_4^-|B \text{ M } UO_2^{2+},\ 0.01 \text{ M } Ag^+,\ 0.19 \text{ M } Na^+,\ I \text{ M } ClO_4^-|Ag$$

It so happens that the predominating species for UO_2^{2+} seem to have the same types of formula as for Th^{4+}; for the calculations one may then take over a number of equations which were derived and applied in the previous paper [1].

Symbols

A, B = reactants, here OH^- ($-H^+$) and UO_2^{2+} ; a = concentration of free A, here $a = h^{-1}$; b = concentration of free B ; B = total concentration of B ; E = electromotive force of cell (I) or (II) ; E_0 = constant in eqn. (1) ; $f = 2u^2 + 2ku$, eqn (6) ; $F(h) = BZ + \Delta$, eqn (2) ; $h = [H^+]$; H = analytical excess of H^+, often negative ; $I = [ClO_4^-]$ in medium ; j = constant in term for liquid junction potential, eqn (1) ; k = parameter defined by eqn (6) ; p,q = coefficients in formula of complex A_pB_q ; u = normalized variable, corresponding to a, eqn (6) ; Z = average number of A (here OH^-) bound per B (here UO_2^{2+}) ; β_{pq} = equilibrium constant for formation of A_pB_q, eqn (3) ; Δ = analytical error in H, eqn (2).

In the equilibrium constants, and figures, the unit M (mole/liter) is used throughout.

REAGENTS

Uranyl perchlorate. In our first experiments, with $B = 0.4$, we started from ammonium uranyl hydroxide. This substance had long ago been precipitated from uranyl nitrate, which had been purified by ether extraction. The hydroxide was ignited, and the U_3O_8 formed was dissolved in HNO_3. The solution was evaporated repeatedly with $HClO_4$ under an infrared lamp, until no trace of nitrate ion could be detected.

For the experiments with $B = 1.4$, we started with spectroscopically pure UO_3, obtained from AB Atomenergi. A possible impurity of NH_3 was removed by igniting the oxide to U_3O_8, which was then dissolved in 6 M $HClO_4$, 30 % H_2O_2 being added. The excess of acid was removed by evaporation under an infrared lamp.

The total uranium concentration was determined by precipitating with oxine or NH_3 at pH = 7, igniting the precipitate, and weighing as U_3O_8. The results obtained with oxine or NH_3 agreed within 0.1 %.

Total perchlorate was determined by passing a known amount of solution through a H^+-saturated ion exchanger (Wofatit KPS-200), and titrating the eluate with NaOH.

The hydrogen ion excess, H, in the stock solutions was determined by emf titration with NaOH, after diluting to 0.02, 0.04, or 0.08 M UO_2^{2+}, using diagrams according to Gran [2]. The values for H from experiments of different dilutions were consistent, and the estimated uncertainty in H will correspond to an error in Z of at most 0.004, probably only 0.002. The H so determined came out slightly higher than $[ClO_4^-] - 2B$, which is the difference between two much larger numbers and cannot be determined with sufficient accuracy.

Sodium perchlorate was prepared from sodium carbonate p.a. and perchloric acid p.a. *Perchloric acid* was standardized against solid $KHCO_3$ and standard NaOH. *Sodium hydroxide* solution was prepared as described earlier [3].

Apparatus. The Ag, AgCl electrodes were prepared according to Brown [4]. In the quinhydrone half-cell, a bright Pt foil was used. The glass electrodes were Radiometer "red" electrodes G 202A (for $B = 0.4$), G 202 BT57, and G 202 B38 (for $B = 1.4$). The electrode vessel was of the usual "Wilhelm" type [5], and the cells were kept in a paraffin oil thermostat at 25.0 ± 0.1°C in a thermostated room. The emfs were measured with a Vernier compensator, or with a Radiometer potentiometer PHM 3.

With the medium 0.4 UO_2^{2+}, 1.0 (Na)ClO_4, E became constant within 5 min; in general, the reading was taken 10 min after each addition. In the medium 1.4 UO_2^{2+}, 3.0 (Na)ClO_4, the emfs stabilized somewhat more slowly, especially with the glass electrodes, so one had to wait 15–30 min for a constant reading.

TREATMENT OF DATA

The primary data given by each titration were sets of values (E,H), where E is the emf of cell (I) or (II), and H is the analytical excess of hydrogen ions calculated for each point; (in the range with appreciable hydrolysis, H was negative). The fundamental equations are

$$E = E_0 - 59.15 \log h + jh \quad (1)$$
$$H = h - BZ - \Delta = h - F(h) \quad (2)$$

Here, E_0 and j are constants; jh is the liquid junction potential, which is expected to be linear with h. BZ is the amount of OH^- bound by B per liter of solution, and may be expressed as a function of h applying the law of mass action, eqns (4) and (5) below; Δ is the analytical error in H.

The $E(H)$ plots for various titrations did not coincide exactly, which might be ascribed either to variations in E_0, or to variations in Δ. In the same way as described in our previous paper [1], it was checked graphically that the spread is in E_0 and not in Δ. Indeed, there was no reason to assume an appreciable

Table 2. Medium 0.4 UO_2^{2+}, 1 (Na)ClO_4. Experimental data H and E (corrected) for four titrations. Every other point given, log h calculated from E with $E_0 + 3 \cdot 59.15 = 164.9$ mV for quinhydrone titrations, and $E_0 + 3 \cdot 59.15 = 493.7$ for glass electrode titrations, $j = 51.0$ mV M^{-1}.

error Δ. Since UO_2^{2+} hydrolyses at lower acidities than Th^{4+}, one may determine H accurately by acid-base titration and Gran plot, which was not possible for Th^{4+}. In the following, $\Delta = 0$ was assumed.

The quinhydrone and glass electrode measurements for $B = 0.4$ were made to coincide by applying shifts along the E axis, whereas for $B = 1.4$, data with glass and quinhydrone were treated separately. Thus three separate curves $E(H)$ were obtained for the calculations. These corrected data are given in Tables 2 ($B = 0.4$) and 3 ($B = 1.4$).

Just as in the case of thorium, a preliminary treatment showed that the data for the lowest Z agreed well with a mechanism with a complex containing one OH group, whereas for higher Z, they indicated a complex with 2 OH. Data up to about $Z = 0.15$ were used in the calculations.

It was concluded that the main products are the complexes $AB_2 = (UO_2)_2OH^{3+}$ and $A_2B_2 = (UO_2)_2(OH)_2^{2+}$. The assumption of 2 B per complex will be justified in the discussion below. Later on also the complex A_4B_3 had to be included to account for certain deviations.

We denote by β_{pq} the equilibrium constant for the formation of A_pB_q:

$$p\ H_2O + q\ UO_2^{2+} \rightleftharpoons (UO_2)_q(OH)_p^{(2q-p)+} + p\ H^+;$$

$$[A_pB_q] = \beta_{pq}[H^+]^{-p}[UO_2^{2+}]^q = \beta_{pq}a^pb^q \qquad (3)$$

The law of mass action, and the definitions, then give

$$B = b + 2\ \beta_{12}ab^2 + 2\ \beta_{22}a^2b^2\ (+ 3\ \beta_{43}a^4b^3) \qquad (4)$$

$$BZ = \beta_{12}ab^2 + 2\beta_{22}a^2b^2\ (+ 4\beta_{43}a^4b^3) \qquad (5)$$

In the calculations, eqns (1) and (2)' were used alternately for successive approximations, as described in the thorium paper [1] until a theoretical function $F(h)$, and values for E_0 and j, had been found which generated each other on application of (1) and (2) to the experimental data (E,H).

In the calculations, the auxiliary normalized variable u, the parameter k, and the abbreviation $f(u)$ were used [1]:

$$u^2 = 2\beta_{22}a^2B\ ;\ ku = 2\beta_{12}aB\ ;\ f = 2u^2 + 2ku \qquad (6)$$

One may then derive an expression (Ref [1], eqn 13) for Z as a function of u, and construct plots of $Z(\log u)_k$ for a number of values for k, which may be compared with experimental curves $Z(\log a)$. From the value of k, and the difference of coordinates ($\log u - \log a$), at the position of the best fit, $\log \beta_{22}$ and $\log \beta_{12}$ could be obtained, using (6) above or Ref.[1], eqns 14 and 15.

When this method was applied, it was seen that for the very lowest acidities there was an unavoidable bend in the plot ($E + 59.15 \log h$) *versus* h, indicating the existence of at least one more complex. Now, the data in inert medium [6,7] had indicated the existence of a series of complexes, $B(A_2B)_n$. The first member, A_2B_2, had already been found with self-medium. It was then reasonable

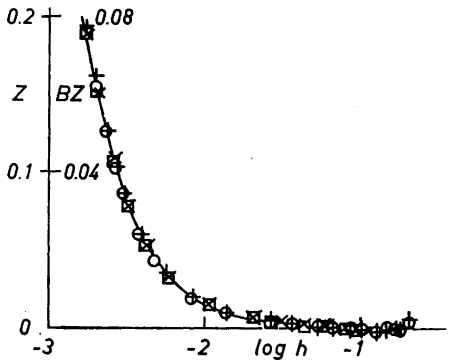

Fig. 1. Hydrolysis of UO_2^{2+}, medium 0.4 UO_2^{2+}, 1.0 (Na)ClO_4. *Z versus* log *h*. Points: calculated from experimental data *E*(*H*), Table 2, using E_0 and *j* from Table 4. Curve: calculated *Z*, assuming values for β_{22} and β_{12} from Table 4.

to assume that the deviations are due to the second member, A_4B_3, and on this assumption, β_{43} was calculated using (5), which gives

$$BZ-\beta_{12}ab^2-2\beta_{22}a^2b^2 = 4\beta_{43}a^4b^3 \qquad (7)$$

The value for *b* in each point was obtained from *B*, *a*, and eqn (4). In this way, log β_{43} was estimated for the stronger medium ($B = 1.4$); if this correction was applied to *BZ* in *F*(*h*), the E_0 plots were found to be more nearly linear (Fig. 4, Fig. 5). Because of the greater spread of the glass electrode data, the value for β_{43} derived from them is especially uncertain. For the weaker medium ($B = 0.4$), the deviation is smaller, and no attempt was made to estimate β_{43}.

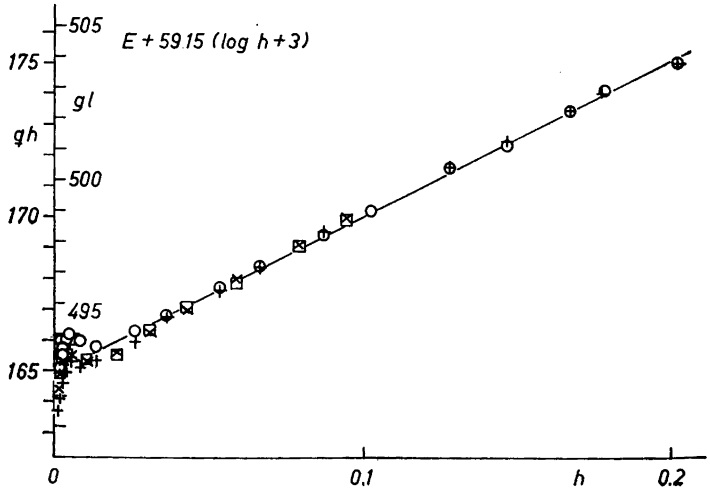

Fig. 2. Medium 0.4 UO_2^{2+}, 1.0 (Na)ClO_4. Abscissa: log *h*, calculated from *H* and *Z*, using values for β_{12} and β_{22} in Table 4. Ordinate: $E + 59.15$ (log h + 3). Straight line: given by values of *j* and E_0 in Table 4.

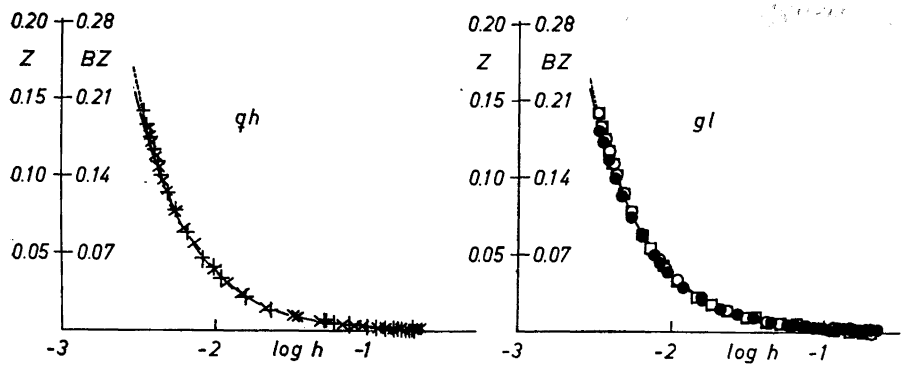

Fig. 3. Hydrolysis of UO_2^{2+}, medium 1.4 UO_2^{2+}, 3.0 (Na)ClO_4. Experimental points and full-drawn curve obtained as in Fig. 1. Left: quinhydrone electrode data, right: glass electrode data. The dotted lines show the correction obtained by assuming the complex A_4B_3.

It has been pointed out by Professor Robert Connick that if the liquid junction potential is calculated from the Henderson equation, a plot like Fig. 2 would show an upward bend of (E + 59.15 log h) at the lowest values for h, because in this range Na^+ ions replace a considerable part of the UO_2^{2+} ions. Rough estimates of the ionic mobilities, using unpublished data of Dr George Biedermann, indicate that this effect would be of the order of a few 0.1 mV thus much less than the observed effect, which we have ascribed to β_{43}. Although this estimate is too uncertain to justify any correction, it shows that one should be careful not to press the data too much in this region.

The values finally obtained for equilibrium constants, E_0, and j, are given in Table 4. The calculated values for h and Z are given in Tables 2 and 3

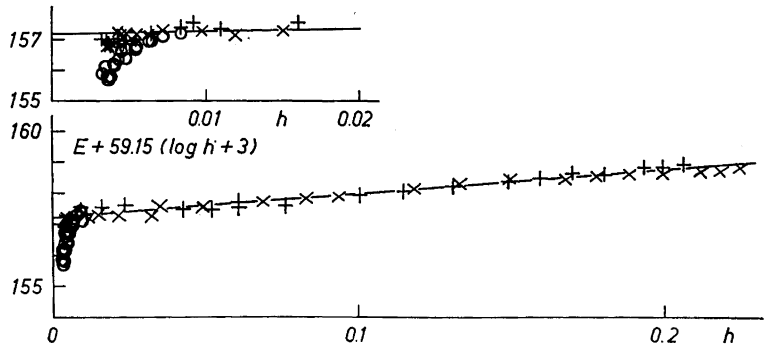

Fig. 4. Medium 1.4 UO_2^{2+}, 3.0 (Na)ClO_4, quinhydrone electrode. Plots for E_0 and j, calculated as in Fig. 2. Crosses: corrected for β_{43}. Circles: not corrected for β_{43}, shown only for $h < 10$ mM; for higher h, the difference is negligible.

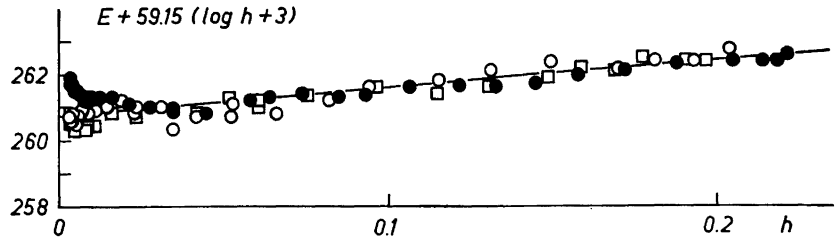

Fig. 5. Medium: 1.4 UO_2^{2+}, 3.0 (Na)ClO_4, glass electrode. Plot of $E + 59.15$ (log $h + 3$) *versus* h, calculated as in Fig. 2, assuming log $\beta_{43} = -12.9$. Difference between series indicates spread in glass electrode data.

(every other point given), and the corresponding diagrams are given in Figs. 1, 2 ($B = 0.4$), 3, 4, and 5 ($B = 1.4$).

It has been asked, whether the assumption of AB_2 is necessary and whether the whole effect could not be explained by A_2B_2, and some deviation of the liquid junction potential from linear behavior. To answer this question, it was assumed that A_2B_2 is the only complex present; assuming various values for β_{22}, eqn (2) makes it possible to calculate h directly from H; inserting this in (1), one might plot $E + 59.15$ log h *versus* h; the results for $B = 1.4$ M are shown in Fig. 6. Deviations from linearity of the order of 10—15 mV cannot be avoided, whatever value for β_{22} is chosen, and so it does not seem possible to dispense with AB_2 in the explanation.

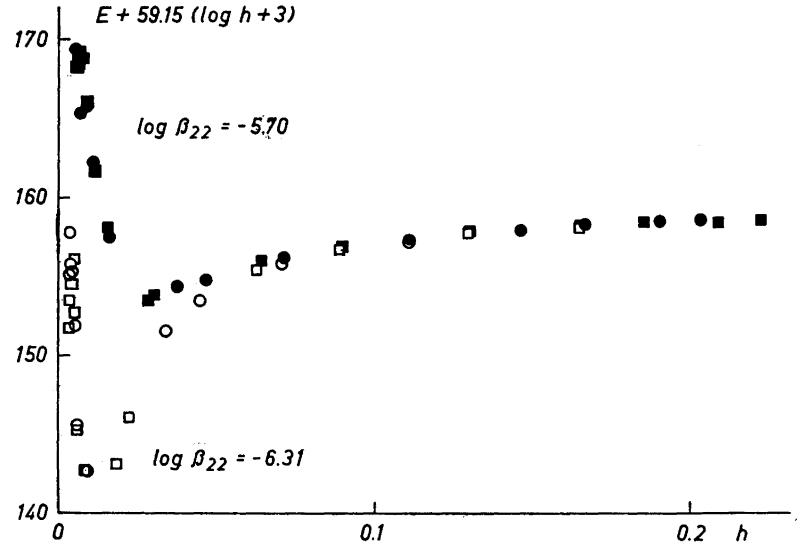

Fig. 6. Medium: 1.4 UO_2^{2+}, 3.0 (Na)ClO_4. Plots for E_0 and j, calculated neglecting AB_2 and assuming log $\beta_{22} = -5.70$ (black symbols) and -6.31 (open symbols). Quinhydrone electrode; circles correspond to + in Fig. 4, squares to ×. Non-linearity of plot indicates that the data cannot be explained by A_2B_2 alone.

Table 4. Equilibrium constants etc obtained by successive approximations from the experimental data $E(H)$. Emfs in mV, concentrations in M.

Quantity	0.4 UO_2^{2+}, 1.0 (Na)ClO_4	1.4 UO_2^{2+}, 3.0 (Na)ClO_4 quinh	1.4 UO_2^{2+}, 3.0 (Na)ClO_4 glass
log k	−0.7	−0.3	−0.3
log u − log a	−3.06	−2.93	−2.94
log β_{22}	−6.02	−6.31	−6.32
log β_{12}	−3.66	−3.68	−3.69
log β_{43}	(not est.)	−12.6	(−12.9)
j	51.0	8.0	8.8
E_0 + 3 . 59.15	164.9 (qh), 493.7 (gl)	157.2	260.7

Estimated uncertainty: approximately ± 0.2 in log k and log β_{12}, ±0.03 in log β_{22}. Different type of glass electrode was used in the two media. Of the j values 8.0 and 8.8, that for "quinh" was more accurately determined. The difference is within the limits of error of the "glass" values.

DISCUSSION

When equilibria A—B are studied in a self-medium with a high and constant concentration of B, the data allow a rather certain conclusion on the values of p in the predominating complexes A_pB_q, whereas the assignment of q cannot be made with certainty from self-medium data alone.

From the data presented in this paper one may conclude that there are species with 1 OH, 2 OH, and probably 4 OH. The formulas ascribed above have been AB_2, A_2B_2, and A_4B_3, thus $(UO_2)_2OH^{3+}$, $(UO_2)_2(OH)_2^{2+}$, and $(UO_2)_3(OH)_4^{2+}$, as usual with unknown amounts of H_2O and ClO_4^-.

For the uranyl ion, just as in the case of thorium [1], the predominating complexes cannot reasonably be mononuclear. If they had been, the measurements at lower B in an inert medium [6,7] would have come out much differently from what is actually observed: hydrolysis would have set in at higher acidities, and moreover, one would have obtained a single curve ("mononuclear wall"). instead of a family of parallel curves.

The assignment of the formula A_2B_2 rather than, say, A_2B_3, or A_2B_4, is made probable by the fact that the log β_{22} so obtained is of the same order of magnitude as the log β_{22} obtained for other ionic media: 1 (Na)ClO_4, −6.05 to −6.10 [7,8], 0.1 ClO_4^- −5.94 [9], and similar values in other media studied in this laboratory.

The value for log β_{43}, which appears only as a correction term, also is of the same order as obtained in earlier work, −12.4 to −12.5 *etc.*[7,8].

It seems reasonable for structural reasons that the complex with one A is AB_2. Had it been, say, AB_3, one might also have expected "log β_{12}" to be about 0.5 units higher in 1.4 than in 0.4 M uranyl medium.

Two of the ions inferred from the self-medium measurements are the same as those observed in inert medium, whereas AB_2 is new. It is understandable that it has not been observed in the earlier inert medium measurements, if it is noticed that the equilibrium constant for

$$(UO_2)_2(OH)_2^{2+} + H^+ \rightleftharpoons (UO_2)_2OH^{3+} + H_2O$$

will give

$$[(UO_2)_2OH^{3+}][(UO_2)_2(OH)_2^{2+}]^{-1} = \beta_{12}\beta_{22}^{-1}h \approx 10^{2.5}h$$

Thus, $[AB_2] > [A_2B_2]$ only for $h > \beta_{22}\beta_{12}^{-1} \approx 10^{-2.5}$. Hydrolysis at such a high acidity is appreciable only at rather high concentrations of uranyl. For instance, at $h = \beta_{22}\beta_{12}^{-2}$, $Z \approx 3\ B\beta_{12}^{2}\beta_{22}^{-1} \approx 0.2\ B$. Even at $B = 0.1$ M, a high value for inert medium measurements, Z is then only 0.02.

An Electrophoretic Investigation of the Effect of pH on the Degradation of α-Casein by Crystalline Rennin

BÖRJE LINDQVIST and TORSTEN STORGÅRDS

The Central Laboratory of Mjölkcentralen, Stockholm, Sweden

The enzymatic degradation of electrophoretically homogeneous α-casein by crystalline rennin breaks down the casein into a few high molecular weight components. These are degraded further in various ways depending on the pH of the solution. In both the primary and most of the later degradation reactions the parent substance is split into two components with electrophoretic mobilities above and below, respectively, that of the original substance. In addition to the simple fission of α-casein and its primary degradation products there was also observed a slow loss of low molecular weight substances (NPN). The pH optima for the fission and for the NPN formation do not coincide. These results provide a simple explanation of the earlier contradictory properties ascribed to the different components of α-casein and "para-α-casein". Most of these components can now be described as enzymatic cleavage products of the α-casein and of the κ-casein and λ-casein which also contribute to the α-peak.

Although a number of electrophoretic investigations of the enzymatic degradation of α-casein, β-casein and whole casein have been carried out [1–8], only a few of these have dealt with the action of the rennet enzyme (rennin or chymosin) as a proteolytic enzyme in casein hydrolysis [2,4,5]. From these reports it is not possible to draw more than limited conclusions about the groups in the casein that can be split off and about the factors that govern the enzymatic processes. Particularly, little work has been done on the effect of pH on the degradation of α-casein and β-casein by pure rennet enzyme. Several extensive investigations have, however, been carried out without the use of electrophoresis. Nitschmann and coworkers, for instance, have made a detailed study of the primary reaction in the attack of rennin on the casein [9–11] and Ågren [12] and others have separated and identified several components of enzymatic hydrolysates of casein.

In the present investigation it has been found that the enzymatic hydrolysis of casein can proceed in a number of different ways depending on the pH. This explains the somewhat problematic nature of the results of earlier investigations on casein degradation.

METHODS

Preparation of α-casein. α-Casein was prepared by a method essentially the same as the urea method developed by Hipp and coworkers [13]. Great importance was attached to carrying out the preparation rapidly and under mild conditions. In the preparation of the acid casein, only two hours passed between precipitation and the dissolution of the casein in the urea solution. To make this possible the washing and the reprecipitation of the casein was done once only. If a longer time is taken for the preparation there may be enzymatic destruction of the casein and there is a risk of oxidation of sensitive groups in the protein. Three reprecipitations from the urea solution were usually sufficient to give an electrophoretically pure preparation. The casein was obtained in an enzyme-free state by dissolving in dilute alkali and heating at 80° for 30 min. To prepare a suitable form for storage the casein was precipitated with acid, washed and freeze dried. When a very pure preparation was required the casein solution was freed from fat and colloidal material by sedimentation in a Spinco model L ultracentrifuge at 30 000 rpm for 1 hour. 0.5 % thioglycol was added to all the solutions used in the preparation in order to reduce oxidation by atmospheric oxygen, and toluene was added as a bacteriostatic agent.

Preparation of rennin. Crystalline rennin was prepared from "Chr. Hansens Standardlöpe" in powder form by the method of Berridge [14]. The preparation was followed by microscopic examination and by electrophoresis and only preparations with pure, typical crystals and a well defined single peak in the electrophoresis curve were used. It was usually necessary to recrystallise from a magnesium acetate buffer to get crystals that dissolved to give a colorless, clear solution.

The experimental work was done in sets of three parallel runs about 0.2 pH units apart which took between two and three weeks depending on the speed of the degradation. The following conditions are typical of those used for a three week run:

α-Casein (72 g), which was checked electrophoretically immediately before use to ensure that it had not been affected enzymatically during storage, was dispersed in distilled water (*ca.* 1 500 ml) and the pH was adjusted to between 7 and 9 by dropwise addition of 10 % sodium hydroxide solution with vigorous stirring. After a few hours when the casein had dissolved, the pH was adjusted to 9.0 with 1 N NaOH using a Beckman Automatic Titrator and the solution was made up to 1 800 ml. The 4 % casein solution obtained was then heated to 80° for 10 min to destroy any micro-organisms and any enzymes remaining and then cooled after adding 1 % toluene.

Three buffered rennin solutions were prepared containing:

16 g NaCl
8.4 g NaH_2PO_4
x ml 1 N HCl or NaOH (0—30 ml)
y ml rennin solution (*ca.* 1 ml with 300—400 Ru/ml *)
distilled water to 200 ml.

These quantities were chosen so that a 3:1 mixture of casein solution and buffer solution would have the following concentrations:

NaCl	2 %
NaH_2PO_4	0.0675 M
Rennin	400 Ru/ml

The following volumes of HCl or NaOH solution were added in making up the rennin buffer solutions.

The 4 % casein solution was measured out in 15 ml portions into three sets of twelve 25 ml test-tubes with glass stoppers and in 60 ml portions into three sets of six 100 ml conical flasks with glass stoppers. Buffer solution (5 and 20 ml, respectively) was added to each of these casein solutions and the test-tubes were immediately shaken strongly to give a mixture as homogeneous as possible. Toluene (0.2 and 0.8 ml, respectively) was added to each mixture and they were again shaken.

* Ru indicates rennin activity units according to Berridge[14]

Table 1. Volumes of acid or alkali solution added to the buffer solution and corresponding pH values in the substrate (see text).

1 N HCl or NaOH, ml	pH of casein-buffer solution
17.5 NaOH	7.0
12.5 »	6.7
7.5 »	6.4
0 »	5.89
1.5 HCl	5.81
3 »	5.75
5 »	5.45
10 »	5.21
15 »	4.85
20 »	4.79
25 »	4.48
30 »	4.21

A sticky precipitate was formed when the solutions were mixed, occluding part of the buffer salts and enzyme. Full equilibrium inside and outside this gel was not attained immediately but was gradually reached in about a day. Flasks from each mixture were withdrawn for analysis of the contents every Monday, Wednesday and Friday.

Analyses. To determine the distribution of nitrogen the flasks containing 80 ml of mixture were shaken lightly, trichloroacetic acid (TCA, 5 ml, 25 %) was added and the flasks were shaken again vigorously and then centrifuged for 15 min at 3 500 rpm. The supernatant was then decanted through a filter and a nitrogen determination was made on a 20 ml sample of the filtrate by the macro-Kjeldahl method. The amount of nitrogen soluble in 2 % TCA as found by this method was corrected for the amount of soluble nitrogen in the original casein before the rennin was added. The $NPN_{2\%\ TCA}$ (non-protein nitrogen soluble in 2 % TCA) was then expressed as a percentage of the total nitrogen in the original mixture.

The electrophoreses were run on the mixture in the 25 ml tubes. The contents of each tube were first treated with EDTA (0.4 g) to bind any traces of calcium remaining in the casein and with 0.2 ml of 30 % NaOH to raise the pH. After rapid mixing by shaking the pH of the mixture had risen to about 9. This destroyed the rennin and stopped the enzyme reaction. At the same time the casein began to dissolve and after shaking for 2 h the casein was completely dissolved. The protein solution was then dialysed against two changes of the electrophoresis buffer in a rotary dialyser, first for 3 h and then for 16 h. The ratio of sample to buffer during the dialysis was about 1:100.

After dialysis the protein solution was slightly opaque due to the presence of globules of fat and toluene and particles of other material in suspension. After sedimentation in a Spinco model L ultracentrifuge * at 30 000 rpm for 1 h the solution gave a very small bottom layer (*ca.* 0.1 ml), a clear middle layer, and an opaque top layer. A 15 ml sample of the clear layer was taken for the electrophoresis. Centrifuging gave optically clear solutions much more rapidly and conveniently than any of the methods used previously and gave much better reproducibility.

The electrophoreses were run in a Spince model H instrument at 1°C using a phosphate buffer, μ 0.1, pH 7.3, containing 0.02 % merthiolate as preservative. Standard conditions of 120 min at 12 mA were used throughout the investigation.

The sensitivity of the optical recording device and the protein concentration in the sample were kept constant and the electrophoresis curves were therefore directly comparable. The pH of the electrophoresis samples was measured before the addition of EDTA and sodium hydroxide. The variations between tubes were usually about 0.03—0.04 pH units; the values given below are means of the values found for each series.

The conductivity of the buffer and of the electrophoresis sample were measured with an LKB conductivity bridge with the electrodes immersed in the electrophoresis bath.

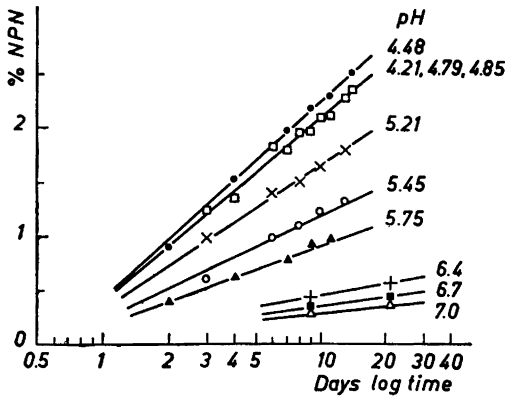

Fig. 1. The release of NPN from α-casein by rennin.

RESULTS

A. Formation of soluble nitrogen

The soluble nitrogen values obtained, when plotted against a logarithmic time scale, gave a linear set of curves with a common origin at 0 % NPN. This point lies rather high on the logarithmic time scale — at approximately 0.6 days (Fig. 1). The slope of the curves which is of course a measure of the rate of the enzymatic process, has a pH optimum at 4.48. At pH 7.0 the reaction rate is very low.

Plotting the NPN value at 15 days as a function of the pH gives curves of the type shown in Fig. 2. To decide whether the curve is symmetrical around the pH 4.5 ordinate would require measurements further down the pH scale

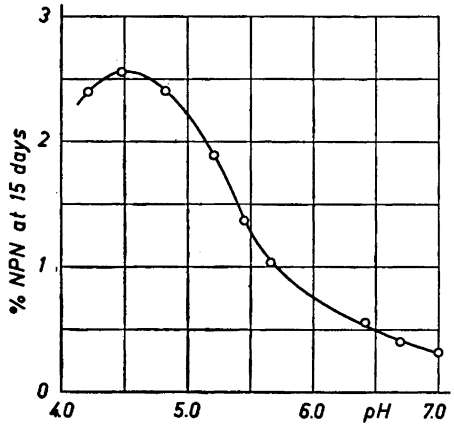

Fig. 2. NPN liberated from α-casein in 15 days.

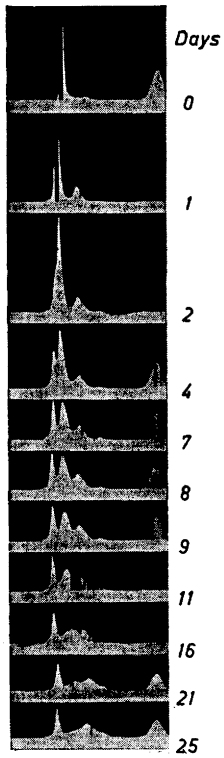

Fig. 3. Electrophoresis curves showing the course of degradation of α-casein by rennin at pH 5.81.

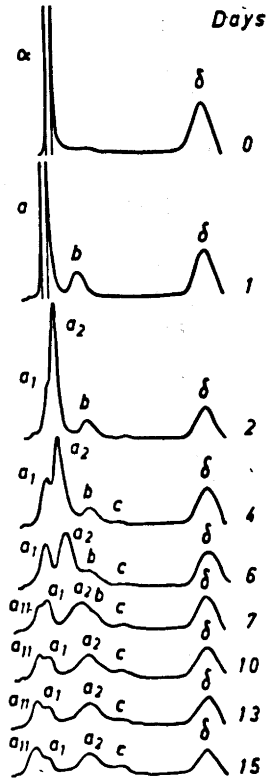

Fig. 4. Electrophoresis curves showing the course of degradation of α-casein by rennin at pH 5.21. Tracings from the photographic curves.

B. Course of the degradation

More than 200 electrophoreses were run in order to elucidate the course of the degradation and approximately 75 of these would be essential to show the phenomena observed completely. For practical reasons only a few will be given here. The curves selected have been supplemented by diagrams showing the course of the more important phenomena occurring during the degradation.

Fig. 3, for example, shows the degradation of α-casein at pH 5.81. The sequence of changes shown is typical of that occurring at pH values between 5 and 7. It shows clearly the successive breakdown of the α-casein into a few components which then undergo further degradation at different rates.

Fig. 4 shows the degradation at pH 5.21. By using only tracings of the curves it has been possible to get the curves close enough to each other to show successive changes more clearly. In this case the degradation is more compli-

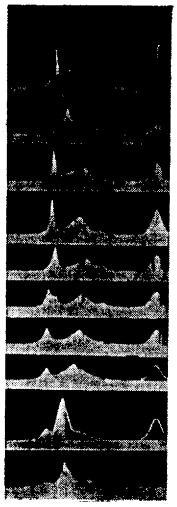

Fig. 5. Typical electrophoresis curves at an intermediate stage of the degradation for different pH values.

cated than at pH 5.81 and some of the components formed first are split again into two components before the subsequent degradation.

Fig. 5 shows a cross section of the electrophoresis curves through the whole pH scale. These have been selected to show the typical sequence at eacn pH. It is apparent that at a pH greater than 6 or less than 4.5 the electrophcresis curves are much simpler than in the interval between. The appearance and degradation of some of these main components will be discussed below.

The two components first formed are designated here as a and b. Component a splits into a_1 and a_2 and then a_1 is further degraded to a_{11}. Component a_2 is degraded more or less continuously without forming any definite degradation product. In some cases where indications of degradation products of a_2 were observed they have been numbered 1, 2 and 3. No special designation has been given to minor substances that could not be traced back to any parent substance except in the case of a component labelled c.

General description of the degradation. At all pH values between 4 and 7 the α-casein is split immediately after adding the enzyme (within a few hours) into two components, a main component (a) with a slightly higher migration rate than the α-casein and a component present in smaller amount (b) with a lower migration rate. The course of the subsequent degradation varies considerably depending on the pH. The b component appears to break down comparatively slowly at a rate independent of the pH and its migration rate changes little once the component has been formed. The formation of the final form of the b component proceeds more slowly the higher the pH and at a pH above 6.5 it takes more than 25 days under the conditions used here. At a pH lower than this it reaches a stable migration rate in two to three days.

Fig. 6 which illustrates the changes in the migration rates of all components shows that there is a strong reduction in the mobility of the b component after 7 to 10 days at pH 5.8—6.4. This may, however, be only an artifact due

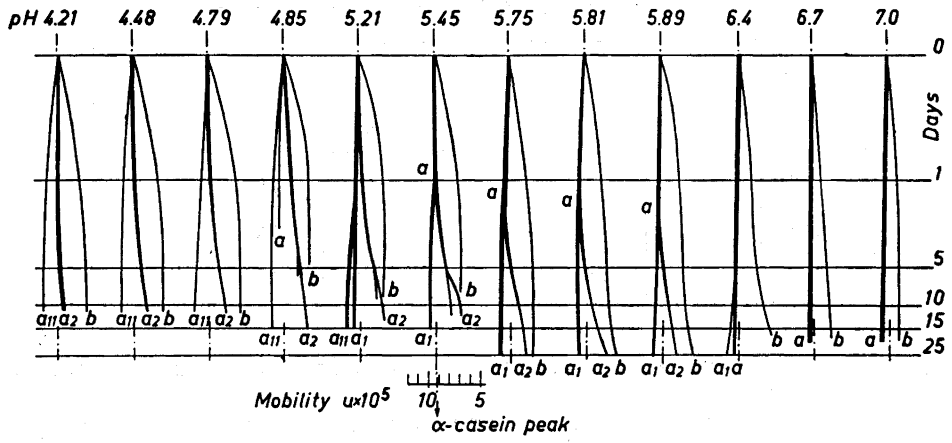

Fig. 6. Changes in electrophoretic mobility during degradation at different pH values. The dotted line shows the position of the α-casein peak at the start of the experiment. The full lines show the changes of mobility of those peaks that can be followed. The thickness of the lines gives a rough indication of the amount of the component present in the mixture.
The electrophoretic migration is from right to left; mobilities can be read from the scale under the pH 5.45 curve.

to the movement through the b component peak of peaks due to other components as their speed changes in the course of the degradation. This would either displace the apparent position or the b peak or form an asymmetric peak with a displaced centre of gravity.

The a-component. The migration rate of the a component is only slightly higher than that of the α-casein (9.3×10^{-5} as aginst 9.1×10^{-5}). The degradation of the a-casein becomes apparent quite soon after it is formed but the rate of degradation depends strongly on the pH. At pH 6.4 it can be observed after 10 days and at pH 5.2—5.3 the degradation is so fast that the a-casein is completely changed after only a day. At pH values lower than this the a-casein is not observed and only its degradation products, a_1 and a_2, appear.

Component a_2. The a_1 and a_2 caseins have mobilities higher and lower, respectively, than that of the parent a-casein in the same way as the a and b caseins have higher and lower migrations rates, respectively, than that of the α-casein. This simultaneous formation of fission products with migration rates higher and lower than that of the parent substance appears to be a general rule in this type of casein degradation.

The mobility of the a_2 component gradually falls in the same way as that of the b-casein. The final product with a stable migration rate is reached most rapidly at a pH of about 5.2. Both at lower and at higher pH values the change is much slower. The final migration rate coincides at optimal pH values with that of the b component but at other pH values is usually higher.

In the pH range 4.8—5.5 there is a tendency for a_2 to split up in the intermediate stages into several components. Later, however, these are largely

Table 2. Composition (%) of the casein degradation product.

Preparation		a		b	c
pH	days	a_1	a_2		
5.75	2	83.2		15.0	1.7
5.45	1	83.3		15.0	1.7
5.75	4	25.5	53.2	19.3	2.0

broken down and only one or two remain. The final migration speed of a_2 coincides even in this case more or less with that of the b-component but varies somewhat depending on the amount and type of these intermediate components left. The degradation of the a_2 subcomponents apparently does not stop but continues as long as there is any material left in the sample.

Component a_1. The a_1 component like the a component is broken down very rapidly at certain pH values. However, within the pH range 4.85—6.4 the ratio of the rate of formation to the rate of degradation is such that it can be observed during relatively long period. At a pH of 5.21 or lower it changes to a form with a slightly higher migration rate as shown in Figs 7 and 8; this has been designated here as a_{11}. At a pH of 4.8 or less a_1 is broken down so rapidly that a appears to be transformed directly into a_{11} and a_2. Like other components a_{11} gradually attains a fairly stable migration rate.

Quantitative measurements. The electrophoresis curves obtained were suitable for quantitative estimates only during the first part of the degradation. The rates of breakdown of a into a and b and the rate of formation of the component c, which is discussed below, can be measured fairly readily. In some cases it was also possible to measure the splitting of a into a_1 and a_2 but the subsequent breakdown of a_2 is rapid and gives components which coincide with b so that the measurements are then much less certain. Table 2 gives estimates of the proportions of the different degradation products.

DISCUSSION

Even though the α-casein and the crystalline rennin used in these experiments were electrophoretically pure they cannot be regarded as homogeneous. Waugh and von Hippel [15] have reported the presence in α-casein of up to 12 % of a component which they named $\varkappa$-casein and Long, Winkle and Gould [16] have isolated from electrophoretically homogeneous α-casein an additional substance, which they named λ-casein, that forms about 3 % of the α-casein. The degradation products observed here cannot therefore be referred immediately to any particular one of the three substances in the mixture formerly regarded as α-casein.

Crystalline, electrophoretically pure rennin has been found by Schwander *et al.*[17] to contain a small amount of a substance which, according to the

results of sedimentation in an ultracentrifuge and of diffusion measurements, is of higher molecular weight. Ernstrom [18] has found, moreover, by electrophoretic examination of crystalline rennin, that the single rennin peak obtained under normal conditions is split into several components at low ionic strengths. It cannot be excluded that one or more of these components may have proteolytic properties different from those of the main component of the rennin.

It is thus apparent that the present investigation, no more than any other hitherto published on the enzymatic degradation of casein, cannot satisfy the requirements set out by Ogston for a defined biochemical process [19]. Nevertheless, while awaiting the development of methods for the preparation of absolutely homogeneous casein fractions and chemically pure rennin, the results obtained give some perspective to the investigations that have been made on the structure and properties of the phosphopeptones and polypeptides obtained from casein. The results of the present investigation show more directly that it is possible to find experimental conditions under which the degradation products have simpler electrophoretic properties than are found under other conditions. It now seems possible on the basis of the present observations to give a fairly simple explanation of some older observations on "paracasein".

Enzymatic processes in a heterogeneous mixture of the type concerned here do not lend themselves to rate determinations nearly as readily as when they occur in a homogeneous phase. In the present case there was strong gel formation and precipitation of α-casein as soon as the pH came below 5.3. However, by adapting the technique used to these conditions it was found possible to obtain more or less reproducible results, as is apparent from Figs. 1 and 2. At pH 5.45 and higher pH values where the α-casein is in solution the curves obtained had approximately the same origin on the time scale as when the pH was less than 5.45 and the casein insoluble. This shows that the rate and the course of the processes occurring were more or less the same in both cases. The delay of 0.6 days that was observed in all these experiments may be due to the presence of an inhibitor of the type mentioned by Dixon [20]. The results of Amundstad's investigations [21], when plotted on a semi-logarithmic scale as in Fig. 1 show a similar delay. In this case the delay varied rather more than in the present investigation but was of approximately the same order. Amundstad worked with total casein and technical rennet and the chances of some poisoning effect occurring are rather different from the present case. An alternative explanation of the delay could be that the NPN is not liberated in the first stages of the degradation but only after certain key links are broken by the rennin.

Some support for this hypothesis is obtained from a comparison of the changes in the electrophoresis curve with the change in the amount of NPN. At a given degree of degradation, for instance 1 % NPN, the electrophoresis curves are different for different pH values (Fig. 7). The primary degradation thus cannot have any direct effect on the formation of NPN. This supposition was supported by the very slow formation of NPN at pH 7 and the simultaneous relatively rapid fission of the α-casein at this pH into a and b components (Figs. 5 and 7). Another criterion supporting this is that the optimum pH

Fig. 7. Electrophoresis curves at NPN 1 %. The absence of any relationship between the NPN content and the appearance of the curve is an indication that these concern two independent processes.

for NPN formation is 4.5, as shown in Fig. 2, but is 5.2—5.5 for the degradation of a_2 as is visible in Figs. 6 and 7.

These phenomena are parallelled by the rapidity with which a glyco-macropeptide is split off during the primary reaction observed by Nitschmann *et al.*[10] in the coagulation of casein with rennet and the slowness of the subsequent, general proteolytic action noted by Nitschmann[9] in the tertiary stage. There is as yet no proof that any of our components is identical with Nitschmann's glyco-macropeptide nor, on the other hand, is there any contradictory evidence.

Nitschmann and Lehmann[2] found that the paracasein which is formed when casein is coagulated with rennet gave two peaks in place of the α-casein peak. They called these rennet α_1- and rennet α_2- caseins and recorded mobilities in phosphate buffer at pH 7.35, μ 0.077, 2°C of

$$\alpha_1 : 9.55 \times 10^{-5} \quad \text{and} \quad \alpha_2 : 8.83 \times 10^{-5}$$

The α-casein had a mobility of 9.30×10^{-5}. This is in good agreement with our observations where the α-casein had a mobility in phosphate buffer at pH 7.3, μ 0.1, 1°C of 9.09×10^{-5}. The mobilities of the a and a_1 components fall within the range $9.2—10.8 \times 10^{-5}$ while a_2 has a mobility between 9.1 and 7.0 depending on the extent of the degradation of the casein.

It seems quite possible that Nitschmann's rennet α_1-and rennet α_2-caseins are identical with the a or a_1 components and with a_2 respectively, with Nitschmann's material representing forms of an intermediate degree of degradation.

More difficult to explain is the observation of Cherbuliez[22] that casein that has not been treated with rennet also gives two α peaks which he called

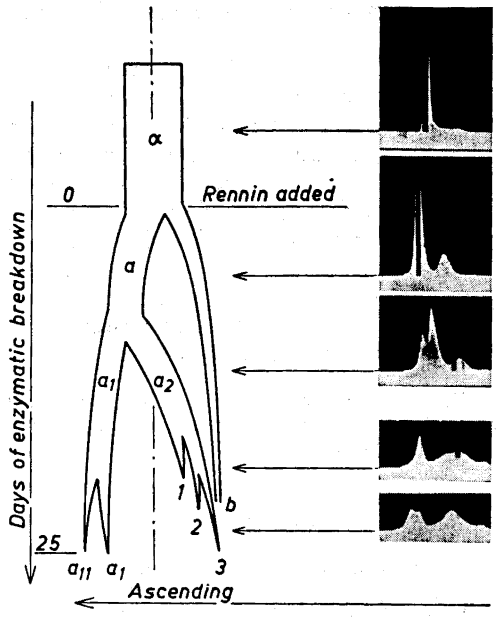

Fig. 8. The curves in Fig. 7 slightly idealized to cover the pH range 5.0—5.5 and to illustrate the major changes taking place during the α-casein decomposition.

α_I and α_{II}. However, he used a rather time-consuming method to obtain ash-free and fat-free preparations and it is quite possible that proteolytic enzymes originally present in the milk, which would accompany the α-casein in the preparation, may easily have given rise to a degradation similar to that produced by the rennet. The components later found by Cherbuliez [23] in para α-casein may very well have been rather degraded products formed according to the scheme described here for the further degradation of a_1 and a_2. In this case it would not be possible to compare the mobilities since the experimental conditions would be quite different.

Fig. 6 summarises all the electrophoresis results obtained as branched curves showing how the mobilities of the different degradation products are related to the mobilities of the parent substance, which is marked with a dashed line. As is shown in the figure the rates of the secondary, tertiary and further degradation reactions, that is the branching points of the curves, are very strongly dependent on the pH. A diagram showing the full course of the degradation for the pH range 5.0—5.5 is given in Fig. 8. The course of the degradation at pH values outside this range can be seen from a comparison of Figs. 7 and 8. The most striking point about these diagrams is that components such as a_{11} and a_1 and b are either extremely stable to rennin or else their migration rates do not change at all on further degradation while a_2 on the other hand is rapidly broken down forming substances of lower mobility.

This must of course be dependent on the amino-acid composition of the fission products.

Since the a and b produced in the first step of the degradation of the α-casein have a higher and a lower mobility, respectively, than the parent substance it is probable that a contains relatively more serine-threonine bound phosphoric acid and more glutamic acid and aspartic acid than the α-casein, while b must contain more basic amino acids than the α-casein or a. The large changes in the mobility of a_2 during the degradation must be ascribed to the presence of relatively greater amounts of easily removed acidic amino-acids and of difficultly removable basic amino-acids. The distribution of the amino-acids in a_1 and a_{11} on the other hand must be such that the neutral amino-acids predominate or that any acidic and basic amino-acids present neutralise each other and, moreover, are not too readily accessible to proteolysis.

Acknowledgement. The authors wish to express their gratitude to the Scientific Council of Swedish Dairies' Association wich made the investigation possible by placing the ultracentrifuge at their disposal.

Further Investigations on Displacement Potentials

F. CARLSEN, W. DANSGAARD and C. E. JENSEN †

Universitetets biofysiske laboratorium, and Universitetets fysisk-kemiske institut, Copenhagen, Denmark

By the aid of a vibrating reed electrometer it is shown that displacement potentials of the order of 100—150 mV can be generated when very high molecular hyaluronate is used. The phenomenon exhibits effects of fatigue and hysteresis.

It was shown by Jensen, Koefoed and Vilstrup [1] that if a solution of high molecular hyaluronate is displaced in a glass capillary an electric potential is generated which is characterized by the fact that the potential difference persists as long as the solution is strained. The same phenomenon was observed with regard to genuine endolymph from the piked dogfish *(Acanthias vulgaris)*, and Vilstrup, Jensen and Koefoed [2] suggested that these potentials might be of the greatest importance for the function of the labyrinth. Very recently also Dohlman [3] has accepted the conclusion that the transformation of mechanical movements to electrical charges is what we have reason to believe to be the fundamental potential, influencing the generation of excitatory reactions in the nerve endings at the crista. The presence of acid mucopolysaccharides in the gelatinous substance in the internal ear (Jensen and Vilstrup [4], Dohlman, Ormerod and Mc Lay [5], and Poulsen [6]) suggests reversible electrical changes due to displacement potentials which might be collected by the hairs, acting as electro-sounds for the hair cells of the sound-perceiving organs of the inner ear (suggested in an oral discussion, 1955, by J. A. Christiansen).

In the first published experiments the electrical effect seemed to be relatively small, varying from fractions of mV to a few mV, but recently it was found (Jensen, Christiansen and Vilstrup [7]) that the potentials resulting from displacements of very high molecular polyelectrolytes in a glass capillary and measured potentiometrically amounted to about 100 mV.

In the present work this observation has been confirmed by using a vibration reed electrometer, and further it is shown that the relation between displacement and potential can be described by hysteresis loops, and that the phenomenon exhibits an effect of fatigue.

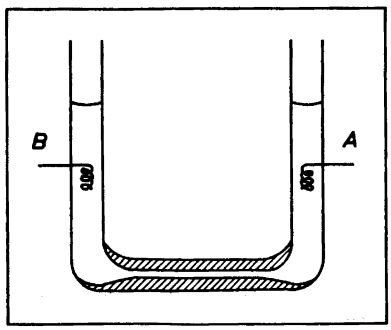

Fig. 1. U-Tube in which palladium electrodes are inserted.

MATERIALS

The sample of alginate used was a commercial preparation ("Protanal HF", manufactured and kindly supplied to us by A/S Protan, Drammen, Norway). The number average molecular weight was determined to be about 1×10^5 after the osmotic method of Christiansen and Jensen [8]. By fractional precipitation with alcohol we obtained a sample with a molecular weight of about 2×10^5.

The sample of potassium hyaluronate employed was prepared from human umbilical cords according to Jensen [9]. The molecular weight of hyaluronate obtained by this method is about 5×10^5 (determined at a concentration of 1 %). By adding alcohol to an 0.1 % aqueous solution of this precipitation until the solution was about 35 % in respect of alcohol we obtained a preparation which had a molecular weight greater than 1.5×10^6 as judged from osmotic measurements. In all experiments care was taken to avoid bacterial contamination. All measurements of the potentials were performed at room temperature.

EXPERIMENTS AND RESULTS

The employed glass apparatus with palladium electrodes is shown in Fig. 1. The deflection of a highly sensitive galvanometer (aperiodically damped; resistance 455 ohms) connected to the electrodes indicated their potential difference.

With distilled water in the apparatus no significant potentials were observed. However, when a 0.05 % solution of alginate was introduced into the apparatus through the branch called A in Fig. 1 the electrode in branch B became positive. The magnitude of the potential difference (called V_0 below) depended upon the concentration of the solute, the method of filling and the dimensions of the apparatus.

Taking V_0 as a zero point, displacement of the solution towards A rendered this branch negative relative to B as long as the solution was moving, but positive when the solution came at rest. By displacing the solution towards B the temporary as well as the final potential differences changed their signs. Repeating of this procedure decreased the potential differences (effect of fatigue, shown in Fig. 2). After some days, however, the effect regenerated.

The potentials appeared to be a function not only of the actual displacement. They were also influenced by the magnitude and direction of former

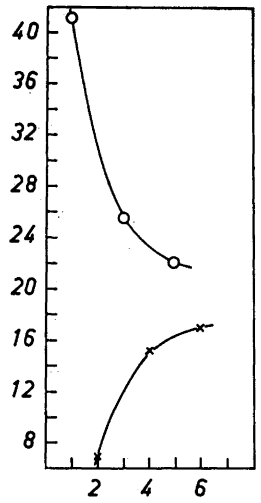

Fig. 2. Curves showing the phenomenon of fatigue. Ordinates: Arbitrary galvanometer readings. Abscissae: Sequence of displacements. Circles represent the potentials following displacements to the right, crosses to the left.

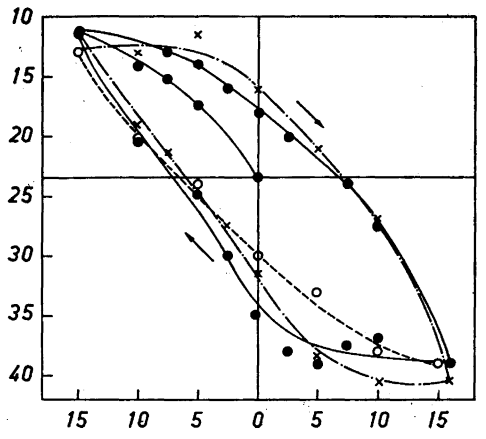

Fig. 3. Hysteresis loops. Ordinates: Arbitrary galvanometer readings. Abscissae: Displacements in mm to the right and to the left.

displacements (hysteresis, shown in Fig. 3). Increased potentials were observed upon insertion of thin glass rods in the capillary tube.

By recent application of a vibrating reed electrometer the electric current through the apparatus became negligible. Under these circumstances values of V_0 up to 140 mV were registered after filling the apparatus with a 0.25 % solution of hyaluronate. Furthermore potentials of the order of 10 mV occurred as a result of displacements of the order of 1 cm. V_0 was not quite constant in time, but generally the drift was less than 20 % during several days.

DISCUSSION

The experiments reported here show that under laboratory conditions the displacement potential may exceed 100 mV, and although such high voltages may not be present in the sensulae of the inner ear, an even much smaller voltage may be considered sufficient for adequate stimulation of the hair cells, *i. e.* for the modulation of the spontaneous cell action.

As shown above the displacement potential displays the phenomenon of fatigue; in this connection it may be mentioned that the phenomenon of fatigue is also well-known in the labyrinth.

We wish to thank Professor J. A. Christiansen, Head of the Physico-chemical Institute of the University of Copenhagen, for many valuable discussions and suggestions. One of us (C. E. J.) gratefully acknowledge financial support from *Philips Fond of 1958.*

Studies on the Chemistry of Lichens

XIII.* The Structure of Pannaric Acid

B. ÅKERMARK, H. ERDTMAN and C. A. WACHTMEISTER

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Pannaric acid, $C_{16}H_{12}O_7$, a phenolic acid from *Crocynea membranacea* (Dicks.) Zahlbr., has been shown to contain two carboxyl groups, two phenolic hydroxyl groups and two C-methyl groups. On decarboxylation, it forms a phenol $C_{14}H_{12}O_3$, identified as 3,9-dihydroxy-1,7-dimethyldibenzofuran, which was synthesised. From biogenetic considerations, the most probable structure would be (V). This structure has been confirmed by permanganate oxidation of di-O-methylpannaric acid to 1,2,6,7-tetracarboxy-3,9-dimethoxydibenzofuran, previously obtained from porphyrilic acid (I). Structure (V) is also in harmony with colour reactions and the infra-red absorption spectra of pannaric acid and its derivatives.

One of the main aims of these investigations has been the isolation of compounds illustrating the role of oxidative coupling of phenols in biosynthesis. The importance of this reaction in lichen chemistry, in the lignan field and also to an understanding of the biosynthesis of thyroxin [1] was discussed by one of us in a lecture to the Chemical Society, Stockholm, in December 1933 shortly after the structural elucidation of the depsidone salazinic acid by Asahina [2]. The depsidones were considered to be coupling products of phenol oxygen radicals and mesomeric carbon radicals.

Examples of the pairing of carbon radicals were expected and have since been found: usnic acid [3], the "depsone" picrolichenic acid [4,5] and the dibenzofurans strepsilin [6], didymic acid [7] and porphyrilic acid [8,9]. Usnic acid and picrolichenic acid are particularly interesting because one of the nuclei has not returned to the aromatic state.

The biosynthetic aspects of phenol dehydrogenation in general have been recently discussed by Barton and Cohen [10] and by Erdtman and Wachtmeister [11] and with particular reference to lichen chemistry by Wachtmeister [12].

* Part XI *Acta Chem. Scand.* **12** (1958) 147.
Part XII *Svensk Kem. Tidskr.* **70** (1958) 117.

In this search for new oxidative coupling products attention has been focussed on lichen acids which cannot be cleaved hydrolytically into two or more components; these can easily be found by paper chromatography [13].

Hesse's pannaric acid * from *Crocynea membranacea* (Dicks.) Zahlbr. (= *Pannaria lanuginosa* Ach.) has such properties. According to Hesse [14], pannaric acid has the composition $C_9H_8O_4$ but the high melting point (Hesse reports 224°) indicates a higher molecular weight.

Exhaustive extraction of the lichen with ether afforded a crude crystalline product from which roccellic acid could be removed by extraction with hot petroleum ether. The residual crude pannaric acid (about 1.5 % of the dry lichen) was conveniently recrystallised from diacetone alcohol and further purified by filtration through alumina. The purity of the acid was checked chromatographically on phosphate-impregnated paper [13].

Pannaric acid exhibits a bluish-white fluorescence in ultra-violet light. It is readily soluble in the lower alcohols and in acetone containing about 2 % of water but only sparingly soluble in dry acetone, ether, benzene and chloroform. It dissolves with effervescence in aqueous sodium hydrogen carbonate to give a colourless solution. Like porphyrilic acid [9], pannaric acid gives a blue colour with iron(III) chloride and a blue colour with Gibb's reagent [15]; with bleaching powder it gives the green colour characteristic of all known lichen acids belonging to the dibenzofuran group.

Pannaric acid crystallises from aqueous acetone as colourless needles containing solvent of crystallisation. It melts with decomposition at 243—245° and after drying *in vacuo* gave analytical results in agreement with the composition $C_{16}H_{12}O_7$. Pannaric acid possesses two strongly acidic groups and carbon dioxide is evolved on thermal decomposition. Kuhn-Roth determination indicated the presence of two C-methyl groups.

Methylation of pannaric acid with a large excess of diazomethane in the presence of some methanol yielded dimethyl di-O-methylpannarate, $C_{12}H_2O(CH_3)_2(OCH_3)_2(COOCH_3)_2$ which on hydrolysis gave di-O-methyl pannaric acid, $C_{12}H_2O(CH_3)_2(OCH_3)_2(COOH)_2$. Treatment of pannaric acid at −10° with a slight excess of diazomethane for 1—2 min afforded dimethyl pannarate, $C_{12}H_2O(CH_3)_2(OH)_2(COOCH_3)_2$, which was readily acetylated to a diacetate.

Pannaric acid itself yielded a diacetate $C_{12}H_2O(CH_3)_2(OCOCH_3)_2(COOH)_2$ which decomposed above 240° without melting.

On prolonged boiling with formic acid, pannaric acid was decarboxylated with the formation of pannarol, $C_{12}H_4O(CH_3)_2(OH)_2$, m.p. 183—184°, which gave a diacetate and a dimethyl ether. As described by Hesse, pannarol was also formed on thermal decomposition of the dry acid.

The ultra-violet absorption curves of pannarol and of its diacetate were very similar to those of 3,7-dihydroxy-1,9-dimethyldibenzofuran [7] (II) and its diacetate, respectively, but pannarol was not identical with compound II.

---

* The name pannaric acid, unfortunately, has also been given to an oxidation product obtained from pannarin, a chlorine-containing depsidone isolated from the Japanese *Pannaria lanuginosa* and some other *Pannaria* species by Yosioka. Compare Asahina, Y. and Shibata, S. *Chemistry of Lichen Substances*, Tokyo 1954.

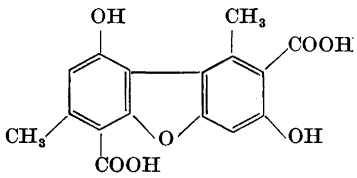
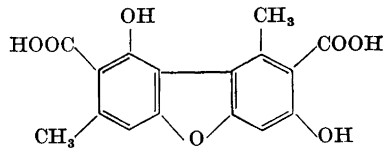
IV



V



VI

For biogenetic reasons, pannarol was considered to be either 3,9-dihydroxy-1,7-dimethyldibenzofuran (III) or 1,9-dihydroxy-3,7-dimethyldibenzofuran (IV). These phenols were therefore synthesised.

Dibenzofurans of these types are readily available by Ullmann coupling of the appropriate iodides and cyclisation of the tetramethoxydiphenyl obtained. Although 2-iodo-3,5-dimethoxytoluene [5] is formed in high yield by direct iodination of orcinol dimethyl ether, the 4-iodo-analogue has so far only been prepared from 4-nitroorcinol which is obtained in very low yield on nitration of orcinol. It is known, however, that resorcinol dimethyl ether reacts with phenyl lithium forming mainly the 2-lithium derivative [17]. Orcinol dimethyl ether when metalated in the same way and treated with iodine gave 4-iodo-3,5-dimethoxytoluene in an overall yield of 50 %.

Ullmann coupling of 4-iodo-3,5-dimethoxytoluene afforded 2,6,2′,6′-tetramethoxy-4,4′-dimethyldiphenyl [16]. On boiling with hydrobromic acid this compound was demethylated and dehydrated, giving 1,9-dihydroxy-3,7-dimethyldibenzofuran (IV), m.p. 190—192°, which was different from pannarol. Like its lower homologue, 1,9-dihydroxydibenzofuran, it showed abnormally high R_F-values (*cf.* Ref.[12]).

A mixed Ullmann coupling with 4-iodo-3,5-dimethoxytoluene and an excess of 2-iodo-3,5-dimethoxytoluene furnished a mixture of diphenyls. On prolonged boiling with hydrobromic acid the crude product gave a mixture of phenols, the main component of which proved paper-chromatographically identical with 3,7-dihydroxy-1,9-dimethyldibenzofuran (II). Paper chroma-

tography also revealed a minor component of the same high R_F-value as 1,9-dihydroxy-3,7-dimethyldibenzofuran (IV). On treatment of the chromatogram with Gibbs' reagent a third component appeared as a blue spot as would be expected for 3,9-dihydroxy-1,7-dimethyldibenzofuran (III). This spot behaved in all respects like that of pannarol.

The main part of the 3,7-dihydroxy-1,9-dimethyldibenzofuran was separated from the crude phenol mixture by crystallisation from benzene. The mother liquor was evaporated and the residue was chromatographed on a column of cellulose powder impregnated with dimethyl sulphoxide, using diethyl ether as the mobile phase. The fractions eluted were analysed by paper chromatography using the same solvent system [18]. 3,9-Dihydroxy-1,7-dimethyldibenzofuran, m.p. 184—185°, was shown to be identical with pannarol by mixed melting point determination as well as by comparison of the infra-red absorption curves. Methylation gave 3,9-dimethoxy-1,7-dimethyldibenzofuran, similarly identified as pannarol dimethyl ether.

From these results, pannaric acid may be formulated as (V) or (VI), the only structures which are consistent with biosynthesis from orsellinic acid. A strong indication in favour of structure (V) was given by the negative reaction of dimethyl pannarate with Gibb's reagent [15]. Moreover, the infra-red absorption curve of dimethyl pannarate in potassium bromide showed two separate carbonyl bands at 1 660 cm^{-1} and 1 690 cm^{-1}, respectively, indicating intramolecular as well as intermolecular hydrogen bonding. The absorption curve of dimethyl di-O-methyl pannarate, as expected, showed a single carbonyl band at 1 725 cm^{-1}.

A confirmation of structure (V) was obtained by permanganate oxidation of di-O-methylpannaric acid to a tetracarboxylic acid which on heating gave a yellow di-anhydride and on methylation gave a tetramethyl ester $(CH_3O)_2C_{12}H_2O(COOCH_3)_4$, m.p. 225—226°, undepressed on admixture with 3,9-dimethoxy-1,2,6,7-tetracarbomethoxydibenzofuran [9] previously obtained from porphyrilic acid (I). The identity was confirmed by comparison of the infra-red spectra.

Porphyrilic acid (I) from *Haematomma coccineum* and pannaric acid (V) from *Crocynea membranacea* contain the same carbon skeleton and are both major phenolic compounds of the respective lichens. It is noteworthy that no lichen acid containing the carbon skeleton (VI) has so far been found. This gives some support to the proposed mechanism for oxidative coupling of orsellinic acid homologues, involving intermediate radicals, stabilised by chelation, that are formed by participation of the most acidic phenolic hydroxyl group, that *para* to the carboxyl group [12].

Fertile specimens of *Crocynea membranacea* have never been found and the classification appears somewhat questionable. Other *Crocynea* species are well defined. From a chemical point of view a relationship with the genus *Haematomma* would appear probable.

EXPERIMENTAL

All melting points were determined on a Kofler micro hot stage. Whatman No. 1 paper was used for paper chromatography. Ultra-violet absorption spectra were measured with a Beckman spectrophotometer, model DU. The infra-red spectra were recorded with

a Perkin-Elmer double beam spectrophotometer, model 21 (sodium chloride prism; potassium bromide discs).

Isolation of pannaric acid. *Crocynea membranacea* (3.14 kg) was extracted with ether for 5 days in a Soxhlet apparatus. The ether extract (10 l) deposited a crystallisate (10 g, m. p. 172—181°) which was not further investigated *. The mother liquor was evaporated to dryness and the crystalline residue was extracted repeatedly with boiling petroleum ether (b. p. 100—120°). The material extracted was crystallised from ethanol giving roccellic acid (90 g), m. p. 130.5—132.0°, $[\alpha]_D^{20}$ +18.0 (EtOH, *c* 1.94). Lit. m. p. 131°, $[\alpha]_D$ +17.4 (EtOH) [19].

The insoluble fraction (45 g, m. p. 228—234°) on crystallisation from diacetone alcohol afforded crude pannaric acid as yellowish needles (25 g, m. p. 230—235°) of sufficient purity for most of the degradative work. A solution of the crude acid (1.2 g) in acetone (20 ml), water (0.5 ml) and ether (200 ml) was filtered through a 3 cm column of alkali-free alumina (5 g) and followed by 200 ml ether-acetone (10:1). The combined filtrates on evaporation afforded pannaric acid (700 mg), which crystallised as colourless needles (300 mg) from aqueous acetone. The purity of the acid was checked by chromatography on phosphate-impregnated paper [9,13] using a *n*-butanol-water solvent system. The acid showed the R_F-values 0.05 (0.1 M Na_3PO_4); 0.10 (0.1 M Na_2HPO_4 + 0.1 M NaH_2PO_4 1:1) and 0.65 (0.1 M NaH_2PO_4). The spots were visible in ultraviolet light (bluish-white fluorescence under alkaline conditions) and gave a blue colour with Gibbs' reagent and a dark red-brown colour with *bis*-diazotised benzidine [20] under alkaline conditions.

Pannaric acid was dried for analysis *in vacuo* for 1 h at 120°; loss of weight: 9.6 %; $C_{16}H_{12}O_7$, $2H_2O$ requires 10.2 %; m. p. 243—245°. The equivalent weight was determined by potentiometric titration in 50 % methanol. (Found: C 60.6; H 4.2; equiv. wt. 160. $C_{16}H_{12}O_7$ requires C 60.8; H 3.8; equiv. wt. required for a dicarboxylic acid, 158.)

Di-O-acetylpannaric acid. Pannaric acid (75 mg) was boiled for 5 min with acetic anhydride (1 ml) containing pyridine (0.05 ml). The solution was evaporated *in vacuo* and the residue crystallised from aqueous methanol to give the diacetate, colourless needles decomposing from 240°. (Found: C 59.6; H 4.0; CH_3CO 20.5. $C_{20}H_{16}O_9$ requires C 60.0; H 4.0; $(CH_3CO)_2$ 21.5.)

Dimethyl pannarate. A solution of pannaric acid (160 mg) in acetone containing 2 % of water (20 ml) was cooled to −10° and a slight excess of ethereal diazomethane added. After 2 min, the reaction was interrupted by the addition of acetic acid. The dimethyl ester crystallised from methanol as needles m. p. 254—255°, sparingly soluble in most solvents. (Found: C 62.7; H 4.6; OCH_3 18.0. $C_{18}H_{16}O_7$ requires C 62.8; H 4.65; $(OCH_3)_2$ 18.0.) The infra-red absorption curve showed carbonyl bands at 1 690 and 1 660 cm^{-1}.

The ester gave a light brown colour with *bis*-diazotised benzidine when tested on alkaline paper (Na_3PO_4) but no colour with Gibbs' reagent. A saturated solution of the ester in 96 % ethanol did not give any colour with ferric chloride. R_F-values (*n*-butanol-water): 0.78 (Na_3PO_4); 0.84 (Na_3PO_4 + Na_2HPO_4 1:1).

Dimethyl di-O-acetylpannarate. Dimethyl pannarate was warmed for a few minutes with acetic anhydride containing pyridine. The dimethyl di-O-acetylpannarate was crystallised from ethanol as needles, m. p. 162—164°. (Found: C 61.7; H 4.7; OCH_3 14.5; CH_3CO 21.1. $C_{22}H_{20}O_9$ requires C 61.7; H 4.7; $(OCH_3)_2$ 14.5; $(CH_3CO)_2$ 20.1.)

Dimethyl di-O-methylpannarate. Pannaric acid suspended in acetone containing methanol was treated for two days with an excess of ethereal diazomethane; the acid gradually dissolved. The reaction product crystallised from methanol to give dimethyl di-O-methylpannarate, needles, m. p. 166—168°. (Found: C 64.2; H 5.8; OCH_3 32.6; C—CH_3 (Kuhn-Roth) 7.55. $C_{20}H_{20}O_7$ requires C 64.5; H 5.4; $(OCH_3)_4$ 33.3; $(C-CH_3)_2$ 8.06.) The infra-red absorption curve showed carbonyl band at 1 725 cm^{-1}.

Di-O-methylpannaric acid. Dimethyl di-O-methylpannarate (2.25 g) was heated for 1 h on a boiling water bath with ethanol (25 ml) and 2 N aqueous sodium hydroxide (25 ml). Acidification with hydrochloric acid afforded a precipitate which was collected (1.9 g) and crystallised from ethanol to give di-O-methylpannaric acid, m. p. 240—246°

* It is not certain that these products are constituents of *Crocynea* since the material collected is always contaminated with small amounts of other lichens. It is, however, easy to prove by paper chromatography that the pure *Crocynea* contains pannaric acid.

(decomp.). R_F-values (*n*-butanol-water): 0.05 (Na_3PO_4); 0.10 (NaH_2PO_4, Na_2HPO_4 1:1); 0.75 (NaH_2PO_4). The spots were detected by their bluish-white fluorescence in ultraviolet light. (Found: C 62.3; H 4.8; OCH_3 16.8. $C_{18}H_{16}O_7$ requires C 62.8; H 4.65; $(OCH_3)_2$ 18.0.)

Pannarol (III). *a*) Pannaric acid (400 mg) was boiled for 12 h under reflux in an atmosphere of carbon dioxide with 88 % formic acid (10 ml). The dark solution was evaporated to dryness under reduced pressure and the residue dissolved in ether. The ether solution was extracted with aqueous sodium bicarbonate, dried and filtered through a small column of alkalifree alumina. Evaporation of the filtrate afforded pannarol (230 mg) which crystallised from aqueous ethanol as needles, m. p. 184—185°, undepressed on admixture with 3,9-dihydroxy-1,7-dimethyldibenzofuran, m. p. 184—185°, described below. The identity was confirmed by comparison of the infra-red absorption curves. (Found: C 74.0; H 5.6. $C_{14}H_{12}O_3$ requires C 73.7; H 5.3.) U.V. absorption (in 96 % ethanol): λ_{max} 233 mμ (log ε 4.74); 267 mμ (4.46); 287 mμ (4.40); 300 mμ (4.21); 312 mμ (4.39).

b) Pannaric acid (50 mg) placed in a small test tube was heated cautiously over a free flame under reduced pressure. It decomposed and sublimed. Loss of weight, 28.5 %. $C_{16}H_{12}O_7$ — 2 CO_2 requires a loss of weight of 27.8 %. The sublimate was identical with the pannarol obtained in the previous experiment.

Pannarol gave a red-brown colour with *bis*-diazotised benzidine, a blue colour with Gibbs' reagent, a red colour with bleaching powder but no colour with ferric chloride in ethanol. Paper chromatography (benzene-water): R_F 0.33. The spot was fairly elongated. A more convenient solvent system is described below (see 3,9-dihydroxy-1,7-dimethyldibenzofuran).

Di-O-methylpannarol. Pannarol (90 mg) in dry acetone (10 ml) was boiled under reflux with potassium carbonate (1.10 g) and dimethyl sulphate (0.38 g). After 6 h, excess dimethyl sulphate was destroyed by the addition of water and heating for 1 h. The solution was filtered and evaporated to dryness, the residue was dissolved in benzene and the solution was filtered through a small column of alumina. The filtrate was evaporated and the residue crystallised from aqueous methanol and finally distilled under reduced pressure to give di-O-methylpannarol, m. p. 94.5—95.5°, undepressed on admixture with the 3,9-dimethoxy-1,7-dimethyldibenzofuran, m. p. 94—95°, described below. The identity of the two compounds was confirmed by comparison of the I.R. absorption curves. (Found: C 74.7; H 6.0; OCH_3 24.2. $C_{16}H_{16}O_3$ requires C 75.0; H 6.3; $(OCH_3)_2$ 24.0.)

Di-O-acetylpannarol. Pannarol was acetylated at room temperature with acetic anhydride containing pyridine to give di-O-acetylpannarol which was crystallised from methanol, needles, m. p. 136.5—137.5°. (Found: C 68.6; H 5.1; CH_3CO 27.3. $C_{18}H_{16}O_5$ requires C 69.2; H 5.1; $(CH_3CO)_2$ 26.9). U.V. absorption (in 96 % ethanol) λ_{max} 226 mμ (log ε 4.38), 258 mμ (4.15), 285 mμ (4.28).

Permanganate oxidation of di-O-methylpannaric acid. Pannaric acid dimethyl ether (400 mg) in water (60 ml) containing potassium carbonate (700 mg) was heated on a boiling water bath and a solution of potassium permanganate (4 g) in water (100 ml) was added dropwise with stirring over 3 h. After heating for another 12 h, the excess permanganate was destroyed and the manganese sludge was filtered off and washed with water. The combined filtrates were concentrated to a volume of 40 ml and acidified with concentrated hydrochloric acid (2 ml). On standing in the refrigerator, the solution deposited a crystalline acid (A) which was collected, washed and dried at room temperature. Yield, 250 mg. It showed no definite melting point but readily formed a yellow anhydride. (Found: Equiv. wt. 94. $C_{18}H_{12}O_{11}$ requires equiv. wt. as a tetracarboxylic acid, 102.)

Dianhydride of the acid A. The acid (A) (80 mg) was dried *in vacuo* at 150° (loss of weight, 9.5 %. $C_{18}H_{12}O_{11}$ requires a loss of weight of 9.6 %) and the anhydride was purified by sublimation. M. p. 320—325°. (Found: C 58.5; H 2.1; OCH_3 16.1. $C_{18}H_8O_9$ requires C 58.7; H 2.2; $(OCH_3)_2$ 16.8.) The I.R. absorption curve showed carbonyl bands at 1 850 and 1 785 cm^{-1}.

Tetramethyl ester of the acid A. The acid (A) (80 mg) in methanol suspension was methylated with an excess of ethereal diazomethane. The ester crystallised from acetone as prisms, m. p. 225—226°, undepressed on admixture with 3,9-dimethoxy-1,2,6,7-tetracarbomethoxydibenzofuran [9], m. p. 225—226.5°. (Found: C 57.0; H 4.3; OCH_3 38.0.

$C_{22}H_{20}O_{11}$ requires C 57.4; H 4.3; $(OCH_3)_6$ 40.4.) The identity was confirmed by comparison of the I.R. absorption curves.

3,5-Dimethoxy-4-iodotoluene. Phenyllithium (20 mmole) in ether (10 ml) was added to a solution of orcinol dimethyl ether (10 mmole) in ether (10 ml) in an atmosphere of oxygen-free nitrogen. The orcinol-lithium compound started to crystallise after 24 h at room temperature. After another 5 days at 0° no further crystallisation was observed. The ethereal solution was decanted and the crystals were dissolved in dry tetrahydrofuran (10 ml). Iodine (8 mmole) was added and the solution was refluxed for 15 min. Excess iodine was destroyed with aqueous sodium thiosulphate and the solution was extracted with ether. Evaporation of the ether extract afforded a crystalline product which was crystallised from ethanol to give 3,5-dimethoxy-4-iodotoluene (1.4 g, 5 mmole), m. p. 96—97°, undepressed on admixture with an authentic specimen synthesised according to Posternak *et al.*[16]

1,9-Dihydroxy-3,7-dimethyldibenzofuran. 2,6,2′,6′-tetramethoxy-4,4′-dimethyldiphenyl was synthesised by Ullmann coupling of 3,5-dimethoxy-4-iodotoluene as described by Posternak *et al.*[16] The crude diphenyl (300 mg, m. p. 139—145°) was boiled with hydrobromic acid (10 ml; d, 1.54) for 6 h in an atmosphere of carbon dioxide. The reaction product was collected, washed with water, dried and dissolved in benzene. The solution was filtered through a short column of alumina, evaporated and the product was crystallised from dimethyl sulphoxide-water (1:4) giving 1,9-dihydroxy-3,7-dimethyldibenzofuran (100 mg), m. p. 190—192°. (Found: C 73.9; H 5.4. $C_{14}H_{12}O_3$ requires C 73.7 H 5.3.)

This phenol gave a blue colour with ferric chloride in ethanol and a blue colour with Gibbs' reagent.

3,9-Dihydroxy-1,7-dimethyldibenzofuran. Ullmann coupling of 3,5-dimethoxy-2-iodotoluene (7.5 g) and 3,5-dimethoxy-4-iodotoluene (0.8 g) with copper powder (25 g) followed by extraction of the reaction product with light petroleum afforded a crude mixture of diphenyls (3.2 g, 71 %) which was boiled for 16 h with hydrobromic acid (50 ml; *d*, 1.54) to effect demethylation and ring closure. The crude phenol mixture (2.2 g) was analysed by paper chromatography, using dimethyl sulphoxide as stationary phase [18] and either (A) diethyl ether or (B) toluene-petroleum ether b. p. 60—80° 3:1 as mobile phase. It was extracted with benzene overnight in a Soxhlet apparatus; the larger part of the main component (1.8 g), 3.7-dihydroxy-1,9-dimethyldibenzofuran, (R_F = (A) 0.68; (B) 0.18) crystallised in a fairly pure state (m. p. 239—242°; Shibata [7] gives m. p. 243°).

The mother liquor was evaporated to dryness and chromatographed on a column of cellulose powder (15 g) impregnated with 4 % dimethyl sulphoxide in ether, using 1 % dimethyl sulphoxide in ether as an eluant. The separation was followed by paper chromatography. The first fractions contained a small amount of 1,9-dihydroxy-3,7-dimethyldibenzofuran, described above (R_F = (A) 0.92; (B) 0.75.) The last fractions gave further amounts (150 mg) of 3,7-dihydroxy-1,9-dimethyldibenzofuran. The middle fractions gave 3,9-dihydroxy-1,7-dimethyldibenzofuran (250 mg) (R_F = (A) 0.79; (B) 0.21), characterised by a blue colour with Gibbs' reagent. It was crystallised from aqueous ethanol, needles, m. p. 184—185°. (Found: C 73.7; H 5.4. $C_{14}H_{12}O_3$ requires C 73.7; H 5.3.) U.V. absorption (96 % ethanol): λ_{max} 233 mμ (log ε 4.74); 267 mμ (4.46); 287 mμ (4.40); 300 mμ (4.21); 312 mμ (4.39).

3,9-Dimethoxy-1,7-dimethyldibenzofuran The phenol was methylated in boiling acetone with dimethyl sulphate and potassium carbonate giving the dimethyl ether, needles, m. p. 94.5—95.5°, from aqueous methanol. (Found: C 75.5; H 6.2. $C_{16}H_{16}O_3$ requires C 75.0; H 6.3.)

Quantitative Paper Chromatography of Carotenoids

ARNE JENSEN and SYNNØVE LIAAEN JENSEN

Norwegian Institute of Seaweed Research, and Organic Chemistry Laboratories, Norges Tekniske Høgskole, Trondheim, Norway

A highly selective, rapid and simple method for the quantitative, circular chromatography of carotenoids on a commercially available paper with a kieselguhr filler is described. The R_F-values for a series of carotenoids are listed in Tables 1 and 3. The applications of the method are discussed.

The indisputable success of paper chromatography for the separation of complex mixtures of closely related compounds would lead one to expect that this method has been well developed also in carotenoid chemistry. One of the reasons for this not being the case may be the efficiency of column chromatography in the carotenoid field. The few published records of paper chromatography are concerned mainly with the separation of carotenoids from chlorophylls [1-3]. No simple and satisfactory system for separation of carotenoid mixtures on paper seems to have been developed.

Since kieselguhr columns have been used successfully in column chromatography of carotenoids [4], it was expected that paper with a kieselguhr filler might prove useful. The present work led to the development of a highly selective, rapid and simple method for the separation of carotenoid mixtures.

MATERIALS AND METHODS

Schleicher and Schüll filter paper No. 287 (Kieselguhrfilter, kieselguhr content about 20 %) was used throughout this work. The solvents were of analytical grade and used without further purification. The β-carotene, lutein and zeaxanthin were synthetic products obtained commercially. A sample of synthetic cryptoxanthin was kindly supplied by Hoffmann-La Roche & Co., a crystalline sample of chloroxanthin from a green mutant of *Rhodopseudomonas spheroides* by Dr. T. O. M. Nakayama and a crystalline specimen of rhodoxanthin from *Narthecium ossifragum* (L.) Huds, by Dr. A. Stabursvik. Crystalline samples of astaxanthin from lobster shells, lycopene from tomatoes, fucoxanthin from brown seaweeds and violaxanthin from *Viola tricolor* were provided by the Organic Chemistry Laboratories of this University. Crystalline bacterioruberine *a* was isolated from a *Halobacterium* sp. (Strain 1c, from the Department of Biochemistry, this University), whilst spirilloxanthin, P481, OH-P481 and rhodopin were isolated in the crystalline state from *Rhodospirillum rubrum* (Strain S1) and *Rhodopseudomonas palustris* (from dried cells kindly supplied by Dr. C. B. van Niel, Hopkins Marine Station, Pacific Grove, Calif.);

* acetone in pet. eth. b.p. 60—70°C.

γ-carotene was isolated from *Chlorobium thiosulfatophilum* (Strain L1, obtained from Dr. J. Lascelles, Department of Microbiology, University of Oxford).

The chromatographic separations were carried out on circular papers at room temperature in a Petri dish or a desiccator using the technique of Rutter [5]. The solvent system consisted of petroleum ether (b.p. 60—70°C) alone or mixed with various amounts of acetone. For the separation of chloroplast pigments of brown algae petroleum ether with 0.5—2 % *iso*propanol was found favourable. The carotenoid mixtures were dissolved either in acetone or in acetone-petroleum ether mixtures. An aliquot containing 10—100 μg of carotenoids was applied in portions to the centre of the paper by means of a capillary such that the diameter of the spot did not exceed 1 cm. After the application of each portion the solvent was evaporated at room temperature in a stream of pure nitrogen. When the whole aliquot had been put on, a small amount of acetone was applied to the paper on the wick just outside the edge of the spot. This caused the carotenoids to form a narrow ring shaped band surrounding the centre of the paper and was found to result in more regular zones. The separation took 15 min with a 12.5 cm and 20 min with an 18 cm diameter paper. For determination of R_F-values the papers were dried in a stream of warm air, the zones marked with a pencil and the position of the solvent front was determined in UV light (bluish fluorescence). Otherwise the chromatograms were not dried before elution of the pigments in order to avoid oxidation of the carotenoids. The coloured zones containing the carotenoids were cut out immediately after separation, tightly packed in small glass tubes with one end drawn out to a capillary and eluted with acetone, whereafter the extracts were made up to a known volume with acetone and the absorption spectrum determined in a Zeiss PMQ2 spectrophotometer. When separating compounds with low R_F-values the solvent was allowed to evaporate from the rim of the paper which extended outside the petri dish.

APPLICATIONS

In the present work the method has been applied mainly to the separation of carotenoids from brown seaweeds and bacteria. The R_F-values obtained for a series of carotenoids are presented in Table 1.

1. Grouping and separation of carotenoids. Quantitative separation of bicyclic carotenes, mono-hydroxy-xanthophylls and dihydroxy-xanthophylls was accomplished as exemplified by the separation of the series β-carotene, cryptoxanthin and zeaxanthin. These groups could be further separated into their individual components in the cases investigated.

Within the group of aliphatic, bacterial carotenoids studied a similarly satisfactory separation of the different all-*trans* compounds was obtained.

2. Separation of stereoisomeric sets. Separation of *cis-trans* isomers belonging to the same set could easily be obtained as seen from Table 1.

3. Recoveries and quantitative determinations. Recoveries obtained by this method were determined by applying known amounts of pure carotenoids to the paper. After the chromatographic development the amount of carotenoid eluted was measured in the spectrophotometer. The results are presented in Table 2.

Table 2. Pigment recovery after chromatography.

Compound	Amount in μg	
	Applied	Recovered
β-Carotene	14.3	14.3
	7.2	7.1
Zeaxanthin	3.9	3.8
	7.8	7.8
	7.8	7.6

The recoveries obtained both with β-carotene and with zeaxanthin were between 97 and 100 %.

The carotene content of dried grass and of seaweed meal was determined by means of paper chromatography. Details of the procedure are to be published[15]. Using the paper chromatographic method, the values obtained for the carotene content were somewhat higher than those obtained with the conventional procedure. This may be a result of the higher over-all recoveries of the new method.

4. Separation of chloroplast pigments. Minor variations in the composition of the solvent system allowed a ready separation of the chloroplast pigments from various sources as shown in Table 3.

DISCUSSION

The efficiency of the Schleicher and Schüll filter paper No. 287 for the separation of carotenoids must be ascribed to its content of kieselguhr, since ordinary filter paper gave very poor separations. Used in circular chromatography the kieselguhr paper allowed a ready separation of carotenoid mixtures into carotenes, mono-hydroxy- and dihydroxy-xanthophylls. These groups could be separated further into their components provided they were more strongly adsorbed than β-carotene.

Table 3. Separation of chloroplast pigments.

Extract of		R_F-values	
		1.5 % *iso*propanol *	10 % acetone *
Ascophyllum nodosum	β-carotene	0.96	
	lutein	0.80	
	violaxanthin	0.36

	zeaxanthin		0.60
	chlorophyll a		0.41
	chlorophyll b		0.21

* in petroleum ether b.p. 60–70°C.

Probably the best demonstration of the efficiency of the method was the ready separation of *cis-trans* isomers of carotenoids belonging to the same stereoisomeric set. The method allowed quantitative studies of different *cis-trans* isomerization processes to be carried out much more easily, with greater accuracy and with much smaller amounts of pigments than are required for column chromatography. A mixture containing approximately 50 μg of carotenoid could be separated quantitatively into the main stereoisomers which were eluted and examined in the spectrophotometer. The rapidity of the method is particularly valuable for studies of carotenoids which isomerize readily or are otherwise very labile. Thus, it was possible to carry out a stereochemical investigation of bacterioruberine α[8] which was sterically too labile to allow exact *cis-trans* isomerization studies by means of column chromatography.

With slightly modified solvent systems the method gave satisfactory separation of the chloroplast pigments of both algae and grass extracts, and allowed quantitative determination of the major components.

When care was taken, the R_F-values of the compounds were reproducible within ± 0.01 units. The solvent mixtures should be used only once when determining R_F-values; the reason for this is probably that the paper removes relatively more of the acetone than of the petroleum ether. Evaporation of the solvent from the Petri dish during the chromatographic run must be avoided. Large amounts of fatty material in the extracts may influence the R_F-values of the pigments considerably. In such cases saponification or some other purification process should precede the chromatographic separation in order to obtain the characteristic R_F-values.

It may be seen from Table 1 by comparing the R_F-values of the bacterial carotenoids with those of carotenoids from other sources that the R_F-values were not influenced merely by the number of functional groups and the number of double bonds. The nature of the skeleton (aliphatic or cyclic) and the character of the hydroxyl groups (secondary or tertiary) obviously have a definite effect on the R_F-value. For example OH-P481 is more strongly adsorbed to the paper than zeaxanthin and lutein; the reverse is true for adsorption on alumina columns. Bacterioruberine α chromatographs very similarly to lutein on alumina, but is held more strongly than lutein on paper. Also for some of the other pigments investigated the order of adsorbtion on paper differed from that obtained with other adsorbents. The method thus offers an additional tool for identification of chloroplast pigments.

The recovery of pigments extracted from the paper was found to be quantitative, and the eluted pigments showed absorption spectra in visible light comparable with the best recorded in the literature. Quantitative determination of the main components of several complex carotenoid mixtures were successfully performed by means of the above method.

Paper chromatography is particularly useful for purity tests of small samples, for following chemical and biochemical transformations and for investigations in which only very small amounts of material are available. The fact that only small amounts of material are required, and that the method gives a high resolving power, makes it a very good test for identification of carotenoids when combined with co-chromatography of known substances.

Acknowledgements. We are indebted to Mr. Ian Dundas of the Department of Biochemistry for the cultivation of *Chlorobium thiosulfatophilum* and the *Halobacterium* sp., and to Professor N. A. Sørensen, Organic Chemistry Laboratories, for critically reading the manuscript. One of us (SLJ) gratefully acknowledges a maintenance grant from *Norges Tekniske Høgskole.*

Studies on Arabogalactans

III.* Degradation Products of Arabogalactan A from *Larix occidentalis* Nutt. and an Electrophoretic Examination of Arabogalactans from other *Larix* Species

HANS O. BOUVENG

Institutionen för Träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

The arabogalactan A obtained from *Larix occidentalis*, on mild hydrolysis to remove the arabinose residues, gave two different galactan fractions which were easily separated by fractional precipitation of their cetyl-trimethylammonium borate complexes. On methylation and hydrolysis of the methylated derivatives, both galactans afforded 2-*O*-methyl-D-galactose, 4-*O*-methyl-D-galactose, 2,4-di-*O*-methyl-D-galactose, 2,6-di-*O*-methyl-D-galactose, 2,3,4-tri-*O*-methyl-D-galactose, 2,4,6-tri-*O*-methyl-D-galactose and 2,3,4,6-tetra-*O*-methyl-D-galactose though in significantly different proportions. Some arabogalactans from other *Larix* species were examined by electrophoresis and by fractionation and were found in all cases to be of the same complex nature as the *L. occidentalis* polysaccharide.

INVESTIGATION OF DEGRADED ARABOGALACTAN A

In part II of this series [1] an account was given of the fractionation of the arabogalactan fraction from Western larch (*Larix occidentalis* Nutt.) into two fractions (A and B) and of a methylation study of the component A with the higher degree of polymerisation and the higher electrophoretic mobility. Neither sedimentation analysis nor electrophoresis in borate buffer gave any indication of heterogeneity in the two polysaccharides. However, it was later observed that polysaccharide A after brief, mild hydrolysis gave two distinct components on electrophoresis, one with slightly higher electrophoretic mobility than arabogalactan A and one with about the same mobility as arabogalactan B.

In contrast to the behaviour of the material studied by Aspinall *et al.*[2], the arabinose could be removed by prolonged mild hydrolysis without unduly

* Part III and IV of this series were presented at the 136th Meeting of the American Chemical Society in Atlantic City, N. J., September 1959 (abstract 14E).

extensive break-down of the remaining polysaccharide. After removal of the low molecular weight oligosaccharides, a fractional precipitation with cetyltrimethylammonium hydroxide (CTA-OH) — boric acid gave two electrophoretically pure galactans, A'I, $[\alpha]_D^{20}$ +13°, M_G 0.84 and A'II, $[\alpha]_D^{20}$ +19°, M_G 0.66. The arabogalactans A and B had M_G values of 0.76 and 0.63 and rotations of +7° and +10°, respectively. An osmometric determination gave a $\overline{DP}_n$ value of 48 for A'II. An approximate calculation of the degree of polymerisation of A'I from the proportion of terminal groups appearing as tetramethylgalactose on hydrolysis of the methylated polysaccharide gave a value of 20. Arabogalactan B was degraded in the same manner to yield a single component (B') with the same electrophoretic mobility as the original polysaccharide and with a rotation of +21°.

The two galactans were methylated following the procedure described in part II[1] with the exception that A'I after the preliminary methylation with methyl sulphate and sodium hydroxide was methylated once with methyl iodide and barium oxide in dimethyl formamide solution as proposed by Kuhn *et al.*[3] for the methylation of low molecular weight carbohydrates. The barium oxide seemed to give slightly lower methoxyl content than silver oxide but may be useful since the oxidising silver oxide depolymerises more incompletely methylated polysaccharides [4].

The methylated polysaccharides were hydrolysed in a mixture of 30 % glacial acetic acid and 70 % 0.5 N hydrochloric acid and each mixture of methyl ethers obtained was resolved on a carbon-Celite column. Further separation, if required, was done on thick filter paper. The amount of each ether was estimated by hypoiodite oxidation [5]. The results are summarised in Table 1.

Table 1. Methyl ethers (in mole %) obtained from the methylated hydrolysed galactans A'I and A'II from degraded larch arabogalactan A.

Sugar	% (A'I)	% (A'II)
4-Methylgalactose	0.6	0.3
2-Methylgalactose	2.5	3.4
2,4-Dimethylgalactose	27.9	20.5
2,6-Dimethylgalactose	2.1	2.7
2,3,4-Trimethylgalactose	13.8	21.8
2,4,6-Trimethylgalactose	13.6	19.6
2,3,4,6-Tetramethylgalactose	39.6	31.7

These results show that A'I and A'II contain the same types of linkages but in different proportions. A'II is a more moderately branched polysaccharide, while A'I has the same heavily branched structure as the original polysaccharide. The 2-*O*-methyl-D-galactose and 2,6-di-*O*-methyl-D-galactose must be assigned at least some structural significance which implies the presence of a small fraction of 1,4-linkages partly combined with doubly branched units, but the 4-*O*-methyl-D-galactose is probably a result either of incomplete methylation or of demethylation during hydrolysis. The amount of 2,4,6-tri-

O-methyl-D-galactose is strikingly larger than that obtained from arabogalactans A and B. This indicates that the easily hydrolysed units of the original polysaccharide (L-arabinose, 3-*O*-β-L-arabopyranosyl-L-arabinose, D-galactose and 6-*O*-β-D-galactopyranosyl-D-galactose) are attached to the rest of the molecule mainly through 1,6-linkages as has been suggested by White [6] in the case of the arabinose.

These results indicate a possibility that the arabogalactan A could be heterogeneous. A separation of the material into the hypothetical components corresponding to the galactans A'I and A'II * by fractional precipitation with CTA-OH—boric acid did not appear feasible since no separation could be obtained on electrophoresis in borate buffer or by trial precipitations. On hydrolysis of arabogalactan A in 0.01 N acid at 100°C for 2 h only, it was found possible to isolate a small quantity of electrophoretically pure A II from the main fraction of the A I type (M_G *ca.* 0.85) by fractionation in the usual way. This fraction probaly contained still unchanged arabogalactan A beside A I. Chromatograms of hydrolysates indicated that these two fractions contained about the same proportions of arabinose. Electrophoretic examination of the material obtained from A I on hydrolysis for a further 2 h showed that more A II had been formed. The A I fraction after precipitation as the CTA-borate complex and isolation in the usual manner was subjected to hydrolysis under the same conditions for another 4 h. Further amounts of A II were again found.

It is not yet possible to decide whether A I and A II are fragments of a single molecular species or of two. It is however known that part of the galactopyranosidic linkages in the polysaccharide must be of a weaker type, possibly due to non-bonded steric interaction in the heavily branched structure (*cf.* the preceding paper in this series). If arabogalactan A is homogeneous a possible explanation of the appearance of A I and A II is that they correspond to two molecular fragments of different degrees of branching which are joined by linkages of this type. The observation, that the rates of formation of A I and A II and of galactose and 6-β-galactopyranosyl-galactose under these hydrolytic conditions are of the same order of magnitude, is in agreement with this view. A further indication of the homogeneity of arabogalactan A is the fact that on electrophoresis of the hydrolysed polysaccharides there is little trailing between the two spots corresponding to A I and A II. It therefore seems more probable that A I and A II are released as such during the hydrolysis from a homogeneous polysaccharide and not from separate macromolecules; in the latter case the M_G values should change gradually from the original value (0.76) to the final values (0.84 and 0.66 for A'I and A'II, respectively) with consequent trailing. The small difference between the M_G values for B and B' shows that the removal by hydrolysis of the simple oligosaccharide residues

* The designation A I will be used below to refer to any polysaccharide material obtained by mild hydrolysis of arabogalactan A that has an electrophoretic mobility of the same order as the original arabogalactan A (*ca.* 0.80). A II will be used to refer to any material obtained from arabogalactan A in the same way that has the same electrophoretic mobility as arabogalactan B (*ca.* 0.65). A'I and A'II will be used exclusively for the arabinosefree galactans (M_G values 0.84 and 0.66, resp.) obtained by prolonged mild hydrolysis of arabogalactan A.

containing arabinose and galactose [7] appearently has very little effect on the electrophoretic mobility of this type of polysaccharide.

Examination of the arabogalactans from a number of larches (*cf.* the preceding section of this paper) showed that the proportions of A I and A II as estimated from electrophoretograms were fairly constant but that the proportion of A to B varied considerably.

INVESTIGATION OF THE ARABOGALACTANS FROM OTHER *LARIX* SPECIES

In view of the complex nature of the arabogalactans from *Larix occidentalis* it seemed desirable to make a brief examination of the arabogalactans of other *Larix* species to see if they were of the same type. The following species were investigated (the yields of arabogalactan calculated on acetone-extracted, airdried heart wood are given in brackets; the results obtained from *L. occidentalis* are included for comparison):

Order *Multiseriales* Patschke [8]:
L. Potaninii Batal. (7.2 %)
L. occidentalis Nutt. (9.3 %)
L. Lyallii Parl. (7.7 %).
Order *Pauciseriales* Patschke:
L. leptolepis (Sieb. & Zucc.) Gord. (8.0 %)
L. laricina (Du Roi) K. Koch (3.9 %)
L. Sukaczevii Djil. (5.3 %)
L. decidua Mill. (3.4 %)
L. Gmelinii (Rupr.) Kuzeneva var. *japonica* (Reg.) Pilger (15.7 %).

EXPERIMENTAL

All melting points are corrected. Evaporations were done under reduced pressure.

Chromatography: Papers: Whatman 1 and Schleicher and Schüll 602 hP. Solvent: Butanol, ethanol, water, 10:3:5. Spray reagent: anisidine hydrochloride.

Electrophoresis. Papers: Whatman 1 and Schleicher and Schüll glass fibre paper. Buffer: 0.1 M borate buffer of pH 10. Spray reagents: anisidine hydrochloride and α-naphtol-sulphuric acid in butanol. In the electrophoresis it was not possible to determine the temperature of the papers accurately and the M_G values are therefore only relative. The variation in different measurements was about ± 0.03 units.

Hydrolysis of the arabogalactan. Arabogalactan A was hydrolysed in 0.01 N hydrochloric acid at 100°C for 18 h. After cooling the solution was neutralised with silver carbonate, filtered, concentrated to a small volume and poured into ethanol. The product was filtered off giving a white powder. This was freed from low molecular weight oligosaccharides by reprecipitation twice with ethanol. A chromatogram of a hydrolysate showed only faint traces of arabinose. On electrophoresis the hydrolysate gave two distinct spots, the faster of which was designated as A′I and the slower as A′II. Hydrolysis of arabogalactan B and isolation of the product in the same way gave the degraded polysaccharide (B′). On electrophoresis this gave only a single spot. The characteristics of these polysaccharides are shown in Table 2.

Table 2. Arabogalactans and corresponding galactans from *Larix occidentalis.*

Polysaccharide	$[\alpha]_D^{20}$	% arabinose (molar)	% galactose (molar)	M_G
A	+ 7°	19	81	0.76
B	+10°	21	79	0.63
A'I	+13°	trace	100	0.84
A'II	+19°	—	100	0.66
B'	+21°	trace	100	0.63

Separation of A'I and A'II. The results of a typical experiment are summarised in Table 3 which shows the fractionation of the galactan mixture (7.51 g = 46 mmole anhydrogalactose) dissolved in water (300 ml) and 0.6 M boric acid solution (50 ml).

Table 3. Fractionation of hydrolysed arabogalactan A (7.51 g).

CTH-OH added (mmoles)	NaOH added (mmoles)	Weight of fraction (g)	Components
2.0	—	2.50	A'I
2.0	1.5	2.08	A'I
4.0	3.0	1.83	A'II
Residue		0.42	A'II

A'I and A'II were obtained in the approximate ratio 2:1. A'I contained traces of arabinose.

Methylation of the galactans A'I and A'II. The galactans were methylated first with methyl sulphate and sodium hydroxide. The product from methylation of A'I was then subjected to a methylation with methyl iodide and barium oxide in dimethyl formamide as described by Kuhn *et al.*[3]. After a reaction time of 20 h the unreacted barium oxide was removed by filtration and the dimethyl formamide was evaporated. The product was freed from barium iodide by treatment with freshly precipitated silver acetate in alcoholic solution. This treatment raised the methoxyl content from 25.3 to 38.7 %. The partially methylated galactans were exhaustively methylated with methyl iodide and silver oxide in dimethyl formamide following the procedure described in part II [1]. No trace of unmethylated monomer was found on chromatograms of hydrolysates of the methylated derivatives.

Hydrolysis of the methylated galactans and fractionation of the hydrolysates. The two galactans were each hydrolysed at a concentration of about 1.5 % in a mixture of glacial acetic acid and 0.5 N hydrochloric acid (1:2) at 100°C for 18 h. The reaction mixture was treated with excess silver acetate, concentrated to a small volume, taken up in ethanol and filtered. The mixture of ethers obtained on evaporation of the ethanol was dissolved in water and adsorbed on a carbon-Celite column 3.5 × 46 cm.

A'I (0.47 g) was eluted with 4 l 6 → 25 % ethanol + 2 l 25 → 40 % ethanol + 1 l 50 % acetone, and A'II (0.65 g) with 5 l 6 → 35 % ethanol + 1 l 50 % acetone. Both were collected in 25 ml fractions. The amount of reducing sugar in each fraction was determined by hypoiodite oxidation [5] and the mixed fractions were further resolved on Schleicher and Schüll 602 hP filter papers for quantitative estimation as described in part II [1]. The results of the fractionations are summarised in Table 4.

*Characterisation of the methyl ethers. 2-O-Methyl-*D*-galactose, 4-O-methyl-*D*-galactose* and *2,6-di-O-methyl-*D*-galactose* were indistinguishable from authentic material by chromatography or electrophoresis.

Table 4. Fractionation of the methylated hydrolysed galactans A'I and A'II.

Fract. No.	mmoles(total)	Sugars	% of fraction	mmoles

		2,3,4,6-Tetramethylgalactose	87	0.836

* Contained traces of arabinose methyl ethers.

2,4-Di-O-methyl-D-galactose was crystallised from acetone, m. p. 101°, sintering at 85°, aniline derivative m. p. 213—215° and mixed m. p. 212—215°.

2,3,4-Tri-O-methyl-D-galactose. Aniline derivative, m. p. and mixed m. p. 169—170°.

2,4,6-Tri-O-methyl-D-galactose was obtained in a crystalline state from galactan A'II, m. p. 96—98° after recrystallisation from ethanol-ethyl acetate. Aniline derivative, m. p. 176—178°, in both cases undepressed on admixture with authentic samples.

2,3,4,6-Tetra-O-methyl-D-galactose. Aniline derivative in both cases, m. p. 199—201° and mixed m. p. 198—200°.

Estimation of the degree of polymerisation of A'I and A'II. For *A'II* the estimation was made osmometrically using the same type of osmometer as Lindberg and Meier [9]. The measurements were made in aqueous solution with "Ultrafilter allerfeinst" membranes from Membrangesellschaft Göttingen, Germany. This gave a $\overline{DP_n}$ value of 48 but this is of course subject to inaccuracies due to the use of water as solvent. The methylation data did not permit any reliable estimate of the DP value.

A'I. This galactan leaked too much through the membrane to allow osmometric measurement. Calculation from the excess of endgroups found from the methylation data gave a DP value of 20. Although precautions were taken, small losses due to the volatility [10] of the tetramethylgalactose corresponding to these endgroups were probably unavoidable. Allowing for losses of the order of 5 % (*cf.* Part II of this series) would give a DP value of 17. These DP values of course depend on the hydrolysis time used in the preparation of the galactans. It appears however that the ratio of the DP values for A'I and A'II is about 1:3.

Isolation and electrophoresis of the arabogalactans from other larchwoods. The polysaccharides were isolated mainly as described in Part I [7]. Extraction 3—4 times with water at room temperature afforded about 95 % of the arabogalactan accessible to cold water extraction.

Electrophoresis on glass fibre sheets in borate buffer and fractionation experiments showed that the arabogalactans from the closely related *L. occidentalis* and *L. Lyallii* by containing a larger proportion of the arabogalactan B (25—30 %) differed distinctly from all the other species investigated, which contained only 5—10 % of arabogalactan B. Due either to lack of material or to the small amounts present, arabogalactan B was only isolated in a pure state from *L. Lyallii* and in about 90 % purity from *L. Gmelinii*.

Investigation of the A fractions. The A fractions were isolated as described in Part II [1] of this series. They were analysed for arabinose and galactose according to Saeman *et al.*[11] The results of these analyses and of the analyses of the B fractions isolated are summarised in Table 5.

Table 5. The composition of the arabogalactans from some *Larix* species.

Species	Fraction	Galactose (weight %)	Arabinose (weight %)	Moles galactose per mole arabinose
L Potaninii	A	89.7	10.3	7.3
L occidentalis	A	83.9	16.1	4.3
»	B	81.6	18.4	3.7
L. Lyallii	A	85.5	14.5	4.9
»	B	75.7	24.3	2.6
L. leptolepis	A	90.3	9.7	7.8
L. laricina	A	86.7	13.3	5.4
L. Sukaczevii	A	86.7	13.3	5.4
L. decidua	A	87.2	12.8	5.7
L. Gmelinii var. *japonica*	A	92.2	7.8	9.8
»	B	83.7	16.3	4.3

From these results it is evident that the arabinose content of larch arabogalactans from different sources is subject to large variations. The higher arabinose content of the B fractions may be partly due to a contaminating araban (*cf.* the preceeding paper of this series). The detection of traces of a slow-moving component on an electrophoretogram heavily spotted with the B fraction of *L. Lyallii* is in agreement with this view.

The M_G values of the A fractions lay within the range 0.81—0.86 except for the fraction from *L. occidentalis* which had $M_G = 0.76 \pm 0.03$. The low M_G value of this polysaccharide can be attributed to its comparatively high arabinose content, the main part of which is present as terminal arabofuranosidic residues incapable of forming borate complexes [12]. The B fractions had M_G values of 0.63 ± 0.03.

Hydrolytic degradation of the A fractions. Samples (1.5 g) of the A fractions were subjected to hydrolysis in 0.005 N hydrochloric acid at 100°C for 18 h, and the polysaccharide material in the reaction mixture was precipitated with ethanol. Estimations from electrophoretograms indicated that all samples gave both A I and A II in proportions varying between 2:1 and 3:1. These variations are probably not significant since a slight fractionation of the galactans may occur during isolation.

The author is indebted to Dr. B. Lindberg for his keen interest in this work and also to Dr. R. H. Farmer, Princes Risborough, Dr. T. E. Timell, Montreal, Dr. E. v. Rudloff, Saskatoon and Dr. E. Rennerfelt, Stockholm, for gifts of wood, to the late Dr. E. Söderberg for valuable botanical advice, to Miss Anita Myhrman for her skilful assistance and to *Fonden för Skoglig Forskning* for financial support.

Studies on Arabogalactans

IV. A Methylation Study of Arabogalactan B from *Larix occidentalis* Nutt.

HANS O. BOUVENG

Institutionen för Träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

Arabogalactan B, the lower molecular weight arabogalactan from Western larch *(Larix occidentalis)*, was methylated and hydrolysed, giving 2-*O*-methyl-D-galactose, 4-*O*-methyl-D-galactose, 2,4-di-*O*-methyl-D-galactose, 2,6-di-*O*-methyl-D-galactose, an unknown methyl-galactose, 2,3,4-tri-*O*-methyl-D-galactose, 2,4,6-tri-*O*-methyl-D-galactose, 2,3,4,6-tetra-*O*-methyl-D-galactose, 2-*O*-methyl-L-arabinose, 2,3-di-*O*-methyl-L-arabinose, 2,5-di-*O*-methyl-L-arabinose, 2,3,4-tri-*O*-methyl-L-arabinose and 2,3,5-tri-*O*-methyl-L-arabinose.

The arabogalactans found in a number of species of *Larix* have been shown to consist of two main fractions (A and B) [1,2]. B, which has a lower degree of polymerisation, usually forms about 5—10 % of the total arabogalactan fraction but in *L. occidentalis* Nutt. and *L. Lyalli* Parl. it is about 30 % of the arabogalactan. The isolation of arabogalactan B on a preparative scale from the arabogalactan of *L. occidentalis* was described in part II of this series [1]. The polysaccharide was obtained as a white powder, $[\alpha]_D^{20}$ +10°, containing 21 % (molar) arabinose. It appeared from the results of paper electrophoresis and sedimentation analysis to be homogeneous.

Arabogalactan B was swollen in dimethyl formamide and then methylated with methyl iodide and silver oxide [3] to yield a methylated polysaccharide containing 35.6 % methoxyl. A second methylation raised the methoxyl content to 42.6 % but four more methylations in the same way raised the methoxyl content only to 43.0 %, the theoretical value being 44.6 %. The formation of a precipitate of silver halogenide on hydrolysis of the methylated polysaccharide indicated that it was contaminated with complex silver salts formed during the methylation [4]. Careful examination of a hydrolysate of the methylated polysaccharide showed that unmethylated monomer was absent, which is a good criterion of exhaustive methylation.

The methylated polysaccharide was hydrolysed and the mixture of methyl ethers obtained was resolved on a carbon-Celite column. The amount of reduc-

ing sugar in each fraction was determined by hypoiodite oxidation and the mixed fractions were further separated on filter papers both for preparative purposes and for quantitative estimation of the components present. The results are summarised in Table 1.

Table 1. Methylated sugars obtained from 2.0 g of methylated arabogalactan B.

Methyl ether	mmoles	molar %	M_G value
Unmethylated monomers	—	<0.1	
4-Methylgalactose	0.03	0.3	0.30
2-Methylgalactose	0.20	2.3	0.43
2-Methylarabinose	0.05	0.6	0.34
2,4-Dimethylgalactose	2.65	31.0	<0.05
2,6-Dimethylgalactose	0.33	3.9	0.38
2,3-Dimethylarabinose	0.04	0.5	<0.05
Unknown methylgalactose	0.06	0.7	0.30
2,3,4-Trimethylgalactose	1.01	11.8	
2,3,4-Trimethylarabinose	0.44	5.1	
2,5-Dimethylarabinose	0.69	8.1	
2,4,6-Trimethylgalactose	0.34	4.0	
2,3,4,6-Tetramethylgalactose	2.06	24.1	
2,3,5-Trimethylarabinose	0.65	7.6	

The appearance of 2-*O*-methyl-L-arabinose and 2,3-di-*O*-methyl-L-arabinose in approximately equimolecular quantities can be explained as due to the presence of about 1.7 % of an araban as an impurity in the original polysaccharide [5]. As arabofuranosidic residues should not form complexes with borate ions [6] such an araban would not be precipitated in the fractionation with cetyltrimethylammonium hydroxide—boric acid. It should therefore be found only in the unprecipitated fraction, which is in agreement with the total absence of the corresponding ethers in the hydrolysate of methylated arabogalactan A[1].

The isolation of 2-*O*-methyl-D-galactose and 2,6-di-*O*-methyl-D-galactose from hydrolysates of the methylated derivatives of arabogalactan A and of the galactans obtained on mild hydrolysis of arabogalactan A was reported in parts II [1] and III [2] of this series. The argument presented there on their structural significance must also be valid in the present case. The possibility that these ethers originate from a branched galactan built up of 1,4-linked units cannot be disregarded. However they constitute 4,6—6,6 mole % of the hydrolysates which would correspond to at least 10 % of such a galactan in the original polysaccharide. Such a quantity would not easily have been overlooked in the fractionation and electrophoresis and it therefore seems more probable that these ethers are derived from the arabogalactans and not from a contaminating galactan. The isolation of 2-*O*-methyl-D-galactose from methylated European larch arabogalactan [7] and of 2,6-di-*O*-methyl-D-galactose from the arabogalactans of White spruce [8] and Jack pine [9] suggests that a small proportion of 1,4-linkages is normally present in the arabogalactans from coniferous woods.

A comparison of the present results with those obtained on the methylated arabogalactan A shows that the chains of galactose residues forming the backbones of the two polysaccharides are very similar both in the types of linkage present and in their proportions. However, in making such a comparison the possibility must be born in mind that A may be heterogeneous. The amount of end groups as calculated from methylation data is 34.8 and 36.8 % for A and B, respectively. However, due to various deficiencies in the methods used these figures will be too low, especially in the case of A. Estimation of the amount of endgroups from the amount of branching points gives values of 42.3 and 39.0 % respectively. There is a higher proportion of 3-*O*-β-L-arabopyranosyl-L-arabofuranose units in fraction B than in A. The excess of 2,5-di-*O*-methyl-L-arabinose relative to 2,3,4-tri-*O*-methyl-L-arabinose shows that some arabinose must be present in 3-*O*-L-arabofuranosyl-L-arabofuranose residues. The existence of 3-*O*-L-arabofuranosyl-3-β-L-arabopyranosyl-L-arabofuranose is less probable as no 2,4-di-*O*-methyl-L-arabinose was found in the hydrolysate.

Tests, made by courtesy of Dr. M. Heidelberger, State University, New Jersey, USA, of the reactivity of the arabogalactans towards Type XIV antipneumococcal horse serum, showed differences between the two polysaccharides. Arabogalactan A not only reacted faster than B but precipitated considerably more antibody. It seems unlikely that the slight differences between A and B indicated by the methylation data are sufficient to account for the differences in their reactivity towards antipneumococcal serum and in their rate of migration on electrophoresis (M_G 0.76 for A and 0.63 for B). It is more probable that the two molecules are built up in a different manner with concomitant differences in the accessibility of those groups which are normally involved in the formation of borate complexes and of complexes with antipneumococcal serum (*cf.* Ref.[10]).

Some reference should be made to possible deficiencies in the methods used to obtain the methylation data given in Parts II, III and IV of this series. As was pointed out in Part II estimates of the number of endgroups present from the yield of tetramethylgalactose and trimethylarabinose give lower values than those required by estimates of the numbers of branching points from the yield of monomethyl and dimethyl galactose. This is partly due to the slight volatility of the tetramethylagactose and the trimethylarabinose. This discrepancy was greatly diminished by chloroform extraction of the distillates obtained on concentration of solutions of these highly methylated ethers and returning the recovered material to the ether mixture. The quantitative estimation of difficultly separated substances after fractionation on thick filter paper is of course subject to some inaccuracy. This was especially the case in the estimation of 2,6-di-*O*-methyl-D-galactose, 2,3,4-tri-*O*-methyl-D-galactose, 2,5-di-*O*-methyl-L-arabinose and 2,3,4-tri-*O*-methyl-L-arabinose but since the relative error probably lies within the range 5—10 %, this inaccuracy should not seriously affect the results.

It appears from the analytical data (*cf.* Table 4, Part II [1] and Table 2 in the present paper) that some trailing occurred in the elution from the carbon column. It was possible to take this trailing into account only in the case of the most abundant components as the material trailing was only a few percent

of the total present in each case. In the investigation of degraded arabogalactan A [2] when a different batch of activated carbon was used in the column, practically no trailing occurred.

It was found that the mild hydrolysis of larch arabogalactan, in addition to removing the arabofuranose residues also splits off large amounts of galactose and 6-*O*-β-D-galactopyranosyl-D-galactose at the same time [12]. It was assumed that these units were originally attached to the rest of the molecule through furanosidic linkages. That galactofuranose units are present in larch arabogalactan has already been suggested by Jones [13]. Normal paper chromatographic methods proved inadequate for the separation of the expected 2,3,5-tri-*O*-methyl-D-galactose from the accompanying 2,3,4,6-tetra-*O*-methyl-D-galactose and of 2,3,5,6-tetra-*O*-methyl-D-galactose from 2,3,5-tri-*O*-methyl-L-arabinose. However the chromatographic technique developed by Wickberg [14] using paper impregnated with dimethyl sulphoxide as stationary phase and ether or benzene as mobile phase gave an excellent separation of these methyl ethers. This showed clearly that no methylated galactofuranoses were present in the hydrolysates from the methylated arabogalactans A and B.

The easy release of these galactose residues is unexpected. Estimation of the amounts of oligosaccharides formed on hydrolysis of unfractionated arabogalactan A in 0.01 N hydrochloric acid at 100°C[15] showed that after 8 h about 80 % of the arabinose is split off and that the oligosaccharide part of the hydrolysate contains 55 % arabinose and 3-β-arabopyranosyl-arabinose, 35—40 % galactose and 6-β-galactopyranosyl-galactose and 5—10 % of larger fragments containing galactose. Detectable amounts of 3-β-galactopyranosyl-galactose were found only after 10 h. This disaccharide is usually present in mixtures of oligosaccharides obtained on stronger hydrolysis of the arabogalactan [7,15]. These results indicate that a part of the galactopyranosidic linkages is hydrolysed with about the same rate as the arabofuranosidic linkages. Hydrolysis at those linkages leads to the loss of about 15 % of the galactose originally present.

A comparison of these results with those obtained from methylation studies on arabogalactans from *Larix decidua* [7] and from *Pinus* [9,16] and *Picea* [8] shows that the *Pinus* and *Picea* arabogalactans are of a different, less branched type with the arabinose present as single, terminal furanose residues. The arabogalactans from *Larix decidua* are appearently very similar in structure to those from *L. occidentalis* except for a slightly different arrangement of the arabinose residues.

EXPERIMENTAL

All melting points are corrected. All evaporations were done under reduced pressure.

Chromatography. Papers: Whatman No. 1 and 3 MM, Schleicher and Schüll 602 hP. Solvent: Butanol, ethanol, water, 10:3:5. Spray reagent: anisidine hydrochloride.

Methylation of arabogalactan B. Arabogalactan B ($[a]_D^{20}$ + 10° (*c*, 1.0 in water), 21 mole-% arabinose) was prepared as described in Part II. The polysaccharide (4.72 g) was swollen in dry dimethyl formamide (50 ml) overnight, silver oxide was then added and the mixture was stirred vigorously to give a suspension. Dry methyl iodide (25 ml) was distilled into the reaction flask in small portions over a period of 3 h and further silver oxide (14 g) was added during the same time in 2 g portions. The mixture was stirred for a further 15 h at room temperature and then worked up as described in Part II. The product

(5.30 g; OCH_3, 35.6 %) was then methylated five times in the normal way but the methoxyl content could not be raised above 43 % (theoretical value 44.6 %).

Fractionation of the hydrolysate of methylated arabogalactan B. Methylated arabogalactan B (2.0 g) was heated with formic acid (100 ml) at 100°C for 6 h. The solution was concentrated and the product was dissolved in aqueous 0.5 N hydrochloric acid (100 ml) and kept at 100°C for 14 h. This solution was then neutralised by filtering through an ion exchange column (IR 4-B), and concentrated to small volume. The aqueous distillate from this concentration was extracted three times with chloroform and the minute residue obtained on evaporation was dissolved in a few drops of water and combined with the concentrated hydrolysate. The same procedure was always used in the concentration of solutions containing free, highly methylated ethers.

The hydrolysate was adsorbed on a carbon-Celite column (3.5 × 43 cm) and separated by gradient elution with 5.5 1 6 — 24 % aqueous ethanol followed by 1 1 50 % acetone. 20 ml fractions were collected.

The results of the fractionation are summarised in Table 2. The amount of reducing sugar in each of the combined fractions was determined by hypoiodite oxidation [17]. The mixed fractions were further separated by chromatography of 10—15 mg samples on Schleicher and Schüll 602 hP paper for quantitative estimation [1] and by chromatography of the remainder for preparative purposes on Schleicher and Schüll 602 hP or Whatman 3 MM papers.

Table 2. Fractionation of methylated hydrolysed arabogalactan B.

Characterisation of the methyl ethers. 4-O-Methyl-D-galactose. The ether was separated from the accompanying 2-*O*-methyl-D-galactose and 2-*O*-methyl-L-arabinose on Schleicher and Schüll 602 hP papers. The small quantity obtained (about 3 mg) was crystallised from ethanol, m. p. 195° and mixed m. p. 195—205°. It was chromatographically and electrophoretically indistinguishable from an authentic specimen of 4-*O*-methyl-D-galactose.

2-O-Methyl-D-galactose. The ether was recrystallised from ethanol, m. p. and mixed m. p. 150—152°, chromatographically and electrophoretically indistinguishable from authentic 2-*O*-methyl-D-galactose.

2-O-Methyl-L-arabinose. This ether gave only arabinose on demethylation and travelled on chromatograms at about 90 % of the rate of 2,4-di-*O*-methyl-D-galactose. On electrophoresis it migrated faster (M_G 0.34) than 4-*O*-methyl-D-galactose (M_G 0.30) but slower than 2-*O*-methyl-D-galactose (M_G 0.43). These characteristics make a 2-*O*-methyl-L-arabinose structure very probable.

2,4-Di-O-methyl-D-galactose. The ether was recrystallised from chloroform-moist ethanol, m. p. 97°, sintering at 85°; aniline derivative, m. p. 210—212° undepressed on admixture with an authentic specimen of 2,4-di-*O*-methyl-D-galactosyl-N-phenylamine.

2,3-Di-O-methyl-L-arabinose. The ether was obtained by separation of fractions 82—91 on thick filter paper. It gave arabinose only on demethylation and travelled slightly faster than 2,4-di-*O*-methyl-L-arabinose on chromatography. It was immobile on electrophoresis and therefore a 2,3-di-*O*-methyl-L-arabinose structure is the most probable.

2,6-Di-O-methyl-D-galactose. The ether was separated from the accompanying unknown methylgalactose and 2,4-di-*O*-methyl-D-galactose by fractionation of fractions 92—106 on thick filter paper. M. p. and mixed m. p. 116—118°. It was chromatographically and electrophoretically (M_G 0.38) indistinguishable from authentic 2,6-di-*O*-methyl-D-galactose.

Unknown methylgalactose. This ether, probably an artifact, gave galactose on demethylation and on chromatography moved about 20 % faster than 2,4-di-*O*-methyl-D-galactose. It had M_G 0.30 which shows that either the 1,2- or the 3,4-glycol grouping was unsubstituted [18]. Of the possible ethers with this structural feature 3,4-di-*O*-methyl-D-galactose would probably be more easily desorbed from the column. This indicates the alternatives 4,6-di- or 3,4,6-tri-*O*-methyl-D-galactose, the latter being in best agreement with the high R_F value.

2,3,4-Tri-O-methyl-D-galactose. This ether and the next two were obtained from fract. 107—179 by fractionation on thick filter paper. It was characterised as the aniline derivative, m. p. 170—172°, undepressed on admixture with an authentic specimen of 2,3,4-tri-*O*-methyl-D-galactosyl-*N*-phenylamine.

2,3,4-Tri-O-methyl-L-arabinose. The ether was converted to the phenylhydrazide of the corresponding acid which was recrystallised from ethyl acetate-*iso*propyl ether, m. p. 159—161°, undepressed on admixture with an authentic specimen of 2,3,4-tri-*O*-methyl-L-arabonic acid *N*-phenylhydrazide.

2,5-Di-O-methyl-L-arabinose. The ether was converted to the amide of the corresponding acid. After recrystallisation from ethyl acetate it had m. p. 133—134° in good agreement with values previously reported [19].

2,4,6-Tri-O-methyl-D-galactose. The ether was converted to the aniline derivative, m. p. 181—182°, undepressed on admixture with an authentic specimen of 2,4,6-tri-*O*-methyl-D-galactosyl-*N*-phenylamine.

2,3,4,6-Tetra-O-methyl-D-galactose and 2,3,5-tri-O-methyl-L-arabinose. After removal of a suitable amount for quantitative estimation and chromatography, the fraction containing these ethers (550 mg) was boiled with aniline in ethanol. Crystalline 2,3,4,6-tetra-*O*-methyl-D-galactosyl-*N*-phenylamine (250 mg), m. p. and mixed m. p. 197—198° separated from the reaction mixture. The non-crystalline portion was heated with aqueous 0.5 N sulphuric acid (10 ml) for 3 h, neutralised and concentrated to dryness. After removal of a small quantity for chromatography, the remainder was fractionated on a small cellulose column which had previously been impregnated with the lower phase of the *n*-butanol-water system and then washed with the upper phase which was also used as eluant. The top fraction afforded pure 2,3,5-tri-*O*-methyl-L-arabinose which was converted to the amide of the corresponding acid, m. p. 138—139°, in good agreement with values previously reported [19].

Chromatography on paper impregnated with dimethyl sulphoxide (DMSO). For an attempted detection of furanosidic galactose methyl ethers, fractions 120—136, 137—179, 180—245 and the residue were chromatographed according to the technique described by Wickberg [14]. 20 % DMSO in toluene was used for impregnation of the papers. Ethyl ether-DMSO 24:1 was used as mobile phase for tetramethylgalactose and trimethylarabinose ethers and benzene-DMSO 20:1 for trimethylgalactose and dimethylarabinose ethers. The following R_F-values were obtained when ether was used as mobile phase: 2,3,5,6-tetra-*O*-methyl-D-galactose 0.72, 2,3,5-tri-*O*-methyl-L-arabinose 0.64, and 2,3,4,6-tetra-*O*-methyl-D-galactose (two spots with trailing) 0.52 and 0.47. When benzene was used as mobile phase the chromatograms were run for 2.5 h giving the following migration lengths: 2,3,4-tri-*O*-methyl-D-galactose 2.2 cm, 2,4,6-tri-*O*-methyl-D-galactose 3.5 cm, 2,3,5-tri-*O*-methyl-D-galactose 4.4 cm, 2.5-di-*O*-methyl-L-arabinose 3.0 cm, and 2,3,4-tri-*O*-methyl-L-arabinose 10 cm. No furanosidic methylgalactoses were found in the fractions investigated.

The author is indebted to Dr. B. Lindberg for his keen interest in this work, to Miss Anita Myhrman for skilful assistance, and to *Fonden för Skoglig forskning* for financial support.

Studies on a Galactan from Norwegian Spruce Compression Wood (*Picea abies* Karst.)

HANS O. BOUVENG and HANS MEIER

Träkemiska avdelningen, Svenska Träforskningsintitutet, Stockholm, Sweden

A galactan, containing about 13 % uronic acid residues, was isolated from Norwegian spruce compression wood. Partial hydrolysis gave D-galactose and a number of neutral oligosaccharides, which were shown by paper chromatography and paper electrophoresis to belong to the same homologous series. The first member of this series was crystalline and identified as 4-*O*-β-D-galactopyranosyl-D-galactose. The neutral part of the polysaccharide must therefore be composed essentially of linear chains of 1:4-β-linked D-galactose residues.

It has been known for some time that compression wood on hydrolysis yields a much higher proportion of galactose than normal wood [1]. In the present investigation a polysaccharide containing galactose residues was isolated from compression wood from Norwegian spruce (*Picea abies* Karst.) and characterised. Acetone-extracted, milled compression wood, on extraction with hot water, yielded only a small fraction (A). However, a large amount of polysaccharide was isolated from the solution obtained on delignification of the wood meal with chlorite. This fraction (B) contained about half the galactose residues in the wood. Further extraction of the holocellulose successively with hot water, 14 % potassium hydroxide and 24 % potassium hydroxide containing 3 % boric acid [2] yielded fractions C, D and E, respectively. The results of these extractions are summarised in Table 1.

Fractions B and C were subfractionated by precipitation with barium hydroxide [3], yielding precipitates B I and C I, and soluble fractions B II and C II. From analysis of hydrolysates of these fractions (Table 1) it was evident that B I was a fairly pure galactan containing 12.9 % uronic acids and contaminated with small amounts of glucomannan. This fraction, representing about 44 % of the galactose residues originally present in the wood, was used for the present investigation.

Arabogalactans have been isolated from several coniferous woods, including spruce wood [4], and the possibility was considered that the present galactan might be derived from an arabogalactan, from which arabinose residues had been hydrolysed during delignification. It was found, however, that a larch

Table 1. Carbohydrate analyses of polysaccharide fractions from spruce compression wood.

	Yield g	Galactose %	Glucose %	Mannose %	Arabinose %	Xylose %
Spruce compression wood, extracted with acetone (Klason lignin: 38.8 %)	391.0	19.6	55.6	11.5	2.6	10.7

arabogalactan, after similar treatment, could be recovered unchanged. Furthermore the arabogalactans have highly branched structures, while the present polysaccharide gave a fairly strong film, characteristic for a polysaccharide with an essentially linear structure [5a]. The infrared spectrum of the polysaccharide showed a strong band at 886 cm^{-1}, indicating a β-pyranosidic structure [6].

Hydrolysis gave D-galactose and a number of acidic components, four of which were isolated in a fairly pure state by chromatography on thick filter paper. One of these acids was very probably galacturonic acid. A preliminary examination by paper chromatography and electrophoresis of hydrolysates of the other three acids indicated that in addition to galactose, one of them contained galacturonic acid and the other two glucuronic acid.

The possibility that part of the galacturonic acid originated from pectic acid was examined but attempted fractionation with cetyl-trimethylammonium hydroxide (CTA-OH), which is known to precipitate acidic polysaccharides [7], was not successful. A spectrophotometric investigation of the polysaccharide revealed the presence of about 9 % lignin; by treatment with chlorine and extraction with ethanolic ethanolamine this value was reduced to 1 %. The delignified material on electrophoresis on glass paper gave a very elongated spot with M_G-value ranging from about 0.45 to 0.97. This indicated that the sample was highly polymolecular but no distinct components could be detected. Even after delignification the sample could not be separated by fractionation with CTA-OH into a neutral galactan and a pectic acid. This corroborates the results of the hydrolyses mentioned above, that showed that at least part

of the uronic acid is bound to the galactan. Whether these residues are present on the galactan chains as single residues or as chains of pectic acid type, as was recently suggested by Aspinall *et al.*[8] for a galactan and a pectic acid from sisal hemp, could not be decided.

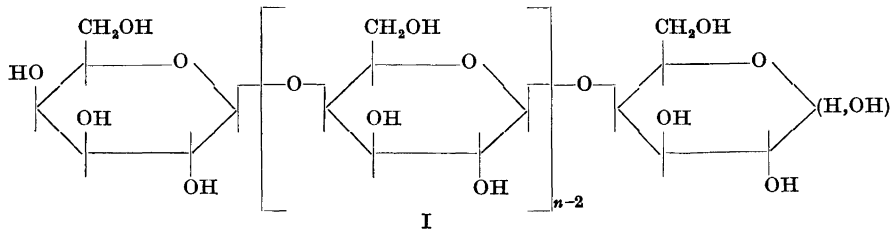
Since a nitrate ester of the galactan (N 11.8 %) was only partly soluble in acetone or butyl acetate, the osmotic pressure was determined on the sodium salt of the unsubstituted galactan in 0.1 N sodium chloride solution. The value obtained, $\overline{DP}_n$ 52, is however rather uncertain since the sample also contained lignin.

Partial hydrolysis of the galactan and removal of the acidic components left a number of neutral sugars, which were fractionated by carbon column chromatography. The first four components were completely separated but only a partial separation was obtained of four more components which followed

Table 2. R_F (solvent b) and M_G (borate buffer, pH 10) values of the neutral components.

Fraction No.	Component	R_F	M_G
34— 64	galactose	0.39	0.95
116—148	galactobiose	0.27	0.48
180—202	galactotriose	0.19	0.40
210—230	galactotetraose	0.14	0.35
232—246	galactopentaose	0.10	0.32
243—255	galactohexaose	0.07	0.31
253—270	galactoheptaose	0.05	0.30
262—281	galactooctaose	0.04	0.28

these. D-Galactose and a galactobiose were obtained crystalline. The galactobiose, $[\alpha]_D^{25}$ +67° showed the same paper chromatographic and electrophoretic data and the same X-ray diffraction pattern as the 4-*O*-β-D-galactopyranosyl-D-galactose isolated from white birch [9], a sample of which was obtained by courtesy of Dr. T. E. Timell. Further its melting point 210—212° was undepressed on admixture with Timell's sample. The R_F and M_G values of the sugars are given in Table 2. The R_M-values, plotted against n, give a straight line (Fig. 1), indicating that the sugars belong to a homologous series of the general formula I.



I

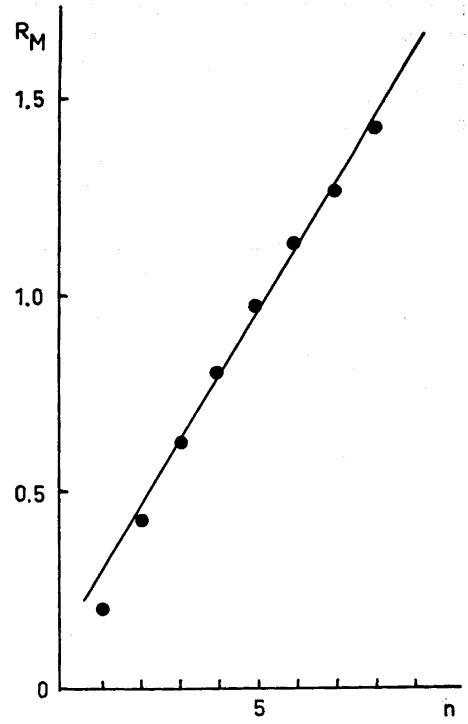


Fig. 1. Relation between R_M-values and chain length.

The electrophoretic data are also in agreement with this conclusion and each of the components on partial hydrolysis yielded all the lower oligosaccharides. Only traces of neutral oligosaccharides, other than those belonging to this series, were observed in the hydrolysate of the galactan, and the galactan must therefore be composed essentially of linear chains of β-1,4-linked D-galactose residues. Uronic acid residues are linked to some of these. The nature of these linkages and the question of whether some of the uronic acid residues are present in pectic acid chains must await further study.

The galactan from spruce compression wood is thus of similar type to that belonging to the pectic triad [5b]. A similar galactan has recently been obtained by Andrews *et al.*[10] from *Strychnos nux vomica* seeds and the isolation of 4-β-D-galactopyranosyl-D-galactose by Gillham and Timell [11] from a hydrolysate of white birch α-cellulose also indicates the presence of a polysaccharide of this type. The presence of pectic substances in the middle lamella of wood fibres has long been assumed, and it has recently been demonstrated [12,13], that the middle lamella of unripe aspen fibres and of pine tracheids contain a high percentage of polymers, built up from galactose, arabinose and galacturonic acids, which are the constituent sugars of the pectic triad. Although a large part of the galactans from the compression wood was extracted during the delignification, a considerable part remained undissolved even after treat-

ment with 14 % potassium hydroxide. This does not necessarily imply that the wood contains galactans that are structurally very different. The same difference has also been observed in spruce glucomannans [14], two extreme fractions of which showed some difference in DP but had eseentially the same chemical structure.

EXPERIMENTAL

Melting points are corrected. Optical rotations were determined in water: *c*, 1.5. The concentration of solutions was done under reduced pressure, at a bath temperature of about 40°.

Paper chromatograms were run on Whatman No. 1 and 3 MM papers, using the solvent systems (v/v):

a) Ethyl acetate-acetic acid-water, 3:1:3 (upper phase)

b) Ethyl acetate-pyridine-water, 2:1:2 (upper phase).

The method of Saeman *et al.*[15] was used for quantitative determinations. Paper electrophoreses were run on Schleicher and Schüll glass fibre papers and on Whatman No. 3 MM paper in 0.1 M borate buffer of pH 10 or 0.1 M acetate buffer of pH 4.

Isolation and fractionation of polysaccharides. Acetone-extracted wood meal (18—35 mesh) was extracted with hot water. Acidification and precipitation with ethanol, yielded fraction A. The wood meal was then delignified by the chlorite method at 60° and pH 4.7. The combined chlorite solutions were dialysed against running tap water for 11 days, acidified and precipitated with ethanol, yielding fraction B. The holocellulose was then extracted successively with hot water, 14 % potassium hydroxide and 24 % potassium hydroxide with 3 % boric acid. The latter two extractions were made under nitrogen, and the polysaccharides extracted were recovered by precipitation with ethanol (fractions C, D and E respectively).

Fractions B and C were dissolved in water and a saturated solution of barium hydroxide was added [3]. The material in the precipitates and in the supernatants was recovered, yielding fractions B I, C I and B II, C II respectively.

B I was delignified with chlorine and ethanolic ethanolamine, as described previously[16]. Treatment with cetyl-trimethylammonium hydroxide (CTA-OH) precipitated about 2/3 of the material. The precipitate and the material remaining in solution were isolated as described by Bouveng and Lindberg [17]. They had optical rotations of +80° and +55°, resp., the first fraction having a considerably higher content of uronic acid residues. Attempted fractionation of undelignified material with CTA-OH failed.

B I was readily soluble in water, $[\alpha]_D^{25}$ +57°. It contained about 9 % lignin [16] and 12.9 % of uronic acid residues [18], calculated as galacturonic acid. The $\overline{DP}_n$ was determined osmometrically as already described for an araboglucuronoxylan [16].

Hydrolysis of B I. A solution of B I (3 g) in 4 % sulphuric acid (800 ml) was kept at 120° for 1 h and then neutralised with barium hydroxide. The neutral solution was passed successively through columns of Dowex 50 (H^+) and Dowex 3 (free base) ion exchange resin. D-Galactose was recovered from the deionised solution. The acids were eluted from the anion exchange resin with 1 N ammonium hydroxide and the solution obtained was concentrated to a syrup. Electrophoresis and paper chromatography (solvent a) revealed the presence of galacturonic acid and of at least three acids with lower R_F values. The latter were separated by chromatography on thick filter paper. A chromatographic and electrophoretic examination of these acids after hydrolysis with 6 % sulphuric acid at 120° for 6 h indicated that one of them contained galactose and galacturonic acid while the other two were composed of galactose and, probably, glucuronic acid.

Partial hydrolysis of BI. A sample of BI (3 g) was heated with N sulphuric acid (200 ml) for 40 min on a steam bath, cooled and deionised. The solution was concentrated to 10 ml and then adsorbed on a carbon-Celite column (4 × 45 cm). Gradient elution with aqueous ethanol, 1 — 10 % (4 l) followed by 10—35 % (6 l) effected a separation of the components. The first four members, galactose to galactotetraose were completely separated. From the pentaose to the octaose they only partially separated, but relatively

pure top fractions were obtained of all components. The R_F- and M_G-values of the components are given in Table 2.

D-*Galactose* (346 mg), $[\alpha]_D^{25}$ +82°, m. p. 164—167°, undepressed on admixture of an authentic sample.

Galactobiose (278 mg), $[\alpha]_{25}^{D}$ +67°, m. p. 210—212°, alone or mixed with β-1,4-galactobiose, kindly supplied by Dr. T. E. Timell, Montreal. The X-ray diffraction pattern was identical with that reported by Gillham *et al.*[9] The M_G-value in borate buffer, 0.48, was, as expected, lower than the values reported for the corresponding β-1,3- and β-1,6-linked disaccharides [19] (0.69 and 0.84).

Galactotriose (213 mg), $[\alpha]_D^{25}$ +58°. Amorphous.

Galactotetraose (151 mg), $[\alpha]_D^{25}$ +53°. Amorphous.

Acknowledgment. The authors thank Docent B. Lindberg for his keen interest in this work.

Solvent Extraction of Metal Chelates

II. An Investigation on some 1-Phenyl-3-methyl-4-acyl-pyrazolones-5

BROR SKYTTE JENSEN

Danish Atomic Energy Commission, Risø, Denmark

The apparent mean complexity constants of various 1-phenyl-3-methyl-4-acyl-pyrazolones-5 with Be^{2+}, Mn^{2+}, Zn^{2+}, Pb^{2+}, UO_2^{2+}, La^{3+} and Th^{4+} in a chloroform-water system are compared and discussed.

A linear relationship between the logarithm of the distribution coefficient of an uncharged metal chelate and the logarithm of the distribution coefficient of the undissociated chelating agent is proposed, the slope of the line being characteristic of the metal ion in question.

The compounds investigated are compared with the more common extractive chelating agents with regard to capacity and separation possibilities in a chloroform-water system, and show promise as valuable reagents for analytical and radiochemical separations.

Among the extractive chelating agents the β-diketones, as a group, range among the most useful. Compounds such as acetylacetone and thenoyltrifluoroacetone are to be regarded as standard chemicals in laboratories performing analytical or radiochemical work.

Several investigations on the extractive properties of different chelating agents have been published previously [1,2].

In this paper the results of an investigation on a class of β-diketones, the 1-phenyl-3-methyl-4-acyl-pyrazolones-5, in a chloroform-water system will be reported.

The 1-phenyl-3-methyl-4-acyl-pyrazolones are readily accessible compounds [3]. Furthermore their physico-chemical constants such as acid dissociation constants, distribution coefficients *etc.* can be varied within a wide range by proper substitution in the molecules. Hence this class of compounds seems to serve well as a basis for a closer study of the influence of the physical and chemical properties of a chelating agent on its extractive and chelating behaviour.

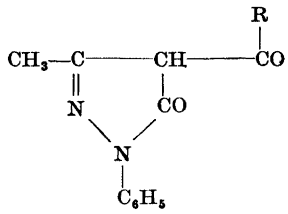

Fig. 1.

RESULTS AND DISCUSSION

The metal ion extractions have been investigated by means of a titration procedure [4], which has been described previously. By this method the chelating agent is characterized by a $pK_{a,E}$ value, which is the apparent pK_a value shown by an acid in the two-phase system under consideration. When only the undissociated acid HA is expected to distribute between the two phases with a distribution coefficient K_d, the following relation was shown to be valid [4,5].

$$pK_{a,E} = pK_a + \log\ (1 + K_d) \qquad (1)$$

where pK_a is the value of the acid dissociation constant in aqueous solution.

The chelating agent, metal ion, solvent systems are characterized by either the pH_{50} of 50 % extraction of the metal ion under consideration or by an apparent mean complexity constant K_{av}[4].

As K_{av} is a real constant of the system whereas pH_{50} depends on the actual concentrations involved, the former will be used to characterize the extractive behaviour of a specified metal ion in the system under consideration.

In the case where the uncharged species MA_N is the only one extracted with a distribution coefficient λ and a complexity product β_N, the following relation has been shown to be valid [4].

$$\log\ K_{av} = \tfrac{1}{N}\ \log\ \beta_N\ (1 + \lambda) \qquad (2)$$

where it is assumed that N is the maximum coordination number of the metal ion for the ligand.

By changing the pK_a value of a chelating agent by a proper substitution we generally also change the K_d value of a compound. Conversely it might be possible to change the K_d value of a compound without influencing the pK_a value to any larger degree.

In the acetyl-, propionyl-, butyryl-, valeryl- and capronyl substituted pyrazolones we have such a set of compounds where we expect the pK_a values to remain almost constant throughout the series.

In Fig. 2 is shown a plot of log K_{av} against $pK_{a,E}$ for these compounds and different metal ions. The points corresponding to a specified metal ion are seen to satisfy a linear relationship.

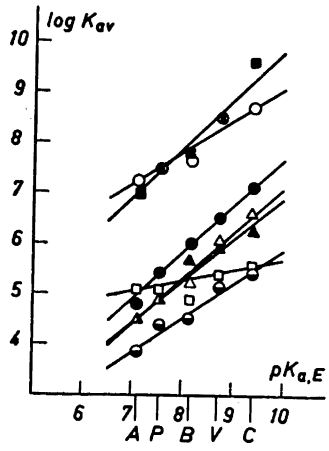

Fig. 2. The apparent mean complexity constants of the 4-acetyl (propionyl, butyryl, valeryl, capronyl) substituted pyrazolones (A, P, B, V, C) with different metal ions in a chloroform-water system plotted against the apparent $pK_{a,E}$ values of the chelating agents in this system.

■Th^{4+}, OUO_2^{2+}, ●Pb^{2+}, △Zn^{2+}, ▲La^{3+}, □Be^{2+}, ◒Mn^{2+}

As is well established [6] a relationship between $\frac{1}{N}\log\beta_N$ and pK_a for a series of related compounds can be expressed as:

$$\frac{1}{N}\log\beta_N = rpK_a + q \qquad (3)$$

This equation implies that for pK_a constant β_N will also be constant, and the plot in Fig. 2 should then be expected to represent a relationship between the distribution coefficients K_d and λ.

A linear relationship between the logarithm of the distribution coefficients as

$$\frac{1}{N}\log(1+\lambda) = s\log(1+K_d) + t \qquad (4)$$

when combined with (3) leads to (5)

$$\frac{1}{N}\log\beta_N(1+\lambda) = \log K_{av} = spK_{a,E} + (r-s)pK_a + (q+t) \qquad (5)$$

expressing the above observed linear relationship between $\log K_{av}$ and $pK_{a,E}$ when pK_a is assumed constant.

The behaviour of each metal ion in the above described systems may therefore be regarded as characterized by the combined action of eqns (3) and (4), and hence on the constants r, q, s, and t.

The magnitudes of s and t might be expected to depend much on the choice of organic solvent whereas r and q can be regarded as independent of this choice.

It is seen that the values of s in the order of magnitude of 0.85 to 1.00 are most common. For the uranyl and manganese ions values 0.60 to 0.65 are found and for the beryllium ion a value as low as 0.20.

That s and r are generally of different magnitude is exemplified in Fig. 3 which shows available data of $\log K_{av}$ for the beryllium ion and uranyl ion plotted against $pK_{a,E}$ for variously substituted pyrazolones. The change in

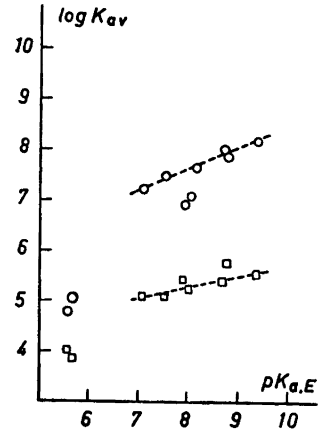

Fig. 3. The apparent mean complexity constants for variously substituted pyrazolones with the uranyl ion (O) and the beryllium ion (□) in a chloroform-water system plotted against the apparent $pK_{a,E}$ values of the chelating agents in this system. Data in Table 1.

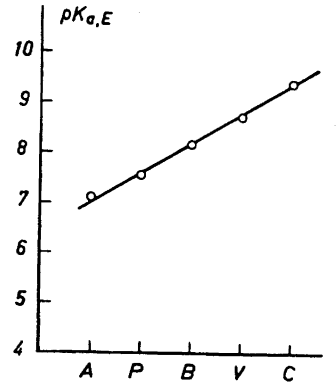

Fig. 4. The apparent $pK_{a,E}$ values of 4-acetyl (propionyl, butyryl, valeryl, capronyl) substituted pyrazolones (A, P, B, V, C) in chloroform plotted as a function of substitution.

$pK_{a,E}$ must be attributed to changes in either pK_a, K_d or in both. The plot contains the data used in the construction of Fig. 2, shown to lie on the dashed lines. In Fig. 3 no simple straight line relationship, apart from this, can be found.

To the author it seems to be too optimistic to expect the validity of eqn (5) to be strictly conserved in changing pK_a and K_d at will. No sharp definition of what is meant by "closely related compounds", can be set up. Many factors, such as steric hindrance, *etc.*, which may alter the complexity constants cannot be included in an equation like (5). Therefore an expression of general validity cannot be expected to be found.

It might be of interest to show the effect of substitution on the distribution coefficient K_d of a chelating agent.

In Fig. 4 is shown a plot of $pK_{a,E}$ in going from acetyl substitution on the pyrazolone through propionyl, butyryl, valeryl to capronyl substitution. A linear relationship is obvious. The slight alternating effect shown might be significant. As is to be expected, an increase of the aliphatic sidechain parallels an increase in lipophilic character of the chelating agent, and hence increases its distribution coefficient between an organic phase and water.

The data used in the construction of Figs. 2, 3 and 4 are collected in Table 1.

The empty places in the table indicate cases where the capacity of the systems has been exceeded by the concentrations used. This means that precipitations of chelates occurred during the titration, and hence no K_{av} values could be determined. The concentrations of chelating agents were 0.05 M, and those of the metal salts *ca.* 0.005 M, in the titration experiments [4]. With metals,

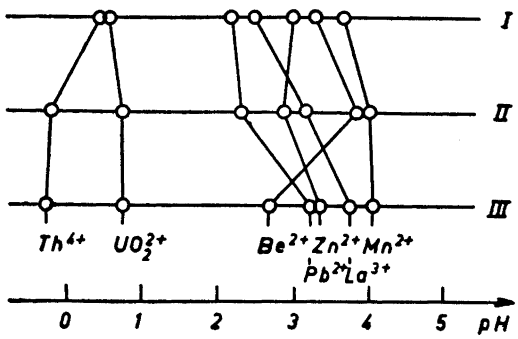

Fig. 5. The pH values of 50 % extraction of tracer amounts of different metals by 1 M solutions of 4-butyryl-1-phenyl-3-methyl-pyrazolone-5 (I) and 4-capronyl-1-phenyl-3-methyl-pyrazolone-5 (II) in chloroform are compared with those for thenoyltrifluoroacetone (III).

which form slightly soluble hydroxides, these were often precipitated when alkaline conditions were reached during the titration. These precipitations did not interfere with the determinations of the K_{av} values, as the pH changes of importance for this determination occurred in acid media.

For each system the pH_{50} of 50 % extraction of tracer amounts of the metal by 1 M solutions of the chelating agent in chloroform can be calculated by means of the following relation [1,4]

$$pH_{50} = pK_{a,E} - \frac{1}{N} \log \beta_N \ (1 + \lambda) \qquad (6)$$

This pH_{50} value is identical with the constant $\frac{1}{N} \log K$ used by Dyrssen to characterize the metal ion, chelate, solvent systems.

Inspection of Table 1 shows that, except for the beryllium ion, no large change in the pH_{50} is observed when varying the substituents in the 1-phenyl-3-methyl-pyrazolone-5 nucleus. Data for thenoyltrifluoroacetone (TTA) in chloroform, determined by the titration procedure, have been included in the table.

In Fig. 5 the pH_{50} values determined from eqn (6) for the butyryl- and capronyl-derivatives are compared with those of TTA.

CONCLUSIONS

It has been the aim of the present investigation to separate and clarify some of the various factors involved in metal ion extractions by chelating agents. The ultimate goal of such an investigation is to find chelating agents with properties which make them suitable for a large scale application, *e. g.* in the reprocessing of spent reactor fuels.

Chelating agents might be found which serve well in the laboratory where losses of chemicals and attainments of equilibria play a smaller role than in a large scale application, where a compound for those reasons might be useless.

Many polyvalent metal ions show a large degree of hydrolysis even in rather acid solutions, so a chelating agent capable of extraction of these metals from strongly acid solutions would seem to be desirable, as then problems of adsorption and colloid formation could be avoided. Fortunately the polyvalent metal ions are also prone to complex formation so they will possibly combine with a chelating agent even if it is slightly dissociated, *i. e.* in acid solution.

By increasing the acid strength of a chelating agent a correspondingly larger concentration of the complexing anion can be obtained in acid solutions. But, as is well established, the increase in acid strength of an acid, within a series of closely related compounds, parallels a decrease in the metal ion affinity of the anion. The net result of a variation of pK_a in a series of chelating agents might therefore well be only a slight change in the pH_{50} of a metal ion when going from one compound to the other. This has in fact been shown to be the case for the compounds discussed in this paper.

With regard to the separation possibilities, inspection of Fig. 5 shows, that in some cases the acylated pyrazolones are inferior; in other cases superior to

TTA. On the average the capronyl substituted pyrazolone seems to offer even better separation possibilities than TTA for the metal ions investigated.

As the capacities of the systems investigated are rather large, and the separation possibilities adequate for many purposes, the compounds show promise as extractive chelating agents, for analytical and radiochemical work.

Short Communications

Synthesis of Disodium S-[2-(methoxycarbonyl)ethyl] Phosphorothioate and a Barium Salt of S-(carboxymethyl) Phosphorothioic Acid

STIG ÅKERFELDT

Eastern Pennsylvania Psychiatric Institute, Philadelphia, Pennsylvania, U.S.A.

Recently [1] it was shown that trisodium phosphorothioate can be used for the preparation of a S-substituted phosphorothioic acid. Thus 2-bromoethylamine was found to react quantitatively with trisodium phosphorothioate in the presence of N,N-dimethylformamide to yield a sodium S-(2-aminoethyl) phosphorothioate.

To investigate the usefulness of trisodium phosphorothioate as a starting material for the preparation of other S-substituted phosphorothioic acids the reaction between this compound and acrylic acid methyl ester and bromoacetic acid has now been investigated. In both cases a rapid reaction was observed without the presence of a catalyst. Bromoacetic acid was found to react with trisodium phosphorothioate in a manner analogous to that described for 2-bromoethylamine [1], whereas acrylic acid methyl ester adds the phosphorothioate to the double bond forming a S-[2-(methoxycarbonyl) ethyl] phosphorothioate:

$$CH_2 = CHCOOCH_3 + H_2O + Na_3SPO_3 \rightarrow Na_2PO_3SCH_2CH_2COOCH_3 + NaOH$$

The addition takes place in contradistinction to Markownikoff's rule. This behaviour is similar to that observed by Dahlbom [2] in the diethylamine catalyzed reaction between acrylic acid and hydrogen sulfide.

The prepared substances are easily hydrolyzed by acids to the corresponding thiols. Thus these compounds constitute intermediates in a route for the preparation of thiols.

Materials and methods. Trisodium phosphorothioate was prepared according to Yasuda and Lambert [3]. Acrylic acid methyl ester (stabilized with *p*-methoxyphenol) and bromoacetic acid were products of Eastman Kodak Company. Phosphate determinations were performed according to Gomori [4] after hydrolysis of the samples in 1 M hydrochloric acid at 100° for 30 min. When barium ions were present, the hydrolysis was carried out in the presence of sulfuric acid and the precipitated barium sulfate was removed before analysis.

Melting points are corrected.

Preparation of disodium S-[2-(methoxycarbonyl)ethyl] phosphorothioate. 10 g (56 mmole) of trisodium phosphorothioate were dissolved in 75 ml of water and 10 ml (110 mmole) of acrylic acid methyl ester were added. The mixture was vigorously stirred* for 5 min after which time all phosphorothioate had reacted (no black precipitate obtained with silver ions). 200 ml of ethanol were added and the precipitated oil was separated. 100 ml of methanol and 100 ml of ethanol were added to the oil in the order indicated under stirring. The precipitated substance was filtered off and dried in vacuum. Yield 10.2 g (68 %). (Found: C 17.6; H 3.7; P 11.4. Calc. for $Na_2PO_3SCH_2CH_2COOCH_3$, 1.5 H_2O (271.16): C 17.7; H 3.7; P 11.4.)

Preparation of barium S-(carboxymethyl) phosphorothioate. 9.0 g (50 mmole) of trisodium phosphorothioate were dissolved in 60 ml of

* The methoxycarbonyl group was found to be easily hydrolyzed when the reaction was carried out at temperatures above *ca.* 25°.

water and 7.7 g (55 mmole) of bromoacetic acid were added. The solution was stirred for 15 min at 0°. After that time all the phosphorothioate had reacted. A solution of 20 g (82 mmole) barium chloride dihydrate and 2.2 g (55 mmole) of sodium hydroxide in 75 ml of water was then added under stirring at 0°. The precipitate was filtered off and washed with 50 ml of ice cold water and with 100 ml of ethanol. 13.1 g (61 %) of substance were obtained after drying in vacuum. (Found: C 5.5; H 1.7; P 7.1; Ba 48.5. Calc. for $(BaPO_3SCH_2COO)_2Ba,6H_2O$ (858.34): C 5.6; H 1.9; P 7.2; Ba 48.0.) The prepared substance hydrolyzes spontaneously upon storage.

Acid hydrolysis of the prepared compounds. 7.61 mmole of $Na_2PO_3SCH_2CH_2COOCH_3$, 1.5 H_2O were hydrolyzed for 30 min in 50 ml of 1 M hydrochloric acid under nitrogen at 100°. Hydrogen sulfide or phosphorothioate were not detected after hydrolysis. The hydrolysate consumed 7.46 matom of iodine as titrated with a standardized iodine solution (98 % of theoretical amount). The oxidized hydrolysate was extracted with peroxide free ethyl ether giving 0.8 g of 3,3'-dithiodipropionic acid, m.p. 154—155° (from 4-methyl-2-pentanone), undepressed by admixture with an authentical sample.

3.37 mmole of $(BaPO_3SCH_2COO)_2Ba$, $6H_2O$ were hydrolyzed as described above. The hydrolysate consumed 6.41 matom of iodine (95 % of theoretical amount). Hydrogen sulfide or phosphorothioate could not be detected in the hydrolysate, which was then tested for glycolic acid by the two tests described by Feigl [5]. These were both negative. The thiol present in the hydrolysate was identified as mercaptoacetic acid by the paper chromatographic method recently described [6]. For chromatography the solvents Nos. 3 and 4 in Ref.[6] were used.

The Isolation of S-Methylcysteinesulphoxide and *S-n*-Propylcysteinesulphoxide from Onion *(Allium cepa)* and the Antibiotic Activity of Crushed Onion

ARTTURI I. VIRTANEN and E. J. MATIKKALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Fresh homogenized onions *(Allium cepa)* have a strong antimicrobial effect. 50 to 100 mg of crushed onions in 1 ml of nutrient solution inhibits the growth of the *Staphylococcus aureus* strain used in our experiments completely, and 15 mg still has a retarding effect on the growth. When the enzymes in whole onions *(Allium cepa)* are inactivated using different methods (heating to about 100°C in a sealed glass tube, or keeping in boiling ethanol for a shorter time, or homogenizing with ethanol after freezing with CO_2 ice) the antimicrobial effect of the extracts is again very low. A total inhibition is not then yet achieved with extracts corresponding to 1 g of onion in 1 ml of nutrient solution. Most of the antimicrobial activity is thus formed in onion through enzymatic reactions.

In a lecture the senior author [1] earlier mentioned that according to investigations in this laboratory onion contains both S-methylcysteinesulphoxide (MCSO) and S-*n*-propylcysteinesulphoxide (PCSO) from which the corresponding thiolsulphinates are formed enzymatically. These have a strong antibiotic effect against many microbes. This effect is generally somewhat weaker than that of allylthiolsulphinate formed from S-allylcysteinesulphoxide present in garlic *(Allium sativum)*, but nevertheless of the same order of magnitude [2].

PCSO was isolated from onion in the following way: 3 kg of chilled onions grown in Finland were extracted with cold methanol (added methanol + the water contained in the onion = 80 % methanol). The free amino acids were separated on an Amberlite IR-120 column and fractionated with water on a 2.2 × 95 cm column filled with Dowex 1 resin (the resin in acetate form was washed with water).

When 100 ml of solution had been let through, fractions of 8 ml each were taken.

water and 7.7 g (55 mmole) of bromoacetic acid were added. The solution was stirred for 15 min at 0°. After that time all the phosphorothioate had reacted. The Isolation of S-Methylcysteinesulphoxide and *S-n*-Propylcysteinesulphoxide from Onion *(Allium cepa)* and the Antibiotic Activity of Crushed Onion

ARTTURI I. VIRTANEN and E. J. MATIKKALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Fresh homogenized onions *(Allium cepa)* have a strong antimicrobial effect. 50 to 100 mg of crushed onions in 1 ml of nutrient solution inhibits the growth of the *Staphylococcus aureus* strain used in our experiments completely, and 15 mg still has a retarding effect on the growth. When the enzymes in whole onions *(Allium cepa)* are inactivated using different methods (heating to about 100°C in a sealed glass tube, or keeping in boiling ethanol for a shorter time, or homogenizing with ethanol after freezing with CO_2 ice) the antimicrobial effect of the extracts is again very low. A total inhibition is not then yet achieved with extracts corresponding to 1 g of onion in 1 ml of nutrient solution. Most of the antimicrobial activity is thus formed in onion through enzymatic reactions.

In a lecture the senior author [1] earlier mentioned that according to investigations in this laboratory onion contains both S-methylcysteinesulphoxide (MCSO) and S-*n*-propylcysteinesulphoxide (PCSO) from which the corresponding thiolsulphinates are formed enzymatically. These have a strong antibiotic effect against many microbes. This effect is generally somewhat weaker than that of allylthiolsulphinate formed from S-allylcysteinesulphoxide present in garlic *(Allium sativum)*, but nevertheless of the same order of magnitude [2].

PCSO was isolated from onion in the following way: 3 kg of chilled onions grown in Finland were extracted with cold methanol (added methanol + the water contained in the onion = 80 % methanol). The free amino acids were separated on an Amberlite IR-120 column and fractionated with water on a 2.2 × 95 cm column filled with Dowex 1 resin (the resin in acetate form was washed with water).

When 100 ml of solution had been let through, fractions of 8 ml each were taken.

Fractions 15—42 were combined, evaporated, and the extract obtained was fractionated on a column (3 × 105 cm) containing Dowex 50 resin in the H-form (1 N HCl). Fractions of 20 ml each were taken. PCSO emerged in fractions 172—218 together with some other amino acids. These fractions were combined, the amino acids separated in an Amberlite IR-120 column and refractionated in a 3.3 × 80 cm column containing Dowex 50 resin in equilibrium with 1.5 N HCl. 470 ml of the eluant emerging first from the column were discarded, then fractions of 20 ml each were taken. PCSO emerged in fractions 205—230. These fractions were combined and the amino acids separated in an Amberlite IR-120 column. Besides PCSO the solution still contained valine. The solution, freed from ammonia, was therefore fractionated on a cellulose powder column (3.2 × 34 cm) using water-saturated butanol as solvent. PCSO emerged in pure form in fractions 67—85 (12 ml/30 min). It was crystallized from a water-acetone solution. The crystals (30 mg) were small needles. When this substance and synthetic PCSO were run on a two-dimensional chromatogram (butanol-acetic acid-water and phenol-water-NH_3) the spots covered each other completely. (Found: C 40.63; H 7.71. Calc. for $C_6H_{13}O_3NS$: C 40.20; H 7.31.)

The thioether formed from PCSO on reduction was also isolated in crystalline form. On paper chromatographic comparison with synthetic S-*n*-propylcysteine both compounds showed to be identical. (Found: N 8.60. Calc. for $C_6H_{13}O_2S$: N 8.58.)

In order to ascertain that the PCSO isolated from onion is an *n*-propyl and not an *iso*-propyl derivative, S-*iso*-propylcysteine was prepared from L-cysteine and *iso*-propylbromide according to Stoll and Seebeck [3]. It was further oxidized with H_2O_2 to the sulphoxide. When comparing the travelling of PCSO with that of the obtained S-*iso*-propylcysteinesulphoxide on a one-dimensional paper chromatogram (solvent butanol-acetic acid-water), the *iso*-propyl compound was found to move so much slower than PCSO that when the substances had reached the middle of a Whatman sheet the spots separated from each other. Synthetic S-*n*-propylcysteinesulphoxide moved with the same speed as the PCSO isolated from onion. On the basis of this the structure of PCSO can be established as S-*n*-propylcysteinesulphoxide.

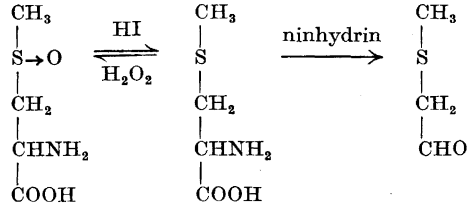
$$CH_3 \cdot CH_2 \cdot CH_2 \cdot SO \cdot CH_2 \cdot CHNH_2 \cdot COOH \underset{H_2O_2}{\overset{HI}{\rightleftharpoons}} CH_3 \cdot CH_2 \cdot CH_2 \cdot S \cdot CH_2 \cdot CHNH_2 \cdot COOH$$

S-*n*-propylcysteinesulphoxide (PCSO) or dihydroalliin

S-*n*-propylcysteine (PCS)

The isolation of MCSO. A methanol extract was prepared from 3 kg of onions in the same way as when PCSO was isolated. Amino acids were also separated on an Amberlite IR-120 column as before. The first fractionation was performed on a Dowex 1 resin (column 2.5 × 83 cm) in 0.5 N acetic acid form. When 150 ml of the eluant had emerged, fractions of 9 ml/20 min were taken. Fractions 3—30 were evaporated and then fractionated with a solvent of butanol-acetic acid-water on a cellulose powder column (5.7 × 80 cm). Because of the thick syrupy consistence the evaporated solution had to be placed on the column in 100 ml, and hence the separation of amino acids was not good. Fractions which contained MCSO and *cyclo*-alliin [4] were evaporated and fractionated on Dowex 50 resin in 0.5 N HCl form (column 3.1 × 112 cm). Fractions of 10 ml/25 min were first taken and then 350 fractions of 15 ml/20 min, *i. e.* 570 fractions in all. The solvent was still 0.5 N HCl. MCSO emerged in pure form in fractions 419—445. It was crystallized with ethanol from water solution. Yield 149 mg. It was identified by paper chromatography with S-methylcysteinesulphoxide which had earlier been isolated in this laboratory from *Capsella bursa pastoris* and chemically characterized. (Found: N 9.23. Calc. for $C_4H_9NSO_3$: N 9.27.) *Cyclo*alliin emerged in fractions 529—560. 4.6 g were obtained as crystals.

The structure of MCSO isolated from onion was confirmed by first reducing it to S-methyl-



S-Methylcysteine-sulphoxide S-Methyl-cysteine Methylthio-acetaldehyde

cysteine and oxidizing this with ninhydrin to S-methylthioacetaldehyde according to Virtanen *et al.*[5]

30 mg of MCSO were added to 1 ml of 57 % HI. The solution was allowed to stand for 3 h after which a small amount of water was added. After extraction with ether the water solution was passed through a column containing Dowex 1 in acetate form (1.3 × 13 cm, resin 200—400 mesh). S-Methylcysteine was eluted with 100 ml of water. The solution was evaporated to dryness *in vacuo*, and the residue washed with 20 ml into a distillation flask which contained 3 g of KH_2PO_4, 4.5 g of NaCl, and 75 mg of ninhydrin. 10 ml of water was added, and the mixture was distilled with steam for 40 min. The distillate, 380 ml, was taken up in 20 ml dimedone solution. The crystals formed during 24 h were separated by filtration. They were recrystallized two or three times from an alcohol-water solution. The crystals melted at 126—127°C. The m. p. of the methylthioacetaldehyde, obtained in a similar way from synthetic S-methylcysteinesulphoxide, was the same, and so was the mixed m. p. The IR-spectra also confirmed the identity of the compounds.

Semi-quantitative estimation of MCSO and PCSO. 100 g of chilled, peeled onions were extracted in 85 % methanol. After 24 h the extract was filtered, and the procedure was repeated twice. The residue was pressed as dry as possible. The combined methanol solutions were passed through an Amberlite IR-120 column, and amino acids were eluted from the resin by 1 N ammonia. Two-dimensional chromatograms were run (butanol-acetic acid-water and phenol-water-NH_3) with different amounts of the evaporated extract. Parallel chromatograms were run with different concentrations of MCSO and PCSO. By comparing the colour of the spots it was possible to calculate that the onions used had contained about 50 μg of PCSO per 1 g of fresh material. The error of determination hardly exceeds ± 10 %. Using the above solvents MCSO travels in much the same way as does glutamine. Another solvent system had therefore to be used in the determination of MCSO. Substituting butanol-acetic acid-water with the solvent butanol-benzylalcohol (1:1)-water, the time of running being 9 days, MCSO could be separated from glutamine. 200 μg of MCSO were then found in 1 g of fresh onion. In another batch of onion 60 μg of PCSO and 240 μg of MCSO were found.

The financial support of the *Rockefeller Foundation* is gratefully acknowledged. Thanks are due to Mrs. Anneli Lehtinen for skilful technical assistance.

Microbiological Activity of Some Mixed Disulfides of Thiamine for *Lactobacillus fermenti*

Z. G. BÁNHIDI

Wenner-Gren Institute for Experimental Biology, University of Stockholm, Sweden

Thiamine, its ortho-, and pyrophosphate form (as well as other phosphorylated forms) are equally active for growth promotion of *Lactobacillus fermenti* strain 36 (ATCC 9338) in the absence of cystine and cysteine. [1,2] Under these conditions, however, the homomeric disulfides of thiamine and its phosphorylated derivatives will not be utilized by the bacterial cells. Addition of cysteine, ascorbic acid and other reducing agents or reduction of the disulfides by heating is necessary for these substances to satisfy the absolute requirement of thiamine for *L. fermenti*. *

Our results obtained by growth analysis in living cells, were in full agreement with reports based on enzymatic model systems, in which the homomeric disulfide of thiamine pyrophosphate (cocarboxylase) was found to require activation by reduction for function as coenzyme during anoxidative or oxidative pyruvate-decarboxylation [3-5]. Both the data obtained with our growth test and those of the enzymatic model system must be considered as *per se* counter-evidences against a sulfhydryl-disulfide function of thiamine in the cells, according to

$$2\ T_{ol} \rightleftharpoons T\text{-}SS\text{-}T \quad \ldots\ldots\ldots\ a$$

or more correctly

$$2\ TPP_{ol} \rightleftharpoons TPP\text{-}SS \quad \ldots\ldots\ldots\ b$$

Nevertheless, none of these results exclude the probability that thiamine or its phosphates function as carriers of alien sulfhydryl compounds by forming heteromeric mixed disulfides in connection with some physiological process. Extended work on the biological effect of the mixed disulfides was justified because of the discovery of formation of several allithiamine derivatives in the garlic [6] and the report on the superiority of thiamine propyl disulfide toward thiamine in the treatment of some thiamine deficiency symptoms [7]. For the test, our growth system was used instead of enzymatic models, partly because the mixed disulfides of thiamine are more readily available than those of thiamine pyrophosphate, and because the utilization of a substituted nutrient by a homogeneous population of growing cells offers more general information than an isolated enzymatic model system, which has unfortunately not yet reached the desirable purity.

Experimental. The term »utilization» of some substances related to thiamine was intermittently used by us to denote the growth promoting ability of a compound in a defined medium. In this sense the compound in question was considered as a nutrient and not as an established metabolite. We tacitly assume, however, that the inability of the *L. fermenti* cells to grow on a certain thiamine derivative might depend on several different reasons, *e. g.*, on the cell wall barrier, or on the lack of enzymes

Table 1.

* Numerical values are means of two turbidimetric readings at each concentration and are expressed as per cent of light transmitted at 5 950 Å.

* *Abbreviations* not explained in the legend of Fig. 1.: The thiol form of thiamine (or its derivatives) T_{ol}; the thiazole form of the same, T_{tz}; the homomeric disulfide of thiamine T—SS—T, and that of thiamine pyrophosphate TPP—SS, while cocarboxylase is denoted as TPP.

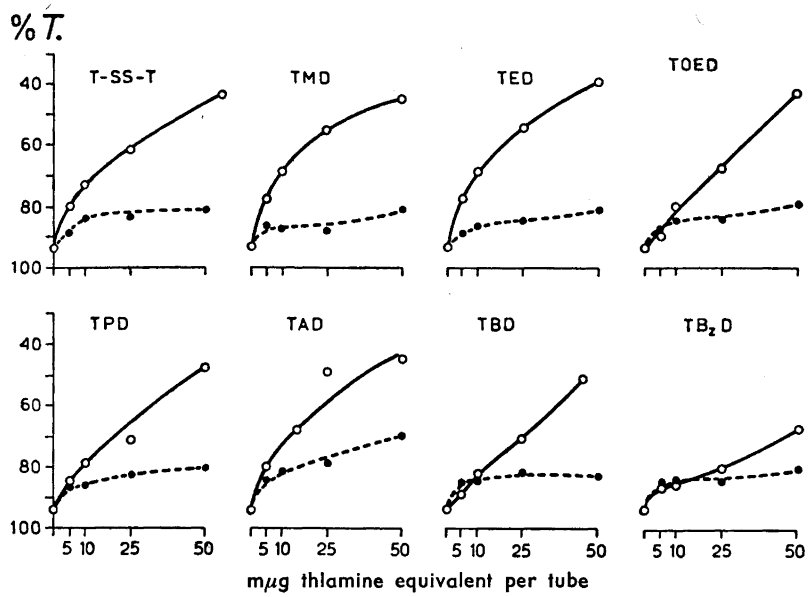

Fig. 1. Growth test of different disulfide derivatives of thiamine with *Lactobacillus fermenti* strain 36 on fluid medium. Abbreviations not occurring in the text are in accordance with the terminology proposed by Matsukawa [13], *viz.*, TMD, thiamine methyl disulfide; TED, thiamine ethyl disulfide; TOED, thiamine hydroxyethyl disulfide; TPD, thiamine propyl disulfide. TAD, thiamine allyl disulfide; TBD, thiamine butyl disulfide; TB_ZD, thiamine benzyl disulfide. Dotted lines represent test in absence of cysteine and full lines were used when 500 μg cysteine was added to each ml of the medium. All thiamin derivatives were added aseptically to the autoclaved medium in order to protect the disulfides from reduction. Growth was measured turbidimetrically in dublicates, and expressed as per cent transmittance (% *T.*).

able to convert the disulfides to a form available for thiaminokinases.

With these possibilities in mind we tried to split the homomeric disulfide of thiamine with the aid of cell free extracts of *L. fermenti* as well as with large amounts of living bacterial cells.

One day old culture of *L. fermenti*, grown on a complete medium (micro inoculum broth, Difco) was washed twice in saline, frozen in acetone-dry ice mixture and subjected to desintegration, according to Hughes [6]. Disruption of the cells was registered microscopically. Ten mg of the homogenized cell mash was Seitz-filtered and incubated with one mg of T—SS—T at 37°C for 30 min in 1/15 M phosphate buffer at different pH's, as seen in Table 1.

Intact washed cells were also subjected to incubation with T—SS—T for comparison. In each case 10 mg wet cell sediment was used as starting material and combined with 1 mg T—SS—T in 5 ml buffer solution. Similar batches were supplemented with 400 μg cysteine, for controls. The batches, containing intact cells, were Seitz-filtered after incubation in order to ensure aseptic test. Activity tests with *L. fermenti* were performed, according to former experiments on fluid media lacking cysteine [9,2] by using suitable dilutions of the above preparations. The results show that neither the cell mash nor the intact cells were able to liberate thiamine activity from T-SS-T under conditions where cysteine easily performed the activation of T—SS—T to growth factor for *L. fermenti*.

An enzymatic test which shows inability of cells or cell free preparations to perform an expected reaction must be considered cautiously since physical conditions might have been unfavorable during the experiment. In the present case, however, we are dealing with a substrate (T—SS—T) which is labile enough

at the conditions used (at least at slightly basic pH) to be easily converted to free thiamine as was shown by controls containing cysteine.

As an extension of the enzymatic work, *L. fermenti* was cultivated on the synthetic basal medium supplemented with thiamine sufficient for more than half-maximum growth. Cells were then harvested and washed twice by centrifuging and Seitz-filtration in order to make available the thiamine factors of the bacteria for analysis. Batches of the cell mash were chromatographed on paper in several solvent systems and afterwards developed bioautographically according to the procedure detailed in the subsequent paper [10]. The bioautographs of the bacterial cell mash revealed the presence of four distinct spots tentatively identified as thiamine pyrophosphate, thiamine orthophosphate, free thiamine-thiazole and a minor fraction (less than about one tenth of any of the former) behaving in all respect as T−SS−T.

An explanation for the contradiction between the cell mash experiment showing inability to split T−SS−T and the bioautographic analysis showing the presence of minute but distinct zones of T−SS−T in the cell mash, would be the theory that T−SS−T represents the end product of the thiamine/cocarboxylase metabolism.

In the hope of obtaining more information about the possible role of the disulfides of thiamine in the cells, experiments were performed with some mixed disulfides of thiamine.

The disulfides of thiamine subjected to microbial growth test were T−SS−T (prepared according to Zima *et al* [11] and seven different allithiamine homologues prepared by and obtained from Matsukawa [12,13]. Description of the compounds, explanation of abbreviations and the results obtained are given in Fig. 1. The conditions of the tube test for growth of *L. fermenti* on a chemically defined basal medium as well as details of cultivation of stock culture and the technique of turbidimetric readings were the same as in our earlier work [9,2]. Each substance was tested in both cysteine free medium and with added cysteine. Under these conditions thiamine was active in both cases giving quantitative results rather similar to that of T−SS−T with cysteine. (For this reasons thiamine values were left out from Fig. 1.) On the other hand only six of the thiamine alkyl disulfides supported the growth of *L. fermenti* to an extent comparable with T−SS−T on molar basis. All these derivatives required, however, activation by cysteine in a similar way as T−SS−T, demonstrating that the mixed disulfides of thiamine tested in this work, are not directly utilizable by the cells of *L. fermenti*. Thiamine benzyl disulfide showed very little increase in activity after addition of cysteine. This suggests the presence of a structural hindrance in the molecule for splitting the disulfide linkage with cysteine or for replacement of the benzylmercaptan with the same.

Conclusion. Intact or disrupted cells of *Lactobacillus fermenti* are probably not able to liberate thiamine from thiamine disulfide

Several different alkyldisulfides of thiamine behave similary to the homomeric disulfide of thiamine in a growth test with *L. fermenti* and serve as nutrient for the cells only after activation by cysteine or other reducing agents in contrast to thiamine, which supports growth without activation. Thiamine benzyl disulfide resists cysteine activation.

Thiamine Pantetheine Disulfide as a Microbial Growth Factor

Z. G. BÁNHIDI

Wenner-Gren Institute for Experimental Biology, University of Stockholm, Sweden

In connection with our study on the nutritional requirements of *Lactobacillus fermenti*, strain 36 (ATCC 9338), a growth enhancement with thiamine was observed, when yeast extract or pantethine was added to the basal medium [1]. The stimuli could, however, be compensated by addition of cysteine or other reducing agents to the medium. *

More detailed investigation showed later that both the homomeric disulfide of thiamine and several mixed disulfides of the allithiamine type are inactive as growth factors for *L. fermenti*, except when reduced or treated with cysteine [2-4]. It remained to establish whether a postulated thiamine pantetheine disulfide could account for the observed enhancement with pantethine. If so, this would require rather different physiological aspects for the thiamine pantetheine derivative when compared with the allithiamines.

Experimental. The mixed disulfide of the thiol form of thiamine and pantetheine (the mercaptoethanolamine of pantothenic acid) was first mentioned by Sahashi *et al.*[5] who observed a new spot on the chromatograms of a mixture of the two vitamins. It was presumed that the two compounds form a mixed disulfide:

$$\text{T}-\text{SS}-\text{T} + 2\,\text{LBF}-\text{SH} \rightleftharpoons 2\,\text{T}-\text{SS}-\text{LBF} \quad \ldots a$$

We prepared T−SS−LBF through incubation of equimolar amounts of the parent compounds (on sulfhydryl basis) in a 1/15 M phosphate buffer solution of pH 7.5−8.5 for 20−30 min at 37°C.

T−SS−T was prepared according to Zima *et al.*[6] After repeated recrystallization from aqueous acetone the product was tested bioautographically for purity as below.

Commercial pantethine (Nutritional Biochemicals Inc.) was reduced to LBF−SH by forcing the solution of 100 mg LBF−SS in 5 ml 0.5 N H_2SO_4 through a 0.8 × 12 cm column of freshly amalgamated 20 mesh zinc granules (Jones reductor) with the aid of nitrogen gas, according to the reduction of coenzyme-A by Buyske *et al.*[7]

In analogy with the work of Matsukawa and Yurugi [8] on the thiamine cysteine mixed disulfides we prepared T−SS−LBF also through

$$2\,\text{T}_{\text{ol}} + \text{LBF}-\text{SS} \rightleftharpoons 2\,\text{T}-\text{SS}-\text{LBF} \quad \ldots\ldots b$$

Chromatographic analysis and growth test gave similar results with both preparations according to equations *a* and *b*, in agreement with the presumed analogy.

The reaction mixtures were subjected to paper chromatographic separation in several solvent systems (*viz.*, *n*-butanol : water : acetic acid 125:125:30; *n*-butanol: ethanol : acetic acid:water 4:1:1:10; *iso*-butanol: pyridine : water 3:2:5; and *tert.*-butanol : water : methylethylketone 2:2:1). Ascending chromatograms were carefully dried in hot air current, and developed bioautographically by laying on the surface of large agar plates in which the basal medium was completed with 2 % agar and seeded with a heavy suspension of *L. fermenti*. The technique was otherwise similar to our agar cup plate method described elsewhere [9].

Separation of the T−SS−T reaction mixture resulted in more than two spots as shown in the corresponding columns of Fig. 1. This was also the case with the other solvent systems used. Among the spots the factor next to the fastest moving component was identified as T−SS−T by its R_F, and by its disappearance on the bioautograms which were developed with a basal medium lacking cysteine. Under these conditions all components other than T−SS−T were active including the fastest moving factor. Thus the fastest moving factor behaved differently as the starting materials used for the synthesis, or as the other predictable compounds of known structure (*e. g.*, T−SS−T) and must be considered to be the actual T−SS−LBF complex.

Meanwhile, the slowest moving spots of columns II and III in Fig. 1, are evidently representing the thiol form of thiamine since this appears only at slightly alkaline pH according to the equilibrium:

$$\text{T}_{\text{tz}} \rightleftharpoons (\text{T}_{\text{pseudobase}}) \rightleftharpoons \text{T}_{\text{ol}} \quad \ldots\ldots\ldots c$$

Considering eqn. *c* as well as eqns. *a* and *b*, the partition in column III reflects the simultaneous presence of all factors of the three equilibria.

* *Abbreviations:* T, T_{tz}, T_{ol} and T−SS−T denote thiamine, the thiazole (amino) form of thiamine, the thiol form of the same, and the homomeric disulfide form. For pantethine and pantetheine, respectively, the letters LBF−SS and LBF−SH were applied in view of the early name of these factors (Lactobacillus Bulgaricus Factor) while the mixed disulfide of thiamine with pantetheine is represented with T−SS−LBF.

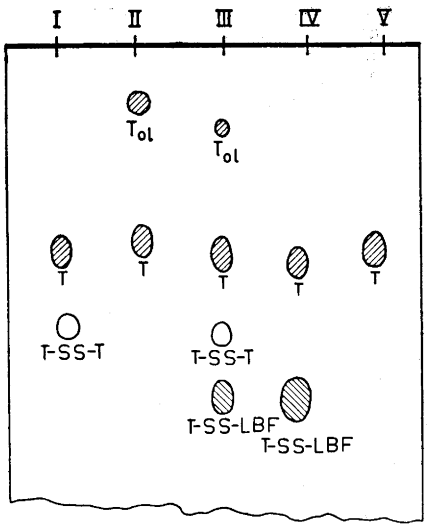

Fig. 1. Selective bioautography of thiamine pantethein disulfide (T—SS—LBF). Ascending chromatography on Whatman No. 1 paper in *n*-butanol : ethanol : acetic acid : water 4:1:1:10 solvent system (upper layer). Bioautographic development was made with *L. fermenti* 36 by using media with or without cysteine. Unshaded zones do not support growth in absence of cysteine.

Attention should be paid in this connection to the fact that in the agar plate bioautography, T—SS—LBF is active for *L. fermenti* both in presence and in absence of cysteine. This is also the case with the thiol form of thiamine, the activity of which could not be decided with the tube test [3].

The fastest moving spot of T—SS—LBF marked in column III of Fig. 1, was subjected to elution with ethanol water mixture and rechromatographed. Column IV of Fig. 1 shows that thiamine will be easily liberated from the eluate despite the mild conditions of the elution and that of the chromatographic procedure. Also slight acidity or addition of traces of cysteine will shunt reaction *b* to the left.

Batches of the eluate of the T—SS—LBF spot were subjected to quantitative test with the agar cup plate method and the tube method using *L. fermenti*. Analysis in absence and in presence of cysteine in the medium showed that T—SS—LBF i fully active as a growth factor (tube test in Fig. 2) in contrast to our experience with the homomeric and heteromeric disulfides of thiamine [4]. It is, however, not decided at present whether the thiamine like activity of thiamine pantetheine disulfide can be considered as a physiological peculiarity or should be attributed to the chemical lability of this compound.

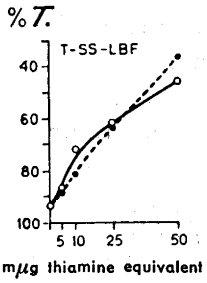

Fig. 2. Quantitative test of thiamine pantetheine disulfide with *L. fermenti* 36 on fluid media with 500 μg cysteine per ml and without cysteine (the latter marked with dotted line). Growth was measured turbidimetrically in dublicates at 5 950 Å and is expressed in per cent transmittance (% *T.*).

Conclusion. Thiamine pantetheine disulfide functions as a growth factor for *Lactobacillus fermenti* similarly to the thiazole and thiol forms of thiamine under experimental conditions which are unfavourable for the utilization of thiamine disulfide or allithiamine analogues.

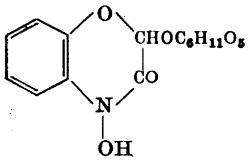
The Precursors of 6-Methoxybenzoxazolinone in Maize and Wheat Plants, their Isolation and Some of their Properties

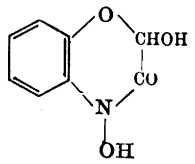
ÖRN WAHLROOS and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In preliminary papers from this laboratory it was reported that 6-methoxybenzoxazolinone (MBOA) and benzoxazolinone (BOA), which were earlier isolated from wheat and maize plants (MBOA) and from rye plants (BOA), were formed from precursors in these plants [1]. A glucoside $C_{14}H_{17}O_9N$ was isolated in crystalline form from rye seedlings after inactivation of the enzymes present in intact plants. From this glucoside an aglucone $C_8H_7O_4N$ was enzymatically formed when fresh plants were crushed [2]. For the glucoside and the aglucone the following structures have been presented[3] by Virtanen and Hietala[3].



Glucoside
$C_{14}H_{17}O_9N$



Aglucone
precursor of BOA
2,4-dihydroxy-1,4-benzoxazin-3-one

The glucoside

The isolation of the glucoside from maize seedlings. 2.8 kg fresh weight of maize seedlings (grown in a greenhouse, about 10 days old, plants about 10 cm high, green parts) were put into 7 l of boiling water, keeping the temperature of the water above 80°C. When all seedlings were added (about 15 min), the mixture was cooled with tap water. It was filtered, the seedlings were homogenized in water of room temperature and filtered. The combined filtrates were evaporated *in vacuo* to about 0.5 l. The concentrate was extracted six times with *n*-butanol. The butanol extract was evaporated *in vacuo*, water was added to 0.5 l, and the suspension was extracted five times with ether. 56 g of carbon were added to the water phase (the carbon had previously been washed with 2 N hydrochloric acid and water, deactivated with cyanide according to Schramm and Primosigh [4] and washed with water). It was mixed for 30 min and filtered (washed cellulose powder as filter aid). The carbon was washed on the filter with 0.5 l of distilled water, and was eluted with 1.5 l of a mixture containing benzene, methanol, and water 3:7:1 v/v. The eluate was evaporated to dryness *in vacuo*, the residue dissolved in a small amount of water, and chromatographed on a polyamide column (5.5 × 34 cm) using water as solvent. The polyamide powder was mixed into water and allowed to stand for 2 h, occasionally stirring, before it was poured into the column. It was washed in the column with 700 ml of methanol and 1.5 l of water before chromatographing. At the solvent front a small amount of ninhydrin-positive material appeared, and immediately after that the precursor. Other UV-absorbing material remained in the column. The red coloured fractions containing the precursor were pooled, evaporated to dryness *in vacuo* and rechromatographed on a cellulose powder column (7.5 × 27 cm) with *n*-butanol saturated with water. The cellulose powder was washed with 2 N hydrochloric acid, distilled water, hydroxy-quinoline-containing methanol, to remove heavy metal ions, and methanol, and was air-dried before packed into the column. First a red front emerged from the column. It contained part of the precursor. After it a colourless front emerged, containing the precursor. This crystallized from the colourless fraction when evaporated *in vacuo*. It was recrystallized from absolute ethanol. Yield: 1.23 g of red material, containing a large amount of the precursor, 1.22 g of crystalline crude preparation (pink), and 0.143 g of colourless narrow prisms, m. p. 168—170°C (decomp.).

During the isolation of the glucoside its presence in different fractions was followed by treating the samples with fresh, crushed wheat seedlings, after which MBOA was determined. The homogenate was prepared by grinding 20 g of 7 to 10-day-old wheat seedlings in a homogenizer with 50 ml of water, and was sieved to obtain an even suspension. Each sample to be tested for the glucoside was mixed with 10 ml of this suspension. 10 ml of the suspension was used as a blank. The samples were allowed to stand for 30 min to 1 h at room temperature. They were kept in boiling water for 15 min and filtered. The filtrates were extracted with equal amounts of ether. Equal parts of the ether extracts were chromatographed one-dimensionally on paper with the solvent *n*-propanol-ammonia (25 %), 7:3. Pieces of the

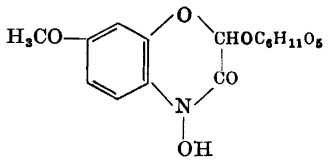
same size were cut out between R_F-values 0.6 and 0.8. They were eluted with equivalent volumes of absolute ethanol. The UV-spectra between 230 and 310 mμ were measured against the ethanol eluate of the chromatographic spot of the blank. The spectrum thus obtained shows the MBOA formed from the precursor in the preparation added.

A comparison of the glucoside in maize and wheat plants. Wheat seedlings (grown in a greenhouse, about 10 days) were put into boiling water. They were cooled, ground in water of room temperature, and filtered. The filtrate was extracted with ether and the waterphase remaining six times with *n*-butanol. A butanol extract was prepared in the same way from maize seedlings. Two-dimensional chromatograms were made from the butanol extracts obtained from maize and wheat, as well as from their mixture, with the solvents water-saturated *n*-butanol and 2 % acetic acid. In this solvent system the glucoside of maize and wheat moved as one spot. By chromatography it was also established that this precursor is not present in wheat seeds.

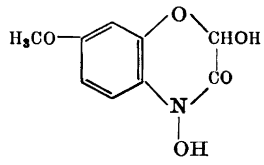
Properties of the glucoside. When dissolved in 25 % ammonia, the glucoside turns dark brown in a day. With ferric chloride it gives a blue colour. The UV-spectrum in water: Max. 270 mμ (K = 29.6). A knee at 282–283 mμ (K = 27.6). Min. 237 mμ.

Identification of the sugar part: The glucoside was kept for 2 h in a boiling water bath in 2 N hydrochloric acid. It was cooled, and extracted with ether. In the water phase the chloride-ions were exchanged to acetate-ions by pouring through a Dowex 1 column in acetate form. The effluent was evaporated to dryness *in vacuo*, dissolved in a small amount of water, and chromatographed parallel with glucose on Whatman No. 4 paper (aniline hydrogen phthalate spray). The sugar formed on hydrolysis was characterized as glucose by using different solvent systems: a) water-saturated *n*-butanol (ascending), b) *n*-butanol-glacial acetic acid-water, 63 : 10 : 27 v/v (descending), and c) water-saturated phenol (descending).

The nitrogen content of the glucoside (Kjeldahl determination, using permanganate). (Found: N 4.13. Calc. for $C_{15}H_{19}O_{10}N$: 3.85.) The methoxy content of the glucoside: 8.1 %, calc. for $C_{15}H_{19}O_{10}N$: 8.3. The molecular weight calculated from the obtained methoxy value was 382, calc. for $C_{15}H_{19}O_{10}N$: 373.



Glucoside
$C_{15}H_{19}O_{10}N$



Aglucone
precursor of MBOA
2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one

The growth-inhibiting effect of the glucoside on *Fusarium nivale* was negligible. 6 mg per 1 ml of oat-glycerol nutrient solution, pH 6.5–6.8, caused about 50 % inhibition.

The aglucone

The isolation of the aglucone. 400 g fresh weight of maize seedlings (grown as mentioned above) were treated in a juice press. After 30 min the press juice was centrifuged for 40 min at 10 000 *g* and a temperature between 0 and 10°C. The clear supernatant was decanted and extracted twice with ether. The ether solution was dried for about 2 h with sodium sulphate, filtered, and evaporated at room temperature to a small volume. The precipitate thus obtained was recrystallized several times from methanol and then from an ether-*cyclo*hexane mixture. 75 mg of pink needle-like crystals, m. p. 156–157°C (decomp., gas evolution), were obtained.

Properties of the aglucone. Conversion into MBOA: A solution of the aglucone was made up in water to a concentration of 10 μg per ml. The UV-spectrum was measured: Maxima at 267 mμ (K = 34.7) and 292 mμ (K = 32.5), minima at 237 mμ (K = 5) and 280 mμ (K = 29.4). This solution was heated under reflux for 30 min in a boiling water bath and its UV-spectrum was measured once more.

Table 1. The growth-inhibiting effect of the aglucone on *Fusarium nivale*. Oat-glycerol nutrient solution, pH 6.5–6.8. Numbers refer to the diameter of the colony in mm.

Concentration mg/ml	Growth +						
	1	2	3	4	5	6	days
0 (contr.)	12	14	14	16	22	29	
0.5	10	10	14	15	16	22	
1.0	?	+	+	+	+	+	
1.5	+?	+?	+?	0	0	0	
2.0	0	0	0	0	0	0	
2.5	0	0	0	0	0	0	
3.0	0	0	0	0	0	0	

Table 2. R_F-values of the glucoside and the aglucone. Whatman No. 4 paper.

Solvent	R_F	
	The glucoside	The aglucone
H_2O-sat.*n*-BuOH	0.4–0.6 (tailing)	0.72–0.78
n-BuOH:AcOH:H_2O, 8:2:2	0.33	0.81
n-BuOH:MeOH:Bz:H_2O, 3:1:1:1	0.53	0.84
2 % AcOH in water	0.90	0.74
n-PrOH:NH_3(25 %), 7:3	0.30	decomposes

The spectrum then obtained was identical with the spectrum of MBOA, $E_{286} = 0.266$. Because the molar extinction of MBOA is 5 690 this absorbtion corresponds to 7.7 μg of MBOA per ml. From this concentration and that of the aglucone the following molecular weight for the aglucone is obtained: $\frac{10}{7.7} \cdot 165 = 214$, calc. for $C_9H_9O_5N = 211$.

When dissolved in 25 % ammonia, the aglucone turns yellow-brown within a few minutes. After 30 min the solution is green, and after about 2 h it is dark brown. This solution was chromatographed, and one of the products was chromatographically and spectrophotometrically identified with MBOA. With ferric chloride the aglucone gave a blue-violet colour.

The nitrogen content of the aglucone was 6.91 %, calc. for $C_9H_9O_5N$: 6.63. The methoxy content of the aglucone was 15.01 %; the molecular weight calculated from the methoxy content was 207, calc. for $C_9H_9O_5N$: 211.

The growth-inhibiting effect of the aglucone is nearly as high as that of MBOA and BOA (Table 1). The effect is mainly fungistatic. R_F-values can be seen in Table 2.

Mixed Solvent Effect with Dibutyl Phosphate

Modification of a Method[1] for the Preparation of Carrier-free Yttrium-90

DAVID DYRSSEN and SOLVEIG EKBERG

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Dialkyl phosphoric acids have been used[1,2] for the separation of ^{90}Y from its parent ^{90}Sr. Dibutyl phosphate (= HA) is preferred by us since the equilibrium constant, $K = [YA_3(HA)_3]_{org}\,[Y^{3+}]^{-1}[H^+]^3[H_2A_2]_{org}^{-3}$, is larger for the dibutyl phosphate (DBP) – chloroform system[1] (log $K = 3.22 \pm 0.13$) than for the dioctyl phosphate-toluene system[3] (log $K \sim 1.3$), and since the equilibria for DBP have been more fully investigated[4,5]. Dioctyl phosphate (DOP) has a lower solubility in water[3] than DBP due to the fact that it contains larger hydrocarbon groups. Consequently, DOP will have a larger distribution ratio than DBP. However, with chloroform the distribution ratio of DBP is 74 for a 0.1 M solution, and the loss of DBP into 0.1 M HNO_3 is not a serious problem.

This suggested modification of the method previously given by Dyrssen[1] allows ^{90}Y to be back-extracted into HNO_3 with better recovery at lower acidity and less contamination of DBP. This is accomplished by the addition of methyl *iso*butyl carbinol (hexol) to the chloroform phase containing 0.1 M DBP and the ^{90}Y extracted from $^{90}Sr + {}^{90}Y$ in 0.1 M HNO_3.

This mixed solvent effect may be explained by the formation of a 1 : 1 complex between DBP (HA) and hexol (B) which reduces the concentration of HA and H_2A_2, and thus the extraction of Y^{3+} according to equations given below. There is no reason to believe that a trialkyl phosphate is formed, *i.e.* $(BuO)_2((CH_3)_2CHCH_2CH(CH_3)O)PO$, in the presence of an aqueous phase. These conclusions were drawn from a study[5] of the extraction of Eu^{3+} and Am^{3+} by DBP in different solvents carried out at this institute, as well as a study[5] of DBP itself in the same set of solvents.

The effect of addition of hexol on the distribution of ^{90}Y (org/aq) is shown in Table 1. It is possible from these data to calculate $[H_2A_2]_{org}$ from

$$[H_2A_2]_{org}^3 = qK^{-1}[H^+]^3 \,;\, \log K = 3.03$$

and C_B from the known volume of hexol added:

$$C_B = v(v + 15)^{-1}\,7.95$$

Using the following relations

$$C_B = [HAB]_{org} + [B]_{org}$$

$$0.1 \cdot 15(v + 15)^{-1} = 2\,[H_2A_2]_{org} + [HAB]_{org}$$

$$10^{4.61} = [H_2A_2]_{org}[HA]_{org}^{-2} \quad \text{(Ref.}^5\text{)}$$

we could calculate the value of

$$K_B = [HAB]_{org}[HA]_{org}^{-1}[B]_{org}^{-1}$$

as log $K_B = 2.21$ for hexol and DBP in chloroform. This value is larger than for TBP in chloroform[1], probably because TBP and $CHCl_3$ form a complex.

With these constants and equations it is possible to calculate the distribution of ^{90}Y and DBP for the following two pairs of organic–aqueous solvents (*cf.* Fig 1):

0.1 M DBP in $CHCl_3$/0.1 M HNO_3:

$$\log q_Y = +2.13$$
$$\log q_A = +1.87$$

hexol + 0.1 M DBP in $CHCl_3$ (1 + 5)/1 M HNO_3:

$$\log q_Y = -3.43$$
$$\log q_A = +2.58$$

Recommended procedure: 5 ml of a 0.1 M HNO_3 solution containing ^{90}Sr is shaken

Table 1. Distribution of ^{90}Y at 25°C between 15 ml 0.1 M DBP in chloroform (alcohol-free) and 15 ml 0.1 M HNO_3, for various amounts of hexol added. The two phases were shaken for one minute by hand and then separated by centrifugation.

ml hexol	0	0.05	0.1	0.2	0.5	1	2	5
log q	(+2.13)[a]	+2.055	+2.012	+1.897	+1.523	+1.040	+0.154	−1.655

[a] extrapolated value, measured value in Ref.[5]: 2.17.

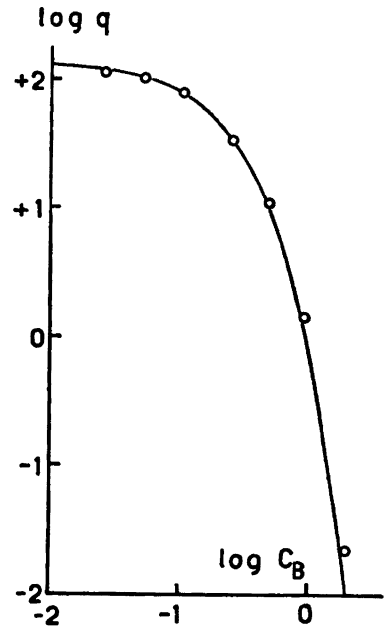

Fig. 1. Distribution of ^{90}Y between a solution of 0.1 M DBP in chloroform and 0.1 M HNO_3 as a function of the conc. of hexol in the chloroform phase. The curve is calculated with equations in the text assuming that the lowering of q is due to formation of a complex between DBP and hexol.

with 5 ml of 0.1 M DBP in alcohol-free chloroform. The amount of ^{90}Sr extracted is less than 10^{-2} %. This amount may be reduced by a factor of 10^4 by washing the organic layer with 5 ml of 0.1 M HNO_3; 1 % of ^{90}Y is lost for each wash. The ^{90}Y is quantitatively back-extracted into 5 ml of 1 M HNO_3 after the addition of 1 ml of methyl *iso*butyl carbinol (hexol). The aqueous phase then contains about 0.0003 M DBP. The DBP conc. can, however, be lowered by a factor of 400 by washing the 1 M HNO_3 phase with 1 ml of hexol + 5 ml of chloroform. In this way the conc. of DBP can be reduced to a very low level and the final solution will only contain volatile substances (HNO_3), water, chloroform and hexol) in addition to the ^{90}Y.

The Composition of Rat Milk Fat

AAGE JART, J. P. FUNCH and H. DAM

Danish Fat Research Institute, Copenhagen, Denmark

Rats are extensively used in experiments on nutrition, *e.g.* for the study of the role of fats. It is therefore of interest to know the composition of the fat in the milk consumed by the suckling young rat.

Investigations on this problem have been carried out by Hallanger and Schultze [1], who found it possible to increase the content of polyenoic acids (mainly dienoic) by increasing the content of such fatty acids in the diet.

The aim of the present study was to determine not only the polyenoic fatty acids but also the chain length of the fatty acids in milk fat of rats receiving the stock diet commonly used in our laboratory.

To study this problem the fat fraction of rat milk was isolated and converted into methyl esters which were analyzed by means of gas-liquid chromatography [2]. The column consisted of 0.9 m Celite 545 with silicone elastomer E 301. The carrier gas used was nitrogen at a rate of 1 l per hour, and the temperatures applied ranged from 160°C to 225°C. Assuming the areas lying under the recorded curves to be proportional to the molar percentages of the individual components, the following composition (Table 1) was found (in per cent w/w of the fatty acid mixture).

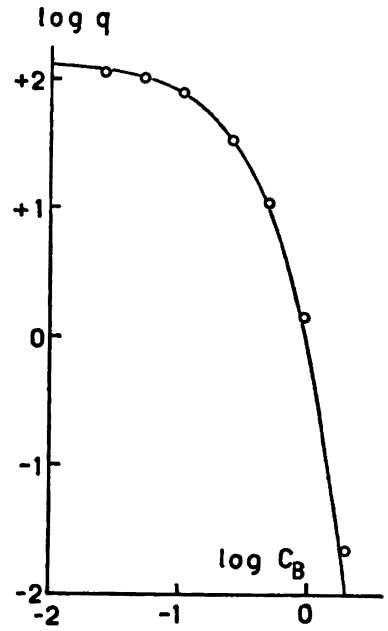

Fig. 1. Distribution of ^{90}Y between a solution of 0.1 M DBP in chloroform and 0.1 M HNO_3 as a function of the conc. of hexol in the chloroform phase. The curve is calculated with equations in the text assuming that the lowering of q is due to formation of a complex between DBP and hexol.

The Composition of Rat Milk Fat

AAGE JART, J. P. FUNCH and H. DAM

Danish Fat Research Institute, Copenhagen, Denmark

Rats are extensively used in experiments on nutrition, *e.g.* for the study of the role of fats. It is therefore of interest to know the composition of the fat in the milk consumed by the suckling young rat.

Investigations on this problem have been carried out by Hallanger and Schultze [1], who found it possible to increase the content of polyenoic acids (mainly dienoic) by increasing the content of such fatty acids in the diet.

The aim of the present study was to determine not only the polyenoic fatty acids but also the chain length of the fatty acids in milk fat of rats receiving the stock diet commonly used in our laboratory.

To study this problem the fat fraction of rat milk was isolated and converted into methyl esters which were analyzed by means of gas-liquid chromatography [2]. The column consisted of 0.9 m Celite 545 with silicone elastomer E 301. The carrier gas used was nitrogen at a rate of 1 l per hour, and the temperatures applied ranged from 160°C to 225°C. Assuming the areas lying under the recorded curves to be proportional to the molar percentages of the individual components, the following composition (Table 1) was found (in per cent w/w of the fatty acid mixture).

Table 1.

Acid	%
C_7	<0.05
C_8	2
C_9	0.1
C_{10}	6
C_{11}	0.15
C_{12}	4
C_{13}	0.1
C_{14}	6
C_{15}	0.5
C_{16}	22
C_{17}	0.1
C_{18}	59

It will be seen that the analyzed fat from rat milk contains about 1 % of fatty acids with an uneven number of carbon atoms in the chain, and that it is a characteristic feature that it contains appreciable quantities (about 0.5 %) of a fatty acid with a 15-carbon atom chain. In agreement with other investigations [3], butyric acid and caproic acid were not found in the rat milk fat.

To determine the content of unsaturated fatty acids the fats isolated from another milk sample (with approximately the same distribution of the fatty acids as regards chain length) was examined by alkali isomerization analysis [4]. The following results were obtained (unsaturated linkages being assumed to occur chiefly in the C_{18}-fraction):

linoleic acid	11	%
linolenic acid	4	»
conjugated dienoic acids	0.9	»

It appeared, moreover, from the iodine value (65.7 for the methyl esters) that the triglycerides of rat milk contain about 40 % oleic acid.

Experimental. The milk was collected 15—18 days after parturition from 15 rats which had been fed on the diets listed in Table 2. The milk donors were separated from the litter in the afternoon preceding milk collection the following morning. The rats were anesthetized with 0.1—0.2 ml of a 6 % Nembutal sodium solution (Abbott), given subcutaneously. The milk was expressed by the thumb and forefinger, and the droplets were collected in a pipette. About 1 ml was collected from each rat.

To a 10—12 ml sample of the collected milk was added 1 ml 10 % ammonium hydroxide and 10 ml ethanol (96 %), and the mixture was shaken vigorously. Now 25 ml ethyl ether were added and the mixture again shaken; the treatment was repeated with 25 ml petroleum ether, whereupon the mixture was allowed to stand over night for complete separation. The ether phase was separated and evaporated to dryness — finally in vacuum. The residue was dissolved in 20 ml methanol, and 20 mg sodium methoxide were added in the form of 2 ml of a methanolic solution. The reaction mixture was refluxed for a couple of hours and then set aside over night. After addition of 20 ml ethyl ether, just sufficient distilled water was added dropwise to cause the solution to separate into two phases (*i. e.* about 20 ml distilled water). The ether phase with the methyl esters was separated, and the aqueous phase was extracted once more with 25 ml ethyl ether. The two ether phases were combined, and an equal

Table 2. Percentage composition of the diets.

The Osmotic Pressure of Macroions

JOHN GRAAE

Kemisk Laboratorium B, Polyteknisk Læreanstalt, Copenhagen, Denmark

and

KJELD MARCKER

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

A theoretical study on the colloidal osmotic pressure and the Donnan-effect is presented. 1) An expression for osmotic pressure under ideal conditions is derived. 2) Deviations from the expression as regards colloidal osmotic pressure are explained by an "excluded volume" theory. 3) Deviations from the expression as regards the Donnan-effect are explained by a lowering of the effective charge of the macroion at salt concentrations greater then 0.1 M and in the case of hyaluronic acid by the formation of a network of hyaluronate molecules at salt concentrations lower then 0.1 M.

In this paper will be presented some theoretical considerations about the osmotic pressure of macroions, both in the case where the Donnan-effect is eliminated by high salt concentrations as where this is not so. The paper will fall in three parts: 1) The derivation of the osmotic pressure under ideal conditions; 2) The deviations from ideality when the Donnan-effect may be neglected; 3) The deviations from ideality as regards the Donnan-effect and the possibility of explaining this by accepting a lowering of the effective charge of the macroion when the salt concentration is increased. In all three cases the calculations will be illustrated with experimental data published earlier from this laboratory.

1. Let us denote the macroion R^- with the charge $-\nu$, and further:

Substance		H_2O	K^+	Cl^-	R^-
Symbol		M_o	M_+	M_-	M_2
Mole fractions	outer liquid	$1-2y$	y	y	0
	inner liquid	$1 - x_+ - x_- - x_2$	x_+	x_-	x_2

The condition of electroneutrality yields:

$$x_+ = x_- + \nu\ x_2 \tag{0}$$

Assuming ideal conditions we have:

$$\mu_i = \mathrm{J}_i + RT\ln z_i$$

where z_i is the mole fraction of M_i and J_i is independent of all the different mole fractions.

Denoting chemical potentials of the two liquids μ' and μ, respectively, and denoting the pressures by p^+ and p, respectively, we get:

$$\mu'_o = \mathrm{J}^+_o + RT\ln\ (1 - 2y)$$

$$\mu_o = \mathrm{J}_o + RT\ln\ (1 - x_+ - x_- - x_2)$$

and from

$$u'_o = u_o:$$

$$1 - x_+ - x_- - x_2 = (1 - 2y)e^{-\alpha_o}$$

where

$$\alpha_o = (\mathrm{J}_o - \mathrm{J}^+_o)/RT = (p - p^+)V_o/RT = PV_o/RT$$

P is osmotic pressure and V_o the molar volume of pure water at the temperature in question. As P in the experiments is only a minute fraction of an atmosphere, it never exceeds 20 cm water, and is usually, much lower, we can substitute $1 - \alpha_o$ for $e^{-\alpha_o}$. Consequently we get:

$$x_+ + x_- + x_2 - 2y\ (1 - \alpha_o) = \alpha_o \tag{1}$$

Next we express that the potential μ_1 of KCl must be the same on both sides of the membrane. With $\mathrm{J}_+ + \mathrm{J}_- = \mathrm{J}_1$ we get:

$$\mu'_1 = \mathrm{J}^+_1 + 2RT\ln y$$

$$\mu_1 = \mathrm{J}_1 + RT\ln(x_+x_-)$$

proceeding in the same way as above, and substituting $e^{-\alpha_1}$ with $(1 - \alpha_1)$, where $\alpha_1 = P(V_+ + V_-)/RT = PV_1/RT$ we get:

$$x_+x_- = (1 - \alpha_1)y^2 \tag{2}$$

Expressing (0) by the two equations:

$$x_+ = Z + \tfrac{1}{2}\ \nu\ x_2$$
$$x_- = Z - \tfrac{1}{2}\ \nu\ x_2$$

we get from (1)

$$Z = \tfrac{1}{2}\ (\alpha_0 - x_2) + y\ (1 - \alpha_0) \tag{1a}$$

and from (2)

$$Z^2 = y^2\ (1 - \alpha_1) + \tfrac{1}{4}\ \nu^2\ x_2^2 \tag{2a}$$

Squaring (1a) and accepting that α_0 is so much smaller than 1 that α_0^2 can be neglected compared to 1, we arrive at the equation:

$$0 = \tfrac{1}{4}(x^2)(\nu^2-1) + x_2[\tfrac{1}{2}\alpha_0 + y(1-\alpha_0)] - y\alpha_0(1-2y+\alpha_0) - y^2\alpha_1 - \tfrac{1}{4}\alpha_0^2 \qquad (3)$$

In the case where $y = 0$ this equation becomes:

$$x_2^2\ (\nu^2-1) + 2x_2\alpha_0 - \alpha_0^2 = 0$$

which gives:

$$P = RTx_2\ (\nu + 1)/V_0$$

If we now consider the case where $\alpha_0 \ll 1$ and $\alpha_0 \ll y$ eqn. (3) is reduced to:

$$\tfrac{1}{4}\ x_2^2(\nu^2-1) + x_2y - \alpha_0(y-2y^2) - y^2\alpha_1 = 0 \qquad (3a)$$

and introducing again that $\alpha_0 = PV_0/RT$ and $\alpha_1 = PV_1/RT$ we find for the osmotic pressure:

$$P = \frac{\tfrac{1}{4}x_2^2(\nu^2-1) + x_2y}{\frac{V_0}{RT}(y - 2y^2) + \frac{V_1}{RT}\ y^2}$$

or by rearrangement

$$P = \frac{RTx_2}{V_0(1-2y) + V_1y}\left[1 + \frac{x_2(\nu^2-1)}{4y}\right] \qquad (4)$$

Eqn. (4) differs from a commonly accepted formula [1] by having the term (ν^2-1) instead of ν^2. In the case of hyaluronic acid where the mean charge exceeds several hundred this is of course insignificant, but in the case of proteins near the isoelectric point the difference may be significant.

2. It is a well known fact that even when the salt concentration is so high that the figure in the brackets in (4) is 1, deviations from the theoretical expression are found in many cases. Jensen and Marcker [2] have demonstrated that dextran obeys the theoretical laws with good accuracy, but this is definitely not true when measurements are performed with hyaluronic acid, where Jensen and Marcker [2] find the law

$$c/p = A\ (1-Bc)$$

to be the one which fits the experimental results best. (c is concentration of hyaluronate in g/l, P is osmotic pressure in cm water and A and B are constants, of which A is proportional to the molecular weight of the sample in question and B is the same for different samples.)

The problems concerned with the dependence of osmotic pressure on concentration have been studied theoretically by Güntelberg and Linderstrøm-Lang [3] and Scatchard [4] specially in the case where the high molecular substance is a protein. Here we shall present a simple explanation of the experimental results obtained earlier in this laboratory.

The assumption which is the basis of the following calculations is that the volume of the solvent should be corrected by subtraction of the "effective" volume of the dissolved molecules. In the case of dextran this volume could be expected to be relatively small at the concentrations used by Jensen and

Marcker, but in the case of hyaluronate where we have molecules with high negative charges the correction may be important either because of the repulsive forces of the charges or because of the ionic clouds which make it impossible for the molecules to come so close to each other, as when uncharged.

The following symbols will be used: c_g = weight concentration, P = osmotic pressure, N = number of molecules, v = total volume of solution, M = molecular weight of preparation used.

Let us have N molecules in a total volume of v. The "effective" volume of the molecules is then BNM, where B is a constant that includes the "effective" volume of the charged molecular unit. We then assume that the osmotic pressure is proportional to the "effective" concentration, *i. e.*:

$$P = A' \frac{N}{v - BNM}$$

substituting $N = c_g v/M$ and rearranging we get:

$$c_g/P = AM\ (1 - Bc_g) \qquad (5)$$

which is identical with the expression found empirically by Jensen and Marcker [2].

It must be supposed that B varies with the salt concentration, pH and other factors influencing the charge of the molecule. In the case of ampholytes as, *e. g.*, proteins, it must further be assumed that B has its smallest value at the isoelectric point in good agreement with Christiansen, Jensen and Marcker [5] who measured the osmotic pressure of bovine plasma albumin at different pH values and found a minimal osmotic pressure at pH 4.64.

Let us suppose that in this case the constant B could be written $B = D(1 + E\ \Delta\text{pH})$, where ΔpH is the difference between the actual pH and the isoelectric pH, and D and E are constants. Introducing this in eqn (5) we find at constant concentration

$$K'P - L\ P\ |\Delta\text{pH}| - 1 = 0$$

where K' and L are new constants. This means that p plotted *versus* pH should be a hyperble, in good agreement with Fig. 2 in Christiansen, Jensen and Marcker [5]. This could be re-written as:

$$1/P = K - L\ |\Delta\text{pH}|$$

and $1/P$ plotted *versus* pH should yield a straight line. This is shown in Fig. 1, using the points from the right half of Fig. 2 in Christiansen, Jensen and Marcker. (Note in this figure the point at about pH 3.6 which makes it reasonable to believe that the curve should have shown a higher degree of symmetry.)

3. We have now accounted for the osmotic pressure in the case where the Donnan-effect has been eliminated by a suitably high concentration of salt. However measurements performed by Robinson and Jensen [6] show that the salt concentration necessary to eliminate the Donnan effect is much smaller than calculated from (4). A fraction of hyaluronate with a molecular weight of 500 000 will have ν about 1 000. Inserting this in (4) gives that a concentra-

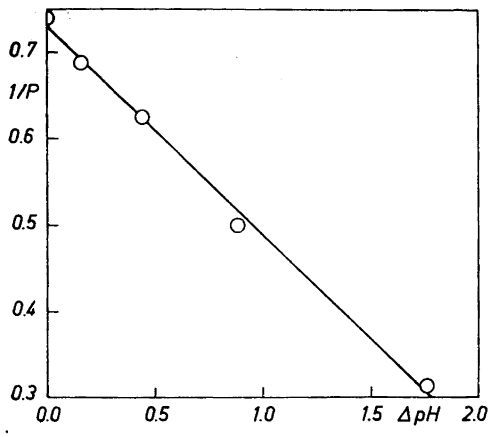

Fig. 1. A graph of $1/P$ cm water^{-1} plotted against ΔpH for the experiment recorded in Fig. 2 in Christiansen, Jensen and Marcker [5].

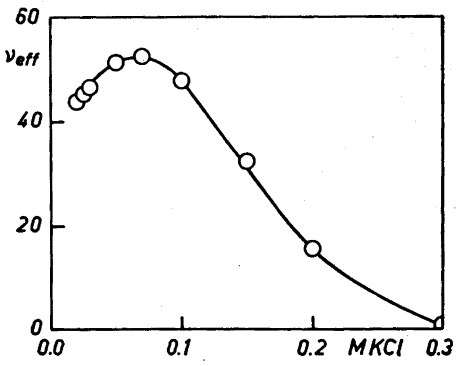

Fig. 2. A graph of ν_{eff} calculated from (7) using figures from Robinson and Jensen [6] plotted against concentration of KCl. Molecular weight of sample is about 120 000, $\nu_{theor.} \simeq 240$.

tion of hyaluronate at 10 g/l demands about 100 M KCl to reduce the Donnan effect to 5 % of the measured osmotic pressure. In this case, however, Robinson and Jensen find that there is no change in osmotic pressure when salt concentration varies from 2 M to 1 M and only when salt concentration is lower than 1 M is an increase in osmotic pressure observed. It seems reasonable to explain this by assuming an effective charge of the hyaluronate lower than the theoretical charge, due to the presence of potassium ions. To see whether this assumption is justified we shall use the figures recorded by Robinson and Jensen [6] to calculate the effective charges necessary to make eqn (4) fit with the experimental results.

We change (4) to

$$P = P_{min}\left[1 + \frac{x_2(\nu^2-1)}{4y}\right] \tag{6}$$

where P_{min} is the osmotic pressure measured at salt concentrations so high that the addition of more salt would cause no change. By calculating the concentration of hyaluronate, x_2 we use the apparent molecular weight at the concentration used by Robinson and Jensen (10 g/l) and do not try to extrapolate to infinite dilution, as this procedure should automatically correct for volume effect and possibly other deviations from the van't Hoff theory. For the same reason we simply use P_{min} as the factor, and do not try to calculate this factor. Solving (6) in respect of ν gives us

$$\nu_{eff} = \sqrt{\frac{4y}{x_2}\left(\frac{P}{P_{min}} - 1\right) + 1} \tag{7}$$

If we now calculate ν_{eff} we do not find as expected that ν_{eff} increases with decreasing salt concentration, with the theoretical value as the upper limit, but we find as demonstrated in Fig. 2 that this is only the case when the salt concentration is higher than about 0.1 M, and that below this concentration ν_{eff} decreases with decreasing salt concentration.

It should be noticed that a change in the behaviour of hyaluronic acid at salt concentrations about 0.1—0.2 M is observed in other properties of hyaluronic acid [6,7]. This may be explained by the assumption that hyaluronic acid at low salt concentrations forms some sort of a network and only at higher salt concentrations is it dissolved as single molecules. This too can explain the results found here, as this would cause a decrease in x_2, which would make the values of ν_{eff} calculated from (6) higher than those recorded in Fig. 2.

Acknowledgements. We are very much indebted to Professor, Dr. J. A. Christiansen for his interest in this work and for his many valuable suggestions.

The authors' thanks are due to Dr. C. E. Jensen who has kindly allowed us to use his experimental results in our calculations and has given us valuable information about the behaviour of hyaluronic acid, as well as about the immense literature on the subject.

Financial support from *NOVO Terapeutisk Laboratorium* and *Købmand i Odense Johann og Hanne Weimann, født Seedorf's foundation* is acknowledged by Kjeld Marcker.

Chromatographic Separation of Chondrosin and Hyalobiuronic Acid on an Acidic Resin

ANUND HALLÉN

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

Aminopolysaccharides, consisting of chondroitin sulphuric acid, hyaluronic acid, keratosulphate, β-heparin and ordinary heparin, as well as tissue specimens, were submitted to mild acid hydrolysis, and the hydrolysate chromatographed on a cation exchange resin. The ninhydrin-positive components obtained were identified as chondrosin, hyalobiuronic acid, glucosamine and galactosamine. A component obtained from β-heparin showed the same chromatographic behaviour as chondrosin. The front material possibly contained hexosamine ester sulphate derivatives.

It seems to be relatively well documented that aldobiuronic acids containing β-D-glucuronide bonds are fairly resistant to acid hydrolysis. For instance, Heidelberger and Goebel [1] boiled Type III pneumococcus polysaccharide for 5 h in 3 % sulphuric acid in order to obtain cellobiuronic acid. This has also proved to apply to hexosamine-containing mucopolysaccharides. The hexosamine-hexuronic acid containing disaccharide chondrosin obtained by Schmiedeberg [2] after boiling chondroitin sulphuric acid *(C.S.A.)* or chondroitin with 2—4 % nitric acid for 1—1.5 h was shown in Levene's laboratory [3] to consist of glucuronic acid and galactosamine in glycosidic junction, and in Masamune's [4] and Meyer's [5] laboratories to be 3-*O*-(β-D-glucopyranosyluronic acid)-2-amino-2-deoxy-D-galactopyranose. A similar disaccharide, mucosin [6] or hyalobiuronic acid [7,8], was obtained by Isikawa [6] in Masamune's laboratory by boiling hyaluronic acid (*H.A.*) with 55 % oxalic acid for 5 h. Independently it was obtained in Meyer's laboratory [7,8] by boiling *H.A.* with 0.5 M sulphuric acid for 3 h. It has been shown to be 3-*O*-(β-D-glucopyranosyluronic acid)-2-amino-2-deoxy-D-glucopyranose [9]. As indicated by the investigations of Jeanloz [10] the resistance of the glucuronide bond is also encountered in acidic methanol solution of methylated mucopolysaccharides.

Both the D-galactoside bond in keratosulphate and the L-iduronide bond in β-heparin are comparatively acid-labile [11]. Ordinary heparin is unique in having very acid-stable glucosaminide bonds [12].

During unsuccessful attempts to isolate an oligosaccharide fraction from mild acid hydrolysates of keratosulphate according to Cifonelli and Dorfman [11] I observed that chondrosin and hyalobiuronic acid could be separated from one another by chromatography on Zeo-Karb 225. Whereas the behaviour of unsubstituted hexosamine on acidic resins has been studied by many authors [13-19] there are only sporadic reports on partial hydrolysis products [5,11,16]. This paper deals with an ion exchange method for quantitative determination and for isolation of the mild acid hydrolysis products from mucopolysaccharides. For the same purpose Fischer and Dörfel [20] have described a paper-chromatographic technique.

EXPERIMENTAL

Preparation of the polysaccharides. *C.S.A.* and *H.A.* were prepared as Mg salts from bovine cartilage and vitreous body, respectively, using the method of Scott [21], including digestion with papain and fractionation with cetyl pyridinium chloride. Chondroitin was obtained from *C.S.A.* by hydrolytic removal of ester sulphate groups in acidic methanol, followed by mild alkaline hydrolysis of the methyl ester groups, according to Kantor and Schubert [22]. Keratosulphate was obtained from human nucleus pulposus with the method of Gardell [23], including digestion with pancreatic and intestinal enzymes, phenol extraction and fractionation with alcohol. Crude heparin was prepared essentially according to Charles and Scott [24], and was then precipitated as the insoluble Ba salt. Heparin monosulphuric acid was obtained from the heparin mother liquor, according to Jorpes and Gardell [12]. β-Heparin was prepared from lung heparin mother liquor, according to Marbet and Winterstein [25], and was then further purified by hyaluronidase digestion according to Rodén and Dorfman [26].

Hydrolysis of the polysaccharides. 125 mg of the *H.A.* preparation (ash 16 %, moisture 15 %) was dissolved in 250 ml of hot 0.6 M hydrochloric acid, and put in a strongly boiling water bath. Every 10 min, a 5-ml sample was taken, cooled, and neutralized by the addition of 10 drops of pyridine. Suitable amounts were taken for determination of the reducing power [27] (2.5 ml), Elson-Morgan colour [28,16] (0.5 ml) and ninhydrin colour [29] (0.3 ml). Crystalline glucosamine-HCl was used as standard. The results of these analyses are summarized in Fig. 1, where the values are expressed as μmole glucosamine equivalents per 2 ml of solution (containing 1 mg of *H.A.*).

For the chromatographic experiments, 0.5—10 mg of the polysaccharide preparations were hydrolyzed with reflux in 10 ml of 0.6 M hydrochloric acid. The hydrolysate was evaporated *in vacuo* to a small volume, and dried in a desiccator over concentrated sulphuric acid and sodium hydroxide pellets.

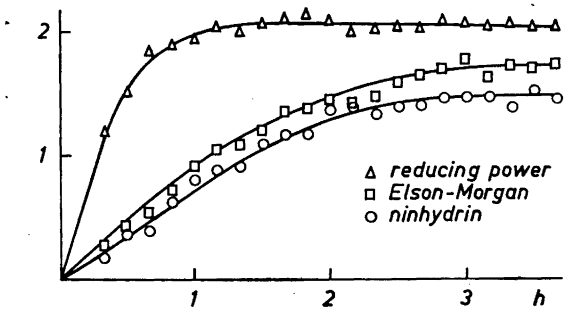

Fig. 1. Course of hydrolysis of *H.A.* in 0.6 M hydrochloric acid at 100°C. The values are expressed as μmole glucosamine equivalents per mg of *H.A.* preparation.

In experiments with some tissues, such as the annulus fibrosus of the intervertebral disc, it proved necessary first to gelatinize the collagen by boiling in water for 30 min and, after grinding, to make a dry powder with alcohol and ether. Humins were removed by filtration.

For hexosamine determinations, hydrolysis was performed in sealed tubes with 0.5—1 ml of 6M hydrochloric acid for 8 h [16].

The dried hydrolysate was put on the column in the usual way, dissolved in a total volume of 0.2—0.4 ml of the buffer.

Chromatography of the hydrolysate. The sodium form of Zeo-Karb 225 X 8, 200—400 mesh, was used in 0.6 × 40 cm columns with a flow rate of 1 ml/h. The effluent was collected in 0.5- or 1.0-ml fractions.

To study the influence of pH on the chromatography of the components several experiments were performed, where different amounts of sodium carbonate had been added to the eluting hydrochloric, sulphuric or phosphoric acids. It was found that in the pH range 0.5—7.0 the hexosamines (analyzed with the Elson-Morgan method [28,16]) chromatographed fairly independently of changes in pH, the ionic strength being the only factor of importance. This was in sharp contrast to the amino acids (analyzed with ninhydrin [29]), which were extremely sensitive to changes in pH. Thus, above pH 2.4 the hexosamines appeared among the amino acids, whereas at lower pH they appeared in front of the amino acids. At pH 2.3, the effluent volume of the hexosamines was only slightly less than that of hydroxyproline (recognized by its yellow tint in the ninhydrin test), the first amino acid to appear.

0.10—0.15 M $NaHSO_4/Na_2SO_4$ buffer, pH 1.9 (*i.e.*, the pK_s of HSO_4^-) was found suitable for the present purpose. The effluent volume of the hydroxyproline was then about twice that of the hexosamines. The ammonium ion came after the hydroxyproline as did other components in protein hydrolysates.

The buffer was easily prepared, for instance by adding sodium hydroxide pellets (60 g) to 0.10 M sulphuric acid (10 l) until 10 ml of the buffer needed 5 ml 0.10 M sodium hydroxide for neutralization. Toluene, 0.5 ml per liter of buffer, was added to prevent growth of microorganisms. At room temperature it could be stored in stoppered vessels for at least one month. Before use, dissolved gases were removed by a water suction pump.

Analysis of the fractions. The ninhydrin method of Moore and Stein [29] proved to be more sensitive and to give better standard curves than both the Elson-Morgan [28,16], the Dische-Borenfreund [30] or the Tracey [31] methods. 0.5 ml of the ninhydrin reagent [29] was added to each fraction. Although it was verified that leucine could have been used as a standard [18,29], crystalline glucosamine-HCl was chosen instead. This was because the colour development of this reagent, dissolved in the buffer described above, was constant during one month's storage in the refrigerator.

RESULTS

Conditions of hydrolysis. From Fig. 1 it was inferred that when using boiling 0.6 M hydrochloric acid 2.5 h should be a highly appropriate time for obtaining partial hydrolysis products. This was because the ninhydrin colour development then reached a plateau, indicating maximal liberation of amino-groups under the mildest possible conditions. It also proved to be useful in view of the fact that maximal yields of the disaccharides were then obtained in the chromatograms.

Identification of the peaks. Fig. 2 shows a typical chromatogram of the *C.S.A.* and *H.A.* hydrolysates. Several peaks, labelled 1, 2a, 2b, 3a and 3b, were present. In this chromatogram, in which 2 mg of each of the polysaccharides had been hydrolyzed for 4 h in 0.6 M hydrochloric acid, the components were obtained in the following amounts: component 1, 0.19 μmole; 2a, 1.14 μmole; 2b, 1.12 μmole; 3a, 0.34 μmole and 3b, 0.22 μmole glucosamine (or leucine) equivalents. All the components contained hexosamine, as indicated

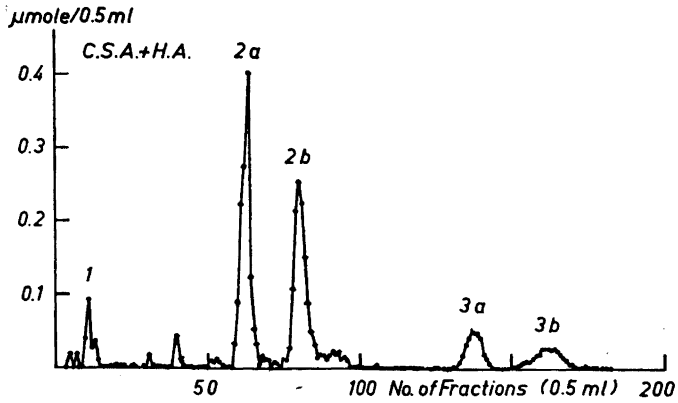

Fig. 2. 2 mg each of the *C.S.A.* and *H.A.* preparations hydrolyzed for 4 h in 0.6 M hydrochloric acid, chromatographed on Zeo-Karb 225 with 0.10 M $NaHSO_4/Na_2SO_4$ buffer, pH 1.9, and analyzed with ninhydrin. Component 1 identified as hexosamine ester sulphate derivatives (?), 2a as chondrosin, 2b as hyalobiuronic acid, 3a as glucosamine and 3b as galactosamine.

by a positive Elson-Morgan [28,16] and Dische-Borenfreund [30] reaction. Components 1, 2a and 2b gave a positive Dische carbazol reaction [32], indicating the presence of uronic acid. When chondroitin was substituted for *C.S.A.*, component 1 was lacking. When the proportions of *C.S.A.* and *H.A.* were varied, component 2a proved to vary in quantity parallel with the amount of *C.S.A.* (see Table 1). Glucosamine-HCl added to the hydrolysate increased the amount of component 3a, and galactosamine-HCl that of 3b. Such simple experiments made identification possible with a high degree of probability, of component 2a as chondrosin, 2b as hyalobiuronic acid, 3a as glucosamine and 3b as galactosamine.

In order to study the components in more detail, chromatograms were run on a larger scale. The fractions belonging to the same peak were pooled, and suitable amounts were taken from the solutions thus obtained for determination of the ninhydrin colour [29], reducing power [27], Elson-Morgan colour [28], Dische carbazole colour [32] and ester sulphate. Leucine, glucose, glucosamine and glucurone, respectively, were used as standard.

Table 1. Amount of components 2a and 2b obtained from different *C.S.A.* and *H.A.* mixtures hydrolyzed for 2.5 h in 0.6 M hydrochloric acid.

C.S.A.	*H.A.*	2a	2b
mg	mg	µmole	µmole
—	2.0	—	1.30
0.2	2.0	0.17	1.39
1.2	2.0	1.05	1.56
2.0	2.0	1.70	1.54
2.0	—	1.60	—

Table 2. Analysis of the components. The values are referred on a molar basis to the ninhydrin colour.

Component	Reducing power	Elson-Morgan *	Dische carbazole	Ester sulphate
1 **	4.7	3.5	3.8	2.1
2a	0.9	1.1	1.1	—
2b	1.0	1.1	1.1	—
3a	1.0	1.0	—	—
3b	0.9	1.0	—	—

* After hydrolysis.
** From a chromatogram with *C. S. A.* only.

In accordance with Rapport *et al.*[7], it was found that the Elson-Morgan values of components 2a and 2b were about half the theoretical ones. Hydrolysis in 3 M hydrochloric acid for 6 h was therefore performed for these determinations. The acid was removed in the desiccator. For the ester sulphate determination, an excess of barium chloride was added, and the resulting barium sulphate precipitate was centrifuged down, washed and discarded. After addition of the washing water to the clear solution, one volume of concentrated hydrochloric acid was added, and the solution boiled for 4 h. On the next day the precipitate was collected on a platinum-iridium Gooch filter, ignited and weighed.

The results of these analyses are presented in Table 2. For convenience the values have been referred, on a molar basis, to the ninhydrin colour.

Within the errors of the methods, components 2a and 2b (see Table 2) seemed to contain amino groups, reducing groups, hexosamine and uronic acid in equimolar amounts. This indicated that these components were aldobiuronic acids. After N-acetylation with acetic anhydride [33], the Morgan-Elson reaction [34,33] was positive, implying [35,36] that components 2a and 2b did not contain 4-*O*-substituted hexosamines. The 3-*O*-substitution was indicated by a modified Elson-Morgan reaction [17], showing a 510 mμ maximum typical of this substitution [11].

For preparative purpose it was found convenient to use the resin in hydrogen cycle and elute the components with dilute volatile acids [5,16]. In

Table 3. Components obtained from different polysaccharides hydrolyzed for 2.5 h in 0.6 M hydrochloric acid.

Polysaccharide	% recovery of component				
	1	2a	2b	3a	3b
C.S.A.	7	65	—	—	6
H.A.	—	—	35	5	—
Keratosulphate	7	—	—	65	—
β-Heparin	12	20	—	—	40
Ordinary heparin	5	—	—	—	—
Heparin monoacid	—	—	—	—	—

one experiment complete separation was obtained on a 4 × 50 cm column of the components 2a and 2b from the hydrolysate of about 0.2 g each of *C.S.A.* and *H.A.* by eluting with 0.05 M hydrochloric acid. The effluent volume of component 2a was 1.2—1.7 l, that of 2b 1.8—2.5 l. The fractions belonging to the same peak were pooled and evaporated in vacuo to a small volume. On freeze-drying there was some tendency to syrup formation, but when redissolved in water and freeze-dried again the components were obtained as white powders; 2a 63 mg, 2b 44 mg. The component 2a obtained in this way proved also to be component 2a in the sulphate buffer chromatogram. The hexosamine of component 2a was identified as galactosamine, that of 2b as glucosamine with the chromatographic method of Gardell [16] after hydrolysis with 6 M HCl for 8 h. The identities were secured by the effluent volumes and by the fact that glucosamine added to the hydrolysate of component 2a yielded two peaks, whereas only one peak was obtained when it was added to the hydrolysate of component 2b.

As indicated by a high reducing power and by containing ester sulphate (see Table 2) component 1 could be composed of low molecular hexosamine ester sulphate derivatives (with a free amino group capable of reacting with ninhydrin). This was also supported by the fact that it was obtained from sulphated polysaccharides, but not from *H.A.* or chondroitin. It was prepared in an impure state by hydrolyzing *C.S.A.* in 0.6 M hydrochloric acid for 2.5 h in the presence of excess barium chloride. The hydrolysate was evaporated *in vacuo* to a small volume and put on Zeo-Karb 225 in hydrogen cycle. Component 1 was eluted with distilled water. After boiling with strong hydrochloric acid and filtration a heavy barium sulphate opalescence was obtained on the addition of barium chloride. The component also contains N-acetyl groups since the Morgan-Elson reaction [34] was positive.

Behaviour of the different polysaccharides. The recovery of the components varied somewhat in different experiments. In Table 3, the quantity recovered (in per cent) is referred to the hexosamine content after hydrolysis for 8 h in 6 M hydrochloric acid. It is evident that *C.S.A.* yielded essentially only chondrosin (2a) in the chromatograms, *H.A.* only hyalobiuronic acid (2b), keratosulphate glucosamine (3a) and β-heparin galactosamine (3b) together with a small amount of component 2a.

On hydrolysis with strong hydrochloric acid, the keratosulphate and heparin monosulphuric acid preparations yielded a small amount of galactosamine, indicating contamination by *C.S.A.* For this reason traces of component 2a obtained in the analysis of these polysaccharides are not included in the table. Nor was the β-heparin pure, since it contained glucosamine. In this case, however, component 2a probably originated essentially from the β-heparin, since Cifonelli *et al.*[37] isolated such a disaccharide in small amounts after hydrolysis of β-heparin in M hydrochloric acid for 1 h.

Behaviour of certain tissues. Up to 50 mg of tissue could be analyzed with this technique. A chromatogram of the hydrolysate of 10 mg of freeze-dried nucleus pulposus is shown in Fig. 3. The following amounts of the different components were obtained from a specimen of nucleus pulposus of a 19-year-old subject: component 1, 0.76 μmole; 2a, 2.90; 2b, 0.0; 3a, 1.60; 3b, 0.32 μmole glucosamine equivalents. The corresponding values for the specimen

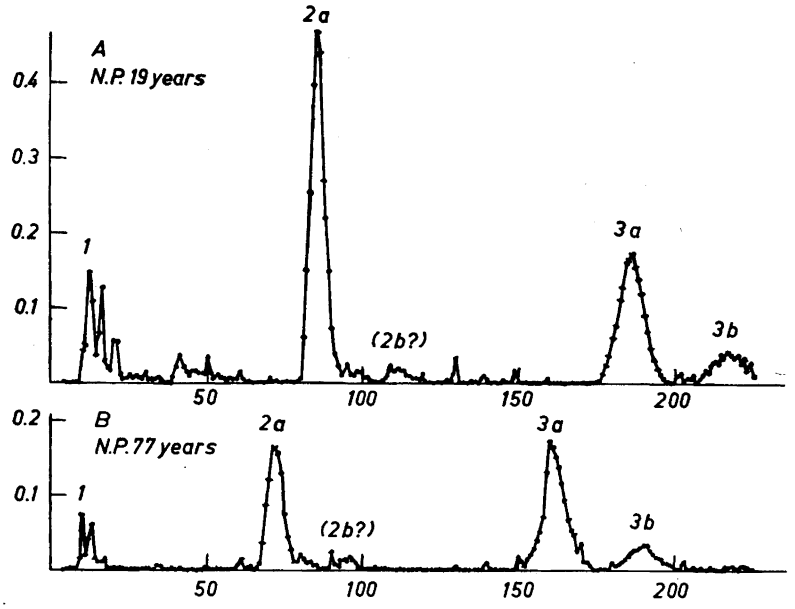

Fig. 3. Chromatogram of 10 mg of nucleus pulposus hydrolyzed for 2.5 h, otherwise as in Fig. 2. A from a man aged 19 years, B 77 years.

from a 77-year-old subject were: component 1, 0.24 μmole; 2a, 1.05; 2b, 0.0; 3a, 1.48; 3b, 0.27 μmole. These results are in agreement with the presence of *C.S.A.* and keratosulphate, and with the increase in the ratio of keratosulphate/*C.S.A.* with rising age postulated in an earlier paper [38]. Thus, the ratio of 3a/2a increased from 0.55 in the 19-year-old subject to 1.41 in the 77-year-old.

From 44 mg of annulus fibrosus, the following amounts were obtained: component 1, 0.50 μmole; 2a, 1.32; 2b, 0.0; 3a, 0.84; 3b, 0.36 μmole, indicating the presence chiefly of *C.S.A.* and keratosulphate.

From 55 mg of human adult rib cartilage, the corresponding amounts were: 1, 0.16 μmole; 2a, 1.65; 2b, 0.0; 3a 2.64; 3b, 0.63 μmole, indicating that *C.S.A.* and keratosulphate were present, as is also indicated by the investigation of Kaplan and Meyer [39].

From 38 mg of umbilical cord, the yields were; component 1, 0.10 μmole; 2a, 0.22; 2b, 0.75; 3a, 0.50; 3b, 0.40 μmole, indicating the presence of *H.A.* in particular, but of other polysaccharides as well.

Acknowledgements. I am greatly indebted to Docent Lennart Rodén for valuable discussions, and to Mrs. Ruth Flagell for skilful technical assistance.

The investigation has been aided by grants from *Karolinska Institutets reservationsanslag.*

Studies on Rennin

II. On the Crystallisation, Stability and Proteolytic Activity of Rennin

BENT FOLTMANN

Chr. Hansen's Laboratory, Ltd., Copenhagen, Denmark

Rennin has been crystallised from commercial preparations as well as from laboratory extracts from calf stomachs after clarification with $Al_2(SO_4)_3$ and Na_2HPO_4 followed by 2 precipitations with NaCl.

Solutions of crystalline rennin are shown to have optimum stability at pH 5.5 to 6.0. The stability is also good at pH 2, whilst at pH around 3.5 and above 6.5 the enzyme is unstable.

Proteolytic experiments have shown that casein is digested by rennin over a wide range of pH (2–6.5), whereas bovine serum albumin is digested only in a rather narrow interval around pH 3.4.

1. INTRODUCTION

Crystallisation of the milk-clotting enzyme, rennin, has been described by several authors [1–9], but only few systematic studies have been published on the chemistry and properties of rennin. Alais [5] has stated that crystalline rennin is homogeneous on free electrophoresis in phosphate buffer 0.1 M pH 6.8, whilst Ernstrom [9] found that crystalline rennin on electrophoresis in phosphate buffer, pH 6.8, ionic strength 0.2, consisted of a main component and a component of slower mobility representing about 3.8 % of the total protein. According to Schwander *et al.*[10], crystalline rennin prepared by Berridge [1] was electrohomogeneous on paper electrophoresis. The preparation was found to be not quite homogeneous in the ultracentrifuge and by diffusion measurements. Schwander *et al.*[10] also confirmed Hankinson's [2] observation that the isoelectric point of rennin is about pH 4.6.

No investigations concerning the stability of rennin * solutions in relation to pH have been published, but it has been stated earlier that rennet is rapidly inactivated by alkali, and that its maximum stability lies between pHs 5.3 and 6.3 (Holwerda [11], Porcher [12], Ege and Lundsteen [13]).

* Here and in the following rennin means the enzyme purified by crystallisation, and rennet means a preparation containing rennin and other proteins.

Having isolated the crystalline rennin, Berridge [1] proved that it was a proteolytic enzyme with pH optimum at 3.7 against hemoglobin as substrate. Using the same substrate, de Baun *et al.*[3] have confirmed Berridge's statement. The proteolytic degradation of casein by rennin from pH 2 to pH 7 has been studied by Nitschmann and Bohren [14]. However, these investigations have mostly concerned the primary proteolytic action which, according to Alais *et al.*[15], is thought to be the essential change for the coagulation of casein with calcium as observed in the ordinary clotting of milk by rennet.

In the course of the present work, 19 preparations of crystalline rennin have been made. The raw materials for the crystallisations have been Chr. Hansen's commercial rennet preparations, as well as extracts made in the laboratory from calf stomachs directly. On electrophoresis by the moving-boundary method, the preparations appeared electrohomogeneous at pH 5.19, 5.78 and 6.35, ionic strength 0.2. The stability experiments have shown that solutions of rennin have optimum stability in the same interval of pH as stated earlier for rennet. The experiments on proteolytic degradation of casein and serum albumin with rennin have shown maximum proteolytic activity at pH 3.4 to 4.0.

2. METHODS AND RESULTS

2.1. Determination of the milk-clotting activity

The activity is expressed in rennin units (RU) according to Berridge [1]. This unit is defined as the rennin activity which clots 10 ml of reconstituted skim milk in 100 sec at 30°C. The substrate consists of 12 g spray-dried skim milk powder reconstituted in 100 ml 0.01 M $CaCl_2$.

Though the differences in clotting ability of various skim milk powders are diminished to some extent by reconstitution in 0.01 M $CaCl_2$, the powders may still show differences from batch to batch. Instead of using correction factors to overcome this difficulty, as suggested by Berridge [16], it was considered preferable to carry out the routine milk-clotting tests as relative tests. The activity of unknown samples was compared with that of a sample of liquid rennet as reference standard. The stability of this reference standard was checked at intervals by means of a basic standard consisting of freeze-dried rennin crystals stored at −15°C.

The crystals of the basic standard were prepared as described below. After crystallisation, most of the salt from the mother liquor was removed by rapid washing with ice cold water. After centrifugation, the crystals were suspended in water and freeze-dried as a suspension. Using a sample of good-quality spray-dried skim milk powder, the activity of the basic standard was determined using Berridge's [16] method, 900 RU/mg N being obtained.

The routine assays were performed at 35°C, and took place in a water thermostat similar to that described by Sommer and Matsen [17]. 50 ml of fresh skim milk were pipetted into wide-necked, 125-ml glass bottles. The bottles were placed on rollers in the thermostat. They had a 20° inclination, and the opening was just above the surface of the water. During the experiments, the bottles were slowly rotated (18 r.p.m.). 1 ml of rennin dilution was added to each bottle and thoroughly mixed with the contents. The clottingpoint,

indicated by the appearance of the first grains in the film flowing down the sides of the bottles, was noted. It was arranged that the rennin concentration chosen would give a clotting-time of 6—8 min. This could generally be achieved by using rennin concentrations of about 4 RU/ml.

The dilutions were made so that the difference between the clotting-time of the unknown sample and that of the reference standard was less than 20 sec. The rennin activity of the unknown sample was then calculated on the assumption of inverse proportionality between the clotting-time and rennin concentration (Storch and Segelcke[18]).

Care was taken that the unknown sample and the reference standard used in the milk-clotting test had the same buffer composition, as even small amounts of buffers with pH different to that of the skim milk could influence the clotting-time.

2.2. Preparation of crystalline rennin

28 dried calf stomachs (450 g) were finely cut and extracted at room temperature under continuous stirring in 7 litres 1 N NaCl. After 4 h, the suspended tissue was separated by passing through a coarse strainer. 5.5 litres of raw extract was obtained (pH 5.8, pre-formed activity 9.8 RU/ml).

Clarification and activation were carried out in one process: 150 ml of 1/3 M $Al_2(SO_4)_3$ was added to the raw extract; pH after addition, 3.65. Immediately after, 150 ml of 1 M Na_2HPO_4 was added and the resulting pH was 4.6. In order to diminish the dilution caused by clarification, concentrated solutions of alum and phosphate, temperature 40°C, were used. The preparation was left to stand 24 h at room temperature, after which the suspension was neutralised to pH 5.6 with 70 ml 1 M Na_2HPO_4, and the precipitate formed was discarded after centrifugation. The last traces of turbidity disappeared after filtration. The volume of the clarified extract was 5 400 ml. Yield and activity of this extract and of the extract in the following steps of the preparation are illustrated in Table 1.

The clear yellow extract was precipitated by saturation with NaCl. After 24 h, the precipitate was collected by means of centrifugation. It was re-dissolved in 450 ml 1/20 M phosphate buffer, pH 6.3. The volume of the resulting solution was 500 ml, pH 5.5. The second precipitation took place in a refrigerator (2°C) as a slow salting-out according to McMeekin[19]. A dialysing bag

Table 1. Crystallisation of rennin.

	ml	RU/ml	mgN/ml	RU/mgN	RU thousands	% recovery
Clarified extract	5 400	164	2.40	68.4	886	100
Dissolved 1st precipitation	500	1 240	2.88	431	620	70
» 2nd »	140	3 830	7.06	542	536	60
» 1st crystallisation	90	3 880	4.30	902	349	39

Suspension 3rd »	50	4 300	4.59	937	215	24

(Visking cellulose) with solid NaCl was slowly rotated whilst submerged 2 cm in the solution. 130 g of NaCl was dissolved in the course of 5 days. The bag was removed, and the globular precipitate was collected by centrifugation. It was dissolved in 115 ml 1/20 M phosphate buffer pH 6.3, and after one day in the refrigerator, a little insoluble residue was removed by means of centrifugation.

The clear solution (140 ml, pH 5.4) was left in the refrigerator. After 3 days, the first traces of crystals appeared, and the following week a rapid crystallisation took place. After 18 days, the suspension was centrifuged. The activity of the supernatant was 930 RU/ml. The crystals were washed in distilled water (2°C). The activity of the washings (100 ml) was 236 RU/ml. The crystals were dissolved in distilled water, and left to stand overnight in the refrigerator. A small, insoluble residue was discarded.

Re-crystallisation took place after addition of 5.4 g NaCl, and after 3 weeks in the refrigerator, the activity of the clear supernatant had fallen to 180 RU/ml. The crystals were once more collected, dissolved, and recrystallised as above. After the third crystallisation, the crystals were washed three times in 2 N, 3 N and 4 N NaCl respectivly. The crystals were stored in 4 N NaCl at 2°C.

Regarding the shape of rennin crystals, various statements have been published by different authors. Berridge [1], Alais [5] and Ernstrom [9] have published photos of rectangular crystals which appear to be identical with most of the preparations made in this laboratory. Hankinson [2] and Oeda [6] describe their preparations as needles. De Baun *et al.*[3] state that their crystals resemble Hankinson's, whilst Hostettler [7] has published a photo of some crystal fragments.

Nearly all our preparations of rennin have crystallised in rectangular plates or blocks, but two smaller samples crystallised in needles or long thin rods. The preparations were stored in a freezer at −15°C, and after 4 months, the needle-formed crystals had been transformed into rectangular plates. In spite of several attempts, it has not been possible to reproduce the needles, whether by re-crystallisation or in other preparations.

The homogeneity of the preparations was controlled by means of moving-boundary electrophoresis in a Tiselius apparatus equipped with the Svensson

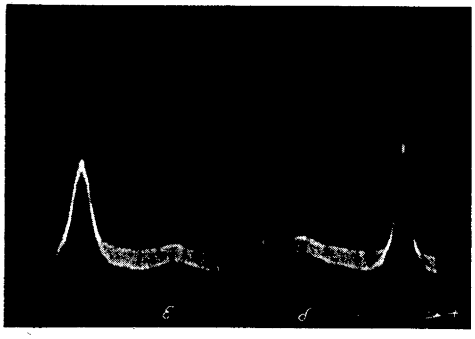

Fig. 1. Electrophoretic pattern of twice re-crystallised rennin. Concentration 0.29 % in phosphate buffer pH 5.78, ionic strength 0.1 + 0.1 M NaCl. The pattern is shown after 31 440 sec of migration, field strength 4.1 V/cm. Temperature in the bath 1.3°C. Svensson's optical system with parallel slit was used.

Table 2. Stability of rennin in solutions.

	pH	Ionic strength	Initial activity	Activity after: 2	4	7	11	days
2°C			RU/ml	RU/ml				
Citrate buffer	3.5	0.05	196	160	150	137	130	
Phosphate buffer	7.0	0.05	196	184	181	169	158	
25°C				6	24	48	96	hours
Citrate buffer	3.5	0.05	196	164	133	112	92	
Phosphate buffer	7.0	0.05	196	176	147	113	95	

optical system. The runs were made at 1.3°C in phosphate buffers, ionic strength 0.1, to which was added NaCl to a total ionic strength of 0.2, pH 5.19, 5.78 and 6.35. The runs were made with a field strength of 3.7 to 4.4 V/cm. The mobility of the descending boundary was determined and found to be -2.05, -3.44 and -3.53 10^{-5} cm^2 volt^{-1} sec^{-1}. Under these conditions, the rennin appeared to be electrohomogeneous, Fig. 1. A solubility test also showed that the enzyme was free of significant contamination with other proteins (Foltmann [20]).

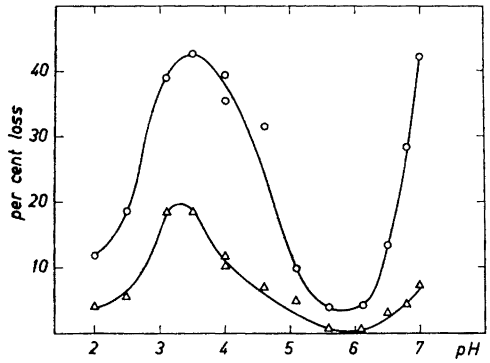

Fig. 2. The influence of pH on the stability of rennin expressed as per cent loss of initial activity after 48 h at 25°C (○) and 48 h at 2°C (△). Ionic strength of all solutions 0.05, pH 2—4 citrate buffers, pH 4—5.1 acetate buffers, pH 5.1—7 phosphate buffers. The upper points at pH 4 represent loss in citrate buffers, and the lower loss in acetate buffers.

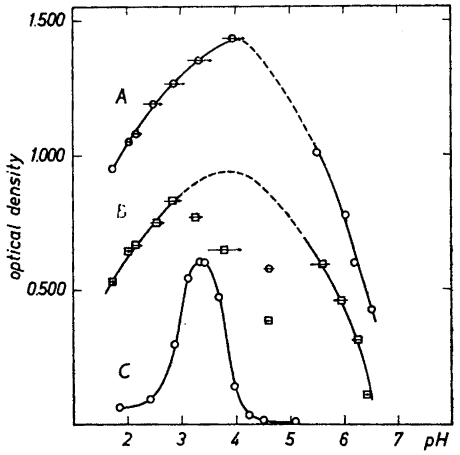

Fig. 3. Proteolytic activity of rennin. Substrate: A and B, 0.89 % casein; C, 0.86 % bovine serum albumin. Enzyme activity per ml reaction mixture: A, 5.33 RU; B, 1.33 RU; C, 14 RU. All experiments, 1 h reaction at 32°C. Ordinate, optical density at 275 mμ of supernatant after precipitation with TCA.

2.3. The influence of pH on the stability of rennin solutions

A 10-ml suspension of rennin crystals was centrifuged. The crystals were washed with cold, distilled water, and after suspension in water, were dialysed in a Visking bag against 3 × 2 litres distilled water at 2°C (6 + 20 + 24 h). By conductivity measurement, it was established that the final concentration of NaCl was less than 10^{-4} N. The activity of the solution was, after dilution to 200 ml, 392 RU/ml, pH 6.0. Equal volumes (5 ml) of buffers, ionic strength 0.1, and rennin solutions were mixed, and to each tube were added three drops of toluene. The tubes were stoppered and divided into two series, one being placed in a water thermostat at 25°C, and the other being in a refrigerator at 2°C. The result of the experiment, expressed as the per cent loss of the initial activity after two days, is illustrated in Fig. 2. Table 2 shows the course of the inactivation at pH 3.5 and 7.0.

The stability experiments were performed in citrate buffers, pH from 2.0 to 4.0. Acetate buffers were used from 4.0 to 5.1, and phosphate buffers for pH over 5.1. At pH 4.0, acetate and citrate buffers were tested in parallel. In all experiments, citrate buffers gave slightly higher losses in activity than acetate buffers at pH 4.0. As the inactivation of rennin at pH below 5 may be considered to be an autolysis, it is of interest to note that similar results have been obtained with digestion of serum albumin in citrate and acetate buffers. The former gave a more rapid degradation than the latter, indicating that citrate has an activating effect upon the proteolytic activity of rennin. At pH 5.1, experiments were made in parallel with acetate and phosphate buffers, but no difference in stability was noted.

2.4. The proteolytic activity of rennin

Digestion of casein by rennin. The casein was precipitated from fresh skim milk by adding 0.1 N HCl to pH 4.6, redissolved in water by slowly adding 0.1 N NaOH to pH 6.7, and was then re-precipitated twice. After washing with distilled water, the casein was dried with alcohol and ether. For the experiments, the casein was dissolved by slowly adding 0.1 N NaOH to pH 6.7. Two ml of a 2 % casein solution was mixed with 2 ml of diluted HCl (the concentration of HCl required to give a suitable pH was determined in preliminary experiments). Digestion took place in a water thermostat at 32°C. The casein mixtures were stirred for 60 min by mechanical inversions of the tubes (three inversions per min). 0.5 ml of rennin was added to each tube, and after a further 60 min, during which time the inversions were continued, 3 ml of the reaction mixture was precipitated with 3 ml 1 M trichloroacetic acid (TCA). The precipitate was removed by centrifugation, and the optical density of the supernatant was determined at 275 mμ. A blank test, in which rennin was added after addition of TCA, was run at each pH. The pH was measured at the beginning and at the end of the reaction. The results are illustrated in Fig. 3 A and B. In most of the tubes the pH was displaced during the reaction as illustrated by the length of the arrows.

Due to the insolubility of casein around the isoelectric point pH 4.6, the proteolytic activity gives irregular results in this range of pH. In Fig. 3, the branches of the curves outside the range of pH in which casein is precipitated, are connected with dotted lines in order to obtain regular curves with only one maximum.

Digestion of serum albumin by rennin. The substrate in these experiments was "bovine serum albumin — Armour". The substrate was supplied as a 30 % solution and was diluted down to 6 % before use. 1 ml substrate solution was mixed with 5 ml citrate buffer, ionic strength 0.1. The reaction took place at 32°C. The substrate mixtures were placed in the thermostat 15 min before addition of 1 ml rennin dilution to each tube. The reaction was stopped after 60 min by adding 5 ml 1 M TCA to each tube, and after centrifugation, the optical density of the supernatant was determined at 275 mμ. A blank test was run at each pH. No displacement of pH was noticed during the reaction. The results are shown in Fig. 3 C.

3. DISCUSSION

As the clotting ability of re-constituted skim milk depends to a great extent upon the milk powder used, it has been very difficult to compare the enzymic activity of preparations of rennin crystals made at different laboratories, even if the activity has been expressed in rennin units according to Berridge [1].

Alais [5] made an attempt to compare his crystals to those of Berridge but came to rather divergent results, probably owing to the above-mentioned difficulties. Fortunately, the activity of several preparations of crystals has been compared against Chr. Hansen's commercial rennet, and the author has therefore been able to convert the activities to the same RU used in this work.

The author is grateful to C. Alais for personal communication of results on crystals made after salt fractionation and after preparative electrophoresis on agar gel(published [21]). The author is likewise indebted to M. T. Sode-Mogensen and J. Thomasov, and to M. T. Sode-Mogensen and N. Tofte Jespersen for permission to publish their analyses of a sample of Berridge's crystals (prepared 1945), analysed in 1951 and 1955. H. Dan of Chr. Hansen's Laboratory, Inc., Milwaukee, has independently prepared a sample of rennin crystals, which has been analysed at this laboratory. Ernstrom's result is taken from his publication [9]. The various results appear in Table 3.

Table 3. Comparison between the rennin activity per mg N of different preparations of crystalline rennin.

Preparation	Analysed by	RU/mg N
Average this work	B. Foltmann	944
H. Dan	B. Foltmann	1 066
C. A. Ernstrom [9]	C. A. Ernstrom	922
N. J. Berridge [1] (1945)	M. T. Sode-Mogensen and J. Thomasov (1951)	889
N. J. Berridge [1] (1945)	M. T. Sode-Mogensen and N. Tofte Jespersen (1955)	731
C. Alais [5] (prepared by salt fractionation)	C. Alais	662
C. Alais [21] (prepared by electrophoresis)	C. Alais	858

Though there are appreciable differences between the various preparations, the activity of all is of the same order of magnitude. It should be added that deviations in the preparations made at this laboratory have been from 880 RU/mgN to 1 000 RU/mgN. Alais, analysing a sample of our crystals, found a deviation of only 4 % from that found here.

The stability of solutions of crystalline rennin is considerably less than that of commercial liquid rennet. This is often met with in the purification of enzymes (Anson [22]). The results of the present work confirm the well-known fact that rennin is very sensitive to alkaline or even neutral reaction. Around pH 3.5, the enzyme is unstable. As this range coincides with that of the maximum of proteolytic activity, it indicates that the loss may be due to autolysis. When comparing the inactivation of rennin at 2° and 25°C it is noticed that by raising the temperature, the inactivation at pH 7 is increased considerably more than at pH 3.5.

Casein is the natural substrate for rennin, but as it is only very slightly soluble around its isoelectric point (pH 4.6) it is not well suited to characterise the proteolytic activity of rennin in relation to pH. The precipitated casein is not particularly accessible to the proteolytic activity of rennin, and this will cause irregular observations around pH 4.6. On deeper degradation, these irregularities will be reduced to some extent. However, if the observations plotted in Fig. 3 are connected in such a way that regular curves with only one maximum are obtained, the "maximum" of proteolytic activity is found at pH 4. As it was observed that citrate precipitates casein over a greater range of pH than does HCl, the experiments have been performed without addition of buffer, although this had the disadvantage of the pH being displaced during the reaction. On comparing the degradation of casein and serum albumin, it was noticed that, 1: serum albumin is only degraded in a rather narrow interval around pH 3.4, and 2: that the degradation of serum albumin proceeds much more slowly than that of casein. However, this cannot be regarded as a special case for casein and rennin, as casein in general is more easily digested by proteolytic enzymes than are globular proteins.

Though the general proteolytic activity of rennin is only feeble at pH 6.6—6.7, which is the normal pH of fresh skim milk, Alais *et al.*[15] have shown that the clotting of casein starts with a rapid release of non protein nitrogen (NPN) soluble in 12 % TCA. A study on the enzymatic and the coagulation stages of the clotting of milk by rennin (Foltmann [23]) has supported the point of view that the increase of NPN soluble in 12 % TCA corresponds to the enzymatic phase proper. The lack of linearity between the rennin concentration and the reciprocal of the clotting time may be explained by the time lag of the coagulation stage, when the clotting point observed occurs some time after the increase of NPN comes to an end.

Acknowledgements. The electrophoretic experiments were carried out at the Protein Laboratory of the University of Copenhagen by Dr. N. Harboe. The author is grateful to Dr. N. Harboe for his kind help and for many inspiring discussions. The author wishes to thank the management of Chr. Hansen's Laboratory Ltd. for permission to publish the results. Thanks are also due to the staff of the laboratory for their kind interest in the work, especially to Mrs. K. M. Djurtoft for her valuable co-operation and to Mrs. I. M.

Kristensen for skilled technical help. The author is indebted to Prof. C. Faurholt, Dr. R. Djurtoft and Dr. N. Harboe for critical review of the manuscripts. Mr. R. Gillman has kindly assisted in the translation to English.

Studies on Rennin

III. On the Solubility of Rennin

BENT FOLTMANN

Chr. Hansen's Laboratory, Ltd., Copenhagen, Denmark

Rennin crystals show a slow solubility rate. They are very soluble in distilled water (more than 8 %) and very slightly soluble in concentrated salt solutions (about 0.02 % in 1 N NaCl, pH 5.5). Amorphous precipitates prepared of crystallised rennin fulfil the requirements of the phase rule for a single-component system at the pH of optimum stability. Amorphous rennin shows a solubility minimum in Na-acetate buffers at ionic strength 0.1, pH 5.45. In NaCl solutions, ionic strength 2.5 to 4.85, the log.sol. decreases linearly with ionic strength. The solubility around the isoelectric point (pH 4.6) is small, 0.01 % at ionic strength 0.005, increasing with rising ionic strength.

1. INTRODUCTION

Previous studies on rennin have only contained few remarks on its solubility. Hankinson and Palmer [1] have stated that purified, non-crystallised rennin behaves like a globulin, soluble in a dilute NaCl solution, precipitating at pH 4.5—4.7 (the isoelectric point), insoluble in saturated salt solutions. Berridge [2] has stated that rennin crystals have a slow solubility rate and a very low solubility in salt solutions. Berridge [2] also made a solubility test for homogeneity using an $MgCl_2$/Na-acetate buffer as the liquid phase.

As rennin preparations are most often made using precipitations with NaCl, and as divalent metal ions will interfere in the milk-clotting test, the following experiments are made with NaCl-solutions buffered with Na-acetate.

The crystalline rennin used in these experiments was prepared and recrystallised twice as described earlier (Foltmann [3]). During the experiments, it was very difficult to get exact, reproducible results when working with rennin crystals, as these have a very slow rate of solubility in salt solutions, and as the final phase of the crystallisation also proceeds slowly. The experiments in the sections 3.2, 3.3 and 3.4 were therefore performed using amorphous precipitates of rennin prepared in the following way: Rennin crystals were dissolved by dialysis against distilled water, and by rapid mixing of the rennin solution with the solvent in question, the rennin was precipitated in an amorphous state.

2. EXPERIMENTAL

The rennin activity was assayed and expressed in rennin units (RU) as previously described [3]. The results may be converted to mg rennin after dividing by 140, as the rennin used had an activity of 140 RU/mg dry weight. The optical density of the solutions was determined on a Beckman spectrophotometer DU at 277.5 mμ.

The solubility experiments were made in 2—3 ml centrifuge tubes closed by a rubber stopper. In order to avoid air-bubbles in the tubes during the experiments, the tubes were closed, using a thin syringe needle — through which the air could escape — beside the rubber stopper. However, it was very difficult to expel all the air, and during most of the experiments, air was present in the tubes. Control experiments have shown that the loss of enzymatic activity due to surface inactivation on the air-bubbles in the tubes was negligible.

The tubes were attached to a rectangular grid by means of a rubber band. For experiments with amorphous precipitates, equilibrium between the solid and the liquid phases was ensured by mechanical inversion of the tubes (3 inversions per min) during 18—20 h. For experiments with the crystalline form, the inversions were continued for up to 10 days. The experiments at 2°C were performed in a refrigerator in which the temperature was controlled to ± 1°.

The solid phase was separated from the liquid phase by means of centrifugation in the refrigerator. A possible rise of temperature during the centrifugation could not be observed. For experiments at 25°C, equilibration took place in a water thermostat (± 0.1°C). Centrifugation took place at room temperature, 23°C ± 2°.

As the precipitates of amorphous rennin were formed by mixing rennin solutions with a solvent, the equilibrium was in most cases arrived at from the supersaturated side. However, by salting-out in concentrated salt solutions, where rennin in the amorphous state is more soluble at 2° than at room temperature, the equilibrium was arrived at from both unsaturated and supersaturated solutions.

The unsaturated conditions were established by mixing the rennin and salt solutions at room temperature, and letting them stand at this temperature for 3 h before the inversion process was started in the refrigerator. The supersaturation was obtained by cooling the rennin and salt solution to 2°C before mixing and inversion.

3. RESULTS

3.1. Solubility of rennin crystals

Exact determinations of solubility of rennin crystals in solutions of NaCl are very difficult to carry out. The solubility rate is very slow. When working with a slight surplus of solid phase, even 8 days of inversion of the tubes in the refrigerator will not be sufficient to establish equilibrium. However, it is observed that rennin crystals are very soluble in distilled water. The most concentrated solution we have analysed has had an activity of 11 000 RU/ml, corresponding to an 8 % solution, pH of the solution 5.5. This solution was made by dialysis of the crystals against distilled water. During the process of dialysis, semi-dissolved crystals formed a heavy bottom phase, somewhat like honey; the viscous liquid was not analysed, but it was obviously much more concentrated than the final 8 % solution. However it shall be added, that by electrodialysis of the solution pH was displaced to 4.6 and the rennin was precipitated in an amorphous state.

In salt solutions, the solubility of the crystals decreases very rapidly when the salt concentration is raised. In 0.2 N NaCl, the solubility is around 200 RU/ml, in 1 N NaCl 30 RU/ml and in 4 N NaCl 5 RU/ml, corresponding to 1.43, 0.21 and 0.04 mg rennin/ml. The pH of the liquid phase has been 5.5 ± 0.1

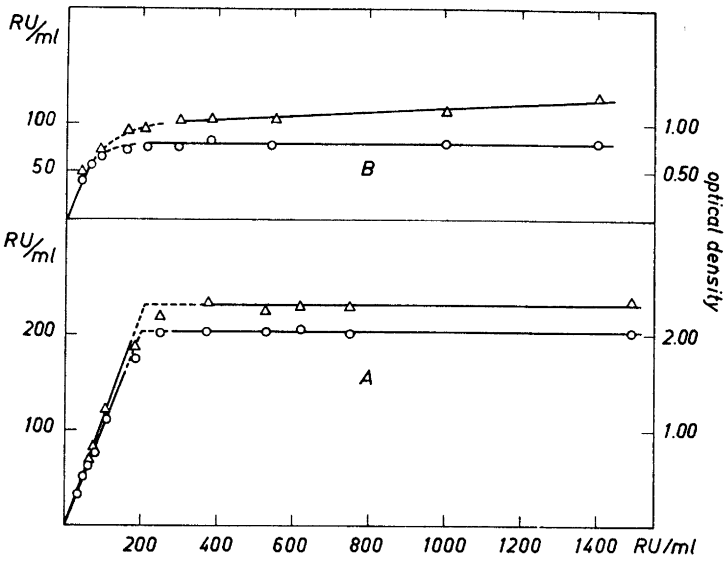

Fig. 1. Solubility test for the homogeneity of rennin. Solid phase: Amorphous precipitates of rennin. Liquid phase: A, NaCl-acetate, pH 5.5, ionic strength 4. B, Na-acetate buffer, pH 4.6, ionic strength 0.05. Abscissa: Total rennin activity of the suspensions. Ordinate: (△) optical density of the liquid phase at 277.5 mμ. (○) rennin activity of the liquid phase. All determinations made at 2°C.

during all these determinations. Contrary to precipitates of amorphous rennin, the rennin crystals seem to be more soluble at 25°C than at 2°C.

In the experiments on the solubility rate of rennin crystals, it was noted that the solubility rate did not only depend on the total amount of the solid phase. Also of importance was whether or not the crystals had been used in earlier solubility experiments. If the crystals had been "extracted" once, the rate of solubility would be much slower in a second experiment, almost as if a superficial layer of rennin molecules was more loosely bound in the crystals than the deeper placed molecules. A constant ratio between the rennin activity and the optical density of the liquid phase suggested that no fractionation took place owing to repeated "extraction" of the crystals.

3.2. Solubility test for homogeneity of rennin (Fig. 1)

Solubility tests for the homogeneity of rennin were made at the pH of optimum stability (pH 5.5) and at a pH near the isoelectric point (pH 4.6). All experiments in this section were made at 2°C. These experiments were performed using amorphous precipitates of rennin as the solid phase. The precipitates were formed by rapid mixing of dialysed rennin solutions with the solvent.

In experiments made at pH 5.5, 0.4 ml rennin solution was mixed with 1.6 ml of a stock salt solution consisting of 117 g NaCl + 41 g Na-acetate + 45

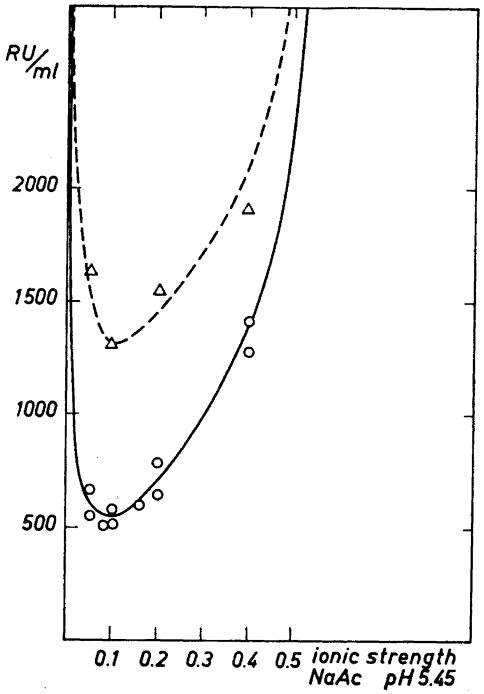

Fig. 2. Solubility of amorphous precipitates of rennin at low salt concentrations. Liquid phase: Na-acetate buffers pH 5.45 ± 0.05. Dotted line, solubility at 25°C. Full line, solubility at 2°C.

ml 1 N acetic acid made up with water to 500 ml. The pH of the solution was 5.5 and the resulting ionic strength of the suspensions was 4.0. The suspensions were equilibrated by 18 h of inversion of the tubes. The activity and the optical density of the supernatants after centrifugation are illustrated in Fig. 1 A. At pH's near the isoelectric point rennin is not quite stable (Foltmann [3]), but as further experiments (section 3.4) were made in this range of pH, the homogeneity was also tested at pH 4.6. In these experiments, 1 ml of rennin solution was mixed with 1 ml Na-acetate buffer pH 4.6, ionic strength 0.1. The activity and optical density of the supernatants after centrifugation are shown in Fig. 1 B.

3.3. Salting-out of rennin (Figs. 2 and 3)

As previously stated (Foltmann [4]), rennin in the amorphous state has a solubility minimum at ionic strength 0.1, pH 5.4. In order to localise this solubility minimum in dilute salt solutions, experiments were made with suspensions of amorphous rennin in solutions of ionic strength from 0.05 to 0.4. To control pH, Na-acetate buffers were used in the liquid phase. When preparing the buffers, the relative concentration of acetic acid was adjusted so as to maintain

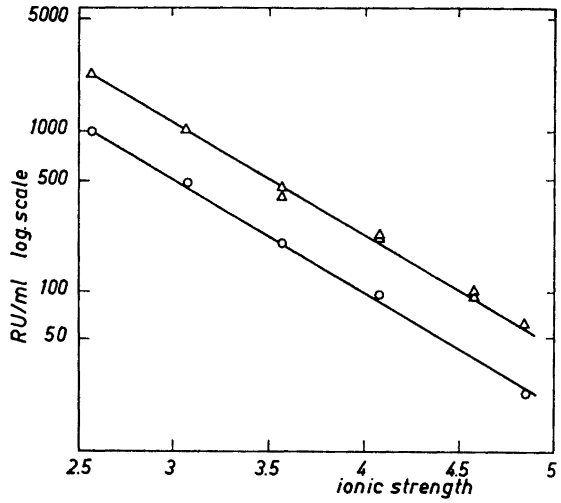

Fig. 3. Salting-out of amorphous rennin by NaCl. pH of the liquid phase 5.3 ± 0.05. Upper line (△) solubility at 2°C. Lower line (○) solubility at 25°C.

the pH at 5.45 ± 0.05. The experiments were made at 2°C and at 25°C. Results are shown in Fig. 2.

In the experiments on salting-out of rennin in concentrated salt solutions, NaCl was dissolved in Na-acetate buffer, pH 5.6, ionic strength 0.1, giving ionic strength of the mixtures from 2.5 to 4.85. The resulting pH, 5.3 ± 0.05. Results are shown in Fig. 3, and it is seen that the enzyme in equilibrium with amorphous precipitates is more soluble in concentrated salt solutions at 2°C than at 25°C.

In Fig. 3, the results are illustrated by log RU/ml, as RU/ml was the quantity observed directly. The logarithm of the solubility decreases linearly with the ionic strength according to Cohn's equation [5], $\log s = B - Ks \cdot \frac{\Gamma}{2}$. After the concentration of soluble rennin was converted from RU/ml to g/litre, the constants of Cohn's equation were calculated by the method of the least squares. The following values were obtained:

$$2°,\ B = 3.00,\ Ks = -0.703$$
$$25°,\ B = 2.67,\ Ks = -0.708$$

As experience has shown that crystallisation often starts at glass surfaces, these experiments were performed in polyethylene tubes, assuming the polyethylene surface to be more inactive than the glass surface. In spite of this, it has not been possible to determine the solubility of amorphous rennin at ionic strengths from 0.4 to 2.5. Within this range, the solutions were so supersaturated with respect to crystals, that crystallisation started immediately. In experiments at ionic strengths 2.5 and 3, a microscopic examination of the precipitate disclosed a few crystals, but the granular, amorphous precipitate

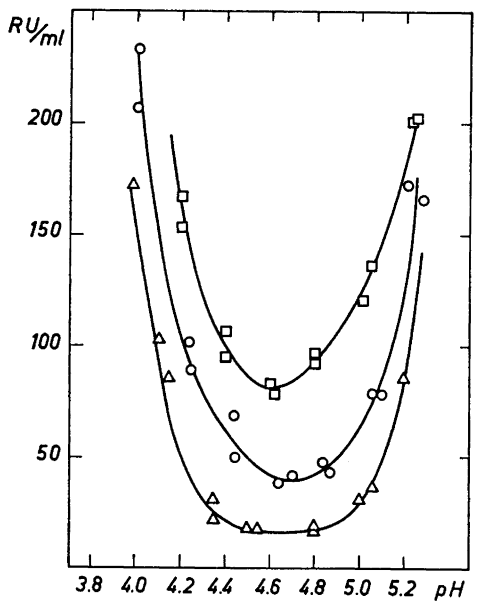

Fig. 4. The influence of pH and ionic strength on the solubility of amorphous precipitates of rennin near the isoelectric point. Liquid phase: Na-acetate buffers, △: ionic strength 0.005; ○: 0.025; □: 0.05.

dominated. The great surplus of the most soluble form will have fixed the concentration of the liquid phase. Experience has also shown that at rennin concentrations below 500 RU/ml, crystallisation starts very slowly, although the solutions are supersaturated with respect to crystals.

3.4. Solubility of rennin at the isoelectric point (Fig. 4)

The experiments were made using acetate buffers; ionic strengths of the mixtures: 0.005, 0.025 and 0.05. In each determination, 1 ml of dialysed rennin solution has been mixed with 1 ml of buffer. The dialysed rennin solution had a pH of 5.5. In experiments at low ionic strength especially, the buffer capacity of the rennin was sufficient to displace the pH of the buffer. The pH of every mixture was therefore checked after equilibrium was obtained, and the final pH was used when plotting the results in Fig. 4. All experiments referred to in Fig. 4 were made at 2°C.

Results from experiments made at 25°C are rather uncertain, due to the instability of the enzyme in this range of pH. However, it seems that under these conditions, the solubility is higher at 25°C than at 2°C. At pH 4.6, ionic strengths 0.025 and 0.05, the solubility at 25°C was determined as 54 and 114 RU/ml.

4. DISCUSSION

The solubility test for homogeneity of the rennin, made with 4 N NaCl-acetate as the liquid phase (Fig. 1 A), nearly fulfilled the requirements of the phase rule for a single-component system, although the point of inflection is not absolutely sharp. When using Na-acetate buffer, ionic strength 0.05, pH 4.6, as the liquid phase (Fig. 1 B), the results do not follow the phase rule for a single-component system. The »point of inflection» is round, and the optical density especially will rise with rising concentration of the solid phase. Here, it must be remembered that the enzyme is not stable at pH 4.6, and the deviations may be ascribed to the beginning of degradation. This experiment cannot be regarded as a test for homogeneity, but as further experiments were made at pH's around the isoelectric point, it was considered expedient to report these results.

At pH near the isoelectric point rennin is rather insoluble (Fig. 4), but the instability below pH 5 greatly complicates a theoretical interpretation of the solubility curves. The second solubility minimum at ionic strength 0.1 (Fig. 2), further complicates a theoretical examination. Because of this second solubility minimum the solubility at ionic strength 0.1 will be diminished, relative to lower ionic strength, on raising pH from 4.6 to 5.4. This means that the rising branches of the solubility curves, above pH 4.6, will intersect between pH 5.2 and pH 5.4. The point of intersection has not yet been fixed.

At pH 5.3—pH 5.5, the solubility of amorphous rennin is greater at 25°C than at 2°C, this when the ionic strength is below 0.4, whilst the opposite is the case at ionic strengths above 2.5. However, it has not been possible to determine the point of intersection of the curves owing to crystallisation of the rennin.

In Figs. 2, 3 and 4, the results of the experiments are only illustrated by means of rennin activity curves, this for purposes of clarity. However, the ratio between the milk-clotting activity and the optical density at 277.5 mμ has been checked in all experiments. As could be expected (Fig. 1B), this ratio was found not to be constant in the experiments around the isoelectric point (Fig. 4). In the other experiments made at 2°C, the ratio was constant ± 5 %. However, the ratio decreased up to 30 % in the least active supernatants from experiments at 25°C. As a corresponding increase in the same ratio was not found after dissolution of the remaining solid phase, the decrease of the enzymatic activity of the liquid phase was probably due to beginning inactivation and not to fractionation.

Conjugate Additions of Grignard Reagents to alpha,beta-Unsaturated Esters

V. Additions of *n*-Butylmagnesium Bromide to *sec*-Butyl Esters of Maleic, Fumaric, Citraconic, and Mesaconic Acids

EIGIL BJERL NIELSEN, JON MUNCH-PETERSEN, PEER MØLLER JØRGENSEN and SUSANNE REFN

Organisk-kemisk Laboratorium, Polyteknisk Læreanstalt, Copenhagen, Denmark

n-Butylmagnesium bromide reacts with *sec*-butyl maleate, fumarate, citraconate and mesaconate by addition to the carbon-carbon double bond (1,4-addition) as well as by addition to one of the carbonyl groups (1,2-addition). 1,4-Additions lead to substituted succinic esters, while 1,2-additions followed by 1,4-additions result in saturated lactones. With maleic and fumaric esters the yields of simple 1,4-addition product (*n*-butylsuccinic ester) are rather low, but the yield from the maleic ester is greatly improved by cuprous chloride catalysis. The yields from citraconic and mesaconic esters are quite satisfactory with respect to the amounts of 1,4 addition product formed, but the products are mixtures of the two isomeric methyl-*n*-butylsuccinic esters. From mesaconic ester the major product is the α,α'-disubstituted ester, whereas the product from citraconic ester is mainly the α,α-disubstitute. In the presence of cuprous chloride citraconic and mesaconic esters are to a large extent reduced (to pyrotartaric ester). The effect of inverse addition of the Grignard reagent has been studied with certain esters. The mechanisms of the reactions are considered.

This paper is concerned with the behaviour of the *sec*-butyl esters of maleic, fumaric, citraconic and mesaconic acids in reactions with Grignard reagents under certain conditions which have previously been found favourable for conjugate addition in the reactions of esters of mono-carboxylic α,β-unsaturated acids such as *sec*-butyl crotonate[1]:

$$CH_3CH{=}CH{-}COO\text{-}sec\text{-}C_4H_9 \xrightarrow{n\text{-}C_4H_9MgBr} CH_3\underset{\displaystyle n\text{-}C_4H_9}{\underset{|}{C}}H{-}CH_2COO\text{-}sec\text{-}C_4H_9$$

Reactions between maleic and fumaric esters and metalloörganic compounds have occasionally been described in the literature [2-6] and maleic anhydride has also been included in these studies [4-6]. In most cases methyl or ethyl esters have been employed, and the reactions have generally taken place as 1,2-additions (to the carbonyl group), although 1,4-additions (to the carbon-carbon double bond) have often been reported as well. The products obtained have thus been either unsaturated or saturated diketones or tertiary alcohols (*cf.* Ref.[7]). Usually, no yields are given.

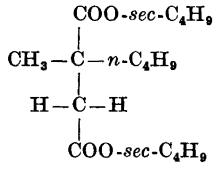
Marvel *et al.*[6], however, have obtained about 30 % yield of diethyl *iso*propylsuccinate from equivalent amounts of either diethyl maleate or fumarate and *iso*propylmagnesium bromide, when the Grignard reagent was added to the ester (no special mention was made of addition time or temperature). Furthermore, the same authors report that the 1,4-addition of *iso*propylcadmium reagent to diethyl maleate also gives a 30 % yield of diethyl *iso*propylsuccinate; in this case the ester was added to the reagent at 0° during 3 1/2 h. This latter result is remarkable, since usually cadmium reagents are believed to react by nucleophilic substitutions rather than as additions, and are consequently quite unreactive towards double bonds [8].

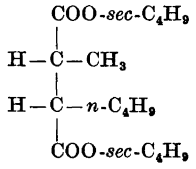
Also a zinc reagent has apparently been used in reactions of this type, since Michael [9] report the formation in 20—25 % yield of diethyl ethylsuccinate and diethyl α-methyl-α'-ethylsuccinate by the prolonged action of ethyl iodide and zinc upon diethyl fumarate and citraconate, respectively. No details are mentioned.

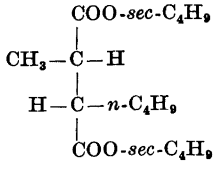
Much better results have been reported [10] with tetraethyl ethylenetetracarboxylate to which methyl-, ethyl- and phenylmagnesium bromides have been added (in yields of 79, 56 and 71 %, respectively) without taking any special precautions (cooling or prolonged addition time).

In the present investigation, elucidation of the following three questions has been attempted: 1. Does conjugate addition to the double bond take place and in what yield? 2. Could any difference in this respect be found between geometrically isomeric esters (such as maleic and fumaric esters)? 3. Which would be the orientation (if any) of addition to unsymmetrically substituted esters (such as citraconic and mesaconic esters)? The possible catalytic effect of cuprous chloride on the course of the reactions has also been investigated.

From maleic and fumaric esters only one simple 1,4-addition product is possible: *d,l-n*-butylsuccinic ester; but from citraconic and mesaconic esters, in fact, three different racemic methyl-*n*-butylsuccinic esters are conceivable: *d,l-α*-methyl-*α*-*n*-butylsuccinic, *d,l-erythro-* and *d,l-threo-α*-methyl-*α'*-*n*-butylsuccinic esters:





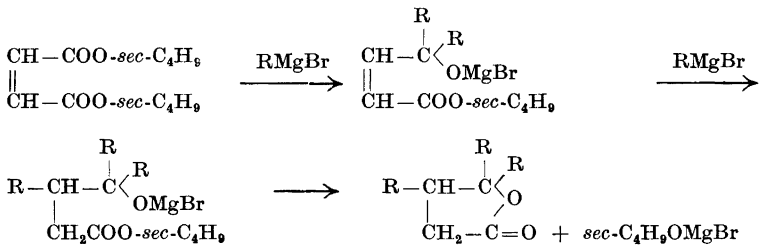


Since the addition process can hardly be visualized as being stereospecific (*cf.* below), the possibility that only one of the two different stereo-isomers (or a mixture of unequal amounts thereof) is formed has not been considered *.

The results of the addition reactions with *n*-butylmagnesium bromide are given in Table 1.

Non-catalyzed additions. When the general procedure [1] is followed, the maleic and fumaric esters give rather unsatisfactory yields (30—40 %) of the conjugate addition product (*n*-butylsuccinic ester), considerable amounts (17 %) of 1,2-addition product (lactone, see below) being formed. From the citraconic and mesaconic esters, on the other hand, quite satisfactory yields (66 and 55 %, resp.) of addition products are obtained, with only little lactone being produced. In one run with mesaconic ester a small quantity of reduction product (se below) was isolated.

The high-boiling by-products (II, IV and VII) are believed to be lactones, which are formed by initial 1,2-addition to one ester group, followed by 1,4-addition and ring-closure, according to the following scheme (*e.g.* with maleic ester):



The lactone structure of II, IV and VII has been confirmed by analyses and infra-red spectroscopy. The formation of small amounts of lactones has also been observed by earlier workers [2,5].

The reduction process is discussed below.

Cuprous chloride catalyzed reactions. Since cuprous chloride has been previously found to catalyze 1,4-addition in competition with 1,2-addition [7,12] and reduction [13], this catalytic procedure was also tried in the present work, but the results were not entirely consistent with the earlier findings.

In the case of the maleic ester the yield of the conjugate addition product was indeed considerably increased (to 67 %); very little lactone was now produced. The reaction with the fumaric ester was little affected by the presence of cuprous chloride; the amount of 1,4-addition product was somewhat increased at the expense of the lactone.

In the case of the citraconic and mesaconic esters, however, the yield of the 1,4-addition product was strongly decreased (to 30 and 20 %, resp.) by the presence of cuprous chloride, and the reduction of the double bond (leading to

* It is quite likely, however, that one of the stereo-isomeric α,α'-disubstituted acids has been isolated in a comparatively pure form (by the recrystallizations during the identification work, see experimental part), since the melting point of our α,α'-compound is rather sharp and considerably higher (136°) than that reported in the literature [11]: 85—105°. No attempt has been made to determine the configuration.

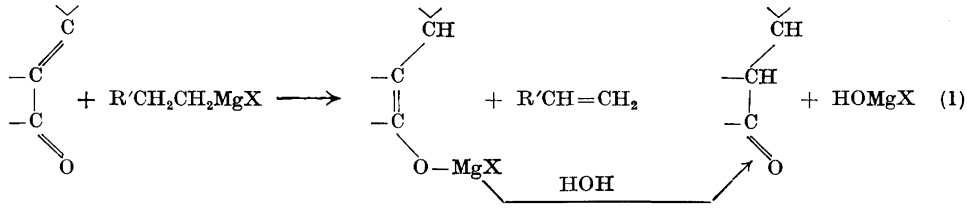
methylsuccinic (pyrotartaric) ester) now became correspondingly dominating. This reaction could be written:



(1)

The mechanism of the reduction process is considered below (eqn. 5). The observation that cuprous chloride promotes reduction in competition with 1,4-addition of the Grignard reagent was surprising in view of the above-mentioned findings by Brändström and Forsblad [13], who report a pronounced effect of this catalyst to favour addition over reduction in the reaction of Grignard reagents with alkylidenecyanoacetic esters. This apparent inconsistency is discussed below.

Table 2. Ratios of isomeric methyl-*n*-butylsuccinic esters formed from citraconic and mesaconic esters, determined by infra-red spectroscopy (IR) and by gas-liquid chromatography* (GLC).

		Uncatalyzed		CuCl-catalyzed		CuCl-catalyzed inverse addition

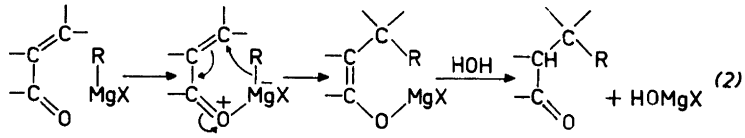
* Carried out and interpreted by A. Jart, Danish Fat Research Institut, Copenhagen.

*The formation of isomeric methyl-*n*-butylsuccinic esters from citraconic and mesaconic esters.* Regarding the question of the methyl-*n*-butylsuccinic esters obtained by the addition processes with citraconic (*cis*) and mesaconic (*trans*) esters, it was found that both isomers (*α*-methyl-*α*-*n*-butylsuccinic and *α*-methyl-*α'*-*n*-butylsuccinic esters) were formed, but in very different quantities in the two cases. More than 80 % of the *α,α*-isomer and less than 20 % of the *α,α'*-isomer was found in the product from the citraconic ester, while the product from the mesaconic ester contained the isomers in an approximately opposite ratio (Table 2). The ratios were determined by comparing the infra-red spectra of the crude mixtures of isomeric acids, obtained by saponification of the addition products, with the spectra of known mixtures of authentic acids. Although this procedure does not lead to exact values for the ratios, the difference in reactivity of the two geometrically isomeric esters with respect to orientation is quite clear. Somewhat more accurate values were obtained by gas chromatography, see experimental part.

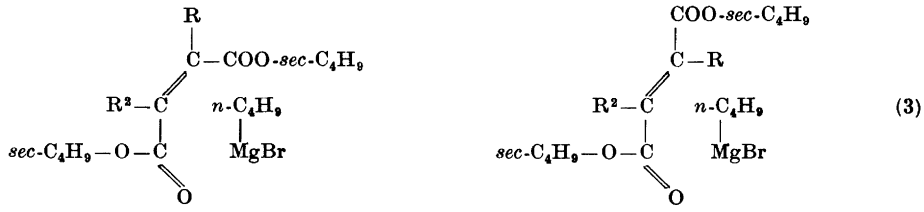
DISCUSSION

For the conjugate addition of Grignard reagents to α,β-unsaturated systems the following cyclic mechanism has been proposed [14]:



(2)

In the case of the esters under consideration, the first step in the above scheme should be represented as follows:



(3)

a. R = R^2 = H: Maleic
b. R = H, R^2 = CH_3: Citraconic
c. R = CH_3, R^2 = H: »
d. R = R^2 = H: Fumaric
e. R = H, R^2 = CH_3: Mesaconic
f. R = CH_3, R^2 = H: »

From this mechanism no stereospecificity could be expected and, in cases where α-methyl-α'-*n*-butylsuccinic esters (3*b* and *e*, above) are formed, the reaction products should be mixtures of nearly equal parts of *erythro*- and *threo*-isomers.

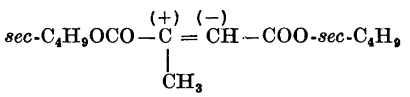
In the reactions with maleic and fumaric esters (3*a* and *d*), two factors should be important for the yield; the reactivity of the double bond and the steric conditions for the cyclic mechanism. Obviously, the configuration of the fumaric ester is more favourable in the latter respect than that of the maleic ester. However, the double bond of the maleic ester is probably much more reactive than that of the fumaric ester, since maleic esters are under considerable steric strain because of the two ester groups in the *cis*-position, which prevent co-planarity between the two carbonyl groups and the ethylenic bond. This strain would be particularly high in the case of the *sec*-butyl esters, and this factor, apparently, is the more important one.

In the reactions with citraconic and mesaconic esters (3*b* or *c* and *e* or *f*) the same two factors, mentioned above for maleic and fumaric esters, should be operative, again resulting in a higher yield of addition product from the *cis*-isomer (citraconic ester) than from the *trans*-isomer (mesaconic ester).

One further point should be mentioned, which may be significant. Whereas the yield of addition product from fumaric ester was considerably less than from maleic ester, the total yield of addition *and* reduction products from mesaconic ester was only little less than the corresponding yield from citraconic ester. This was true of both the uncatalyzed and the catalyzed reactions.

These findings are in agreement with the view that the strain caused by the groups in the *cis*-position is an enhancing factor in the addition reaction since mesaconic ester may be expected to be under considerably more strain than fumaric ester, although less than citraconic and maleic esters.

Considering the above mechanism, an understanding may also be reached, as to why the two — structurally different — isomers predominate in the ester-mixtures produced by the two additions to citraconic and mesaconic esters. Here, again, two factors may be important: the polarization of the double bond and the steric conditions for the cyclic mechanism. In the case of citraconic ester (*cis*) the two ester groups are equal in stereo-chemical respect. The polarization of the double bond:



then, is apparently a more important directing factor than the overcrowding at the methyl-substituted carbon atom (situation 3*c*, above). Thus the α,α-disubstituted succinic ester is the main product. In the case of mesaconic ester (*trans*), the steric conditions for situation 3*e* (above) is much more favourable than situation 3*f*. The polarization factor then becomes of minor importance with the α,α'-compound now being produced in the larger quantity.

Effects of cuprous chloride catalysis. While the orientation of the addition to citraconic and mesaconic esters is rather unaffected by the presence of cuprous chloride during the addition process (*cf.* Table 2), the reduction of these esters (to pyrotartaric ester), which in the uncatalyzed reaction is only of minor importance in comparison to the 1,4-addition, becomes a dominating side-reaction when cuprous chloride is present.

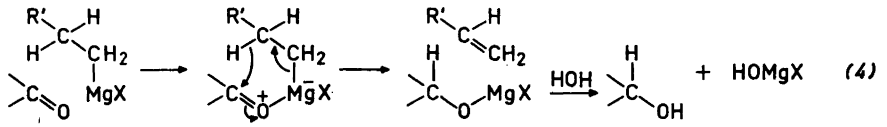
A general statement, that this catalyst appears to enhance the electrophilic reactivity of the carbon-carbon double bond, does not provide any explanation for this experimental fact. Tentatively, one might suggest that an understanding may be sought in the concept of a regular complex formation between cuprous chloride and the carbon-carbon double bond. A great deal of evidence for such complexes can be found in the literature [15], and they also have acquired some technical interest [16]. Andrews and his co-workers [17] have studied the partition of cuprous chloride between water and an organic solvent containing alkenes, unsaturated alcohols (such as allylalcohol) and a number of α,β-unsaturated acids (including those, the *sec*-butyl esters of which have been studied in the present series). Cuprous chloride appears usually to form 1:1 complexes with the unsaturated compounds; the bonding is presumed to occur between the cuprous ion and a carbon atom, an electron pair being furnished by the carbon-carbon double bond. It appears reasonable that, by this coordination, the reactivity of the double bond towards nucleophilic reagents should be augmented. There seems to be no general agreement as to the complexing properties of *cis*, *trans* isomers *, but the negligible effect of cuprous

* Basolo and Pearson (Ref.[15], p. 352 -353) state that *cis*-olefins form more stable complexes than do *trans*-olefins.

chloride on the reaction with fumaric ester indicate that the *trans* compound in this case is the poorer complexing agent, corresponding to the generally lower reactivity mentioned above.

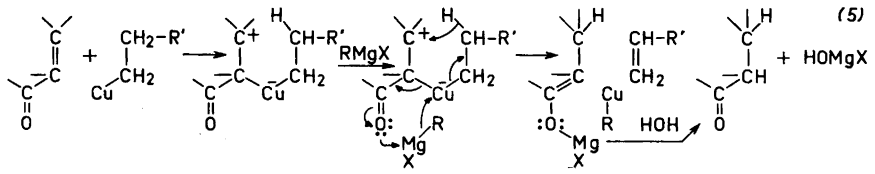
By the coordination also the overcrowding at the double-bonded carbon atoms should be increased. This might favour sterically less demanding reactions, in this case the reduction.

While the cyclic mechanism mentioned above for the 1,4-addition should still be valid in the case of cuprous chloride catalysis, this is not possible for the corresponding mechanism, which has been suggested [18] for the reduction of carbonyl compounds by means of Grignard reagents:



Reduction of the *carbon-carbon* double bond of an α,β-unsaturated carbonyl compound could not take place according to such a mechanism involving a *six*-membered ring and the coordination of the Grignard magnesium with *oxygen*. Provisionally, the following cyclic concerted mechanism is put forward (R = $R'CH_2CH_2$, *cf.* the over-all reaction (eqn. 1)):

$$RMgX + CuCl \rightleftharpoons RCu + MgXCl$$



This mechanism involves an exchange reaction between cuprous chloride and the Grignard reagent leading to the formation of a copper-alkyl compound [19], which is then supposed to coordinate with carbon instead of with oxygen. These synchronous shifts also account for the fact that the effect of cuprous chloride is a catalytic one, with the copper-alkyl being continuously regenerated. Nothing could be stated about the orientation of the attack of the cuprous chloride at the double bond, since the polarization effect and the steric effect have an opposite influence, and in this case the nature of the reaction product does not, of course, give any information.

Effects of using inverse addition procedure. As mentioned in the foregoing, the reduction-promoting action of cuprous chloride appeared to be in contrast to the effect found by Brändström and Forsblad [13]. However, these authors emphasize the importance of inverse addition (that is the addition of the Grignard reagent *to* the ester containing the cuprous chloride). With the three

Table 3. Yields of 1,4-addition and reduction products from reactions of *n*-butylmagnesium bromide with α,β-unsaturated esters under different conditions.

Ester	Product	Normal addition no cat.	Normal addition CuCl	Inverse addition no cat.	Inverse addition CuCl

[a] Ethyl 2-cyano-3,3-dimethylheptanoate (ethyl 1,1-dimethylpentyl-cyano-acetate), b.p. 128°/13 mm, n_D^{20} 1,4412. Calc. for $C_{12}H_{21}O_2N$ (211.30): C 68.21; H 10.02. Found: C 68.05; H 9.80. [b] Ethyl *iso*propylcyanoacetate, b.p. 92—93°/13 mm, n_D^{20} 1.4238. This product did not give the correct analyses; it is probably contaminated with ethyl cyanoacetate, which may arise by a reversal of the condensation of this ester with acetone (the formation of ethyl *iso*propylidene-cyanoacetate). [c] 1,1-Dicarbethoxy-2,2-dimethylhexane (ethyl 1,1-dimethylpentyl-malonate), b.p. 132—133°/13 mm, n_D^{25} 1.4360. Calc. for $C_{14}H_{26}O_4$ (258.35): C 65.08; H 10.14. Found: C 65.50; H 9.98. [d] Ethyl *iso*propylmalonate, b.p. 96—98°/13 mm, n_D^{25} 1.4223. Calc. for $C_{10}H_{18}O_4$ (202.24): C 59.38; H 8.97. Found: C 59.60; H 8.77. [e] See Table 1.

esters of Table 3 we have, therefore, investigated the influence of changing conditions in this respect.

Our results with *iso*propylidenecyanoacetic ester are, in fact, in complete accordance with those of Brändström and Forsblad: cuprous chloride has no effect upon the addition/reduction ratio in the normal addition, but when inverse addition is used, the reduction is largely suppressed and the addition favoured.

With citraconic ester, on the other hand, the normal, uncatalyzed addition procedure appear to be the method which gives the best yields of 1,4-addition. The presence of cuprous chloride strongly favours the reduction when normal addition procedure is used (*cf.* also Table 1), and the catalyzed, inverse addition method, although preventing reduction, gives very low yield of 1,4-addition product, a non-destillable residue being the main reaction product.

Finally, with *iso*propylidenemalonic ester cuprous chloride promotes reduction in the normal addition procedure, but prevents reduction in the inverse procedure, whereas the yields in the uncatalyzed reactions are independent of the addition method.

The results with *iso*propylidenecyanoacetic and citraconic esters with respect to the competition between 1,4-addition and reduction are obscured by the rather low yields of the products in question. The results with *iso*-propylidenemalonic ester, on the other hand, may perhaps be taken as typical, since here, apparently, other reactions take place only to a small extent.

These results are not inconsistent with the above suggested mechanisms. The increased reduction in the normal addition procedure is already considered (eqn.5). In the inverse addition, on the other hand, the cuprous chloride is mixed with the ester, and the Grignard reagent is then slowly added. The catalyst could thus be expected to coordinate with the double bond of the ester, and, by the subsequent slow addition of the Grignard reagent, the ordinary cyclic mechanism (eqn. 2) could be operative, only with an activated double bond.

EXPERIMENTAL

Microanalyses are by Mr. Preben Hansen, Microanalytical Division, The Chemical Laboratory, The University of Copenhagen. Fractional distillations were through a simple 45 cm × 8 mm Podbielniak-type column with a tantalum wire spiral, a heated jacket and a partial reflux head. All products were checked by infra-red spectroscopy using a Beckman IR 2 single-beam spectrophotometer with sodium chloride optics. The spectra of the solid compounds (*i. e.* the methylbutylsuccinic acids) were recorded using the potassium bromide technique, whereas those of the liquids were measured in solutions in carbon tetrachloride.

Preparation of starting materials. sec-*Butyl* esters were prepared from commercial acids according to the general esterification procedure previously described [20]: *maleinate*, b.p. 85°/0.8 mm, n_D^{20} 1.4432, yield 85 %; *fumarate*, b. p. 80°/0.5 mm, n_D^{20} 1.4430, yield 32 % (65 % fumaric acid recovered); *citraconate*, b. p. 86–87°/0.5 mm, n_D^{20} 1.4457, yield 72 %; *mesaconate*, b. p. 89.5°/0.6 mm, n_D^{20} 1.4491, yield 93 %. The identity of the esters was checked by elementary analyses. Infra-red spectra of *sec*-butyl maleate and fumarate agreed with those published in the literature [21]. The spectra of citraconic and mesaconic esters differed from one another, which was taken as evidence that the stereochemical structures were retained during the esterification processes.

The spectra of these four esters, as well as of those products mentioned in the following, which are saturated *sec*-butyl esters * have all been found to show a strong absorption, split in three peaks, around 1 111 cm^{-1} (9.00 μ). This group of bands is, therefore, considered to be a characteristic absorption for *sec*-butyl esters of carboxylic acids.

Ethyl isopropylidenecyanoacetate, b. p. 113°/17 mm, n_D^{25} 1.4653, was prepared according to Wideqvist [22], *diethyl isopropylidenemalonate*, b. p. 108–110°/13 mm, n_D^{20} 1.4484, according to Cope and Hancock [23].

Additions of n-*butylmagnesium bromide to* sec-*butyl esters of maleic, fumaric, citraconic and mesaconic acids.* The uncatalyzed reactions were carried out as described previously [1]; during 1.5–2 h, 0.1 mole of ester, dissolved in 100 ml of ether, was added to a Grignard solution, prepared from 6.3 g (0.26 g-atom) of magnesium turnings, 42.5 g (0.31 mole) of *n*-butyl bromide and 120 ml of ether, and cooled in ice-water during the addition.

In the cuprous chloride catalyzed reactions [20,7,12] the same amounts of the reagents were used, but 0.3 g of cuprous chloride was added in one portion after the Grignard solution had been cooled in ice-water for 15 min. The ester was dissolved in 200 ml of ether and added over a 2–3 h period. In one case with maleic ester cooling in ice-salt was applied during the addition of cuprous chloride and the ester, but the yield was no better than that obtained when only ice-water was used.

In the inverse addition reactions the Grignard solution was transferred to a siphoning vessel. From this it was added, by means of nitrogen pressure, dropwise to the ester cooled in ice-water during 1.5–2 h under vigourous stirring. When the inverse addition reaction was cuprous chloride catalyzed, the catalyst was added to the ester before adding the Grignard solution.

The inverse reactions with *iso*propylidenecyanoacetic ester were somewhat disturbed by the almost instantaneous formation of a viscous, sticky precipitate when the addition of the Grignard reagent was started. The addition of another 100 ml of ether and the

* And also of all other *sec*-butyl esters recorded during the work of this series.

interruption of the cooling seemed to improve dissolution of the precipitate and the effeciency of the stirring.

Identification of products. The products were isolated by fractional distillations and investigated by microanalyses and infra-red spectroscopy (*cf.* Table 1).

The spectra of the addition products, esters I, III and VI, are very similar and can hardly be distinguished significantly. The spectrum of the reduction product V shows a strong resemblance to those of the three addition products. These four spectra all show a carbonyl band at 1 725 cm^{-1} and the group of absorption bands at 1 111 cm^{-1}, which is considered to be characteristic for *sec*-butyl esters (se above), but no absorption was found for C=C or OH. These data, as well as the low refractive indices constitute strong evidence that the products are saturated *sec*-butyl esters.

The spectra of the high-boiling products II, IV and VII have a carbonyl peak at 1 772 cm^{-1} (5.64 μ), which is within the area reported [24] to be characteristic for saturated γ-lactones (1 780—1 760 cm^{-1}); there was no absorption found for saturated ester (1 750—1 735 cm^{-1}), saturated ketone (1 725—1 705 cm^{-1}), hydroxyl group or carbon-carbon double bond. Also an attempt at alkaline hydrolysis indicated a lactone structure: a very unsharp first end-point in the back-titration gave an equivalent weight of about 225 for II (calc. 254.4), but after some time more acid was required until eventually an amount of acid was used, which was equivalent to the amount of base employed.

The addition products from citraconic and mesaconic esters, III and VI, were saponified according to the saponification procedure previously described [20], except that the saponification time was prolonged to 24 h. The crude acids were obtained as oils, which in the case of VI slowly crystallized completely, whereas the acid-mixture from III only after long standing (a week or more) partially solidified. Crude crystalline products (m. p. range 85—110°) were obtained by recrystallization from ethanol-water. For identification purposes authentic samples of α-methyl-α-*n*-butylsuccinic acid, m. p. 86—88°, and α-methyl-α'-*n*-butylsuccinic acid, m. p. 121—132°, were prepared (see below). The infra-red spectra of these isomers could be distinguished from each other, especially by a difference in absorption around 1 190—1 330 cm^{-1}. Comparison of the spectra of the acids from III and VI with those of the authentic samples, showed the product from citraconic ester ($acid_{III}$) to be the α,α-isomer, whereas the product from mesaconic ester ($acid_{VI}$) was the α,α'-isomer.

By subsequent numerous recrystallizations from very diluted ethanol, the following melting points could indeed be obtained. $Acid_{III}$: m. p. 91—94° (neutr. equiv. 93.6); authentic α,α-isomer: m. p. 91—93° (neutr. equiv. 95.5); $acid_{VI}$: m. p. 132—137° (neutr. equiv. 95.5); authentic α,α'-isomer: m. p. 136—138° (neutr. equiv. 95.2). Mixed melting points of the two pairs of compounds showed no depressions; calc. neutr. equiv. 94.11.

In later experiments, however, also the α,α'-isomer was isolated from runs with citraconic ester, and both addition products (III and VI) might thus presumably be mixtures. The above-mentioned difference in the infra-red absorption groups around 1 190—1 330 cm^{-1} was utilized for estimating the approximate ratio of the isomers formed, by comparing the spectra of the crude acid-mixtures with spectra of suitable mixtures of authentic acids (Table 2).

The proportions of isomers in the mixtures were further checked by gas-liquid chromatography (Table 2), kindly performed and interpreted by Mr. Aage Jart, M.Sc., of the Danish Fat Research Institute, Copenhagen. The acids were transformed into their methyl esters by means of diazomethane. It was found that the retention time was rather strongly dependent on the size of the sample. Therefore, that mixture-component which was present in the smaller concentration was appearing first on the chromatogram in all cases. The ratios were estimated accurate to the nearest 5 %.

Preparations of authentic methyl-n-butylsuccinic acids. α-Methyl-α-*n*-butylsuccinic acid was prepared as described in literature [25]. The addition of hydrogen cyanide to ethyl α-cyano-β-*n*-butyl-β-methylacrylate (below) was followed by hydrolysis and decarboxylation of the dicyano-compound. The latter (ethyl α,β-dicyano-β-methylheptanoate) showed the b.p. 96—100°/1.5 mm (n_D^{23} 1.4399), whereas Miller and Long [25] report the b.p. 141—145°/2.3 mm. Ethyl α-cyano-β-*n*-butyl-β-methylacrylate, b.p. 142—144°/14 mm, n_D^{25} 1.4672, was obtained according to Cope *et al.*[26] by the condensation of methyl *n*-butyl ketone with ethyl cyanoacetate. The α-methyl-α-*n*-butylsuccinic acid had the m. p. 91—93° (rep.[25]: 93°) and the neutr. equiv. 95.5.

α-Methyl-α'-*n*-butylsuccinic acid was synthesized by the alkylation of ethyl *n*-butylmalonate [27] with ethyl α-bromopropionate, followed by hydrolysis and decarboxylation. The procedures used were those described in Organic Syntheses [28]. The α-methyl-α'-*n*-butylsuccinic acid had the m. p. 136—138° (rep.[11]: 85—105°) and neutr. equiv. 95.2.

The authors want to express their gratitude towards *Otto Mønsteds Fond* and *Det Teknisk-Videnskabelige Forskningsraad* for financial support.

Conjugate Additions of Grignard Reagents to alpha,beta-Unsaturated Esters

VI. The Course of Reactions with Allylic Grignard Reagents

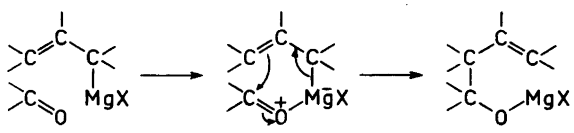
JON MUNCH-PETERSEN, PEER MØLLER JØRGENSEN and SUSANNE REFN

Organisk-kemisk Laboratorium, Polyteknisk Læreanstalt, Copenhagen, Denmark

In contrast to ordinary Grignard reagents, allylic Grignard reagents with *sec*-butyl esters of crotonic, tiglic and cinnamic acids give exclusively and in high yields tertiary alcohols as a result of additions to the carbonyl group (1,2-addition). Benzylmagnesium chloride, on the other hand, adds to the carbon-carbon double bonds in crotonic and cinnamic esters (1,4-addition), whereas tiglic ester with this Grignard reagent gives, in low yields, mixtures of both 1,2- and 1,4-additions products. Cuprous chloride has no effect in the reactions here described.

Grignard reagents from allylic halides differ in several respects from ordinary alkyl- and arylmagnesium halides. Not only must special measures usually be applied by their preparation (*cf.* below, experimental part) in order to prevent nucleophilic attack by the reagent on unreacted halide leading to hydrocarbons of the type biallyl, bibenzyl *etc.*, but also the Grignard reagent itself in its reactions may show a reactivity different from that of other Grignard reagents *. Thus, with allylic Grignard reagents very often the formation of "inverted" products (involving an allylic "rearrangement") is encountered and furthermore, many reactions, which take one course with ordinary Grignard reagents, give rise to other reaction products or to different yields with allylic Grignard reagents. Particularly the reactions of the so-called butenyl Grignard reagent (prepared from crotyl bromide) were thoroughly studied by Young, Roberts and co-workers [2]. These authors give extensive evidence that allylic Grignard reagents react by a cyclic mechanism, involving a synchronous electron shift, resulting in inversion of the allylic group:

* Reactions of allylic Grignard reagents, especially the work of Young, Roberts *et al.* (*e. g.* Ref.[2]), are discussed in several advanced treatises of organic chemistry [1].

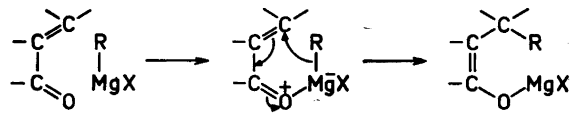


(1)

Consistent with this mechanism are the facts that addition of allylic Grignard reagents to the carbonyl group of sterically hindered ketones is facilitated, compared to the addition of other Grignard reagents, and that the allylic grouping is inverted during the addition process.

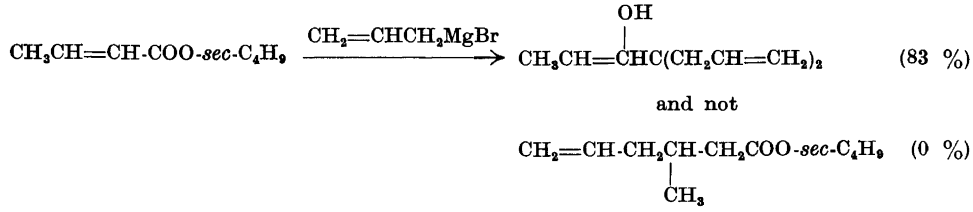
The present paper describes the reaction between *sec*-butyl esters of certain α,β-unsaturated acids and some allylic Grignard reagents under conditions which have previously been found favourable for conjugate addition (to the carbon-carbon double bond) of ordinary Grignard reagents [3]. As model substances have been used crotonic, tiglic and cinnamic esters, and as allylic halides: allyl, methallyl and crotyl (butenyl) bromides and benzyl chloride. The results are given in Table 1. They are seen to be in agreement with the findings of Young and Roberts [2], that 1,2-addition to the carbonyl group is greatly favoured. In contrast to the corresponding reactions with *n*-butylmagnesium bromide and other Grignard reagents, the reactions with allyl-, methallyl- and crotylmagnesium bromides all give tertiary alcohols in high yields. Benzylmagnesium chloride, on the other hand, gives 1,4-addition (ester) with crotonic and cinnamic esters, whereas it gives low yields and mixtures of ester and impure tertiary alcohol with tiglic ester *.

In the conjugate addition of Grignard reagents to α,β-unsaturated carbonyl compounds a different cyclic mechanism is generally believed to operate [4]:



(2)

but in the case of allylic Grignard reagents the above-mentioned cyclic electron shift (1) competes successfully with (2), unsaturated ketones and tertiary alcohols being formed in stead of "saturated" esters, *e. g.*



(83 %)

and not

(0 %)

* The tertiary alcohols formed by these reactions are presumably rather unstable, eliminating water easily. Many of them, after standing for a few weeks, turned into viscous polymers, insoluble in most solvents.

Table 1. Products and yields from reactions of *sec*-butyl esters of α,β-unsaturated acids with allylic Grignard reagents (RMgX).

Ester \ R	Allyl	Methallyl	Crotyl	Benzyl

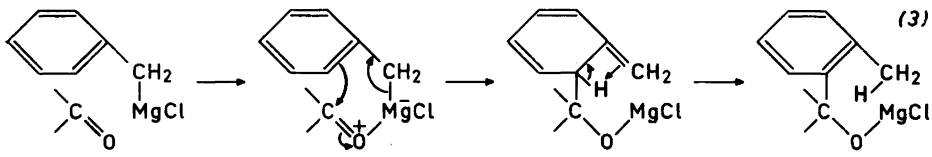
These results constitute further evidence, that the enhanced reactivity of allylic Grignard reagents towards carbonyl groups is caused by a special mechanism operating and is not merely due to a generally greater reactivity of these Grignard reagents as compared to others. Thus, they lend support to the cyclic mechanism of Young and Roberts *.

The fact that benzylmagnesium chloride does give the "normal" conjugate addition product (*i. e.* not reacting as an allylic reagent) is not incompatible

* In fact, Young and Roberts have themselves tried the reaction between butenylmagnesium bromide and *tert*-butyl cinnamate [5]. Very little 1,4-addition product was found, but the main reaction product was not identified.

with these considerations. As pointed out above, the Young-Roberts mechanism involves the inversion of the allylic system, which is well known to occur also in the case of the benzyl grouping, *e.g.* the formation of *o*-methylbenzylalcohol from benzylmagnesium chloride and formaldehyde [7]. However, this inversion must imply a transitory loss of the aromaticity of the ring and, consequently, require a rather high energy of activation:



In this case, therefore, the conjugate addition process (2) is the one mostly favoured. Indeed, the results with the benzyl reagent may thus be considered to be consistent with the Young-Roberts mechanism.

Cuprous chloride, which is known to catalyze 1,4-addition of Grignard reagents in competion with 1,2-addition [8], has been found to have no effect in the cases of allylic Grignard reagents here described.

During this work no attempt was made to determine the structure of the butenyl group in the tertiary alcohols formed. According to Young and Roberts [2], they are assumed to have the α-methylallyl structure.

EXPERIMENTAL

Microanalyses are by Mr. Preben Hansen, Microanalytical Division, The Chemical Laboratory, The University of Copenhagen. Fractional distillations were through a simple 45 cm × 8 mm Podbielniak-type column with a tantalum wire spiral, a heated jacket and a partial reflux head.

sec-*Butyl esters* were prepared as previously described [9]. Allyl bromide was obtained according to Organic Syntheses [10]. Methallyl (β-methylallyl) bromide, b. p. 95—96°, n_D^{20} 1.4718, was synthesized from the alcohol (Fluka, pract.) according to Jones *et al.*[11] Crotyl bromide, b. p. 102—105°, n_D^{20} 1.4775, was the Fluka, purum, product, which was purified by washing with sodium bicarbonate solution, drying and destillation. Benzyl chloride was the commercial product (Fluka, purum), which was redistilled, b. p. 64°/14 mm, n_D^{20} 1.5398. The magnesium turnings used were those from May & Baker; this product is much more finely cut than ordinary Grignard magnesium, and it has been found particularly suitable for the preparation of allylic Grignard reagents (below).

The Grignard reagents were prepared according to the general procedure of Gilman and McGlumphy [12], which consists in using a great excess of magnesium, effective stirring and slow addition of the halide.

The reactions between the Grignard reagents and the α,β-unsaturated esters and the isolation of the products were carried out as previously described [3]. The products are given in Table 1.

The identities of the reaction products were further checked by infra-red spectroscopy. The spectra were measured with a Beckman IR2 spectrophotometer with sodium chloride prisms, using 5 % solutions in carbon tetrachloride. The alcohols were identified by their hydroxyl band in the 3 μ region and by the absence of a carbonyl absorption. The spectra of the esters (from benzylmagnesium chloride) showed — besides a carbonyl band — the

group of absorption bands (around 1 111 cm^{-1}), which has previously been found to be characteristic for *sec*-butyl esters [13].

The authors want to express their gratitude towards *Otto Mønsteds Fond* and *Det Teknisk-Videnskabelige Forskningsraad* for financial support.

On Vitamins in Sewage Sludge

X. Production of Vitamin B_{12} by Sulphate-Reducing Bacteria

HALINA Y. NEUJAHR

Royal Institute of Technology, Division of Food Chemistry, Stockholm 70, Sweden

Vitamin B_{12} and some other growth factors were determined in sewage sludge fermented by sulphate-reducing bacteria according to Butlin [1] and in an extract of dry *Desulphovibrio desulphuricans* cells *.

The vitamin B_{12} activity, calculated as cyanocobalamin in *E. coli* cup plate assay, of sludge fermented by sulphate reducers was found to be approximately 0.2—0.3 μg/ml or 10—15 μg/g dry solids which is of the same order of magnitude as the corresponding activity of sludge fermented by methane bacteria. Bioautographic studies revealed the presence of cyanocobalamin and also some factor or factors with an R_c-value (R_F-value of the factor relative to that of cyanocobalamin) = 0.6—0.7 the nature of which was not elucidated.

The fermented sludge contained only small amounts of folic and folinic acid activity.

The dry cell extracts were found to contain 9 μg vitamin B_{12} activity/g dry cell material when assayed by the *E. coli* cup method but 15 μg/g when assayed by the *E. coli* turbidimetric method. The reasons for this discrepancy are discussed and some attempts to elucidate them are described.

The *E. coli* activity of the dry cell extract represents a mixture of at least four factors. Cyanocobalamin is present in small amounts. The predominating factor(s) may be identical with factor A and some unidentified factor(s) which behave slightly basically upon paper electrophoresis at pH 2.5. Factors: B(Ford), [19] aetiocobalamin phosphoribose (Bernhauer) [11], 2-methyl-mercapto-adenin-cobalamin (Bernhauer) [18] and factors Z2 + Z3 (Neujahr) [8] are absent or present only in very small amounts.

Three or four desoxyriboside factors were also found to be present in the cell extracts.

The cell extract was found to contain three factors which had a growth inhibiting activity for *L. leichmannii 313*. Attempts to purify these factors are described and their possible nature is discussed.

Butlin and co-workers [1] have prepared enrichment cultures of sulphate-reducing bacteria which can be successfully used for the production of sulphide from sulphate-enriched sewage sludges. When such sulphide fermentation

* The dry cell material was kindly provided by Dr. John Postgate of National Chemical Laboratory, Teddington, England.

takes place in sewage sludge, the otherwise spontaneously occurring methane fermentation is inhibited and the production of methane gas ceases. Butlin and co-workers have shown that the inhibition of methane fermentation by sulphide fermentation in combined, methane- and sulphide-producing fermentations depends a.o. on the preferential utilization of nutrients or (and) reducing material by sulphate-reducing bacteria [1]. In their subsequent work Butlin and co-workers [21] have found also certain other reasons for the inhibition of the methane fermentation.

Furthermore, the above cited authors have shown that pure cultures of laboratory strains of *Desulphovibrio desulphuricans* inoculated into sterile raw sludge produced negligible sulphide in contrast to crude enrichment cultures which were very active in this respect [1].

It has been reported from this laboratory [2,4] as well as from several others [3,5] that considerable amounts of vitamin B_{12} activity are formed during the methane fermentation of sewage sludge. It has also been reported that many of the organisms active during the methane fermentation of sewage sludge produce vitamin B_{12} activity when cultivated in synthetic media [6]. It was therefore considered to be of interest to investigate if vitamin B_{12} was formed also during the sulphide fermentation of sewage sludge and if it was formed by pure strains of *Desulphovibrio desulphuricans* grown in synthetic media.

EXPERIMENTAL

Using an active sulphide-producing crude culture of sulphate-reducing bacteria kindly provided by Dr. Butlin, the author performed two semicontinuous fermentations of raw sulphated sewage sludge according to the technique described by Butlin and co-workers [1]. Raw sludge was homogenized in a Turmix blendor and sieved through a sieve with a 0.80 mm mesh. The material obtained in this way contained 2 % dry solids. It was sulphated (50 g $CaSO_4$/l) and 1 l batches were inoculated with the active culture. Samples of 50 ml were removed daily and replaced by 50 ml raw sulphated sludge (2.5 g $CaSO_4$/50 ml). Nitrogen gas was blown through the fermentation flask. The H_2S formed was trapped in a solution of $CdCl_2 \cdot 5H_2O$.

The vitamin B_{12} activity of the removed samples was investigated using *E. coli 113—3* in plate assay and by bioautography as described elsewhere [7]. The growth activity for *S. faecalis ATCC 8043* and *L. citrovorum ATCC 8081* was also determined in some samples and calculated as folic acid and folinic acid activity, respectively. The results of the two series can be seen in Tables 1 and 2.

The determination of the ability of a pure strain of *Desulphovibrio desulphuricans* to produce vitamin B_{12} activity was performed on dry cell material *. The cells were autoclaved for 10 min at 121°C in water containing 0.01 % KCN at pH 6.5. The proportion of the dry cell material and water was 1:30. The autoclaved mixture was centrifuged and the supernatant used as cell extract for the different assays. For assaying desoxyriboside factors, the extract was concentrated tenfold by evaporation under reduced pressure at 30—40°C.

The values found for vitamin B_{12} activities, calculated as cyanocobalamin, are given in Table 3.

* *Cf.* footnote on p. 1960.

RESULTS AND DISCUSSION

Vitamin B_{12} activity of sulphate-enriched sludge fermented by the crude culture of sulphate-reducing bacteria

It is seen in Tables 1 and 2 that approximately 0.2—0.3 mg/l of vitamin B_{12} activity was produced in a sludge containing 2 % dry solids. This corresponds to 10—15 mg/kg dry solids which is of the same order of magnitude as in sludge which has undergone methane fermentation (10—15 mg/kg).

Paper chromatography followed by bioautography on *E. coli* plates gave two spots, one of which was identified as cyanocobalamin. The second spot, R_c = 0.6—0.7, could not be conclusively identified since, as reported before [8], it may correspond to several vitamin B_{12} factors having R_c-values (= R_F-values relative to that of cyanocobalamin) in the range 0.6—0.7. It can further be seen in Table 2 that the sludge fermented by sulphate-reducing bacteria exhibited only a small activity for *S. faecalis* and *L. citrovorum*. These activities were considerably higher in fresh sludge. A similar relation has been observed earlier in the methane fermentation of sewage sludge [2,4].

Vitamin B_{12} activity of dry cells of a pure strain of *Desulphovibrio desulphuricans.*

It can be seen in Table 3 that extracts of *Desulphovibrio desulphuricans* cells exhibit a greater vitamin B_{12} activity when assayed with *L. leichmannii* than when assayed with *E. coli*. The difference is expecially pronounced in the cup

plate assay. It was found that the higher activity values obtained with *L. leichmannii* could be accounted for by the presence of certain desoxyribosides which are also active for this organism. Paper chromatography in two solvent systems [7] followed by bioautography on agar plates seeded with *L. leichmannii*, and *L. acidophilus* R-26, ATCC 11506 gave three spots with R_F-values close to those of the desoxyribosides of adenine, uracil and 5-methylcytosine and/or guanine. These substances were present in the cell extracts in amounts of about 5—10 μg/ml as estimated by comparison with spots obtained on the bioautographs with standard solutions, *i.e.* they may constitute about 150—300 μg in 1 g dry cell material. Other desoxyriboside factors, if present, may occur in much smaller amounts than the three (or four) mentioned above since they could not be detected even in the tenfold concentrated cell extract.

Table 3. Vitamin B_{12} activity of *Desulphovibrio desulphuricans* cell extracts.

Test organism	Assay method	Vit. B_{12} activity calculated as cyanocobalamin μg/g dry cell material *
E. coli 113-3	cup plate	9
» » *113-3*	turbidimetry	15
L. leichmannii 313	cup plate	30
» »	turbidimetry	17

* average of three different determinations.

It can further be seen in Table 3 that the extracts of *Desulphovibrio desulphuricans* cells exhibit a greater vitamin B_{12} activity when assayed with *E. coli* by the turbidimetric method than by the cup plate technique. This phenomenon is quite unusual compared with previous experience. The vitamin B_{12} activity of natural materials investigated hitherto was always found to be greater when assayed by the cup plate technique than by the turbidimetric one. This is generally attributed to the presence in natural materials of different vitamin B_{12} factors together with cyanocobalamin.

In his work on the vitamin B_{12} requirement in certain soil bacteria Ford suggests that certain vitamin B_{12}-like factors, the "inactive analogues may slow down the rate at which vitamin B_{12} is absorbed and utilized by the cells" [9]. The presence of the "inactive analogues" in relatively high concentrations together with vitamin B_{12} gives, according to Ford [9], rise to larger and correspondingly less dense zones of growth in the plate assays than those obtained with vitamin B_{12} alone. A similar relation may apply also to *E. coli 113—3* and the reasoning of Ford [9] could thus give a plausible explanation of the often much larger and more diffuse, as compared with pure solutions of cyanocobalamin, growth zones obtained in *E.coli* plates with solutions containing a mixture of several vitamin B_{12} factors. However, a number of vitamin B_{12}-like factors, even those which lack the nucleotide part, *e.g.* factor B, are active for *E.coli*. Many of those "active analogues" give also larger and less dense zones

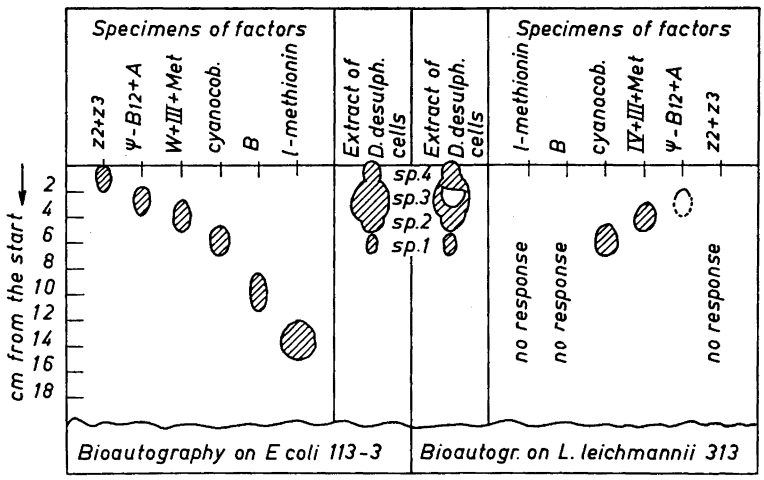

Fig. 1. Chromatographic separation of the vitamin B_{12} activity present in cell extracts of *Desulphovibrio desulphuricans*. Solvent system I [7], development: 18 h at 24°C.

of growth than cyanocobalamin when assayed with *E.coli* by the plate method, even when a solution of a single vitamin B_{12} factor is applied (*cf.* Ref. 8). Coates and Ford [20] suggest that cyanocobalamin may be utilized more rapidly by the *E.coli* cells than the other vitamin B_{12} factors active for this organism. The other factors may thus have time to diffuse further away from the cup until they can be utilized for growth than is the case with cyanocobalamin. This may perhaps explain why the solutions of such factors give rise to larger but less dense growth zones than those obtained with cyanocobalamin.

Reasoning in a similar way may lead to the supposition that the greater *E.coli* activity of *Desulphovibrio desulphuricans* cells exhibited in tube assay than in cup plate assay may depend on the presence in the cell extracts of a vitamin B_{12} factor which is still more rapidly utilized by the test organism cells than cyanocobalamin. Furthermore, this factor may be a dominant one in the cell extract.

Paper chromatography in two-solvent systems [7] combined with bioautography on *E.coli* and *L. leichmannii* plates gave four spots equally active for *E.coli* and *L. leichmannii*. The chromatographic separation after 18 h of development in solvent system I [7] is represented in Fig. 1. A consideration of Fig. 1 leads to following conclusions.

1) factor B is not present in the cell extract.

2) the spot corresponding to cyanocobalamin (spot 1), if identical with this factor, indicates that cyanocobalamin is present only in a small amount.

3) spot 2 and the largest spot of vitamin B_{12} activity (spot 3) cannot be identified after chromatographic separation during 18 h since they have R_c-values which may correspond to several vitamin B_{12} factors.

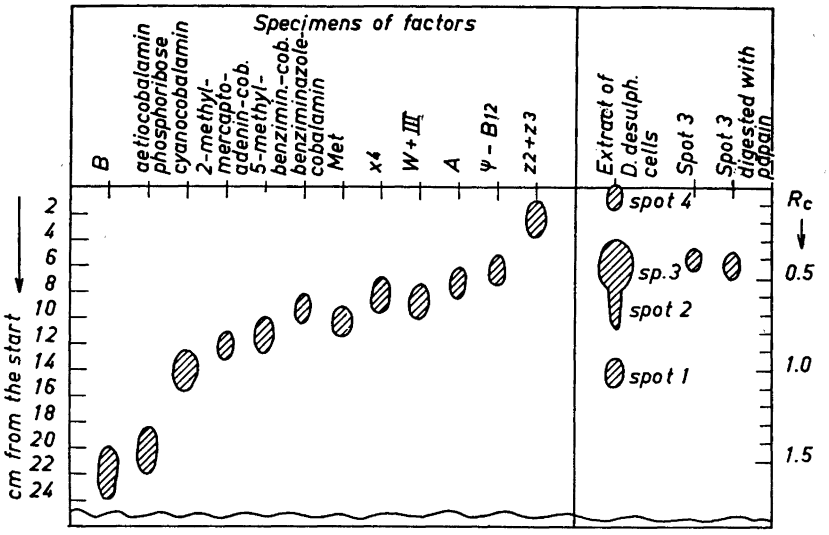

Fig. 2. Chromatographic separation of the *E. coli* activity exhibited by cell extracts of *Desulphovibrio desulphuricans*. Solvent system I [7], development: 48 h at 24°C.

4) spot 4 which corresponds on the *E.coli* bioautogram to factors Z (Z2 + Z3) cannot be identical with these factors since it is also active for *L. leichmannii* which is not the case with specimens of factors Z2 and Z3.

5) the extract of *Desulphovibrio* cells contains a growth inhibitor for *L. leichmannii* with an R_F-value close to that of spot 3.

By electrophoresis in 2 M Hac containing 0.01 % KCN according to Holdsworth [10], the *E. coli* activity of the cell extract could be separated into four spots, one slightly basic or almost neutral, one basic and two acidic. The largest part of the *E. coli* activity was represented by the basic and neutral factors while the acidic factors were present only in lesser amounts.

In order to identify spots 2 and 3, further chromatographic and electrophoretic studies were performed using for comparison specimens of several vitamin B_{12} factors kindly provided by Prof. Bernhauer. Fig. 2 shows the chromatographic separation of the *E. coli* activity after 48 h at 24°C in solvent system I [7].

From Fig. 2, the following conclusions can be drawn:

1) a prolonged period of development gives once again only four spots but provides, on the other hand, a better possibility for characterizing the spots obtained.

2) factor B (Ford) [19], aetiocobalamin phosphoribose (Bernhauer) [11] and factors Z2 + Z3 (Neujahr) [8] are not present in the cell extract.

3) spot 4 thus corresponds to some factor (or factors) which could not be identified with any of the available specimens. Its immobile character upon development with solvent system I [7] ressembles the behaviour of factor C_2 [12]. The possible identity of spot 4 with factor C_2 was not excluded by the results

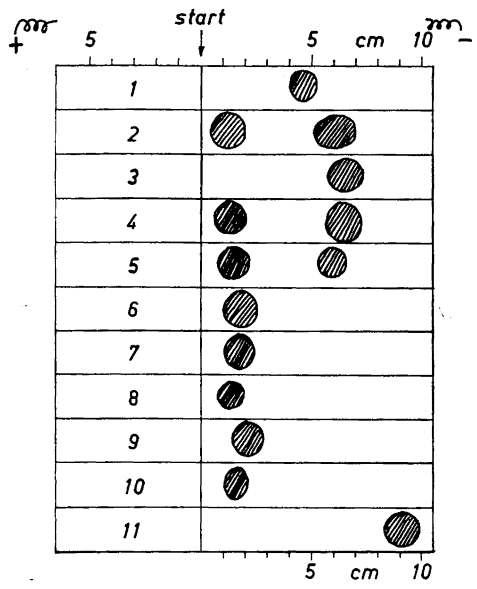

Fig. 3. Electrophoretic separation of the *E. coli* activity exhibited by cell extracts of *Desulphovibrio desulphuricans*. 2 M HAc containing 0.01 % KCN, pH 2.5, 10 V/cm, 18 h at +4°C; 1. ψ $-B_{12}$; 2. cell extract*; 3. factor A; 4. "spot 3" eluted from chromatograms; 5. "spot 3" after digestion with papain; 6. factor III; 7. cyanocobalamin; 8. benziminazole cobalamin; 9. factor W; 10. factor Met; 11. factor B.

of the electrophoretic studies since, as mentioned above minor quantities of two acidic factors could be observed, at pH 2.5, in the cell extract.

4) spot 1 most probably represents cyanocobalamin — this is in agreement with the presence of an electrophoretically almost neutral factor at pH 2.5.

5) Spot 2 is more difficult to identify. It can be seen in Fig. 2 that it may correspond to at least 6 factors, *viz.* benziminazole cobalamin (Bernhauer) [3], factor Met (Neujahr) [13], factor X [4] (Neujahr) [8], factor W (Neujahr) [8], factor 111 (Bernhauer) [3] and possibly others. The elongated character of this spot indicates also that it is a mixture of several factors. Further identification of this spot by means of paper electrophoresis was not possible since the six factors mentioned above behave similarily upon electrophoresis.

6) The main spot of *E. coli* activity (spot 3) seems at first sight to correspond to ψ-B_{12} as judged by its R_c-value. However, this is excluded by the results of electrophoretic studies shown in Fig. 3 where once again factor A seems to be present in the cell extract. Thus the nature of spot 3 could not be conclusively determined.

Due to a suspicion that spot 3 may represent some combined form of vitamin B_{12}, a number of spots 3 was cut out from the chromatograms, eluted with water and concentrated under reduced pressure. A part of the concentrated solution was digested with papain and another part autoclaved with KCN (1 mg/ml) for 15 min. The vitamin B_{12} activity of the resulting solutions was determined in plate assay and tube assay using *E. coli* and *L. leichmannii* and

* With the amount of cell extract applied in this experiment the two acidic factors mentioned in text (*cf.* p. 1966) did not appear. It was, however, couvenient to use this amount in order to identify the two basic factors.

also by chromatography and electrophoresis. The *E. coli* activity of the eluted spots 3 did not show the same relation between cup plate and tube assay values as the whole extracts. On the contrary, the activities found in tube assay were now lower than those found in the cup plate assay. Spots 1, 2 and 4 were also cut out from the chromatograms, eluted with water and assayed for *E. coli* activity alone and together with each other and with spot 3, but no evidence for synenergetic phenomena could be obtained. The problem could not be more thoroughly investigated because of the small amount of material available. The vitamin B_{12} activity values of the eluted spots 3 found with *L. leichmannii* in cup plate assay were once again higher than those found with *E. coli*. Upon electrophoresis in 2 M HAc at pH 2,5, the chromatographically homogenous spot 3 separated into two spots, one almost neutral and one basic with a mobility corresponding to factor A. Autoclaving with KCN (1 mg/ml) destroyed the greater part of the *E. coli* activity. Digestion with papain did not alter the position of spot 3 on the chromatograms noteworthly (Fig. 2) nor the position of the resulting two spots on electrophorograms (Fig 3), although the *E. coli* activity found in tube assay was now once again much higher than the activity found in cup plate assay. It is possible that the discrepancy of the values was at least to some extent due to methionine derived from the papain preparation.

Since the supposition that spot 3 represents some combined form of vitamin B_{12} could not be confirmed, it may be assumed that it is a mixture of factor A and some factor(s) which behave slightly basically upon electrophoresis at pH 2,5.

Inhibition factor.

It was mentioned above and, in addition, can be seen in Fig. 1 that the extract of *Desulphovibrio desulphuricans* cells contains a substance inhibiting the growth of *Lactobacillus leichmannii*. In solvent systems I and II[7], the substance had R_c-values corresponding to those of spot 3 of *E. coli* activity in these solvent systems. On electrophoresis in 2 M HAc at pH 2.5, it was neutral or slightly basic. Attempts were made to purify the substance. 6 g of dry cell material were autoclaved in 180 ml water containing 100 μg KCN/ml. After centrifugation the supernatant was evaporated to dryness under reduced pressure at 40°C. The dry residue was then extracted with 70 % EtOH several times and the combined extracts as well as the residue were assayed for the inhibiting activity using *L. leichmannii* plates for vitamin B_{12} assay but supplemented with cyanocobalamin (1 μg/ml). Almost all the growth inhibiting activity was found in the extracts. The combined extracts were then evaporated to dryness under the conditions described above. The dry residue was dissolved in a small amount of water and chromatographed on Wh 1 paper sheets of 18 × 38 cm for 48 h in solvent system I[7]. After drying, chromatogram strips of 1 cm width were cut at the right and the left side of each sheet and the position of the inhibition factor determined by putting the strips on *L. leichmannii* plates for vitamin B_{12} which contained cyanocobalamin. On this occasion, it was found that not one but three distinctly different inhibition zones were given by the extract. The three zones: Inh 1, Inh 2, Inh 3 had approximately following R_c-values:

Inh 1	1.10
Inh 2	0.65
Inh 3	0.37

These R_c-values are thus closely related to the R_c-values of many vitamin B_{12} factors [8]. Inh 1 seems to be present in much greater amounts than the other two inhibition factors. The three inhibition zones were cut out from chromatograms and eluted with water. The eluates were concentrated by evaporation under reduced pressure at 40°C. Attempts were made to determine absorption spectra of the three solutions thus obtained, but they were not successful.

The solutions were not sufficiently purified and concentrated. The experiments could not be continued due to the small amount of material available. However, even if the solutions had been sufficiently purified and concentrated the determination of their absorption spectra would have been quite uncertain since they contained considerable amounts of vitamin B_{12} activity. The separation of this activity from the inhibitor factors by the conventional chromatographic and electrophoretic techniques may be a rather difficult task as can be understood from the fact that the R_c-values of the inhibitor factors are very closely related to the R_c-values of many vitamin B_{12} factors (*cf.* Fig. 2) and that their neutral or slightly basic electrophoretic character at pH 2.5 ressembles that of cyanocobalamin and several other vitamin B_{12} factors.

The occurrence of bacterial inhibition factors in bacterial cell extracts has been reported by several authors. Bolinder [14] in this laboratory has found that several purine nucleotides, notably adenine ribotides and desoxyribotides, possess a growth inhibiting activity for *L. leichmannii* 313 in agar plates for the assay of vitamin B_{12}, desoxyribotides and desoxyribosides. However, the identity of the inhibitor factors found in *Desulphovibrio desulphuricans* cells with any of the compounds found by Bolinder [14] to have an inhibitory activity is unlikely since they behave quite differently upon chromatography.

Juillard [15] has isolated from a *Bacillus megaterium* mutant a growth inhibition factor for *E. coli 113—3* and identified it chromatographically as the monocarboxylic acid of factor B. This inhibition factor behaved as a competitive antimetabolite for *E. coli 113—3*.

Smith *et al.*[16] and Cuthbertson *et al.* [17] describe the antimetabolic activities for a B_{12}-requiring *E. coli* mutant of several compounds structurally closely related to vitamin B_{12}. In their experiments they used rigorously purified substances obtained by the chemical degradation of cyanocobalamin. As mentioned above, a further purification of the inhibition factors extracted from *Desulphovibrio desulphuricans* cells was not possible. The fact that the preparations did not exhibit any growth inhibiting activity on *E. coli 113—3* plates (*cf.* Fig. 1) may depend upon their high content of vitamin B_{12} which may overcome their possible growth inhibiting activity for *E. coli* whereas in *L. leichmannii 313* plates the growth inhibiting activity could not be overcome. Thus it cannot be decided whether the inhibition factors found in *Desulphovibrio* cell extracts are of the kind described by Juillard [15], Smith *et al.* [16] and Cuthbertson *et al.* [17], although their chromatographic and electrophoretic behaviour points to the suggestion that they may be structurally closely related to vitamin B_{12}.

Acknowledgements. The author is greatly indebted to dr. K. R. Butlin of the National Chemical Laboratory, Teddington, England, for his generosity in providing the active crude culture of sulphate-reducing bacteria and to dr. J. Postgate for the dried cells of *Desulphovibrio desulphuricans*. The author is also greatly indebted to Professor K. Bernhauer for the generous gift of specimens of different vitamin B_{12} factors. The author wishes to thank Professor H. Lundin, Head of the Division, for his encouraging interest in this work and to dr. D.A. Callieri for kind assistance during the first part of this investigation.

Equilibrium Studies of Polyanions

VI. Polyvanadates in Alkaline Na(Cl) Medium *

NILS INGRI and FELIPE BRITO

Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

Equilibria in alkaline vanadate(V) solutions have been studied at 25°C with 0.5 Na(Cl) as ionic medium. Emf measurements were made using a glass or a hydrogen electrode, which together gave concordant results. For an average charge, z, per vanadium, between -0.6 and -1.0 ("instability range"), equilibrium was attained very slowly. Reproducible equilibria were obtained from $z = -1$ to $z = -2$; in this range z was determined as a function of h for various total concentrations, B, of vanadium between 0.080 and 0.00062_5 M.

An analysis of the data indicated that the principal species in this range are B^{2-} $[VO_2(OH)_3^{2-}, HVO_4^{2-}]$, HB_2^{3-} $[(VO_2)_2(OH)_5^{3-}, HV_2O_7^{3-}]$ and $H_3B_3^{3-}$ $[(VO_2)_3(OH)_6^{3-}, V_3O_9^{3-}]$. There was also evidence for a mononuclear complex HB^- $[VO_2(OH)_2^-, H_2VO_4^-, VO_3^-]$. The following formation constants were obtained:

$$2B^{2-} + H_2O \rightleftharpoons HB_2^{3-} + OH^- \quad \log \beta_{12} = -3.18 \pm 0.05$$
$$3B^{2-} + 3H_2O \rightleftharpoons H_3B_3^{3-} + 3OH^- \quad \log \beta_{33} = -10.42 \pm 0.04$$
$$\text{and } B^{2-} + H_2O \rightleftharpoons HB^- + OH^- \quad \log \beta_1 = -6.0 \pm 0.1$$

In this paper also tentative structures are given for the polynuclear complexes formed. The structures are based on five-coordination around vanadium and may give justification for the formulas $VO_2(OH)_3^{2-}$, $(VO_2)_2(OH)_5^{3-}$ and $(VO_2)_3(OH)_6^{3-}$.

The polyanions of vanadium have received a large amount of attention, but information concerning them has been most chaotic because no two workers have agreed and many different classifications, species, and types of reactions have been proposed. Among the methods used for studying these complicated equilibria the emf method seems to be the one that gives data of the highest accuracy. In a careful emf study using glass electrode, Francis and Hazel

* The experimental part of this work was started by Nils Ingri of this laboratory, and then carried out jointly by Nils Ingri and Dr. Felipe Brito, of the University of La Laguna (Canary Islands, Spain), who is working here as a guest research associate. It was clear immediately from

Rossotti [1] investigated the polyvanadates formed in acid solutions. From these data they concluded that VO_2^+ is the only species in strong acid solution and that with increasing pH it reacts with H_2O forming a series of decavanadates. They could explain the data with the following reactions and constants (1 M $NaClO_4$, 25°C)

	log K
$10\ VO_2^+ + 8H_2O \rightleftharpoons H_2V_{10}O_{28}^{4-} + 14H^+$	-6.75 ± 0.15
$H_2V_{10}O_{28}^{4-} \rightleftharpoons HV_{10}O_{28}^{5-} + H^+$	-3.6 ± 0.3
$HV_{10}O_{28}^{5-} \rightleftharpoons V_{10}O_{28}^{6-} + H^+$	-5.8 ± 0.1

The existence of such decavanadate groups has also been indicated by X-ray investigations of crystals (Lindqvist [2], Evans, Mrose and Marvin [3]). Newman and Quinlan [4] found that their spectrophotometric data on equilibrium solutions can be explained by assuming the formation of the decavanadate ions proposed by Rossotti and Rossotti [1].

It is generally believed that these highly condensed anions are broken down with increasing pH, and that the end product in this process is the mononuclear orthovanadate ion, VO_4^{3-}. Our intention when we started this work was to use the same method as Rossotti and Rossotti but to go from the opposite direction and study the reactions taking place when H^+ is added to VO_4^{3-}; in this way we had hoped to find out the formulas and the equilibrium constants for the intermediate complexes formed when VO_4^{3-} is transformed to a decavanadate.

However, experimental difficulties reduced the range available, and the average charge per vanadium, z, could only be varied between -2 and -1. At higher z-values an "instability range" exists giving slow equilibria, and at lower z-values it is difficult to measure z accurately enough. The range studied corresponds to the transition from "pyrovanadate" ($z = -2$) to "metavanadate" ($z = -1$) following the common misleading nomenclature; the position on the pH-scale is shown in Fig. 1.

---

the data that the predominant species in the range studied are those denoted here as B^{2-}, $H_3B_3^{3-}$, and HB_2^{3-}. Some deviations showed, however, that other species must be present also. After the experimental work was completed and they had agreed upon a reliable set of data, Felipe Brito and Nils Ingri decided to make the following calculations separately and then to compare their results. When they parted, they had been inclined to try to ascribe the disturbances to $H_2B_2^{2-}$, "$V_2O_6^{2-}$".

When each of them had completed his calculations both had come to the same conclusion, namely that the deviations were due to HB^-, and their values for the equilibrium constants agreed within the limits of error given; this is shown in Tables 3 and 4. Although both had used methods taken out of the general arsenal of methods used in this laboratory, their approach had been quite different, and the fact that their results agree seems to give added confidence in the data and methods. It was agreed that the work should be published in Spanish [1a] (giving the approach of Felipe Brito), and in English (giving the approach of Nils Ingri). After finishing the calculations, they have discussed each others' work quite thoroughly, and so it is only fair that they should be joint authors to the two papers. Since there would be no point in giving values for the log(equilibrium constants) differing by 0.01 or so (thus within the limits of error given), they have agreed on a single set of constants, which is given after Tables 3 and 4. May I use this opportunity of thanking them for their very pleasant cooperation.

Lars Gunnar Sillén.

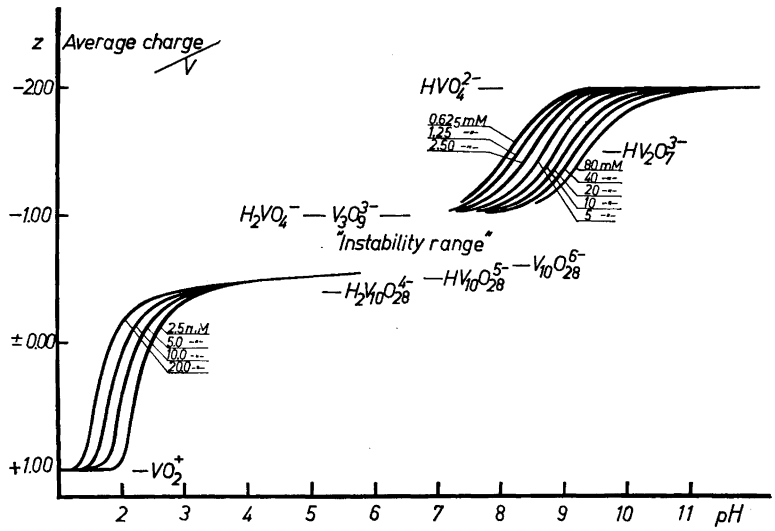

Fig. 1. Survey of data for vanadate (V) solutions: average charge, z, versus pH for various total concentrations, B. Curves on acid side from Rossotti and Rossotti [1] (1 M (Na) ClO_4). Curves on alkaline side from the present work. Between them is an "instability range", where equilibria are slowly attained. Note that the "phosphate" nomenclature has been used.

Like earlier work (Parts I[1], II[5], III[6] and IV[7] in this series) the present study was carried out as a number of potentiometric titrations at 25°C. In each titration the hydroxide ion concentration $[OH^-]$ was varied, and the total vanadium concentration, B, was kept constant. $[OH^-]$ was measured with a glass electrode with an accuracy of $\pm$ 0.3 mV. (Some experiments were also carried out using a hydrogen electrode). The variation of activity factors has largely been eliminated by keeping $[Na^+]$ = constant = 0.5 M. The experimental emf gave $[OH^-]$ (see eqn. 8), and the analytical composition of the solution gave B and H. H is the analytical excess concentration of hydrogen ions, H^+, assuming all vanadium to be in the form with $z = -2$, B^{2-} (= $VO_2(OH)_3^{2-}$, HVO_4^{2-}). From these quantities one could then calculate Z, the average number of protons H^+ bound to B^{2-}, the dominating species at $z = -2$, from the relation

$$BZ = H + [OH^-] \tag{1}$$

From Z we obtained z, the average (negative) charge per vanadium;

$$z = Z - 2 \tag{2}$$

and Z_+, the average number of OH^- bound to every VO_2^+ group (the quantity used by Rossotti and Rossotti [1]) from

$$Z_+ = 3 - Z = 1 - z \tag{3}$$

For the mathematical treatment the experimental data have been plotted (Fig. 2) with Z and z against $-\log [OH^-]$, with a separate curve for each B-value.

NOTATIONS

The way of writing the formulas. The relationship between phosphates and vanadates was deduced from the isomorphism of the minerals vanadinite, $Pb_5(VO_4)_3Cl$, and apatite, $Ca_5(PO_4)_3F$, by the work of Rammelsberg [8]; in addition, both Rammelsberg [8] and Roscoe [9] prepared a number of crystalline vanadates with analytical formulas similar to the corresponding phosphates. From these experiments Roscoe concluded that the solid vanadates could be classified in analogy to the phosphates, and he gave the following names and formulas to three groups of vanadates.

VO_4^{3-}	$V_2O_7^{4-}$(or HVO_4^{2-})	VO_3^-(or $H_2VO_4^-$)
"orthovanadate"	"pyrovanadate"	"metavanadate"

These formulas, which are based upon the idea of VO_4^- tetrahedra, were soon used [10] also to describe vanadium species in aqueous solutions, and this nomenclature is still used frequently; when the "metavanadate" ions have proved to be polynuclear, formulas like $V_3O_9^{3-}$ and $V_4O_{12}^{4-}$ have been proposed, in analogy with the polymetaphosphate ions.

In this paper the "VO_4"-nomenclature will be used sometimes, but more often the species found in this work will be written as complexes of VO_2^+ and OH^-. Thus $H_2VO_4^-$ will be written as $VO_2(OH)_2^-$, HVO_4^{2-} as $VO_2(OH)_3^{2-}$, $HV_2O_7^{3-}$ as $(VO_2)_2(OH)_5^{3-}$, and $V_3O_9^{3-}$ as $(VO_2)_3(OH)_6^{3-}$. These formulas may have some structural justification.

In our discussion about vanadates crystallized from solution and investigated with X-ray methods, analytical formulas like $(NH_4)_6V_{10}O_{28}(H_2O)_4$, $Ca_3V_{10}O_{28}(H_2O)_{16}$, KVO_3H_2O and KV_3O_8 will be used.

In the mathematical discussion, however, it will prove advantageous, for brevity and simplicity, to treat the complexes as composed of H^+ and B^{2-}, where B^{2-} is the mononuclear complex of charge 2—, thus HVO_4^{2-}, or $VO_2(OH)_3^{2-}$. Anticipating our results, the major complexes found by us in alkaline solutions may be written as

$$B^{2-} = VO_2(OH)_3^{2-} = HVO_4^{2-}$$
$$HB_2^{3-} = (VO_2)_2(OH)_5^{3-} = HV_2O_7^{3-}$$
$$H_3B_3^{3-} = (VO_2)_3(OH)_6^{3-} = V_3O_9^{3-}$$

Other complexes are

$$HB^- = VO_2(OH)_2^- = H_2VO_4^- = VO_3^-$$
$$H_{-1}B^{3-} = VO_2(OH)_4^{3-} = VO_4^{3-}$$

Dubious species are $H_2B_2^{2-}$, *etc.*

In essential parts the symbols are the same as in AB II[11] and Part II[5] in this series but will be repeated in order to simplify the reading.

a = $[OH^-]^{-1} = h\,K_w^{-1}$; corresponds to reagent A = $-OH^-$ (= H^+)
B^{2-} = species with one V and charge 2−, "HVO_4^{2-}" or $VO_2(OH)_3^{2-}$; $b = [B^{2-}]$
B total vanadium concentration
$\boldsymbol{B}$ a normalized quantity corresponding to B
E the measured emf in mV
E_{oa} = $E + 59.15 \log [OH^-] + E_j$. (8)
E_j = const. $[OH^-]$, liquid junction emf.
H total analytical concentration of H^+ over B^{2-} and H_2O; H may be negative
h = $[H^+]$
l = $\beta_{11}\beta_{12}^2\beta_{33}^{-1}$; (27)
n number of links (H_tB) per complex $B(H_tB)_n$
N unique value for n
P unique value for the number of H in H_PB_Q
$\bar{p}$ average number of H per complex formed from B^{2-} by addition of H^+
Q unique value for the number of B in H_PB_Q
$\bar{q}$ average number of B per complex formed from B^{2-} by addition of H^+
R^{-1} the average degree of condensation of B^{2-}
t number of H per B group in the link (H_tB)
u normalized quantity corresponding to a (24)
s number of B^{2-} in predominating complex B_s^{2s-}
v normalized quantity corresponding to ab (24)
w normalized quantity corresponding to a^2b. (15 c)
x $\log B - 1.5 \log [OH^-]$ (17)
y $1.5^{-1}Z$ (17)
z the average negative charge per vanadium (2)
Z the average number of H^+ bound to the dominating species of $z = -2$. (1)
Z_+ the average number of OH^- bound to every VO_2^+ group (the Z used by Rossotti and Rossotti [1]) (3)

The formation of a complex $H_pB_q^{(2q-p)-}$ can be written with H^+, or OH^- as reactant. We shall denote the corresponding equilibrium constants by $*\beta_{pq}$ and β_{pq}, to conform with the IUPAC tables of stability constants [12]:

$$pH^+ + qB^{2-} \rightleftharpoons H_pB_q^{(2q-p)-}\,;\ [H_pB_q^{(2q-p)-}] = *\beta_{pq}h^pb^q \qquad (4)$$

$$pH_2O + qB^{2-} \rightleftharpoons H_pB_q^{(2q-p)-} + pOH^-,\ [H_pB_q^{(2q-p)-}] = \beta_{pq}a^pb^q \qquad (5)$$

Since $[OH^-]$ is determined directly whereas h contains the uncertainty of K_w, it seems preferable to use instead of h the quantity

$$a = [OH^-]^{-1} = hK_w^{-1} \qquad (6)$$

which is proportional to h. It is seen from (4), (5) and (6) that

$$*\beta_{pq} = \beta_{pq}K_w^{-p} \qquad (7)$$

Chemical symbols are in Roman, concentrations in italic type. Concentrations and equilibrium constants will be expressed in M (moles per liter).

EARLIER WORK

The orthovanadate ion, VO_4^{3-}, was studied by Düllberg [10] using conductometric titrations. He found that, when solid orthovanadate is dissolved in water, an equivalent amount of OH^- is released. From that he concluded that the orthovanadate ion is such a strong base that it cannot exist in aqueous solution but reacts thus: $VO_4^{3-} + H_2O \rightleftharpoons HVO_4^{2-} + OH^-$.

In subsequent potentiometric studies, Britton, Robinson [13] and Ducret [14] came to the same conclusion.

However, in another paper Britton and Robinson [15] say that 49 % of the vanadate ions are hydrolysed in a solution where the total vanadium concentration = 83.3 mM.

In solubility measurements carried out by Britton and Robinson [16], an orthovanadate solution was titrated with a silver solution, and the silver concentration in the solution was measured with a silver electrode. The data obtained were in agreement with the solubility product: $[Ag^+]^3[HVO_4^{2-}][OH^-] = 10^{-24}$.

In a recent spectrophotometric investigation, Newman [17] and coworkers could explain their data on vanadium(V) in strongly alkaline solution by assuming a mixture of VO_4^{3-} and HVO_4^{2-}. They give $K = 0.097 \pm 0.005$ M for $VO_4^{3-} + H_2O \rightleftharpoons HVO_4^{2-} + OH^-$ at an ionic strength of 3.0 M.

The existence of a "*pyrovanadate*" *ion*, $V_2O_7^{4-}$, has been claimed by many authors. In an early cryoscopic investigation, Düllberg [10] found evidence for a dimeric vanadate species in solutions containing $2OH^-/V$. Jander and Jahr [18] reached the same conclusion from diffusion data.

Electrometric titrations [16] of sodium vanadate solution with Ag^+ (using a silver electrode) gave evidence only for the species HVO_4^{2-}, and the data could be explained assuming the solubility product $[Ag^+]^2[HVO_4^{2-}] = 10^{-13.7}$.

The solubility of $Ag_4V_2O_7$ in various solutions of sodium vanadate, $z = -2$, was measured by Souchay [19] and he found that the solubility was in accordance with the solubility product $[Ag^+]^2[HVO_4^{2-}] = \text{const}$. However, in more concentrated solutions this constant could not explain the data which were in better agreement with $[Ag^+]^4[V_2O_7^{4-}] = \text{const}$.

From spectrophotometric work [17] Newman claimed that the following dimerisation took place: $2HVO_4^{2-} \rightleftharpoons V_2O_7^{4-} + H_2O$ with $K = 48 \pm 5$.

From conductometric studies, Trujillo and Beltrán [20] concluded that the dimer in solutions with z between -1 and -2 has the charge -3. Emf measurements by Lefebvre [21] indicated the same complex together with its dimer.

The studies of pyrovanadate solutions by Russel and Salmon [22] with an ion exchanger also indicate that solutions with $z = -2$ contain a dimer with the charge -3.

Schwarzenbach and Parissakis [23] dissolved small amounts of $Na_4V_2O_7$ in a $Na_2SO_4(H_2O)_{10}$ melt and studied the change of the transition point. The data obtained were used for calculating the average number of vanadium atoms per complex. In concentrated solutions the ion $V_2O_7^{4-}$ was claimed to be formed whereas diluting gave equilibria $H_2O + V_2O_7^{4-} \rightleftharpoons 2HVO_4^{2-}$.

An early cryoscopic investigation *on the condensation of* "*metavanadate*" carried out by Düllberg [10] indicated a trimer. Jander and Jahr [18] concluded

from their diffusion data that the metavanadate ion should be a tetramer. Souchay [24] has criticized Jander and Jahr's conclusion and maintains that the solution contains trimers.

On the other hand Britton and Robinson [16] titrated vanadate solutions with Ag^+ using a silver electrode. The data could be explaned assuming $[Ag^+][VO_3^-] = 10^{-6.3}$ and not by $[Ag^+]^3[V_3O_9^{3-}] = \text{const}$. Souchay [25] says, however, that Britton and Robinson's result may be incorrect since, using the same method, he could explain the data assuming a trimer at high concentrations, and VO_3^- at low concentrations.

By studying the solubility of ammonium metavanadate Trujillo and Tejera [26] concluded that the metavandate is tetrameric. Also, Lefevbre [21] came to the same conclusion in his treatment of vanadate data with the method of "potentiometric surface".

Hazel, McNabb, and Santini [27] postulated, from emf measurements, that a complex $H_2V_2O_7^{2-}$ dimerizes to a tetramer.

From their cryoscopic studies in melting Glauber salt, Schwarzenbach and Parissakis [23] came to the conclusion that a tetramer, $V_4O_{12}^{4-}$, was formed in a range where the present work indicates a trimer, ($z = -1$).

Russel and Salmon's ion exchange work [22] indicated a trimer with the charge 3−.

From determination of vapor pressures over solutions with $z = -1$, Robinson and Sinclair [28] could calculate the average degree of condensation in the solution, which they found to be 3.

EXPERIMENTAL DETAILS

Reagents and analysis

Sodium hydroxide free from carbonate was prepared and analysed as described in Part II [5].

Sodium chloride, Merck p.a. was used after drying at 200−300°C without further purification.

Hydrochloric acid, Kebo p.a. was used. Standardisation against $KHCO_3$ and standard NaOH agreed within 0.1 %.

Vanadium(V)oxide, LKB p.a. was used. The vanadium(V)oxide was analysed by reducing an acid suspension of V_2O_5 with SO_2, boiling off the excess SO_2, and titrating with standard $KMnO_4$. Analysis of the product always gave > 99.93 % V_2O_5. In order to check if the oxide contained some impurities, which could affect the result of our titrations, V_2O_5 was prepared also from sodium vanadate according to the method proposed by Rossotti and Rossotti [1], and used for preparing the solutions in some titrations. The commercial product and that one prepared from sodium vanadate gave identical titration curves.

Apparatus

As in earlier work [5–7] in alkaline solution, Jena Geräte glass has been used for titration vessels and burets.

The electrode vessel and the salt bridge were of the same type as described Part II[5]. The glass electrode was a Radiometer (Copenhagen) type G 202 BT and the emf values were read to ±0.1 mV with a Radiometer PHM3 valve

potentiometer. The hydrogen electrode and the silver reference electrode cell were prepared as described in Part IV[7].

The cells including the titration vessel were kept in an oil thermostat at 25°C ± 0.1°C and the whole equipment kept in a thermostated room at 25°C. The solutions were introduced into the titration cell from burets calibrated by weighing water. The equilibrium solution was stirred by means of commercial nitrogen freed from O_2 which had passed through 10 % H_2SO_4, 10 % NaOH and 0.5 M NaCl.

The emf measurements

In our titrations a constant ionic medium has been maintained in order to keep the activity factors as constant as possible and thus use concentrations instead of activities in the law of mass action. To conform with earlier investigations it would be desirable to use 3 M $Na(ClO_4)$. However, in this work 0.5 M Na(Cl) has been used. The concentration 0.5 M has been chosen because of the low solubility of vanadate in stronger Na^+ media.

In this work the total vanadium concentration has been varied between $0.62_5 \times 10^{-3}$ and 80.0×10^{-3} M and as the concentration of the vanadate ions and $[OH^-]$ never exceed 20 % of the total anions, we assumed, following Biedermann and Sillén [29], the activity factors for all species to be approximately constant.

The determination of the equilibrium value for $[OH^-]$ was made with a glass or hydrogen electrode in combination with the half-cell

SE = 0.5 M NaCl | 0.5 M NaCl saturated with AgCl | AgCl, Ag

The cell used was thus:

— glass electrode | vanadate solution | SE +

or — Pt, H_2 (1 atm) | vanadate solution | SE +

Assuming the activity factors to be constant the emf of these cells can be written

$$E = E_{oa} + 59.15 \log [OH^-] + E_j = E_{oa} - 59.15 \log a + E_j \qquad (8)$$

where E_{oa} is a constant and E_j the liquid junction potential. The constant E_{oa} was determined from a solution of known $[OH^-]$ and with $[Na^+] = 0.5$ M as described in Part II[5]. Before and after every titration, the glass electrode was checked in a solution with known $[OH^-]$. It was found that this check was necessary as E_{oa} sometimes could change during a titration by several millivolts, in which case the whole titration was rejected.

For the liquid junction potential we found $E_j \approx 41\ [OH^-]$mV[7]; since $[OH^-]$ was usually < 0.001 M, E_j could be neglected in the range studied.

TITRATION PROCEDURE AND ATTAINMENT OF EQUILIBRIA

The present investigation started with a number of "bottle experiments". To a number of polythene bottles containing about 50 ml strongly alkaline vanadate solution with $z \approx -3.0$ (uncolored solutions), various amounts of acid vanadate solution with $z \approx +1.0$ (yellow solution) were added. After

the addition, all solutions were at first yellow. In some of the bottles the color faded immediately, in others it faded in the course of several days, but in the bottles containing most acid the color did not change. It was found out that colorless solutions could always be obtained as long as the average charge per vanadium, z, in the mixture was $\leqq -1.0$; the time for discoloration increased when z approached -1.0. By mixing two solutions, both with $z < -1$, uncolored solutions were always obtained.

The experiments described above were then carried out as titrations where the acid solution was added with a buret and the alkaline solution kept in a titration vessel; the change of $[OH^-]$ was followed with a *hydrogen* electrode. As long as the measured solution with $z \leqq -1$ was yellow the emf crept appreciably, whereas an uncolored solution showed a nearly constant potential. On mixing two uncolored solutions with $z \leqq -1.0$, stable potentials were obtained rapidly, and only a creep of the order of 0.06 mV per hour caused by very slow reduction of vanadium(V) was observed.

From these preliminary observations we concluded that when the two solutions are mixed in such a way that the average charge per vanadium, z, is allowed even momentarily to increase above -1, equilibrium is slowly obtained, but as long as all solutions have $z \leqq -1$ equilibrium is momentarily obtained.

Rossotti and Rossotti [1] found in their study of acid vanadate solutions that rapid equilibria could always be obtained when $z > -0.6$. Thus we concluded that equilibrium is obtained slowly for solutions with z ranging between -0.6 and -1.0, and in the following this range will be denoted as the "instability range" (see Fig. 1).

Even if the vanadate(V) solutions were slowly reduced by hydrogen, reproducible emfs were obtained if one consistently used the E value obtained after 20—30 min (the time usually required for H_2 electrodes to reach equilibrium) and did not allow the titration to take more than one day. However, for several reasons we decided to use the *glass* electrode for our final data. The data for our first titrations, using the hydrogen electrode, together with the glass electrode data are given in Table 1 and a comparison shows that the two electrodes give the same results within ± 0.3 mV. This agreement seems to show that no serious systematic error was involved in using glass electrodes in our alkaline vanadate solutions, which was most welcome since we do not pretend to understand how the glass electrode works.

Remembering the fact that rapid equilibria can always be obtained when $z \leqq -1$ for all solutions, the following two titration procedures have been worked out, and both have been used.

1) $z(\log[OH^-])_B$-titrations. In these titrations the total concentration of vanadium, B, has been kept constant and log $[OH^-]$ and thus z has been varied. The total hydroxide ion concentration was varied usually by decreasing z; then the solution in the titration vessel had $z \approx -1.03$ and was titrated with a more alkaline solution with $z < -2$. In a check titration with increasing z, the solution with $z \approx -1.03$ was in the buret and the alkaline solution in the titration vessel. The points so obtained, (see Fig. 2, 0.010 M points □) were on the same titration curve as the others (■), and there was no difference in the time for attainment of equilibria.

2) $B(\log[OH^-])_z$-titrations. In these titrations two ways for changing the total concentration of vanadium have been used. In one of them the solution in the titration vessel was 0.5 M Na(Cl), and a solution with known z and B was added; in the other way the solution containing the vanadium (known z and B) was kept in the titration vessel, and 0.5 M Na(Cl) was added by buret. From eqn. (1) and (2) it can be seen that during these titrations z was nearly constant, (In the range studied $[OH^-]$ can be neglected in comparison with H).

All these methods for getting experimental data have given consistent results, and equilibrium was always obtained rapidly.

Preparation of the vanadate solutions

Solution for the titration vessel. A weighed quantity of vanadium(V) oxide was added to a volumetric flask (of Jena-Geräte glass) and a calculated amount of standard sodium hydroxide was added. The addition of NaOH was chosen so as to make $z \approx -1.03$. In the preparation of the solutions with the lowest vanadium concentrations, the oxide dissolved rapidly giving an apparently colorless solution, but for higher concentrations it was necessary to dilute with de-aerated distilled water and raise the temperature to about 50—80°C for a short time. After dissolution of the vanadium(V) oxide, calculated amounts of solid NaCl were added. After waiting until the temperature had fallen to 25°C, the flask was carefully filled to the mark with de-aerated water. It was checked that the volume of the flask had not changed after heating and cooling. The manipulations described above were always carried out in a CO_2-free N_2 atmosphere.

The buret solution was prepared as described above except that the solutions were made more alkaline.

TREATMENT OF EXPERIMENTAL DATA

The primary experimental data: the emf values and the analytical composition of the solution were recalculated using eqns. (1), (2) and (8), to give z $(\log[OH^-])_B$. The data are given in this form in Fig. 2 and Table 1.

If mononuclear complexes only were formed, z would be a function of $[OH^-]$ only. From Fig. 2 it is seen that z is a function of both B and $[OH^-]$, and so, apparently, one polynuclear complex at least must be formed.

The $z(\log[OH^-])_B$ curves range between two z limits, $z = -1$ and $z = -2$. The complex or the complexes predominating at $z = -2$ and $z = -1$ may be polymers, and for our analysis it is convenient to start with one of these limiting complexes. As a concentrated vanadate solution became more acid on dilution (see Fig. 2) we concluded that $(B^{2-})_s$, the complex at $z = -2$, is of lower nuclearity than the complex at $z = -1$. To conform with previous methods we decided to study a condensation reaction and thus analyse the reactions taking place when H^+ is added to $(B^{2-})_s$. Before starting this analysis it is, however, necessary to find the value for s.

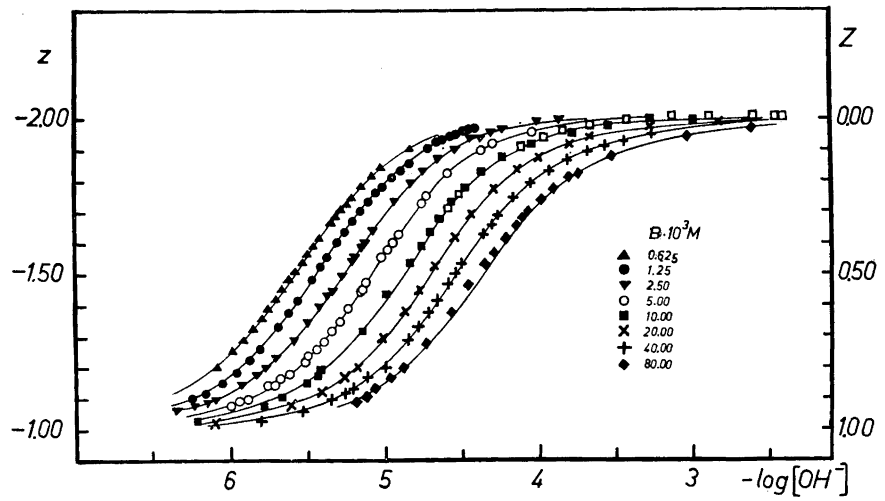

Fig. 2. Experimental data plotted as z ($\log[OH^-]$)$_B$. The average number, $Z = (2-z)$, of H^+ bound to B^{2-} is also given. The curves are calculated assuming the formation of HB_2^{3-} ($\log \beta_{12} = -3.19$) $H_3B_3^{3-}$ ($\log \beta_{33} = -10.42$) and HB^- ($\log \beta_1 = -6.04$). The open symbols for $B = 0.010$ M represent a back titration.

Table 1. Vanadates at 25°C in 0.5 M Na(Cl).

Data $B(\log[OH^-])_z$ obtained with hydrogen electrode

$z \approx 1.59$. $B.10^3$, $-\log [OH^-]$, $-z$: 40.00, 4.42, 1.59; 35.00, 4.45, 1.59; 30.00, 4.49, 1.59; 2.50, 4.54, 1.59; 20.00, 4.60, 1.59; 10.00, 4.78, 1.59; 5.10, 4.88, 1.59; 2.50, 4.92, 1.59.

The nuclearity at $z = -2$

For $B = 0.0025-0.0200$ M and for z from -1.0 to -1.5 the experimental $z(\log[OH^-])_B$-curves are parallel within the limits of experimental errors, and according to AB I[29] the complex or the complexes formed may be written in the "core and links" form $(B^{2-})_s[(B^{2-})_sH_t]_n^{[2s+n(2s-t)]-}$ where t and n are quantities

which can be determined independently of the value of s. In our "core + links" analysis, which will be described in a following section, we found $t = 1.5$ and $n = N = 2$. With these values for t and n the upper limiting value for z may be expressed as a function of s

$$z_{\text{lim}} = \frac{t\ N - 2(N+1)s}{(N+1)s} = \frac{1-2s}{s}$$

and for $s = 1$, $z_{\text{lim}} = -1.0$; $s = 2$, $z_{\text{lim}} = -1.5$; $s = 3$, $z_{\text{lim}} = -1.67$. Experimentally, $z_{\text{lim}} = -1.00$ (see Fig. 2) and consequently our data are in agreement only with $s = 1$, and the species at $z = -2$ must be monomeric with the charge -2, B^{2-}, whereas the limiting species at $z = -1$ would be $H_3B_3^{3-}$.

The first step in our analysis of the experimental curves $z(\log[OH^-])_B$ will be a determination of $\bar{q}$, the average number of vanadium atoms in all complexes except B^{2-}, and $\bar{p}$, the average number of protons bound (in excess to B^{2-}) in these complexes. A description of this calculation will be given in a following section, (in connection with eqns (10), (11) and (12)), but a part of it will be given here as it gives a further proof of the mononuclearity for vanadium at $z = -2$.

As pointed out earlier the complex dominating at $z = -2$, may be written in the form $(B^{2-})_s$. If H^+ is added, a condensation takes place and the average degree of condensation, R^{-1}, increases as H^+ increases. Sillén [30] has shown that R^{-1} may be calculated from the experimental $Z(\log a)_B$-curves and the general formula he gives may be written

$$R = R_0 - \int_{\log a_1}^{\log a} \left(\frac{\partial\ (2+z)}{\partial \log B}\right)_a \mathrm{d} \log a = \frac{1}{s} - \int_{\log a_1}^{\log a} \left(\frac{\partial\ Z}{\partial \log B}\right)_a \mathrm{d} \log a \text{ at constant } B \qquad (9)$$

In this formula $R_0 = \frac{1}{s}$ is an integration constant, the value of which can be determined from the lower limit of integration, s is the number of B^{2-} units in $(B^{2-})_s$, $\log a_1$ the value of $\log a = -\log [OH^-]$ where the integration starts and $(2 + z) = Z$, the average number of H^+ bound per $(B^{2-})_s$.

For obtaining R^{-1} at an arbitrary point on the $z(\log a)_B$-curve the value of s and the integral in (9) must be known. The calculated values for the integral at various $-\log [OH^-]$ obtained from our experimental data are given in Table 2. From this table it is evident that low experimental z-values and high B-values give integrated quantities > 0.5; if $s \geqq 2$ negative values for R^{-1} would then be obtained, according to (9). That must mean that the integrated area is too large to be in agreement with other s-values than $s = 1$.

Again we conclude $s = 1$. The complex with $z = -2$, B^{2-}, is mononuclear.

The mean composition of the polynuclear complexes

To find the species in these vanadate solutions we shall start with the "direct integration method", previously used in the borate study [5], which gives the *mean composition of the complexes formed*. With this integration as

Table 2. Values for $\bar{q}$ and $\bar{p}$ obtained with the "direct integration" method.

$$* \int \left(\frac{\partial Z}{\partial \log B}\right)_a \mathrm{d} \log a \qquad ** \int \left[Z + \left(\frac{\partial Z}{\partial \log B}\right)_a\right] \mathrm{d} \log a$$

the basis we shall try to find the *formulas of the complexes;* the final step in the analysis will be a confirmation of the complexes with one or two *projection maps*.

In the foregoing we have shown that there is a single monomeric complex, B^{2-}, at $z = -2$, ($Z = 0$), and thus polynuclear complexes must be formed when Z increases (see Fig. 2). For high Z values there is a mixture of mononuclear and polynuclear complexes. If direct measurements on $b = [B^{2-}]$ were possible it should be very easy to obtain

$$\bar{q} = \frac{B-b}{BR-b} \qquad (10) \qquad \text{and} \qquad \bar{p} = \frac{BZ}{BR-b} \qquad (11)$$

In these formulas B is the total concentration of vanadium and R is the reciprocal of the average degree of condensation of B^{2-}; so, $(BR-b)$ is the total molar concentration of all species except B^{2-}.

However, even in absence of direct measurements on b, this quantity may be calculated. General expressions for this calculation have been given by Sillén [30] and his formulas will be used here for getting R and b. The formula for getting R has already been given in eqn. (9) and the formula for calculating b is

$$\log \frac{B}{b} = \int_{\log a_1}^{\log a} \left[Z + \left(\frac{\partial Z}{\partial \log B} \right)_a \right] \mathrm{d} \log a \qquad \text{at constant } B \qquad (12)$$

Log a_1 is the log a value where the integration starts, B the total concentration of vanadium and $Z = (z + 2)$, the average number of H^+ bound to B^{2-}, the dominating species at $z = -2$; at $a = a_1$, $b \approx B$ and $\log B/b \approx 0$.

The integration has been carried out numerically from the experimental Z (log a)-curves at a given value of B. $(\partial Z/\partial \log B)_a$ was obtained as the average of the quotients $(\Delta Z/\Delta \log B)_a$ from the plot Z (log B)$_a$ for two neighbouring intervals.

In Table 2 a part of our result from the integration is given, and in Fig 3 $\bar{q}$ and $\bar{p}$ for some concentrations have been plotted against $-\log [OH^-]$. It is indicated by this integration that complexes are formed with $\bar{q}$ ranging bet-

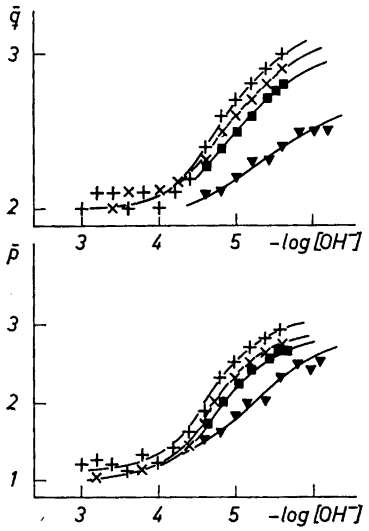

Fig. 3. Analysis by "direct integration"; $\bar{q}$ and $\bar{p}$ plotted against $-\log[OH^-]$. + = 0.040 M; × = 0.020 M; ■ = 0.010 M and ▲ = 0.0025 M.

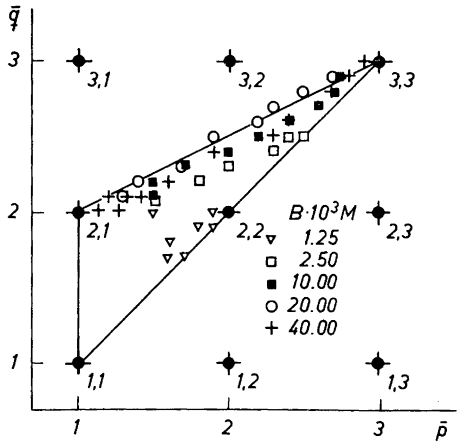

Fig. 4. $\bar{q}$ *versus* $\bar{p}$; note that all points fall within the triangle between (2,1), (3,3) and (1,1).

ween 2.0 and 3.0 and $\bar{p}$ between 1.0 and 3.0. The plot $\bar{q}$ against $\bar{p}$ for $B = 0.040$, 0.020, 0.010 M in Fig. 4 gives a nearly straight line between the sets $(\bar{q}, \bar{p}) = (2,1)$ and (3,3), indicating that the main complexes for these concentrations are HB_2^{3-} and $H_3B_3^{3-}$.

At lower concentrations, $B = 0.0025$ and 0.0012_5 M, the $(\bar{q}\ \bar{p})$ points deviate markedly from this line, thus indicating the formation of some additional complex or complexes at lower B. If one tries to explain these deviations with the formation of a single complex, $\bar{q}$ for this complex must be <3; thus the species may be a monomer $H_{p'}B$ or a dimer $H_{p'}B_2$; p' must be <2 and p'' <3 as the deviations are found at low Z-values and Z is ranging between 0.00 and 1.00. Then only the complexes HB^- and $H_2B_2^{2-}$ remain and of these two HB^- seems to be the more likely one as all data, $\bar{q}$ $(\bar{p})$ in that case fall within the triangle formed by the $(\bar{q}\ \bar{p},)$-coordinates, (3,3); (2,1) and (1,1) corresponding to the composition of the complexes $H_3B_3^{3-}$, HB_2^{3-} and HB^-.

If the two complexes HB_2^{3-} and $H_3B_3^{3-}$ only were formed (10) and (11) may be written

$$\bar{q} = \frac{2\,[HB_2] + 3\,[H_3B_3]}{[HB_2] + [H_3B_3]} = \frac{2 + 3\beta_{33}\beta_{1\,2}^{-1}a^2b}{1 + \beta_{33}\beta_{1\,2}^{-1}a^2b} \qquad (13)$$

$$\bar{p} = \frac{[HB_2] + 3\,[H_3B_3]}{[HB_2] + [H_3B_3]} = \frac{1 + 3\beta_{33}\beta_{1\,2}^{-1}a^2b}{1 + \beta_{33}\beta_{1\,2}a^2b} \qquad (14)$$

or in a normalized form

$$\bar{q} = \frac{2 + 3\,w}{1 + w} \qquad (15a) \qquad\qquad \bar{p} = \frac{1 + 3\,w}{1 + w} \qquad (15b)$$

where $w = \beta_{33}\beta_{1\,2}^{\cdot}a^2b$ (15c)

With (15a) and (15b) it is possible to construct two theoretical curves $\bar{q}$ (log w) and $\bar{p}$ (log w) and compare them with the experimental $\bar{q}$ (log a^2b)- and $\bar{p}$ (log a^2b)-curves. If the assumption is right the experimental $\bar{q}$ and $\bar{p}$ values plotted against log a^2b must give two single curves with the same shape as the calculated $\bar{q}$ (log w)- and $\bar{p}$ (log w)-curves. In Fig. 5 experimental and calculated curves are compared and the fit must be considered satisfactory (except for $B = 2.5.10^{-3}$ M). The difference in coordinates between log a^2b and log w in the position of best fit gives the ratio $\beta_{33}\beta_{1\,2}^{-1}$:

log w − log a^2b = log β_{33} − log β_{12} = -7.40 ± 0.20. (The final constants give log $\beta_{33}\beta_{1\,2}^{-1} = -7.24 \pm 0.10$).

Thus this treatment has indicated the species $H_3B_3^{3-}$ and HB_2^{3-} and given an approximate relationship between their formation constants. For low B values indications were found for a complex HB^- or $H_2B_2^{2-}$.

"Core and links" treatment

In the first instance only the data for $B = 0.0025$—0.020 M and for Z from 0.45 to 1.00 will be discussed. In this range the $Z(\log a)_B$-curves form within

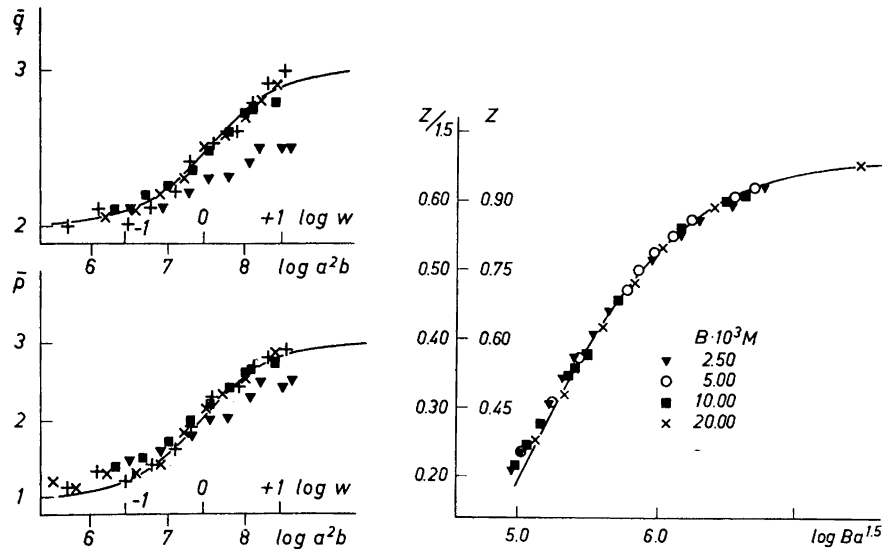

Fig. 5. $\bar{q}$ and $\bar{p}$ plotted against log a^2b. Full curve calculated assuming only HB_2^{3-} and $H_3B_3^{3-}$ (log $\beta_{33}\beta_{12}^{-1} = -7.40 \pm 0.20$) + = 0.040 M; × = 0.020 M; ■ = 0.010 M and ▲ = 0.0025 M.

Fig. 6. Z or $y = 1.5^{-1}\ Z$ as a function of $x = \log B + 1.5 \log a$; Data for $B = 0.0025$ to 0.020 M, and for Z from 0.45 to 1.00 are given. Full curve calculated assuming the single complex $H_3B_3^{3-}$; with log $\beta_{33} = -10.50$.

the limits of experimental error, apparently parallel curves. That should mean that the complex or the complexes formed may be written in the "core + links" form $B(BH_t)_n^{[2+n(2-t)]-}$; t is a constant and n may be an unique integer N or a series of integers such that the product nt is an integer. In ABI[31] it has been shown that

$$t = -\left(\frac{\partial \log B}{\partial \log a}\right)_z \tag{16}$$

From our experimental $Z(\log a)_B$-data in Fig. 2 it is easily found that $t = 1.5$. That should mean that the main species formed have the composition $B(BH_{1.5})_n^{(2+0.5\,n)-}$. If only complexes with that composition are formed, the validity of (16) can be tested, as all experimental points should lie now on a single $y(x)$-curve, with the coordinates

$$x = \log B - 1.5 \log [OH^-] \quad y = 1.5^{-1}\ Z \tag{17}$$

In Fig. 6 the experimental plot of y against x is shown. It is seen that the experimental points according to (16) lie satisfactorily on a single curve and the "core + links" hypothesis may be considered as a good explanation of these data.

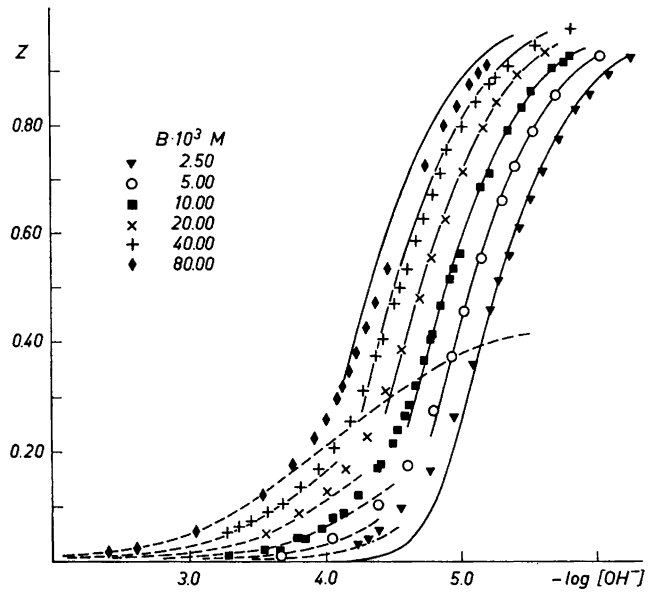

Fig. 7. Data Z (log $[OH^-])_B$. Full curves calculated assuming only $H_3B_3^{3-}$ (log $\beta_{33} = -10.48$). Dotted curves calculated assuming only HB_2^{3-} (log $\beta_{12} = -3.12$).

To decide whether n is a constant or not the curve $y(x)$ was compared with the normalized $y(X)$-curves calculated on the following three assumptions given in ABII [11] page 321:

I no soluble complexes are formed but a precipitate is obtained
II a unique complex $B(A_tB)_N$ is formed in solution
III a series of complexes $B(A_tB)_n$ is formed in solution, with values of n ranging from unity to infinity.

This comparison indicated a single complex, $H_3B_3^{3-}$, with $N = 2$. The normalized $y(x)$-curves used were so constructed that the difference in reading on the X- and log $Ba^{1.5}$-coordinates in the position of best fit gave log β_{33} (see eqns. (24) and (25) in ABII [11]). We found log $\beta_{33} = -10.50 \pm 0.10$.

In order to get further confirmation for that complex and to check the shape of the experimental curves, a normalized $Z(X)_{PQ}$ curve was constructed under the assumption that a single complex H_PB_Q with $P = 3$ and $Q = 3$ was formed. If only one complex is formed, we have

$$B = b + Q\,[H_PB_Q] = b + Q\beta_{PQ}a^Pb^Q$$
$$BZ = P\beta_{PQ}a^P b^Q$$

Elimination of b and rearranging gives:

$$Q\beta_{PQ}B^{Q-1}a^P = w(1-w)^{-Q} = 10^{PX}$$

where $w = QZP^{-1}$. Using w as auxiliary variable it is possible to calculate a normalized $Z(X)_{PQ}$-curve where

$$X = P^{-1} \log w - QP^{-1} \log (1-w) \quad (18a)$$

and $$Z = wPQ^{-1}. \quad (18b)$$

The normalized curve with $Q = 3$ and $P = 3$ was found to fit well with the experimental Z (log $a)_B$-curves (see Fig. 7) for low Z values and the concentrations $B = 0.0025-0.020$ M; the difference in coordinates on the horizontal axis gave $\beta_{33} = -10.48 \pm 0.1$

$$\log a - X = -P^{-1} \log \beta_{PQ}Q - (Q-1)P^{-1} \log B = -\tfrac{1}{3} \log 3\beta_{33} - \tfrac{2}{3} \log B \quad (19)$$

The main product is thus $H_3B_3^{3-}$, which, however, does not suffice to explain the data in the range for $B = 0.0025-0.080$ M and for Z from 0.00 up to 0.45.

In the direct integration we found that $\bar{q}$ and $\bar{p}$ approach the limiting values $\bar{q} = 2$ and $\bar{p} = 1$ when $Z \to 0$. From that we may conclude that the polynuclear complex first formed must be HB_2^{3-}.

With the aid of (18a) and (18b) a normalized $Z(X)_{PQ}$ curve was constructed for a single complex H_PB_Q with Q = 2 and $P = 1$ and compared with the experimental Z(log $[OH^-])_B$-data at low Z-values. An acceptable fit (see Fig. 7) was obtained for the four highest vanadium concentrations, $B = 0.080-0.010$ M, and the difference in reading on the horizontal axis gave, for all concentrations log $\beta_{12} = -3.12 \pm 0.1$.

Confirmation of HB_2^{3-} and $H_3B_3^{3-}$ with a normalized graph log B (log $u)_Z$

In order to get a final confirmation for the formation of the complexes HB_2^{3-} and $H_3B_3^{3-}$, a normalized graph [31a] for the three species, B^{2-}, HB_2^{3-} and $H_3B_3^{3-}$ was constructed and compared with the experimental data.
Reactions:

$$2B^{2-} + H^+ \rightleftharpoons HB_2^{3-}; [HB_2^{3-}] = {}^*\beta_{12}[H^+][B^{2-}]^2 = \beta_{12}ab^2$$
$$3B^{2-} + 3H^+ \rightleftharpoons H_3B_3^{3-}; [H_3B_3^{3-}] = {}^*\beta_{33}[H^+]^3[B^{2-}]^3 = \beta_{33}a^3b^3$$

The condition for the concentrations gives

$$B = b + 2\beta_{12}ab^2 + 3\beta_{33}a^3b^3 \quad (20)$$

$$BZ = \beta_{12}ab^2 + 3\beta_{33}a^3b^3 \quad (21)$$

We wish to transform these expressions to the normalized form

$$Bu = v(1 + 2v + 3uv^2) \quad (22), \qquad BZu = v(v + 3uv^2) \quad (23)$$

and this is achieved by the substitutions

$$u = \beta_{33}\beta_{12}^{-2}a\,; v = \beta_{12}ab\,; B = B\beta_{12}^{3}\beta_{33}^{-1} \quad (24)$$

Elimination of u from (22) and (23) gives

$$u = (Z + v(2Z-1))(1-Z)^{-1}(3v^2)^{-1}$$

and $B = 3v^3(1 + v)\ (Z + v(2Z-1))^{-1}$

With these formulas it is possible to calculate $\log B$ as a function of Z and $\log u$.

The calculated $\log B(\log u)_Z$ graph was compared with the experimental $\log B(\log a)_Z$-data and in the position of best fit the difference in reading along the coordinate axes on the two graphs gives the constants β_{12} and β_{33}

$$\log B - \log B = 3 \log \beta_{12} - \log \beta_{33} \tag{25}$$

$$\log u - \log a = \log \beta_{33} - 2 \log \beta_{12} \tag{26}$$

and $\log \beta_{12} = -3.12 \pm 0.05 = \log \beta_{33} = -10.42 \pm 0.05$.

The dotted curves in Fig. 8 are calculated with these constants. It is seen from this figure, that the agreement is satisfactory. However, small deviations at $B = 0.00125$ M, $B = 0.00062_5$ M and low z-values were found.

Deviations caused by additional complex

It remains now to explain the deviations from the dotted curve in Fig. 8. Such low total concentrations as 0.00125 and 0.00062_5 M can usually be studied with high accuracy only in very favorable cases. Now in our case measurements on low vanadium concentrations can be made in a very sensitive pH-range, and the deviations cannot be due only to experimental error but must be caused also by the formation of some additional complex.

In our treatment of the experimental data with the direct integration method the main part of the data could be explained with HB_2^{3-} and $H_3B_3^{3-}$ but deviations were found for low B and if a single additional complex was formed this could indicate either HB^- or $H_2B_2^{2-}$. These two possibilities have been tested with the aid of normalized graphs $\log B(\log a)_{Z,l}$, and it was found that only the combination with the species B^{2-}, HB^-, HB_2^{3-} and $H_3B_3^{3-}$ gave normalized graphs, which fitted satisfactorily with the experimental data (see Fig. 8). The equations valid for the construction of this normalized graph are

$$Bu = v(1 + lu + 2v + 3uv^2)$$
$$BZu = v(lu + v + 3uv^2)$$

where the same substitutions as in (22) and (23) has been used and

$$l = \beta_1\beta_{12}^2\beta_{33}^{-1} \tag{27}$$

Elimination of u gives

$$u = (Z + v(2Z-1))(1-Z)^{-1}(3v^2 + l)^{-1} \tag{28}$$

and $B = v(1 + v)\ (3v^2 + l)\ (Z + v(2Z-1))^{-1}$ (29)

From (28) and (29) two $\log B\ (\log u)_Z$ graphs with different values of l, $l = 0.005$ and $l = 0.010$, were constructed and compared with the experimental graph. From the calculated graph which fitted best with the experimental

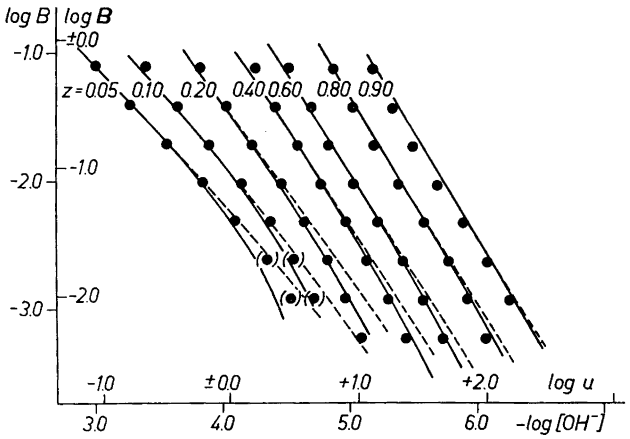

Fig. 8. Projection maps experimental data log $B(\log[OH^-])z$ and normalized curves log $B(\log u)z$ calculated for a) HB_2^{3-} and $H_3B_3^{3-}$ (dotted curve) b) HB^-, HB_2^{3-} and $H_3B_3^{3-}$ assumming $\beta_{11}\beta_{12}^2\beta_{33}^{-1} = 0.01$ (full curve). The position of best fit gave log $\beta_1 = -6.04 \pm 0.08$, log $\beta_{12} = -3.19 \pm 0.05$ and log $\beta_{33} = -10.42 \pm 0.05$.

data, the full curve in Fig. 8, we obtained the constants β_{12} and β_{33} from (25) and (26)

$$\log \beta_{12} = -3.19 \pm 0.05; \quad \log \beta_{33} = -10.42 \pm 0.05$$

and the constant β_1 from eqn. (27) and the value of l giving the best fit ($l = 0.01$).

$$\log \beta_1 = -2 \pm 0.03 - 4.04 \pm 0.05 = -6.04 \pm 0.08$$

Final sets of equilibrium constants

Our potentiometric measurements give a set of data (B,Z,a) for concentrations $0.080\ \mathrm{M} < B < 0.00062_5\ \mathrm{M}$, which may be explained most simply by a successive condensation of B^{2-} to HB_2^{3-} and $H_3B_3^{3-}$. Low concentrations indicated also a mononuclear species HB^-. No evidence has been found for the existence of higher polyions e.g. tetranuclear species.

The equilibrium constants obtained in this work have been deduced according to the methods developed in this institute and are summarized in Table 3.

Table 3.

The constants deduced by:	log β_1	log β_{12}	log β_{33}
Curve fitting $1.5^{-1}Z(\log Ba^{1.5})$			-10.50 ± 0.1
$Z(X)_{PQ}$		-3.12 ± 0.1	-10.48 ± 0.1

After we had finished our calculations we discussed the methods used and have agreed on the following set of constants.

$$\log \beta_1 = -6.0 \pm 0.1; \log \beta_{12} = -3.18 \pm 0.05; \log \beta_{33} = -10.42 \pm 0.04$$

Fig. 9 shows the distribution of the various species as a function of $\log [OH^-]$ for the total concentrations $B = 0.00062_5$ M and 0.040 M.

Possible structures of the complexes

Now one may ask if the ions found can be given a reasonable structural interpretation. There are many different methods for evaluating the structure of complexes in aqueous solution (X-ray diffraction of solutions, thermodynamic considerations, various types of spectra *etc.*) but very few of them have been used for studying vanadate(V) solutions.

From a structure-entropy consideration, however, La Salle and Cobble [42] have shown that VO_2^+ rather than $V(OH)_4^+$ is the more probable form of vanadium(V) in very strong acid solution.

Siebert [41] has studied strong alkaline vanadate(V) solutions, using Raman spectra, and from similarities between spectra obtained and spectra of PO_4^{3-} solutions he concluded that the vanadate ion in these solutions is tetrahedral, VO_4^{3-}.

For solutions of intermediate pH this kind of data is lacking. In this case one may guess from what is known on the solid state and assume that vanadium(V) forms the same type of ions or units or least has the same coordination number in solutions as in the solid.

Previous X-ray studies of crystalline vanadium(V) compounds prepared from water solutions indicate that the coordination number of vanadium(V) may be 4,5, or 6.

In solid V_2O_5 investigated by Byström, Brotzen and Wilhelmi (1950) [32], vanadium is surrounded by five oxygen atoms forming a distorted trigonal bipyramid. The bipyramids are coupled by sharing two edges giving infinite chains. These chains are linked laterally to sheets. The lateral linking is established by the attraction between a vanadium atom and an oxygen in two different chains. Thus the coordination around vanadium is between 5 and 6. From water solution V_2O_5 is precipitated at $pH \approx 1.6$. The same type of V-O-sheets have also been found in the mineral hewettite $CaV_6O_{16}(H_2O)_9$ (Barnes, Qurashi [33]).

Evans [34] has pointed out that it may be reasonable to expect the same type of bipyramidal chains, modified to give vanadium a distorted octahedral coordination, also in the solid decavanadates, crystallizing at $pH \approx 6.5$, $(NH_4)_6V_{10}O_{28}(H_2O)_6$ (Lindqvist [2]) $K_6V_{10}O_{28}(H_2O)_9$, $K_6V_{10}O_{28}(H_2O)_{10}$, $Ca_3V_{10}O_{28}(H_2O)_{16}$ (pascoite), $K_2Mg_2V_{10}O_{28}(H_2O)_{16}$ (hummerite) and $K_2Zn_2V_{10}O_{28}(H_2O)_{16}$ (Evans, Mrose and Marvin [3]).

KV_3O_8 belongs to this group also and has been investigated with X-rays by Evans and Block [34]. According to Evans [34] this vanadate contains bipyramidal chains "folded in a herringbone fashion".

At higher pH, 6—8, colorless "metavanadates" may be crystallised and among then KVO_3 (Evans and Block [35], 1954, Petràsovà, Madar and Hanic [36] 1958) and $KVO_3(H_2O)$ (Christ, Clark and Evans [37] 1954) have been investigated by X-ray analysis. In $KVO_3(H_2O)$, the units are trigonal bipyramids which share edges forming a chain. In the structure two V-O-distances are shorter than the other and Hanic [38] has pointed out that this should indicate the existence of VO_2^+ groups in the crystal.

In KVO_3 which crystallizes together with $KVO_3(H_2O)$ one would expect the same trigonal staggered chain but here vanadium is four-coordinated and the tetrahedra share corners forming a string similar to diopside. It is easy to derive the diopside chain from the staggered trigonal bipyramid by a simple stretching process. In fact it may be possible also to convert $KVO_3(H_2O)$ to KVO_3 by grinding (Evans [35]). Diopside structures have been found also for $NaVO_3$ (Sörum [39] 1943) and NH_4VO_3 (Lukesh [40] 1950).

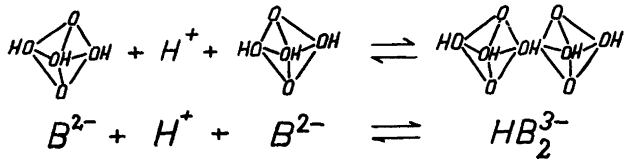

Fig. 10.

From the most alkaline solutions "orthovanadates" may be crystallized, and tetrahedral VO_4^- groups have been established in a number of vanadium compounds especially minerals ($BiVO_4$ [43], (Pb, Zn, Cu)(OH)(VO_4) [44], $Pb_3(VO_4)_2$ [45], $ScVO_4$ [46], and others).

From the configurations in the solid vanadate(V) crystals investigated with X-rays it seems reasonable to propose, for the polynuclear complexes in solution, structures where vanadium either is four- or five-coordinated.

Assuming four-coordination, the vanadium species $H_3B_3^{3-}$ may be given the formula $V_3O_9^{3-}$; structurally that means three VO_4 tetrahedra sharing two corners forming a 6-membered ring. With VO_4-tetrahedra, however, it is difficult to understand the formation of HB_2^{3-}.

On the other hand assuming vanadium to be five-coordinated it is possible to give a mechanism for formation of both HB_2^{3-} and $H_3B_3^{3-}$. In this case the first step in the condensation reaction may be written (Fig. 10)

$$B^{2-} + H^+ + B^{2-} \rightleftharpoons HB_2^{3-}$$

$$VO_2(OH)_3^{2-} + H^+ + VO_2(OH)_3^{2-} \rightleftharpoons (VO_2)_2(OH)_5^{3-} + H_2O$$

and for the reaction (Fig. 11) when HB_2^{3-} reacts with H^+ and B^{2-} forming the trimer $H_3B_3^{3-}$

$$HB_2^{3-} + 2H^+ + B^{2-} \rightleftharpoons H_3B_3^{3-}$$

$$(VO_2)_2(OH)_5^{3-} + 2H^+ + VO_2(OH)_3^{2-} \rightleftharpoons (VO_2)_3(OH)_6^{3-} + 2H_2O$$

Instead of a ring structure $H_3B_3^{3-}$ may also be a chain, coupled as in $KVO_3(H_2O)$, but in this case it is difficult to explain why higher complexes e.g. four — or five-nuclear complexes, have not been detected in our solutions.

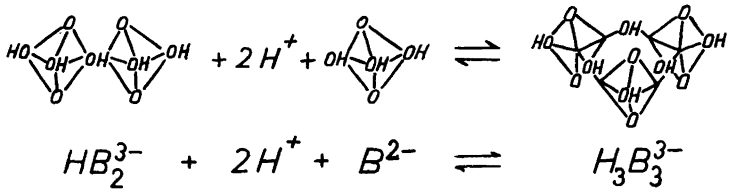

Fig. 11.

Added in proof: Recently K. F. Jahr and L. Schoepp *(Z. Naturforsch. 14 b* (1959) 467, 468) presented the results from an investigation of water solutions of metavanadate using three different cryoscopic methods. They used much higher concentrations than that one used in this work ($C \approx 0.140-0.196$ moles $NaVO_3$ per kg) and concluded that the solutions contained the tetrameric ion, $V_4O_{12}^{4-}$. In addition to that they also found that thallium(I)metavanadate is dissolved in tertbutylchloride giving the compound $(C_6H_9)_4V_4O_{12}$. Whatever the reason for the discrepancy between cryoscopic measurements of Schwarzenbach and Jahr on one side and our emf work on the other side may be, our data certainly cannot be explained by a mechanism where $V_4O_{12}^{4-}$ is the main product.

The authors are indebted to Professor Lars Gunnar Sillén for his great interest and for the many valuable discussions in connection with the preparation of this paper.

We also wish to thank Dr Georg Lundgren for advice and discussions during the work, Mr. Per Jerkeman for his help during the preliminary titrations and Mr. Frans Ericson for practical aid in many ways.

One of us (F. B.) is also indebted to the Spanish Foreign Office for an interchange grant with *Svenska institutet för kulturellt utbyte med utlandet* as well as to *Juan March* Foundation.

Thanks are also due to Mr. David Martin for correcting the English text.

The Viscosity of Degrading Polymer Solutions

THOR A. BAK and KATE BAK

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

The viscosity of a polymer solution is calculated as a function of time for several simplified degradation models, assuming the validity of Staudinger's rule. It is shown how the theoretical results may be compared with measurements obtained using an Ostwald viscometer, which only give a sliding time average of the viscosity, and finally the application of the present very crude theories to enzymatic reactions is discussed. The theoretical results obtained are compared with the experiments of Andersen and Graae on the enzymatic hydrolysis of hyaluronic acid.

In his classical work on the degradation of high polymers W. Kuhn [1] derived an approximate expression for the molecular weight distribution in a sample which before degradation had been monodisperse and of virtually infinite molecular weight. The derivation was based on statistical considerations, and the results are only valid for samples with an average molecular weight small compared to that of the initial sample.

His results have been rederived several times. Sakurada and Okamura [2] used a method similar to Kuhn as did Montroll and Simha [3]. The latter authors, however, generalized the results to be valid for polymers with finite initial molecular weight. Simha [4] and Sillén [5] derived similar results, using a kinetic model which is essentially identical with the first model to be discussed in this paper.

Hultin [6] has used the results of Sillén to derive an approximate expression for the excess viscosity of a solution of a degrading polymer as a function of time. In this derivation is used a limiting process in which it is implicitly assumed that a long time t has elapsed since the start of the experiment. The result obtained, namely that the excess viscosity is proportional to t^{-1}, is therefore meaningless in the limit $t \sim 0$.

It is the aim of this paper to derive formulae for the viscosity for the model discussed by Sillén and for a few other models which may be relevant in connection with the work on enzymatic degradation of high polymers. To do so we shall make use of a different limiting process and obtain results which are correct for all times, in particular for $t = 0$. One of the formulae we obtain may be found in Silléns work too, but there it is stated that it is only an

approximation. We shall show that the result can be derived without approximations save for the trivial one of assuming that the molecular weight of the initial sample is virtually infinite. Finally we want to discuss the applicability of the present very crude theory to systems where the degradation is caused by enzymes.

GENERAL ASSUMPTIONS

The usual model of a degrading polymer is a chain where each link has the same probability of breaking per unit time. Furthermore this probability is independent of the number of bonds in the molecule. It is believed that this is a fairly realistic picture, and therefore we shall first consider this model, but since there is experimental evidence that some polymers, *e. g.* hyaluronic acid [7] may have a preference for breaking in the middle when degraded enzymatically, we also investigate a crude model where the molecules split exclusively in the middle. In this model we can, because of its simplicity, introduce that the probability of splitting the central bond depends on the chain length.

Throughout the paper we shall assume the validity of Staudinger's rule [8], *viz.*

$$\eta_n = k\ c_n M_n^2 \tag{1}$$

in which η_n is the increase in viscosity caused by a solute of molar concentration c_n and molecular weight M_n, and k is a constant. The general validity of this rule may well be questioned, and it is well to bear in mind that the following considerations apply only to polymers which follow the Staudinger rule. In the case of hyaluronic acid this has been shown experimentally [9].

Furthermore we shall assume that for a solution of several species the excess viscosity is additive, *viz.*

$$\eta = \sum \eta_n = k \sum c_n M_n^2 \tag{2}$$

Our last general assumptions are that the degradation is such that the end-product is a repeated unit in the macromolecule which is the starting material, although not necessarily the smallest repeated unit, and that the initial high polymer is monodisperse. We shall indicate below, however, how this last assumption could be dispensed with.

Let the weight of the repeated unit be M. We then have $M_n = nM$, and

$$\eta(t) = k \sum_n c_n(t)(nM)^2 = k' \sum_n n^2 c_n(t) \tag{3}$$

so that, except for a constant factor, $\eta(t)$ is the second moment of the molecular weight distribution.

Following Andersen and Graae [10] we shall denote the reduced excess viscosity $\eta(t)/\eta\ (t = 0)$ by $y(t)$. We then have $y = 1$ for $t = 0$ and, loosely speaking, $1-y$ is a degree of advancement.

MODELS OF DEGRADATION

We shall now study a few simple models. In each case we start by stating the additional assumptions we make for the particular model.

Model 1

Assumption: All bonds between repeated units split with equal probability (w) per unit of time.

Notation: c_k is the concentration of molecules of molecular weight kM. NM is the molecular weight of the initial substance. $k-1$ is the number of bonds in the molecule with concentration c_k.

The equations for the time-dependence of the concentrations are thus:

$$\begin{aligned}
\dot{c}_N &= -w(N-1)c_N \\
&\cdots \\
\dot{c}_k &= 2w\sum_{i=k+1}^{N} c_i - (k-1)wc_k \qquad (4) \\
&\cdots \\
\dot{c}_1 &= 2w\sum_{i=2}^{N} c_i
\end{aligned}$$

By straight-forward integration we get for $c_k(0) = \delta_{kN}$ (that is, $c_k = 1$ for $k = N$, and otherwise zero)

$$\begin{aligned}
c_N &= e^{-(N-1)wt} \\
c_{N-1} &= 2e^{-(N-2)wt} - 2e^{-(N-1)wt} \\
c_{N-2} &= 3e^{-(N-3)wt} - 4e^{-(N-2)wt} + e^{-(N-1)wt} \\
&\cdots \qquad (5) \\
c_2 &= (N-1)e^{-wt} - 2(N-2)e^{-2wt} + (N-3)e^{-3wt} \\
c_1 &= N - 2(N-1)e^{-wt} + (N-2)e^{-2wt}
\end{aligned}$$

These expressions we insert in

$$\eta = k'\sum_n n^2 c_n$$

and get

$$\eta = k' \left[N + 2N \sum_{n=1}^{N-1} e^{-nwt} - 2 \sum_{n=1}^{N-1} n e^{-nwt} \right]$$

or

$$y = \frac{1}{N^2} \left[N + 2N \sum_{n=1}^{N-1} e^{-nwt} - 2 \sum_{n=1}^{N-1} n e^{-nwt} \right] \tag{6}$$

which is the final expression for $y(t)$.

It is easily verified that these expressions for the excess viscosity are identical with the one derived by Sillén: (our notation)

$$\eta = k' \left\{ \frac{1 + e^{-wt}}{1 - e^{-wt}} - \frac{2e^{-wt}(1 - e^{-Nwt})}{N(1-e^{-wt})^2} \right\}$$

The expression for $y(t)$ can be simplified considerably by letting $N \to \infty$, but this limiting process can be carried out in different ways.

Sillén argued that for $N \to \infty$, one will have

$$\eta \sim \frac{1 + e^{-wt}}{1 - e^{-wt}} = \coth \frac{wt}{2}$$

since the last term on the right hand side in the expression for η contains N^{-1}. This limiting process corresponds to increasing the size of the molecule, keeping the size of the repeated unit constant. This leads to an infinite viscosity at $t = 0$, whereas the measured viscosity of course is finite, but at the same time the unnormalized probability of breaking some bond goes to infinity as $(N-1)w$. Therefore the viscosity calculated using this approximation is infinite at $t = 0$, but its rate of change is infinite also, and so the expression $\eta \sim \coth wt/2$ may be a useful approximation at some later time.

The reason for the inconsistency in the result derived above is that one cannot let N go to infinity separately without changing M and w. What is required is to go from the discrete model to a continuous model, *i. e.*, a model where the molecule consists of infinitely many repeated units with infinitely small mass. We let $N \to \infty$ and at the same time $M \to 0$ so that NM stays constant. During this limiting process the number of bonds in a molecule goes to infinity too, but since Nw is an observable quantity practically equal to the rate constant in the first order expression for the disappearance of the initial polymer, we must let $w \to 0$ such that Nw stays constant ($= \alpha$).

We therefore have

$$y = \lim_{\substack{N \to \infty \\ w \to 0}} \frac{1}{N^2} \left[N + 2N \sum_{n=1}^{N-1} e^{-nwt} - 2 \sum_{n=1}^{N-1} n e^{-nwt} \right.$$

$$= \frac{2(\alpha t - 1 + e^{-\alpha t})}{\alpha^2 t^2} \tag{7}$$

Table 1. Θ as a function of y (eqn. 7).

y	0.5	0.4	0.3	0.2	0.1
0.5 +	0.0000	0.3247	0.7101	1.1796	1.7720
0.0 +	2.5569	3.6733	5.4486	8.8732	18.9443

It is easily verified that $y(0) = 1$ as it should be. $\dot{y}(0) = -\alpha/3$ which can be used in fitting the expression to experimental data. For $\alpha t \gg 1$ we have $y \sim t^{-1}$ which is the result obtained by Hultin using the other limiting process.

When one wants to compare the theoretical result with experiments it is convenient to introduce a dimensionless quantity $\Theta = \alpha t$. In terms of this we have

$$y = \frac{2(\Theta - 1 + e^{-\Theta})}{\Theta^2} \tag{8}$$

Table 1 is a tabulation of $\Theta(y)$ which can be compared with $t(y)$ which one gets from experiments and thereby give a determination of α. The data given below for hyaluronic acid do not fit this expression.

So far we have only considered the case where the initial polymer is monodisperse. Although one can in general approximate this fairly well experimentally, it would be interesting to study the case where one starts with an arbitrary initial distribution. We plan to return to this problem in a later publication, but we shall here briefly indicate how, in our mind, this problem best could be attacked. Eqn (4) is rewritten as

$$\dot{c}_k = 2Nw \sum_{i=k+1}^{N} c_i \frac{1}{N} - N^{-1}(k-1)\, Nwc_k$$

and we see that in the limit $N \to \infty$, $w \to 0$, $Nw \to \alpha$ we can introduce the continuous variable $\xi = k/N$ such that $c = c\,(\xi, t)$ satisfies the integral equation

$$\frac{\partial c}{\partial t} = 2\alpha \int_{\xi}^{1} c d\xi - \alpha \xi c \tag{9}$$

which can be rewritten as

$$\frac{\partial^2 c}{\partial \xi \partial t} + \alpha \xi \frac{\partial c}{\partial \xi} + 3\alpha c = 0 \tag{10}$$

after differentiation with respect to ξ. To see the influence of an initial polydispersity this equation is solved subject to the initial condition $c(\xi, 0) = f(\xi)$ where $f(\xi)$ is the molecular weight distribution at time zero.

The model discussed above is reasonable when we consider, for instance, a thermal degradation of the macromolecule, since Pelzer has shown [11] that

for a linear chain the probability of breaking a bond by a unimolecular mechanism is to a first approximation independent of the position of the bond in the molecule and of the molecular weight. When we consider a catalyzed decomposition it may no longer be a reasonable assumption. In particular when we consider an enzymatic decomposition it is in all probability a poor approximation to assume that all bonds break with equal probability, since the enzyme itself is a rather bulky molecule which has to be fitted onto a certain pattern in the degrading macromolecule.

As mentioned above [7] there is experimental evidence that some polymers break preferentially to give very large fragments. We shall now investigate a model where this feature has been further simplified so that we consider molecules which split exclusively in the middle.

Model 2

Assumption: The molecules split only in the middle.
Notation: c_k is the concentration of the molecules with molecular weight $NM2^{-k}$
w_k is the probability that the k'th molecule will break.

2A. (trivial case) $w^k = w$ (all k)
We have

$$\dot{c}_n = - wc_n + 2wc_{n-1} \tag{11}$$

It is convenient to use the generating function:

$$G(x,t) = \sum_n c_n(t)x^n \tag{12}$$

since evidently $y = G(\frac{1}{4},t)$. Multiplying the original differential equation with powers of x and summing we get

$$\frac{\partial G}{\partial t} = - w(1 - 2x)G \tag{13}$$

i. e., $G = e^{-w(1-2x)t}$

$$y = e^{-\frac{1}{2}wt} \tag{14}$$

This case which is in itself without any interest shows the method we shall use to get y directly from the kinetic equations in the more complicated cases.

We shall now let w_k depend on k. For an enzymatic decomposition it is reasonable to assume that this dependence is such that w_k decreases when k increases, since supposedly the enzyme is one suited for decomposition of the original macromolecule. By introducing this in the model we hope to be able to account, for instance, for the rapid initial decrease in viscosity which is

characteristic of the degradation of hyaluronic acid. The initial decrease during which the excess viscosity drops to about one third of its initial value is followed by a very slow decrease.

The simplest dependence is $w_k = w\ 2^{-k}$ (w being a constant) so that w_k is proportional to the molecular weight of the molecule to which it belongs. This model therefore resembles model 1 somewhat, only here all the probability of breaking a bond is located at one particular bond.

2B. Assumption: $w_k = w\ 2^{-k}$ (w constant)

This gives the following equation for c_k:

$$\dot{c}_k = -\ w\ 2^{-k}c_k + 2w\ 2^{-k+1}c_{k-1} \tag{15}$$

From this we get the equation for the generating function:

$$\frac{\partial}{\partial t}\ G(x,t) = -\ w(1 - 2x)G\left(\frac{x}{2},t\right) \tag{16}$$

To solve this we use the Laplace transformation, introducing

$$g(x,s) = \int_0^\infty e^{-st}G(x,t)dt$$

We have ther.

$$s\ g(x,s) - 1 = -\ w(1 - 2x)g\left(\frac{x}{2},s\right) \tag{17}$$

and making a power series expansion of g

$$g(x,\ s) = \sum_{n=0}^{\infty} S_n(s)x^n \tag{18}$$

we get by comparing terms

$$S_0 = \frac{1}{w + s}$$

. . .

. . .

$$S_n = \frac{w}{2^{n-2}\left(s + \frac{w}{2^n}\right)} S_{n-1} \tag{19}$$

. . .

. . .

Transforming back we obtain

$$y = \sum_{n=0}^{\infty} A_n e^{-wt/2^n} \tag{20}$$

$$\text{with } A_0 = \frac{1}{3} - \frac{1}{3 \cdot 7} + \frac{1}{3 \cdot 7 \cdot 15} - \frac{1}{3 \cdot 7 \cdot 15 \cdot 31} + \cdots \tag{21}$$

$$\text{and } A_n = 2^{(n^2-n)/2} \prod_{k=1}^{n} \frac{1}{2^k - 1} A_0 \tag{22}$$

Since $A_{n+1}/A_n \sim 1/2$, the series for y converges for all fixed t. It is convenient to consider y as a function of $\Theta = wt$. We have

$$\left[\frac{dy}{d\Theta}\right]_{\Theta=0} = -\sum 2^{-n} A_n = -\frac{1}{2} \tag{23}$$

which can be used in fitting the theory to experimental data. Because of the rapid convergence of the above series it is easy to calculate a sufficient number of points.

It is interesting to note that this complicated expression gives values for $y(\Theta)$ which almost coincide with those given by the expression derived for model 2A, *viz.* $y = \exp(-\frac{1}{2}\Theta)$. The slopes for $\Theta = 0$ are the same, and in the range $1 < y < 0.35$ the difference $y_B - y_A$ is only 1—2 %. For smaller y this difference increases rapidly, being about 20 % for $y \sim 0.2$. This shows clearly how accurately one must measure in order to be able to decide between two models of this kind. Furthermore it shows that the last mentioned theory does not give any abrupt change in y as we might have hoped.

If we want to keep the idea of molecules breaking in the middle only and obtain the above mentioned abrupt change in viscosity we must change the dependence of w_k on k rather drastically. The only simple relationship we have been able to find which gives a reasonable result is one where w_k has a constant value for all molecules above a certain size and another constant value for molecules with smaller molecular weight. If we consider an enzymatic process, this corresponds to an enzyme which has a selective catalytic effect on large, resp. small molecules.

Model 3

Assumptions:
1. Molecules break in the middle only
2. For molecules with a molecular weight $> M^*$ the rate-constant is w_1, for molecules with molecular weight $\leq M^*$ the rate-constant is $\overline{w_2}$.

Notation:

$w_2 = \frac{1}{2}\overline{w_2}$

c_k is the concentration of molecules with molecular weight $NM2^{-k}$

3A. $M^* = \frac{N}{2} M$

$$\begin{aligned} \dot{c}_0 &= -w_1 c_0 \\ \dot{c}_1 &= -\overline{w_2} c_1 + 2w_1 c_0 \\ \dot{c}_2 &= -\overline{w_2} c_2 + 2\overline{w_2} c_1 \\ &\quad etc. \end{aligned} \tag{24}$$

We solve the first equation to get $c_0 = e^{-w_1 t}$ and use this to get an equation for the generating function

$$\frac{\partial G}{\partial t} + \overline{w_2}(1 - 2x)G = -(w_1 - \overline{w_2})(1 - 2x)e^{-w_1 t} \tag{25}$$

from which we get

$$G = \frac{1}{w_1 - (1-2x)\overline{w_2}}\left[(w_1 - \overline{w_2})(1-2x)e^{-w_1 t} + 2w_1 x e^{-(1-2x)\overline{w_2} t}\right] \tag{26}$$

and

$$y = \frac{w_1 - 2w_2}{2(w_1 - w_2)} e^{-w_1 t} + \frac{w_1}{2(w_1 - w_2)} e^{-w_2 t} \tag{27}$$

3B. $M^* = \frac{N}{4} M$

Using a similar technique we get:

$$y = (a_0 + a_1 t)e^{-w_1 t} + b e^{-w_2 t} \tag{28}$$

with

$$\begin{aligned} a_0 &= \frac{w_1 - 2w_2}{2(w_1 - w_2)} + \frac{w_1(w_1 - 2w_2)}{4(w_1 - w_2)^2} \\ a_1 &= \frac{w_1(w_1 - 2w_2)}{4(w_1 - w_2)} \\ b &= 1 - a_0 \end{aligned} \tag{29}$$

It is easy to see that the general form is

$$y = \left[\sum_{n=0}^{k} a_n t^n\right] e^{-w_1 t} + b e^{-w_2 t} \tag{30}$$

for $M^* = NM2^{-k-1}$. The most important general feature of these equations is that b is smaller the higher n is. If in these models we put $w_2 << w_1$, *i. e.*, if the selectivity of the enzyme is pronounced, we get a sharp change in y. For model 3B this change occurs at $y \gtrsim \frac{1}{4}$, which is fairly close to what one can

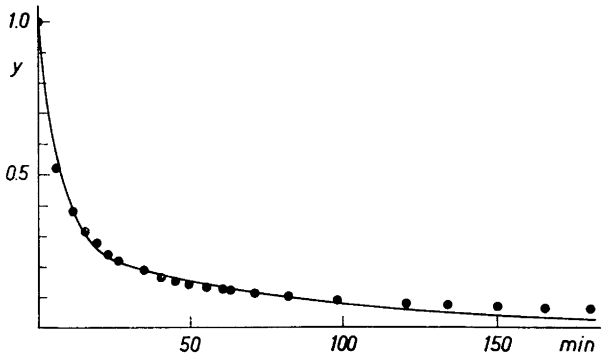

Fig. 1. Relative excess viscosity y as a function of time. The theoretical curve is calculated from eqn. 28, and the points are the experimental results of Andersen and Graae.

observe experimentally for hyaluronic acid. Fig. 1 shows the shape of the curve using $w_1 = 0.2019$ and $w_2 = 0.0130$ and the experimental points of Andersen and Graae [10]. The values for w_1 and w_2 have been calculated from the experimental data using an iterative least square procedure as described by Bond [15]. The agreement is not nearly as good as is the agreement with the empirical formula suggested by Andersen and Graae, but the expression used here has the advantage that it is derived from a specific model.

COMPARISON WITH EXPERIMENTAL DATA

Usually the viscosity of the polymer solution is measured with an Ostwald viscometer, while the degradation is going on, and in that case if the measurement takes 2τ seconds, the measured "viscosity" η is related to the true viscosity y by the equation

$$\eta^{-1}(t) = \frac{1}{2\tau} \int_{-\tau}^{+\tau} y^{-1}(t + t')\mathrm{d}t' \tag{31}$$

This equation is obtained by expressing the length of the capillary in the viscometer in terms of η and y and equating the two expressions. If τ is constant, it is easy to find y from the given function [12] $\eta(t)$. But unfortunately τ is not constant, it is proportional to η, so that the equation reads

$$\eta^{-1}(t) = \frac{1}{2k\eta} \int_{-k\eta}^{+k\eta} y^{-1}(t + t')\mathrm{d}t' \tag{32}$$

We have not been able to solve this equation, but by finding η using different expressions for y we have been able to estimate the error one makes in using η for y. In the experiments published by Andersen and Graae the error (for

$y \sim 0.52$, $t \sim 6$ min.) is approximately 2 % for the most reasonable shapes of $y = y(t)$. For $t \to 0$ the error becomes very large. Even within the measurable range the error can amount to about 10 %.

If experimental data have to be corrected by some iterative procedure using the above integral equation, they have to be extremely accurate in order that one may draw any conclusions whatsoever from the corrected data, and we believe that no such data have been published so far.

If one could measure the viscosity in such a way that each measurement took the same time, or if the measurements were almost instantaneous such as for instance is the case in the Couette viscometer, the correction would be much easier, and in the latter case actually superfluous.

As mentioned above, we have tried to fit the expression derived for model 3B to the uncorrected data given by Andersen and Graae; Fig. 1 shows the agreement obtained. Not too much importance should be attached to the experimental points for small t (where the correction is large) nor to the values for large t (where transglucosidation may be the dominating reaction).

It is easy to make a better fit by adding an extra term or by letting the pre-exponential factors be parameters which can be varied to get a better fit, but these additions would not be explicable in terms of a molecular mechanism.

APPLICATION OF THE THEORY TO CATALYZED PROCESSES

So far we have assumed that the degradation can be described in terms of monomolecular rate constants w_k. When we consider a thermal degradation this seems very reasonable, but it is not at all clear that the same considerations apply to a reaction catalyzed for instance by an enzyme.

In order to see to what extent it may still be a good approximation we shall have to consider the detailed mechanism of the enzymatic degradation. We consider the simplest possible mechanism:

$P_n + E_1 \rightleftharpoons E_2$ (rate constants k_{12} and k_{21})
$E_2 \to P_m + P_l + E_1$ (rate constant k_{23})

where P_n is a polymer with n basic units ($m + l = n$)
E_1 is the enzyme
E_2 is a molecule of composition E_1P_n
Using steady state kinetics [13] we have readily:

$$[E]\frac{dt}{d[P_n]} = \frac{1}{k_{12}}\left(1 + \frac{k_{21}}{k_{23}}\right)\frac{1}{[P_n]} + \frac{1}{k_{23}} \tag{33}$$

letting $[P_n]$ denote the concentration of P_n and [E] denote the concentration of $E_1 + E_2$.

If k_{23} is large, so that the last term on the right hand side is small, we have a first order degradation of P_n. Furthermore, since in this case the concentration of E_2 is low, only very small amounts of the enzyme is bound in the substrate-complex, and the different first order degradations of P-molecules are therefore effectively independent. In that case the previous considerations

therefore are valid, and a "local stationarity" exists in which all the separate first order reactions are in steady states, but not in steady states with respect to each other.

If k_{23} is small so that the term k_{23}^{-1} cannot be neglected, one will usually find that the first term is negligibly small [14], and that the concentration of E_2 is comparatively high. In that case, therefore, the degradation of the macromolecule must be considered as a large number of zero order reactions competing to form complexes with the enzyme, and thereby degrading P-molecules. In this case, as in the rare case where both terms will have to be considered, the previous considerations are not valid.

We are indebted to professor J. A. Christiansen for encouragement and advice and to Mr. A. E. Nielsen for pointing out an error in the first draft of the manuscript. K. B. gratefully acknowledges financial support from *Det teknisk-videnskabelige Forskningsraad.*

The Crystal and Molecular Structure of 2,2′,2″-Triamino-triethyl-amine-Ni(II)-di-thiocyanate

SVEND ERIK RASMUSSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark *

The crystal structure of 2,2',2''-triamino-triethylamine-Ni(II)-dithiocyanate (Ni tren $(SCN)_2$) was determined from its three-dimensional Patterson function. Superposition methods were applied using both the nickel atom and the two sulphur atoms as searcher atoms. The structure was refined by a least squares analysis, employing three-dimensional data.

The crystal is built up from Ni tren$(SCN)_2$ units. The four nitrogen atoms from the amine and the two nitrogen atoms from the thiocyanate groups form a distorted octahedron around the nickel atom, the thiocyanate groups being in *cis* positions. A full account is given in the text of axial lengths, atomic coordinates, temperature factors, bond lengths and bond angles, and reliability index.

The polyamine 2,2',2''-triamino-triethylamine, usually abbreviated as "tren", was introduced into complex chemistry in 1925 by Mann and Pope [1], who prepared Pt(II)tren I_2 and Pt(IV)tren Cl_2 Cl. They pointed out that the four nitrogen atoms of the amine could hardly form a planar complex with the divalent platinum atom, and they concluded that the Pt(IV) complex probably was of octahedral configuration with the two chlorine atoms occupying *cis* positions.

In later publications [2,3] Mann and Pope described a number of nickel-tren complexes, especially Ni tren$(SCN)_2$. They were of the opinion that the nickel atom was tetracoordinated in this compound. In Ref.[3] a crystal-morphological investigation, carried out by Notham is mentioned. He found that Ni tren$(SCN)_2$ is orthorhombic, with the axial ratios: $a:b:c = 0.736:1:1.167$. In 1935 Cox and Webster [4] confirmed by an X-ray crystallographic investigation that Ni tren$(SCN)_2$ belongs to the orthorhombic system. The size of the unit cell was given as: $a = 10.79$, $b = 14.69$, $c = 8.59$ presumably KX units. The axial ratios are: $a:b:c = 0.736 : 1 : \frac{1.172}{2}$. The space group was found to be $P2_12_12_1$.

* Present address: Chemical Institute, University of Aarhus, Aarhus, Denmark.

The density was measured as 1.55 g/cm^3. Hence there are four Ni tren$(SCN)_2$ units in the unit cell. According to the space group these units must be asymmetric.

It was not possible at that time to solve the structure. The authors pointed out that two alternatives were possible: Either a tetrahedral structure or a *cis*-octahedral structure.

In the same year Jaeger and Beintema [5] determined the unit cell and space group of tren$(HCl)_3$. This compound crystallizes in the cubic system with the space group $P2_13$. Consequently it is highly probable that the tren molecule in this crystal has the symmetry C_3 which means that the four nitrogen atoms are at the corners of a tetrahedron.

Some authors, *e.g.* Reihlen [6], have taken the compound Ni tren$(SCN)_2$ as a proof of the existence of tetrahedral nickel complexes. Asmussen [7] concluded from magnetic measurements that Ni tren-complexes were probably of tetrahedral configuration.

At the discussion of the conference on coordination chemistry in Copenhagen in 1953 [8] Ni tren$(SCN)_2$ was mentioned as an example of a tetrahedral nickel-complex. When the investigation reported here was started, no X-ray evidence had ever been reported of any tetrahedral nickel-complex. As the Ni tren$(SCN)_2$ in my opinion would be the most likely of any known nickel-compound to have a tetrahedral structure, I decided to solve its crystal structure in order to get an unambigous answer to an often debated problem.

A preliminary communication was presented at the conference of coordination chemistry, Rome 1957. It appeared in print in 1958 [9].

EXPERIMENTAL

Professor Schwarzenbach, Zürich, and Professor Basolo, Northwestern University, Illinois, kindly supplied me with samples of tren$(HCl)_3$. The nickel complex was prepared in the following way:

0.01 mole tren$(HCl)_3$ was dissolved in water with 0.03 moles of NaOH. The solution was heated until boiling. A hot solution containing 0.01 mole of $Ni(SCN)_2$ was added dropwise. (No systematic experiments were carried out in order to determine the best possible conditions with respect to the concentrations of the solutions, *etc.*) From the hot solution Ni tren$(SCN)_2$ crystallizes at cooling. It is only slightly soluble in cold water. It was purified by recrystallization from water. In the microanalysis laboratory of the Chemistry Department of the University of Copenhagen the following results were found: S 19.86, C 29.30, N 26.85, H 5.40. Calc. for $NiS_2C_8N_6H_{18}$: S 19.97, C 29.92, N 26.18, H 5.65.

Analysis for nickel was carried out by Ole Bostrup: Calc. 18.28, found 18.11.

The crystals are blue and different habits may be observed; both needles and spheroids. A needle-shaped crystal, 0.5 mm long and approximately 0.1 mm × 0.1 mm square, was mounted on a Weissenberg-goniometer and orientated along the needle axis which proved to be the *c*-axis of Cox and Webster [4]. Equi-inclination diagrams were taken using Cu-radiation. $hk0-hk3$ reflexions were registered. Another crystal was orientated along the *b*-axis. It was 0.2 mm long, rather irregularly shaped and it was less than 0.04 mm thick. The reflexions $h0l-h6l$ were registered with Cu-radiation. Multiple film technique was employed. Intensities of X-ray reflexions were estimated visually using an intensity scale constructed by exposing different parts of a film to an X-ray reflexion from the crystal for regularly increasing intervals of time. 711 independent spectra were measured; 1 399 are accessible with Cu-radiation with the cameras employed. The intensities were converted into relative F^2 values, using Cochran's chart [10]. An approximately absolute scale was established using Wilson's [11] statistical

method, which also yields an average temperature factor, found to be equal to 2.3 Å². No correction for absorption was applied. Guinier powder photographs were taken to obtain accurate lattice constants. The space group given by Cox and Webster was confirmed. All numerical crystallographic data are collected below.

THE SOLUTION OF THE STRUCTURE

In the space group $P2_12_12_1(D_2^4)$, No. 19, a general point is fourfold and its symmetry is 1. As there are four units of Ni tren$(SCN)_2$ in the unit cell, each atom must be in a general position. If the origin is taken as halfway between the three pairs of non intersecting screw axes the coordinates of equivalent positions are: x,y,z; $1/2-x, \bar{y}$, $1/2+z$; $1/2+x$, $1/2-y, \bar{z}$; $\bar{x}$, $1/2+y$, $1/2-z$.

The x,y coordinates of the nickel atom were easily found from a Patterson projection along the c-axis, but the positions of the sulphur atoms could not be determined with the same certainty.

The nickel atom is not heavy enough to dominate the phases of a sufficient number of reflexions to permit determination of the structure. Therefore the Patterson-Harker cuts were calculated (Fig. 1, a, b, c) in order to obtain more information about the lighter atoms. The x,y coordinates of the nickel atom found by the Patterson projection were confirmed by the Harker cuts and the z-coordinate was also determined. The determination of the coordinates of the sulphur atoms was, however, not quite straightforward. There are three high peaks in the Patterson function at 0, 1/2, 1/2; 1/2, 1/2, 1/2; and at 1/2, 0, 0. The two first ones are about four times the height expected for an S-S peak, while the peak at 1/2, 0, 0 has exactly the height of an S-S peak. The three peaks might be caused by one or more atoms in one or more of the following non-equivalent positions: 1/4, 1/4, 0; 1/4, 1/4, 1/2; 1/2, 1/4, 0; 1/2, 1/4, 1/2. The Patterson projection is of no use in this special case in distinguishing between the x-coordinates 0.250 and 0.500 by aid of the vectors between these two points and the nickel atom, because the x-coordinate of nickel is 0.375.

It is well known from the work of Buerger [12] that crystal coordinates cannot be determined unambiguosly from Harker cuts. The ambiguities mentioned above are, however, of a rather special type, as they are connected with the fact that the peak at 0, 1/2, 1/2 is common for two Harker cuts and the peak at 1/2, 1/2, 1/2 is common for three Harker cuts.

The general ambiguities which arise in the determination of crystal coordinates from a Harker cut belonging to a twofold screw axis, may be stated in the following way:

Coordinate transformations, such as $x' = x \pm 1/2$; $y' = y$; $y' = y \pm 1/2$; $x' = x$ and $x' = x \pm 1/2$; $y' = y \pm 1/2$ cause no changes in the Patterson function. It causes, however, a fundamental difference, whether different atoms are referred to the same origin or to different origins. For each atom that is recognized in the Harker cut there are four possible choices of origin for its crystal coordinates. Once an origin has been chosen for one atom, all other atoms must be referred to the same origin to give a correct structure.

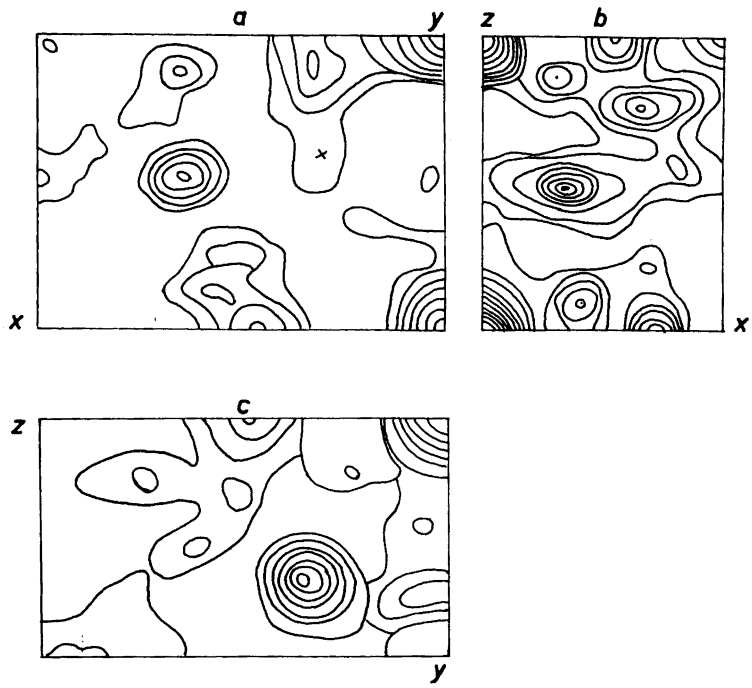

Fig. 1. The three Patterson Harker cuts.

In order to make the correct choice for all atoms it is necessary to have other informations than those obtainable from the Harker cut.

In the present investigation the Harker cuts were severely masked by non-Harker peaks and consequently they gave no information of the positions of the lighter atoms.

The benefit of sharpening the Patterson projection in order to obtain greater resolution was considered to be somewhat doubtful. It was considered to be safer to operate with artificial point atoms on "the other side" of the Fourier transform, and the Harker-Kasper [13] inequalities were applied to the $hk0$ reflexions.

The coordinate transformations stated above influence the signs of certain classes of $hk0$ structure factors. Once an origin is chosen, the signs of these structure factors are determined. On the other hand, a choice of sign for a structure factor determines the origin.

In the projection of $P2_12_12_1$ on a pinacoid it is convenient to take the origin in a screw axis. There are four non-translational equivalent screw axes in a unit cell, and the transformations mentioned above move the origin from one screw axis to another. The structure factors of the types: $h = 2n + 1$; $k = 2n+1$ and $h+k = 2n + 1$, change signs at certain of these transformations, and that means that the sign of one structure factor of each of these two classes of reflexions may be chosen arbitrarily.

The first Harker-Kasper inequality,

$$2|U(hk0)|^2 \leq 1 + U(2h2k0),$$

gave one sign. (840). The inequality,

$$4|U(hk0)|^2 \leq [1 + U(2h00)]\ [1 + U(02k0)],$$

gave a few other signs. These relations only give signs for $h = 2n$, $k = 2n$. With these signs and the two signs which could be chosen abitrarily, a large number of signs was obtained by application of the relations,

$$[U(hk0) \pm U(h'k'0)]^2 \leq [1 \pm U(h+h',\ k+k',\ 0)]\ [1 \pm U(h-h',\ k-k',\ 0)].$$

The nomenclature applied is that of Gillis [14].

In all 66 signs were obtained by these methods. 14 signs were later proved to be wrong.

The Fourier projection calculated with the signs obtained from the inequalities is given in Fig. 2. In the projections shown the origin is taken in a c screw axis. No refinement was obtained, because the projection was not interpreted correctly. It is not very much different from the correct final projection (Fig. 3), and the value of the Harker-Kasper method should be judged from a comparison between these two projections, and not from the fact that the structure was finally solved in another way.

A full three-dimensional Patterson was calculated. The a and b axes were divided in 60ths and the c axis in 30ths. The term $F(000)^2$ obtained by Wilsons method was included in the calculations. If the height of a peak may be taken as proportional to its volume, the height of a single Patterson peak with the scale applied here is given as $H_{ij} = 0.35 \cdot z_i z_j$, where z_i and z_j are the atomic numbers of atoms i and j. On this scale we should expect peaks in the following order: 3 Ni-Ni (218), 8 Ni-S (140), 10 S-S (90), 24 Ni-N (62), 32 Ni-C (52), 48 S-N (39), 64 S-C (34), the rest of the peaks are so low that they disappear in the general background. The Patterson function of $P2_12_12_1$ has the symmetry P_{mmm}. Consequently it is only necessary to compute it within the space defined by $\frac{a}{2}, \frac{b}{2}, \frac{c}{2}$. All peaks must appear within this volume. If the volume of a peak is approximately 1 Å^3, only about 140 spherical peaks could be "packed" into the octant of the Patterson space without overlapping. It is very unlikely that a close "packing" of peaks should ever occur, but even if it were the case, the number of peaks here is so great that overlapping cannot be avoided.

The nickel-nickel vectors had already been recognized in the Harker cuts and the following coordinates were chosen for the nickel atom given in 60ths of the coordinate axes with the origin halfway between the three screw axes: $22\frac{1}{2}$, 25, 5; $\overline{7\frac{1}{2}}$, 5, $\overline{5}$; $7\frac{1}{2}$, $\overline{25}$, $\overline{25}$; $37\frac{1}{2}$, $\overline{5}$, 25.

The structure was solved by what has been called "image seeking" or "super-position" methods. Buerger [15] has given a very profound analysis of

the existing methods of extracting a crystal structure from its vector diagram. The principle of these methods is an extensive use of the symmetry of the Patterson space. If the coordinates of one atom, a, may be fixed, *e.g.* x_a, y_a, z_a, the following vectors to another atom, *e.g.* b, must exist. These are: x_b-x_a, y_b-y_a, z_b-z_a; $1/2 - (x_b + x_a)$, $(y_b + y_a)$, $1/2 + (z_b-z_a)$; $1/2 + (x_b-x_a)$, $1/2 - (y_b + y_a)$ $(z_b + z_a)$; $x_b + x_a$, $1/2 + (y_b-y_a)$, $1/2 - (z_a+z_b)$, with the symmetry of the space group considered here. By shifting the origin of the Patterson function to the four equivalent points of the searcher atom, a, the vectors to the atom, b, are all gathered in the point x_b, y_b, z_b. Different methods may be used to recognize the interatomic vectors. Robertson and Beevers [16] and McLachlan [17] added the numbers of the transcribed Patterson functions, McLachlan [18] and Buerger [15] suggested a multiplication of the vectors, but the closest approach to the electron density is the minimum function of Buerger [15]. Buerger realized that the smallest of symmetry related Patterson peaks would have the greatest chance of being a genuine single peak, and therefore its value should be close to being proportional to the electron density of the crystal. A few examples of the application of the minimum function will be given. Graphical methods were first applied to give a rough idea of the whereabouts of the atoms, but more accurate results were obtained by studying the numerical values of the Patterson function. First the sulphur atoms were sought, using nickel as the searcher atom. One of the positions which could be deduced from the Harker cuts, was confirmed. In 60ths of the coordinate axes its position was found to be 15, $\bar{1}6$, 0 on the basis of the following vectors with their weights given in parentheses,
$7\frac{1}{2}$, 19, 5(191); $22\frac{1}{2}$, 21, 5(146); $7\frac{1}{2}$, 9, 25(170); $22\frac{1}{2}$, 11, 25(196).

The effective atomic number of nickel towards Cu-radiation is 25. The height of a nickel vector is, therefore, according to the relation given above; $H_{ij} = 0.35 \cdot 25 \cdot z_j$.

The minimum of the four peaks given above is 146. The atomic number, z_j, of the atom which yields this vector with the nickel atom is therefore $z \leq \frac{146}{0.35 \cdot 25} = 16.7$. Thus it seems highly probable that the atom found is a sulphur atom. The other sulphur atom was placed in $26\frac{1}{2}$, $8\frac{1}{2}$, $\bar{1}\bar{1}$ on the basis of the following vectors with the nickel atom: 19, $26\frac{1}{2}$, 14(169); 4, $16\frac{1}{2}$, 16(146); 11, $13\frac{1}{2}$, 24(152); 26, $3\frac{1}{2}$, 6(161). Minimum 146, atomic number 16.7. This close correspondence between the atomic numbers of the two sulphur atoms must be purely accidental and is by no means characteristic of the accuracy of the method. The correctness of the coordinates may be checked by the vectors between the two non-symmetry related sulphur atoms, $11\frac{1}{2}$, $24\frac{1}{2}$, 11(103); $18\frac{1}{2}$, $5\frac{1}{2}$, 19(110); $11\frac{1}{2}$, $7\frac{1}{2}$, 19(132); $18\frac{1}{2}$, 22, 11(122). As the minimum here is 103, the atomic number is $z \leq \frac{103}{0.35 \cdot 16} = 18.3$.

It was not possible to determine the positions of the C and N atoms from the nickel vectors alone, as there were more vectors of appropriate height than there were atoms. Because of this, the vectors between the S and the C and N atoms were also employed, and in that way a number of positions suggested by the nickel atom could be ruled out. In Buerger's [15] formulation

it would be: "The image seeking polyhedron comprised of the four nickel atoms and the eight sulphur atoms roved over the Patterson function finding images of itself, whereby the appropriately weighted minimum funtion was mapped out". When applying the minimum function due regard must be taken to the uncertainty of the values of the Patterson function. With the errors inherent in the measurement of intensities, non-convergence of series *etc.* an indeterminacy of about 30 % must be allowed for. This means that atomic numbers as low as 4—4 1/2 must be accepted for C and N atoms, although if more than two or three of the twelve vectors indicated such a low atomic number, the position was not accepted as an atomic site. A few examples will be given of the best and of the worst of the results:

C_1 : 31, 25, $\bar{1}\bar{1}$,

Ni-C vectors: $8\frac{1}{2}$, 0, 16 (106); $21\frac{1}{2}$, 20, 6 (146); $23\frac{1}{2}$, 10, 14 (76); $6\frac{1}{2}$, 30, 24 (61).

$$z \leq \frac{61}{0.35 \cdot 25} = 7.$$

S-C vectors: 16, 9, 41 (73); 14, 11, 41 (55); 14, 39, 11 (53); 16, 41, 11, (80); $5\frac{1}{2}$, $16\frac{1}{2}$, 0 (64); $25\frac{1}{2}$, $3\frac{1}{2}$, 22 (75); $2\frac{1}{2}$, $13\frac{1}{2}$, 8 (45); $27\frac{1}{2}$, $33\frac{1}{2}$ $33\frac{1}{2}$, 30 (80),

$$z \leq \frac{45}{0.35 \cdot 16} = 8.8$$

C_6: 36, 20, 7.

Ni-C vectors: $13\frac{1}{2}$, 5, 2 (75); $16\frac{1}{2}$, 15, 12 (40); $1\frac{1}{2}$, 25, 18 (98); $28\frac{1}{2}$, 15, 28 (146),

$$z \leq \frac{40}{0.35 \cdot 25} = 4.6$$

S-C vectors: 21, 4, 23 (25); 9, 6, 23 (82); 9, 26, 7 (56); 21, 24, 7 (82); $9\frac{1}{2}$, $11\frac{1}{2}$, 18 (80); $20\frac{1}{2}$, $1\frac{1}{2}$, 4 (25); $2\frac{1}{2}$, $18\frac{1}{2}$, 26 (50); $27\frac{1}{2}$, $28\frac{1}{2}$, 12 (95),

$$z \leq \frac{25}{0.35 \cdot 16} = 4.5$$

N_6: $11\frac{1}{2}$, 25, 5.

Ni-N vectors: 11, 0, 0 (256); 19, 20, 10 (188); 26, 30, 20 (115); 4, 10, 30 (148);

$$z \leq \frac{115}{0.35 \cdot 25} = 13.$$

S-N vectors: $3\frac{1}{2}$, 9, 25 (65); $26\frac{1}{2}$, 11, 25 (58); $26\frac{1}{2}$, 21, 5(98); $3\frac{1}{2}$, 19, 5 (82); 15, $16\frac{1}{2}$, 16 (26); 15, $3\frac{1}{2}$, 6 (66); 22, $13\frac{1}{2}$, 24 (120); 15, $26\frac{1}{2}$, 14 (43),

$$z \leq \frac{26}{0.35 \cdot 16} = 5.$$

By a systematic application of this modification of the minimum function, a satisfactory solution of the structure was obtained.

A refinement of the structure was started by difference projections along the *c*-axis. By two successive difference projections the *R*-index decreased from 29 % to 21.7 % without application of a temperature factor. At that

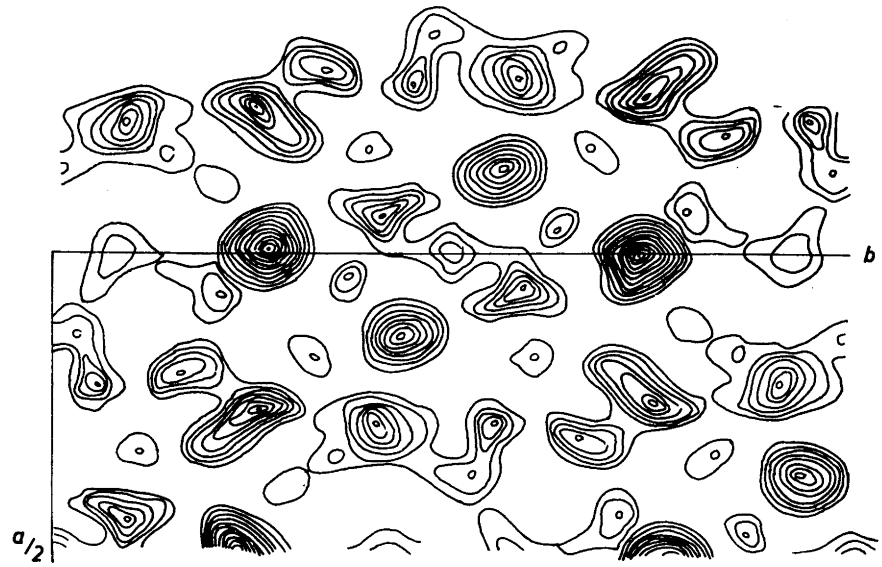

Fig. 2. Fourier projection along the c-axis calculated with signs obtained from Harker-Kasper inequalities.

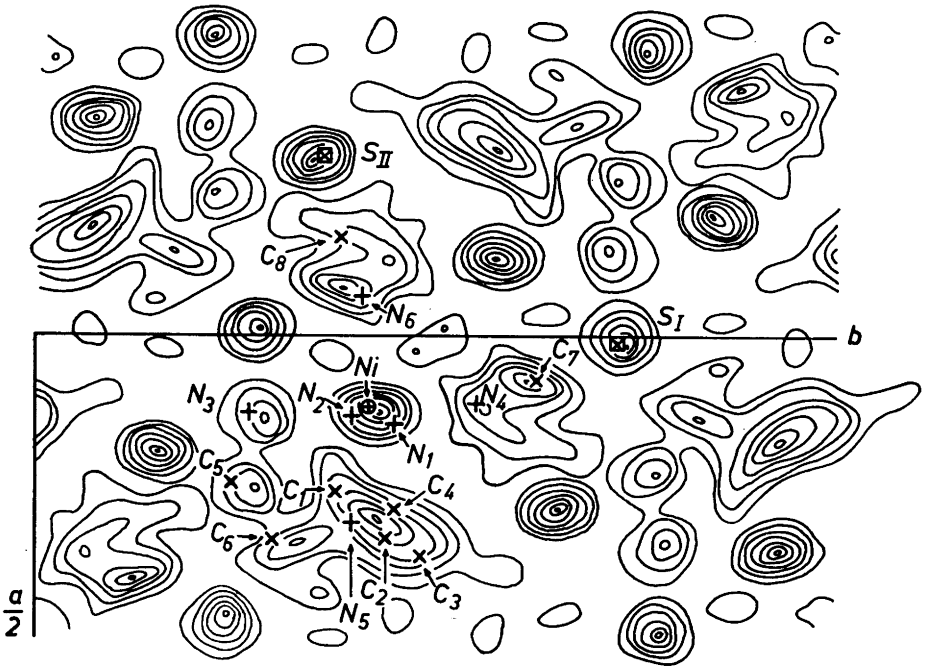

Fig. 3. Final Fourier projection. The atomic positions obtained from the least squares analysis are marked for one molecule.

stage a least squares analysis was carried out using the method of Sayre [19]. Miss Dolores Leagus carried out the work of programming and machine computation.

Two runs were made. One using only 711 observed F values, the other including 181 non observed F values, which were within the $\sin\Theta$ range of the observed F values. The weights of the F values were taken as proportional to their multiplicity (Geller and Abrahams [20], 1958).

The scattering factors used were the following: for Ni the values of Thomas and Umeda [21] corrected for dispersion for Cu-radiation using $\Delta f = -3.1$. For S the values of Tomiie and Stam [22] and for C and N those of Freeman [23].

The final coordinates and temperature factors, as well as the coordinate changes used for the final calculations are stated below. The results are those obtained using observed F values only. The reliability index $R = \frac{\Sigma||F_o| - |F_c||}{\Sigma|F_o|}$ is 13.6 % for these computations. The calculations which included non-observed intensities, gave only slightly different results. The former results were chosen because a re-examination of the Weissenberg-diagrams revealed that 26 observable, although weak intensities were overlooked in the first measurements.

Three strong intensities were evidently affected by extinction, as the calculated F values were 30—40 % higher than the observed values. There are no grave discrepancies between observed and calculated F values. The calculated values of the non-observed intensities are all small, except the ones mentioned above, which could be found on the Weissenberg diagrams. Because of the individual agreements between observed and calculated F values the structure must be essentially correct.

DISCUSSION OF THE STRUCTURE

For convenience all pertinent data of the crystal structure are collected here.

Crystal system: Orthorhombic.

Unit cell from Guinier powder diagrams with Cu$K\alpha$-radiation:

$$a = 10.82_1 \text{ Å}, \qquad b = 14.71_9 \text{ Å}, \qquad c = 8.62_0 \text{ Å}.$$

Space group: $P2_12_12_1$ No. 19, (D_2^4).

Chemical formula: $NiS_2C_8N_6H_{18}$. Four units in the unit cell.

Origin halfway between screw axes. The coordinates and temperature factors obtained are stated below.

Final coordinates and temperature factors, and parameter changes applied for the last least squares calculations.

$Ni-N_4$	= 2.104 Å		
$Ni-N_5$	= 2.127 Å		
$Ni-N_6$	= 2.020 Å		

The accuracy of this structure determination may be more difficult to assert than its correctness. During the last refinement the R-index only decreased from 13.8 % to 13.6 %. The coordinate changes used for this calculation might be used as a criterion for the underterminacy of the bond lengths. The nickel atom was moved 0.0014 Å for the last refinement, the two sulphur atoms 0.0005 Å, and the light atoms somewhat more. The arithmetic

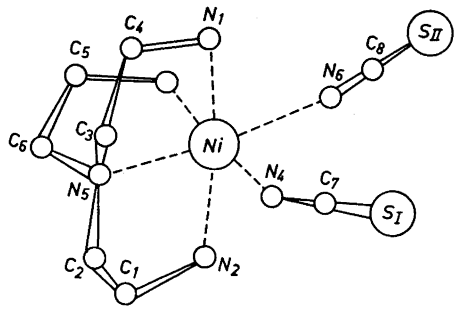

Fig. 4. Parallel projection of the Ni tren molecule.

mean of their displacements is 0.006 Å. Hence one might believe that bond lengths were determined with an accuracy of 0.01 Å.

There are, however, several reasons for viewing this low figure with some scepticism. In the first place, no correction has been applied for either extinction or absorption. Secondly, the effect of 18 hydrogen atoms has been neglected. They are almost bound to affect some of the intensities as they after all carry 10 % of the scattering electrons, although they can hardly ever, all of them, scatter in phase. Thirdly, isotropic temperature factors have been used, although it is certain that the heat oscillations are anisotropic.

A more empirical viewpoint will be taken on the accuracy of the results.

The two thiocyanate groups will be taken as completely equivalent with respect to bond lengths and bond angles. Consequently we shall take the mean values of the two sets of interatomic distances as standard values: N—C = 1.19 ± 0.03 Å, C—S = 1.62 ± 0.01 Å, < N—C—S = 171°.

This means that the N—C distance may be as much as 0.06 Å in error, and the C—S distance 0.02 Å in error. For comparison the following results will be quoted:

Compound	N—C	C—S	<N—C—S	Ni—N—C—S	Ref.
$Nien_2(NCS)_2$	1.20	1.66	175°	2.14	24
$Ni(NH_3)_4(NCS)_2$	1.20	1.61	180°	2.07	25
$Ni[CS(NH_2)_2]_2(NCS)_2$	1.16	1.60	180°	1.99	26
AgSCN	1.186 ± 0.086	1.636 ± 0.029	~180°		27
$C_2H_4(SCN)_2$	1.18	1.63	172°		28
NH_4SCN	1.24 ± 0.02	1.58 ± 0.02	180°		29
$NH_4[Cr(SCN)_4(NH_3)_2]$	1.14 ± 0.03	1.80 ± 0.03	180°		30

The results are all from X-ray investigations.

Beard and Dailey [31] find by microwave spectroscopy on HNCS the following results:

N—C = 1.218 Å, C—S = 1.557 Å, N—H = 1.01 Å, < H—N—C = 136°, assuming that the N—C—S group is linear.

The following conclusion may tentatively be drawn from these figures.

The bond lengths and angles of the thiocyanate group in complexes, in which it is considered as being predominantly ionically bond, falls within the limits: N—C = 1.19 ± 0.03 Å, C—S = 1.63 ± 0.03 Å, < N—C—S = 175±5°. By the complex formation the N—C bond is apparently shortened and the C—S bond is stretched with respect to the bonds of the SCN^- ion of the NH_4SCN lattice. In the Reinecke ion $[Cr(SCN)_4(NH_3)_2]^-$ the N—C bond is the shortest and the C—S bond the longest of any known distances of the thiocyanate group. This is probably connected with the fact that the Reinecke salt exhibits an absorption spectrum of the electron transfer type.

This survey indicates that the indeterminacy of the bond lengths of the thiocyanate group obtained in this paper is probably ± 0.03 Å and at most 0.06 Å.

It is difficult to say whether the bond lengths of the tren molecule are determined with the same accuracy or not.

It is established with certainty that the three N—C—C—N rings are non-planar. In the free tren molecule the three rings are probably equivalent as the molecule has almost certainly the symmetry C_3. With this symmetry it is impossible to fix the four nitrogen atoms at the four corners of an octahedron. The octahedral structure becomes possible when *one* of the rings changes its conformation into one, which is symmetrical with the original one. In Fig. 4 the rings $N_5—C_6—C_5—N_3$ and $N_5—C_2—C_1—N_2$ have identical conformations. One ring can be made to cover the other by rotating the molecule around an axis passing through the N_5 atom, and the nickel atom. But none of these two rings can be made to cover the $N_5—C_3—C_4—N_1$ ring, as this ring in enantiomorphous with the two other ones. Some of the distances of the tren molecule are anomalous. This may be connected with the fact that the molecule is severely strained in the complex. By forming an octahedral complex, only one ring can avoid strain. The distances of the ring $N_5—C_6—C_5—N_3$ are quite normal. In the ring of which the conformation is different from the two other ones, the nitrogen-carbon distance, $N_5—C_3$, is rather high: 1.68 Å. The distance $C_2—C_1$ is also higher than the usual single bond distance. It is at present difficult to say, whether these abnormal distances are really caused by steric strain, or are the results of inadequate measurements, assumptions and computations. By comparison with the accuracy of the determination of the dimensions of the thiocyanate groups, one might be inclined to believe that the apparent effects of the strain are real. By looking through "Interatomic Distances" [32] one finds that C—C distances above 1.60 Å often are reported for strained molecules.

The nickel-nitrogen distances appear to exhibit the following systematics:

Nickel-primary amine nitrogen:	2.20 ± 0.04 Å
Nickel-tertiary amine nitrogen:	2.13 ± 0.04 Å
Nickel-thiocyanate nitrogen:	2.06 ± 0.04 Å

The octahedron of the six nitrogen atoms has no more than triclinic symmetry. The deviations from the regular octahedron are made clear by giving the angles between *trans*-nitrogen atoms and the nickel atom:

$$< N_1NiN_2 = 152°, \quad < N_5NiN_6 = 168°, \quad < N_3NiN_4 = 178°.$$

It is still an open question whether X-ray diffraction methods at present are able to yield determinations of bond lengths of very high precision. Two examples will be quoted which may throw some doubt on the validity of "established" bond lengths. Lynton and Cox [33] and Rowe and Post [34] independently determined the structure of thianthrene and refined the structure by essentially equivalent mathematical methods. Visual estimations of intensities were used in both determinations. Many of the C—C distances of the two determinations agree within 0.01—0.02 Å, but three of the distances deviate with 0.04 Å. In both cases a standard deviation of 0.012 Å is quoted.

The detailed structure of the glycine zwitter ion is another case for discussion. Hahn and Buerger [35] determined the structure of diglycine hydrochloride using Cu-radiation, and measured intensities with a Geiger counter. Marsh [36] redetermined the structure of glycine itself, using Mo-radiation, and visual estimation of intensities. Hahn and Buerger find the following distances for the glycine molecule: N—C = 1.52 ± 0.01 Å, C—C = 1.48 ± 0.01 Å. Marsh reports that N—C = 1.474 Å, and C—C = 1.523 Å. It is as yet an open question whether these discrepancies are real and are caused by the different packing in the different crystals, or whether they are fictitious, and caused by the different ways of measuring intensities or in the different ways of refining the structure. Hahn and Buerger employed isotropic temperature factors, while Marsh used anisotropic B factors.

Because of the non-planarity of the N—C—C—N rings, the Ni tren$(SCN)_2$ molecule is asymmetric and should exist in two enantiomorphous forms. The space group $P2_12_12_1$ permits a separation of left-handed and right-handed crystals simply by handpicking. In that way it should be possible to make optically active solutions of the complex. The non-planar conformation of N—C—C—N rings seems to occur generally in complexes. An interesting consequence of this conformation is the possibility of stereoisomers of *trans*-bis-ethylene-diamine complexes.

At the same time as the structure of Ni tren$(SCN)_2$ was established, Venanzi [37] reported that Powell had proved by X-ray methods that $[(C_6H_5)_3P]_2NiCl_2$ has a tetrahedral structure. In a preliminary publication Gill, Nyholm and Pauling [38] have presented X-ray evidence for a tetrahedral $NiCl_4^{--}$ ion in the compound $[(C_6H_5)_4As]_2NiCl_4$.

It is at present very difficult to say, which factors are decisive for the stereochemistry of nickel complexes.

An investigation has been started on tren$(HCl)_3$ in order to obtain accurate details of the stereochemistry of the non-complexed tren molecule.

While the present paper was in preparation, a note on the structure of Ni tren$(SCN)_2$ by Hall and Woulfe [39] appeared. I have been in correspondence with the authors. The two independent solutions of the structure appear to be essentially in agreement.

When the structure of Hall and Woulfe has been refined, a comparison of the results will be published.

A complete table of observed and calculated F values and a more complete account of the present work will be published in a forthcoming monograph in Danish, with an English summary [40].

Acknowledgements. I am greatly indebted to Prof. Dr. A. Tovborg Jensen for the hospitality he has shown me by allowing me to work in his laboratory at the Royal Veterinary and Agricultural College, where part of the experimental work was performed.

I also wish to thank Prof. Dr. Bodil Jerslev of the Danish School of Pharmacy for the loan of a Weissenberg honiometer.

The *Carlsberg Foundation* is thanked for providing part of the equipment used in the investigations, and economic support from the *Ole Rømer Foundation* is gratefully acknowledged. The Fourier summations were performed by aid of a Hägg-Laurent computer built by Frank[41].

Last, but not least, I wish to express my sincere thanks to Miss Dolores Leagus of the *Bell Telephone Company* for planning and carrying out the lengthy machine computations.

The Use of High Speed Digital Computers for the Least Squares Calculation of Complexity Constants *

JAMES C. SULLIVAN, JAN RYDBERG** and WILLIAM F. MILLER

Chemistry Division and Applied Mathematics Division, Argonne National Laboratory, Lemont, Illinois, U.S.A.

Some general aspects are given of the calculation of stability constants for mononuclear complexes by means of a weighted least squares technique. Computor (the IBM 704, and the GEORGE) programs are developed for the treatment of solvent extraction and potentiometric titration data. The results of the use of these programs are compared in a number of examples with results of earlier (usually graphical) calculations.

Despite the extensive amount of research that has been conducted during the past twenty years the problems encountered in the study of the association between cations and complexing ligands, in aqueous systems, are far from completely resolved. Most of the data in the literature has been interpreted on the basis of the model, originally suggested by N. Bjerrum [1], that the formation of complexes always appears to occur in step-wise fashion with the stabilities of the various species characterized by a series of mass action constants.

If the free energy data of complex ion systems are to be correlated with other properties of the constituents of such systems (as for example the radii of the cations) it is imperative that the original data be summarized in a manner efficient for comparative purposes.

Approximation techniques have been generally employed for the calculation of association constants [2,3]. The increasing availability of high speed digital computers makes it feasible to use a standard objective treatment, *e.g.*, the least squares adjustment, in the calculation of such constants. Computations involved in such an adjustment become difficult when a desk type of calculator is used both because of the large amount of data generally accumulated in the study of a complex ion system and because of the fact that the normal equations are often illconditioned.

* Based on work performed under the auspices of the U. S. Atomic Energy Commission.

** On leave of absence from the University of Stockholm, and the Research Institute of National Defense, Stockholm, Sweden.

Along with the calculation of the best values for the association constants, the digital computer calculation makes it feasible to calculate the standard deviation to be assigned to each constant (based on the over-all fit of the calculated curve to the experimental points) as well as to provide some measure of the consistency of the model used (based on the same criteria) without recourse to *a priori* assumptions concerning the specific number of entities involved.

In the present communication we will present an outline of the methods that have been used to express the relevant equations in forms suitable for the digital computer computations and present the results obtained for a few selected systems.

1. GENERAL ASPECTS OF THE CALCULATION OF SUCCESSIVE CONSTANTS OF MONONUCLEAR COMPLEXES BY A WEIGHTED LEAST SQUARES TECHNIQUE

Basic equations and definitions

[M] = concentration of uncomplexed central ion or molecule
[A] = concentration of unbound ligand
[MA_n] = concentration of the nth complex

$$M + A = MA,\ M + 2A = MA_2, \ldots,\ M + nA = MA_n \tag{1}$$

The equilibrium constant for the nth complex is

$$\beta_n = \frac{[MA_n]}{[M][A]^n} = \prod_1^n k_n \tag{2}$$

where the k's are constants for the formation of the individual complexes formed in a stepwise manner. The total central ion concentration C_M is

$$C_M = [M] + \sum_{n=1}^{N} [MA_n] \tag{3}$$

and the total ligand concentration C_A is

$$C_A = [A] + \sum_{n=1}^{N} n\ [MA_n] \tag{4}$$

where N is the maximum number of ligands bound per metal atom. The ligand number, $\bar{n}$, is defined [2] as the average number of ligands combined with each central atom

$$\bar{n} = \frac{C_A - [A]}{C_M} = \frac{\sum_{n=1}^{N} n\ \beta_n [A]^n}{\sum_{n=0}^{N} \beta_n\ [A]^n} \tag{5}$$

The degree of formation [2] of a given complex, MA_C, is

$$\alpha_C = \frac{[MA_C]}{C_M} = \frac{\beta_C[A]^C}{\sum_{n=0}^{N} \beta_n [A]^n} \quad (6)$$

Various combinations of the above basic equations have been used for the estimation of association constants [3]. Underlying eqn. 2 is the basic assumption that the ratio of the activity coefficients of the various species involved in the equilibrium are constant. A test of the validity of the model specified by eqn. 2 is not included in this investigation.

Some general aspects of the calculations

When, as in our examples below, either a potentiometric titration or a solvent extraction procedure is used to investigate the formation of complex ions, the particular equations that are relevant for the specific procedure can be expressed in terms of a power series. The parameters of this power series (which are to be determined by a least squares procedure) are constants of the type defined in eqn. 2 or related to that type of constant by an elementary transformation. On the basis of the model we are using, negative parameters and those whose standard deviation spans zero will be rejected, that is, we shall determine the best set of parameters in the least squares sense subject to the restriction that each parameter be positive, in fact, that each parameter minus one standard deviation be positive.

An outline of the least squares analysis used as a basis for the computer programing is given in Appendix I.

The equations that we are to subject to the least squares adjustment generally merit the term of opprobrium, "illconditioned" [4]. One can understand how a condition sufficient to bring about this state of the equations arises from a consideration of the physical aspects of the problem.

An experiment to determine association constants involves the variation of the concentration of the complexing ligand under consideration over as wide a range possible concomitant with the conditions of observational feasibility and invariance of activity coefficient ratios. The usual result is the variation of such a concentration (or independent variable) over many orders of magnitude with a much smaller range covered by the measured property (or dependent variable). Such a disparity in the range of the dependent and independent variables is sufficient to bring about ill-conditioned systems.

From the computational viewpoint this ill-conditioning means that there are a large number of nearly correct solutions to the equations. The existence of this wide variety of nearly correct solutions leads to difficulties in obtaining numerical values for the parameters. Although it is feasible to compute a measure of the degree of conditioning of the equations to be solved [4,5] since we are primarily concerned with the parameters obtained, and their standard deviation, we have not performed any such calculations in the course of this investigation.

The capacity of the digital computers is generally large enough so that the effect of rounding off errors on the matrix inversion is minimal for the computations to be described. This tends to eliminate one of the sources of difficulty encountered when the matrix inversion technique is used for the solution of the normal equations.

Prior to any computer calculation, the data is (of course) studied graphically to determine: (a) the highest power of the independent variable in the series that should be considered (*i.e.* N); (b) that a smooth curve can indeed be drawn through the experimental points.

After the calculation has been completed the computed curve is plotted and the scatter of the experimental points around this curve is examined to determine if there are systematic deviations, *i.e.*, a large number of consecutive points which lie on one side of the curve. In addition, since a log-log scale (with its attendant distortion) is generally most convenient for a graphical representation of the type of data considered here, a point by point comparison between experimental and calculated values is carried out to insure the adequacy of the functional form used in the computation.

Weighting procedures

In the analysis outlined in the Appendix it has been explicity assumed that only the measured distribution coefficients (in the case of solvent extraction experiments) and the measured free ligand concentration (for the potentiometric titration investigations) have associated random errors. The validity of this assumption is securely based on the experimental procedures used in these investigations. It is also apparent from considerations of the experimental procedures that the individual observations have different variances over the range of free ligand concentrations studied. This necessitates weighting the individual measurements.

With the foregoing in mind an estimate of the weight of an individua observation in experiments of the type to be considered here is most reasonably obtained by detailed considerations of the specific investigation. For example, in the case of the Np(IV)—HSO_4^- system [6], since the measured distribution was always adjusted to approximately unity and replication indicated the same precision at all points, the use of $1/y$ as a weighting parameter is reasonable.

For other distribution studies the initial approximation of the weights may be obtained from the measured standard deviation at free ligand concentrations for which replicate measurements were made or by considering the error to be feared in the distribution coefficient caused by the error in the analysis of each phase. For studies in which a radiometric assay procedure is used this latter quantity is readily estimated using standard formulas [7]. Caution must be exercised in assigning weights based on the variance from replicate measurements unless the number of measurements at each point is large. When only a few sets of duplicate measurements are available consideration should be given to using an average percentage uncertainty as first approximation to the individual weights.

For potentiometric titration experiments similar considerations may be used as the basis for initial weight approximations. For example in the absence of replicate experiments the type of precision to be expected in an emf measurement might be used as the basis of assigning weights to an individual observation. To avoid prolixity, further discussion of this point will be deferred until the individual examples are considered.

In the calculations to be described use has been made of the errors of external consistency [8] for the computation of the standard derivations of the parameters and as a test of the validity of the hypothesis under consideration. This approach is a reasonable one to use if we consider the type of data that is to be treated. For example, it is easy to visualize a solvent extraction experiment with systematic errors in a certain region of free ligand concentration. Errors of this type would never be observed by replication and consequently weights based on the apparent precision of measurements at a point in this region would not be realistic for the calculation of the weights of the parameters. Therefore the square of the actual deviation between experimental and calculated points is a logical scale to use for the calculation of the standard deviations of the parameters.

In addition, the reasonableness of an arbitrary assignment of weights to individual observations can be justified by the fact that if one is fitting with the correct functional form and has assigned the correct weights, then the mean value of $\chi^2/k-1 = 1$ *.

Computer programs

Three separate programs were used in the course of this study, two of them being specifically developed for this investigation.

The digital computer "George", developed at Argonne National Laboratory [9], has available a program for the least squares calculation of the a_n in the polynomial

$$y = \sum_{0}^{N} a_n x^n \tag{7}$$

The input data for this program are y, x and the weight of y. This program is suitable for the computation of the β_n in the polynomials used by either Leden [10] or Olerup [11] for graphical estimations of the parameters.

$$\frac{C_M-[M]}{[M]\,[A]} = \sum_{n=1}^{N} \beta_n\,[A]^{n-1} \text{ (Leden)} \tag{7a}$$

$$\frac{C_M}{[M]} = \sum_{n=0}^{N} \beta_n\,[A]^n \text{ (Olerup)} \tag{7b}$$

As illustrated by the treatment of the Np(IV)$-HSO_4^-$ data, the form of the input is altered depending on the type of measurements made; *cf.* Ref.[12].

* See Appendix for a definition of this quantity.

A program was developed for the IBM 704 for use in solvent extraction investigations. This procedure calculates the best (in the least squares sense) a_n in the polynomial

$$yx^N = z = \sum_0^N a_n x^n \tag{8}$$

The input data are x, y, and estimated errors in the determination of the concentrations in both phases from which weights are calculated [12]. This program can, *e.g.*, be used for data that can be summarized by eqn. 6. The development of the program in the specific form used in the present investigation emphasizes the underlying philosophy of machine computations, *i.e.*, the minimization of transformations applied to the original experimental data prior to computer input.

The $\bar{n}$ relation of Bjerrum [2] (eqn. 5) can be rearranged

$$\sum_{n=0}^{N} (\bar{n}-n)\,\beta_n\,[\mathrm{A}]^n = \sum_{n=0}^{N} (C_\mathrm{A}-[\mathrm{A}] - n\,C_\mathrm{M})\,\beta_n\,[\mathrm{A}]^n = 0 \tag{9}$$

A program was developed for the IBM 704 to calculate the best values for the β_n from the equation:

$$0 = \sum_0^N (y-x-nz)\;\beta_n x^n \tag{9a}$$

The input data are $y = C_\mathrm{A}$, $x = [\mathrm{A}]$ and $z = C_\mathrm{M}$ as well as the estimated standard deviation that occurs in the measurement of x.

Output data that are common to all three programs includes: the values of the parameters with their standard deviation (based on external consistency); the value of $S_{min.}$ *, calculated values of the function, using the derived constants, for the original experimental x values.

2. EXAMPLES OF THE TREATMENT OF SOLVENT EXTRACTION DATA

The System Np(IV)-HSO_4^- [6]. The use of theonyltrifluoroacetone (TTA) as a chelating agent for the extraction of cations from an aqueous into an organic phase has been used by a number of investigators [13] to obtain data that may be interpreted in terms of ionic association. The assumptions upon which this interpretation is based have been clearly stated [13a] and will be used in the following treatment. The partition ratio of the concentration of Np(IV) in the organic phase to the total concentration of Np(IV) in the aqueous phase, Q, under conditions of constant acidity and ionic strength and corrected to unit activity of TTA in the organic phase can be expressed as,

$$Q = Q_0 / \sum_0^N \beta_n\,[\mathrm{HSO_4^-}]^n \tag{10}$$

where $\beta_0 = 1$, and $N = 2$.

* See Appendix.

Simple transformations lead to

$$y = a_0 + a_1 [HSO_4^-] + a_2 [HSO_4^-]^2 \quad (11)$$

where $y = 1/Q$, $a_0 = 1/Q_0$ (Q_0 is the normalized distribution coefficient of Np(IV) in the absence of HSO_4^-), $a_1 = \beta_1/Q_0$, $a_2 = \beta_2/Q_0$. This puts the original data in a form suitable for the least squares calculation of the a_n using the computer program based on eqn. 7.

The weight of the individual observation was taken as $1/y$ as previously indicated. In this case a test of the internal consistency of the data is made possible by comparison of the calculated value of Q_0 with the independent experimental determination of this quantity. The relevant output data are

Table 1. Parameters describing the system Np(IV)-HSO_4^-, 25°C, μ = 2.00, $[H^+]$ =2.00.

	Q_0	k_1	k_2
This work	$(2.94 \pm .23) \times 10^4$	118 ± 14	16 ± 2
Original [6]	$(2.84 \pm .04) \times 10^4$	135 ± 14	16 ± 2

summarized in Table 1, along with the results of the original computations made by the limiting value method of Leden [10]. The uncertainties listed in the above are standard deviations as are all such uncertainties stated in this work.

The values for the parameters obtained by the least squares adjustment are in reasonable agreement with the original graphical estimates. It is of interest to note that the original estimate of the errors (%) in the parameters k_1 and k_2 are of the same order of magnitude as those determined by the more objective computation described here. However the estimation of the uncertainty in Q_0, based on the experiments summarized in Table 2 of the original investigation, is seen to be significantly smaller than the standard error based on eqn. 8, Appendix. This emphasizes the logic of the choice of external consistency as a basis for weighting the parameters determined by the least squares adjustment.

Pu(IV)-acetylacetone. A large number of solvent extraction investigations have been conducted for the purpose of determining association constants between metal ions and organic ligands [14]. The assumptions basic to such an interpretation have been outlined [15] and are implicitly accepted in the following treatment.

We will consider the least squares adjustment of the data presented for the Pu(IV)-acetylacetone system [3i] as an example of the utility of digital computers in the interpretation of such distribution results. Considering only uncharged species in the organic phase, and under conditions of constant ionic strength from considerations similar to those previously discussed, we may write eqn. 8 as

$$y = [Aa]^4/Q = a_0 + a_1 [Aa] + a_2 [Aa]^2 + a_3 [Aa]^3 + a_4 [Aa]^4 \quad (12)$$

where Q is the measured partition ratio of the concentration of $PuAa_4$ in the organic phase to all species of Pu in the aqueous phase, [Aa] is the free

acetylacetone ligand concentration in the aqueous phase, $a_4 = 1/\lambda_4$ where λ_4 is the distribution coefficient of $PuAa_4$, $a_3 = \beta_3/\lambda_4\beta_4$, $a_2 = \beta_2/\lambda_4\beta_4$, $a_1 = \beta_1/\lambda_4\beta_4$, and $a_0 = 1/\lambda_4\beta_4$. From the published data one may estimate a weight for the original observations based on a 20 % standard error in the measured partition ratio Q. This type of estimate is obtained from a consideration of the results of replicate experiments since the analytical scheme does not readily afford a basis for choosing weights based on the uncertainties to be expected in the determination of Q.

The relevant output data is summarized in Table 2 along with the graphical estimates of the parameters computed in the original publication.

The most interesting aspect of the results obtained is that the least squares treatment of the data allows a complete description of the results using only three parameters. Attempts to force a fit to the data in terms of five parameters, *i.e.*, in terms of the *a priori* assumption that the formation of the complex ions $PuAa^{+3}$, $PuAa_2^{+2}$, $PuAa_3^{+}$, $PuAa_4$, proceeds in a regular manner, always resulted in values for the parameters a_0 and a_2 which were inconsistent with the specified model. This example emphasizes one of the most useful features of the computational method under consideration that it provides a description of the results in a manner consistent only with the precision of the observations.

Chemical bias coupled with a highly ill-conditioned system made possible the results obtained originally by the limiting value and ligand number methods. The results obtained with the two parameter method are a reflection of the assumptions used in that approach and emphasize the limitations imposed by Dyrssen and Sillen in their development of this technique [3b], *i.e.*, that the equations developed are exact only for the cases where one or two species are formed.

From the chemical viewpoint this result implies that, at equilibrium, in the experiments considered, the aqueous phase concentration of the species $PuAa_2^{2+}$ was not large enough to have any observable influence on the measured distribution coefficient. The data are adequate to provide reliable values of the distribution coefficient, the product k_2k_3 and k_4. Any further information adduced form these results must be viewed with the reservation accorded postulates of unknown scientific validity.

3. POTENTIOMETRIC TITRATION DATA

Eqn. 9 is the basis for computation of complexity constants in systems where the total metal, ligand and free ligand concentrations are the measured quantities. Data from the pioneering work of J. Bjerrum [2] will be used to demonstrate applications of this computer program.

The Systems Ag(I)—NH_3 and Cu(II)—NH_3. The results obtained for the first mentioned system with an estimated weight of an individual observation corresponding to a standard deviation of 0.7 % in the free ligand concentration (yielding $\chi^2/k-1=1.00$) are presented in Table 3. For comparison we also include the values obtained from the computations in the original paper as well as a set of values for the association constants computed by Irving and Rossotti [3c]. The later investigators made their computations by rearranging what is essentially eqn. 9 into a form linear in β_1 and β_2 and performing an unweighted least squares computation. The results obtained in this example emphasize a number of important aspects of the present investigation.

Table 3. Association constants for the system Ag(I)-NH_3, μ = 2.0 (NH_4NO_3), t = 30°C.

	log k_1	log k_2
Bjerrum [2]	3.20	3.83
This work	3.181 ± 0.008	3.848 ± 0.008
Irving and Rossotti [3c]	3.19	3.84

(1) When experiments of high precision (as in this case) are available a weighted least squares treatment provides the best summary of such data. This is demonstrated by the fact that the precision of the original data justifies the use of one more significant figure than was originally presented. Another question is if the third decimal figure is of any significance because of systematic errors; however, this will not be discussed here.

(2) When graphical adjustments are properly carried out they will provide values for the constants consistent with the results obtained by the analytical methods being discussed here.

(3) The values given by the third treatment tabularized points out a pitfall for the unwary. The maximum amount of informations consistent with the precision of the experiments is not obtained unless the least squares treatment of the data is carried out in a proper manner.

It is instructuve to consider a second example from the same work [2] in order to point out difficulties that may arise when using the present computer program. It is obvious that if any two rows or columns of the matrix **W** (eqn. 5, Appendix) are nearly multiples of one another a situation will exist that makes for near indeterminancy with the consequent difficulties in a computation of the parameters. Another more subtle point that will be troublesome can be shown by the following example.

For the system Cu—NH_3 calculations based on all the observations failed to yield significant parameters. Inspection of the data will show that at the point with $\bar{n} = 4.002$ there is a change in the value of χ by approximately a factor of 10. The introduction of this number into the matrix **W** may req-

uire a range of numerical values exceeding the capacity of the computor. The use of other techniques, such as orthogonal polynomials is under investigation in an attempt to extend the computations over the complete range of the variables. A computation excluding this point gives the results summarized in Table 4. A weight proportional to a standard deviation in the free ligand concentration of 0.72 % will yield a value of $\chi^2/k-1 = 1.00$ for this system.

The conclusions to be drawn from these results are self-evident in the light of our previous discussion.

CONCLUSIONS

If quantitative comparisons between the association constants of complex ion systems are to be made in terms of electrostatic effects or any other of the fundamental properties of these systems such as suggested by J. Bjerrum [2] it is necessary not only that precise data be available but also that such data is summarized in the most efficient possible manner. Such a summary is provided by the least squares adjustment of experimental observations. It should be emphasized that the least squares adjustment of data for the calculation of complexity constants is readily feasible at the present because of the development of high speed computers. The concepts involved have been well known for over a hundred years.

Attention should be directed to the limitations on the information that is provided by such an adjustment. This particular method of treating the data can only compensate for the ubiquitous random errors which plague the experimentalist. The use of this method cannot compensate for inadequate data.

However, when properly applied, the least squares treatment does provide the best summary of experimental observations. We hope that the availability of the programs for the IBM 704 will be of assistance to investigators who do desire to use this treatment of their data.

APPENDIX

Presented below, in outline form, is the analysis upon which the computer programs we have described are based. Consider the equation

$$y = \sum_{n=0}^{N} a_n x^n \tag{1}$$

where the dependent variable is subject to random errors. The weighted least squares method requires that a set of a_n be determined which minimizes

$$S = \sum_{i=1}^{I} w_i \left(\sum_{0}^{N} a_n x_i^n - y_i \right)^2 \tag{2}$$

The choice of

$$w_i = \frac{1}{\sigma_i^2} \tag{3}$$

where σ_i^2 is the variance of the measurement y_i, corresponds to the Chi-squared minimum method *.

The normal equations resulting from the minimization of S with respect to variations in the a_n are:

$$\begin{bmatrix} \sum_i w_i & \sum_i w_i x_i & \dots & \sum_i w_i x_i^N \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \sum_i w_i x_i^N & \sum_i w_i x_i^{N+1} & & \sum_i w_i x_i^{2N} \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \\ \cdot \\ \cdot \\ \cdot \\ a_N \end{bmatrix} = \begin{bmatrix} \sum_i w_i y_i \\ \sum_i w_i y_i x_i \\ \cdot \\ \cdot \\ \cdot \\ \sum_i w_i y_i x_i^N \end{bmatrix} \tag{4}$$

or in matrix notation $\mathbf{WA} = \mathbf{Y}$. (5)

Eqn. 5 is solved by inverting $\mathbf{W}$ and multiplying this inverse matrix into the vector $\mathbf{Y}$. Thus

$$\mathbf{A} = \mathbf{W}^{-1}\,\mathbf{Y} \tag{6}$$

yields the best values of the parameters $a_0, a_1, \dots, a_N$. The minimum value of S, that is the right hand side of eqn. 2 using the best values of the $\{a_n\}$, is then calculated, and the standard deviations of the parameters are calculated by external consistency *via*

$$\sigma_{a_i}{}^2 = \mathbf{W}_{ii}^{-1} \frac{S_{\min}}{k-1}, \tag{7}$$

where $\mathbf{W}_{ii}^{-1}$ is the ith diagonal element of the inverse of $\mathbf{W}$, and k is the number of degrees of freedom for the system (4)**. In this formulation the number of degrees for the system is $[I-(N+1)]$***. Furthermore the sample values of $S_{\min}$ for a system of k degrees of freedom have the Chi-squared distribution for $k-1$ degrees of freedom****. Thus we should expect $S_{\min}$ to have the χ^2 distribution for $(I-N)$ degrees of freedom and eqn. 7 becomes

$$\sigma_{a_i}{}^2 = \mathbf{W}_{ii}^{-1} \frac{S_{\min}}{I-N} \tag{8}$$

The consistency of the resulting parameters $\{a_n\}$, the measurements $\{y_i\}$, and the estimated errors of measurement $\{\sigma_i\}$ is tested by comparing the value of $S_{\min}$ with the expected value of χ^2 for $(I-N)$ degrees of freedom.

With the following modifications, eqn. 9, as applied to the titration data, can be given the same treatment.

Let

$$U = \sum_{n=0}^{N} (y - x - nx)\, \beta_n x^n \tag{9}$$

In the titration experiment, one should have $U = 0$. One can determine that set of $\{\beta_n\}$ which, for a given set of $\{x_i, y_i, z_i\}$, makes U nearest to zero in the least squares sense by minimizing

$$S = \sum_{i=1}^{I} w_i\ U^2(x_i,\ y_i\ z_i) \tag{10}$$

with respect to variation of the parameters $\{\beta_n\}$. The weights, w_i, should be taken as

$$w_i = \frac{1}{\delta U^2} \tag{11}$$

where δU is the variation in U for fluctuations in the variables (x, y, z). If most of the variation in U is due to variation in x, then

$$\delta U = \frac{\partial U}{\partial x}\ \sigma_x \tag{12}$$

Since one needs to know the β_n in order to calculate $\partial U/\partial x$, an iterative procedure was employed here. First a set of approximate β's was calculated for $w_i = 1$. Using these approximate β's, the weights *via* eqnns. 12 and 11 were calculated. Then an improved set of β's are calculated. Generally three such iterations yield a consistent solution.

Acknowledgement. The authors wish to express their appreciation to Dr. J. C. Hindman whose advice and criticism have enhanced the development of this investigation. In addition we wish to thank the personnel of the Applied Mathematics Division, in particular the programmers, Mrs. M. Hanson, Mrs. S. Steidl and Mr. W. Greenhow, for their technical assistance.

Preparation of a New Zinc-rich Insulin Compound

K. MARCKER*

Roskilde Medical Company, Roskilde, Denmark

It is shown, that crystalline insulin, when treated with alcoholic solutions of zinc chloride in concentrations up to 10 % w/w in the limit combines with two moles of Zn and five moles of $ZnCl_2$. Thus the stoichiometric composition of the compound is insulin,2Zn,5$ZnCl_2$. The compounds with $MgCl_2$, $CaCl_2$, $NiCl_2$, $MnCl_2$, $CdCl_2$, and $CoCl_2$ have been prepared in a similar way. Their compositions are approximately: (Insulin, 1/2 Zn, 1/2 Mg); (Insulin, 1/2 Zn, 1 Ca); (Insulin, 1/2 Zn, 1 1/2 Ni) $NiCl_2$; (Insulin, 1/3 Zn, 1 2/3 Mn)6 $MnCl_2$; (Insulin, 1/3 Zn, 1 2/3 Cd)3 $CdCl_2$; (Insulin, 2 Co)5$CoCl_2$.

For a long time it has been known that zinc combines with insulin forming a zinc-insulin complex. Hallas-Møller *et al.*[1] have shown that the zinc content in crystalline insulin under certain conditions rises to a figure of about two moles per Sanger unit or even higher. It is the purpose of this paper to describe the preparation of a new zinc-rich crystalline insulin compound which in chemical composition differs from those previously described.

The following technique is used in preparing the zinc-rich insulin: 0.5 g of crystalline insulin (0.8 % Zn) is suspended in solutions containing various amounts of dry $ZnCl_2$ in 50 ml of absolute alcohol. The suspension is shaken overnight and filtered the following day on a Büchner funnel. The insulin is washed twice with 20 ml of absolute alcohol and once with 30 ml of dry ether. It is then dried in air, and finally the zinc-content is determined by titration with EDTA and Eriochromblack T as indicator. The results are shown in Fig. 1. By gradually increasing the concentration of $ZnCl_2$ in the suspension it is found that the zinc-content in insulin at concentrations higher than 10 % remained constant at a value of about 7.7—7.8 %. Assuming a molecular weight of 6 000 (a Sanger unit = 5 778 + 6 % which is the water content of dry insulin) this figure corresponds fairly closely with seven zinc atoms per molecule of insulin. The zinc-rich insulin contains chloride and the content of chloride is then determined according to Volhard. The results of these analyses are that five atoms of the total zinc-content in insulin are present

* Present address: Københavns Universitets Fysisk-Kemiske Institut, Copenhagen, Denmark.

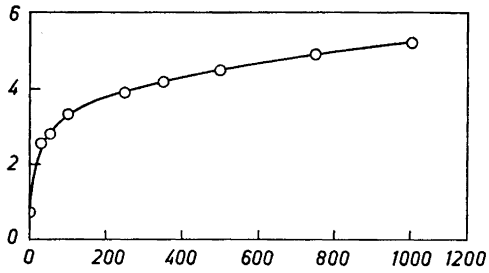

Fig. 1. The reaction between insulin and $ZnCl_2$. Ordinate: moles of Zn per unit of 6 000. Abscissa: mg $ZnCl_2$ in 50 ml of absolute alcohol.

as the chloride. The stoichiometry of the zinc-rich insulin compound is thus as follows: Insulin,2Zn,5$ZnCl_2$.

In order to evaluate the influence of the crystal size of insulin on the zinc uptake from the solution, two different insulin preparations with a crystal diameter of about 10 μ and 20 μ, respectively, were prepared and subjected to the procedure described above. The results were:

Crystal diameter appr. 10 μ	Crystal diameter appr. 20 μ
% Zn in insulin 7.79 =	% Zn in insulin 7.42 =
7.15 moles per unit of 6 000	6.81 moles per unit of 6 000

Although the zinc contents of the two preparations are not identical it is evident that the crystal size is relatively unimportant for the zinc uptake.

A few other zinc salts have been tried. These are $Zn(OOCCH_3)_2$, $ZnBr_2$ and ZnI_2. The results expressed in stoichiometric formulas are: (Insulin, 2Zn) $4ZnBr_2$; (Insulin, 2Zn)$3ZnI_2$ and for $Zn(OOCCH_3)_2$, (Insulin, 2Zn). These results might be explained by assumption of steric hindrances on the sites of binding between the insulin and the metal salt.

By suspending the zinc-rich insulin in absolute alcohol a small amount of the $ZnCl_2$ diffuses out of the crystal until an equilibrium has been attained. By suspending the zinc-rich insulin in water, however, all the $ZnCl_2$ rapidly

Table 1. The reaction between insulin and metal salts. The zinc content in untreated insulin is 0.8 % = 0.73 atoms per unit of 6 000.

Metal chloride	% metal in insulin	moles of metal per unit of 6 000	moles of Zn per unit of 6 000	Proposed stoichiometric formula
$MgCl_2$	0.23 [a]	0.57	0.62	(insulin,$\frac{1}{2}$Zn,$\frac{1}{2}$ Mg)
$CaCl_2$	0.65 [a]	0.97	0.55	(insulin,$\frac{1}{2}$Zn,1 Ca)
$NiCl_2$	2.60	2.65	0.51	(insulin,$\frac{1}{2}$Zn,1$\frac{1}{2}$Ni)1$NiCl_2$
$MnCl_2$	6.80	7.42	0.34	(insulin,$\frac{1}{3}$Zn,1$\frac{2}{3}$Mn)6$MnCl_2$
$CdCl_2$ [b]	9.24	4.93	0.29	(insulin,$\frac{1}{3}$Zn,1$\frac{2}{3}$Cd)3$CdCl_2$
$CoCl_2$	6.70	6.81	<0.1	(insulin,2Co)5$CoCl_2$

[a] These preparations contain no chloride.

[b] $CdCl_2$ is only sparingly soluble in absolute alcohol. The figure quoted is thus probably not the final value.

diffuses out, and the zinc content of the insulin decreases to a value of about 2 moles per Sanger unit. This effect shows that the binding between $ZnCl_2$ and insulin is unstable in aqueous solution.

The reaction between insulin and other metal chlorides has also been investigated. The metal salts used are $NiCl_2$, $CdCl_2$, $MgCl_2$, $MnCl_2$, and $CoCl_2$. The results are shown in Table 1.

As indicated in Table 1 the incorporation of metal chloride into insulin replaces zinc from the insulin. This phenomenon proved to have a remarkable effect on the crystal structure of insulin. When the preparations of insulin contain more than 1/3 mole Zn per unit of 6 000 it is still crystalline, but containing less than this amount the crystal structure is deteriorated. A more detailed report on the above mentioned effects including an X-ray crystallographic investigation on insulin preparations containing varying amounts of zinc will be published elsewhere.

I am gratefully indebted to Dr. med. H. Christensen, Roskilde Medical Company, for his guidance and valuable suggestions and to Miss Tove Ahrens for excellent technical assistance.

The Position of the Primary Amino Group in the Steroidal Alkaloid Solanocapsine

PER M. BOLL* and HANS A. LILLEVIK

The Kedzie Chemical Laboratory, Michigan State University, East Lansing, Michigan, U.S.A.

Even under conditions preventing hydrolysis of a possible glycosidic linkage in the steroidal alkaloid solanocapsine, the compound could not be isolated as a glycoside. Data suggesting that the compound has a 3α-amino group instead of the 3α-hydroxyl group usually present in *Solanum* alkaloids are presented. Based on the behavior of acetyl derivatives the hydroxyl group of solanocapsine hitherto considered unreactive is found reactive.

This work was started with the purpose of isolating the antibacterial principle from *Solanum pseudocapsicum*. *In vitro* activity against *Mycobacterium tuberculosis* of root extracts had been reported previously [1]. During the isolation work the antibacterial principle was also found to be present in leaves and stems and was identified as the alkaloid solanocapsine [2].

In 1936 Barger and Fraenkel-Conrat [3] reported the isolation of solanocapsine from *S. pseudocapsicum* and assigned the empirical formula $C_{26}H_{44}N_2O_2$ or $C_{25}H_{42}N_2O_2$ to the compound. Furthermore, the two workers obtained an amorphous alkaloid, solanocapsidine, which was found to have the formula $C_{26}H_{42}N_2O_4$. No alkaloidal glycoside was isolated.

In 1945 Rochelmeyer *et al.*[4] suggested a structural formula for solanocapsine with 27 carbon atoms. The formula was proposed without any experimental evidence.

Later, Schlittler and Uehlinger [5] found that the empirical formula $C_{27}H_{46}N_2O_2$, H_2O was more in agreement with elementary analyses of solanocapsine. By this formula solanocapsine can be classified together with other 27 carbon atom *Solanum* alkaloids (other being solanidine, tomatidine, solasodine *etc.*).

Solanocapsine is the only alkaloid from the genus *Solanum* which has not been isolated as a glycoside. So far, both Barger and Fraenkel-Conrat and Schlittler and Uehlinger have isolated the alkaloid from dried leaf material and have not been able to isolate a glycoside, although the former authors

* Present adress: Royal Danish School of Pharmacy, Chemical Laboratory B, Copenhagen, Denmark.

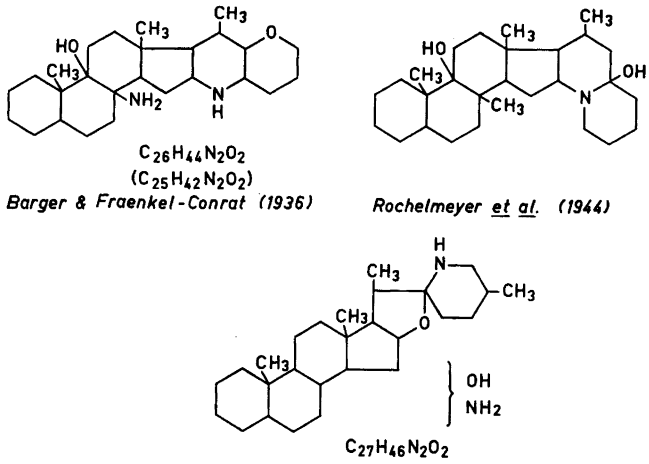

Fig. 1.

obtained reactions for carbohydrates on crude alkaloid preparations, an observation we have confirmed. Therefore, the possibility of an extraordinary labile glycosidic bond being acted upon enzymatically during drying of the plant or during isolation was carefully examined. Enzyme inactivation by placing the plants, immediately after harvesting, in absolute ethanol or in boiling water and using weak acids in the isolation procedure did not yield a glycoside. It is regarded that solanocapsine is present in the plant as a free alkaloid.

It has been stated that *Solanum pseudocapsicum* besides solanocapsine contains an amorphous alkaloid solanocapsidine [3], solanine [6], and solanidine [6]. During the isolation and purification of solanocapsine an amorphous, resinous material was often obtained; but it was always possible, as Schlittler and Uehlinger also observed, by repeated precipitation from aqueous ethanol to convert this material to crystalline solanocapsine. By paper chromatography only one alkaloid was observed, although it has to be mentioned that Schreiber [7] also by paper chromatography has detected another minor alkaloid.

The elementary analysis of solanocapsine was in agreement with the empirical formula proposed by Schlittler and Uehlinger. Since both Barger and Fraenkel-Conrat and Schlittler and Uehlinger have isolated 3′-methyl*cyclo*pentenophenanthrene and 2-ethyl-5-methylpyridine after selenium dehydrogenation of solanocapsine, we have assumed that solanocapsine has a solasodan nucleus and have mainly been interested in the position of the functional groups.

The two above mentioned groups have found that solanocapsine contains a primary amino group, a secondary amino group and a hydroxyl group. The evidence for two amino groups came from methylation of the nitrogen atoms with formic acid and formaldehyde, which gave a trimethyl derivative $C_{30}H_{52}N_2O_2$. This observation was confirmed by the present investigation.

Further evidence for the existence of the two amino groups was given by Schlittler and Uehlinger by reacting solanocapsine with nitrous acid. They observed that by reacting with two equivalents of nitric acid, a neutral, unsaturated nitroso derivative $C_{27}H_{42}N_2O_3$ resulted. In this study the same was observed and a Van Slyke amino nitrogen determination indicated that one mole of nitrogen was liberated per mole of solanocapsine, from which can be concluded that a primary amino group is present. The ultraviolet spectrum of the obtained nitroso derivative showed a peak at 346 mμ and another of

Table 1.

Compound	Maxima	
Nitroso derivative of solanocapsine	346 mμ (log E 2.05)	240 mμ (log E 3.89)
Di(*cyclo*hexylmethyl)-N-nitrosamine [8]	355 mμ (log E 1.95)	240 mμ (log E 3.90)
1-Nitrosopiperidine [8]	350 mμ (log E 2.00)	235 mμ (log E 4.25)
N-Nitrososolasodine [9]	370 mμ (log E 1.98)	234.5 mμ (log E 3.78)

low intensity at 240 mμ. In Table 1 this spectrum is compared with spectra of three nitrosamines. Solanocapsine therefore contains a secondary amino group.

Solanocapsine does not give any precipitate with digitonin contrary to the other *Solanum* alkaloids and is, therefore, not considered to have a 3β-hydroxyl group. It can not have a 3α-hydroxyl group, since it would have been possible to dehydrate such a group. Barger and Fraenkel-Conrat maintain that they could eliminate the hydroxyl group with boiling alkali, but neither Schlittler and Uehlinger nor our investigation could repeat it. On the other hand, the nitroso derivative of solanocapsine gives a precipitate with digitonin. Therefore, it seems plausible to conclude that the primary amino group is placed in the 3-position.

Not only 3β-hydroxy steroids (with 3-OH and 10-CH_3 *cis* to each other) are precipitated as digitonides, but several 3β-amino steroids give precipitates contrary to the corresponding 3α-amino steroids. It is, therefore, assumed that the amino group in solanocapsine is in the 3α-position. An inversion of configuration must have happened during the deamination. Mills [10] described deamination of aminodecalins with nitrous acid and found it to be a true stereospecific reaction. Equatorial amino groups afforded alcohols of same configuration, while axial amino groups reacted by inversion of configuration. That is in agreement with the concept that the 3β-hydroxy group in steroids with the same stereochemical configuration as cholesterol is equatorial and, therefore, thermodynamically more stable.

Hydrogenation of solanocapsine at room temperature and about 3 atm pressure with reduced platinum oxide catalyst gave a derivative, which did not show any melting point depression mixed with solanocapsine, but the

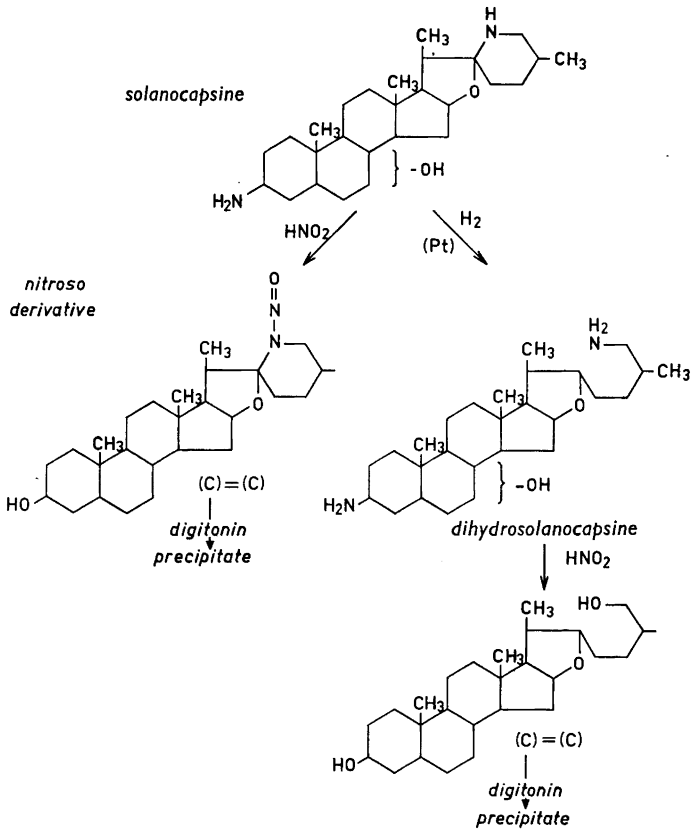

Fig. 2.

specific rotation was changed. A Van Slyke amino nitrogen analysis of the dihydro compound showed that two moles of nitrogen were liberated per mole of compound and that the resulting compound did not give the ultraviolet absorption characteristic for a nitrosamine. It seems safe to conclude that an opening of the piperidine ring has occurred. This is contrary to the opening of the oxide ring in solasodine during hydrogenation.

Schlittler and Uehlinger prepared an amorphous acetyl derivative of solanocapsine, considered by them to be N,N-diacetylsolanocapsine. Several attempts to prepare a diacetate after their procedure never gave the exact elementary analysis expected for a diacetylsolanocapsine. But the compound is not a N,N-diacetylsolanocapsine, but rather an O,N-diacetylsolanocapsine. The reasons for such a conclusion are the following: 1) The derivative was soluble in dilute acetic acid indicating that a basic group probably is present. 2) The infrared spectrum of the derivative showed the characteristic absorption bands for an O-acetyl group and a secondary amide.

Barger and Fraenkel-Conrat acetylated solanocapsine by refluxing with acetic anhydride for 5 h and obtained an amorphous acetate. On the basis of the elementary analysis it was considered to be a diacetate. But it seems that the authors based their calculation on the wrong empirical formula. When recalculated on the basis of a solanocapsine with 27 carbon atoms, the analysis is more in agreement with a triacetate. The acetate prepared in this investigation after their procedure gave an elementary analysis which is in agreement with a triacetate and acetyl group analysis also indicated three acetyl groups. The infrared spectrum showed the bands characteristic for an O-acetyl group and a secondary amide. Furthermore, the intensity of the 6.06 μ band was considerably higher than that of the 6.45 μ band. Since a tertiary amide ($CH_3CO-NRR'$) only shows one characteristic absorption band at 6.06 μ, it is concluded that the third acetyl group is attached to the secondary amino group. The derivative is considered to be O,N,N'-triacetylsolanocapsine.

Barger's as well as Schlittler's group considered the hydroxyl group to be a tertiary or an unreactive hydroxyl group. The conclusion was based on the acetyl derivatives. This investigation has shown that the hydroxyl group can be acetylated, but not tosylated.

EXPERIMENTAL

Isolation. Solanocapsine was isolated and purified by the method of Schlittler and Uehlinger [3]. The plants were grown in the fields belonging to the Department of Horticulture, harvested late fall, and dried in a forced draft oven at 60°. As an example of obtained yields: 500 g of ground leaves gave 8.0 g crude solanocapsine dihydrochloride (1.6 %).

Attemps to isolate an alkaloidal glycoside. Two methods of enzyme inactivation were utilized: 1) Submersion of the harvested plants in absolute ethanol and 2) immediate freezing in dry ice and storage in a deep-freeze until the day of isolation when they were boiled with water.

1) The roots and tops of 15 fresh plants were immediately separated and each part covered with absolute ethanol and stored until time for isolation. A total of 1 400 g of dehydrated tops were macerated in a Waring blender with 14 l of 2 % acetic acid and allowed to stand for 48 h with occasional stirring. The supernatant was removed by filtration and the plant pulp was similarly re-extracted with 5 l of 2 % acetic acid for 24 h and filtered. The combined filtrates were made distinctly alkaline with ammonia and heated to about 50°. After standing overnight the supernatant was decanted and the precipitate collected on a filter. After drying at room temperature the precipitate weighed 0.76 g. The dark brown precipitate was refluxed five times with 100-ml portions of methanol, each time for an hour. 61 mg of residue was obtained. The roots (350 g) were treated in the same manner as described for the tops. After removal of the methanol 20 mg of green residue remained.

2) For the second part of the experiment 13 plants were harvested, immediately placed in dry ice and preserved in the deep-freeze. At the time of glycoside extraction the plants were placed in boiling water for 10 min and then isolation procedure continued in the same manner as above. 128 mg of residue was obtained.

After recrystallization from ethanol the three residues isolated all melted in the broad range of 175—195°C, which suggested impurities. Chromatography in three different solvents showed that the three residues all gave same R_F-value as solanocapsine, when the spots were developed with Dragendorff reagent. If the compounds were chromatographed in 1-butanol-ethanol-water (80:20:20) and the spots developed with aniline hydrogen phthalate, only the compound isolated from the plant tops and the compound isolated from the frozen plants showed spots of D-glucose.

Solanocapsine. To a solution of 500 mg solanocapsine dihydrochloride in 10 ml ethanol-water (1:1) was under stirring added dilute ammonium hydroxide. The yield of crude solanocapsine was 370 mg. After recrystallization from ethanol-water (1:1) it crystallized as platelets which melted with decomposition at 215—216° (lit.[5] m. p. 216— 217°, lit.[3] m. p. 222°); $[\alpha]_D^{25}$ +25 (methanol). The m. p. was usually lower. Only in one case was it possible to reproduce the given m. p. (Found: N 6.20, 6.29; H_2O 3.98; m.wt. 456, 481 (Rast); 482 (neutr. equiv.). Calc. for $C_{27}H_{46}N_2O_2$, H_2O: N 6.24; H_2O 4.01; m.wt. 448.7.)

A Van Slyke amino nitrogen determination gave evolution of 0.99 mole of nitrogen.

No unsaturation and no absorption in the ultraviolet part of the spectrum was observed.

To a solution of 10 mg solanocapsine in 10 ml of ethanol was added 10 ml of a 1 % ethanolic solution of digitonin. The solution remained clear, even after 10 h of standing.

No consumption of periodic acid was observed, even after 10 h. The oxidation was attempted at 3 different hydrogen ion concentrations.

Solanocapsine dihydrochloride. 200 mg of crude solanocapsine dihydrochloride was recrystallized twice from water. The yield was 105 mg and the substance did not melt below 300° (lit.[5] m. p. 300°, lit.[3] m. p. 324°). (Found: C 62.27; H 9.40; N 5.59; H_2O 3.34. Calc. for $C_{27}H_{46}N_2O_2$, 2 HCl, H_2O: C 62.17; H 9.66; N 5.37; H_2O 3.36.)

Solanocapsine picrate. The picrate was prepared as described by Schlittler and Uehlinger. The derivative melted at 198—199° (lit.[3] m. p. 200—201°).

Solanocapsine oxalate. Again the procedure of Schlittler and Uehlinger was followed; m. p. 287—289° (lit.[5] m. p. 288—289°).

Trimethylsolanocapsine. The derivative was prepared following the procedure of Schlittler and Uehlinger. Recrystallized from absolute methanol the compound melted at 208° (lit.[5] m. p. 209°). (Found: N 5.86, 5.72. Calc. for $C_{30}H_{52}N_2O_2$: N 5.93.)

Nitroso derivative. The derivative was prepared according to Schlittler and Uehlinger. After recrystallization from absolute methanol the derivative melted at 194—196° (lit.[3] m. p. 194°, lit.[2] 200°). Microhydrogenation (PtO_2): 0.92 double bond.

Digitonide of nitroso derivative. To a solution of 70 mg of the nitroso derivative in 20 ml ethanol was added 20 ml of a 1 % ethanolic digitonin solution. After standing overnight the copious precipitate was filtered, washed with water and dried to give 45 mg of digitonide. The derivative was washed with 5 ml of ethanol and dried. (Found: N 1.82; 1.90. Calc. for $C_{83}H_{134}N_2O_{32}$: N 1.68.)

Dihydrosolanocapsine. A mixture of 200 mg solanocapsine and 200 mg of platinum oxide in 10 ml of glacial acetic acid and 5 ml of ethanol was shaken under 3 atm pressure in an Adams hydrogen apparatus. After filtration of the catalyst the solvent was removed by distillation under diminished pressure. The residue was dissolved in ethanol-water (1:1) and dilute ammonium hydroxide was added to precipitate 170 mg of compound. It was recrystallized from ethanol-water (1:1), melted at 210—212°, and a mixed melting point with solanocapsine did not show any depression. $[\alpha]_D^{25}$ +40 (methanol). Determination of active "H": Found: 0.42 (room temp.), 0.84 (100°). Calc. for 2 active "H": 0.44, for 4 active "H": 0.89.

A Van Slyke amino nitrogen determination gave evolution of 1.97 moles of nitrogen.

Diacetylsolanocapsine. The derivative was prepared using the procedure of Schlittler and Uehlinger. 150 mg solanocapsine gave 150 mg of a gelatinous acetate. The acetylated alkaloid was chromatographed on 8.7 g of alumina. Eluate fractions of 20 ml were collected. The composition of the fractions is given in Table 2.

Fractions 10—13 were combined and re-precipitated three times from methanol-ethyl ether (1:5). It was not possible to obtain a crystalline product. The amorphous derivative after drying melted at 198—200° (lit.[3] m. p. 193—196°). The compound is soluble in dilute acetic acid. (Found: C 69.90; H 9.84; CH_3CO 1.3 eq, 1.6 eq. Calc. for $C_{31}H_{50}N_2O_4$, H_2O: C 70.77; H 9.62; CH_3CO 2 eq.)

Triacetylsolanocapsine. Barger and Fraenkel-Conrat's procedure was followed. A mixture of 500 mg solanocapsine and 10 ml of acetic anhydride was refluxed in an oil bath for 5 h. The solvent was removed under diminished pressure and the brown, oily residue dissolved in ethanol. Water was added to slight turbidity and the compound was allowed to crystallize. Thus a yield of 400 mg of product melting at 140—150° was obtained. The compound was amorphous and even repeated solution in hot benzene-ligroin

Table 2.

Fraction	Eluant	Residue
1— 3	benzene	9 mg brown oil, soluble in ether
4— 5	benzene + 5 % chloroform	7 mg colorless oil, soluble in ether
6— 7	benzene + 10 % chloroform	9 mg colorless oil, soluble in ether
8— 9	benzene + 25 % chloroform	5 mg colorless oil, soluble in ether
10—13	chloroform + 1 % methanol	79 mg white foam, insoluble in ether
14—16	chloroform + 2 % methanol	6 mg greenish oil, insoluble in ether

did not change it to a crystalline compound. The melting point of the purified compound was 150—155° (lit.[2] m. p. 150—160°).

A further attempt was made to convert the derivative into a crystalline compound by column chromatography. A solution of 83 mg of acetylated solanocapsine in 5 ml benzene was chromatographed on 9 g of alumina and eluate fractions of 20 ml were collected. The composition of the fractions is shown in Table 3.

Table 3.

Fraction	Eluant	Residue
1— 3	benzene	5 mg brownish oil, soluble in ether
4— 5	benzene + 5 % chloroform	4 mg colorless oil, soluble in ether
6— 7	benzene + 10 % chloroform	6 mg colorless oil, soluble in ether
8— 9	benzene + 25 % chloroform	4 mg colorless oil, soluble in ether
10—13	chloroform + 1 % methanol	56 mg white foam, insoluble in ether
14—16	chloroform + 2 % methanol	5 mg greenish oil, insoluble in ether

Fractions 10—13 were combined and after evaporation of solvent gave an amorphous product still melting at 150—155°. The derivative was insoluble in dilute acetic acid. (Found: C 71.61; H 9.49; CH_3CO 2.8 eq. Calc. for $C_{33}H_{52}N_2O_5$: C 71.17, H 9.42; CH_3CO 3 eq.)

Attempted tosylation. A solution of 100 mg solanocapsine in 2.5 ml of pyridine was treated with 100 mg of *p*-toluene sulfonyl chloride. After standing 12 h, 5 ml of water was added and the resulting precipitate was washed with much water. The product was recrystallized from ethanol-water (1:1). Only solanocapsine was recovered as evidenced by mixed melting point and infrared spectrum.

Attempted dehydration. By acid catalysis: A solution of 50 mg of solanocapsine in 15 ml concentrated hydrochloric acid and 35 ml ethanol was refluxed for 10 h. After 50 ml of water was added, the solution was made distinctly ammoniacal and then extracted four times with 100-ml portions of ethyl ether. The combined fractions were dried over anhydrous sodium sulfate and evaporated to dryness. The residue was recrystallized from ethanol-water (1:1). Only solanocapsine was recovered as evidenced by mixed melting point and infrared spectrum. *By base catalysis:* Dehydration in alkaline solution was attempted using the procedure of Barger and Fraenkel-Conrat. The product obtained was found by mixed melting point and infrared spectrum to be solanocapsine. The product gave a condensation product with acetone, which is contrary to the compound thus obtained by Barger and Fraenkel-Conrat.

This investigation was supported in part by research grant E-227 from the *National Institutes of Health.* We wish to thank Professors J. L. Faierley and J. C. Speck of this laboratory for valuable advice.

Changes in Molecular Weight of Acid Mucopolysaccharides in Connective Tissue Due to Hormone Treatment, Dehydration and Age

EIGILL HVIDBERG and C. E. JENSEN († 6/11—1959)

Department of Pharmacology, and Institute of Physical Chemistry, University of Copenhagen, Copenhagen, Denmark

Acid mucopolysaccharides have been isolated from animal skin and characterized by means of viscosimetry, chromatography and metachromasia. It is shown that the molecular weight of these substances decreases with age. A depolymerization of these substances apparently also takes place during severe dehydration and under the influence of cortisone, while oestradiol treatment results in a polymerization. It is concluded that the size of the hyaluronic acid molecule is an important factor in the waterbinding mechanism of connective tissue.

It is generally accepted that in the connective tissue there is a close relationship between the amount and physical state of the acid mucopolysaccharides on one side and the water content on the other side. Oestrogenic treatment has for some time been known to increase the amount of mucopolysaccharides as well as the content of water in the skin (Taylor and Sprunt [1], and Schmidt [2]), and severe dehydration causes a minor decrease in the hexosamine content in the skin of mice and rats, (Hvidberg [3,4]). Further it has been observed (Boas and Foley [5], Hvidberg [4]) that both the hexosamine and the water content of the connective tissue decrease during growth in rats. From these and other investigations the amount of the acid mucopolysaccharides seems to be important for the waterbinding mechanism of connective tissue. However, we also found it worth while to study the possible rôle played by the degree of polymerization of the mucopolysaccharides. We therefore have determined the molecular weights of these substances isolated from animals of different ages and after different treatments, in order to provide some information on the waterbinding mechanism of connective tissue.

MATERIALS AND METHODS

As experimental animals were used white male mice, 7—8 weeks old, weighing about 25 g, and white female rats of different ages, namely: 2 days, 10 days, 26 days, 6 weeks, about 3 months, and about 6 months old. In the experiments with mice the groups contained about 40 animals, and in the experiments with rats the groups contained from about 60 to about 25 animals depending on the age. The animals were kept under constant environmental conditions with free access to commercial food-stuff and also to water, except the group of dehydrated mice.

Groups of mice treated in different ways: 1. Control group. 2. Group deprived of water for 7 days. 3. Group treated with oestradiol monobenzoate (Ovex ® Leo), 10 μg in 0.1 ml of vegetable oil, injected subcutaneously in the occipital region on the 1st and the 3rd day; killed on the 7th day. 4. Group treated with cortisone acetate (Organon ®) 1 mg in 0.1 ml (diluted with physiological saline) given intraperitoneally daily from the 1st to the 15 th day, and killed just after.

Only skin from the distal part of the back was used. After depilation the skin and underlaying connective tissue were removed, freeze-dried, and defatted carefully according to the method described by Hvidberg [3]. Then all the tissue pieces from each group were pooled.

Isolation processes. In order to isolate mucopolysaccharides from the dry and defatted tissue the following methods were employed. It appeared necessary to use different techniques depending upon the origin of skin. *Mice:* The minced skin was stored under acetone for a fortnight in order to denature proteins thus rendering these substances insoluble (Schütte and Greiling [6], Jensen [7]). Then the acetone was removed by soaking in distilled water for 2 h. The broth was then treated with acetic acid for 2 days in order to remove iron, and then the broth was neutralised with potassium hydroxide to pH 8—9. The broth was filtered througth 8 layers of gauze, and dialysed against running tap water for three days. To the dialysate were added 3 volumes of absolute alcohol. The precipitate was partly stringy, and partly flocculent. After rinsing with alcohol and ether a white powder was obtained. *Rats*: The above method did not appear to be successful regarding isolation of mucopolysaccharides from rat skin, as the tissue would not disintegrate. Therefore we employed enzyme digestion using a crude extract from pancreas (Pancreatin ® Novo). In agreement with Gardell [8] we found that crystalline trypsin and chymotrypsin were less effective than the pancreatic enzymes. The pH was adjusted to 7—8 and the digestion lasted for three days at room temperature. The broth was then filtered through gauze. The protein split products were precipitated with 10 % trichloroacetic acid after the method of Lundquist [9]. After neutralisation and dialysis the mucopolysaccharides were obtained and rinsed as described above. During the isolation processes care was taken that the temperature did not exceed room temperature and the pH was less than 9. This was done as both high temperature and alkaline reaction involve the danger of degrading effects of mucopolysaccharides (Snellman [10]).

The isolated substances were tested for metachromasia by preparing dry smears. These were fixed in basic lead acetate, and stained with a 0.05 % solution of toluidine blue (Toluidinblau nach Hoyer Riedel-de Haën A. G., Hannover, Germany) at pH 6.5, beforé and after incubation with hyaluronidases. Testicular hyaluronidase was prepared by Leo Pharmaceutical Products, Copenhangen and bacterial hyaluronidase was prepared by dr. V. Faber, the Danish State Serum Institute.

Viscosimetric investigations were performed in the viscosimeter described by Dalgård-Mikkelsen and Kvorning [11].

Chromatographic investigations were undertaken after the isolated substances had been hydrolysed with 2.0 N HCl for 15 h at 100°C in sealed ampullae. Samples containing 10 mg/ml were placed on Whatman filter paper No. 1 in a volume of 20 μl, and run in 2,6-lutidine:water (65:35) for 24 h using the descending type of chromatography. Standard solutions (10 mg/ml) of D-glucosamine hydrochloride (Nutritional Biochemical Corporation) and D-galactosamine hydrochloride (Mann Research Laboratories) were placed on the paper in a volumn of 5 μl each. For the development was used a 0.1 % ninhydrin solution in acetone. For publication the chromatogrammes, were copied in drawings as shown in Fig. 4.

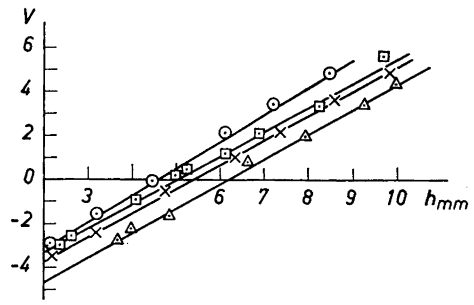

Fig. 1. Osmotic pressure of isolated mucopolysaccharides from skin of mice. The graph shows the relation between height of the air column (abscissae) and the rate of movement of the upper miniscus of the air column (ordinates) in micrometer divisions in 10 min. The values for the equilibrium length are given in Table 1.

⊙ — ⊙ Control (untreated animals)
△ — △ Dehydrated animals
× — × Animals treated with cortisone
⊡ — ⊡ Animals treated with oestradiol

The molecular weight was calculated from osmotic pressure measurements, which were performed by the micro-osmometer described by Christiansen and Jensen [12]. The semipermeable membranes were prepared from a pyroxylin solution (Parlodion "Mallinckrodt") containing 4 g in 100 ml of an alcohol-ether mixture (75:25); to this mixture were added 5 ml of ethylene glycol freshly distilled *in vacuo*. The membranes were dried for about one hour.

RESULTS

From the following reasons we conclude that the substances isolated from the skin of the experimental animals really are mucopolysaccharides, more or less contaminated with impurities. The powders were 1) white or nearly white, 2) highly hygroscopic, and 3) easily soluble in water. 4) The aqueous solutions were viscid, and 5) the viscosity decreased considerably upon incubation with both hyaluronidases. 6) Further more, the substances were strongly metachromatic with toluidineblue, this metachromasia being highly sensitive to testicular hyaluronidase and partly sensitive to the streptococcal enzyme. 7) Chromatography of the hydrolysates showed spots corresponding to authentic glucosamine and galactosamine. 8) Although being not a proof the calculat-

Table 1. The molecular weight of mucopolysaccharides isolated from skin of mice, calculated from the measurement of the osmotic pressure (w = weight of the material in mg per ml, and h = equilibrium length in cm) M means the molecular weight. 1 and 2 refer to two seperate experiments with the same material.

Treatment	w 1	w 2	h 1	h 2	$M \times 10^{-3}$ 1	$M \times 10^{-3}$ 2	$M \times 10^{-3}$ mean	± % of control group	Hexosamine and Water contents * Hex. mean	Hex. sem	Water mean	Water sem
Control	7.02	5.80	0.54	0.46	321	320	321	—	521	± 9	316	± 8
Dehydrated	4.48	4.92	0.55	0.62	201	196	198	−40	481	± 8	211	± 5
Oestradiol	9.01	9.40	0.48	0.50	463	464	464	+44	1 065	±24	540	±15
Cortisone	5.04	5.50	0.51	0.54	251	244	247	−20	528	± 9	261	± 7

* The figures of these columnes are taken from completely equal series published by Hvidberg and Schmidt [16], and Hvidberg [3]. The content of hexosamine is in mg, and the content of water is in g, both per 100 g dry, defatted tissue. sem = Standard error of the mean.

Table 2. The molecular weight (M) of mucopolysaccharides isolated from skin of rats of different ages, calculated from the measurement of the osmotic pressure (w = weight of material in mg per ml, and h = equilibrium length in cm).

Age	w	h	$M \times 10^{-3}$	Hexosamine and Water contents *			
				Hex.		Water	
				mean	sem	mean	sem
2 days	7.58	0.61	266	676	±14	571	±7
10 days	6.01	0.62	239	540	±6	400	±2
26 days	5.59	0.62	219	538	±7	318	±2
6 weeks	5.88	0.74	196	488	±7	272	±4
3 months	5.68	0.84	167	410	±6	228	±2
6 months	6.68	1.15	143	342	±6	218	±2

* The figures of these columnes are taken from an other investigation using equal groups of rats (Hvidberg [4]). Hexosamine and water contents are given in mg and g, respectively, per 100 g dry, defatted tissue. sem = Standard error of the mean.

ed molecular weights do not exclude the anticipation that the substances are mucopolysaccharides.

As seen from Table 1, which shows the molecular weights of substances isolated from mice skin, the molecular weight is considerably lower, when the mice had been dehydrated for seven days. Also cortisone treatment seems to cause a marked fall in the molecular weight, while the oestrogenic treatment causes a considerable increase. According to our experience on the relationship between substrate concentration and osmotic pressure (Jensen [7], Jensen and Marcker [13]), the differences between the molecular weights are likely still greater than the figures apparently indicate. An example of the osmotic measurements are given in Fig. 1.

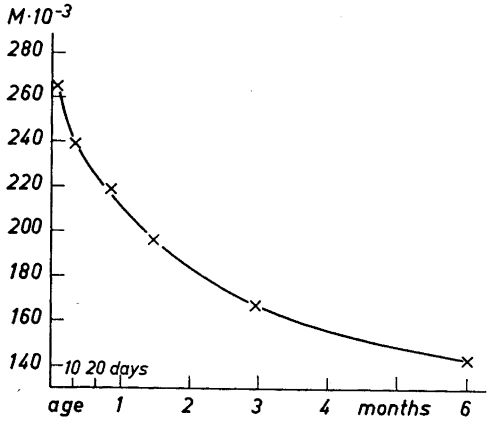

Fig. 2. The relation between age (abscissae) and molecular weight (ordinates) of mucopolysaccharides isolated from skin of rats of different ages.

Table 3. Metachromasia of the isolated mucopolysaccharides from skin of mice and rats.
Intensities: + + + + : very strong reaction
+ + + : strong reaction
+ + : medium reaction
+ : weak reaction
O : no or practically no reaction
The quoted intensities of the metachromatic reactions are based only on the subjective impressions of the authors and involves no exact measurements.

Animals	Group	Intensity of metachromasia		
		Genuine metachromasia	After treatment with bacterial hyaluronidase	After further treatment with testicular hyaluronidase
Mice	Control	+ + +	+	O
—	Dehydrated	+ +	+	O
—	Oestradiol	+ + + +	+	O
—	Cortisone	+ (+ + ?)	+	O
Rats	2 days old	+ + +	+	O
—	10 days old	+ + +	+	O
—	26 days old	+ + +	+	O
—	6 weeks old	+ + +	+ +	O
—	3 months old	+ + +	+ +	O
—	6 months old	+ + +	+ +	O

Table 2 gives the results of the osmotic measurements and the calculated molecular weights of the substances isolated from skin of rats of different ages. It is obvious from Table 2 and from Fig. 2, that the molecular weight decreases with age. The decrease is greatest during the first weeks of life.

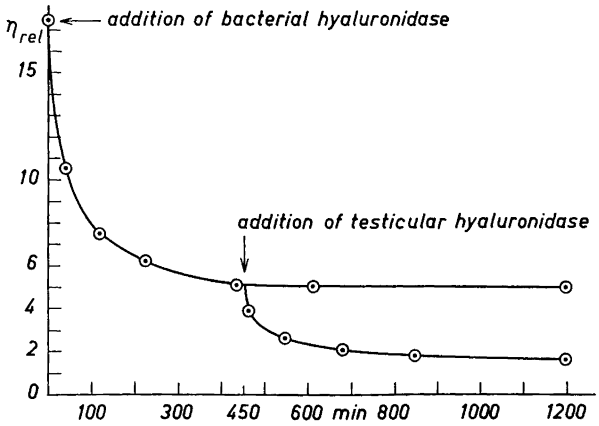

Fig. 3. Degradation of isolated mucopolysaccharides from skin of control mice, after enzymatic incubation, shown by the fall in viscosity. Abscissae: Times after incubation. Ordinates: Relative viscosities.

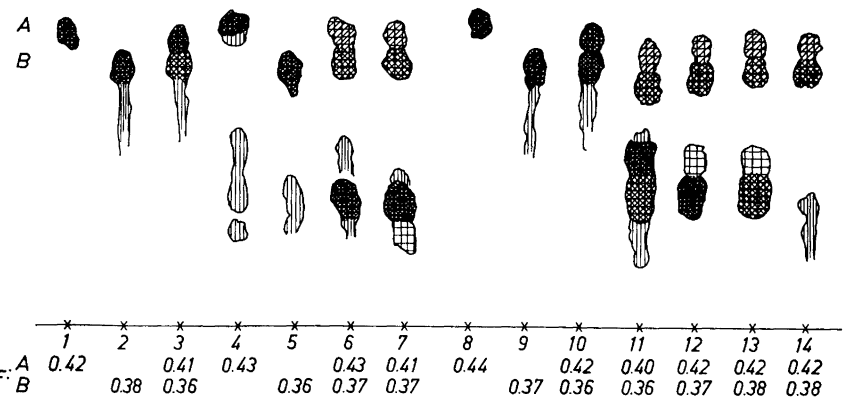

Fig. 4. Drawing of paper chromatogrammes of hydrolyzed mucopolysaccharides isolated isolated from skin of rats and mice, showing the spots of glucosamine (A) and galactosamine (B). Further the R_F-values are given. Other spots are impurities, probably hydrolysates of protein.

1. Authentic glucosamine
2. Authentic galactosamine
3. Authentic glucosamine and galactosamine
4. Hydrolysate of hyaluronic acid (from human umbilical cords)
5. Hydrolysate of chondroitin sulphuric acids (from ox nasal septa)
6. 2 days old rats
7. 10 days old rats
8. As No. 1
9. As No. 2
10. As No. 3
11. 26 days old rats
12. 3 months old rats
13. 6 months old rats
14. Control mice (untreated animals)

From Table 2 it is further seen that hexosamine as well as water content also decrease with age (compare Hvidberg [4]).

Table 3 shows the metachromasia of the isolated substances. We have to point out that the quoted intensities are based only on subjective impressions and involve no exact measurements. The most remarkable observations are that the intensities of the metachromatic reactions in the dehydrated and the cortisone treated animals are weaker than in the normal and especially than in the oestradiol treated mice. As seen the intensities do not appear to change with age. Further it is seen that practically all metachromasia is abolished by treatment with testicular hyaluronidase. When the substances were incubated with streptococcal hyaluronidase an obvious decrease in intensity is seen, but this decrease is not so marked in the older groups of rats.

Fig. 3 gives an example of the viscosimetric investigation showing the degradation of the isolated substance following incubations partly with testicular, partly with streptococcal hyaluronidases. The curves indicate that the preparation contains both hyaluronic acid and chondroitin sulphuric acids.

The chromatographic investigations are shown in Fig. 4 which gives a drawing of the paper chromatogrammes. From this study it might be concluded that the isolated powders contain substances which upon hydrolysis yielded both glucosamine and galactosamine. Perhaps the investigation indicates that the ratio between hyaluronic acid and chondroitin sulphuric acids decreases slightly with increasing age. Unfortunately, we had not so great amounts of the substances which allowed us to perform chromatographic investigations on dehydrated and hormone treated mice and on the 6 weeks old rats. As references were used, besides authentic glucosamine and galatosamine, hydrolysates of hyaluronic acid prepared from human umbilical cords according to Jensen [14] and chondroitin sulphuric acid isolated from ox nasal septa according to Blix and Snellman [15]. As seen most preparations are contaminated with impurities, probably protein split products.

DISCUSSION

As we think it most valuable to know the physico-chemical behaviour of the acid mucopolysaccharides in the state in which they occur in the living connective tissue, we have made use of very mild isolation procedures. However, we are well aware, indeed, that this demand is not obtainable, the substances being always altered during the isolation procedures. But we think that the experiments in this study with the isolated material, help us to give a fairly good picture of the real conditions. The quantitative extraction of the acid mucopolysaccharides is a matter of considerable difficulty, and considering the mild methods here used, we are of the opinion, that only a relative small part of the total amount of the mucopolysaccharides has been isolated at all. This might be considered as a source of error too.

As shown in the experiments with mice the molecular weight of the mucopolysaccharides decreases after intense cortisone treatment. At the same time the relative amount of these substances is not altered as judged from the hexosamine determinations (Hvidberg and Schmidt [16]), but the content of water in the connective tissue is significantly lower. Also in dehydrated mice the molecular weight was found to be considerably lower than in normal animals. According to Hvidberg [3] the relative hexosamine content was somewhat smaller in the dehydrated mice, and naturally the water content of the connective tissue was markedly reduced. On the other hand the molecular weight of the mucopolysaccharides from the oestradiol treated animals was much higher than in normal animals; besides, this treatment nearly doubled the relative amount of mucopolysaccharides, and caused a considerable increase in the water content, (*cf.* Schmidt [2], Hvidberg [3]).

These observations are also interesting when compared to the findings in the metachromatic studies, because the metachromasia of the mucopolysaccharide is closely connected to the degree of polymerization. But it is important to stress once again that we are well aware that these observations are based only on subjective impressions. We have found that the metachromatic intensity is weaker in the cortisone treated animals. Histochemical studies performed by several investigators, *e.g.* Asboe-Hansen [17], have demonstrated that

cortisone treatment decreases the metachromasia of the connective tissue ground substance. This seems to agree with our findings. Dehydrated animals also showed a weaker metachromasia (Table 3). The experiments on these two groups (cortisone treated and dehydrated animals) suggest that a depolymerization of the mucopolysaccharides is followed by a decrease in the metachromasia, and this is, as mentioned above, in agreement with the opinion of most investigators.

In the experiments with rats it is shown that the molecular weight of the mucopolysaccharides is decreasing with age. During the same period a decrease in the water and in the hexosamine content is observed (Table 2, Hvidberg [4]). As may be inferred from the above experiments with hormone treated and dehydrated mice, it is not directly obvious that only the hydrophilic hyaluronic acid is depolymerized with increasing age. The findings with toluidine blue and with chromatography seem to indicate a minor increase in the ratio between chondroitin sulphuric acids and hyaluronic acid. This point of view is supported by the general observation that hyaluronic acid is preferably found in foetal connective tissues (Slack [18]). Furthermore, in experiments on pig skin, Meyer *et al.*[19] found that the ratio of chondroitin sulphate to hyaluronic acid was 1.25 in grown up animals, while this ratio was only 0.2 in the skin of pig embryos.

The fact that connective tissue, containing hyaluronic acid, really binds great amounts of water, is easily explainable when considering the physicochemical properties of hyaluronic acid. This molecule is threadlike (highly asymmetric, Jensen and Carlsen [20]), very large, and carries a great many negative charges (one per disaccharide unit). As it contains many OH-groups there are great possibilities for establishing hydrogen bondings, resulting in a threedimensional network. Thus it is obvious that this mucopolysaccharide is capable of forming a highly hydrophilic gel. It must be anticipated that this gel can bind great amounts of water even when present in low concentrations, as the more asymmetrical the colloidal particles are, the lower is the minimum concentration of the colloid at which gelation occurs (Jirgensons and Straumanis [21]) Although not a proof, it is likely that the water of the connective tissue (also skin) is found in a gel-like structure as no water escapes from the tissue, when it is punctured (Schmidt [2], Gibian [22]). According to our experience hyaluronic acid must be associated with protein in order to form a typical gel (see below).

Thus the ground substance of the connective tissue in which the structural elements are imbedded is a hydrophilic gel. Most probably this gel consists of a protein-hyaluronate complex (Bensley [23], Meyer [24], and Day [25]). The waterbinding mechanism of the connective tissue is most likely closely related to the gel-structure of the ground substance, but this mechanism depends on several, partly unknown, factors. The gel-like structure of the ground substance can be broken and the viscosity destroyed if the hyaluronic acid is depolymerized, (Jensen and Vilstrup [26] and a review by Schmidt [2]). It is a question if this rapid procedure influences the waterbinding mechanism, but from our investigations and the above considerations it might be suggested, that the waterbinding in the gel of the ground substance partly depends on the size of the hyaluronic acid molecules. This theory, already touched by

other investigators (see Altschuler and Angevine [27]), is supported by our findings, that there is a connection between the decrease in the molecular weight and the water content (cortisone treated animals), and between the increase in molecular weight and the water content (oestradiol treated animals). Furthermore it was observed, that when the water had been drawn from the connective tissue (the dehydration experiments), the molecular weight was found to be smaller, this also indicating that the waterbinding mechanism is altered (secondarily?). Finally the relation between the decrease in the molecular weight and the decrease in the water content of the connective tissue during growth also supports the hypothesis here forwarded. It must, however, be added, that the drop in the molecular weight of the isolated mucopolysaccharides during growth might partly be caused by alterations in the ratio between the two types of acid mucopolysaccharides in the connective tissue. As is known chondroitin sulphuric acids have smaller molecular weights than hyaluronic acid and do not have nearly as strong hygroscopic properties as this substance (Jensen [7]).

Acknowledgements. A part of this investigation was carried out in The Laboratory for Investigation of the Pharmacology of Connective Tissue with a grant from the *Danish National Association against Pheumatic Deseases.*

We are very indebted to professor J. A. Christiansen, Ph. D. and to professor K. O. Møller, M. D. for constant interest and advices.

We are grateful to Mrs. Inger Andreassen for technical assistance.

We want to thank Dr. V. Faber, the Danish State Serum Institute, Copenhagen, for preparing the streptococcal enzyme.

We are grateful to Novo Therapeutisk Laboratorium for generous supply of Pancreatin, to Leo Pharmaceutical Products, Copenhagen, for donations of Ovex and testicular hyaluronidase, and to Alfred Benzon A/S for the supply of cortisone acetate, Organon.

Least Squares Computer Calculations of Equilibrium Constants from Solvent Extraction Data *

JAN RYDBERG** and JAMES C. SULLIVAN

Chemistry Division, Argonne National Laboratory, Lemont, Illinois, U.S.A.

The principle of weighted least squares was used for calculating equilibrium constants from solvent extraction data. Two different programs for digital electronic computers were developed, depending on the type of complexes investigated. With these programs, the equilibrium constants in the systems Th(IV)-acetylacetone-benzene-0.01 M $NaClO_4$, and Zr(IV)-F^- (and $-HSO_4^-$)-thenoyltrifluoroacetone-benzene-2.0 M $HClO_4$, were calculated. The results are discussed and compared with the equilibrium constants originally computed by graphical methods.

The methods used for calculation of equilibrium constants from solvent extraction data have been generally graphical in nature (*e.g.* Connick and McVey [1], Rydberg [2,3], Dyrssen and Sillén [4], and Irving, Rossotti and Williams [5]) These methods do not give an objective measure of precision of the constants and may lead to the calculation of more parameters than are justified by the data. A more accurate procedure is to treat the data according to the principle of least squares which leads to the best values and maximum number of parameters together with their standard deviations.

The application of high speed digital computers to least squares calculations of complexity constants has been outlined in a recent paper (Sullivan, Rydberg and Miller [6]). In that study, solvent extraction was discussed only briefly. The purpose of the present paper is to give a fuller account of the application of these methods to solvent extraction data.

SOLVENT EXTRACTION EQUATIONS

Here we shall consider only the case when mononuclear complexes are formed between a metal ion $M^{\nu+}$ and negatively charged anions A^{r-} and B^{s-},

* Based on work performed under the auspices of the U. S. Atomic Energy Commission.

** On leave of absence from the University of Stockholm, and the Research Institute of National Defense, Stockholm, Sweden.

and where only uncharged complexes MA_vB_p, where $v = (v-ps)/r$, are extracted into the organic solvent. If Q is the partition ratio of all species of M between the organic and aqueous phase, Q can be expressed in terms of concconcentrations of the free ligands, $[A^{r-}]$ and $[B^{s-}]$, as

$$Q = \frac{\sum_{0}^{P'} \lambda_{vp}\beta_{vp}[A^{r-}]^v\,[B^{s-}]^p}{\sum_{n=0}^{N}\sum_{p=1}^{P} \beta_{np}[A^{r-}]^n\,[B^{s-}]^p} \tag{1}$$

where

$$\lambda_{vp} = \frac{[MA_vB_p]_{org}}{[MA_vB_p]_{aq}} \tag{2}$$

and

$$\beta_{np} = \frac{[MA_nB_p]}{[M][A]^n[B]^p} \tag{3}$$

In eqn. 1, $P' \leq P$. For simplicity, charges are here omitted, and index "org" refers to the organic phase, while index "aq" or no index refers to the aqueous phase. Brackets indicate concentrations, and it is understood that the equations refer only to experimental conditions, where the activity factors of all species may reasonably be assumed constant; *cf.* Refs.[7,8]

Few solvent extraction studies of the formation of mixed complexes MA_nB_p have been carried out.[3,5] Instead the purpose has generally been to study the formation of complexes either with an inorganic or with an organic ligand, *cf. e.g.* Ref.[9] The conditions are therefore usually chosen so that no mixed complexes are formed, and so that only species of one of the ligands (say A) are extracted into the organic solvent. Under these circumstances eqn. 1 can be reduced to

$$Q = \frac{\lambda_v\beta_v[A]^v}{1 + \sum_{1}^{N} \beta_n[A]^n + \sum_{1}^{P} \beta_p[B]^p} \tag{4}$$

It is always possible to test if eqn. 1 or 4 is valid, *i.e.* if mixed or only simple complexes are formed, by running experiments at various [A] for constant values of [B]; *cf.* Ref.[10]

Here we shall consider only the cases of eqn. 4 when complexes with one type of ligand can be neglected compared to complexes with the other kind of ligand, *i.e.* when $\Sigma\beta_n[A]^n$ is either much greater or much smaller than $\Sigma\beta_p[B]^p$. The experimental conditions can usually be chosen to fit these mathematical conditions. For example, if complexes with an organic ligand A are being studied, B is chosen to be ClO_4^- which is known to have a negligible tendency to form complexes. Or if, for example, an inorganic ligand B is being studied, which does not form extractable complexes with M, the conditions are chosen so that in the absence of B the partition curve log Q *versus*

log [A] has the slope v, which means that complexes with A in the aqueous phase can be neglected, *i.e.* $\Sigma\beta_n[A]^n \ll 1$.

Thus eqn. 4 can be written (choosing $r = 1$),

$$\text{for } \sum \beta_p[B]^p \ll 1, \qquad \frac{[A]^v}{Q} = \frac{1}{\lambda_v\beta_v}\sum_0^N \beta_n[A]^n \tag{5a}$$

Introducing the abbreviations $x = [A]$, $y = 1/Q$, and $a_n = \beta_n/\lambda_v\beta_v$, eqn. 5a can be written

$$y \cdot x^N = \sum_0^N a_n x^n \tag{6a}$$

Similarly, eqn. 4 can be written ($r = s = 1$),

$$\text{for } \sum \beta_n[A]^n \ll 1, \qquad \frac{[A]^v}{Q} = \frac{1}{\lambda_v\beta_v}\sum_0^P \beta_p[B]^p \tag{5b}$$

Introducing the abbreviations $x = [B]$, $z = [A]^v/Q$ and $a_p = \beta_p/\lambda_v\beta_v$, eqn. 5b can be written

$$z = \sum_0^P a_p x^p \tag{6b}$$

We shall for simplicity refer to eqns 5a and 5b as to the equations representing investigations on "extractable" and "non-extractable" complexes, respectively.

Eqns. 6a and 6b are solved by the methods of weighted least squares as outlined in a previous paper [6]. The equations for the "non-extractable" complexes will be further discussed in a later section.

THE WEIGHT OF THE DATA

The weight ω_i for an individual observation i of unit weight is (*cf.*, *e.g.*, Ref.[13])

$$\omega_i = 1/\sigma_i^2 \tag{7}$$

where here a measure of the variance σ_i^2 is to be obtained from a consideration of the errors σ_i encountered in the experimental work. If the weight of all points is changed by multiplying the variances by a constant factor, this does not change the values of the computed parameters nor their standard deviations (*i.e.* $a_n \pm \sigma_{a_n}$, where σ_{a_n} is computed by external consistency), but changes the value of $S_{\min}$, where

$$S_{\min} = \Sigma\omega_i \; V_i^2 \tag{8}$$

V_i is the difference between the measured value of the function and that calculated with the best set of parameters at that point. $S_{\min}$ has the same statistical distribution as χ^2 (see, *e.g.*, Deming [13] or Fisher [14]) with k degrees of freedom; as the weight is defined above, we can put $S_{\min} = \chi^2$. Here, k is the number of observations (L) minus the number of parameters minus 1,

i.e. $k = L-N-1$. When the mathematical model (here eqn. 5) and the weights are consistent with the experimental data, the mean value of χ^2/k will be equal to 1, with a range of $\pm$ 0.5 at the 70 % probability level (*cf.* Ref.[14]).

TYPES OF ERRORS IN SOLVENT EXTRACTION

We will obtain estimates of the weights by considering the random errors encountered in the experimental work. It is assumed that systematic errors are minimized by appropriate methods.

Only three measures of random errors will be considered, namely errors in Q caused by errors in the counting when radiometric methods are used, errors in Q caused by the measuring technique when other methods are used, and errors in Q caused by errors in the determination of the free ligand concentration.

Errors in Q due to radiometric counting, $\sigma_Q(\mathrm{I})$. In radiometric measurements, the partition ratio Q is determined from the specific radioactivities (*i.e.*, counts per min, cpm, for a fixed amount of sample) of the organic and aqueous phases, I_{org} and I_{aq}, respectively; *i.e.*, $Q = I_{org}/I_{aq}$, provided the measuring conditions are equal for the samples from both phases. The corresponding standard deviations σ_{org} and σ_{aq} are obtained from the number of counts measured; if the time of mesurement is t, $\sigma = \sqrt{I/t}$ (*cf.*, *e.g.*, Ref.[11]). Thus we can define

$$\sigma_Q(I) = Q \sqrt{\left(\frac{\sigma_{org}}{I_{org}}\right)^2 + \left(\frac{\sigma_{aq}}{I_{aq}}\right)^2} \tag{9}$$

Constant percentage error in Q, $\sigma_Q(\%)$. When Q is not directly calculated from radioactivity measurements or when the analyses are carried out in so many different steps that it becomes hard to separate the individual errors involved, the error may be estimated from the spread of Q values at constant ligand concentration. This error will be given in P % of the Q value; thus the percentage standard error is

$$\sigma_Q(\%) = PQ \tag{10}$$

Error in Q caused by error in the ligand concentration, $\sigma_Q(A)$ *and* $\sigma_Q(B)$. The equations for the least squares treatment were developed on the basis that [A] and [B] were free of error [6,12]. However, this is not always the case, though these errors can often be neglected compared to the error in the Q measurement. In order to make possible an approximate test of the influence of an error in the free ligand concentration, this error has to be attributed to Q as the present computor program is set up. It is possible to do so, if Q([A]) and ([B]) are known. At the present, we shall only consider the influence of an error σ_A in [A].

A graphical function Q([A]) is obtained from the smooth line through the points of a log Q plot against log [A]. It has been shown [2] that this line can be represented by

$$\frac{\mathrm{d}\ \log\ Q}{\mathrm{d}\ \log[\mathrm{A}]} = \nu - \bar{n} \tag{11}$$

where $\bar{n}$ is the mean ligand number. This equation may be rearranged to give

$$\mathrm{d}\,Q = 2.303\ Q\ (\nu - \bar{n})\ \mathrm{d}\ \log[\mathrm{A}] \qquad (12)$$

If the standard deviation in log [A] is called $\sigma_{\log \mathrm{A}}$, this equation can also be written

$$\sigma_Q(\mathrm{A}) \approx 2.3\ Q\ (\nu - \bar{n})\ \sigma_{\log \mathrm{A}} \qquad (13)$$

provided σ_A is small compared to [A].*

Generally (in practice) $\sigma_Q(\mathrm{A})$ is $\gg \sigma_Q(\mathrm{B})$. When the error in [B] has to be computed, equations similar to those above can be derived for $\sigma_Q(\mathrm{B})$.

COMPUTER PROCEDURE

Two computers of the Applied Mathematics Division of this laboratory were used: the IBM 704 and the GEORGE. While the 704 program was only designed for the so-called "extractable complexes" where $\nu = N$ (eqn. 6a), the GEORGE program is set up to handle both "extractable complexes" and "non-extractable complexes" because of the simpler mathematical form of eqn. 6b. The input and output data of these programs are given in Table 1. Both computors use a floating point decimal system.

When the 704 program is used for non-radiometric data, $I_\mathrm{aq} \pm \sigma_\mathrm{aq}$ is replaced by $1 \pm \sigma_Q/Q$, and $I_\mathrm{org} \pm \sigma_\mathrm{org}$ is replaced by $Q \pm 0$.

The programs are so arranged that when negative parameter values are obtained, they are automatically omitted and the least squares computations are rerun withouth them; however, the computations yielding the negative parameters are always printed out.

The time at the 704 is about 20 seconds for feeding in the program and data cards and carrying out the computations for a regular program, while the printing out may take from less than a minute to several minutes depending on the length of the problem (number of repetitive runs). The GEORGE program, which uses punched tape, is slightly slower than the 704 program.

INVESTIGATION OF AN EXTRACTABLE COMPLEX **

As an example of the use of the least squares procedure on equations 5a and 6a, the Th(IV)-acetylacetone-benzene-0.01 M $NaClO_4$ system (Rydberg [2]) was chosen (see Fig. 1).

Selection of errors. The procedure used in the experimental paper gives directly I_org and I_aq. The standard deviations σ_org and σ_aq are given for some of the measurements; the rest could be obtained from unpublished primary data. From these standard deviations, $\sigma_Q(I)$ can be calculated accord-

* The logarithmic error $\sigma_{\log K}$ of a constant $K \pm \sigma_K$ is equal to $\sigma_K/2.303K$ only for small values of σ_K/K; *e.g.* for $\sigma_K/K = 0.067$, the error in the computed $\sigma_{\log K}$ is 3 %; *cf. e. g.* Ref.[13]

** See definition p. 2059, and eqns 5a and 6a.

Table 1. Input and output data of the IBM 704 and GEORGE programs.

IBM 704, program 495/CHM 104: Equation $x^N I_{aq}/I_{org} = \sum_0^N a_n x^n$.	
Input	Output
$I_{aq} \pm \sigma_{aq}$	x (given x, and $10^{-c_1} \geq x \geq 10^{-c_2}$
$I_{org} \pm \sigma_{org}$	$I_{aq}/I_{org} = y$
x (free ligand concentration, $10^0 > x > 10^{-10}$)	$a_n \pm \sigma_{a_n}$
N (≤ 8)	$\bar{y}$ (y computed with given equation and a_n values above)
L (number of experimental points)	$\sigma_{\bar{y}}$
Θ_n (indicating a_n parameters to be omitted)	χ^2/k
c_1 and c_2 (integer values between 1 and 10 for $c_1 < c_2$)	
GEORGE, program S-3-128: Equation $z = \sum_0^P a_p x^p$	
Input	Output
z (or z' or z'' according to eqn. 18)	$\sum_0^{2P} \omega_i x_i^p = W$, and W^{-1}
ω_z (or corresponding ω_z' and ω_z'')	$\sum_0^P a_p x^p$
x (free ligand concentration)	a_n and σ_{a_n}
P (≤ 10)	$S_{min} = \sum_0^P \omega_i (a_p x_i^p - z_i)^2$
Θ_n (parameters to be omitted)	
L (number of experimental points)	

ing to eqn. 9 (this is not necessary to do in practice when the program is run on the 704 computer; see Table 1).

A constant percentage error was also tested. From the spread of points with approximately identical x_i values (see Fig. 1), a standard deviation of $\pm$ 0.046 log units was estimated. This corresponds approximately to a 10 % error in Q. Thus according to eqn. 10, $\sigma_Q(\%) = 0.10Q$.

The [A] values are calculated from rather accurately known data, except for the pH value; the pH error was assumed [2] to be $\pm$ 0.02. Because all error

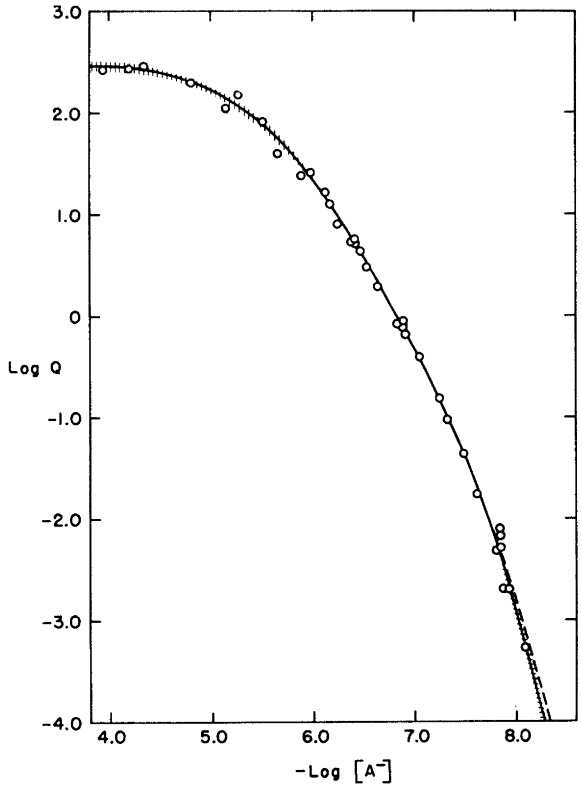

Fig. 1. The Th(IV)-acetylacetone-benzene-0.01 M $NaClO_4$ system. Log Q as a function of $-\log[A^-]$ computed with parameters obtained for a $\sigma_Q(I,A)$ error (solid line) and a $\sigma_Q(\%)$ error (broken line). The shaded area indicates the precision of the computed curve.

in [A] can be attributed to this pH error, we can write $\sigma_{\log A} = \sigma_{pH} = 0.02$. Introducing this into eqn. 13 gives

$$\sigma_Q(A) \approx 0.5\ Q\ (\nu - \bar{n}) \tag{14}$$

The value $\nu - \bar{n}$ is obtained from eqn. 11.

It shall be assumed that $\sigma_Q(A)$ occurs only in combination with the usually much larger $\sigma_Q(I)$. The combined standard deviation in Q is then

$$\sigma_Q(I,A) = \sqrt{(\sigma_Q(I))^2 + (\sigma_Q(A))^2} \tag{15}$$

These standard deviations will be used below to assign weights to the data.

Results of the χ^2 test. When the data were run on the IBM 704 computer, the a_1 values obtained were negative and had standard deviations around or in excess of 100 %. Since negative parameters are of no significance as the equations are derived in this paper, a_1 had to be discarded. Only four para-

Table 2. Computation of χ^2/k for various kinds of errors and various weighing factors in the thorium acetylacetonate system; the left part contains σ_Q (I,A) errors and the right part σ_Q (%) errors.

σ_Q (I)	0.5	1.0	2.0	3.0	4.0	1 σ_Q (%) = est. 10 % error	
σ_Q (A)	χ^2/k	χ^2/k	χ^2/k	χ^2/k	χ^2/k	σ_Q (%)	χ^2/k
0	22.4	5.73	1.43	0.62	0.36	0.5	20.6
0.125	17.9	5.32	1.40	0.63	0.36	1.0	5.14
0.25	12.2	4.82	1.33	0.61	0.35	1.5	2.28
0.50	6.84	3.03	1.12	0.56	0.33	2.0	1.28
0.75	4.61	2.19	0.91	0.50	0.31	2.5	0.82
1.00	3.46	1.69	0.76	0.44	0.28	3.0	0.57

meters (a_0, a_2, a_3 and a_4) were therefore considered in the following. We shall thus assume that eqn. 6a with these four parameters is the correct mathematical model for our experimental data.

The χ^2/k values obtained in the various runs are given in Table 2. The table reveals that the σ_Q(I) value of 1 assumed on the basis of the number of radioactivity counts is too small (*i.e.* χ^2/k is too big, 5.73). The weight should rather correspond to 2 or 3 times σ_Q(I) (*i.e.* $\omega_i = 1/(2 \text{ or } 3 \text{ times } \sigma_Q(\text{I}))^2$), somewhat depending on the correct size of σ_Q(A); a consistent combination is found for 2"σ_Q(I)" and 0.75"σ_Q(A)". These values seem also reasonable from an examination of the original paper; while the pH error may be slightly overestimated, probably the I_{org} and I_{aq} values involve some other errors than the counting errors only; *cf.* Ref.[1]

From Table 2 it is also seen that, if a constant percentage error was justified, it should have been 2.5"σ_Q(%)" rather than 1"σ_Q(%)", where 1σ_Q(%) corresponds to an estimated 10 % error in Q. This can be interpreted as an average 25 % error in the primary Q values, corresponding to $\pm$ 0.11 log units. A reinspection of the points in Fig. 1 does not make such a poor precision in Q improbable.

The equilibrium constants. The parameter values obtained for the various kinds of errors and with different weighing factors are given in Table 3. It is indicated in the table that the parameters and their precisions are unchanged if the errors (here σ_Q(I) and σ_Q(%)) are multiplied by a constant weighing factor. However, there is no constant factor relating the various σ_Q(I,A) errors to each other (see eqn. 15); therefore $a_n \pm \sigma_{a_n}$ varies with these errors, though within a rather limited range. The overlapping of the a_n values illustrates that this is an illconditioned system.

The parameters obtained for the 2"σ_Q(I)"—0.75"σ_Q(A)" combination are given in Table 4, together with the equilibrium constants calculated from the relations

$$k_n = a_n/a_{n-1} \tag{16}$$

and

$$\lambda_\nu = 1/a_\nu \tag{17}$$

Table 3. Parameter values ($a_0 10^{29}$, $a_2 10^{13}$, $a_3 10^7$ and $a_4 10^2$) and χ^2/k (within parenthesis) obtained for the thorium-acetylacetone system when various kinds of standard deviations are multiplied by a constant weighing factor. The upper group corresponds to a counting error only, and the lower group to a percentage error only (parameter values independent of weighing factor), while the twelve central groups represent mixed counting and ligand errors (eqn 15).

σ_Q (%)	.....	0.366 ± 0.070 0.180 ± 0.018 0.259 ± 0.045 0.330 ± 0.047 (1.28 for 20 % error)	.....	

Table 4 also contains the primary constants β_n and ψ_n given in the original paper, where $\psi = \beta_{4-n}/\beta_4$.

The least squares method shows that the experimental data are not accurate enough to provide two separate equilibrium constants k_1 and k_2, which dominate in the lowest Q region. Thus it is not possible from the experimental data to prove the existence of the first complex, MA^{3+}, while the results support the presence of all the other complexes (MA_2^{2+}, MA_3^{+} and MA_4). The computations of separate k_1 and k_2 values in the original paper has been somewhat biased, because of the reasonable chemical assumption that all stepwise complexes should exist. The k_1 and k_2 values of the ligand number and limiting value methods are therefore given within parenthesis in Table 4.

Table 4. Parameters and equilibrium constants for the thorium acetylacetonate system.

Least square method		Ligand number method [2]		Limiting value method [2]	
Primary parameters	Equilibrium constants	Primary parameters	Equilibrium constants	Primary parameters	Equilibrium constants
$a_0\ 10^{30} = 4.89 \pm 0.93$	$\log k_1k_2 = 15.57 \pm 0.08$	$\beta_1\ 10^{-8} = 1.42$	$(\log k_1 = 8.15)$	$\psi_1\ 10^5 = 1.0 \pm 0.1$	$(\log k_1 = 7.82 \pm 0.16)$
		$\beta_2\ 10^{-15} = 3.80$	$(\log k_2 = 7.43)$	$\psi_2\ 10^{12} = 5.4 \pm 0.3$	$(\log k_2 = 7.73 \pm 0.09)$
$a_2\ 10^{14} = 1.81 \pm 0.07$	$\log k_3 = 6.15 \pm 0.04$	$\beta_3\ 10^{-21} = 9.83$	$\log k_3 = 6.41$	$\psi_3\ 10^{19} = 1.0 \pm 0.2$	$\log k_3 = 6.27 \pm 0.05$
$a_3\ 10^8 = 2.53 \pm 0.22$	$\log k_4 = 5.14 \pm 0.07$	$\beta_4\ 10^{-26} = 8.70$	$\log k_4 = 4.95$	$\psi_4\ 10^{27} = 1.5 \pm 0.5$	$\log k_4 = 5.00 \pm 0.04$
$a_4\ 10^3 = 3.41 \pm 0.45$	$\log \lambda_4$* $= 2.48 \pm 0.06$	$\lambda_4 = 330 \pm 30$	$\log \lambda_4 = 2.52 \pm 0.04$	$\lambda_4 = 330 \pm 30$	$\log \lambda_4 = 2.52 \pm 0.04$

* The λ_4 value is corrected in the same manner as in ref.[2] because of the measuring technique.

From Table 4 it is seen that if only the numerical values of the constants are considered (*e.g.* comparing log k_1k_2 of the least squares method with the log k_1 + log k_2 given with the other methods), the values of the different methods agree well.

Fig. 1 shows the primary data and two curves passing through the points. The solid curve is computed with parameters obtained with the σ_Q(I,A) error, and the dashed curve is computed with the parameters of the σ_Q(%) error (parameters found in Table 3). The shaded band indicates the standard deviations in the computed Q values due to the σ_{a_n} error. Approximately the same precision is obtained with the computations based on the σ_Q(%) error, as expected from the approximately identical σ_{a_n}/a_n values (see Table 3) for the two kinds or errors.

INVESTIGATION OF NON-EXTRACTABLE COMPLEXES *

The complex formation between Zr(IV) and F^- and HSO_4^- in 2 M H^+ are chosen as examples (Connick and McVey [1]) of investigations of inorganic systems, *i.e.* where $\Sigma\beta_n[A]^n \ll 1$ in eqn. 4.

Development of suitable equations. In this case eqns 5b and 6b are valid, because complexes formed between Zr(IV) and ligands other than F^- and HSO_4^- in the aqueous phase are neglected [1]. The organic phase (benzene) is supposed to contain only the organic ligand thenoyltrifluoroacetone (HTTA), and its extractable $Zr(TTA)_4$ complex. It can be found that at constant hydrogen ion concentration, $[TTA^-]$ = const. $[HTTA]_{org}$. Eqn. 5b can be written

$$z' = \left(\frac{[HTTA]^4}{Q}\right)_{[H]} = \frac{1}{Q'} = \frac{1}{Q'_0}\sum_{p=0}^{P}\beta_p[B]^p, \qquad (18a)$$

where $[B] = [F^-]$ or $[HSO_4^-]$. Q' is sometimes called the normalized distribution ratio. Since $\beta_0 = 1$, it follows that at $[B] = 0$, $Q' = Q'_0$, *i.e.* Q'_0 is the normalized distribution ratio in the absence of any complexing inorganic ligand. Eqn. 18a can easily be rearranged to

$$z'' = \frac{Q'_0 - Q'}{Q'\,[B]} = \beta_1 + \beta_2[B] + \beta_3[B]^2 + \ldots \qquad (18b)$$

which shall be used below in the F^- case.

Preparing the data for the computer; selection of errors. Eqns 18a and 18b can be solved by the least squares method using the GEORGE program. The parameters computed for z' will be $a_p = \beta_p/Q'_0$, and for the z'' data $a_p = \beta_{p+1}$ for $0 \leq p \leq P$. In both cases it is assumed that only z contains errors. If the standard deviations corresponding to z' and z'' are called σ' and σ'', it can readily be shown that

* See definition p. 2059, and eqns 5b and 6b.

$$\sigma' = P/Q' \tag{19a}$$

$$\sigma'' = \sqrt{2}\left(\frac{PQ_0'}{Q'\,x}\right) \tag{19b}$$

where P is the percentage error in Q' and Q_0' (assumed to be identical). With these standard deviations the weights are computed according to eqn. 7 for known P values.

The standard deviations in Q can be estimated from the experimental data to be about 4.2 % (using the 5 points on the line in Fig. 1 and in Table 1 of Ref.[1]). Thus we have $P = 0.042$.

Results on the Zr(IV)-HSO_4^--system. This system was tested according to eqns 18a and 19a. For $P > 3$, the higher parameters turned out negative or with standard errors over 100 %; thus it could be established that only three complexes between Zr(IV) and HSO_4^- had to be considered.

Using the primary data and the equations to compute Q' from them (eqn. 17 in Ref.[1])* four positive parameters were obtained, from which the three constants β_1, β_2 and β_3 were calculated. With the 4.2 % standard deviation, χ^2/k is 1.00, demonstrating consistency with the estimates from the primary data.

The equilibrium constants k_1, k_2 and k_3 are given in Table 5, together with Connick and McVey's original results. The agreement is found to be quite good.

Results on the Zr(IV)-F^--system. This system was investigated using eqns 18b and 19b. (The Q_0' value was taken from Table III in Ref.[1]) With the data run on GEORGE, three positive parameters β_1, β_2 and β_3 were obtain-

* There seems to be some inconsistency between the primary data and E_0' in Table III of Ref.[1]

Table 5. Equilibrium constants and their precision for the Zr(IV)-HSO_4^- and -F^- complexes investigated by extraction of the $Zr(TTA)_4$ complex into benzene [1]. Constant ionic media: 2 M $HClO_4$ at 25°C.

Ligand	Equilibrium constants			Reference
	k_1	k_2	k_3	
HSO_4^-	460	53 ± 4 *	$1^{+1}_{-0.5}$ *	Connick and McVey
»	431 ± 30 ***	54 ± 7 ***	0.83 ± 0.43 ***	This work
F^-	$(6.3 \pm 0.6)\ 10^5$**	$(2.1 \pm 0.2)\ 10^4$**	$(6.7 \pm 2.0)\ 10^2$**	Connick and McVey
»	$(6.30 \pm 0.52)\ 10^5$	$(1.94 \pm 0.22)\ 10^4$	$(7.5 \pm 1.1)\ 10^2$	This work

* Standard deviation in k_2 is estimated [1] to 8 %, and in k_3 to plus or minus a factor of 2

** Standard deviations in k_1 and k_2 is estimated to 10 %, and in k_3 to 30 %.[1]

*** Computed with E_c^0 from E_c, γ and $(HK)_b$ according to eqn. 17 in Ref.[1]

ed. In order to obtain $\chi^2/k = 1.00$, the standard deviation in Q' and Q_0' has to be 6.3 %. Thus, in this case, the original estimate of 4.2 % was somewhat too small.

The equilibrium constants are given in Table 5; they are seen to agree well with those given in the original paper. Particularly impressive is the good graphical estimates of standard deviations in the equilibrium constants made by the original authors.

Using the equilibrium constants computed with the least squares methods, Q' can be calculated as a function of the free ligand concentration, and the curves thus obtained may be compared with the corresponding curves in the original paper. The curves for both the F^- and HSO_4^- systems were found to coincide over the investigated range with the curves given in the original paper.

Acknowledgement. We wish to express our appreciation to Dr. W. Miller, Mr. W. Greenhow and Mrs. M. Hanson of the Applied Mathematics Division, Drs. J. C. Hindman and A. Zielen of the Chemistry Division, for the valuable assistance rendered to us in this investigation.

Synthesis of Uracil-2, 4, 5, 6-^{14}C with High Specific Activity

Studies in Microsynthesis I

GÖSTA EHRENSVÄRD and JAN LILJEKVIST

Institute of Biochemistry, University of Lund, Lund, Sweden

A method for preparing 2, 4, 5, 6-^{14}C-uracil in small scale from $BaCO_3$-^{14}C of highest possible specific activity is presented. The synthesis is carried out in the 100 μmole range giving a total yield of 10 % of 2, 4, 5, 6-^{14}C-uracil the activity of wich being unchanged from that of the starting material. The technique used may find applications in other fields of organic micro-synthesis.

In the course of an investigation on the chemical and biochemical effects of nuclear decay of some atom species incorporated into the molecular structure of organic compounds it was found necessary to develop procedures for multistep synthesis in the 25—250 μmole range. A special problem has been to synthesize uracil and thymine with a maximal ^{14}C activity (round 100 μC/μmole) in order to study the consequences of the decay of 5-^{131}I-uracil, and the overall effects of the $^{14}C \rightarrow {}^{14}N$ transition [1]. The starting material has been barium carbonate with an activity of 24.75 μC/μmole and the synthesis achieved according to the scheme in Table 1.

Each of the above conventional steps (for references see Table 1) has been modified to enable work in the 100 μmole range. The present procedure, as described below, gives a total yield of uracil from barium carbonate of 10 % with no dilution of the ^{14}C-activity. Of the different single steps the preparation of barium carbide has been considerably simplified, enabling the reduction of the barium carbonate with metallic barium to be carried out without the presence of helium [2]. Step *f*, the hydrolysis of 1,2-dibromovinyl-ethyl-ether to bromoacetic acid [5,6] was considerably difficult to run in small scale until a suitable closed micro vessel was employed. Step *l* involving the hydrogenation of cyanoacetylurea to uracil was found to give very poor yield as carried out according to the original procedure of Rupe *et al* [16]. In acetate buffer of pH 4.15, however, the yield was consistently 45 %.

As regards the technical aspect of the present work the aim has been to keep the number of transfers as low as possible. Reaction $c \rightarrow l$ are thus carried

out in the same reaction vessel, the construction of which enabling amount of solutions of around 500 μl to be effectively closed off, thus avoiding procedures involving heating under reflux. With regard to the latter, we have found that any reflux procedure in the 100 μmole range especially in the case of a two-phase system, involve considerable losses, and should be replaced with closed space procedures. The reaction vessel employed (see Fig. 1) could act as a micro-autoclave, standing a pressure up to 3 atm., as a microhydrogenation vessel, and as a centrifuge tube.

EXPERIMENTAL

Barium carbide-^{14}C. 49.3 mg barium carbonate (250 μmole, spec. act. 24.75 μC/μmole) was weighed on a small aluminum foil (weight about 50 mg) and a lump of ether washed barium metal, corresponding to the double theoretical amount was added. The foil was wrapped around the reactants to form a small pellet, which was put in a 4 ml Pyrex test tube. The tube was heated with a burner to red heat. The reaction was complete in a few seconds and the tube was allowed to cool. The tip containing the reaction mixture was broken off and crushed to a fine powder in a diamond mortar. This powder was used directly for preparing acetylene.

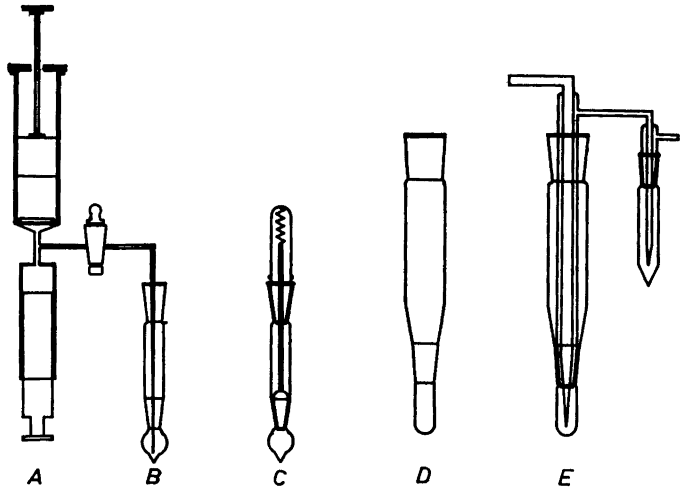

Fig. 1. Gas generator and reaction vessel for small-scale synthesis.

The gas generator A consist of two connected ordinary all-glass syringes, one holding 25 ml, the other 10 ml. In the bottom part of the upper, larger syringe a close-fitting porcellain filter plate is placed, covered with a filter paper disc, cut to exact size. Lubricants were avoided; the stopcock of the assembly was of non-lubricated Teflon-type. The arrangement permits a quantitative generation of acetylene from barium carbide in a closed system, see text.

The receiver tube B fulfills a multiple function as reaction vessel, autoclave and centrifuge tube. The bottom compartment with a volyme of 1 000 μl can be closed off by fitting a stopper into the lower joint, the shaft of the stopper extending 1 cm above the top opening of the vessel. Stopper and joint could be of standard B5- or B7-type, carefully ground. The upper joint of the vessel, a B 10, is closed with a ground stopper, containing a spring housed in the top part, thus enabling the exertion of a pressure upon the shaft of the lower stopper. The tube and its upper stopper are held together with a clip for spherical joints. By this means the small 1 000 μl compartment could act as a micro-autoclave standing a pressure up to 3 atm. Hydrogenation is likewise easy to carry out by connection the vessel to a hydrogen tank *via* an arrangement enabling the flushing out of air. Centrifugation could be carried out in a swing-out head centrifuge at 1 000 $\times$ *g*.

Sodium cyanide-^{14}C was prepared from barium carbonate by a modification of the procedure of Jeanes [11]. After 2.5 hours heating of an intimate mixture of barium carbonate 39.4 mg, metallic sodium 40 mg and zink powder 200 mg in a porcelain combustion boat housed in a quartz tube in ammonia atmosphere, the contents are worked up as follows. The porcelain boat was transferred to a distillation unit, 5 ml 20 % perchloric acid added and 10 ml of distillate collected in 240 μl 1 N sodium hydroxide in a receiver vessel. The solution was now divided into two equal parts and transferred to two vessels of the type shown in Fig. 1 D. The alkaline solution was titrated with 0.1 N silver nitrate solution to a faint turbidity thus enabling a quantitative estimation of the yield of cyanide. Then 250 mg sodium hydrogen carbonate was added and the silver cyanide was precipitated by addition of an equal amount of 1 N silver nitrate solution as titrated before. The silver cyanide was centrifuged off into the smaller compartment of the vessel. After washing with water and acetone, twice with each, the dry silver cyanide samples could be stored for further working up to sodium cyanide.

The conversion of silver cyanide into sodium cyanide was accomplished by inserting into the lower joint a unit (see Fig. 1 E) enabling the sweeping out of hydrogen cyanide with nitrogen. 400 μl 1 N hydrochloric acid was added above the now closed lower joint and the stream of nitrogen accordingly adjusted. After a momentary lifting of the cone,

the hydrochloric acid was allowed to react with silver cyanide. The hydrogen cyanide swept out is absorbed in 120 μl 1 N sodium hydroxide thus yielding a concentrated solution of sodium cyanide, to be immediately utilized whether for making cyanoacetic acid or urea. The time for sweeping out the hydrogen cyanide could be kept as low as 15 min by occasional gentle heating of the reaction mixture. A yield of more than 90 % of concentrated sodium cyanide solution from barium carbonate is obtained.

Urea-^{14}C. The concentrated sodium cyanide solution (120 μl) prepared as above was transferred to a 4 ml centrifuge tube containing freshly prepared copper hydroxide (precipitated from 13.10 mg cryst. copper sulphate). The mixture was cooled in an ice bath and the cyanide was oxidized to cyanate by the dropwise addition of a potassium permanganate solution (12.18 mg in 400 μl of water), excess being destroyed with hydrogen peroxide. After the manganese dioxide formed was separated off by centrifugation and washed three times with water the supernatants were combined and transferred to reaction vessel C (see Fig. 1) and evaporated to round 200 μl *in vacuo*. After addition of 13.2 mg ammonium sulphate and 50 μl concentrated aqueous ammonia the tube was immediately closed off as shown in Fig. 1 C and heated under gentle shaking at 70° for 40 min. The tube was allowed to cool, opened and the contents evaporated to dryness *in vacuo*. The dry residue was extracted 4 times with *n*-butanol with shaking at 70° for 20 min each time. The extracts were evaporated *in vacuo* to dryness at 50°. The dry urea was taken up in 50 μl of water immediately before its further conversion to cyanoacetyl-urea (see below).

Bromoacetic acid- 1,2-^{14}C from barium carbide-^{14}C. The smaller syringe of the plunger arrangement (see Fig. 1, A, B) was separately filled with 4 ml of 1 N hydrochloric acid and attached to the T-tube, carefully avoiding any entrance of the acid into the system. The stopcock should at this stage be open. Freshly prepared barium carbide from 49.3 mg of barium carbonate was carefully deposited on the filter paper at the bottom part of the 25 ml syringe. The plunger was put in place as tightly to the bottom as possible. After this the stopcock is closed, the small vessel B is charged with 100 μl of bromine and 100 μl of water and is attached to the rest of the assembly, so that the capillary outlet safely dips under the surface of the bromine. The plunger of the acid-filled syringe is now slowly pressed up allowing not more acid than to moisten the filter paper disc into the 25 ml syringe, thus starting the reaction. When the gas evolution has started the plunger of the lower syringe is manipulated downwards thereby sucking back most of the acid from the upper system. Excess pressure caused by occasional friction of the plunger is to be avoided. The stopcock is now cautiously opened enabling the gas to pass through the bromine at round 1 bubble per second. Conveniently the upper plunger could now be pressed down with a micrometer screw. When all gas is driven out of the system a small amount of acid is again allowed into the upper compartment — the stopcock being closed at this stage — and the procedure being repeated until no more gas is evolved.

The reaction vessel D, now containing *1, 1, 2, 2, -tetrabromoethane* plus excess bromine and water is centrifuged for a few minutes enabling all droplets of the reaction procedure to collect in the tip. 100 μl of concentrated formic acid is added [17], the mixture gently heated at the water bath to 60° until decolorization, cooled to 10° and recentrifuged. The water solution above the tetrabromoethane droplet is carefully sucked away with a capillary pipette as complete as possible; the remainder of water is removed by storing the open tube over phosphorus pentoxide in a desiccator over night at ordinary pressure.

To the reaction vessel, now containing around 15 μl of dry 1,1,2,2,-tetrabromoethane, 150 μl of a sodium ethoxide solution (50 mg of sodium per 1 000 μl of ethanol) is added, corresponding to 315 μ-atomes of sodium. The bottom part of the reaction vessel is then closed with the stopper arrangement (see Fig. 1) and the content heated to 60° in a small oilbath under shaking (a "Microid flask shaker" is used throughout). After 1 h the vessel is allowed to cool off, is opened and 300 μl of water added. After centrifugation for 10 min a droplet slightly colored, has separated out, representing mainly *1,2-dibromovinyl-ethyl ether*. A check should be made that actually all oil is separated from the alcohol-water supernatant by adding around 50 μl of additional water. In case of cloudiness the vessel should be recentrifuged. The supernatant alcohol-water solution is now removed as complete as possible with a capillary pipette, 300 μl of water added, and the vessel closed again and heated in an oilbath under shaking at 110° for 1 h. At this stage the dibromovinyl-ethyl ether has become completely hydrolysed; no cloudiness should appear upon cooling of the content of the tube. This solution represents *bromoacetic acid-1,2-^{14}C*.

Uracil-2,4,5,6-^{14}C from bromoacetic acid-1,2,-^{14}C. The acid solution containing the bromoacetic acid-1,2-^{14}C is now titrated under gentle shaking with 1 N sodium hydroxide, using an Agla micro-syringe with a fine glass capillary entering the solution, thymol blue being used as an indicator. As an average of 20 experiments 120 μl of 1 N sodium hydroxide solution is required for neutralization. 120 μl of the concentrated sodium cyanide solution prepared as above is now added, the vessel closed and heated for 20 min in an oilbath at 100°. After cooling, the vessel is opened, 150 μl of 1 N hydrochloric acid added and the content evaporated to dryness. This procedure is carried out by attaching the vessel *via* the upper joint to a B 10 male joint, connected by a flexible arrangement to a water aspirator pump. During the evaporation procedure the vessel is vigorously shaken and heated to 30°; at sufficient shaking frequency splashing is prevented. A pilot test of this procedure is recommended. To the dry residue, now representing *cyanoacetic acid-1,2,3-^{14}C* plus salts 15 μl of a water solution of urea prepared as above is added with a micro pipett followed by the addition of 500 μl of acetic anhydride. The solids are suspended in the anhydride and the mixture now heated to 60° for 20 min under gentle shaking; the vessel could at this stage be open. After cooling down the content is evaporated to dryness, as previously described, yet at 50°. The dry residue representing *cyanoacetylurea*, plus salts, is dissolved in 500 μl of sodium acetate buffer pH 4.15 ionic strength 0.1 and approximately 20 mg of Raney nickel (calculated dry weight) is added as a thick paste from an ordinary alcoholic suspension. The upper joint of the reaction vessel is safely connected to a hydrogen tank *via* an arrangement enabling the flushing out of air by intermittent suction and application of hydrogen. The subsequent hydrogenation of cyanoacetyl urea is carried out at a hydrogen pressure of 2.5 atm under vigorous shaking at 65° during 1 h. After release of the hydrogen pressure the reaction vessel is centrifuged and the supernatant is withdrawn with a micro pipett from the catalyst, the latter washed once with 100 μl of water and again centrifuged. The combined solutions are chromatographed on a 23 cm wide strip of Whatman 3 MM paper, the solvent system being methylethylketone-acetone-water-formic acid (100 %) 80:4:12:2 (Reio [17]). R_F for uracil in this system is 0.25; for localization of the compound the paper was photographed after drying in UV-light. After repeated elution of the uracil-containing paper region with a solution of acetone-1 N hydrochloric acid 4:1, totally 40 ml, the evaporated eluate was rechromatographed and again eluted in the same way. Careful evaporation to dryness gives a residue of *uracil-2,4,5,6-^{14}C*, the purity of which was checked by its UV-absorption curve. Yield of uracil from barium carbonate was 10 % with a specific activity of around 100 μC per μmole.

Multiplicity in the Interpretation of Linear Kinetics *

ERIK JØRGENSEN and JANNIK BJERRUM

The Royal Danish School of Pharmacy, and Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Spectrophotometric investigations of multicomponent linear kinetics may lead to several possible interpretations when the spectra of the intermediates are unknown. This is illustrated for an investigation by Schläfer *et al.*[1] on the acidic aquation of the tris(ethylenediamine) to the *cis*-diaquobis(ethylenediamine)chromium(III) ion *via* an unknown intermediate.

Schläfer *et al.* consider only one of the two existing possibilities, *viz.* the one according to which the intermediate should exist in dominating amounts, and have approximately the same spectrum as the luteo ion. However, we are able to show that the other existing possibility, according to which the intermediate is found only in relatively small amounts, is the more probable in view of our results [2] on the aquation of the corresponding hexammine chromium ion and the requirements which the experiments place on the spectrum of the intermediate. This interpretation is further substantiated by Schläfer *et al.*'s experiments [3] on the racemization of the optically active luteo ion.

In our opinion the intermediate which is formed in acidic solution is simply an aquopentammine ion, $Cr\,en_2(enH)H_2O^{++++}$, stabilized by the uptake of a hydrogen ion on the displaced amino group.

It has long been recognized that a system of first order partial reactions leads to a rate expression which is linear in exponential functions [4]. Several authors [5-7] have discussed such systems and one of the present authors has introduced non-orthogonal matrices for the treatment of data additively composed of the properties of the various species [8].

The experimental data may be analyzed into a number of exponential functions, but the fixing of the proper sequence of the exponential coefficients requires additional information.

In a kinetic system of n components the time-dependence of the total property $U = \tilde{\boldsymbol{u}}\,\boldsymbol{x}$, where $\boldsymbol{u}$ is the property vector and $\boldsymbol{x}$ a concentration vector, can be described by

$$U = \tilde{\boldsymbol{u}}\lambda\{\exp(-\lambda_1 t),\exp(-\lambda_2 t), \ldots,\exp(-\lambda_{n-1} t),1\} \qquad (1)$$

* Presented in part at the International Conference on Coordination Chemistry, London 1959.

where $\boldsymbol{u}_\lambda$ is the coefficient vector. The exponential coefficients λ_i may be arranged in several different ways in relation to the reaction paths involved. Each arrangement leads to a requirement for the properties of the species, unique only for consecutive, irreversible reactions. In this case $(n-1)!$ sets of properties, $\boldsymbol{u}$, form the possibilities, and as there is only one proper sequence a choice must be made. The relationship between the property vector, $\boldsymbol{u}$, and the coefficient vector, $\boldsymbol{u}_\lambda$, is given by the previously derived expression [8]

$$\boldsymbol{u} = (x_1^0)^{-1}\widetilde{P}\boldsymbol{u}_\lambda \tag{2}$$

where x_1^0 is the initial concentration of the first component, and P a matrix constructed for the purpose.

The occasion for this paper is a discussion by Schläfer and Kling [1] on the properties of an intermediate shown to be formed as the first reaction product in the acidic hydrolysis of the tris(ethylenediamine)chromium(III) ion. Their discussion is based on the assumption that the spectrum of the intermediate which according to their calculations is formed in relatively high concentrations (up to $\sim$ 80 %) is very close to the spectrum of the luteo ion. For this reason they are forced to make improbable conclusions regarding the constitution of the intermediate. We have therefore reconsidered Schläfer's measurements with a view to an alternative explanation.

According to Schläfer and Kling, the family of spectral curves shows common isosbestic points and the liberation of one ethylenediamine molecule from the tris(ethylenediamine) chromium ion to be the first distinct step. The values of the rate constant calculated with this assumption show, however, a marked dependence on the progression of the aquation. Therefore, the reaction mechanism is proposed to be the following:

$$\mathrm{A} \xrightarrow{k_1} \mathrm{X} \xrightarrow{k_2} \mathrm{B}$$

where the consecutive rate constants are denoted by k_1 and k_2. A stands for the tris(ethylenediamine)chromium ion, and B for the *cis*-diaquobis(ethylenediamine) chromium ion, while X is the unknown intermediate.

Instead of the proper expression for the dependence of the optical density, E_t, on time, t, Schläfer and Kling use a pseudo-zero order rate law as a working hypothesis. In our opinion this is an incorrect simplification. Therefore, we have found it necessary to recalculate their data in terms of exponential functions. We have attempted to get the best representation of the data using (1) in the form

$$E_t = a_0 + a_1\exp(-k_1t) + a_2\exp(-k_2t) \tag{3}$$

where the coefficients a_0, a_1 and a_2 are constants for each wavelength.

Table 1 contains in the first column the time in hours. In the second column are given Schläfer and Kling's experimental values for the optical densities, E_t, with the corresponding uncertainties. In the third column are given the values calculated from Schläfer's linear representations and the deviations from the experimental results. Similarly, the fourth column contains the values calculated from our linear combinations of exponential functions. It is seen

that our theoretical formulae with only one significant figure in the rate constants fit the experimental material at least as well as Schläfer and Kling's linear approximations. As the reaction proceeds, a further aquation of the reaction products takes place. Consequently, we have disregarded all points past 63 h as being influenced by this further aquation.

It is now possible to calculate the spectrum of the intermediate by means of the numerical values of a_0, a_1 and a_2 in (3). Depending upon the choice of k_1 and k_2 between the rate constants, 0.06 and 0.008 h^{-1}, we get two different

Table 1. Optical density, E_t, of 0.01 M tris(ethylenediamine) chromium(III) ion in 0.1 M $HClO_4$ as a function of time at 30°C. Experimental values and values calculated from Schläfer's linear representation (S) and from our sets of exponential functions (J).

spectra by insertion in (2), which takes on a very simple form in the present case. It corresponds to the second example of our previous paper [8].

With the terms of eqn (3) the molar extinction coefficients, ε, are the following:

$$\varepsilon_A = 100(a_0 + a_1 + a_2)$$
$$\varepsilon_B = 100a_0$$
$$\varepsilon_X = 100(a_0 + a_2(k_1-k_2)/k_1)$$

The calculated values of ε_x at the three wavelengths examined by Schläfer and Kling are given in Table 2 and plotted in Fig. 1, which also gives the spectra of the tris(ethylenediamine) ion (A) and the *cis*-diaquobis (ethylenediamine)chromium ion (B). If the suggestion of Schläfer and Kling, *viz.* $k_1 > k_2$ is correct, one would expect a spectrum of the intermediate nearly identical with that of the luteo ion. However, if on the other hand $k_1 < k_2$, nothing need to be said *a priori* about the absorption spectrum of the intermediate. In the latter case the intermediate compound also accumulates to a much smaller extent so the requirement is less rigorous. $k_1 = 0.06$ and $k_2 = 0.008$ h^{-1} leads to a maximum amount of 73 % of the intermediate while the other sequence only involves 10 %.

Table 2. Molar extinction coefficients for the tris(ethylenediamine) chromium ion (A), the cis-diaquobis(ethylenediamine) chromium ion (B) and for the unknown intermediate (X).

wavelength		340 mμ	390 mμ	440 mμ
ε_A		50.7	13.7	63.1
ε_X	$k_1 > k_2$	47.8	15.4	60.3
	$k_1 < k_2$	29.1	26.1	42.0
ε_B		17.4	26.1	25.1

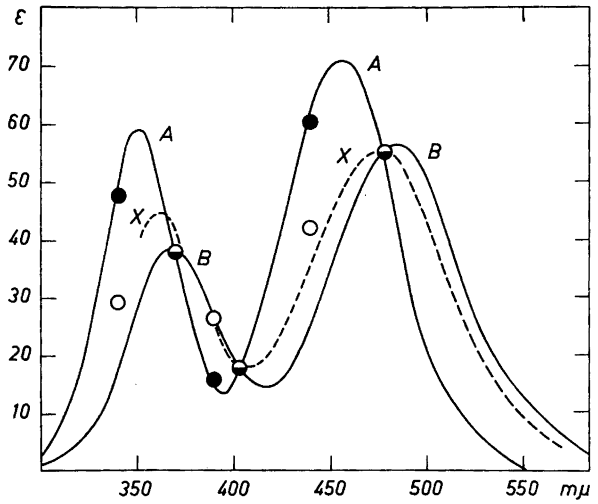

Fig. 1. The spectra of the tris(ethylenediamine) and the *cis*-diaquobis (ethylenediamine) chromium(III) ions (curves A and B) in 0.1 M $HClO_4$ according to Schläfer and Kling[1]. The dashed curve is an estimate of the spectrum of the intermediate complex (X) based on the similarity with the ammine complexes in Fig. 2.

○ — calculated molar extinction coefficient of X in the case $k_1 < k_2$.
● — calculated molar extinction coefficient of X in the case $k_1 > k_2$.

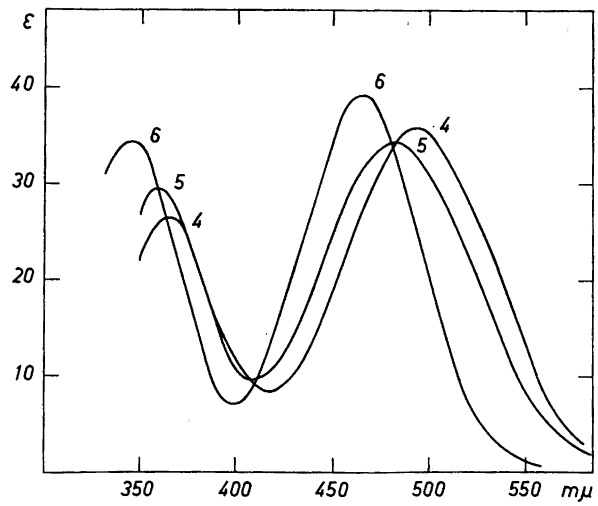

Fig. 2. The spectra of the hexammine, aquopentammine and diaquotetrammine chromium(III) ions (curves 6, 5 and 4) in acidic solution according to Jørgensen and Bjerrum [2].

In our investigation of the aquation of chromium(III) ammines [2] we found at 40°C for the rate constants of the hexammine and aquopentammine the values 0.0051 and 0.085 h^{-1}, respectively. Properly corrected for the difference in temperature (a conversion factor of 0.25) the values directly comparable with the present rate constants, 0.006 and 0.08 h^{-1}, are 0.0013 and 0.021 h^{-1}, respectively.

It is interesting to note that the tris(ethylenediamine) complex reacts more rapidly than the corresponding hexammine ion. The activation energies are 24.3 and 26.0 kcal, respectively. This suggests a considerable tension in the chelate ring, and makes it probable that the first step is simply an opening of the ring followed by the uptake of a proton. Professor R. G. Inskeep * has shown that the rate of aquation of the tris(ethylenediamine)chromium ion is practically independent of the hydrogen ion concentration in the range from 0.1 to 1 M $HClO_4$. Furthermore it is remarkable that the hexammine chromium(III) ion aquates 16 times slower than the aquopentammine chromium(III) ion, and most probably this evidence can be taken as a support for the case $k_1 < k_2$. It is, however, still more indicative to compare the requirements placed on the spectrum of the intermediate with the spectrum actually found in the ammonia system. The spectra of the hexammine (6), aquopentammine (5) and diaquotetrammine (4) chromium ions are shown in Fig. 2. The shape and the position of the spectra of the hexammine and the tetrammine chromium ions are well known to be very similar to those of the tris(ethylenediamine) and bis(ethylenediamine) chromium ions. This argument applied to the spectrum of the pentammine chromium ion would predict a spectrum for the corresponding complex in the ethylenediamine system as outlined in Fig. 1 (the dashed curve). This curve is seen to fit quite well to the points calculated for the sequence of rate constants assumed by us. At the wavelength, 390 mμ, one of the exponential terms in (3) vanishes (see Table 1). Here, X and B seem to have an isosbestic point (see Table 2).

The existence of the pentammine as intermediate is further proved by Schläfer and Seidel's [3] investigations on the racemization of the active luteo ion. The rate-determining constant, 0.00814 h^{-1}, is equal to the slow one found in the hydrolysis reaction, and the peculiar irregularity in the beginning of the experiment points towards two steps with reaction probabilities of approximately 1 h^{-1}. In Schläfer's interpretation, one of these fast reactions must be due to the racemization of the luteo ion, and the slow rate-determining step is the racemization of the never isolated intermediate through aquation. Our interpretation places the slow racemization on the aquation of the luteo ion, while the partially hydrolyzed species racemize fast. This is in agreement with the fact that the luteo ion can only racemize through intramolecular rearrangement while the lower complexes have the possibility of racemization through water exchange.

Thus it seems to us that it has been possible unequivocally to correlate the experimental facts with the assumption that the first reaction product in the hydrolysis of the tris(ethylenediamine) chromium ion in acidic solution

* Guest at Chemistry Department A on sabbatical leave from University of Vermont, Vermont, U.S.A.

is an aquopentammine ion, Cr $en_2(enH)H_2O^{++++}$, stabilized by the uptake of a hydrogen ion on the displaced amino group.

Determination of Oxygen in Silver-Copper and Gold-Silver-Copper Alloys by Hydrogen Reduction

EINAR JACOBSEN*

Central Institute for Industrial Research, Blindern, Norway

A simple apparatus for determination of oxygen in silver and gold is described. The method is based upon the determination of the water formed by reduction of the oxide in the sample with hydrogen gas. In a 1 g sample oxygen contents from 0.0001 to 0.1 % can be determined within 30 min. The apparatus has been used at the Central Institute for Industrial Research, Blindern, Norway, for more than a year with excellent results.

Oxygen in metals is usually determined by the vacuum-fusion method. Since silver is volatile at the temperatures required in this method and because of the cost of such elaborate systems, a more simple method would be desirable. In certain non-ferrous metals, oxygen can be determined by a method based upon reduction with hydrogen. In this method the sample is heated in hydrogen, which reacts with any oxygen present in the sample to form water. The water-vapour formed is either absorbed and weighed [1,2] or condensed in a trap and subsequently vaporized in an otherwise evacuated system [3-7]. The determination of oxide in the sample has also been performed by measuring the hydrogen gas consumed in the above reaction [8].

In the present work samples containing only a few ppm of oxygen were to be analysed, and an extremely accurate apparatus had to be constructed. The present communication describes an apparatus based upon hydrogen reduction, by which as little as 1 ppm of oxygen can be determined within 30 min. The apparatus is somewhat similar in construction to those by Baker [6] and Nitsche [7]. It is modified in several respects, however, in order to increase the accuracy and speed of the analysis.

* Present address: Kjemisk institutt A, Universitetet i Oslo, Blindern, Norway.

DESCRIPTION OF APPARATUS

A schematic diagram of the apparatus is shown in Fig. 1. Hydrogen is taken from a cylinder and purified by passing through a Deoxo catalytic purifier (Baker platinum division, London) (A in Fig. 1) in which oxygen is reduced to water. It is then dried in a 800 ml flask (C) containing phosphorus pentoxide. 800 ml of hydrogen is sufficient for one day's analyses and this amount can be dried completely overnight in the flask. A mercury valve (B) between the Deoxo purifier and the reservoir prevents air from entering the apparatus during the filling of the reservoir.

The combustion unit consists of a clear silica tube (D) with a B 19 male joint in one end. The joint fits to a female joint in the apparatus and is held securely in place by a spring clamp. The quartz tube (14 mm bore and an overall length of 40 cm) is heated by means of a small furnace, consisting of a Mullite tube wound with 0.9 mm Kanthal A-1 wire (E).

The temperature was controlled by means of a Variac and measured with with a chromel-alumel thermocouple (F) placed in the constricted end of the Mullite tube. By appropriate adjustment of the Variac, any desired tempera ture between 20 and 1 000°C could be obtained in less than 5 min. The silica

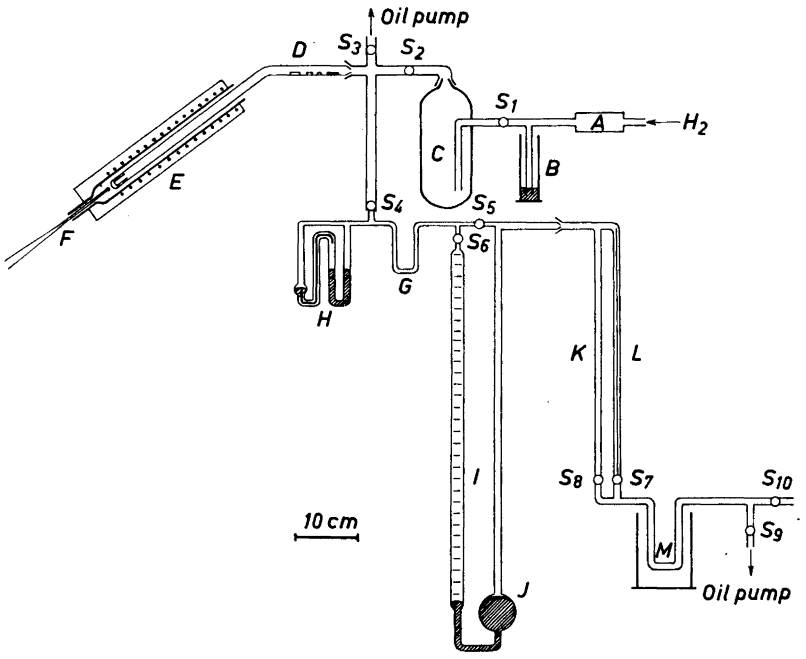

Fig. 1. Schematic diagram of apparatus for determination of oxygen in metals by hydrogen reduction. A Deoxo catalytic purifier, B mercury valve, C 800 ml flask containing phosphorus pentoxide, D combustion tube, E furnace, F thermocouple, G water trap, H mercury manometer, I 100 ml buret, J mercury reservoir, K 8 mm bore tube, L 0.5 mm bore tube, M water trap, $S_1 - S_{10}$ stopcocks.

tube was bent at an angle in order to reduce heat radiation to the joint. The specimens to be analysed were placed in the horizontal part of the combustion tube, in front of a small magnet. The lower end of the tube contained a crucible of sintered alumina.

A U-formed tube (G) with 4 mm bore served as a water trap. It was cooled by a mixture of solid carbon dioxide and acetone. The trap was sealed to a small mercury manometer (H) and a buret (I). The manometer consisted of a 1 mm capillary sealed to 8 mm bore tubes. The capillary and the attached U-tube of the manometer was filled with redistilled mercury. When evacuated, the mercury stem in the upper part of the capillary is broken, and the pressure is recorded as the difference in height of the mercury columns in the U-tube. The buret had a capacity of 100 ml and was graduated into 0.2 ml. The lower end of the buret communicated with a mercury reservoir (J) with a capacity of approximately 120 ml.

The pump train consisted of two 40 cm long tubes (K and L) with 8 mm and 0.5 mm bore, respectively. Between the tubes and the oil pump was placed a U-formed trap immersed in solid carbon dioxide/acetone mixture. The purpose of this trap was to prevent moisture from the air to enter the apparatus, and also to prevent mercury vapour from diffusing to the oil pump, which is connected at S_9.

The entire apparatus, with exception of the combustion tube, was made of Pyrex glass. The stopcocks S_2, S_3, and S_4 were of the hollow plug type with 4 to 5 mm hole through the plug. The rest of the stopcocks had an oblique bore of 4—5 mm through a compact plug. Stopcocks and glass joints were lubricated with a silicone base lubricant. The apparatus could be maintained at a vacuum of 0.01 mm Hg for several days.

PROCEDURE

The specimens to be analysed were cleaned by filing with a clean file, or scraping with a sharp knife in order to remove surface oxide, and then degreased by means of benzene. The samples were then placed in the horizontal part of the combustion tube. Powdered samples were wrapped in a tin foil of known oxygen content.

The apparatus is evacuated through S_9 by a Hyvac oil pump, capable of exhausting the system to 0.01 mm Hg. S_9 is then closed and pure hydrogen admitted to the system through S_2. The apparatus is evacuated once more, and pure hydrogen again admitted until the pressure is 40—60 mm Hg, as indicated by the mercury manometer. A thermos bottle containing the cooling mixture is added to the water trap (G) and the furnace pushed over the inclined part of the combustion tube. After heating the sample at 900°C for 20 min tap S_7 is opened, and excess hydrogen is slowly removed through the capillary by pumping. After 5 min, S_8 is opened, and the system is evacuated for a few more minutes. Stopcocks S_4, S_5, and S_6 are then closed, the cooling mixture removed from the trap and the water vapour allowed to vaporize. The pressure of the water vapour is recorded on the manometer, using a low power microscope or a cathetometer.

Normally a blank run shows less than 0.2 mm Hg. If the blank exceeds this value, the whole procedure is repeated until successive blanks agree to within 0.1 mm Hg. The water vapour is removed through the pump train.

Hydrogen is again admitted to a pressure of 40—70 mm Hg, the cooling mixture added to the trap, and one of the specimens is pushed into the hot zone of the combustion tube by means of the magnet. After heating for 20 minutes, excess hydrogen is slowly pumped out through the capillary. 5 minutes afterwards tap S_8 is opened and the apparatus exhausted for a few more minutes. Stopcocks S_5, S_7, S_8, and S_9 are then closed, and S_{10} opened. Stopcock S_7 is then opened slowly, letting air through the capillary, and forcing the mercury in the reservoir to fill the buret. The last trances of hydrogen are then pumped out through S_3. Stopcocks S_3, S_4, and S_7 are closed, the cooling mixture removed and the water allowed to vaporize. The pressure and temperature of the vapour are recorded.

Since water vapour at room temperature deviates appreciably from ideal gas behaviour for pressures exceeding 10 mm Hg, useful vapour pressures are confined to lower values. Whenever a vapour pressure above or near 10 mm Hg is recorded, the air pressure in the mercury reservoir is reduced by opening S_9 and S_7 of the pump train. The mercury in the buret falls correspondingly, thus increasing the volume of the water vapour. By appropriate adjustment of the pressure in the pump train, any desired volume of the water vapour at its corresponding pressure can be obtained.

Before proceeding with the next sample, the apparatus is exhausted and a new blank determined. If the blank is unchanged compared to the previous check, this indicates that the last specimen has been completely reduced and that no leaks in the apparatus have occurred.

CALIBRATIONS AND CALCULATIONS

The total volume enclosed by stopcocks S_4, S_5, S_6 (*i.e.* water trap, manometer and associated tubings) was calibrated by introducing small volumes of air and recording their pressures at a number of different readings of the buret. The apparatus was also calibrated by reducing known amounts of lead oxide following the above procedure. Both methods gave concordant results, *i.e.* 14.2 ml. The buret had a capacity of 100 ml and, consequently, the volume in which the water vaporizes could be adjusted to any desired value between 14.2 and 114 ml.

If the total volume of the water vapour is V ml, the pressure recorded on the manometer P mm Hg and the room temperature t°C, the weight W_0 of the water formed by the reduction can be calculated from the equation:

$$W_0 = \frac{P}{760} \cdot \frac{V}{1 + \gamma t} \cdot \frac{18.016}{22414} \text{ g } H_2O$$

The corresponding weight of oxygen (W) in the sample is:

$$W = 9.39 \times 10^{-7} \times \frac{P \cdot V}{1 + \gamma t} \text{ g } O_2$$

By means of a cathetometer the water vapour pressure can be measured to ± 0.1 mm Hg. From the above equation it is evident that a pressure of 0.1 mm Hg in a volume of 14.2 ml corresponds to 0.00128 mg oxygen, which is the smallest amount of oxygen that can be detected with the apparatus described. The volume in which the water vaporizes can be increased to a maximum value of 114 ml. A water vapour pressure of 10 mm Hg in this volume corresponds to 0.996 mg oxygen. By using a sample weighing 1 g and adjusting the volume appropriately, the apparatus will cover the entire range from 0.00013 to 0.1 % of oxygen. The determination of oxygen contents lower than 0.00013 % might be performed by increasing the sample weight, or by decreasing the volume of the water trap and associated tubings.

The blank was found to be independent of the initial hydrogen pressure, indicating that the hydrogen gas was completely dry and oxygen-free. At furnace temperatures below 850°C, the blank usually showed 1×10^{-6} g oxygen. At temperatures above 850°C, however, the blank increased with increasing temperature and time of heating. This is probably due to diffusion of oxygen form the atmosphere through the hot zone of the quartz tube. Consequently, the diameter of the tube was chosen as small as possible and the same temperature and time of reaction were employed in both the blank and analysis.

In order to speed up the reduction of the oxides, the specimens were heated to a temperature slightly above the melting point. Metals with high melting

points (copper for instance) were added to a previously deoxidized melt of tin. In this way the reduction temperature could be kept below 900°C, thus taking advantage of a low blank value. Surface oxides in copper and copper-silver alloys are fairly rapidly reduced even at a temperature of about 400°C. This is important when analysing samples having a very rough surface, as the surface oxide could be removed by heating in a hydrogen atmosphere at 400°C prior to the determination of oxygen in the bulk of the sample. According to Baker [6], cleaning with oxidising acids should be avoided as they are liable to leave an oxygen film on the surface.

RESULTS

To test the accuracy and precision of the method, samples of lead oxide (Analar C.P. product of yellow PbO) and cupric oxide (Merck C.P. product of CuO) were analysed by the procedure outlined above. The reduction temperatures were 650 and 950°C for the lead and copper samples, respectively. From the results in Table 1 it appears that only 90 % of the oxygen content is extracted during the first 5 min. A heating time of 20 min, however, was found sufficient for a quantitative reduction of oxygen in the samples. This is in contrast with the results by Nitsche [7] who claims that heating for 5 min at 900°C is sufficient for quantitative reduction of oxygen in copper.

A series of determinations oxygen in silver-copper and gold-copper-silver alloys were then performed. As shown in Table 2, the oxygen content found in different samples of the same alloy, showed a deviation of $\pm$ 2 ppm from the mean value. Considering the small samples and a non-uniform distribution of oxygen in the metal, the results must be considered satisfactory.

The apparatus described is obviously applicable to all metals in which the oxide is reduced by hydrogen below 1 000°C. Volatile constituents in the samples will vaporize and condense in the cool part of the combustion tube. Metallic mirrors of silver and lead were observed, but apparently they did not influence the results of analysis. This was verified by adding samples of known oxygen content to the melt. As stated by Baker [6] errors due to volatile constituents, as zinc for instance, may be minimised by using a large bath of tin in the combustion tube. Metallic mirrors may sometimes be of analytical interest. Thus, even minute amounts of cadmium in gold was detected as a black deposit well separated from those of less volatile constituents as for instance silver.

Crystal Structures of the Compounds Dimethylammonium Bromide-Bromine (2:1) and Dimethylammonium Chloride-Iodine (2:1)

K. O. STRØMME

Universitetets Kjemiske institutt, Blindern-Oslo, Norway

The crystal structures of the compounds (2:1) dimethylammonium bromide-bromine $[(CH_3)_2NH_2Br]_2 \cdot Br_2$ and (2:1) dimethylammonium chloride-iodine $[(CH_3)_2NH_2Cl]_2 \cdot I_2$ have been determined by X-ray methods. The compounds are isomorphous, the space group is $C2$ and the lattice parameters are $a = 20.00$ Å; $b = 6.01$ Å; $c = 5.38$ Å; $\beta = 94.6°$ and $a = 20.43$ Å; $b = 5.88$ Å; $c = 5.45$ Å; $\beta = 94.3°$, respectively.

The halogen atoms are arranged in nearly linear chains, *viz.* Br—Br—Br—Br and Cl—I—I—Cl (the halogen-halogen-halogen angle $\approx 173°$.) In these chains the distance between the two central atoms is a little longer than those in the free halogen molecules (obs. Br—Br dist. = 2.42 Å and obs. I—I = 2.74 Å). The bonds from the central atoms to the nearer of the terminal halogen atoms appear to be moderately strong and the distances intermediate between those to be expected for covalent and van der Waals values.

Each terminal halogen atom is connected to three nitrogen atoms. Two of these halogen-nitrogen distances are similar to the halogen-nitrogen distances found in ammonium halides, but the third halogen-nitrogen distance is appreciably shorter (N—Br = 3.05 Å, 3.49 Å, 3.50 Å; N—Cl = 3.05 Å, 3.27 Å, 3.28 Å). This short bond lies along one of the nitrogen's tetrahedral directions, approximately. The angle between this direction and the line joining halogen-halogen is about 95°.

The structures of salts formed by ammonium cations and polyhalide anions are of considerable interest. Among the substances already investigated are several containing the trihalide ion to which a negative charge is attached.

The present report deals with the crystal structures of the 2:1 addition compounds formed by dimethylammonium bromide and chloride with bromine and iodine, respectively. In these compounds a negative charge should be associated with half the number of halogen atoms present in the compound under consideration.

EXPERIMENTAL

The compounds $[(CH_3)_2NH.HBr]_2.Br_2$ or $[(CH_3)_2NH.HCl].I_2$ are formed by addition of diluted bromine (or iodine) to a solution containing the dimethylammonium bromide (or chloride) in chloroform.[1] Good crystals may be obtained by careful cooling of a saturated solution or by slow evaporation of the chloroform. The compounds may also be obtained by adding diluted bromine (or iodo monochloride) to the free base in chloroform.[2] The halogen thus reacts with the methyl groups giving halogen substituted amine and hydrobromic (or hydrochloric) acid which in turn neutralizes the free base. The salt then combines with bromine (or iodine, liberated from iodomonochloride) in the given ratio.

The active halogen was determined volumetrically by titration against a standardized solution of thiosulphate.

The bromine compound is orange in colour and the iodine compound reddish brown. Their decomposition points are 73 and 100°C, respectively.

The crystals are instable and were kept in thin-walled boron lithium capillaries when under exposure to X-rays.

Weissenberg and oscillation photographs were taken with Cu-*K* radiation and rotation about the *b* and *c* axes. Using the multiple film technique two series of Weissenberg photographs were obtained for each compound with exposure times from 1 to 100 h. The intensities were estimated visually and corrected for Lorentz- and polarization effects. No correction for absorption — or secondary extinction effects — was applied.

For the bromine compound 143 *h0l* and 88 *hk*0 reflexions are theoretically attainable with Cu-*Ka* radiation. Actually 119 and 81 were observed, respectively. For the compound containing iodine there are 143 theoretical, against 123 exptl. *h0l* reflexions. A correction of the form $\exp.(-B \sin^2 \Theta/\lambda^2)$ was applied to the calculated structure factors The *B* factors were found by inspection to be:

	B (*h0l*) (Å^{-2})	*B* (*hk*0) (Å^{-2})
Bromine compound	4.90	2.50
Iodine "	4.80	2.50

The atomic scattering factors employed in the calculation of the structure factors are taken from the *Internationale Tabellen* [3].

CRYSTAL DATA

The crystals of the two species are isomorphous with monoclinic unit cells. The crystals form flat needles, the needle axes coinciding with the *b* axes. According to the observed X-ray extinctions the three *C*-centered space groups *Cm*, *C*2 and *C*2/*m* are possible. The latter is the only one in which centers of symmetry are present. For reasons mentioned below, however, it turned out that *C*2 was the correct space group. It gives rise to only one centrosymmetric projection, that along [010]. The unit cell dimensions are as follows:

	a	*b*	*c*	β
$[(CH_3)_2NH_2Br]_2 \cdot Br_2$	20.00 Å;	6.01 Å;	5.38 Å;	94.6
$[(CH_3)_2NH_2Cl]_2 \cdot I_2$	20.43 Å;	5.88 Å;	5.45 Å;	94.3

With densities found by the flotation method (2.15 g/cm^3 and 2.18 g/cm^3) this leads to 2 molecules of $[(CH_3)_2NH_2Br]_2 \cdot Br_2$ or $[(CH_3)_2NH_2Cl]_2 \cdot I_2$ in the unit cell.

Contours for bromine : 4, 12, 20, 28..... el. Å^{-2}
For nitrogen, carbon. *etc.* : 4, 5, 6, 7, 8, el. Å^{-2}.

DETERMINATION OF THE STRUCTURES

Trial and error computations of the parameters of the independent halogen atoms, starting with the bromine compound, led to results which strongly indicated that the plane group for the projection along the *b* axes is *p*2. This made the space group *Cm* improbable. A Patterson projection along [010] turned out to be in full agreement with these findings and the next step was the computation of the corresponding electron density projection. Starting with the *x* and *z* coordinates of the bromine atoms already derived and neglecting the lighter atoms, a first Fourier map was obtained which, beside the peaks corresponding to the bromines, also contains lower peaks due to carbon and nitrogen atoms. After four refinements no further phase shifts occurred. The final Fourier map is reproduced in Fig. 1. The reliability factor for this projection is $R = 0.12$.

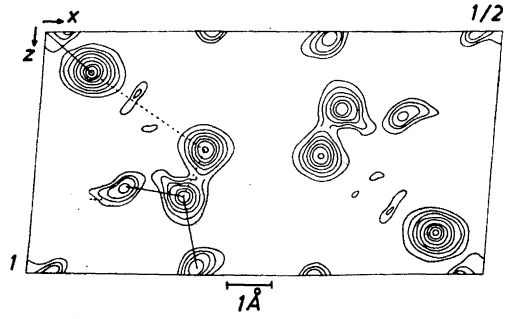

Fig. 2. The electron density projection along the *b*-axis of dimethylammonium chloride-iodine (2:1).

Contours for iodine : 4, 13, 23, 33 .....el. Å^{-2}.
For chlorine : 4, 7, 10, 13, 16 .....el. Å^{-2}.
For nitrogen, carbon *etc.* : as in Fig. 1.

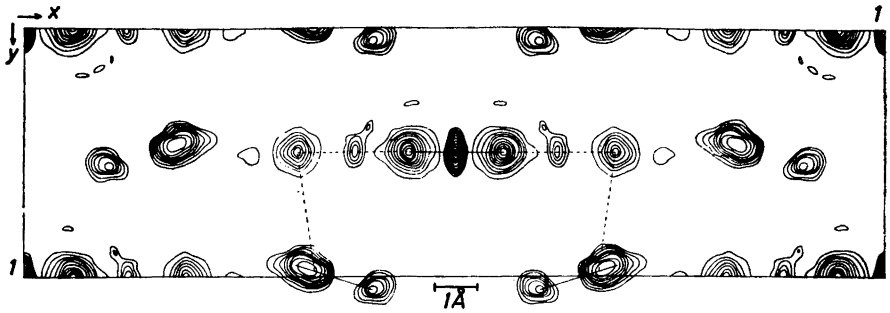

Fig. 3. The electron density projection along the *c* axis of dimethylammonium chloride-iodine (2:1).

Contours for chlorine : 4, 8, 12, 16 .....el. Å^{-2}.
For iodine, nitrogen, carbon *etc.* as in Fig. 2.

Hoping that a further refinement of the x and z parameters should be possible by a difference synthesis, a Fourier chart was worked out subtracting the contributions from the bromine atoms. The map thus obtained did not reveal any electron density gradients in the positions of the removed bromine atoms which could serve as a basis for further refinement. In the case of the light atoms the x and z values obtained from this synthesis have been regarded as the more reliable and chosen as the final ones.

The corresponding [010] projection of the isomorphous compound containing iodine was worked out next. Due to the high scattering power of the iodine atom relative to the other atoms approximate values of its x and z coordinates could easily be determined by trial and error methods. The Fourier map after three refinements is reproduced in Fig. 2. The R factor was found to be 0.16. The larger value of the R factor in this case is probably caused chiefly by more pronounced absorption effects. A difference synthesis led to slight changes in the coordinates of the light atoms but not of the heavy ones.

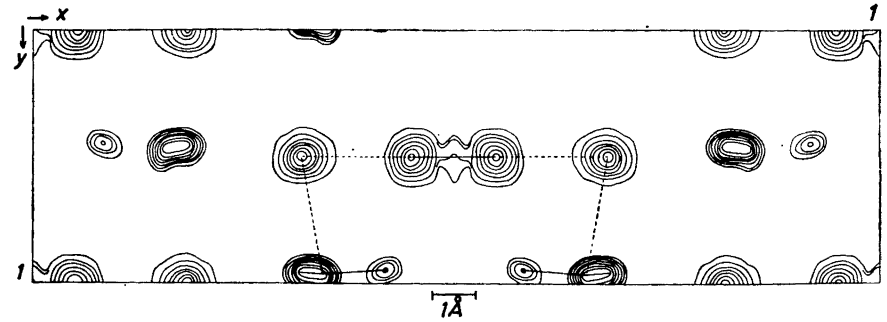

Fig. 4. The electron density projections along the *c* axis of dimethylammonium bromide-bromine (2:1).

Contours as in Fig. 1.

It will be noted that the space group $C2/m$ would have required the four amine groups to be situated in m with the molecular mirror planes coinciding with those of the space group, thus bringing about one double peak for the two amine carbons in the [010] projection. In Figs. 1 and 2 three peaks for the amine group appear. This finding is not compatible with the above requirement, and $C2/m$ is thus ruled out in favour of $C2$, which has a general 4-fold position and therefore imposes no restriction on the position of the amine group.

The y parameters of the independent heavy atoms were determined from Patterson projections along the c axes starting with the iodine compound. It turned out that these parameters in the first step might be set equal to zero, thereby satisfying a condition for a 4-fold position in the centrosymmetric plane group cmm, although the correct plane group is the noncentrosymmetric cm. According to this finding the phase angles were not expected to deviate much from 0 and 180°, the deviations being dependent on the contributions from the light atoms.

Values of the y parameters of the amine groups were obtained by a trial and error computation using the correct expressions for the structure factors, the x parameters obtained from the [010] projection and data for the amine group already known [4]. The contributions from the light and heavy atoms were then included in the calculation of the phase angles and a Fourier synthesis based on the plane group cm was carried out. After three refinements the electron density map reproduced in Fig. 3 was obtained. The R factor was found equal to 0.14. The x parameters found for the halogen atoms in the two projections agree to within 0.001 of the axial lengths.

In the case of the bromine compound the y parameters of the nitrogen atom was arbitrarily put equal to $\frac{1}{2}$(or 0). The corresponding y parameters of the two independent carbon atoms belonging to the same amine group were then calculated using a model before a Fourier refinement process was started. The electron density map after three refinements is shown in Fig. 4. The value of the R factor is 0.12. The x parameters found for the halogen atoms in the two projections agree to within 0.001 of the axial length.

It will be observed from Figs. 3 and 4 that a nitrogen and a carbon atom are overlapping in these projections. The y coordinates of these atoms were found by using standard methods for localization of maxima, the x parameters for these atoms being taken from the [010] projections. Atomic coordinates are listed in Table 1, observed and calculated structure amplitudes including phase angles in Table 2.

DESCRIPTION OF THE STRUCTURE

In Table 3 some calculated bond distances and angles are presented. The listed sums of covalent and ionic radii are based on Pauling's values [5]. Suffixes

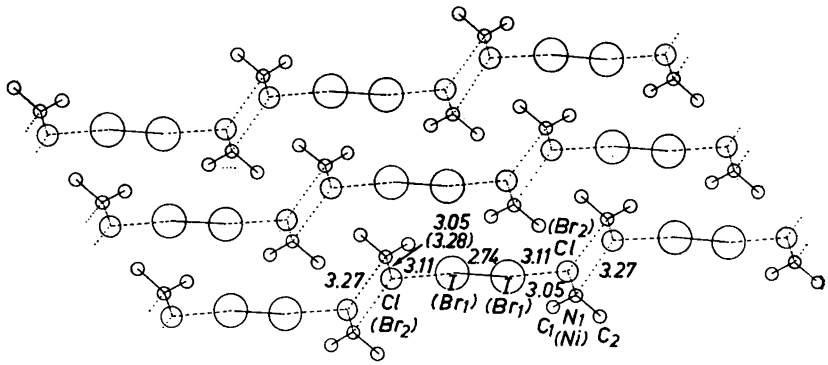

Fig. 5. The structure of dimethylammonium chloride-iodine (2:1) as seen along [010].

attached to the atomic symbols refer to Fig. 5 which shows the structure of dimethylammonium chloride-iodine (2:1) projected along [010].

Standard deviations in bond lengths are as follows:

$$\sigma(\text{I—I}) = 0.003 \text{ Å} \quad ; \quad \sigma = (\text{Br}_1\text{—Br}_1) = 0.004 \text{ Å}$$
$$\sigma(\text{I—Cl}) = 0.008 \text{ Å} \quad ; \quad \sigma = (\text{Br}_1\text{—Br}_2) = 0.004 \text{ Å}$$
$$\sigma(\text{Cl—N}) = 0.021 \text{ Å} \quad ; \quad \sigma = (\text{Br}_2\text{—N}) = 0.020 \text{ Å}$$

A striking feature of these structures is the halogen chains, Cl—I—I—Cl or Br—Br—Br—Br, which show only a slight deviation from linearity, the halogen-halogen-halogen angles being approximately 173°. The bond between the two atoms in the middle of the chain is covalent, although a slight bond elongation is observed in both cases. This change in bond length is due to an interaction between the atoms in the middle of the chain and the adjacent terminal ones. The bond distance between a middle and a terminal halogen atom is nearly equal to the mean of the respective covalent and van der Waals radius sums (*cf.* the structure of caesium tetraiodide)[6]. Moreover, each of the terminal halogen atoms is connected to three nitrogen atoms. It will be noticed from Table 3 that one of the corresponding bond distances (Cl—N_1 or Br—N_1) is considerably shorter than the two others (Cl—N_1' and Cl—N_2 or Br_2—N_1' and Br_2—N_2) which are of practically equal length. Furthermore, the Hal—N_1 bond is directed along one of the tetrahedral bond directions from nitrogen thus indicating the presence of a hydrogen bridge.

The lengths of the two other halogen-nitrogen bonds mentioned above agree well with the nitrogen-halogen distances observed in ammonium halides.

The halogen chain may be interpreted as an addition complex formed by two halogen ions (donors) and one halogen molecule (acceptor).[7]

The author is grateful to Professor O. Hassel for his interest in this work. The investigation has been supported by *The Rockefeller Foundation*.

XXVII. The Synthesis of a Mixture of Trideca-1:3:11-triene-5:7:9-triyne (II) and *trans* 1-phenylhepta-1:3-diyn-5-ene (V). A Novel Cyclisation Reaction

LARS SKATTEBÖL and NILS ANDREAS SÖRENSEN

SINTEF and Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

A synthesis of (II) is described which unexpectedly also yielded some (V). The cyclisation leading to (V) was confirmed by the isolation of diphenylacetylene(IX) from a similar reaction starting with 1-phenylocta-5:7-dien-2-yne-1:4-diol (VIII). A mechanism for this novel cyclisation reaction is briefly discussed.

A number of aliphatic and aromatic polyacetylenic hydrocarbons have been isolated from higher plants [1]. Among these are a series of straight chain C_{13} compounds, isolated from some members of the family *Compositae:*

trans $CH_3 \cdot CH=CH \cdot C\equiv C \cdot C\equiv C \cdot CH=CH \cdot CH=CH-CH=CH_2$ (Ref.[2])

(I)

$CH_3 \cdot CH=CH \cdot C\equiv C \cdot C\equiv C \cdot C\equiv C \cdot CH=CH-CH=CH_2$ (Ref.[3])

(II)

cis and *trans* $CH_3 \cdot CH=CH \cdot C\equiv C \cdot C\equiv C \cdot C\equiv C \cdot C\equiv C \cdot CH=CH_2$ (Refs.[2,13])

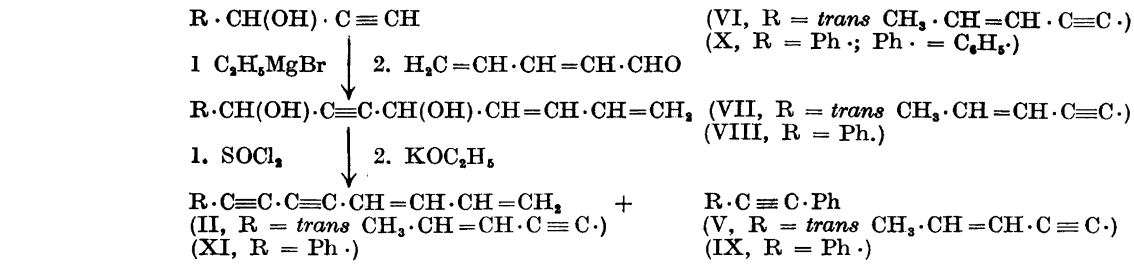
(III)

$CH_3 \cdot C\equiv C \cdot C\equiv C \cdot C\equiv C \cdot C\equiv C \cdot C\equiv C \cdot CH=CH_2$ (Ref.[4])

(IV)

The structures of (I) [5], (II) [6], (III) [7] and (IV) [7] have been confirmed by synthesis but the preparation of (II) has only been reported since the present work was started. This paper describes a different approach to the synthesis of this compound which resulted in a mixture of (II) and *trans* 1-phenylhepta-1:3-diyn-5-ene (V). The latter also occurs naturally [3], accompanying (II) in a number of *Coreopsis* species.

The following sequence of reactions was expected to yield (II):



2:4-Pentadienal was prepared from 2:3-dihydropyran * according to Woods and Sanders [8], and the aldehyde was shown to be the *trans* isomer by infrared spectroscopy. *trans* Octa-6-ene-1:4-diyn-3-ol (VI) was prepared according to Jones, Skatteböl and Whiting [7]. The Grignard reaction between these compounds gave the corresponding glycol (VII) as a crystalline compound in 27 % yield, m.p. 65—67°. The yield of crude material was considerably higher but losses occurred during the careful purification. The ultraviolet absorption maximum at 2 260 Å showed that no anionotropic rearrangement had taken place, and that structure (VII) was correct. This was confirmed by infrared measurements which also indicated that the double bonds had the *trans* configuration.

The subsequent chlorination with thionyl chloride and dehydrochlorination with potassium ethoxide at —40° gave a small amount of a liquid product, which was purified by chromatography on alumina. The ultraviolet spectrum of the petroleum-ether eluate was practically identical with that of (II) [3,6] as far as the long wavelength maxima were concerned (Fig. 1). The infrared spectrum, however, showed some bands at 1 493, 753 and 687 cm^{-1} which indicated the presence of some aromatic contaminant. The product was distilled under high-vacuum and the distillate gave surprisingly an absorption in ultraviolet light (Fig. 1) similar to that of *trans* 1-phenylhepta-1:3-diyn-5-ene (V) [3]. The infrared spectrum was also very similar to that of (V). It seemed probable that a cyclisation had taken place in the dehydrochlorination step.

Chromatography of the distillation residue eventually gave a liquid which, from ultraviolet and infrared spectra, consisted mainly of (II). Because of the very small amounts available, a serious attempt to separate this mixture was not made. The mixture did not give an adduct with maleic anhydride in benzene and illumination with daylight, in the presence of iodine, produced small hypsochromic shift (25—30 Å) of the ultraviolet absorption maxima. These results together with a band at 716 cm^{-1} in the infrared spectrum are in accordance with a *cis* configuration about the double bond at the 3-position in (II). However, the presence of the *trans* isomer was not excluded, and the mixture consisted probably of these two isomers and some (V). The start-

* We are indebted to Dr. R. D. Smith and E. I. duPont de Nemours and Company for a generous gift of 2:3-dihydropyran.

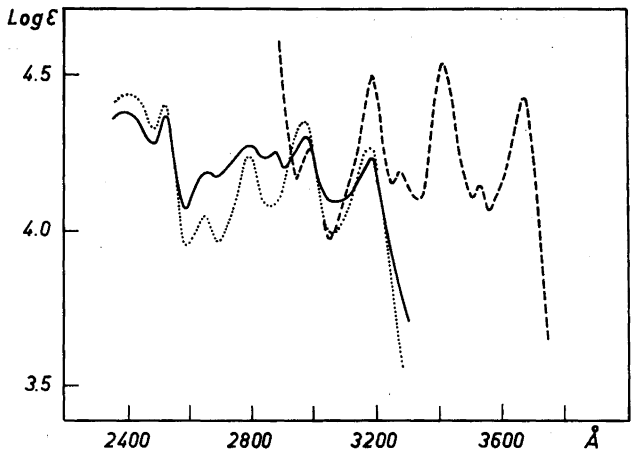


Fig. 1. Ultraviolet absorption in ethanol of:
Trideca-1:3:11-triene-5:7:9-triyne (II) --------
1-Phenylhepta-1:3-diyn-5-ene (V) ————
» » » » , authentic [3] .....

ing material (VI) was definitely the *trans* isomer, and the reactions were not expected to cause any isomerisation of the double bond at the 11-position.

In order to confirm this interesting cyclisation, we wanted to carry out the reactions with 1-phenylocta-5:7-dien-2-yne-1:4-diol (VIII) in the same way as described above for (VII). In this case the anticipated cyclisation product would be diphenylacetylene (IX), a stable crystalline compound, and the isolation of this, and its identity with authentic diphenylacetylene, would provide unambiguous proof for the cyclisation reaction.

The Grignard reaction between 1-phenylprop-2-yn-1-ol (X) and pentadienal was carried out as in the previous case. The glycol (VIII) was obtained in 14 % yield as a pure crystalline compound, m.p. 75—76 . The ultraviolet absorption maximum at 2 245 Å again showed that no anionotropic rearrangement had occurred, and the infrared spectrum was in agreement with a *trans* configuration. Treatment of this with thionyl chloride gave a dichloride which absorbed strongly at 2 705 Å in ultraviolet light. A rearrangement had evidently taken place, with the formation of a dienyne-chromophore, *viz.* —C≡C·CH=CH—CH=CH—CH_2Cl. For comparison,

$$HC{\equiv}C{\cdot}CH{=}CH{\cdot}CH{=}CH{\cdot}CH_2Br$$

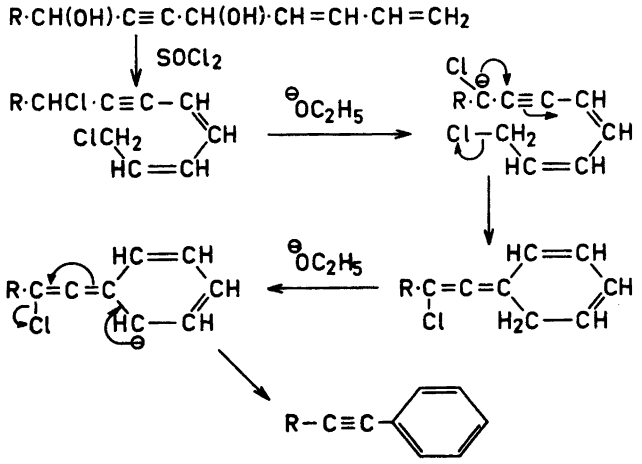
is reported [10] to absorb at 2 720 Å.

The crude dichloride was dehydrohalogenated, and the product chromatographed on alumina. A liquid was obtained by elution with petroleum-ether containing 10—30 % benzene. Its ultraviolet spectrum revealed the presence of a mixture with the longest wavelength maximum at 3 665 Å. This maximum probably belonged to (XI), and a group of maxima at 2 975, 2 865 and 2 770 Å indicated that also some diphenylacetylene was present. The first attempts

to separate diphenylacetylene from the mixture by chromatography were not wholly successful, as only enriched fractions were obtained. However, when a sample was left in air at room temperature for some hours, chromatography gave a small amount of a colourless crystalline substance, m.p. 57°, in all respects identical with an authentic sample of diphenylacetylene [9].

Isolation of the second main product, *viz.* 1-phenylocta-1:3-diyne-5:7-diene (XI), was not attempted as it was expected to be rather tedious and was little interest to this work.

The mechanism of this cyclisation reaction can be visualized in the following way:



The anionotropic rearrangement in the chlorination step would be expected to give a mixture of *cis* and *trans* isomers, by analogy with previous results obtained with similar compounds [11]. The *cis* isomer is sterically favourable for a cyclisation, which would subsequently lead to the formation of a benzene derivative. The scheme given here for the actual dehydrochlorination step is certainly dubious, as the general mechanism for this very fast elimination reaction is not known.

This cyclisation is the more interesting as the two compounds (II) and (V) have been isolated from the same plants, *viz.* some *Coreopsis* species. One cannot exclude the possibility that the benzene derivative (V) is formed by cyclisation of the dienyne system of (II), but it seems more reasonable that they both derive from a common precursor. The resemblance between the two substances $Ph \cdot CH_2C{\equiv}C \cdot$ and

$$CH_2{=}CH \cdot CH{=}CH \cdot C{\equiv}C \cdot C{\equiv}C \cdot C{\equiv}C \cdot CH{=}CH \cdot CH_2OCOCH_3$$

isolated [12] from *Carlina vulgaris*, and

$$Ph \cdot C{\equiv}C \cdot C{\equiv}C \cdot CH{=}CH \cdot CH_2OCOCH_3$$

isolated [2] from some *Coreopsis* species, is also of considerable interest in this connection.

EXPERIMENTAL

All melting points are uncorrected. The ultraviolet absorption data were obtained in ethanol, unless otherwise stated, using a Beckman, Model DK recording spectrophotometer. A Perkin Elmer instrument, Model 21, was used for the infrared measurements. The carbon and hydrogen determinations were carried out by Alfred Bernhardt, Mülheim, Ruhr, Germany.

trans *Octa-6-ene-1:4-diyn-3-ol(VI)* was prepared in Manchester [7] from hex-4-en-2-yn-1-al and ethynylmagnesium bromide.

Penta-2:4-dienal was prepared according to Wooes and Sanders [8], in 25 % overall yield from 2:3-dihydropyran.

trans *Trideca-1:3:11-triene-6:9-diyne-5:8-diol.* (VII). A solution of *trans* octa-6-ene-1:4-diyn-3-ol (VI, 5.8 g) in tetrahydrofuran (10 ml), was added during 30 min to an ice-cooled solution of ethylmagnesium bromide, prepared from magnesium (2.4 g) in tetrahydrofuran (60 ml). After 1.5 h at room temperature, freshly ditilled pentadienal (1.5 g) in tetrahydrofuran (5 ml) was added with stirring and ice-cooling. The reaction mixture was then left with stirring at room temperature for 4 h and decomposed with a saturated aqueous solution of ammonium chloride. Extraction with ether, and evaporation of the solvents gave a dark-coloured liquid which was purified by chromatography on deactivated alumina (5 % of 10 % acetic acid). The glycol was eluted with ether and rechromatographed under the same conditions. The light yellow liquid obtained, was dissolved in ether-petroleum-ether, and after standing at −25° gave some crystals. Recrystallisation from the same solvent yielded the glycol (970 mg, 27 %), m.p. 65−67° (Found: C 76.7; H 6.8. Calc. for $C_{13}H_{14}O_2$; C 77.20; H 6.98). Ultraviolet absorption: λ_{max} 2 260 Å, ε = 43 000. The infrared spectrum (in nujol): 3 300 (O−H), 2 210 (C≡C), 1 605 (C=C), 948 (C=C−H), 983 and 923 cm^{-1} (C=CH−H).

Trideca-1:3:11-trien-5:7:9-triyne (II) and trans *1-phenylhepta-1:3-diyn-5-ene* (V). The glycol (VII, 880 mg) was dissolved in dry ether (3 ml) and cooled in an ice-bath. Thionyl chloride (1 ml) was added with stirring and the reaction mixture left for 2 h. Ether and excess thionyl chloride were evaporated off under vacuum, and the residue dissolved in 10 ml of dry ether. This solution was added with stirring to potassium ethoxide, prepared from potassium (1.5 g) in dry ethanol (25 ml), and cooled to −40°. The reaction mixture was left while the temperature rose to −10° (30 min). Addition of water and isolation with ether gave a dark-coloured liquid which was purified by chromatography on alumina. With petroleum ether a product was eluted, which after further chromatography was obtained as a light yellow oil with the following absorption maxima in ultraviolet light: 3 665, 3 525, 3 410, 3 275, 3 190 and 2 995 Å (Fig. 1). The infrared spectrum (liq.) showed bands at 752 and 688 cm^{-1}, characteristic of a substituted benzene ring, in addition to bands expected for the aliphatic hydrocarbon (II).

Part of the mixture was high-vacuum distilled, and a light yellow liquid was obtained at 40−45° (bath temperature)/10^{-5} mm. The ultraviolet spectrum resembled that of the naturally occurring substance (V)[3] (Fig. 1). The infrared spectrum (liq.) had the following main absorption maxima: 3 060 (ar. C−H), 2 870 (C−H), 2 190 (C≡C), 1 630 (C=C), 1 600, 1 493, (ar. C=C), 1 445 (−CH_3)), 995, 940, 922 (C=C−H), 753, 687 (ar. C−H), 716 cm^{-1} (C=C−H). Except for the fairly weak band at 716 cm^{-1} the spectrum was almost identical with that of (V).

Isomerisation. Part of the mixture, dissolved in hexane with a few crystals of iodine, was placed in daylight for some hours. The ultraviolet maxima were shifted 25−30 Å to shorter wavelengths.

trans *1-Phenylocta-5:7-diene-2-yne-1:4-diol (VIII)* was prepared in the same way as for (II) above, by condensing 1-phenylprop-2-yne-1-ol (X, 13.2 g) with pentadienal (8.2 g). The reaction time in this experiment was 13 h. Chromatography and recrystallisation from ether-petroleum-ether yielded the glycol, (2.90 g, 14 %), m.p. 75−76°. (Found: C 78.61; H 6.66. Calc. for $C_{14}H_{14}O_2$: C 78.48; H 6.59). Ultraviolet absorption: λmax. 2 245, 2 220 (infl.) Å. ε = 36 000 and 35 300. The infrared spectrum (in $CHCl_3$): 3 360 (−H), 1 615 (C=C), 1 500 (ar C=C), 1 000, 953, 905 (C=C−H), 690 cm^{-1} (ar. C−H).

Diphenylacetylene (IX). The glycol (VIII, 2.0 g) was dissolved in dry ether (6 ml) and cooled in an ice-bath. Thionyl chloride (2 ml) was added with stirring, and the reaction mixture left for 1 h at room temperature. Ether and excess thionyl chloride were then evapo-

rated off under vacuum, and the residue dissolved in dry ether (10 ml). Ultraviolet absorption: $\lambda_{max.}$ 2 705 Å. The solution was added dropwise to a stirred solution of potassium ethoxide, prepared from potassium (2.0 g) in ethanol (25 ml.) and cooled to −40°. The mixture was stirred for 30 min, the bath-temperature being allowed to rise to −10°. Addition of water and isolation with ether gave a viscous liquid which was chromatographed on alumina. A light yellow-coloured liquid was eluted with petroleum-ether 10−20 % benzene. Ultraviolet absorption: $\lambda_{max.}$ 3 665, 2 975, 2 865, 2 770, 2 625, 2 570 Å. The last fraction, presumed to be enriched in diphenyl-acetylene, was evaporated and left at room temperature for some hours. Chromatography yielded a small amount (~ 3 mg) of a crystalline substance, eluted with petroleum-ether, 20 % benzene. The compound was recrystallised from ethanol-water, m.p. 57°. Ultraviolet absorption λmax. 2 960, 2 870, 2 785, 2 715, 2 640 and 2 360 Å. ε = 29 000, 23 000, 33 500, 25 500, 23 000 and 9 500, respectively. Infrared absorption (in CCl_4): 3 100 [ar. C−H). 1 610, 1 505, 1 450 (ar. C=C), 1 405, 1 025, 910 and 687 cm^{-1} (ar. C−H).

Authentic diphenylacetylene [9], m.p. 60°, had the following maxima in ultraviolet light: λmax. 2 960, 2 870, 2 785, 2 715, 2 640 and 2 360 Å. ε = 31 700, 23 600, 38 000, 25 600, 23 100, 8 600, respectively. The two compounds, mixed 1:1, melted at 57−58° and their infrared spectra were identical.

Spectrophotometric Determination of Formula, Rate of Formation and Stability Constant of the Boron 1,1′-Dianthrimide Complex

F. J. LANGMYHR and O. B. SKAAR

University of Oslo, Chemical Institute A, Blindern, Norway

The reaction between boron and 1,1′dianthrimide has been investigated spectrophotometrically. By means of the method of continuous variation the mole ratio between the reactants was found to be 1:1. The velocity constant for the formation of the complex in 93.8 % sulphuric acid at 71°C was determined to be $k = 1\,600$ $M^{-1} \cdot h^{-1}$. The stability constant in 93.8 % sulphuric acid and at 70°C was found to be $K = 1.4 \times 10^5$ M^{-1}.

A survey of the literature on the determination of boron with 1,1'-dianthrimide shows that neither the formula nor the stability constant of the complex has been determined previously. Mr. Danielsson [1] of Metallografiska Institutet, Stockholm, has informed the authors that his investigations on the composition of the complex indicate the mole ratio 1:1.

In the present investigation the formula, the rate of formation and the stability constant of the complex have been determined spectrophotometrically.

EXPERIMENTAL

Instruments. Extinction measurements were made with a Zeiss spectrophotometer PMQ II, a matched set of 1.000 cm glass cells being used.

Reagents. Boric acid of reagent grade quality was used for the preparation of standard solutions.

The 1,1′-dianthrimide (E. Merck) was recrystallized twice from nitrobenzene before use.

Sulphuric acid, 95–97 %, and other chemicals were of reagent grade quality. The strength of the sulphuric acid was found to be 96.8 %. Precautions were taken to prevent the acid from absorbing water vapour, and to avoid discoloration by contamination with dust.

Ordinary distilled water from an all metal still was employed.

Standard solutions. 0.5715 g of boric acid (H_3BO_3) were weighed out, dissolved in concentrated sulphuric acid and diluted to 1 000 ml with concentrated sulphuric acid. From this standard solution (containing 100 μg B per ml) 50 ml were pipetted into another

1 000 ml volumetric flask and diluted to the mark with concentrated sulphuric acid. From this latter solution (containing 5 μg B per ml) known amounts of boron were taken.

0.0794 g of 1,1'-dianthrimide were dissolved in concentrated sulphuric acid and diluted to 1 000 ml with the same acid.

Glassware. The different solutions were prepared and heat-treated in 50 ml bottles *(Jena Geräteglas)* with ground-in glass stoppers.

Heat treatment. The heat treatment was given in a thermostatically controlled drying oven of standard construction.

ABSORPTION CURVES

Absorption curves were plotted of solutions of the boron 1,1'-dianthrimide complex and of solutions of 1,1'-dianthrimide.

The solutions measured spectrophotometrically were prepared in the following way. 1 ml of boron standard solution (containing 5 μg boron), 1 ml of distilled water, 11 ml of concentrated sulphuric acid and 5 ml of 1,1'-dianthrimide standard solution were pipetted into a 50 ml bottle *. The concentration of sulphuric acid in the final solution was 93.8 %. After mixing the solution was heated for 16 h at 70° ± 2°C. The corresponding blank solution contained 1 ml of distilled water, 12 ml of concentrated sulphuric acid and 5 ml of 1,1'-dianthrimide standard solution. Heating time and temperature were as described for the sample solution.

Fig. 1, Curve 1 gives the absorption curve of the boron 1,1'-dianthrimide complex measured against the blank solution. Curve 2 shows the absorption curve of the 1,1'-dianthrimide blank solution measured against concentrated sulphuric acid.

The boron 1,1'-dianthrimide complex has a distinct maximum at 630 mμ. At lower wavelengths there are other, smaller maxima. The maximum at 630 mμ is suitable for the spectrophotometric determination of boron. At 630 mμ the Beer—Lambert law is followed up to at least 7 μg B per 17.6 ml, the molar extinction coefficient for the system being $\varepsilon = 1.97 \times 10^4$.

DETERMINATION OF FORMULA

Job's [2] method of continuous variation, as modified by Vosburgh and Cooper [3], was employed for elucidating the composition of the complex.

According to Job's method the extinctions are measured for series of solutions in which the sum of the concentrations of boron and 1,1'-dianthrimide is kept constant, while the ratio between the reactants is varied.

The series of solutions needed for the determination of the formula were prepared from the standard solutions of boron and 1,1'-dianthrimide (*vide supra*). Each sample solution was finally measured against a corresponding blank containing the same amount of 1,1'-dianthrimide. The concentration of sulphuric acid in the final solutions was again 93.8 %.

In the amounts of boron taken are included boron present as impurity in the reagents. The constant concentration of boron in the 17.6 ml reagent solutions was found to be 0.19×10^{-5} mole. The sample solutions were heated for 16 h at 70° ± 2°C. On the other hand, the blanks were not heated. By this

* Due to contraction the final volume is not 18.0, but 17.6 ml.

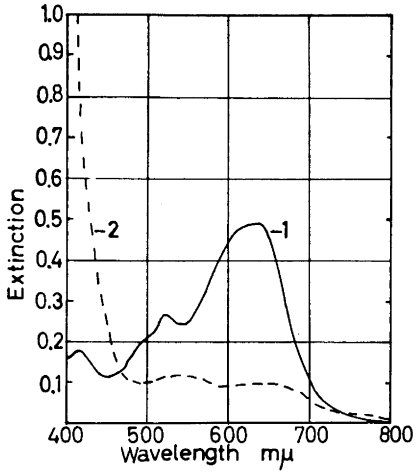

Fig. 1. Curve 1, Absorption curve of the boron 1,1'-dianthrimide complex in 93.8 % sulphuric acid. Curve 2, Absorption curve of 1,1'-dianthrimide in 93.8 % sulphuric acid.

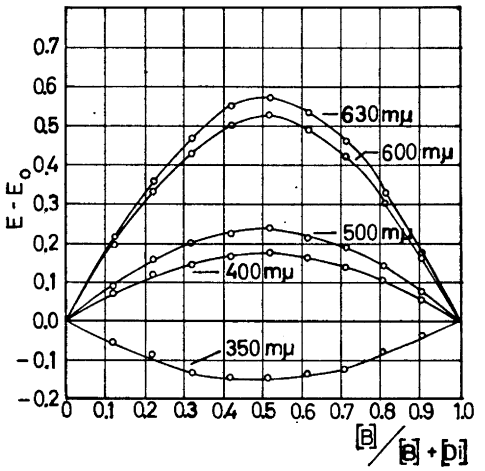

Fig. 2. Curves of continuous variation for mixtures of boron and 1,1'-dianthrimide.

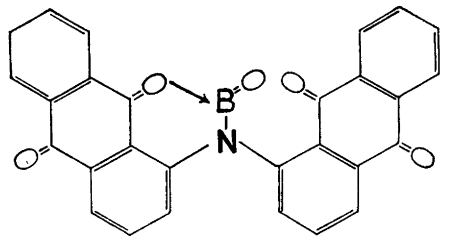
procedure the colour originating from the boron present in the blanks was not developed.

The extinctions were measured at five different wavelengths to guard against the possibility that more than one complex is present. Measurements, in which the sum of concentrations of boron an 1,1'-dianthrimide is varied, have not been carried out.

In Fig. 2 the curves of continuous variation are plotted. It is seen that negative extinction values were obtained for the curve plotted at 350 mμ. At this wavelength the blank solutions absorb more than the corresponding sample solutions.

From Fig. 2 it can be concluded that the mole ratio of boron to 1,1'-dianthrimide is 1:1.

Structure of the complex. Having determined the mole ratio of the complex, it is possible to suggest the following structure of the boron 1,1'-dianthrimide complex in solution.



The structure is in accordance with that given by Grob and Yoe [4] for the complex between boron and 5-benzamido-6'-chloro-1,1'-bis (anthraquinonyl) amine.

DETERMINATION OF RATE OF REACTION

In concentrated sulphuric acid boron (assumed to be present as metaboric acid, HBO_2) and 1,1'-dianthrimide react at a very slow rate. The rate of reaction increases with the temperature, but even at 70°C the colour is developed relatively slowly.

In the present investigation the progress of the reaction between boron and 1,1'-dianthrimide was followed spectrophotometrically. On the basis of these kinetic studies the reaction velocity for the formation of the complex was determined.

The experimental details were as follows: 12 sample solutions were prepared, each consisting of 1 ml of distilled water, 10 ml of concentrated sulphuric acid, 2 ml of boric acid standard solution (corresponding to 10 μg B) and 5 ml of 1,1'-dianthrimide standard solution. In addition a blank solution was prepared, in which the volume of boric acid solution was replaced by 2 ml of concentrated sulphuric acid. All sample solutions were placed in the drying oven at 71° $\pm$0.5°C and heated for different periods of time. After the prefixed time of heating, 2 sample solutions were removed, cooled in the air to room temperature and the extinction was measured against the unheated blank. In the extinctions given in Table 1 for the sample solutions are also included the contribution from the constant amount of boron present as impurity, *viz.* 0.19×10^{-5} mole B per 17.6 ml reagent solution. Corrections were further made for the different amount of free 1,1'-dianthrimide present in sample and blank solutions. The corrected extinction data are given in Table 1.

Table 1. Formation of boron 1,1'-dianthrimide complex in 93.8 % sulphuric acid at 71°C. Extinction (1 000 $\times$ E) for solutions heated for the specified number of hours after the removal of the first pair of sample solutions from drying oven.

Heating time, h	0	2	4	6	18	43
Average E of 2 samples (1)	104	231	326	369	594	720
Blank (not heated) (2)	10	9	8	7	5	3
Increase of E (1−2)	94	222	318	362	589	717

The following, rate-determining mechanism of reaction between metaboric acid (HBO_2) and 1,1'-dianthrimide ($(Anthra)_2NH$)) is suggested:

	$(Anthra)_2NH$ +	$HOBO \rightleftharpoons$	$(Anthra)_2NBO$ +	H_2O
Concentrations at the time $t = 0$	a	b	0	y
Concentrations at the time t	$a - x$	$b - x$	x	y
Concentrations at the time $t = \infty$	$a - z$	$b - z$	z	y

The reaction takes place in concentrated sulphuric acid, and the water formed is taken up by the acid. The concentration of water (y) can then be considered constant.

The following kinetic equation is obtained for the formation of the complex:

$$\frac{dx}{dt} = k(a-x)(b-x) - k''xy \qquad (1)$$

where k and k'' are the velocity constants of the forward and the reverse reaction, respectively.

Further $k''y = k'$ and $K'/y = K$, where K' is the stability constant of the complex. In this investigation y was considered constant at a constant concentration of sulphuric acid, and K was introduced as apparent stability constant. By introducing these values in eqn. 1 and integrating between x_1, t_1 and x_2, t_2 the following expression is obtained for k:

$$k = \frac{2.303 \cdot \log\left[\frac{a+b+1/K+\sqrt{\ }-2x_2}{a+b+1/K-\sqrt{\ }-2x_2} \cdot \frac{a+b+1/K-\sqrt{\ }-2x_1}{a+b+1/K+\sqrt{\ }-2x_1}\right]}{[t_2-t_1]\sqrt{\ }} \qquad (2)$$

The square root sign $\sqrt{\ }$ stands for $\sqrt{(a+b+1/K)^2-4ab}$.

To calculate k from eqn. 2, it is necessary to know K (the apparent stability constant) and the constant impurity of boron originating from the reagents. By means of methods described below approximative data for K and the constant impurity of boron were obtained experimentally, and these data gave a preliminary value of k. This first value of k was employed to adjust the data for K and the constant impurity of boron, and these improved data were again used to correct k. The approximations were carried out until constant values were obtained. The final values were:

$$K = 1.4 \times 10^5 \ \mathrm{M^{-1}}$$
$$k = 1\,600 \ \mathrm{M^{-1} \cdot h^{-1}}$$

These data are valid in 93.8 % sulphuric acid and at 70° and 71°C, respectively.

The constant impurity of boron was found to be 0.19×10^{-5} mole B per 17.6 ml of reagent solution.

The experimental data (Table 1) gave a constant value of k, thus confirming the validity of eqn. 1.

DETERMINATION OF APPARENT STABILITY CONSTANT

The following expression is obtained for the apparent stability constant K of the boron 1,1'-dianthrimide complex:

$$K = \frac{z}{(a-z)(b-z)}$$

For experimental determination of K, the two concentrations in the denominator should preferably be of approximately the same magnitude, and should not differ too much from that of the numerator. These conditions are obtained by choosing small and nearly equal concentrations of the reactants.

The usual equilibrium measurements were not suitable for the determination of the apparent stability constant of the present system. Prolonged heating of solutions of 1,1'-dianthrimide resulted in destruction of considerable amounts of reagent. The following, special procedure was therefore introduced.

A series of sample solutions were prepared according to the formula:

1 ml of distilled water + $(17-v_1-v_2)$ ml of concentrated sulphuric acid $+v_1$ ml of boron standard solution + v_2 ml of 1,1'-dianthrimide standard solution.

In one series of experiments v_1 was 1.2 ml while v_2 was 2, 3.5 and 5 ml. In another series v_1 was 2 and v_2 was 1.5, 2 and 3 ml. Blank solutions were not prepared, but the extinctions due to the amount of 1,1'-dianthrimide not taking part in the reaction were calculated (Specified as Blank in Table 2).

The sample solutions were then heated for 40 h at 70° ± 2°C. By this procedure the solutions were brought near equilibrium without destructing appreciable amounts of 1,1'-dianthrimide. After cooling, the extinctions (E_{40}) were measured against concentrated sulphuric acid. These extinction data gave an approximative value of K (applied for the preliminary determination of k). The final, equilibrium extinction values ($E\infty$) were determined by calculating the difference ($E\infty - E_{40}$). This relatively small correction to the E_{40} data was found by approximation as described above. From the data for $E\infty$ the equilibrium concentration of complex was found with the application of the molar extinction coefficient ($\varepsilon = 1.97 \times 10^4$). Equilibrium concentrations of boron and 1,1'-dianthrimide could then be calculated.

Table 2. Spectrophotometric determination of apparent stability constant of the boron 1,1'-dianthrimide complex. (70°C and 93.8 % sulphuric acid.)

	Extinctions (1 000 × E_{40}) at the concentrations specified					
Concentration of boron/1.05 × 10^{-5} M	3.18	3.18	3.18	5.18	5.18	5.18
Conc. of 1,1'-dianthrimide/1.05 × 10^{-5} M	2.00	3.50	5.00	1.50	2.00	3.00
Average E_{40} for 2 samples (1)	272	406	503	252	330	468
Blank (2) (calculated)	1	3	6	1	1	1
Corrected, average E_{40} values (1 − 2)	271	403	497	251	329	267
$E\infty - E_{40}$	32	36	27	10	15	26
$E\infty$	303	439	524	261	344	493
Calculated apparent stability constant $K/10^5$ M^{-1}	1.54	1.39	1.53	1.35	1.39	1.38

From the data in Table 2 the average value of 1.4×10^5 M^{-1} was obtained for the apparent stability constant of the complex in 93.8 % sulphuric acid.

An approximative value for the constant impurity of boron present in the reagents was found spectrophotometrically. Two identical blank solutions were prepared, and one of the solutions was heated for 40 h at 70°C. The extinction of this solution was measured against the solution not heated and the content of boron was calculated to be 0.16×10^{-5} mole B per 17.6 ml reagent solution. This value was employed for the preliminary calculation of k.

Polarographic Determination of Hydroxylamine, alone and in Comparison with Hydroxamic Acid

TH. ØSTERUD and MILDA PRYTZ

Universitetets Farmasøytiske Institutt, Blindern-Oslo, Norway

Hydroxylamine has been polarographically reduced in ethanol-water solutions of tetraethylammonium iodide. The pH of the supporting electrolyte was increased by addition of small amounts of tetraethylammonium hydroxide.

The pH of the tetraethylammonium iodide solution before addition of hydroxide was 5.4. In this medium the hydroxylamine gave three distinct waves. The first wave which had $E_{½} = -1.44$ *vs* S.C.E. (—1.11 *vs* Hg), disappeared as soon as pH was raised, *i.e.* the buffer-capacity was increased. At pH = 5.6 this wave had disappeared and did not reappear on further increase of pH. In the pH-interval 5.6 to 13.3 the curves showed two well defined waves, the first, which had $E_{½} = -2.1$ *vs* S.C.E. (—1.74 *vs* Hg), being the highest. At pH = 11 it started decreasing, while the height of the second wave having $E_{½} = -2.35$ *vs* S.C.E. (—1.9 *vs* Hg) kept a constant low height. At pH greater than 14 the first wave seemed to coalesce with the second wave, which in this strong alkaline medium suddenly reaches an appreciable height.

The measurements of hydroxamic acid were a corroboration of earlier investigations, as we wanted to test eventual differences as regards the form of the curves and the values of the half wave potentials.

The first wave for the hydroxamic acid shows a half wave potential about 0.2 V lower than for the hydroxylamine, and the second wave about 0.1 V higher. The form of the curves did not differ noticeably.

Inasmuch as hydroxylamine is unstable in alkaline medium we controlled its deterioration at pH = 11.7 to 12.3 by taking a series of diagrams at fixed intervals of half an hour. Already after half an hour a decrease of wave height was unmistakable, and after an hour and a half the wave height had reached a low value which was controlled the next day. It had not changed appreciably over night. Next the reaction velocity was increased by raising the temperature to 60°C and 100°, respectively. A 60°C a wave height of about 1/3 of the original was reached after 30 min, and at 100°C even after a few minutes.

The time effect on solutions of acethydroxamic acid and on solutions of propiohydroxamic acid was also tested at pH = 11 to 11.7; but the polarographic waves of these acids were not influenced by time. The effect of raising the temperature was also tested. No differences in the curves were observed.

These results seem to indicate that eventual hydroxylamine waves need not interfere with polarographic waves of aliphatic hydroxamic acids if the hydroxylamine is decomposed by heating in alkaline solution (pH 12 to 14) before the polarograms are taken.

As our ultimate aim is to determine aliphatic esters polarographically after transformation into hydroxamic acids it is of interest to see if these acids give curves that differ from those of hydroxylamine, inasmuch as the reaction mixture may contain an excess of hydroxylamine.

Some mixtures of hydroxylamine and hydroxamic acid were also polarographed, and the effect of time and heating was tested. The pH was 10 and did not change appreciably during the experiments. The readings were taken at room temperature.

We presume to have established by these experiments that hydroxamic acid may be polarographically determined in a solution containing hydroxylamine, inasmuch as the latter may be destructed by heating, whereas the former is not affected.

EXPERIMENTAL

A recording polarograph from Radiometer, Copenhagen, was employed. As working cell was used an arrangement of Nife cells in series with a rectifier. The usual precautions against oxygen were taken. For investigation of the temperature influence a water bath was used.

The tetraethylammonium iodide for the supporting electrolyte was delivered by Merck, Darmstadt. It had to be recrystallized repeatedly, as it otherwise was apt to give quite

Table 1. Polarographic waves of hydroxylamine and of acethydroxamic acid in relation to pH. Measured at 1/sens. = 50; $c_{aceth.} = 7 \times 10^{-3}$ M; $c_{hydrox.} =$ about 10^{-3} M.

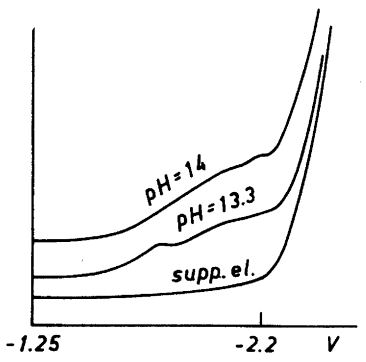

Fig. 1. a. Electroreduction of hydroxylamine at pH 13.3 and 14.

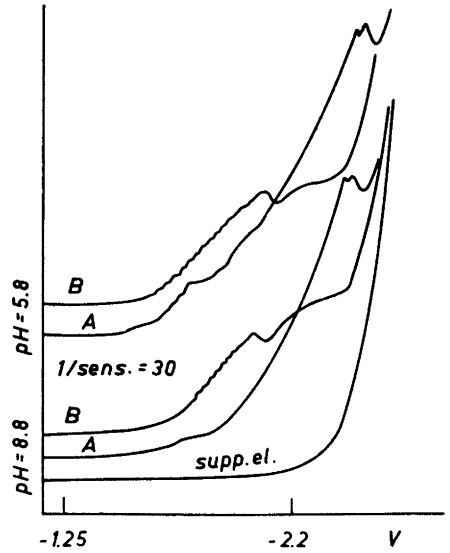

b. Electroreduction of acethydroxamic acid, A, and of hydroxylamine, B, at pH 5.8 and 8.8 1/sens. = 30.

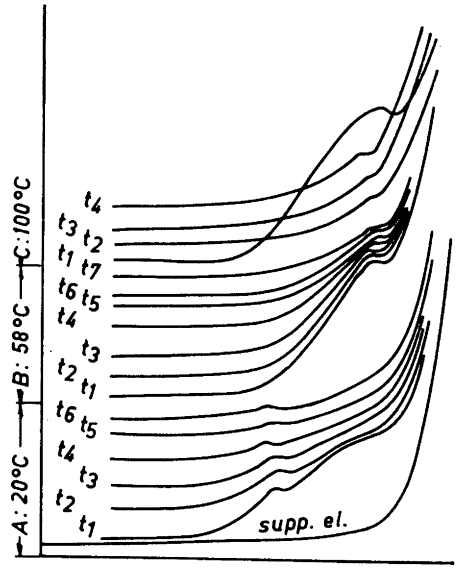

Fig. 2. Reduction of wave height of hydroxylamine with time at different temperatures:
A. at 20°C; $t_1 = 0$; $t_2 = ½$ hour; $t_3 = 1$ hour; $t_4 = 1\ ½$ hour; $t_5 = 2$ hours; $t_6 = 26$ hours
B. at 58°C; $t_1 = 0$; $t_2 = 3$ min.; $t_3 = 5$ min.; $t_4 = 12$ min.; $t_5 = 15$ min.; $t_6 = 18$ min.; $t_7 = 30$ min.
C. at 100°C; $t_1 = 0$; $t_2 = 15$ min; $t_3 = 10$ min.; $t_4 = 20$ min.

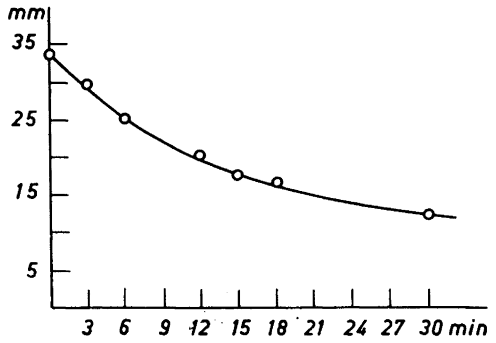

Fig. 3. Destruction of hydroxylamine at 58°C. pH = 12.3 Wave heights as ordinates. Lapse of time as abscissae.

irrelevant maxima and minima. 50 % alcohol proved to be the best solvent for recrystallization. For our previous investigation we used a tetraethylammonium iodide from the British Drughouses; but unfortunately we had very little salt left. Tetrabutylammonium iodide from A. Frederick Smith, Columbus, Ohio, gave straight and good curves without any recrystallization.

As a maximum depressor was used tylose, about 0.005 %.

RESULTS

The polarographic curves for hydroxylamine showed two waves similar to those we had earlier found for hydroxamic acid [1], but with other values for the half wave potentials. These are given for both hydroxylamine and acethydroxamic acid in Table 1.

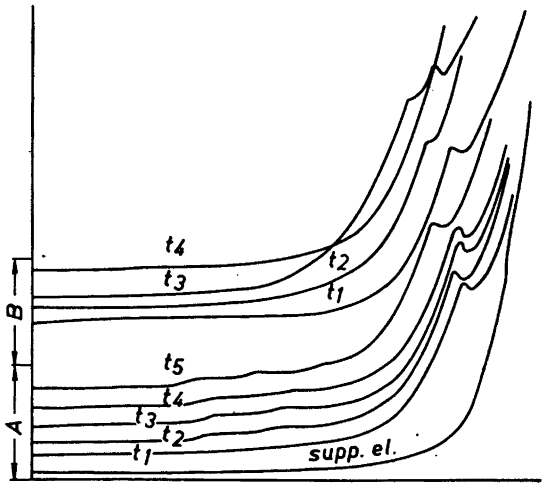

Fig. 4. Electroreduction of acethydroxamic acid at 20°C and at 100°C.
A. at 20°C; $t_1 = 0$; $t_2 = ½$ hour; $t_3 = 1$ hour; $t_4 = 1\ ½$ hour; $t_5 = 50$ hours.
B. at 100°C; $t_1 = 0$; $t_2 = 20$ min.; $t_3 = 50$ min.; t_4 after a lapse of 24 hours.

Some of the curves are given in Fig. 1 a and b.

It appears from Fig. 1 a that the hydroxylamine waves coalesce at pH =14. The first wave can still be seen at pH = 13.3, but at pH = 14 it has disappeared and the second wave has increased highly.

As regards the reduction of the hydroxylamine-waves with time and rise of temperature, Fig. 2 shows that at 20°C the wave height decreases appreciably during one hour and a half, while at 60°C half an hour is sufficient for a corresponding decrease, and at 100°C even a very short time will be enough. The decomposition of hydroxylamine with time at 60°C is shown in Fig. 3.

An inquiry into an eventual time- and temperature-effect for acethydroxamic acid and propiohydroxamic acid was also made. As will be seen from Fig. 4, the polarographic curves remained unaltered with time, even though the temperature was raised.

Mixtures of hydroxylamine and hydroxamic acid were also polarographed; but the polarograms brought no new information.

DISCUSSION

For the hydroxylamine as well as for hydroxamic acids we found that in alkaline solutions (at corresponding pH-intervals) they gave polarographic curves with two distinct waves. The half wave potentials for the hydroxylamine waves lay between those for acethydroxamic acid. At high pH values the hydroxylamine waves seemed to coalesce. The result was a single, rather high wave. A corresponding effect was not found for hydroxamic acids.

On the polarographic waves for hydroxamic acid no time effect was observed even if the test solutions were left standing till next day. The polarographic waves for hydroxylamine in alkaline solutions, on the other hand, decreased perceptibly if the polarographic determination was delayed. Heating accelerated the decrease greatly.

One may conclude as a consequence of these results that esters transformed to hydroxamic acids may be determined polarographically even if the reaction mixture contains some excess of hydroxylamine. All that needs to be done is to heat the mixture on a water bath for a short time before the curves are taken at room temperature.

The authors are indebted to Bjørn Bergmann-Paulsen for the recording of the polarograms.

The Acid Mucopolysaccharides in Human Arterial Tissue

M. O. Dyrbye

Connective Tissue Research Laboratory University Institute of Medical Anatomy, Copenhagen, Denmark

Biochemical analyses of the mucopolysaccharides have shown:

1) The total hexosamine content of human aortae, pulmonary, coronary and cerebral arteries (intima-media layers) varied from 0.3 % to 0.18 % based upon wet weight of the tissues. The content of esterified sulfates — which is taken as the sulfate of the mucopolysaccharides in ester linkage — varied from 0.075 % to 0.042 %. The cerebral arteries showed the lowest concentration of both hexosamine and sulfate. The molar concentration of hexosamine (liberated by acid hydrolysis) was approximately twice as high as the molar concentration of the esterified sulfate in the genuine arterial tissue [1—3].

2) Aortae with severe calcification showed a significantly lower hexosamine concentration than aortae without calcification. The concentration of esterified sulfate in pulmonary arteries was significantly higher for older than for younger subjects [3]. In cerebral arteries both esterified sulfate and hexosamine were found to be higher for older than for younger individuals [3]. Apart from this no correlation between hexosamine, sulfate and age or degree of arteriosclerosis has been observed.

3) The acid mucopolysaccharides have been extracted from large amounts of pooled human aortic tissue. It was found that about 50 % of the extracted material was chondroitin sulfuric acid-A, 15 % was chondroitin sulfuric acid-B, approximately 15 % was heparitin sulfuric acid and the rest (about 20 %) seemed to be composed of substances related to heparin [4].

4) Mucopolysaccharides isolated from 30 different aortae contained hexosamine, hexuronic acid and sulfate in equimolar amounts. The content of galactosamine was 79 % of the total hexosamine. The galactosamine glucosamine ratio was significantly higher in older than in younger individuals [5].

5) Paper electrophoresis of the above-mentioned 30 samples of isolated mucopolysaccharides showed two fractions which stained metachromatically with toluidine blue. The faster moving averaged about 2/3 of the total isolated material and was assumed to be chondroitin sulfuric acid, while the slower moving compound seemed to be a mixture of different mucopolysaccharides [6,7].

6) In vitro experiments on human aortae by means of ^{35}S-labeled sulfate showed that the uptake of sulfate per weight unit of the acid mucopolysaccharides isolated from the tissue decreased definitely with age and with increasing arteriosclerosis [8].

These results indicate that *the acid mucopolysaccharides in the vessel wall may play an essential part in the aging of arterial tissue*, but at the present time little or nothing is known about the underlying mechanism.

Fractionation of Gelatin by Ion-Exchange Resin

T. Tuominen and E. Kulonen

Department of Medical Chemistry, University of Turku, Finland

The figure shows the fractionation of rat bone gelatin (obtained with 50-fold volume of water at + 100°C for 12 h). The resin (Amberlite CG-50, 100—200 mesh) was equilibrated with pH 5.5 citrate buffer (McIlwaine) and used as 15 × 1 cm column, which was eluted first at room temperature with the same buffer and later at + 37°C with 0.1 N NaOH as described by Russell[1]. Fractions of 2 ml were collected (numbers are indicated) and protein estimated with a modified biuret reaction (Lowry). The first peak differred in amino acid composition from gelatin, the second and third resembled each other and gelatin. The fourth peak is not constant and its amino acid composition is not known.

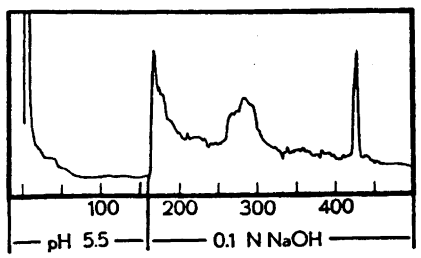

Fig. 1.

Effect of Hydrocortisone on the Nucleotides in Carrageenin Granuloma and Chick Embryo

U. K. Virtanen and E. Kulonen

Department of Medical Chemistry, University of Turku, Finland

The acid-soluble nucleotides were fractionated with Dowex-1 resin using elution with formiate according to Hurlbert *et al.*[1] and estimated by their absorption at 260 mμ. The peaks were further fractionated by paper chromatography and the composition of nucleotides determined by phosphate analysis and by paper chromatography of the purine bases and pyrimidine mononucleotides after acid hydrolysis.

Subcutaneous carrageenin granulomata were produced to cortisone-treated guinea pigs according to Robertson *et al.*[2] The tissue was prepared, homogenized and suspended into 0.6 N cold perchloric acid. The supernatant was neutralized and analyzed. Some differences were found between the cortisone-pretreated and control animals. The individual differences were, however, so large that no exact conclusions could be drawn.

The experiment was therefore repeated with chick embryos, which on the eighth day of incubation received 2.5 mg of hydrocortisone into the yolk sac. The embryos were prepared and analyzed as above after 1, 2, 3 or 4 days. The growth was almost totally inhibited.

Generally the energy-rich di- and triphosphates were decreased. In the region of monophosphates there appeared in all the samples from hydrocortisone-treated embryos a small but distinct peak which was totally absent from the controls. This peak is not yet positively identified. It has an absorption maximum at 262 mμ and in the paper chromatograms (using *iso*propanol-HCl) it migrates almost with the same rate as UMP. However, it cannot be the UMP, which emerges later.

On paper chromatographic evidence it seems that UMP and IMP are decreased after hydrocortisonetreatment apparently in equal degree.

The Acid Mucopolysaccharides of Furth's Mastocytoma in the Mouse

Lennart Rodén and Albert Dorfman

Wenner-Grens Institut, Stockholm, Sweden, and La Rabida-University of Chicago Institute, Chicago, U.S.A.

Mast cells, though widely distributed in mammalian connective tissues, are difficult to isolate in amounts large enough to permit a detailed study of the biosynthesis of one of their most important components, heparin. The recent development of two different transplantable mastocytomas in the mouse [1,2] therefore seems to offer considerable promise in this respect.

In naturally occurring mast cells isolated from peritoneal washings Schiller and Dorfman [3] found no other mucopolysaccharide than heparin. However, before using the malignant mast cells in biosynthetic studies it was considered advisable to carry out a more detailed characterization of their mucopolysaccharide fraction.

Tumours of the Furth type * were used in the present study. The mucopolysaccharides were prepared from a boiled water homogenate by the following procedure: 1) extraction with sodium hydroxide, 2) digestion of the dialyzed extract with trypsin, 3) precipitation of undigested material with trichloroacetic acid and dialysis of supernatant and 4) fractionation of the cetyl pyridinium complexes on a cellulose column according to Borelius, Gardell and Scott [4].

In this way two fractions were obtained in approximately equal amounts, which were eluted from the column with 1.2 N NaCl and 2.0 N NaCl, respectively. The 2.0 N fraction contained glucosamine, uronic acid and sulphate in molar ratios of 1:1:2, was resistant to digestion with testicular hyaluronidase and had an anticoagulant activity of 92 units per mg of the air-dried powder. The 1.2 N fraction contained hexosamine, uronic acid and sulphate in equimolar amounts, was digested to two thirds by hyaluronidase and had an anticoagulant activity of 15 units per mg. Both glucosamine and galactosamine were present in this fraction, as shown with the method of Stoffyn and Jeanloz [5].

On the basis of these observations it is suggested that the mast cell tumours contain, in addition to heparin, a fraction with low sulphur content similar to heparin monosulphuric acid, and chondroitin sulphuric acid A and/or C.

Turbidimetric Analysis of Inorganic Sulfate in Serum, Plasma and Urine

Fredrik Berglund and Bo Sörbo

Department of Pharmacology, Karolinska Institutet, Stockholm, and Research Institute of National Defence, Dept. I, Sundbyberg, Sweden

The method is based on a precipitation of sulfate in the acidified sample by a barium chloride-gelatine reagent. The latter contains preformed barium sulfate (as commercial gelatine is contaminated with sulfate) and this accounts for the accuracy of the method [1]. The resulting turbidity is determined absorptiometrically in the ultraviolet region. Serum is analyzed after deproteinization with an equal volume of 8 % trichloroacetic acid and to a 4 ml aliquot is added 1 ml of the barium chloride-gelatine reagent. The latter is prepared by dissolving 2 g $BaCl_2.2H_2O$ in 400 ml of a 0.5 % solution of commercial gelatine "for microbiological work" (or of equivalent purity). 10–60 min later the absorbancy at 360 mμ is determined against a reagent blank. The standard curve is linear for amounts of sulfate up to 2 μmoles in the test. The method can also be applied to plasma, if citrate is used as anticoagulant, but heparin cannot be used as it strongly interferes in the test. Urine is analyzed by diluting a suitable aliquot with 4 % TCA and proceeding as above. The standard deviation of the method (in per cent of the mean) was obtained as 5 % in case of serum and 1 % in case of urine.

Respiration of Tissue Slices in the Presence of β-Aminopropionitrile

K. Juva, T. Nikkari and E. Kulonen

Department of Medical Chemistry, University of Turku, Finland

Monoamino-oxidase inhibitor ("Marsilid") aggravated the symptoms of experimental lathyrism [1]. This observation prompted us to study the respiration of tissue slices in the presence of β-aminopropionitrile (β-APN).

The experiments were conducted with conventional Warburg-technique. The liver slices (dry weight 8—10 mg) of fasting Wistar rats were incubated at + 37°C in 2 ml of bicarbonate-Ringer solution containing 0.2 % glucose. Sixteen control experiments were made with no additions in the incubation medium, the mean oxygen consumption being 9.29 ± 2.94 µl/mg/h. Decreasing concentrations of β-APN were added to the medium. The resulting oxygen uptakes were

No. of expts	β-APN	% of control
2	1 M	9
2	0.1 M	81
18	0.01 M	152
2	0.001 M	112

Similar stimulating effect of 0.01 M APN was also obtained with epiphyseal cartilage.

In eleven experiments using 0.01 M concentration of APN the disappearance of APN from the medium after 1 h incubation was studied by measuring the green colour, developed of APN by ninhydrin, at 340 mµ. An average of 1.2 µmoles of APN (6 % of the APN present) had disappeared in each experiment. If detoxified to cyanoacetic acid, it would have elevated the oxygen uptake only by about half of the actual increase.

Marsilid, in 0.001 M concentration, did not have any influence on the disappearance of APN. Neither the oxygen uptake of the controls nor the stimulation of oxygen consumption by 0.01 M APN were influenced by the presence of 0.001 M Marsilid in the incubation medium, as stated in 10 experiments.

Determinations of inorganic phosphorus of the incubation fluid indicated a possible impairment of phosphorus uptake by slices incubated with 0.01 M APN.

Histochemical Demonstration of Phosphorylase Activity in Tissue Sections

Arto Palkama

Department of Anatomy, University of Helsinki, Helsinki, Finland

The formation of glycogen from glucose-1-phosphate is due to phosphorylase acitivity. Our preliminary experiments showed that the techniques published as yet tend to be capricious and the results difficult to reproduce. All the published methods include glucose-1-phosphate as a substrate, from which phosphorylase and transglucosidase build glycogen and at the same time liberate phosphoric acid. The newly formed glucogen indicates the phosphorylase activity and can be demonstrated either by iodine solution or by the periodic acid Schiff method.

Fresh frozen sections were cut with a freezing microtome at 10—50 microns. 20 to 30 microns gave best results. The sections were transferred immediately in the incubation solution or dried on coverslips. In the incubation solution the glucose-1-phosphate concentration was varied from 0.1 % up to 5.0 %. Below 0.5 % the results were poor. The pH was varied from 4.5 to 6.0. After preliminary experiments pH 5.9 was found to be most suitable. As an inhibitor of acid phosphatase fluoride was used. Best results were obtained when the sodium fluoride concentration was about 1.7 %. Activators such as muscle adenylic acid, insulin and glycogen had little or no influence on the results. The composition of the final incubation mixture was: 250.0 mg glucose-1-phosphate, 2.0 ml saturated sodium fluoride, 1.0 ml 0.5-M acetate buffer, aq.dest. ad 5.0 ml. The sections were incubated for 2 h at 37°C.

There was a rather strong colour in those control sections which were stained with the periodic acid-Schiff technique. The best way to decrease the nonspecific colour was by ether-chloroform extraction after incubation in the substrate mixture.

Most clear-cut results were obtained with sceletal muscle. Similar or less intense reaction was also seen in heart and smooth muscle. A definitely positive reaction was also seen in heart and smooth muscle. A definitely positive reaction was also seen in the liver. As an observation not previously reported we found a uniform strongly positive reaction in the adrenal medulla.

The technique developed is by no means perfect. The coloured precipitate produced can only be a rough guide to the sites of the enzyme activity. Therefore efforts are continued to refine the technique.

The Phosphotransferase Activity of Alkaline Phosphatases. Studies with Hydroxyamino Acids and Amines as Acceptors

Gunnar Ågren

Department of Medical Chemistry, University of Uppsala, Sweden

In an extensive study Morton [1] recently reported that alkaline phosphatase from calf intestinal mucosa catalysed the synthesis of phosphate esters by direct transfer of the phosphate group from phosphomonoesters to suitable hydroxy compounds. He also used serine, threonine, and ethanolamine as acceptors with some presumptive evidence of a positive result. However, he had no authentic marker compounds for comparison with the suspected phosphorylated components. Clear evidence for the formation of such compounds has now been obtained.

Radioactive glycerophosphate was used as donor. It was prepared according to Bublitz and Kennedy [2] using $AT^{32}P$ and glycerokinase. A simplified method for assay of enzyme activity was used based on the observation of Ernster *et al.*[3] Some radioactive inorganic phosphate formed in the reaction was separated on a Dowex-1 column.

In a series of experiments 10 mg of glycerophosphate, containing 0.46 mC ^{32}P, and 10 mg of a preparation of alkaline bone phosphatase [4] containing 420 Portmann [5] units/mg N were incubated at pH 9.8 in a bicarbonate buffer for 10 min with 1 mmole of serine, threonine, glucosamine, or ethanolamine, respectively, in a total volume of 2 ml. After heating glycerophosphate was separated from the formed phosphorylated product by gradient elution on a Dowex-1 formate column [6]. The total radioactivity of the fractions measured in a L.K.B. Robot Scaler gave the following values in counts per minute:

	With enzyme	Without enzyme
Phosphorylserine	375 000	26 000
Phosphorylthreonine	26 000	460
Phosphorylglucosamine	67 000	41 000
Phosphorylethanolamine	912 000	150 000

Some interesting features are observed, the large proportion of phosphorylserine to phosphorylthreonine also found in hydrolysates of casein and animal phosphoproteins [6]. Of similar interest is the dominance of phosphorylethanolamine over phosphorylglucosamine also found in hydrolysates of the protein fraction from *E. coli* [7]. The significance of these observations with regard to possible ways for the formation of phosphoproteins is, however, unclear. The yield obtained in the enzymatic transphosphorylation was rather small, usually less than 1 μmole. The specific activity calculated as counts per minute per μg of phosphorus had about the same value for all compounds. In controls without enzyme smaller amounts of phosphorylated amino acids and amines were formed. Of interest for the present problem is the recent isolation of a free phosphorylated amino acid from extracts of *L. casei* [8] together with some phosphopeptides.

Radioactive glycerophosphate was used as donor. It was prepared according to Bublitz and Kennedy [2] using $AT^{32}P$ and glycerokinase. A simplified method for assay of enzyme activity was used based on the observation of Ernster *et al.*[3] Some radioactive inorganic phosphate formed in the reaction was separated on a Dowex-1 column.

In a series of experiments 10 mg of glycerophosphate, containing 0.46 mC ^{32}P, and 10 mg of a preparation of alkaline bone phosphatase [4] containing 420 Portmann [5] units/mg N were incubated at pH 9.8 in a bicarbonate buffer for 10 min with 1 mmole of serine, threonine, glucosamine, or ethanolamine, respectively, in a total volume of 2 ml. After heating glycerophosphate was separated from the formed phosphorylated product by gradient elution on a Dowex-1 formate column [6]. The total radioactivity of the fractions measured in a L.K.B. Robot Scaler gave the following values in counts per minute:

	With enzyme	Without enzyme
Phosphorylserine	375 000	26 000
Phosphorylthreonine	26 000	460
Phosphorylglucosamine	67 000	41 000
Phosphorylethanolamine	912 000	150 000

Some interesting features are observed, the large proportion of phosphorylserine to phosphorylthreonine also found in hydrolysates of casein and animal phosphoproteins [6]. Of similar interest is the dominance of phosphorylethanolamine over phosphorylglucosamine also found in hydrolysates of the protein fraction from *E. coli* [7]. The significance of these observations with regard to possible ways for the formation of phosphoproteins is, however, unclear. The yield obtained in the enzymatic transphosphorylation was rather small, usually less than 1 μmole. The specific activity calculated as counts per minute per μg of phosphorus had about the same value for all compounds. In controls without enzyme smaller amounts of phosphorylated amino acids and amines were formed. Of interest for the present problem is the recent isolation of a free phosphorylated amino acid from extracts of *L. casei* [8] together with some phosphopeptides.

The Enzymatic Reduction of Uracil to Dihydrouracil in Rat Liver

Per Fritzson*

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

The reduction of uracil to dihydrouracil is the rate limiting step in the breakdown of uracil to β-alanine in rat liver [1-3]. This fact indicates the central role of this reaction in the uracil-catabolizing system. The present work describes a procedure for the assay of dihydrouracil dehydrogenase in rat liver. The quantitative relation between enzymatic activity and factors which influence the reduction, has been investigated.

Spectrophotometric studies were carried out with an enzyme purified by ammonium sulphate fractionation of the particle-free supernatant. Optimal rate of reduction was in the pH-range 7.0 to 7.6. The reaction is TPNH-dependent [2,4], and the optimal concentration was found to be 7×10^{-5} M. The Michaelis constant was 1.7×10^{-5} M. The optimal uracil concentration was very small and less than 1×10^{-5} M. The reversible reduction of uracil was demonstrated, but the very slow rate suggested that this reaction is without physiological significance.

The quantitative determination of dihydrouracil dehydrogenase was carried out by anaerobic incubation of homogenate or the soluble fraction with uracil-6-^{14}C in the presence of TPNH, with G-6-P and G-6-P dehydrogenase as a TPN reducing system. ATP was found to have a stimulating effect on the reaction under these conditions [5,3]. The effect decreased, however, when the TPNH concentration was increased, indicating that ATP had a sparing action on the cofactor rather than a stimulating influence on the reduction as such. When appropriate amounts of ATP, nicotinamide [6] and fluoride were included in the incubation mixture, a linear relation between the rate of reduction and the amount of homogenate added, was obtained. The enzymatic activities of the homogenate and the soluble fraction were identical, indicating that dihydrouracil dehydrogenase is situated entirely in the soluble fraction. The enzymatic activity per g of liver, wet weight, corresponded to the reduction of about 0.7 μmole of uracil in 10 min.

The TPNH level in normal liver [7,8] is probably greater than that required for optimal enzymatic activity. Hence, the capacity to degrade uracil may be limited only by the amount of enzyme. The rate of uracil breakdown in the intact rat [5] support this view.

Adsorption of Water Vapour by Tissue Polysaccharide

J. Pikkarainen and E. Kulonen

Department of Medical Chemistry, University of Turku, Finland

Since "water-binding" is considered as a special rôle of the connective tissue polysaccharides, the affinity of water vapour to their surface was determined using the Brunauer-Emmett-Teller-plot [1]. The preparation was isolated from human umbilical cords (using $CaCl_2$-extraction, precipitation with 66 % ethanol and repeated Sewag-procedure) and contained nitrogen 0.07 mg/ml and glucosamine 0.32 mg/ml (corresponding to about 76 % polysaccharide and 24 % protein). The solution was lyophilized. Part of this dry residue was depolymerized with hyaluronidase, and the digest was dialyzed and lyophilized. The combustion residues were about 15—17 % and the results are correlated accordingly.

The practical procedure was adopted from Bull [2], except that + 40°C temperature was used. Ten points up to $P/P_o = 0.6$ were determined. The B.E.T. plots were quite straight, and the following constants were obtained from estimating equations:

original preparation Vm 11.3 ml/100 g, C 39;
depolymerized " 12.6 " /100 g, " 99.

* Fellow of The Norwegian Cancer Society, Oslo, Norway.

Hyaluronate adsorbs water more than collagen, but the difference is not large. The effect of depolymerization is seen in the change of the constant C.

Purification and Properties of a Bacterial Glucose Dehydrogenase

J. G. Hauge

The State Institute for Public Health, Oslo, Norway

A bacterium posessing a glucose dehydrogenase was isolated from a secondary culture infection. It has provisionally been assigned to the genus *Alcaligenes*. 100 g quantities (dry wt.) of the organism could be grown in a simple 20 liter continuous culture apparatus in a normal work day. Resting cells oxidize glucose rapidly to the level of 1 atom oxygen consumed per molecule glucose, and from then on at a reduced rate. In this first period CO_2 evolution is slight. Cell-free extracts, prepared by grinding with Ballotini glass beads, also carry out oxidation of glucose with oxygen as acceptor. The primary dehydrogenation could be studied with 2,6-dichlorophenol indophenol as hydrogen acceptor. Using this assay method, the enzyme was purified 250 fold with protamine sulphate, ammonium sulphate, DEAE cellulose, and calcium phosphate gel. At this stage the enzyme catalyzes the reduction of 40 μmoles dye per min per mg protein.

Cytochrome *c* or DPN are not reduced at a significant rate, and reoxidation with oxygen is not measurable, unless phenazine methosulphate is also added. In the presence of phenazine methosulphate and oxygen, the immediate product of the reaction was shown to be gluconolactone. The absorption spectrum of the enzyme preparation shows the presence of a b-type hemoprotein, partially reducible by glucose. The spectrum also suggests the presence of functional flavin, and preliminary inhibition and fluoresence data support this evidence. This soluble dehydrogenase appears to represent a fragment of the particulate glucose oxidation system found in the cells and the extract.

Collagen Fractions in Experimental Lathyrism

L. Mikkonen, T. Tuominen and E. Kulonen

Department of Medical Chemistry, University of Turku, Finland

The collagen fractions of pooled skins of lathyritic and control rats were obtained by a modified procedure by Harkness *et al.*[1]. In the disodium phosphate-soluble fractions the collagen was estimated from the content of hydroxyproline [2], the acid-soluble and insoluble fractions from the nitrogen content. Four extraction series were performed in both groups.

The insoluble collagen was nearly same in lathyritic animals as in controls. The acid-soluble collagen was higher in lathyritic samples (content 0.48 % and 0.18 % from the air-dried skin samples of lathyritic and normal rats, respectively; $P>0.10$).

The most marked difference was in the disodium phosphate-soluble collagen. Calculated from the hydroxyproline contents of the extracts, the averages were 3.15 % and 0.62 % in the lathyritic and normal samples, respectively ($P<0.001$) and after precipitation the alkali-soluble collagen amounted to 1.07 % and 0.30 % ($P<0.01$). It is concluded that in experimental lathyrism the alkali-soluble collagen is increased but there is a defect in the fibre formation.

A New Sensitive Detector for Gas Chromatography

E. Haahti and T. Nikkari

Department of Medical Chemistry, University of Turku, Finland

We constructed Lovelock's type of gas chromatography detector [1] of Pyrex-glass using the ^{90}Sr-covered silver plate as anode. Some incidental observations prompted us to replace the anode by a non-radioactive aluminium plate.

This modification of the detector was equally useful for analysis of methyl esters of fatty acids. It seemed to possess the same characteristics of response as the ^{90}Sr-detector, with some advantages in the operation.

The response of this detector was studied in a gas-chromatography apparatus made in our laboratory according to James [2], using a 4 feet glass column of 4 mm diameter filled with Celite 545 of 100—120 mesh containing 20 % (w/w) Apiezon L grease as stationary phase. Commercial argon (99.8 %) at an inlet pressure of 0.5 atm was used as carrier gas. The column and the detector were maintained at a temperature of 180°C. The ionization current was amplified by a feedback electrometer amplifier with 5 000 MΩ input resistance and recorded by a Honeywell recorder. Different anode-voltages ranging from 450 V to 2 000 V could be applied. Using a potential of 2 000 V and applying 0.1 μl of a 1:200 000 dilution (w/v) of methyl laurate in chloroform, the detector still gave a well detectable response, which corresponds to 5×10^{-4} μg of methyl laurate.

The sensitivity of this detector is at least of the same order as that of Lovelock's detector. The absence of the strontium plate causes a considerable fall of the basic ionization current and increases stability of the detector at higher anode potentials and gives a low noise level.

The Mechanism of Inactivation of SH-Enzymes by X-Rays

Rolf Lange* and Alexander Pihl

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

Previous work in this laboratory has established [1,2] that the SH-enzymes muscle glyceraldehyde dehydrogenase (GAPDH) and yeast alcohol dehydrogenase (ADH) are inactivated by X-rays with ionic yields which fall in the same range as those of non-SH-enzymes. This finding, which stands in contrast to previous claims [3,4], raises the questions as to the radiosensitivity of protein SH-groups and the role of such groups in the radiation induced inactivation of SH-enzymes. In order to throw light on these questions the X-ray inactivation of GAPDH and ADH in dilute solution has been correlated with the concomitant disappearance of titratable SH-groups.

In the case of GAPDH, the disappearance of the protein SH-groups as well as the enzyme inactivation was found to be a linear function of the radiation dose. Complete inactivation of the enzyme occurred when 3 SH-groups per enzyme molecule had been destroyed. Since GAPDH is completely inactivated by the addition of 3 moles of *p*-chloromercuriphenyl sulphonate [5] the present data strongly indicate that the radiation induced inactivation of the enzyme is entirely due to radiochemical destruction of SH-groups.

The ADH was inactivated by X-ray to a somewhat greater extent than could be expected on the basis of the disappearance of the titratable SH-groups. Thus, from a comparison of the experimentally determined number of SH-groups with the theoretical number calculated on the basis of the remaining enzymatic activity [6], it was estimated that approximately 60—80 % of the enzyme inactivation can be accounted for by the radiochemical destruction of SH-groups.

In both enzymes the disappearance of SH-groups proceeds with a low ionic yield compared with that observed on irradiation of low molecular thiols [7]. This finding indicates that the enzyme SH-groups are protected by the rest of the protein molecule and that the major part of the radiation energy is dissipated in reactions not leading to the loss of thiol-groups. The consequent alterations of the enzyme molecule are apparently of little significance for the enzymatic activity.

The Mechanism of Inactivation of SH-Enzymes by X-Rays

Rolf Lange* and Alexander Pihl

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

Previous work in this laboratory has established [1,2] that the SH-enzymes muscle glyceraldehyde dehydrogenase (GAPDH) and yeast alcohol dehydrogenase (ADH) are inactivated by X-rays with ionic yields which fall in the same range as those of non-SH-enzymes. This finding, which stands in contrast to previous claims [3,4], raises the questions as to the radiosensitivity of protein SH-groups and the role of such groups in the radiation induced inactivation of SH-enzymes. In order to throw light on these questions the X-ray inactivation of GAPDH and ADH in dilute solution has been correlated with the concomitant disappearance of titratable SH-groups.

In the case of GAPDH, the disappearance of the protein SH-groups as well as the enzyme inactivation was found to be a linear function of the radiation dose. Complete inactivation of the enzyme occurred when 3 SH-groups per enzyme molecule had been destroyed. Since GAPDH is completely inactivated by the addition of 3 moles of *p*-chloromercuriphenyl sulphonate [5] the present data strongly indicate that the radiation induced inactivation of the enzyme is entirely due to radiochemical destruction of SH-groups.

The ADH was inactivated by X-ray to a somewhat greater extent than could be expected on the basis of the disappearance of the titratable SH-groups. Thus, from a comparison of the experimentally determined number of SH-groups with the theoretical number calculated on the basis of the remaining enzymatic activity [6], it was estimated that approximately 60—80 % of the enzyme inactivation can be accounted for by the radiochemical destruction of SH-groups.

In both enzymes the disappearance of SH-groups proceeds with a low ionic yield compared with that observed on irradiation of low molecular thiols [7]. This finding indicates that the enzyme SH-groups are protected by the rest of the protein molecule and that the major part of the radiation energy is dissipated in reactions not leading to the loss of thiol-groups. The consequent alterations of the enzyme molecule are apparently of little significance for the enzymatic activity.

Purification of Pepsin by Gel Filtration

Bertil Gelotte and Anna-Britta Krantz

Research Laboratories, Pharmacia, Uppsala, Sweden

A new separation method called gel filtration has recently been developed [1]. It is an extension of the observations made by Lathe and Ruthven [2] that molecules of different size can be separated, when filtered through a column of starch. In these experiments the cross-linked polysaccharide Sephadex G-50 (manufactured by Pharmacia, Uppsala, Sweden) was used as bed material.

Sephadex consists of small grains, which swell in aqueous solutions. In the swollen state the gel grains are packed to a column in a glass tube. When a solution is filtered through the bed, solutes of large molecular size are prevented from entering the gel phase and will thus move in the aqueous phase surrounding the grains. Low molecular weight solutes, however, penetrate the gel phase and will pass the column in the water inside as well as outside the grains. They will therefore be eluted from the column later than the larger ones.

The method is very useful for desalting colloid solutions, for fractionation of polymer homologues and for group separation of biological extracts [1,3-5]. It can also be used as a step in a purification procedure, which is exemplified by a purification of pepsin.

A crude pepsin (Pepsin 1:10 000 from A/S Orthana, Copenhagen) was used as starting material. The proteolytic activity was tested spectrophotometrically at 280 mμ with hemoglobin as substrate and expressed as activity per mg of nitrogen. The activity of our preparations was compared with that of a twice crystallized pepsin (Worthington Biochemical). The gel filtration experiments were made on a column 7.5 × 49 cm equilibrated with 0.2 M sodium acetate pH 4.9.

100 ml of the acetate buffer containing 37 g of crude pepsin was filtered through the column with the same buffer as eluent, and with an elution rate of 30 ml/min. After partial concentration in vacuum the eluted pepsin was desalted by a second gel filtration on the same column using distilled water as eluent. The saltfree pepsin was then lyophilized.

A good purification and a quantitative recovery was obtained in the filtration experiments. Unfortunately, there was some loss of activity in the concentration steps. Therefore, in another series of experiments, the concentration was made with Sephadex. The pepsin solution was mixed with the dry powder, which takes up water but leaves the protein molecules outside the grains. By filtration with careful suction a concentrated enzyme solution was obtained without any loss of activity.

The experimental results are summarized in Table 1.

Table 1.

Treatment	Yield, %		Pepsin activity	
	Nitrogen	Activity	Conc. in vacuum	Conc. with Sephadex
Orig. solution	100	100	23	23
1st gel filtration	35	99	65	59
Concentration	35	84	55	64
2nd gel filtration	23	84	84	87
Concentration	23	72	72	95

New Pigments Derived from Vitamin B_{12} by the Use of a Gram Negative Organism

K. Helgeland, J. Jonsen and S. Laland

Department of Biochemistry, University of Oslo, Blindern, Oslo, Norway

We wish to report the bacterial conversion of cyanocobalamin into several different coloured substances by a gram negative rod isolated from soil. The gram negative rod has been classified as *Aerobacter aerogenes*.

The microorganism was grown in a synthetic fluid medium containing 0.8 % glucose, salts and 0.4 mg cyanocobalamin per ml. After incubation at 37°C for 12 days the culture was centrifuged and the supernatant extracted with phenol. The phenol layer was separated by centrifugation, washed with water to remove salts and diluted with ether. Unchanged vitamin B_{12} and the pigments were then re-extracted into water.

By electrophoresis in N acetic acid the extracted material separated into two coloured substances with mobilities different from that of unchanged cyanocobalamin. They both carried a positive charge and exhibited a mobility of 0.75 (I) and 0.25 (II), respectively, relative to aquo-cobalamin.

Substance (I) had a brownish-yellow colour, while substance (II) was yellow. The yield of these two substances was very low and only substance (I) has been further investigated. It was purified by descending chromatography in the usual *sec.* butanol water-1 % acetic acid-0.01 % KCN solvent. In this solvent it had an R_F of 0.35 whereas the R_F of cyanocobalamin was 0.25.

When dissolved in distilled water it exhibited the following absorption maxima, 262, 342 and 474 mμ, and when examined in 0.1 M KCN the brownish-yellow substance turned pink with a concomitant shift in the maxima to 280, 344 and 494–502 mμ. This shift in colour and maxima, as with cyanocobalamin, was shown to be reversible. In water it showed the absorption ratios $O.D._{342}/O.D._{474} = 1.0$ and $O.D._{342}/O.D._{262} = 0.4$, and in 0.1 M KCN $O.D._{344}/O.D._{494} = 1.0$ and $O.D._{344}/O.D._{280} = 0.6$. The absorption spectrum resembles that of cyanocobalamin, the main difference being the lack of the large maximum in the region 300–400 mμ.

The presence of Co as indicated by the absorption spectrum in KCN was verified by the use of ^{58}Co labeled cyanocobalamin.

Substance (I) was purified twice by electrophoresis in N acetic acid and twice by paper chromatography in the previously mentioned solvent and showed then small but definite activity in the *Lactobacillus leichmannii* and *Euglena gracilis* test. Since the presence of contaminating vitamin B_{12} cannot be completely excluded, the microbiological activity of the substance must be interpreted with some caution.

No conversion was found with *E.coli* or several gram positive bacteria tested (*B. subtilis, B. cereus, Str. faecalis* and *Staph. aureus*).

We wish to thank Glaxo Lab. Ltd. for the gift of vitamin B_{12} and *Nansenfondet* for financial support.

A Cytochemical Study of Enzymes in the Alveolar Phagocytes

Mikko Niemi

Department of Anatomy, University of Helsinki, Helsinki, Finland

Alveolar phagocytes of several vertebrates have been studied using histochemical techniques. These cells have been shown to exhibit a strong activity of acid phosphatase, non-specific esterase, cathepsin and leucine aminopeptidase. They were also found to contain a high activity of DPNH diaphorase as well as succinic dehydrogenase. Furthermore, the enzymatic activity of eight out of the nine histochemically demonstrable pyridine nucleotide-linked dehydrogenases was found to be intense, β-hydroxybutyrate dehydrogenase activity, however, being absent in the lungs of all the species studied. This obvious blockage of fatty acid breakdown in alveolar phagocytes may be correlated with some pathological changes in the lungs.

The DPNH diaphorase activity was also demonstrated in the fetal mouse lungs. Here, the staining reaction was, however, localized in the endodermal cells only; thus, towards the end of the foetal life, the forming alveoli were found to be filled with cells of moderate enzyme activity, whereas the mesodermal connective tissue cells exhibited no enzyme activity at all. This finding strongly suggests that the alveolar cells are derived from the alveolar epithelium, *i.e.* of endodermal origin.

The Oxidation of TPNH by Rat Liver Microsomes and its Stimulation by Inducing Agents

Alexandra von der Decken and Tore Hultin

The Wenner-Gren Institute, Stockholm, Sweden

A number of enzymatic reactions related to metabolic detoxication have been shown to be associated with the microsomal structures of the liver. The reactions are aerobic but take place only in the presence of reduced pyridine nucleotides, primarily TPNH. The activity of these enzymes temporarily increases after the intraperitoneal injection of small amounts of methylcholanthrene (MC)[1]. It has been shown that TPNH can be oxidized by rat liver microsomes in the presence of *i.a.* cytochrome c, dichlorophenolindophenol or tetrazolium salts. Cytochrome c, however, is not present in the microsomes, which instead contain another related compound, cytochrome b_5. Preparations of cytochrome b_5 become reduced in the presence of liver microsomes and TPNH.[2]

In our experiments the oxidative demethylation of *p*-methylaminoazobenzene by liver microsomes of young rats was stimulated about 3 times as a result of MC treatment. The reduction of cytochrome b_5 in the presence of TPNH by the same microsomal preparations was measured by following the development of the difference spectrum in the region of 557 mμ. Normal microsomes usually showed an activity of the order 3×10^{-3} μmoles of reduced cytochrome b_5 per mg protein per minute. The cytochrome b_5 reduction was significantly increased in the microsomes from MC-treated animals. Also the TPNH-diaphorase (measured by dichlorophenolindophenol or neotetrazolium) was stimulated, while on the other hand the TPNH cytochrome c reductase showed a significant decrease. The content of cytochrome b_5 in the microsomes did not change appreciably under these conditions.

After partial hepatectomy the activity per mg protein of oxidative demethylase and the content of cytochrome b_5 in rat liver microsomes decrease by about 50 %[3]. Hepatectomized rats were treated with MC 24 hours after the operation. In comparison with non-treated, hepatectomized rats the demethylase activity increased about 4 times. At the same time the reduction of cytochrome b_5 by TPNH was stimulated. The TPNH diaphorase activity increased by 15—25 %, while the TPNH cytochrome c reductase again showed a decrease. In the regenerating livers the cytochrome b_5 content showed a positive response to MC.

The experimental results may imply that an oxidation of TPNH by cytochrome b_5 is somehow involved in the microsomal reactions stimulated by the MC-treatment.

Ethanol and Liver Metabolism

Olof Forsander and Niels Räihä

Research Laboratories of the State Alcohol Monopoly, Helsinki, Finland

During the oxidation of ethanol to acetic acid *ca.* 1/3 of its energy content is liberated in the liver. If it is assumed that the need of energy is constant in the liver, and that the energy derived from ethanol can be utilized as well as that of other substrates, it would seem reasonable to postulate that the breakdown of other substrates would decrease correspondingly during the oxidation of ethanol.

During the artificial perfusion of an isolated normal rat liver the addition of ethanol to the perfused blood decreased the amount of CO_2 liberated, whereas the fasted liver with a low initial CO_2 production was unaffected. The oxidation of ethanol changed the type of metabolism in a normal liver from a complete oxidation of substrate to CO_2 to a partial oxidation to intermediates, whereas the metabolism of the fasted liver, where the partial oxidation already was considerable, was unaffected. In the normal liver the partial oxidation was increased by ethanol and an accumulation of organic acids proportional to the decrease of the complete oxidation was observed. During the perfusion of normal liver 2.27 mg of CO_2 per min was produced. When ethanol was added to the blood the production of CO_2 decreased to 1.48 mg per min and additional energy was produced from the partial oxidation to acetic acid of 1.26 mg of ethanol per min. If it is assumed that the CO_2 production in the normal liver is derived solely from complete oxidation of carbohydrates the energy production would be 5.7 cal per min. In the case where ethanol was added to the blood the calculated energy production would be 6.6 cal per min.

Apparent Phosphate Ion Effect on Activity of Phosphoprotein Phosphatase

Bo Norberg

Kemiska Centrallaboratoriet, Sabbatsbergs Sjukhus, Stockholm, Sverige

Phosphoprotein phosphatase activity was lost upon dialysis of the extract (rat liver and erythrocytes). The studies (to be reported in detail elsewhere) show an activating effect of a small amount of phosphate ion (to a final concentration of 0.1 to 0.3 mM PO_4 depending on substrate concentration) whereas higher concentrations are inhibitory, as found earlier [1].

Effects of Carcinogenic Amines on the Protein and Ribonucleic Acid Metabolism of the Liver

E. Arrhenius and T. Hultin

The Wenner-Gren Institute, University of Stockholm, Sweden

The incorporation in vitro of [^{14}C]-DL- valine into the proteins of rat liver slices was studied after different periods of preincubation with 2-aminofluorene (AF), 2-acetylaminofluorene (AAF), 7-fluoro-2-aminofluorene (FAF), 7-fluoro-2-acetylamino-fluorene (FAAF), 2-aminonaphtalene (AN) and aniline at varied concentrations. While a marked reduction of the incorporation was caused by the polynuclear amines, no significant inhibition was observed in the case of aniline even at relatively high concentrations (10^{-3} M). Similar experiments were performed with AF and AN, with [^{14}C] adenine as isotopic component. Adenine and guanine were isolated from RNA, and their specific activities were determined. Also in this case a marked inhibition was observed, less strong however than in the [^{14}C] valine experiments. Within the group of polynuclear amines the capacity of inhibition was not in detail correlated to the carcinogenic potency. As a rule AN was at least as inhibitory as AF, although AN is known to exert its carcinogenic effect on other target organs than the liver. FAF had a slightly lower inhibitory effect than AF. An inhibition by AF and FAF was observed not only in rat liver slices but also in liver slices of guinea pig, although this animal is refractory to the carcinogenic action of AF derivatives. Rats were treated *in vivo* with AN (100 mg/kg in 1.0 ml of propylene glycol, *per os*). The incorporation of [^{14}C] L-leucine into proteins by a mitochondriafree liver preparation was studied 4 h after the AN- treatment. The activity of the preparation for leucine incorporation *in vitro* was reduced when compared with similar preparations from untreated rats. The microsomes of the system showed a decreased activity in comparison with normal microsomes.

Inhibitor Effects on Light-Induced Phosphorylation. A Comparison between Plant and Bacterial Systems

Herrick Baltscheffsky

Wenner-Gren Institute, University of Stockholm, Sweden

Electron transport in mitochondrial oxidative phosphorylation is strongly inhibited by amytal (I), atebrin (II),antimycin A (III) and 2-*n*-heptyl-4-hydroxyquinoline-N-oxide (IV). The effects of these inhibitors were tested on light-induced phosphorylation (LIP) in washed spinach chloroplasts, and compared with earlier results obtained with washed bacterial (*Rhodospirillum rubrum*) chromatophores [1-4]. The following results were obtained in an ascorbate containing medium, whether or not flavin mononucleotide had been added (aerobic conditions, saturating light intensity, 20°C). A 2×10^{-3} M concentration of I gave only little inhibition, as in bacterial LIP [4]. 5×10^{-5} M concentrations of II, III or IV gave inhibitions between 50 and 100 %. The inhibition with II occurs in the same inhibitor concentration region as with chromatophores and indicates participation of chloroplast flavin in the electron transport in chloroplast LIP. For III and IV, however, the concentrations needed are about 1 000-fold higher than with chromatophores (or animal mitochondria).

Earlier results with these inhibitors have indicated that electron transport in bacterial (*R. rubrum*) LIP proceeds over a chain with at least two electron carriers [3,4]. The present results will be discussed in relation to current schemes of electron transport in plant LIP, and the electron transport chains in plant and bacterial LIP will be compared.

Diphosphothiamine Disulfide in Baker's Yeast

Heikki Suomalainen, Sakari Rihtniemi and Erkki Oura

Research Laboratories of the State Alcohol Monopoly, Helsinki, Finland

About 15 years ago Myrbäck and coworkers [1] indicated that baker's yeast, produced in vigorously aerated conditions, contains nearly all its thiamine as diphosphothiamine disulfide. His findings were met with criticism and his viewpoint was not generally accepted, also owing to the fact that the physiological function of cocarboxylase disulfide has not been conclusively verified.

We have now, in contrary to our earlier attempts [2] been able to confirm the appearance of diphosphothiamine disulfide in aerobically cultivated baker's yeast. We first repeated the experiments of Myrbäck and found a thiamine derivative in baker's yeast, which after cystein reduction acted like cocarboxylase in the thiochrome reaction. With ionexchange chromatography, using Dowex 1-X resin in formiate form, a thiamine derivative was separated from the perchloric acid extract of the commercial stage of baker's yeast, which was eluted by gradient eluation with formic acid or with ammonium formiate considerably later than thiamine, thiamine disulfide or thiamine monophosphate and cocarboxylase, the speed corresponding to that of synthetic diphosphothiamine disulfide (Merck). When oxidized after cystein reduction it gives a thiochrome reaction corresponding to that of cocarboxylase.

Changes in the Microbial Amino Acid Metabolism Induced by 4-Deoxypyridoxine

J. Jännes and T. Lahikainen

Aurora Hospital, Helsinki, Finland

Normal strains of *E.coli* were grown in media containing 4-deoxypyridoxine in amounts of 10, 20, 30 and 40 mg per 10 ml of the culture media. Asparagine was the only source of nitrogen, and the incubation time was 7 to 8 days at 37 C°. At the end of the incubation time the media were centrifuged. The clear supernatants were treated with Amberlite IR 120 resins in acid form and eluated with 1 N ammonium hydroxide. The analyses of the amino acids were performed with paper chromatography. The most characteristic finding was the disappearance of the spots of both glutamic and γ-amino-butyric acids when 4-deoxypyridoxine was present in the culture media. The effect of 4-deoxypyridoxine on the growth was also noticed.

Two Unusual U.V. Absorbing Substances Associated with Amino Acids in Bacterial Extracts

Jon Jonsen, S. Laland and I. Smith-Kielland

Department of Biochemistry, University of Oslo, Blindern, Oslo, Norway

During an investigation of the nucleotides in various extracts from different bacteria we have detected unusual ultraviolet absorbing acidic substances associated with amino acids.

Crude acid-soluble extracts were made by cold perchloric acid treatment of bacteria disrupted in a bacterial press.

Crude water-soluble extracts were obtained by heating living cells in boiling water for 10 min.

The bacteria were harvested during rapid growth. In some cases the extracted material was adsorbed on Norite and again eluted with 50 % ethanol containing 2 % of conc. ammonia. The extracts were fractionated on a Dowex

The bacteria were harvested during rapid growth. In some cases the extracted material was adsorbed on Norite and again eluted with 50 % ethanol containing 2 % of conc. ammonia. The extracts were fractionated on a Dowex

Table 1.

	Spectra in acid max	min	250/260	280/260	Spectra in alkali max	min	250/260	280/260
Substance I	266	237	0.76	0.82	275	244	0.79	1.16
Substance II	261	237	0.63	0.13	261		0.76	0.17

1 × 8 column in the formate form by gradient elution with the formic acid-ammonium formate system of Hurlbert *et al.* A slight modification was introduced as the elution prodecure was started with very dilute formic acid (0.001 M) in the reservoir.

In addition to amino acid complexes containing adenine nucleotides, two other complexes with amino acids were isolated which had U.V. spectra different from any of the usual purines and pyrimidines. Both were eluted early in the fractionation procedure. One (substance I) appeared earlier than any of the known nucleotides, the other (substance II) together with CMP-5' or in a fraction following immediately after CMP-5'.

In paper chromatography both substances moved as single spots in five different solvents. In most solvents the R_F values exceeded those of the known nucleotides. No change in the mobility of the U.V. absorbing substances was observed after hydrolysis for 18 h in N HCl at 120°C. The two substances were homogeneous and negatively charged at pH 7.0 as indicated by electrophoresis in phosphate buffer.

Whereas the unhydrolyzed material was ninhydrine negative, hydrolysis in 6 N HCl gave for both substances ninhydrine positive spots corresponding to the position of alanine, serine, aspartic acid, glutamic acid, glycine and lysine in two dimensional paper chromatography. Small amounts of these amino acids also split off when the unhydrolyzed material was subjected to paper chromatography. None of the substances contained phosphate. One of them (substance I) could be reduced with sodium amalgam and the reduced material gave positive test for ribose.

The two substances exhibited a slight difference in the electrophoretic mobility at acid pH values and pronounced differences in the spectra values as shown in Table 1.

Biologically Active Fractions from *Haemophilus Pertussis*

H. Billaudelle, L. Edebo, E. Hammarsten, C.-G. Hedén, B. Malmgren and H. Palmstierna

Department of Bacteriology, Karolinska Institutet, Stockholm, Sweden

Cells from *H. pertussis*, cultivated in the 500 litres scale, were disintegrated in the frozen state in the Hughes press. The disintegrate was extracted by a series of aqueous salt solutions. The supernatant was highly neurotoxic and dermatonecrotic. The neurotoxin was purified by column electrophoresis on a stabilized medium (320 cm columns). Due to the presence of acid polyelectrolytes the conditions for a purification of the neurotoxin on cellulose ion exchangers are unfavourable. They were consequently removed by electrophoresis before chromatography. The neurotoxin occurs in the same pK region (around 7.4) as a blue coloured protein. There exist dermatonecrotic proteins in other pK regions. The neurotoxin is reasonably stable only in its isoelectric region.

The neurotoxin has been purified to a MLD per 10 g mouse of 10 μg. Further purification is tried.

The residue after extractions forms very stable suspensions after the salts have been removed. It can be spun down at 100 000 *g*. It is salted out by monovalents salts. It can be solubilised again by either removing the salts or by making it 2 M with regard to urea. The residue contains two lipid fractions, protein and (amino-)polysaccharide. It is nontoxic up to at least 2 mg per 10 g mouse, and protects mice against 1 000 MLD of *H. pertussis* down to at least 50 μg per 10 g mouse. Electron microscopy shows that it consists primarily of bacterial cell walls. A *Haemophilus pertussis* immunogen has thus been found that shows no toxic activity on mice even in high dosages.

The work has been performed under a grant from the *U.S. Army European Research Office.*

Table 1.

	Spectra in acid max	min	250/260	280/260	Spectra in alkali max	min	250/260	280/260
Substance I	266	237	0.76	0.82	275	244	0.79	1.16
Substance II	261	237	0.63	0.13	261		0.76	0.17

1 × 8 column in the formate form by gradient elution with the formic acid-ammonium formate system of Hurlbert *et al.* A slight modification was introduced as the elution prodecure was started with very dilute formic acid (0.001 M) in the reservoir.

In addition to amino acid complexes containing adenine nucleotides, two other complexes with amino acids were isolated which had U.V. spectra different from any of the usual purines and pyrimidines. Both were eluted early in the fractionation procedure. One (substance I) appeared earlier than any of the known nucleotides, the other (substance II) together with CMP-5' or in a fraction following immediately after CMP-5'.

In paper chromatography both substances moved as single spots in five different solvents. In most solvents the R_F values exceeded those of the known nucleotides. No change in the mobility of the U.V. absorbing substances was observed after hydrolysis for 18 h in N HCl at 120°C. The two substances were homogeneous and negatively charged at pH 7.0 as indicated by electrophoresis in phosphate buffer.

Whereas the unhydrolyzed material was ninhydrine negative, hydrolysis in 6 N HCl gave for both substances ninhydrine positive spots corresponding to the position of alanine, serine, aspartic acid, glutamic acid, glycine and lysine in two dimensional paper chromatography. Small amounts of these amino acids also split off when the unhydrolyzed material was subjected to paper chromatography. None of the substances contained phosphate. One of them (substance I) could be reduced with sodium amalgam and the reduced material gave positive test for ribose.

The two substances exhibited a slight difference in the electrophoretic mobility at acid pH values and pronounced differences in the spectra values as shown in Table 1.

We wish to thank *Norges Almenvitenskapelige Forskningsråd* for financial support.

On the Enzymatic Formation of Ester Sulphates of Aliphatic Polyols

Anders Vestermark and Harry Boström

Department of Metabolic Research, Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

Sulphate conjugation of phenols [1], steroids [2,3], some amines [4], certain carbohydrate acceptors [5] and primary aliphatic alcohols [6] is known to take place in cell-free media containing sulphate-activating and sulphate-transferring enzymes [7].

Our studies on alcohols have now been extended to aliphatic polyols, and indications have been obtained of an enzymatic sulphurylation of several compounds of this type. As in earlier studies [8,6], ^{35}S-labelled sulphate was used as tracer substance; formation of sulphate esters in the incubating medium [3] (phosphate buffer, ATP, Mg ions, particle-free rat liver supernatant, ^{35}S-labelled sulphate and sample of substance to be tested) was demonstrated by means of two-dimensional paper chromatography and electrophoresis, both methods combined with autoradiography.

The results of this investigation are briefly summarized in Table 1. In most experiments, a new spot appeared in addition to the basic pattern, indicating the formation of a sulphate ester. Higher concentrations of the substance added gave stronger spots, until in some cases inhibition occurred.

As seen in the table, the different glycols studied (Group I) had about the same tendency to form sulphate esters in the system used. Increased number of HCOH groups (II) decreased the tendency to sulphate conjugation. Of the diols tested (Group III), those with a larger distance between the OH groups were more easily combined with sulphate.

Changes in the Phosphatase Activity and Location of Phosphatases in Baker's Yeast Cells

Erkki Oura, Heikki Suomalainen and Matti Linko

Research Laboratories of the State Alcohol Monopoly, Helsinki, Finland

Using phenolphtalein diphosphate as a substrate it was possible to demonstrate three peaks in the pH-curve of the phosphatase activity of baker's yeast, one at the pH optimum of the acid phosphatase, 4.3, and two on the alkaline side at pH 7.9 and 8.9. The acid phosphatase of baker's yeast is mainly located on the cell surface, about one third, however, within the cell. Both alkaline phosphatase components are wholly located inside the cell membrane.

During the industrial cultivation of baker's yeast the nitrogen content decreases stage by stage, as does the phosphorus content during the last two stages. The acid phosphatase activity first increases, but falls sharply to one tenth during the growth period of the precommercial A_4 stage. The activity increases again during the cultivation of the commercial yeast stage when the phosphorus content of the yeast still more decreases. During the phosphorus starvation of the commercial yeast stage the activity of the acid phosphatase increases sharply being 3 to 8 fold in 8 h as compared with the seed yeast.

The activity of the alkaline phosphatases up to the commercial yeast stage does apparently follow the decrease in the phosphorus content of the yeast cells. A sharp increase in the activity 4 to 6 times is, however, observed during the experimental phosphorus starvation of the cells.

A more detailed report will be published elsehwere [1].

Short Communications

New Secular Equations in the Problem of Molecular Vibrations

S. J. CYVIN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The well-known secular equation in the problem of harmonic vibrations of polyatomic molecules may be put in the form [1,2]

$$| GF - E\lambda | = 0 \qquad (1)$$

Here G and F are the energy matrices introduced by Wilson,[1] and E is the identity matrix. The G matrix is composed of the atomic masses and occasionally the structural parameters of the molecule, the F matrix containing the force constants included the interaction terms. Eqn. (1) yields the familiar relations connecting the force constants with the normal frequencies of the molecule. The values of λ are proportional to the squares of the frequencies (ν) according to the equation

$$\lambda_k = 4\pi^2\nu_k^2 \qquad (2)$$

It should be emphasized that the number of normal frequencies of a polyatomic molecule in most cases is not sufficient for the complete determination of the harmonic force field. Therefore usually a simplified force field, *e.g.* a valence force field is assumed, or additional information, *e.g.* normal frequencies from isotopically substituted molecules, or force constant values from related molecules, are utilized.

Let now S be a column matrix consisting of a complete set of internal displacement coordinates and connected with the vibrational normal coordinates (Q) through the linear transformation

$$S = LQ \qquad (3)$$

The following relations involving the transformation matrix L exist.

$$\tilde{L}FL = \Lambda \qquad (4)$$

$$G = L\tilde{L} \qquad (5)$$

Here $\sim$ denotes the transpose of a matrix, and Λ is a diagonal matrix with the elements λ_k given by eqn. (2). The symbol $\langle\rangle$ will be used to indicate that the mean value of each element of the matrix in question has been taken, and the matrix

$$\Sigma = \langle S\tilde{S} \rangle \qquad (6)$$

will be considered. The elements on its main diagonal, *viz.*

$$\Sigma_{ii} = \langle S_i^2 \rangle \qquad (7)$$

have been called the "mean-square amplitudes of vibration" and are of considerable interest in molecular structure studies (see, *e.g.* Refs.[3-5]).

The matrix Σ of eqn. (6) may be computed by means of the L matrix according to

$$\Sigma = L \triangle \tilde{L} \qquad (8)$$

where $\triangle = \langle Q\tilde{Q} \rangle$ is a diagonal matrix with the elements

$$\triangle_k = (h/8\pi^2\nu_k)\coth(h\nu_k/2kT) \qquad (9)$$

If the F matrix has been established, and with the knowledge of the normal frequencies, the L matrix may be obtained according to eqn. (1) by means of the standard method of characteristic vectors applied to the GF matrix. This is the method for computing mean-square amplitudes of vibration which has been evaluated by Morino *et al.*[4]

The progress in gas electron diffraction techniques has made it possible to produce experimental values of root-mean-square

amplitudes of vibration,[5] and it has been proposed to utilize such measurements in force constant determinations. It seems to be doubtful whether the present electron diffraction data of root-mean-square amplitudes are of sufficient accuracy to be of practical value for this purpose. Nevertheless, we may hope that the accuracy still will increase in the future. This discussion indicates the desire of evaluating a method for obtaining some information about the force constants from given values of root-mean-square amplitudes of vibration. The above mentioned method of Morino *et al.*[4] is in practice not convenient for such computations.

From eqns. (5) and (8) a new secular equation may be derived and written in the form

$$| \Sigma G^{-1} - E\Delta | = 0 \qquad (10)$$

This equation makes it possible to treat the mean-square amplitudes of vibration similarly to the treatment of force constants. It may be applied to establish relations connecting the normal frequencies and the mean-square amplitudes including the interaction terms, *i.e.* the off-diagonal Σ matrix elements. Here again the number of normal frequencies is usually not sufficient for the complete determination of the Σ matrix, but approximations may be performed, and additional information about the mean-square amplitudes may be utilized. This method represents a new approach to the calculation of mean-square amplitudes of vibration from spectroscopic data, being different from the method of Morino *et al.*[4] Furthermore, if the complete Σ matrix could be established, it would be possible to determine the L matrix by the method of characteristic vectors applied to the ΣG^{-1} matrix. In consequence, the potential energy matrix could be obtained from the equation *

$$F = \widetilde{L}^{-1} \wedge L^{-1} \qquad (11)$$

being a modification of eqn. (4).

Still another secular equation will be reported, *viz.*

$$| \Sigma F - E\lambda\Delta | = 0 \qquad (12)$$

which may be deduced from eqns. (4) and (8). According to eqns. (2) and (9), the characteristic values of the ΣF matrix are

$$\lambda_k \Delta_k = \tfrac{1}{2} h\nu_k \coth (h\nu_k/2kT) \qquad (13)$$

Eqn. (12) yields relations containing the elements from both of the matrices Σ and F. These relations will be useful in combination with the relations obtained from (1) and (12) if it is desirable to apply some information about the Σ matrix elements for determination of the elements of the F matrix, and *vice versa*. Accordingly, such computations may be performed without determination of the L matrix.

It should be pointed out that the new secular eqns. (10) and (12) will factorize in precisely the same manner as the ordinary secular eqn. (1) if a set of *symmetry* coordinates is chosen.

Finally an isotope rule for mean-square amplitudes of vibration will be reported. The ordinary product rule for isotopically substituted molecules as derived from eqn. (1) may be written in the form [1]

$$\prod_i (\nu_i / \nu_i^*) = | G |^{\frac{1}{2}} / | G^* |^{\frac{1}{2}} \qquad (14)$$

where the quantities of the isotopically substituted molecule are identified by an asterisk. Using the analogous notation, one obtains from eqn. (12)

$$| \Sigma | / | \Sigma^* | = \prod_i \frac{\nu_i \coth(h\nu_i/2kT)}{\nu_i^* \coth(h\nu_i^*/2kT)} \qquad (15)$$

If the mean-square amplitudes at the absolute zero are considered, and the corresponding matrices are identified by the subscript $_0$, one obtains

$$|\Sigma_0| / |\Sigma_0^*| = \prod_i (\nu_i/\nu_i^*) = |G|^{\frac{1}{2}} / |G^*|^{\frac{1}{2}} \qquad (16)$$

Some applications of the here presented secular equations to specific problems, are under preparation.

* The L^{-1} matrix may be computed directly by means of a modified form of equation (10), *viz.* $| G^{-1}\Sigma - E\Delta | = 0$.

Optical Rotatory Dispersion

I. A Recording Spectropolarimeter Based on the Cary 11MS—50 Spectrophotometer

FLEMMING WOLDBYE

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The increasing interest in measurements of optical rotatory dispersion recently developed within several branches of chemistry [1-6] has accentuated the instrumentation problems of spectropolarimetry. The solution of the structural and theoretical problems formulated in the works referenced will require a detailed knowledge of the rotatory dispersion within the widest possible wavelength range, especially within the ranges of absorption. Much effort is being spent, therefore, in developing recording spectropolarimeters, none of which, however, seem to be commercially available as yet.

In the course of studies of the optical rotatory dispersion of some transition metal complex ions [6] we have developed an accessory for the Cary 11MS—50 spectrophotometer which permits the automatic recording of optical rotatory dispersion in the wavelength range $800 \geq \lambda \geq 228$ mμ with a relative accuracy of *ca.* 1 %.

Although unsatisfactory for high precision quantitative analysis optical rotatory dispersion curves of this accuracy may certainly meet the requirements of the structural and theoretical investigations.

The principle by which the rotation, α, of a sample is converted into an apparent optical density which may be recorded by the spectrophotometer is illustrated in Fig. 1 *. If the samples, S, are optically inactive, the two systems, P—S—A, have identical optical densities

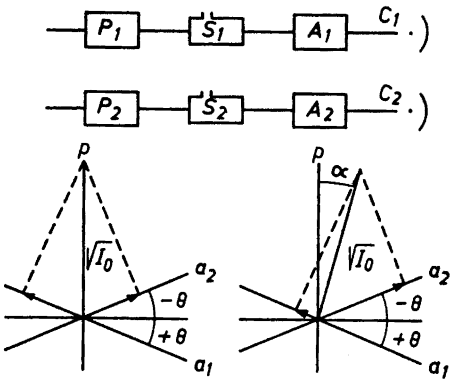

Fig. 1. $P_{1,2}$ polarizers, $S_{1,2}$ identical samples, $A_{1,2}$ analyzers at angles $90° + \Theta$ and $90° - \Theta$, respectively, with the planes of polarization of P_1 and P_2, and C_1 and C_2 sample and standard photomultipliers of the spectrophotometer. p, a_1 and a_2 planes of the electric vector of light polarized by $P_{1 \text{ or } 2}$, A_1 and A_2 viewed from $C_{1 \text{ or } 2}$. The intensities transmitted by the systems are obtained by squaring the lengths of the projections of the electric vector, $\sqrt{I_0}$, upon a_1 and a_2.

$$D_1 = D_2 = \log \frac{I_0}{I} = \log \frac{I_0}{I_0 \cos^2(\pm(90° - \Theta))} + D_u = -2 \log \sin\Theta + D_u$$

where the first term represents the density caused by the relative setting of polarizer and analyzer while D_u represents the density caused by the initial polarization, the absorption in the sample, reflections *etc.* Thus the density recorded by the spectrophotometer, $D_{app} = D_1 - D_2$, will be equal to zero.

If identical, optically active samples, S, causing a rotation $\alpha < \Theta$, are inserted consideration of Fig. 1 shows that $D_1 = -2 \log \sin(\Theta - \alpha) + D_u$ and $D_2 = -2 \log \sin(\Theta + \alpha) + D_u$ so that

$$D_{app} = D_1 - D_2 = 2 \log \frac{\sin(\Theta + \alpha)}{\sin(\Theta - \alpha)} \quad (1)$$

Provided $\Theta + \alpha < 10°$, ($\alpha < \Theta$), the approximate solution [6,9] of (1)

* This principle has been utilized in polarimetry before, *e.g.* by Keston [7]. Also the accessory [8] marketed by the Perkin-Elmer Corporation, which has been developed simultaneously with, but independently of our accessory, is based on this principle.

$$\alpha \approx \Theta \tanh\left(\frac{1}{4 \log e} D_{app}\right) = \Theta \tanh (0.576\, D_{app}) \qquad (2)$$

is correct to within 0.5 %.

For $D_{app} < 1$ this relation between α and D_{app} is nearly linear. The curves recorded are, therefore, very similar to plots of α against wavelength. The exact measuring is most conveniently done by means of a rule graduated so as to permit the direct reading of tanh (0.576 D_{app}).

The necessary attachments to the spectrophotometer consist of two identical units made from brass rod of a square cross section fitting the cell holders of the spectrophotometer equipped with a cylindrical bore accomodating polarizer, polarimeter tube and analyzer. For reasons discussed below the standard light sources of the spectrophotometer have been replaced by a special projector tungsten filament lamp and a 2 kW hydrogen arc for use in the visible and the ultraviolet regions, respectively.

The angles, Θ, are set by means of a special setting apparatus in which adjustments may be made with an accuracy of $\pm$ 0.002°. However, the value of Θ is not measured by means of this instrument but is calculated from measurements of D_{app} for solutions of sucrose of known concentrations by means of (2). The relative accuracy and reproducibility of these determinations of Θ are the same as those obtained in the recording of absorption spectra, *i.e.* $\pm$ 1 % or better.

The details of the construction, operation and performance of the spectropolarimeter together with theoretical considerations regarding the sources of error in the system (ellipticity of the light transmitted by absorbing samples, inequality of the two angles $\pm \Theta$, optical anisotropy of the windows in the sample cells, stray light *etc.*) will be dealt with in a later paper[10], but a few remarks concerning the sensitivity and the accuracy so far obtained should be made.

The main difficulty in measuring optical rotatory dispersion within wavelength ranges of absorption, namely that of getting sufficient light through the sample to be able to measure the rotation, may be expressed quantitatively as

$$A = \frac{D}{|\alpha|} = \frac{100\ \varepsilon}{|[M]|}$$

i.e. the optical density of a sample which will produce a rotation of 1° (ε and $[M]$ being the molar extinction coefficient and rotation, respectively). Being a function of the wavelength this quantity equals zero outside the ranges of absorption but in the vicinity of the peaks (and troughs) of the rotatory dispersion curves which are usually situated within the optically active absorption bands it may often assume values of 7 or 8. Since these parts of the curves are of a particular theoretical interest, a method of measuring rather small rotations with a relatively high accuracy is needed.

Consideration of (2) shows that the sensitivity of the present instrument

$$\frac{D_{app}}{\alpha} \approx \frac{1}{0.576\,\Theta}$$

(tanh $x \approx x$ for small values of x) may, in principle, be increased to any desired value by decreasing Θ. This is, of course, subject to several limitations, the most important of which is the fact that the optical density of the polarimeter units (polarizer-analyzer) increases very rapidly with decreasing Θ at small values of Θ. We are thus facing the problem of finding the optimum value of Θ.

This problem may be attacked as follows [6]. For a given spectrophotometer there will exist a maximum permissible optical density, D_{max}, which cannot be exceeded by the systems inserted into the light paths without seriously affecting the signal-to-noise ratio or the resolution. D_{max} will be a function of the wavelength *and* of the resolution demanded. This maximum condition may be written

$$D_{max} \geq D_1 = -2 \log \sin(\Theta - \alpha) + D_u$$

Splitting D_u into two terms, the optical density due to the absorption in the sample, $D_s = A \times \alpha$, and a constant term, D_p, due to the initial polarization, reflection losses *etc.* we obtain

$$D_m \equiv D_{max} - D_p \geq -2 \log \sin(\Theta - \alpha) + A \times \alpha \qquad (3)$$

Approximating (2) by

$$\alpha = \Theta \times 0.576 \times D_{app} \qquad (2')$$

and $\sin(\Theta - \alpha)$ by $(\Theta - \alpha)$ and eliminating Θ from (2') and (3) we get

$$\frac{dD_{app}}{d\alpha} = 0 \text{ for } \alpha = \frac{2}{A \ln 10} = \frac{0.87}{A}$$

Inserting this value of α into (3) we may calculate the corresponding minimum value (*i.e.* the desired optimum value) of Θ.

If a rough estimate of A has been obtained from preliminary measurements we may adjust the setting of the prisms according to this result and we may use a combination of sample concentration and tube length such that $\alpha = 0.87/A$. Doing this we ensure the highest pen deflection (D_{app}) which may be produced by any sample of the substance in question subject to our requirements of resolution.

The exchange of the ordinary light sources of the spectrophotometer for more powerful ones serves the purpose of increasing D_{max}. In our present setup this has enabled us to work with values of Θ as small as 1.5°, *i.e.* a rotation of 0.001° corresponds to an apparent optical density of *ca.* 0.001, and we believe that it will prove difficult to increase this sensitivity very much. (The Perkin-Elmer attachment [8] is operated at $\Theta \geq 10°$).

The accuracy of the values of α obtained is comparable, or a little inferior, to that with which absorption spectra are recorded by the spectrophotometer, *i.e.* α is correct to within *ca.* $\pm$ 1 %, provided $A < 5$. Substances with appreciably higher values of A must be measured in very dilute solutions, and the correspondingly lower values of D_{app} cannot be evaluated with this relative accuracy.

Isolation of a New Neutral Amino Acid from *Lactarius helvus*

J. CASIMIR* and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

During chromatographic investigations on the soluble nitrogen compounds in the mushroom *Lactarius helvus* we found relatively large amounts of an amino acid which could not be identified with any knovn amino acid already found to occur in plant tissues. This new substance corresponded to spot A in Fig. 1. When treated with ninhydrin on paper, it was easily recognized by a strong yellow colour at 80°C. The colour soon turned violet brown. On two-dimensional chromatograms the substance moved just above glutamine when phenol-water-ammonia and butanolacetic acid-water were used as solvents. The R_F-values

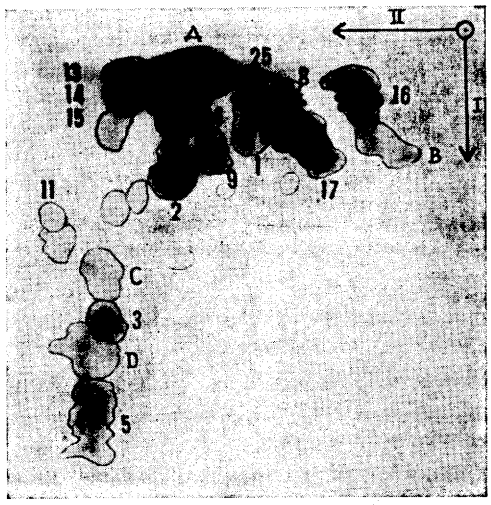

Fig. 1. Two-dimensional paper chromatogram of a 70 % ethanol extract of *Lactarius helvu.*. Spots A, C, and D apparently represent unknown neutral amino acids and spot B an acidic one. 1 gly, 2 ala, 3 val, 5 leu, 8 ser, 9 threo, 11 pro, 13—15 basic, 16 asp, 17 glu, 24 glu-NH_2, 25 asp-NH_2. * Present address: Institut Agronomique de l'Etat, Gembloux, Belgique.

If a rough estimate of A has been obtained from preliminary measurements we may adjust the setting of the prisms according to this result and we may use a combination of sample concentration and tube length such that $\alpha = 0.87/A$. Doing this we ensure the highest pen deflection (D_{app}) which may be produced by any sample of the substance in question subject to our requirements of resolution.

The exchange of the ordinary light sources of the spectrophotometer for more powerful ones serves the purpose of increasing D_{max}. In our present setup this has enabled us to work with values of Θ as small as 1.5°, *i.e.* a rotation of 0.001° corresponds to an apparent optical density of *ca.* 0.001, and we believe that it will prove difficult to increase this sensitivity very much. (The Perkin-Elmer attachment [8] is operated at $\Theta \geq 10°$).

The accuracy of the values of α obtained is comparable, or a little inferior, to that with which absorption spectra are recorded by the spectrophotometer, *i.e.* α is correct to within *ca.* $\pm$ 1 %, provided $A < 5$. Substances with appreciably higher values of A must be measured in very dilute solutions, and the correspondingly lower values of D_{app} cannot be evaluated with this relative accuracy.

Isolation of a New Neutral Amino Acid from *Lactarius helvus*

J. CASIMIR* and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

During chromatographic investigations on the soluble nitrogen compounds in the mushroom *Lactarius helvus* we found relatively large amounts of an amino acid which could not be identified with any knovn amino acid already found to occur in plant tissues. This new substance corresponded to spot A in Fig. 1. When treated with ninhydrin on paper, it was easily recognized by a strong yellow colour at 80°C. The colour soon turned violet brown. On two-dimensional chromatograms the substance moved just above glutamine when phenol-water-ammonia and butanolacetic acid-water were used as solvents. The R_F-values

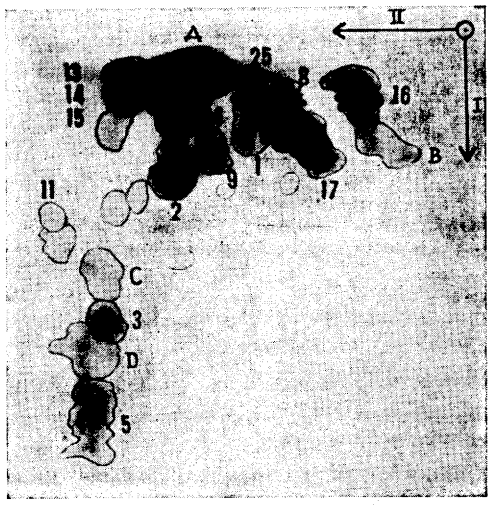

Fig. 1. Two-dimensional paper chromatogram of a 70 % ethanol extract of *Lactarius helvu.*. Spots A, C, and D apparently represent unknown neutral amino acids and spot B an acidic one. 1 gly, 2 ala, 3 val, 5 leu, 8 ser, 9 threo, 11 pro, 13—15 basic, 16 asp, 17 glu, 24 glu-NH_2, 25 asp-NH_2. I butanol-acetic acid-water, II phenol-water-NH_3.

* Present address: Institut Agronomique de l'Etat, Gembloux, Belgique.

(Whatman 4) in the two solvents are 0.54 and 0.06, respectively. Additional unknown spots coloured with ninhydrin are also present on the chromatogram. A substance which gives a yellow spot B near aspartic acid, moves with the acidic fraction on paper electrophoresis at pH 5.6. Brown spots C and D were present in smaller amounts than A, moving with phenol-water-ammonia as valine and with butanol-acetic acid-water just above and below valine, respectively. A, C, and D appeared to be neutral.

Isolation of the amino acid A. About 10 kg (fresh weight) of *Lactarius helvus* were extracted with 40 l of ethanol. After partial decolorization with active charcoal (Darco G 60), which absorbs tyrosine and phenylalanine but not substances A, B, C, or D, the extract was concentrated and passed through an Amberlite IR-120 column. Amino acids were eluted from the column with 1 N ammonium hydroxide. The eluate was evaporated to dryness *in vacuo* giving a yellow powder (26 g). From a 10 g portion of this powder dissolved in 70 ml of 0.5 N acetic acid the acidic amino acids were separated from the neutral and basic ones in a Dowex 1 column (4.5 × 75 cm). 300 fractions, 25 ml each, were first taken using 0.5 N acetic acid and then 100 similar fractions using 1 N HCl as solvent. Fractions 19—28 contained the neutral and basic amino acids, 82—101 glutamic acid, 220—239 aspartic acid, and 358—369 the acidic substance partly decomposed during fractionation and giving two additional yellow spots with phenol-ammonia on a paper chromatogram.

The neutral eluate was evaporated to dryness and the residue dissolved in 65 ml of 1.5 N HCl. The solution was applied to a column of Dowex 50 (4 × 100 cm) which had been treated with 1.5 N HCl. The amino acids were eluted firstly with 1.5 N HCl (150 fractions each of 30 ml), then with 2.5 N HCl (150 fractions of 30 ml), and finally with 4 N HCl (100 fractions of 30 ml). Fractions 175—195 contained spots C and D, and fractions 334—384 only spot A. In another separation it appeared possible to elute the new substance from Dowex 50 with 2.5 N HCl, substance A coming between leucine and lysine.

Fractions 334—384 were combined and evaporated to dryness. Attempts to obtain crystals from methanol or ethanol were unsuccessful. Yellow impure crystals were obtained from *iso*propanol, from a small part of the residue. The unknown A was crystallized as hydrochloride from 6 N HCl and 1.75 g of pure, colourless crystals were obtained. This material corresponded to the unknown A and was found free from contaminants on a two-dimensional chromatogram with the usual solvents. The crystals were soluble in water, methanol, and ethanol. The free amino acid could be prepared by removing the HCl with a small bed of Dowex 1. The colourless crystals were moderately soluble in water but almost insoluble in methanol and ethanol.

Melting point determination on A. The new substance did not melt and on heating it began to turn yellow at about 200°C with a little sublimation and continued to darken until 300°C, when the heating was stopped.

On *total hydrolysis* with 6 N HCl for 24 h at 108°C the amino acid was stable, as it was on *alkaline hydrolysis* with saturated $Ba(OH)_2$ for 1 h at 100°C.

On *catalytic reduction with* PtO_2 *and* H_2 about two moles hydrogen were taken up per 1 mole. Spot A disappeared and a new spot A_1 was formed just above alanine on the two-dimensional chromatogram. The spot was immediately coloured violet by ninhydrin.

The free amino acid showed no absorption maxima in the UV region of the spectrum.

A micro test for the aldehyde or keto group (with 2,4-dinitrophenylhydrazine) was negative. Isatin spraying (proline and its homologue) gave no colour.

Thanks are due to Dr. Heinemann for providing us with the samples of mushrooms.

On the Structure of the New Neutral Amino Acid A Isolated from *Lactarius helvus*

ATSUSHI KOMAMINE and
ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Some characteristics of the amino acid A isolated from *Lactarius helvus* in this laboratory were presented in a previous paper by Casimir and Virtanen [1]. We have continued the investigations on the chemical composition and the structure of this amino acid. Some results of these studies are presented in this paper.

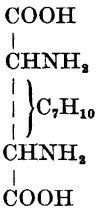
The hydrochloride of the new amino acid (Dr. Casimir's preparation) was dissolved in 0.5 M acetic acid and then passed through a column containing Dowex 1 in the acetate form. The resulting solution was evaporated to dryness *in vacuo* and the residue was dissolved in water. White crystals (needles) separated in an ice box. They were recrystallized from water three times. In accordance with the behaviour of the amino acid on a Dowex 1 column the result of paper electrophoresis showed that it is neutral.

Elementary analysis: Found: C 54.28; H 7.52; N 11.53; O 26.70 (determined). Calc. for $C_{11}H_{18}N_2O_4$: C 54.55; H 7.50; N 11.57; O 26.45. This preparation was used in the present work. An estimation of the molecular weight by isothermal distillation according to Childs [2] gave the value 251 (average of three determinations). The formula of the amino acid is accordingly $C_{11}H_{18}N_2O_4$.

Estimation of α-amino and carboxyl groups. The formation of CO_2 and NH_3 by ninhydrin was determined according to Linko [3]. From 2.562 mg of substance 0.895 mg or 34.9 % of CO_2 was formed, which is 96.9 % of the theoretical value assuming two carboxyl groups in one amino acid molecule. 0.4199 mg of NH_3 or 96.4 % of the total N was found. These results suggest that the amino acid contains two α-amino groups and two carboxyl groups.

The estimation of amino nitrogen by van Slyke's method gave 99.5 % of the total N to be amino N. This result confirms the presence of two α-amino groups in the new amino acid.

By titration of the carboxyl groups in 90 % ethanol, 2.331 mg of substance consumed 1.387 ml of 0.01195 N KOH. This corresponds to 86.2 % of the carboxyl groups, assuming two carboxyl groups in one molecule. Under the same conditions 83.8 % of the carboxyl groups in α,ε-diaminopimelic acid were titratable. Accordingly the titration confirms the presence of two carboxyl groups in the new diamino acid. All the findings presented above suggest that the new amino acid is an aliphatic diamino-dicarboxylic acid



The positions of seven C atoms and ten H atoms in the molecule have thus still to be elucidated. Our knowledge about this part of the molecule is at the moment as follows:

As described in the paper of Casimir and Virtanen, the amino acid takes up 2 moles of H_2 per mole of amino acid on catalytic hydrogenation. The bromine uptake was estimated according to Rossmann [4] and it was found that 1.1075 mg of the amino acid absorbed 0.2055 mg, or 1.9 mole of bromine per molecule of amino acid. Both the uptake of hydrogen and bromine suggest that the amino acid contains two double bonds. The rate of decolorization of $KMnO_4$ in alkaline solution by the amino acid confirms the presence of double bonds in the latter molecule. The amino acid is also attacked by ozone. Acetone, oxalic acid, and acetic acid could be found among the ozonization products. On the basis of the formation of acetone the unknown part of the molecule, C_7H_{10}, contains the group  . In the next paper we hope to be able to present more detailed information about this part of the molecule.

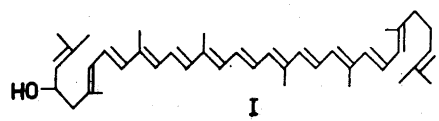
Bacterial Carotenoids

IV *. A Comparative Study of Lycoxanthin and Rhodopin

SYNNÖVE LIAAEN JENSEN

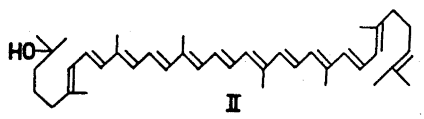
Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

It has been claimed by Goodwin and Land [1] that lycoxanthin (I), first isolated by Zechmeister and Cholnoky [2] from *Solanum dulcamara*, and rhodopin, first isolated by Karrer and Solmssen [3] from purple bacteria, were identical.



I

A critical examination of the literature [1-6] reveals, however, certain data contradictory to this statement. This has recently been pointed out by the present author [6], who proposed the structure (II) for rhodopin in accordance with the properties reported for this carotenoid [1,3-6].



II

It was therefore found desirable to repeat a direct, comparative study of the two carotenoids.

In the present investigation lycoxanthin has been isolated from *Solanum dulcamara*, and rhodopin from *Rhodospirillum rubrum* in the exponential growth stage and also from dried cells of two strains of *Rhodopseudomonas palustris*, as previously described [6].

Lycoxanthin was isolated from the ripe berries of *Solanum dulcamara* by acetone extraction followed by chromatography of the unsaponifiable matter on deactivated alumina. Lycoxanthin crystallized in dark, red needles mp. 167.5—168.5 °C with λ_{max} in petroleum ether at (422), 445, 472.5, 503.5 mμ. The spectrum had a pronounced fine-structure and was indistinguishable from that of rhodopin as well as that of lycopene.

When lycoxanthin was co-chromatographed with a chromatographically homogeneous sample of all-*trans* rhodopin on a column of deactivated alumina, a clear separation into two zones was obtained. This is not in agreement with the statement of Goodwin and Land [1] that rhodopin and lycoxanthin could not be separated on an alumina column. Rhodopin was eluted with petroleum ether containing 14 % of acetone, while lycoxanthin required petroleum ether containing 25 % of acetone for elution.

Paper chromatographical studies according to the method described by Jensen *et al.*[7] gave R_F-values as presented in Table 1.

Table 1. R_F-values on Schleicher and Schüll No. 287 paper.

Carotenoid	R_F-value 5 % acetone *	10 % acetone *
Rhodopin	0.39	0.75
Lycoxanthin	0.35	0.69

* In petroleum ether bp. 60—70°C.

Again rhodopin and lycoxanthin were clearly separated into two zones. As expected, rhodopin with a shielded, tertiary hydroxyl group moved somewhat quicker than lycoxanthin with a secondary hydroxyl group, on alumina as well as on paper.

Further the IR-spectrum (KBr) of lycoxanthin was different from that of rhodopin in the 1 200—1 000 cm^{-1} region. Lycoxanthin showed a fairly strong band at 1 008 cm^{-1}. This band was absent from rhodopin, which exhibits a band of somewhat weaker intensity at 1 140 cm^{-1} characteristic of tertiary hydroxyl groups [6]. It has previously been pointed out [6] that bicyclic carotenoids with secondary hydroxyl groups all exhibit an absorption band around 1 030 cm^{-1}. The shift to 1 008 cm^{-1} for lycoxanthin is possibly due to the aliphatic nature of this carotenoid.

When treated with acetic anhydride in pyridine, lycoxanthin was quantitatively acetylated in 6 h at room temperature. Rhodopin gave no acetate at all under similar conditions. The result of the acetylation again demonstrates the different character of the hydroxyl groups of lycoxanthin and rhodopin.

* Number I, II, III of this series in *Acta Chem. Scand.* **12** (1958) 1698, **13** (1959) 381, **13** (1959) 842.

An additional support of the non-identity of the two carotenoids was obtained by a paper chromatographical study [7] of the stereoisomers obtained by iodine catalysis of the all-*trans* compounds. The composition of the iodine catalyzed equilibrium mixtures was different for the two compounds both qualitatively and quantitatively.

As a consequence of the above study it may be considered as proved that lycoxanthin and rhodopin are not identical. This further strenghtens the suggested structure (II) for rhodopin.

This work will be published in more detail elsewhere.

The author wishes to express her gratitude to Prof. N. A. Sörensen for collecting the berries of *Solanum dulcamara* and for his inspiring interest in this work. Dried cells of two strains of *Rhodopseudomonas palustris* most kindly were supplied by Dr. C. B. van Niel, Hopkins Marine Station, Pacific Grove, California, USA. Bacterial Carotenoids

V. A Note on the Constitution of Rhodovibrin (OH-P481)

SYNNÖVE LIAAEN JENSEN

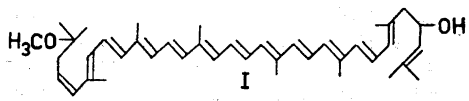
Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

During their investigations on the carotenoids of the purple bacteria, Karrer *et al.*[1-3] described a polyene alcohol with absorption maxima in carbon disulphide at 517 and 556 mμ. In the chromatographic purification procedure employed by these workers, this carotenoid could be separated only with great difficulty from the upper part of the rhodopin zone. A crystalline sample, by Karrer *et al.* considered not to be completely pure, melted at 168°C. Combustion analysis gave 83.97 % C and 10.09 % H, which suggested that two oxygen atoms were present in the carotenoid molecule. According to partition tests, not more than one hydroxyl group could be present. Methoxyl determination was negative. This carotenoid which was rather well characterized in the early work of Karrer *et al.*, was named rhodovibrin.

From a number of purple bacteria, Goodwin *et al.*[4,5] later isolated a similar mono-hydroxy-carotenoid, designated OH-P481. Goodwin and Land [5] suggested that OH-P481 might be identical with rhodovibrin.

OH-P481 was shown by Stanier and collaborators [6] to be an intermediate between lycopene and spirilloxanthin in the biosynthesis of carotenoids in *Rhodospirillum rubrum*. It was pointed out that the absorption spectrum of OH-P481 in visible light corresponded to a chromophore of twelve conjugated carbon-carbon double bonds in an aliphatic system. The presence of one methoxyl group in OH-P481 has been established later [7].

In a speculative transformation scheme for the biochemical conversion of lycopene to spirilloxanthin, Weedon and collaborators [8] on basis of the properties previously reported for OH-P481 [5-7], suggested the structure (I) for this carotenoid.



I

This structure, which contains a secondary hydroxyl group and one *iso*propropylidene end-group is, however, not in agreement with the chemical evidence presented here.

In the present investigation OH-P481 has been isolated from cells of *Rhodospirillum rubrum* in the exponential growth stage and from dried cells of two strains of *Rhodopseudomonas palustris*. The carotenoid was extracted with acetone and isolated from the unsaponifiable matter by repeated chromatography on deactivated alumina. It crystallized as dark,

An additional support of the non-identity of the two carotenoids was obtained by a paper chromatographical study [7] of the stereoisomers obtained by iodine catalysis of the all-*trans* compounds. The composition of the iodine catalyzed equilibrium mixtures was different for the two compounds both qualitatively and quantitatively.

As a consequence of the above study it may be considered as proved that lycoxanthin and rhodopin are not identical. This further strenghtens the suggested structure (II) for rhodopin.

This work will be published in more detail elsewhere.

Bacterial Carotenoids

V. A Note on the Constitution of Rhodovibrin (OH-P481)

SYNNÖVE LIAAEN JENSEN

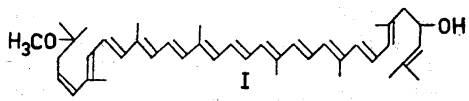
Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

During their investigations on the carotenoids of the purple bacteria, Karrer *et al.*[1-3] described a polyene alcohol with absorption maxima in carbon disulphide at 517 and 556 mμ. In the chromatographic purification procedure employed by these workers, this carotenoid could be separated only with great difficulty from the upper part of the rhodopin zone. A crystalline sample, by Karrer *et al.* considered not to be completely pure, melted at 168°C. Combustion analysis gave 83.97 % C and 10.09 % H, which suggested that two oxygen atoms were present in the carotenoid molecule. According to partition tests, not more than one hydroxyl group could be present. Methoxyl determination was negative. This carotenoid which was rather well characterized in the early work of Karrer *et al.*, was named rhodovibrin.

From a number of purple bacteria, Goodwin *et al.*[4,5] later isolated a similar mono-hydroxy-carotenoid, designated OH-P481. Goodwin and Land [5] suggested that OH-P481 might be identical with rhodovibrin.

OH-P481 was shown by Stanier and collaborators [6] to be an intermediate between lycopene and spirilloxanthin in the biosynthesis of carotenoids in *Rhodospirillum rubrum*. It was pointed out that the absorption spectrum of OH-P481 in visible light corresponded to a chromophore of twelve conjugated carbon-carbon double bonds in an aliphatic system. The presence of one methoxyl group in OH-P481 has been established later [7].

In a speculative transformation scheme for the biochemical conversion of lycopene to spirilloxanthin, Weedon and collaborators [8] on basis of the properties previously reported for OH-P481 [5-7], suggested the structure (I) for this carotenoid.



I

This structure, which contains a secondary hydroxyl group and one *iso*propropylidene end-group is, however, not in agreement with the chemical evidence presented here.

In the present investigation OH-P481 has been isolated from cells of *Rhodospirillum rubrum* in the exponential growth stage and from dried cells of two strains of *Rhodopseudomonas palustris*. The carotenoid was extracted with acetone and isolated from the unsaponifiable matter by repeated chromatography on deactivated alumina. It crystallized as dark,

red needles from petroleum ether-acetone solution. The chromatographic fractions of OH-P481 were accompanied by oily substances in the *Rhodospirillum rubrum* extracts and a white substance mp. 282°C (subl.) in the *Rhodopseudomonas palustris* extracts, which reduced the yield of the pure, crystalline pigment. After several recrystallizations the carotenoid melted at 190.5°C.

Crystalline OH-P481 was readily soluble in acetone and carbon disulphide, fairly soluble in chloroform, benzene and methanol, less soluble in ether and nearly insoluble in cold petroleum ether.

Absorption maxima for OH-P481 in various solvents as recorded quickly after dissolution is given in Table 1. The spectra were determined in a Zeiss PMQ2 spectrophotometer. Reading of correct maxima was checked by a didymium standard filter.

Table 1. The absorption maxima of all-*trans* OH-P481 in various solvents.

Solvent	Absorption maxima in mμ	
Petroleum ether bp. 60–70°C	358 374	455 483 516
Acetone	363 378	460 488 522
Chloroform	370 385	469 498 532
Benzene	372 388	473 503 535
Carbon disulphide	(408)	491 522 559

The two maxima in the first column indicate the position of the *cis*-peak, which was very weak in the spectrum of the all-*trans* compound. The purest sample measured had $E^{1\%}_{1\ cm} = 2\,940$ at 483 mμ in petroleum ether. This sample contained 5.06 % ash as determined by combustion. When corrected for 5.06 % ash the value $E^{1\%}_{1\ cm} = 3\,100$ is obtained. By extrapolation between the extinction coefficients for spirilloxanthin $E^{1\%}_{1\ cm} = 2\,620$ [9] and lycopene $E^{1\%}_{1\ cm} = 3\,460$ [10] at λ_{max} in petroleum ether, and correcting for the presence of an additional oxygen atom the value $E^{1\%}_{1\ cm} = 2\,970$ is obtained. It is therefore likely that the value $E^{1\ cm}_{1\%} = 3\,100$ for OH-P481 at λ_{max} in petroleum ether is close to the correct value. Iodine catalysis caused a shift to 358, 374, (455), 479 and 511 mμ in petroleum ether with 25 % decrease in extinction coefficient at the middle maximum. OH-P481 crystallizes normally in the all-*trans* form, but was readily *cis*-isomerized in solution. The stereochemical lability was studied by means of the paper-chromatographical method reported by Jensen *et al.*[11] The main *cis*-isomers designated Neo A and Neo B showed absorption maxima in acetone at 376, 459, 485, 517 mμ and 376, 453, 481, 513 mμ, respectivly. In the iodine catalyzed equilibrium mixture a content of 58 % all-*trans*, 18 % Neo A and 24 % Neo B was determined colourimetrically. Otherwise the stereochemical lability was comparable with that of spirilloxanthin [9].

In the quantitative partition test recommended by Zechmeister and Petracek [12], the following partition ratio was found:

Petroleum ether/95 % methanol	66:34
Petroleum ether/85 % methanol	95:5

The carotenoid thus distributed as a monohydroxy-carotenoid. The presence of a hydroxyl group further was established by an IR absorption band at 3 420 cm^{-1} in KBr. There was, however, no absorption band in the 1 030 cm^{-1} region, which is characteristic for secondary hydroxyl groups, but a band of weaker intensity at 1 148 cm^{-1}, which previously has been discussed and found typical of carotenoids containing tertiary OH-groups [13]. The tertiary character of the hydroxyl group further was confirmed by the behaviour of the pigment upon acetylation. A series of attempts to acetylate OH-P481 with acetic anhydride or acetyl chloride in pyridine, never gave a compound with properties corresponding to an acetate in yields exceeding 5 % of the unchanged starting material. This resistance to acetylation is similar to that reported for rhodopin [3,13,14] with a tertiary hydroxyl group. Parallel experiments with lutein resulted in quantitative formation of lutein diacetate.

Treatment with $CHCl_3$-HCl according to Entschel and Karrer [15] gave no product with extended conjugated chain. Neither the hydroxyl group, nor the methoxyl group of OH-P481 are therefore likely to be allylic.

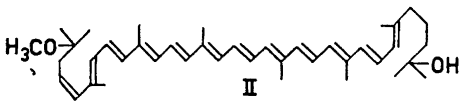
Quantitative determination of *iso*propylidene groups according to the method of Kuhn and Roth [16] gave 0.62 moles of acetone per mole of carotenoid compared with the value 1.70 simultaneously obtained for lycopene which contains two *iso*propylidene end-groups. The value obtained for OH-P481 is lower than expected for one *iso*propylidene group, and is interpreted as being due to the presence of one end-group with a tertiary methoxyl group as in spirilloxanthin [6,17] and another containing a tertiary hydroxyl group as in rhodopin [13].

The possibility for these types of end-groups to yield a small amount of acetone upon ozonolysis has already been pointed out.[17,18]

Catalytic micro-hydrogenation of a specimen with $E_{1\ cm}^{1\%} = 2\,850$ at 483 mμ in petroleum ether gave an uptake of 11.32 and 11.40 moles of hydrogen per mole of carotenoid calculated on the basis of a molecular formula $C_{40}H_{56}(OH)(OCH_3)$. The absorption spectrum in visible light indicates a chromophoric system containing twelve conjugated double bonds, hence the hydrogenation value is obviously somewhat low. Accepting $E_{1\ cm}^{1\%} = 3\,100$ for the pure pigment, the sample used in the hydrogenation has been 92 % pure. Chromatographic purity tests had revealed that the impurities present in the sample were not of carotenoid nature. The hydrogen uptake could then be corrected to a maximum of 12.3 moles per mole of carotenoid, assuming that the impurities do not consume any hydrogen.

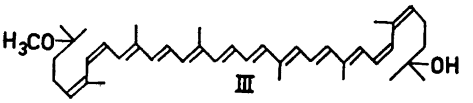
Exact analytical data could not be obtained because of the difficulty of isolating an ash-free substance. The figures given below are corrected for the presence of 5.06 % ash of unknown composition. (Found: C 85.88, H 10.16, O indirect 3.96, direct 3.61. Calc. for $C_{40}H_{56}(OH)(OCH_3)$: C 84.20, H 10.34, O 5.47.) The values obtained correspond to a molecular formula $C_{41}H_{60}O_{1.4}$. The presence of two oxygen atoms in the molecule is, however, clearly demonstrated from (1) the quantitative determination of methoxyl [7], and (2) partition behaviour, chromatographic behaviour, IR-spectrum and acetylation which reveal the presence of a hydroxyl group.

As a consequence of the data presented above, the structure (II) is possible for OH-P481:



II

This formulation is consistent with a chromophoric system of twelve conjugated double bonds in an aliphatic system, one non-allylic methoxyl group at a similar position as in spirilloxanthin, one non-allylic, tertiary hydroxyl group and no *iso*propylidene end-group. The available chemical data, however, do not exclude a symmetrical position of the chromophore as in (III).



III

The structures (II) or (III) for OH-P481 together with the structures previously suggested for rhodopin [13], P481 [8,17] and spirilloxanthin [8,17] make possible a more definite interpretation in chemical terms of the reactions involved in the later steps of carotenoid biosynthesis in the genus *Rhodospirillum* [16], for which the kinetics already has been established [6].

In view of the similar source of isolation, the accompanying carotenoids, the visible absorption spectrum, partition tests and chromatographic behaviour, there is good reason to believe that OH-P481 is identical with rhodovibrin, first described by Karrer and Solmssen [1]. As long as rhodovibrin was not isolated from a definite organism and not in a completely pure state, this cannot be definitely proved. In accordance with the generally accepted nomenclature it is suggested that OH-P481 from now on should be referred to as rhodovibrin. A further reason for changing the name of OH-P481 is the fact that the main absorption maximum of the all-*trans* compound is located at 483 mμ and not at 481 mμ in petroleum ether.

This work will be published in more detail elsewhere.

The author is gratefully indebted to Prof. Richard Kuhn for the catalytic micro-hydrogenations carried out in his laboratory at Max-Planck Institut für Biologie, Heidelberg, to Dr. C. B. van Niel for a generous supply of dried cells of two strains of *Rhodopseudomonas palustris*, to Prof. N. A. Sörensen for his inspiring interest and advice in this work and to *Norges Tekniske Högskole* for a maintenance grant.

Note on the Crystal Structure of Vanadium Dichloride

JØRGEN VILLADSEN

The Haldor Topsøe Research Laboratories, Bøunegaardsvej 73, Hellerup, Denmark

In a paper on transition metal halides [1] Klemm and Grimm were unable to determine the structure of VCl_2 and $TiCl_2$. They stated, however, that VCl_2 was not isomorphous with TiI_2 which was found to have the CdI_2-type structure. Later Baenziger and Rundle have found a preparation of $TiCl_2$ to be isomorphous with CdI_2[2].

We have carried out an X-ray investigation of VCl_2 prepared by K. Riishede of this laboratory by heating vanadium powder in a stream of dry HCl at 950°C. The product was obtained in the form of apple-green, muscovite-like leaflets of a more or less hexagonal appearance. The following data were obtained:

Unit cell dimensions: $a_0 = 3.60 \pm 0.01$ Å, $c_0 = 5.83 \pm 0.01$ Å. Observed density[1]: 3.09 g/cm³, calculated density: 3.09 g/cm³. Diffraction symbol: $\bar{3}mP...$; test for pyroelectricity: negative. Probable space group: $P\bar{3}m$ (No. 164). Arrangement of atoms:

1 V at 0,0,0
2 Cl at $\pm$ (1/3, 2/3, u) with $u \sim 1/4$.

Shortest V-Cl distance: 2.55 ± 0.05 Å. Structure type: CdI_2 ($C6$).

Experimental: Laue photographs were taken along the c-axis. The lattice constants were calculated from Debye-Scherrer diagrams taken in a 19 cm camera using Cr$K\alpha$ radiation ($\lambda = 2.2909$ Å). Intensities were recorded on an X-ray diffractometer with Cu$K\alpha$ radiation. The value of the parameter u was found to deviate only insignificantly from the ideal value 1/4 from a Fourier projection along the c-axis using the $00l$ reflections. The agreement between observed and calculated intensities of the $00l$ and $10l$ reflections is satisfactory but a different scaling factor had to be used because preferred orientation could not be totally depressed.

From the above it may be concluded either that $TiCl_2$ and VCl_2 both exist in two modifications or that the materials investigated by Klemm and Grimm have been partly decomposed before or during their X-ray exposure.

Added in proof: Very recently[3] Ehrlich and Seifert have recorded the structure of VCl_2 in complete agreement with the results given above.

The author is indebted to the head of the Chemistry Department of the Royal Veterinary and Agricultural College in Copenhagen, professor A. Tovborg Jensen, for permission to use the X-ray diffractometer there and to Mr. Haldor Topsøe for permission to publish this note.

Separation and Identification of Alkoxyglycerols

BO HALLGREN and SAM OLOF LARSSON

Department of Medical Biochemistry, University of Gothenburg, Sweden

In the liver oils of several Elasmobranch fishes a relatively large proportion of the unsaponifiable matter consists of alkoxyglycerols [1]. Hitherto three such compounds have been isolated, *viz.* chimyl, batyl and selachyl alcohols. Through the use of the technique described below we were able to discover several new alkoxyglycerols.

We separated the unsaponifiable matter of marine oils or of other biological materials by adsorption on a column of activated aluminium oxide. After elution of the hydrocarbons by light petroleum and the cholesterol by methylene dichloride, the alkoxyglycerols were eluted by 10 % methanol in methylene dichloride. The quantity of alkoxyglycerols was then determined gravimetrically. In order to be able to study the composition of the mixtures of the alkoxyglycerols by gas chromatography we converted the free hydroxy groups into methyl ether groups by the method described by Müller and Rundel [2], treating the hydroxy compound with diazomethane and boron trifluoride. Next the dimethyl ethers of the alkoxyglycerols were separated from monomethyl ethers and unchanged alkoxyglycerols by chromatography on aluminium oxide. The dimethyl ethers were eluted by 25 % diethyl ether in light petroleum and afterwards submitted to gas chromatography.

For the gas chromatographic analyses we used a Perkin Elmer apparatus (model 116) with an outlet system modified to permit collecting of fractions of high-boiling substances. Silicone grease and a polyester Reoplex 400 (Geigy) [3] were used as stationary phases and helium as the carrier gas. The samples were analyzed before and after hydrogenation. The components were identified by mass spectrometry and in the case of batyl alcohol also by comparing the retention time with that of synthetic batyl alcohol. The mass spectra of the dimethyl ethers of the alkoxyglycerols will be published later.

Besides glyceryl ethers with hexadecanyl, octadecanyl or octadecenyl as the long-chain component, we found compounds with tetradecanyl, with monounsaturated C_{16}, C_{20} and C_{22} chains, and with a C_{18} chain with two double bonds. There were also small amounts of glyceryl ethers with a long chain containing an odd number of carbon atoms. In Table 1 the composition of the alkoxyglycerols from the liver oils of three marine species of Elasmobranch fish are presented. The chimyl, batyl and selachyl alcohols to-

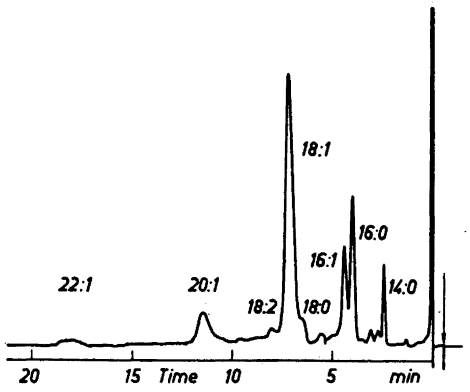

Fig. 2. Gas chromatogram of the dimethyl ethers of the alkoxyglycerols in the liver oil of *Squalus acanthias*. Stationary phase: Reoplex 400. Temperature: 247°C. Column length: 3 m. The figures beside the peaks refer to the long-chain part of the molecule. The figures to the left of the colons denote the number of carbon atoms and the figures after the colon the number of double bonds.

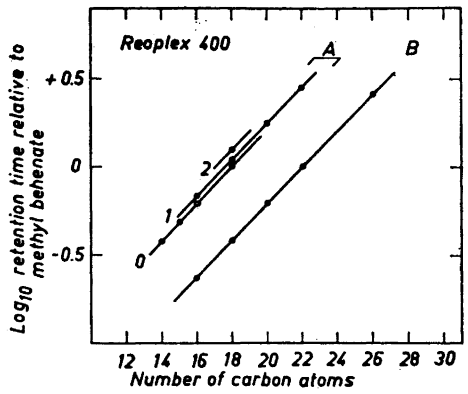

Fig. 3. Relationships between $\log_{10}$ retention times relative to methyl behenate in Reoplex 400 at 247°C and the number of carbon atoms for the alkoxyglycerols (A) and for the saturated straight chain fatty acids (B). For the alkoxyglycerols the number of carbon atoms refer to the long chain part of the molecule. The number of double bonds in the long chains are denoted by 0, 1 or 2.

chromatogram on Reoplex 400 in Fig. 2. The retention time for the component with the highest molecular weight (1,2-dimethoxy-3-docosenoxy-propan) was about 12 min on the silicone and 18 min on the Reoplex column. The logarithms of the retention times on Reoplex 400 relative to methyl behenate were calculated and plotted against the number of carbon atoms (Fig. 3). The saturated ethers fell on a straight line and the mono-unsaturated ones on a line parallell to it.

Oxidation of 1,2-dimethoxy-3-hexadecenoxy-propan by chromium trioxide gave heptanoic acid. This could be established by gas chromatography. Thus the double bond in the hexadecenyl chain is situated between carbon atoms 9 and 10.

This study is a part of investigations supported by grants from the *Swedish Medical Research Council.*

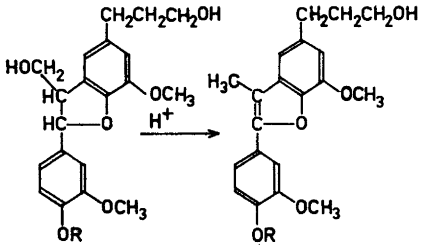
Phenylcoumaran Elements in Spruce Lignin

ERICH ADLER, SUNE DELIN and KNUT LUNDQUIST

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

Dihydro-dehydrodiconiferyl alcohol (I) [1] and its monomethyl ether (II) [1], on heating with 0.2 N HCl in methanol or in dioxane-water (9:1), are converted into the phenylcoumarone derivatives III and IV, respectively [2]. This conversion of a hydroxymethyl-substituted phenylcoumaran into a methyl-substituted phenylcoumarone can readily be accounted for by a sequence of ring opening, allylic rearrangement and recyclisation [2].

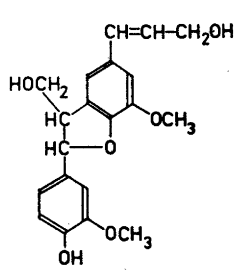


I : R = H
II : R = CH_3
III : R = H
IV : R = CH_3

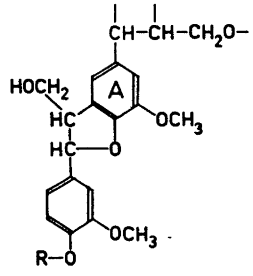
The absorption spectrum of the phenolic coumarone derivative (III), m.p. 172—173° (diacetate, m.p. 114°), shows a maximum at 310 mμ (ε, 27 000) in ethanolic solution and a maximum at 326 mμ (ε, 31 400) in alkaline ethanolic solution. These spectra and the "ionisation $\Delta\varepsilon$" curve (λ_{max} 338 mμ, ε, 27 000) obtained from them are very similar to those previously reported [3] for a related coumarone[4] obtained by dehydrogenation of dihydro-dehydrodi*iso*-eugenol with sulphur. The absorption spectrum of the non-phenolic coumarone IV in ethanol is similar to that of III in the same solvent. Spectrophotometric examination of the reactions I → III and II → IV revealed that a maximum conversion of about 70 % was obtained after 20 h in a boiling 0.2 N HCl dioxane-water mixture.

Dehydrodiconiferyl alcohol (V) is formed, together with other products, by enzymatic dehydrogenation of coniferyl alcohol [1], and the phenylcoumaran system (VIa and VIb, with various modifications of the side-chain of the phenylpropane moiety A) is assumed [5] to be present in lignin.

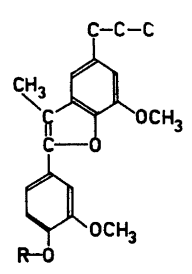
In the present investigation an attempt has been made to demonstrate, by spectrophotometric analysis, the formation of phenylcoumarone systems (type VII) from phenylcoumaran elements (type VI) on treatment of spruce Björkman lignin with hot acid and to estimate the frequency of phenylcoumaran elements in the lignin. A solution of Björkman lignin in dioxane-water (9:1) containing 0.2 N HCl was refluxed for 21 h. As shown in previous work [6], such treatment of lignin ("acidolysis") converts arylglycerol-β-aryl ether elements into arylpropanone structures of various types ("Hibbert ketone" structures), including arylpropanone-1 and arylpropanedione-1,2 structures. These being



V



VIa : R = H
VIb : R = C of propane side-chain of adjacent monomer



VIIa : R = H
VIIb : R = R in VIb

aryl α-ketones have strong light-absorption in the region of 310 mμ and thus would interfere with the intended spectrophotometric determination of the arylcoumarone systems (VII). The acid-treated lignin solution was therefore made alkaline and treated with sodium borohydride to eliminate any carbonyl groups present [7]. From the absorption curve of the reacidified solution a $\Delta\varepsilon$ curve was obtained by "subtraction" of the absorption curve of a similar lignin solution which had been reduced with borohydride and then reacidified but which had not been subjected to "acidolysis". This $\Delta\varepsilon$ curve showed a distinct band with a maximum at 310 mμ and a shape very similar to that of the main absorption band of the arylcoumarones III and IV. This indicates that arylcoumarone systems (VIIa + VIIb) were actually formed during the hot acid treatment of the lignin and, consequently, that arylcoumaran elements (VI) were present in the original lignin. Comparison of the $\Delta\varepsilon$ value at 310 mμ with the corresponding value for the model conversion I→ III indicated that in the Björkman lignin sample used, about 18 % of the phenylpropane units were present in dimeric elements of the phenylcoumaran type (VIa + VIb).

To investigate the proportion of phenolic coumarone elements (VIIa) formed, "ionisation $\Delta\varepsilon$" curves were obtained for the carbonyl-free acidolysis lignin, and for carbonyl-free lignin which had not been subjected to acidolysis. From these two curves a difference curve was prepared which was expected to be the "ionisation $\Delta\varepsilon$" curve for the phenolic guaiacylcoumarone systems (VIIa) formed in the acidolysis. The position of the main band of this difference curve (max 338 mμ) was in fact identical with that of the corresponding band obtained in a model experiment (I → III). Comparison of the $\Delta\varepsilon$ values at 338 mμ for both experiments indicated that about 16 % of the phenylpropane units in the Björkman lignin used had given a phenolic coumarone system (VIIa). The fact that the major part of the coumarone was of the phenolic type (VIIa) rather than the ether type (VIIb) is explained by the previous finding [6] that acidolysis of lignin liberated a considerable amount of phenolic hydroxyl groups.

Preceding work [6] has shown that about 25 % of the phenylpropane units in spruce Björkman lignin are of the phenylglycerol type linked by a β-aryl ether bridge to the adjacent monomer, or in other words, that up to 50 % of the lignin may consist of dimeric elements of the guaiacylglycerol-β-dihydroconiferyl ether type. The present study indicates that nearly 20 % of the lignin is made up of phenylcoumaran dimers (VIa + VIb). Although the various dimeric elements may "overlap" to some extent, one or both of the two phenylpropane moieties of a dimeric element also forming part of a following one, the results obtained account for the structural elements of an appreciable part of the total average lignin molecule.

Determination of ε-Aminocaproic Acid in Urine by Means of High-Voltage Paper Electrophoresis

ALBERT SJOERDSMA* and ARNE HANSON

Medical Clinic and Department of Clinical Chemistry, General Hospital, Malmö, Sweden

It has been reported that ε-amino-*n*-caproic acid (ε-ACA) is a potent inhibitor of plasminogen activation *in vitro* [1,2]. Preliminary studies in this hospital by Nilsson *et al.*[3] suggest that the compound may also be effective *in vivo* in the treatment of fibrinolysis associated with various diseases. It was therefore desirable to obtain information about the fate of ε-ACA in the body and to determine whether it is absorbed efficiently from the intestinal tract. To accomplish this a method for the estimation of ε-ACA in urine was needed.

* Visiting scientist, National Heart Institute, Bethesda 14, Maryland, U.S.A.

aryl α-ketones have strong light-absorption in the region of 310 mμ and thus would interfere with the intended spectrophotometric determination of the arylcoumarone systems (VII). The acid-treated lignin solution was therefore made alkaline and treated with sodium borohydride to eliminate any carbonyl groups present [7]. From the absorption curve of the reacidified solution a $\Delta\varepsilon$ curve was obtained by "subtraction" of the absorption curve of a similar lignin solution which had been reduced with borohydride and then reacidified but which had not been subjected to "acidolysis". This $\Delta\varepsilon$ curve showed a distinct band with a maximum at 310 mμ and a shape very similar to that of the main absorption band of the arylcoumarones III and IV. This indicates that arylcoumarone systems (VIIa + VIIb) were actually formed during the hot acid treatment of the lignin and, consequently, that arylcoumaran elements (VI) were present in the original lignin. Comparison of the $\Delta\varepsilon$ value at 310 mμ with the corresponding value for the model conversion I→ III indicated that in the Björkman lignin sample used, about 18 % of the phenylpropane units were present in dimeric elements of the phenylcoumaran type (VIa + VIb).

To investigate the proportion of phenolic coumarone elements (VIIa) formed, "ionisation $\Delta\varepsilon$" curves were obtained for the carbonyl-free acidolysis lignin, and for carbonyl-free lignin which had not been subjected to acidolysis. From these two curves a difference curve was prepared which was expected to be the "ionisation $\Delta\varepsilon$" curve for the phenolic guaiacylcoumarone systems (VIIa) formed in the acidolysis. The position of the main band of this difference curve (max 338 mμ) was in fact identical with that of the corresponding band obtained in a model experiment (I → III). Comparison of the $\Delta\varepsilon$ values at 338 mμ for both experiments indicated that about 16 % of the phenylpropane units in the Björkman lignin used had given a phenolic coumarone system (VIIa). The fact that the major part of the coumarone was of the phenolic type (VIIa) rather than the ether type (VIIb) is explained by the previous finding [6] that acidolysis of lignin liberated a considerable amount of phenolic hydroxyl groups.

Preceding work [6] has shown that about 25 % of the phenylpropane units in spruce Björkman lignin are of the phenylglycerol type linked by a β-aryl ether bridge to the adjacent monomer, or in other words, that up to 50 % of the lignin may consist of dimeric elements of the guaiacylglycerol-β-dihydroconiferyl ether type. Determination of ε-Aminocaproic Acid in Urine by Means of High-Voltage Paper Electrophoresis

ALBERT SJOERDSMA* and ARNE HANSON

Medical Clinic and Department of Clinical Chemistry, General Hospital, Malmö, Sweden

It has been reported that ε-amino-*n*-caproic acid (ε-ACA) is a potent inhibitor of plasminogen activation *in vitro* [1,2]. Preliminary studies in this hospital by Nilsson *et al.*[3] suggest that the compound may also be effective *in vivo* in the treatment of fibrinolysis associated with various diseases. It was therefore desirable to obtain information about the fate of ε-ACA in the body and to determine whether it is absorbed efficiently from the intestinal tract. To accomplish this a method for the estimation of ε-ACA in urine was needed.

* Visiting scientist, National Heart Institute, Bethesda 14, Maryland, U.S.A.

However, there seemed to be no specific reaction available allowing a direct assay of this amino acid and we regarded the conventional two-dimensional paper chromatography too difficult and time-consuming for our purpose. We therefore developed a quicker and simpler method for the determination of ε-ACA, principally similar to methods already developed in this laboratory for the determination of some other amino acids, *e.g.* γ-aminobutyric and glutamic acids [4]. The method consists of isolation of ε-ACA by high-voltage paper electrophoresis, development of color with a ninhydrin and copper spray, elution of the spots from paper and measurement of the color in a spectrophotometer.

Method. The following reagents were used: 1) Buffer for electrophoresis, a mixture of formic acid, acetic acid, acetone and water (15:10:15:65 v/v) with a final pH of 1.2. 2) Spray reagents, a) Ninhydrin, 0.5 % in *n*-butanol previously saturated with a mixture of pyridine, acetic acid and water (10:1:95) with a pH of 6, and b) Copper reagent [5], prepared by mixing a saturated solution of cupric nitrate, 10 % nitric acid, water and methanol (1:0.2:4:95). 3) Methanol, as eluent, 4) ε-ACA, reference standard solution containing 1 mg per ml of water. The ε-ACA used here was obtained from L. Light & Co. Ltd. Colnbrook, England. The method for high-voltage paper electrophoresis was that of Wieland and Pfleiderer [6] and Wieland and Dose [7] using Whatman No. 3 filter paper.

Preliminary experiments indicated excellent separation of ε-ACA from normally-occurring amino acids in urine except alanine. Separation from the latter could be achieved with paper chromatography in the second dimension in a quick-running solvent mixture of methanol, water and pyridine (80:20:4). However, during the first 24 h after administration of ε-ACA in the usual clinical dosage (6.0 g), the excretion of the compound was of such a magnitude that accurate assays could be performed on diluted urine in which interference from alanine was insignificant. Thus in the procedure to be described, a volume of urine equivalent to 1 minute's excretion was diluted to 10 ml with water prior to analysis. 0.005 to 0.04 ml samples of diluted urine and reference standards (5 to 40 μg) were applied to the paper with micropipettes at a distance of 8 cm from the anode end. With an operating voltage of 2 000 V and a current of 60 mA — resulting in a potential gradient of 50 V/cm — the ε-ACA migrated about 10 cm towards the cathode in an experimental period of 1 h. On removal from the apparatus the paper was dried in an oven at 80°C for at least 1 h. It was then sprayed with the ninhydrin reagent and the color developed by heating in an oven at 80°C for 30 min. The purple color obtained was then converted to a more stable light-red color by spraying with the copper-complexing reagent and the paper was allowed to dry in a cool current of air. Each colored spot was then cut out, placed in a small glass-stoppered test-tube and eluted for 30 min with 4 ml of methanol. A clear portion of the paper of corresponding size was eluted also and used as a blank. The measurements of the color intensity were made at 508 mμ in a Beckman spectrophotometer model B. The extinction values of reference spots were proportionate to concentration over a range 0 to 30 μg, with 1 μg giving an average value of 0.02 to 0.025. From the extinction values obtained with the reference standards a graph was constructed and from this the concentration of the urine sample was read. Recovery of ε-ACA added to diluted urine was satisfactory (95 ± 10 %). In three patients who received on different days single 6.0 g doses of ε-ACA orally and intravenously the compound was found to be excreted rapidly in the urine, 40 to 65 % of the dose being recovered in the first 12 h. Since the percentage excreted after oral and intravenous administration was similar, the compound is thought to be completely absorbed from the intestinal tract.

This work was supported by a grant from the *Swedish Medical Research Council.*

Photoinduced Oxidation of *Iso*propanol by Acid Chromate Studied by Flash Photolysis

ULRIK KLÄNING

Laboratoriet for Fotokemi, Fotografi og Reproduktionsteknik, Technical University, Copenhagen, Denmark

In aqueous solutions at low acidity the oxidation of *iso*propanol by acid chromate is a very slow process. The reaction is accelerated when the solution is irradiated with ultraviolet light [1]. A kinetic study of the photochemically induced oxidation led to the conclusion that the primary process is the decomposition of mono*iso*propyl chromate to give Cr^{IV} and acetone [1,2]. Further it was found that a reaction sequence which included the step

1) $Cr^{IV} + (CH_3)_2CHOH \rightarrow Cr^{II} + (CH_3)_2CO$

satisfactorily explained the kinetic data [2]. However it has now been proved that Cr^{IV} does not react directly with the alcohol [3,4]. An alternative mechanism which fits the results so far obtained [3] is

2) $Cr^{IV} + Cr^{VI} \rightarrow 2Cr^{V}$
3) $Cr^{V} + (CH_3)_2CHOH + H^+ \rightarrow Cr^{III} + (CH_3)_2CO$
4) $Cr^{V} + Cr^{IV} \rightarrow Cr^{VI} + Cr^{III}$

In search for the correct mechanism it is feasible to attempt the direct observation of the chromium intermediates by the flash photolysis technique [5]. Some preliminary experiments making use of this technique are reported here. Deaerated solutions, containing 2.5–10 M *iso*propanol. 5×10^{-4}–3×10^{-3} M perchloric acid, and 5×10^{-4}–2×10^{-3} acid chromate in a 50 ml pyrex cell, 20 cm long, were illuminated in a flash photolysis apparatus similar to those described by Porter and Windsor [6], and Christie, Norrish and Porter [7]. Photographs of the spectrum of the reaction mixtures taken 30 μsec and 200 μsec after an 1 150 Joule photolysis flash revealed a transient absorption extending from 650 mμ (the limit of the photographic plate) towards green and a transient decrease of the Cr^{VI} absorption band in the near ultraviolet. The change of the transient absorption in time was followed photoelectrically [7] at 590 mμ after irradiation with an 810 Joule flash. Three steps in the reaction could be detected, a fast increase of the optical density completed in about 200 μsec, a fast decrease of the optical density with a halftime of about 600 μsec at $C_{HCrO_4^-} = 10^{-3}$ M, $C_{HClO_4} = 10^{-3}$ M, and $C_{alcohol} = 10$ M, and finally a third slow step consisting of a further decrease in optical density, the rate of which seems to be of second order independent of conditions. In the presence of 10^{-3} M manganous sulfate in the solution the third slow step disappeared and a brownish colour developed after the flash indicating a formation of MnO_2. Figs. 1 and 2 show photographs of oscillographic recordings of the transient events. The lines A and B designate 0 % and 100 % light absorption, respectively. C is the decay curve for the intermediates and the straight line D is the absorption to infinite time giving the amount of Cr^{III} formed. In experiments as shown in Fig. 2 the sweep rate on the oscilloscope screen decreased exponentially over the sweep range with a halftime of 6.3×10 sec. The second fast step appears in these measurements as a hook on the decay curve (Fig. 2). Only two measurements were

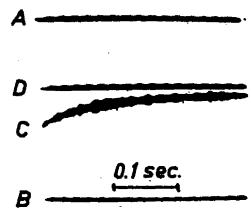

Fig. 1. Experimental decay curve for the third step. ($C_{HClO_4} = 3 \times 10^{-3}$ M, $C_{HCrO_4^-} = 10^{-3}$ M, $C_{alc.} = 10$ M).

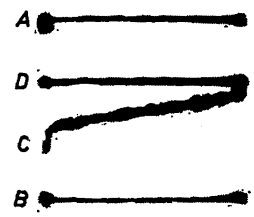

Fig. 2. Experimental decay curve. The sweep rate decreases exponentially over the sweep range, halftime for the sweep is 6.3×10^{-2} sec. ($C_{HClO_4} = 3 \times 10^{-3}$ M, $C_{HCrO_4^-} = 10^{-3}$ M, $C_{alc.} = 10$ M)

Table 1. Results (Temp. 22°C ± 2°C).

$C_{alc.}$ mole litre	C_{HClO_4} mole/litre	$C_{HCrO_4^-}$ mole/litre	D_0	D_∞	$\Delta D/D_0 - D_\infty$	$10^4 \times C_{Cr^{III}}$ mole/litre	$k/\Delta\varepsilon$ sec^{-1}
2.5	10^{-3}	10^{-3}	0.1	0.03	0.7	0.3	—
5	10^{-3}	10^{-3}	0.34	0.10	0.62	1.0	1 800
10	5×10^{-4}	5×10^{-4}	0.54	0.17	0.32	1.8	2 000
10	10^{-3}	5×10^{-4}	—	—	—	—	1 800
10	3×10^{-3}	5×10^{-4}	0.39	0.12	0.37	1.3	2 300
10	10^{-3}	10^{-3}	0.75	0.25	0.37	2.7	2 000
10	3×10^{-3}	10^{-3}	0.58	0.19	0.46	2.0	1 700
10	10^{-3}	2×10^{-3}	0.81	0.28	0.28	3.0	2 000
10	3×10^{-3}	2×10^{-3}	0.62	0.22	0.45	2.3	2 000
10*	10^{-3}	10^{-3}	0.74	—	—	—	—

* $C_{MnSO_4} = 10^{-3}$ M.

made with a halftime of 5×10^{-4} sec for the sweep, revealing the two first fast steps. The findings are compiled in Table 1. D_0 is the maximum transient optical density taken from the experiments where the sweep rate decreased exponentically. D_∞ is the optical density after infinite time. In the expression for the relative extent of step two $\Delta D/D - D_\infty$, ΔD is somewhat arbitrarily taken as the change of the optical density in 2×10^{-3} sec (Fig. 2). The concentration of Cr^{III} formed on photolysis was calculated using 47 litre/mole cm for the molar extinction coefficient of Cr^{III}, a value found by reducing thermally 5×10^{-4} M acid chromate in an aqueous solution, 10 M in *iso*propanol and 3×10^{-3} M in perchloric acid. The last column shows second order rate constants k for the third step divided by the difference in the extinction coefficients $\Delta\varepsilon$ between the intermediate in question and Cr^{III}; $k/\Delta\varepsilon$ is calculated from experiments with constant sweep rates (Fig. 1). Fig. 3 shows a second order plot for the third slow process. From Table 1 one may note that D_0/D_∞ does not vary appreciably with conditions, whereas $\Delta D/D_0 - D_\infty$ varies somewhat with conditions This indicates that reactions by which chromium intermediates disappear by disproportionation are faster than is the oxidation of the alcohol by the intermediates. Further it seems that the relative extent of the second step $\Delta D/D_0 - D_\infty$ increases with increasing acidity.

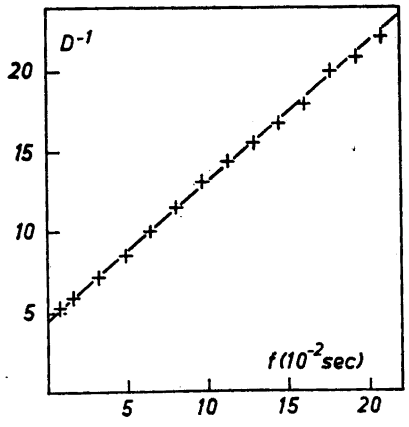

Fig. 3. The experimental decay curve in Fig. 1 as a second order decay.

Although the data are not sufficient to establish the mechanism we may tentatively ascribe the first step to be the breakdown of excited Cr^{VI} esters to give Cr^{IV} and acetone. In presence of Mn^{II} the next step is probably [8]

6) $Mn^{II} + Cr^{IV} \rightarrow Mn^{III} + Cr^{III}$
$(2\ Mn^{III} \rightarrow MnO_2 + Mn^{II})$

The variation of the extent of the second fast step with conditions suggests reactions like

7) $Cr^{IV} + Cr^{VI} + H^+ \rightarrow 2Cr^V$
8) $Cr^{IV} + Cr^{IV} \rightarrow Cr^V + Cr^{III}$
9) $Cr^{IV} + Cr^V + H^+ \rightarrow Cr^{VI} + Cr^{III}$

the third slow step could then be the reverse reaction of 7)

$-7)\ 2\ Cr^V \rightarrow Cr^{VI} + Cr^{IV} + H^+$

The experimental work was made at the Department of Physical Chemistry, University

of Sheffield. The author's sincere thanks are due to professor G. Porter for information and help in the work and for loan of apparatus.

Note on the Infrared Spectra of Pro-γ-carotene and Neo-γ-carotene P

K. LUNDE

Universitetets Kjemiske Institutt, Blindern, Norway

These two *cis* isomers of γ-carotene are natural products and can be isolated easily from ripe berries of *Pyracantha angustifolia* [1,2]. In the visible spectral region, hexane solutions of pro-γ-carotene show two almost equal maxima (434, 457 mμ) while the neo-γ-carotene curve contains only a single main maximum (459 mμ) [2,3]. In spite of this difference a comparison of the infrared spectra showed near-identity[4].

Although, as was pointed out [4], several pairs of *cis* forms are possible in this sterically unsymmetrical set whose IR spectra are expected to be (almost) identical, an experimental error such as mislabeling of samples could not be excluded considering the great number of stereoisomeric carotenoids studied.

At the recommendation of Prof. L. Zechmeister, the author has now reinvestigated the IR spectra using solutions of authentic samples of pro-γ-carotene (m. p. 133—134°) and neo-γ-carotene P (m. p. 89—90°). The identity of the two curves was confirmed in the 2—12 μ region; an important difference was observed, however, in the 12—14 μ region. As Fig. 1 shows, only the neo P curve possesses a band at 13.02—13.19 μ (doublet). This band lies in the region that has been assigned to unmethylated *cis* double bonds [4]. Consequently, our earlier interpretations must be revised. It is proposed that the neo-γ-carotene P molecule contains both methylated and unmethylated *cis* double bond(s) while the latter type is absent from pro-γ-carotene. This difference has a profound influence on the spectra observed in the visible region.

Reactions of Phenyltellurium Trichloride with Thiourea

OLAV FOSS and SVERRE HAUGE

Chemical Institute, University of Bergen, Bergen, Norway

Tellurium dioxide dissolved in hydrochloric or hydrobromic acid reacts with four moles of thiourea to give covalent halides $Te(tu)_2X_2$ (tu = thiourea) and with six moles of thiourea to give salts of the cation $Te(tu)_4^{++}$. These are planar, four-co-ordinated complexes of divalent tellurium [1].

It has been found that phenyltellurium trichloride reacts similarly with thiourea, to give thiourea derivatives of divalent tellurium. The reactions are, with three moles of thiourea:

$$C_6H_5TeCl_3 + 3\ SC(NH_2)_2 = C_6H_5Te[SC(NH_2)_2]Cl + [SC(NH_2)_2]_2^{++} + 2\ Cl^-$$

and with four moles:

$$C_6H_5TeCl_3 + 4\ SC(NH_2)_2 = C_6H_5Te[SC(NH_2)_2]_3^+ + [SC(NH_2)_2]_2^{++} + 3\ Cl^-$$

The following compounds have been prepared and characterized through single-crystal X-ray photographs (Cu$K\alpha$ radiation, $\lambda = 1.542$ Å). Melting points are corrected.

Thiourea-benzenetellurenyl chloride, $C_6H_5Te(tu)Cl$. To 3.11 g (10 mmoles) of phenyltellurium trichloride dissolved in 20 ml of methanol was added 2.28 g (30 mmoles) of thiourea dissolved in 20 ml of warm water. A clear, orange red solution resulted, from which the divalent tellurium compound crystallized on standing. Yield, about 2.5 g (80 %). The product was recrystallized from methanol (2 g dissolved in about 25 ml at boiling temperature). M. p. 166°. (Found: S 9.96; Te 40.11. Calc. for $C_7H_9ClN_2STe$: S 10.14; Te 40.35.)

The crystals are orange red and appear as well developed, monoclinic prisms {011} with $a = 6.32$ Å, $b = 10.62$ Å, $c = 15.16$ Å, $\beta = 90\frac{1}{2}°$. There are four molecules per unit cell; density, calc. 2.06, found 2.07 g/cm³. The space group, from systematic absences, is $C_{2h}^5 - P2_1/n$.

Thiourea-benzenetellurenyl bromide, $C_6H_5Te(tu)Br$. The crystals are isomorphous with those of the chloride, and show the same colour and morphology. The unit cell dimensions are, $a = 6.46$ Å, $b = 10.73$ Å, $c = 15.36$ Å, $\beta = 91\frac{1}{2}°$, and the density, calc. 2.25, found 2.24 g/cm³.

The compound was prepared as described above for the chloride, by dissolving about 3.6 g (30 mmoles) of potassium bromide in the aqueous thiourea solution before mixing with the methanolic phenyltellurium trichloride solution. Yield, about 3.6 g (99 %). M. p. 178° (recrystallized from methanol, 2 g dissolved in about 45 ml at boiling temperature). (Found: Te 35.82. Calc. for $C_7H_9BrN_2STe$: Te 35.37.)

The compounds $C_6H_5Te(tu)X$ dissolve in warm aqueous thiourea to give yellow to orange yellow solutions from which salts of the cation $C_6H_5Te(tu)_3^+$ crystallize on cooling. The chloride was also prepared directly from phenyltellurium trichloride.

Dithiourea-benzenetellurenyl chloride, $C_6H_5Te(tu)_2Cl$. To 3.11 g (10 mmoles) of phenyltellurium trichloride dissolved in 15 ml of methanol was added one drop of conc. hydrochloric acid and, with stirring, 3.8 g (50 mmoles, 25 % excess) of thiourea dissolved in 25 ml of warm water, and then 25 ml of water. On standing, the chloride slowly crystallized, as clusters of yellow needles which ultimately filled the whole liquid. Yield, about 3.4 g (85 %); m. p. 168°. (Found: S 16.30; Te 32.33. Calc. for $C_9H_{13}ClN_4S_2Te$: S 16.34; Te 32.52.) It may be recrystallized from aqueous thiourea, preferrably in presence of a small amount of hydrochloric acid.

The salt forms long orthorhombic prisms elongated in the direction of the c axis. The axial lengths are, $a = 11.98$ Å, $b = 20.80$ Å, $c = 5.79$ Å, and the space group, from systematic absences, is $D_2^4 - P2_12_12_1$. There are four formula units per unit cell; density, calc. 1.81, found 1.81 g/cm³.

The nitrate and perchlorate crystallize on addition of nitric or perchloric acid to aqueous thiourea solutions of the chloride (1 g chloride in 30 ml of warm 10 % thiourea, 3 ml of *ca.* 35 % nitric acid or 2 ml of *ca.* 60 % perchloric acid. Yields on standing to room temperature, about 1 g of each). The salts form long, yellow prisms elongated along the b axis.

Dithiourea-benzenetellurenyl nitrate, $C_6H_5Te(tu)_2NO_3$. M. p. 135°. (Found: S 15.49; Te 29.88. Calc. for $C_8H_{13}N_5O_3S_2Te$: S 15.31; Te 30.46.) Monoclinic, $a = 24.30$ Å, $b = 5.88$ Å, $c = 21.30$ Å, $\beta = 90\frac{1}{2}°$. There are eight formula units per unit cell; density, calc. 1.83, found 1.83 g/cm³. On the basis of the systematic absences, hkl when $h + k$ is odd, $h0l$ when h is odd or l is odd, the space group is either C_{2h}^6—$C2/c$ or C_s^4—Cc.

Dithiourea-benzenetellurenyl perchlorate, $C_6H_5Te(tu)_2ClO_4$. M. p. 136°. (Found: Te 27.97. Calc. for $C_8H_{13}ClN_4O_4S_2Te$: Te 27.96.) Monoclinic prismatic, $a = 12.24$ Å, $b = 5.86$ Å, $c = 22.76$ Å, $\beta = 96°$. There are four formula units per unit cell; density, calc. 1.87, found 1.87 g/cm³. The space group, from systematic absences, is C_{2h}^5—$P2_1/c$.

Dithiourea-benzenetellurenyl thiocyanate, $C_6H_5Te(tu)_2SCN$, was prepared *via* a compound, presumably $C_6H_5Te(tu)SCN$, obtained from phenyltellurium trichloride in the same way as $C_6H_5Te(tu)Br$, by use of 30 mmoles of potassium thiocyanate instead of potassium bromide. The micro-crystalline solid (3 g) which separated on standing at ice temperature, was filtered off and dissolved in 60 ml of warm 10 % aqueous thiourea. On filtering, a clear, orange yellow solution resulted which on standing deposited yellow crystals (2.4 g) of the thiocyanate. M. p. 109°. (Found: S 22.98; Te 30.47. Calc. for $C_9H_{13}N_5S_3Te$: S 23.18; Te 30.75.)

The crystals occur as long, monoclinic prisms extended along the b axis. The unit cell dimensions are, $a = 15.37$ Å, $b = 5.83$ Å, $c = 17.47$ Å, $\beta = 96°$, and the space group, from systematic absences, C_{2h}^5—$P2_1/n$. There are four formula units per unit cell; density, calc. 1.77, found 1.78 g/cm³.

The crystal structures of representatives of the compounds are being studied with a view towards a possible bearing on the transition state in nucleophilic displacements on divalent tellurium, selenium and sulphur.

Specificity of a Purified Hog Intestinal Maltase Fraction

Competitive Inhibition of Maltase Activity by Other Substrates

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

In previous papers the separation of hog intestinal maltase activity into three fractions (maltase I—III) with different enzymatic properties has been described [1-3]. In the present paper the specificity of one of these fractions, *maltase III*, will be further discussed.

Maltase III preparations hydrolyze *phenyl-α-D-glucopyranoside* [2], *isomaltose* (6-(α-D-glucopyranosyl)-D-glucose) [2], *turanose* (3-(α-D-glucopyranosyl)-D-fructose) [2], and *melezitose* (α-D-glucopyranosyl-(1→3)-β-D-fructofuranosyl-(2→1)-α-D-glucopyranoside) [2]. (Melezitose is hydrolyzed to glucose and sucrose). Heat inactivation experiments support the theory that these activities and the maltase activity of the purified maltase III preparation are caused by the same enzyme [2,3].

When two substrates are hydrolyzed by the same enzyme, they act as competitive inhibitors for the hydrolysis of each other. The study of this inhibition usually requires a method for the separate determination of the hydrolysis products of each substrate, when the substrates are present in a mixture [3]. With maltase III, however, the hydrolysis of the other substrates proceeds slowly compared with the hydrolysis of maltose (measured at 0.1388 M substrate concentration the rate for their hydrolysis is 1/20 or less of the rate for the hydrolysis of maltose). When maltose is present in a mixture with one of the other substrates, therefore, it may be assumed that all the glucose produced is derived from maltose, and thus the rate for the hydrolysis of maltose may be measured simply by measuring the increase in reducing power, as if no other substrate were present *.

* This approximation will cause the K_i value measured to be somewhat too high. The error to be expected was calculated from the relative rate of hydrolysis of the different substrates at 0.1388 M substrate concentration and their K_s values. With phenyl-α-D-glycopyranoside as inhibitor the K_i value measured should be about 15 % too high, with *iso*-maltose and turanose about 30 % too high, and with melezitose less than 10 % too high.

Dithiourea-benzenetellurenyl nitrate, $C_6H_5Te(tu)_2NO_3$. M. p. 135°. (Found: S 15.49; Te 29.88. Calc. for $C_8H_{13}N_5O_3S_2Te$: S 15.31; Te 30.46.) Monoclinic, $a = 24.30$ Å, $b = 5.88$ Å, $c = 21.30$ Å, $\beta = 90\frac{1}{2}°$. There are eight formula units per unit cell; density, calc. 1.83, found 1.83 g/cm³. On the basis of the systematic absences, hkl when $h + k$ is odd, $h0l$ when h is odd or l is odd, the space group is either C_{2h}^6—$C2/c$ or C_s^4—Cc.

Dithiourea-benzenetellurenyl perchlorate, $C_6H_5Te(tu)_2ClO_4$. M. p. 136°. (Found: Te 27.97. Calc. for $C_8H_{13}ClN_4O_4S_2Te$: Te 27.96.) Monoclinic prismatic, $a = 12.24$ Å, $b = 5.86$ Å, $c = 22.76$ Å, $\beta = 96°$. There are four formula units per unit cell; density, calc. 1.87, found 1.87 g/cm³. The space group, from systematic absences, is C_{2h}^5—$P2_1/c$.

Dithiourea-benzenetellurenyl thiocyanate, $C_6H_5Te(tu)_2SCN$, was prepared *via* a compound, presumably $C_6H_5Te(tu)SCN$, obtained from phenyltellurium trichloride in the same way as $C_6H_5Te(tu)Br$, by use of 30 mmoles of potassium thiocyanate instead of potassium bromide. The micro-crystalline solid (3 g) which separated on standing at ice temperature, was filtered off and dissolved in 60 ml of warm 10 % aqueous thiourea. Specificity of a Purified Hog Intestinal Maltase Fraction

Competitive Inhibition of Maltase Activity by Other Substrates

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

In previous papers the separation of hog intestinal maltase activity into three fractions (maltase I—III) with different enzymatic properties has been described [1-3]. In the present paper the specificity of one of these fractions, *maltase III*, will be further discussed.

Maltase III preparations hydrolyze *phenyl-α-D-glucopyranoside* [2], *isomaltose* (6-(α-D-glucopyranosyl)-D-glucose) [2], *turanose* (3-(α-D-glucopyranosyl)-D-fructose) [2], and *melezitose* (α-D-glucopyranosyl-(1→3)-β-D-fructofuranosyl-(2→1)-α-D-glucopyranoside) [2]. (Melezitose is hydrolyzed to glucose and sucrose). Heat inactivation experiments support the theory that these activities and the maltase activity of the purified maltase III preparation are caused by the same enzyme [2,3].

When two substrates are hydrolyzed by the same enzyme, they act as competitive inhibitors for the hydrolysis of each other. The study of this inhibition usually requires a method for the separate determination of the hydrolysis products of each substrate, when the substrates are present in a mixture [3]. With maltase III, however, the hydrolysis of the other substrates proceeds slowly compared with the hydrolysis of maltose (measured at 0.1388 M substrate concentration the rate for their hydrolysis is 1/20 or less of the rate for the hydrolysis of maltose). When maltose is present in a mixture with one of the other substrates, therefore, it may be assumed that all the glucose produced is derived from maltose, and thus the rate for the hydrolysis of maltose may be measured simply by measuring the increase in reducing power, as if no other substrate were present *.

* This approximation will cause the K_i value measured to be somewhat too high. The error to be expected was calculated from the relative rate of hydrolysis of the different substrates at 0.1388 M substrate concentration and their K_s values. With phenyl-α-D-glycopyranoside as inhibitor the K_i value measured should be about 15 % too high, with *iso*-maltose and turanose about 30 % too high, and with melezitose less than 10 % too high.

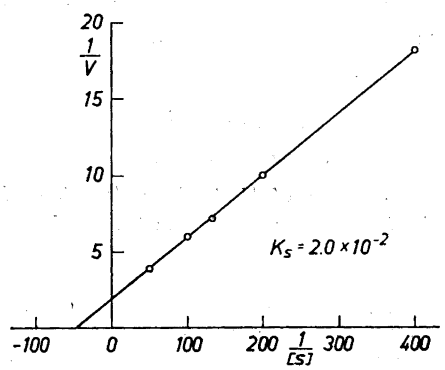

Fig. 1. Determination of K_s for phenyl-α-D-glucopyranosidase activity of purified hog intestinal maltase III. Reaction performed in 0.05 M maleate buffer pH 6.5 at 37°C.

Maltase III was obtained by mutual displacement chromatography [4]. By measuring the rate of hydrolysis (at 37°C in 0.05 M maleate buffer pH 6.5) in a series of maltose solutions containing 0.0020—0.0050 M maltose (chromatographically pure [4]) the K_s for maltase III was determined at 4.2×10^{-3} in agreement with the value obtained earlier [4]. The degree of hydrolysis was measured with acid copper reagent (Caputto's modification) [4,5]. It was not allowed to exceed 20 %. Then the inhibition of maltase III activity was studied, using the same series of maltose solutions in the presence of a suitable amount of the other substrates. The values of K_s and K_i were calculated by Dixon's [8,9] modification of the method of Lineweaver and Burk [10] as described earlier [3]. The calculations for phenyl-α-D-glucopyranoside are seen in Figs. 1 and 2.

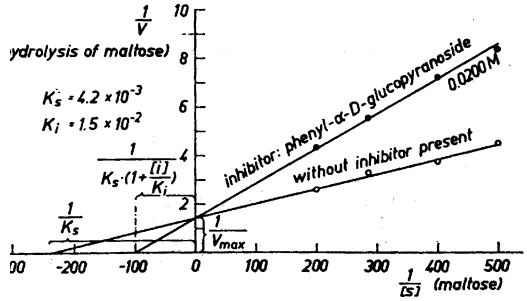

Fig. 2. Inhibition of hog intestinal maltase III activity by phenyl-α-D-glucopyranoside. Reaction performed in 0.05 M maleate buffer pH 6.5 at 37°C. The inhibition is *competitive* (the V_{max} is not altered by the presence of inhibitor). K_s (for maltase III activity) and K_i (for the inhibition by phenyl-α-D-glucopyranoside) are calculated from the intercept with the abscissa as seen in the figure.

The inhibition of maltase III activity was *purely competitive* in all cases (which is seen by the fact that V_{max} was unaltered by the presence of inhibitor). The value for K_i in the different cases are given below, with the concentration of inhibitor used given within parentheses:

Phenyl-α-D-glucopyranoside (0.0200 M) $K_i = 1.5 \times 10^{-2}$ (Fig. 2). The K_s for phenyl-α-D-glucopyranosidase activity was determined to be 2.0×10^{-2} (substrate concentration 0.0025—0.0200 M, and the degree of hydrolysis measured with Somogyi-Nelson's reagents [3], Fig. 1).

Isomaltose (0.0050 M or 0.0100 M) $K_i = 2 \times 10^{-2}$. The K_s for *iso*maltase activity was measured to be 2×10^{-2} (substrate concentration 0.0100—0.0250 M, and the degree of hydrolysis measured by quantitative paper chromatography [6] with 25 μl of the reaction mixture being applied).

Turanose (0.0020 M) $K_i = 3.3 \times 10^{-3}$. The K_s for turanase activity was determined to be 2.2×10^{-3} (substrate concentration 0.0030—0.0200 M, and the degree of hydrolysis determined with glucose oxidase [7]).

Melezitose (0.100 M or 0.200 M*) $K_i = 5.0 \times 10^{-1}$. The K_s for melezitase activity was measured to be 4.5×10^{-1} (substrate concentration 0.0500—0.1400 M, and the degree of hydrolysis determined with 3,5-dinitrosalicylic acid reagent [4]).

Thus in all cases the K_i for the inhibition of the maltase III activity by the other substrates tested was of the same order of magnitude as the K_s for the same substance as substrate. This strongly supports the theory that the phenyl-α-D-glucopyranosidase, *iso*maltase, turanase, and melezitase activities of the purified maltase III preparation are caused by the maltase *per se*, and not by contaminating enzymes.

* In the experiments where 0.200 M melezitose was used as inhibitor, the inhibitor concentration was 100 times the lowest substrate (maltose) concentration. Even during these circumstances, however, it was calculated (from the relative rate of hydrolysis at 0.1388 M substrate concentration and the K_s values) that the amount of glucose produced from melezitose was less than 1 % of the amount produced from maltose.

Sewage as a Substitute for Casein Hydrolyzates in Fermentations with *Propionibacterium shermannii*

HALINA Y. NEUJAHR

Royal Institute of Technology, Division of Food Chemistry, Stockholm 70, Sweden

The bacteria belonging to the genus *Propionibacterium* are characterized by an outstanding ability to produce vitamin B_{12} as reported by several authors [1,2]. Janicki, Pawelkiewicz *et al.*[3-5] used *Propionibacterium shermannii* in their comprehensive studies on vitamin B_{12} production by propionic acid bacteria and isolated several vitamin B_{12} factors from cultures of this organism. These authors found that the addition of small amounts of Aureomycin or sulfathiazole stimulated the synthesis of cyanocobalamin at the expense of other vitamin B_{12} factors [6,7] as is also the case with the addition of 5,6-dimethyl benzimidazole (DMB)[6]. The semi-synthetic medium used in fermentations with *Propionibacterium shermannii* is composed of casein hydrolyzates, glucose, phosphates, certain mineral salts and the vitamins, calcium pantothenate and biotin. Since the most expensive constituents of the medium are the casein hydrolyzates, it was considered

to be of interest to find a suitable cheap substitute for this substrate.

A preliminary series of experiments was devoted to finding ways for stimulating the production of vitamin B_{12} in the semi-synthetic medium used by other authors. This series consisted of three fermentations in 2 l conical flasks using the semi-synthetic medium * supplemented as indicated in Table 1. The fermentations lasted over a period of 12 days and were operated on a semi-continuous basis — 100 ml of the fermented medium was replaced every day by fresh medium. The glucose content was adjusted every day to 1 % and the pH to 6.6. The vitamin B_{12} activity was determined every day using *E. coli* 113—3 in

* Composition of the semi-synthetic medium: Casaminoacids Technical (Difco), 14 g; Bactogen (Vitrum), 12.5 g; $NaH_2PO_4 \cdot 2H_2O$, 2.2 g; K_2PO_4, 1.8 g; $MgCl_2 \cdot 6\ H_2O$, 0.4 g; $FeSO_4 \cdot 7H_2O$, 0.01 g; $CoCl_2 \cdot 6H_2O$, 10 p. p.m.; dist. water to 1 000 ml.

cup plate assay and bioautography as described elsewhere [8]. The results are given in Table 1.

The *E. coli* activity obtained separated upon bioautography into four spots. One of them could be identified as cyanocobalamin and another one as factor B whereas the remaining two were slow moving spots similar to the spots corresponding to factors Z[8] or GDP-factor B[9,10]. Approximately 20–30 % of the activity was due to cyanocobalamin. The addition of DMB increased the cyanocobalamin content to about 50 % of the total *E. coli* activity but had a markedly inhibiting effect upon the total activity (*cf.* Table 1). The addition of corn steep liquor seemed to decrease somewhat the *E. coli* activity formed but had no effect on the distribution of this activity between the different factors.

The fermentation liquors contained, in addition, a factor with a growth inhibiting activity for *L. leichmannii* 313. This factor had a mobility similar to that of factor B upon electrophoresis at pH 2.5 (2 M HAc). The presence of similar inhibitors in cultures of vitamin B_{12}-producing organisms has been reported earlier from this laboratory and by other authors [11,12].

A second series of experiments was performed in 24 test tubes, each containing 20 ml medium. Two of the tubes contained the complete semi-synthetic medium while the remaining 22 tubes contained instead either different fractions of fresh and treated sewage or milk whey, yeast autolyzate or supernatant from cultures of a blue-green alga (*Anabaena*). Each of these substrates was used both without any further supplementation and also supplemented with the constituents of the synthetic medium apart from the casein hydrolyzates. The pH of all media was adjusted to 6.6 and their *E. coli* activity determined. No re-adjustments of the glucose content or pH were made and the fermentations were interrupted after 5 days. The results can be seen in Table 2.

It seems from Table 2 that the sewage fraction 4 supplemented as described above may provide a good substitute for casein hydrolyzates in the semi-synthetic medium. While, under the conditions described, a five days fermentation in the semi-synthetic medium gave only 0.5 μg *E. coli* activity per ml, a corresponding fermentation using the sewage fraction 4 gave 2.4 μg/ml. Bioautographic determinations did not reveal any significant differences in the distribution of the *E. coli* activity between different factors. It seems also that the semi-continuous method and repeated adjustments of pH and glucose content are of great importance for the yield of *E. coli* activity (*cf.* Tables 1 and 2).

Further experiments devoted to these problems are in progress and the results will be reported within the near future.

Inhibition of *Pediococcus cerevisiae* ATCC 8081 by Deoxyuridine

ARNE E. BOLINDER and WOLFGANG G. KURZ

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Plate assays for folinic acid factors and thymidine as well as the bioautography of these growth factors have been carried out in this laboratory using *Pediococcus cerevisiae (Leuconostoc citrovorum)* ATCC 8081 as the test organism [1-3]. This paper deals with the growth inhibitory effect of deoxyuridine on *P. cerevisiae* in cup plate and tube assays generally used for folinic acid * and thymidine determinations.

* Leucovorin (synthetic N^5-formyl tetrahydropteroylglutamic acid) was used as a source of folinic acid throughout these studies.

cup plate assay and bioautography as described elsewhere [8]. The results are given in Table 1.

The *E. coli* activity obtained separated upon bioautography into four spots. One of them could be identified as cyanocobalamin and another one as factor B whereas the remaining two were slow moving spots similar to the spots corresponding to factors Z[8] or GDP-factor B[9,10]. Approximately 20–30 % of the activity was due to cyanocobalamin. The addition of DMB increased the cyanocobalamin content to about 50 % of the total *E. coli* activity but had a markedly inhibiting effect upon the total activity (*cf.* Table 1). The addition of corn steep liquor seemed to decrease somewhat the *E. coli* activity formed but had no effect on the distribution of this activity between the different factors.

The fermentation liquors contained, in addition, a factor with a growth inhibiting activity for *L. leichmannii* 313. This factor had a mobility similar to that of factor B upon electrophoresis at pH 2.5 (2 M HAc). The presence of similar inhibitors in cultures of vitamin B_{12}-producing organisms has been reported earlier from this laboratory and by other authors [11,12].

A second series of experiments was performed in 24 test tubes, each containing 20 ml medium. Two of the tubes contained the complete semi-synthetic medium while the remaining 22 tubes contained instead either different fractions of fresh and treated sewage or milk whey, yeast autolyzate or supernatant from cultures of a blue-green alga (*Anabaena*). Each of these substrates was used both without any further supplementation and also supplemented with the constituents of the synthetic medium apart from the casein hydrolyzates. The pH of all media was adjusted to 6.6 and their *E. coli* activity determined. No re-adjustments of the glucose content or pH were made and the fermentations were interrupted after 5 days. The results can be seen in Table 2.

It seems from Table 2 that the sewage fraction 4 supplemented as described above may provide a good substitute for casein hydrolyzates in the semi-synthetic medium. While, under the conditions described, a five days fermentation in the semi-synthetic medium gave only 0.5 μg *E. coli* activity per ml, a corresponding fermentation using the sewage fraction 4 gave 2.4 μg/ml. Bioautographic determinations did not reveal any significant differences in the distribution of the *E. coli* activity between different factors. It seems also that the semi-continuous method and repeated adjustments of pH and glucose content are of great importance for the yield of *E. coli* activity (*cf.* Tables 1 and 2).

Further experiments devoted to these problems are in progress and the results will be reported within the near future.

Inhibition of *Pediococcus cerevisiae* ATCC 8081 by Deoxyuridine

ARNE E. BOLINDER and WOLFGANG G. KURZ

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Plate assays for folinic acid factors and thymidine as well as the bioautography of these growth factors have been carried out in this laboratory using *Pediococcus cerevisiae (Leuconostoc citrovorum)* ATCC 8081 as the test organism [1-3]. This paper deals with the growth inhibitory effect of deoxyuridine on *P. cerevisiae* in cup plate and tube assays generally used for folinic acid * and thymidine determinations.

* Leucovorin (synthetic N^5-formyl tetrahydropteroylglutamic acid) was used as a source of folinic acid throughout these studies.

For the cup plate tests and the bioautography large plates were used, each containing 150 ml of agar medium inoculated with *P. cerevisiae* [1]. Three types of media were used; unsupplemented media and media supplemented with either 15 mμg of leucovorin or 30 μg of thymidine per plate. The plates with supplemented media were used in order to obtain a good background growth and thereby give a more pronounced appearance of growth inhibition. For the cup plate tests, 0.03 ml aliquots of the test solutions were pipetted into cups, 6 mm in diameter, and the plates were incubated over night at 37°C. Tube tests were made using a final volume of 10 ml per tube. After suitable periods of incubation at 37°C, cell growth was measured turbidimetrically. For making the plates and the tube assays, washed and optically standardized inocula were used. A detailed report of these assays will be published later in this journal.

The growth inhibitory effect of deoxyuridine was discovered while investigating the contamination of a deoxyuridine preparation by thymidine. When checking the results obtained bioautographically with *Lactobacillus leichmannii* 313 ATCC 7830 as the test organism [2] (which responds to vitamin B_{12}-factors, deoxyribonucleosides, and deoxyribonucleotides) against bioautography with *P. cerevisiae*, we found that deoxyuridine produced a spot of nearly complete growth inhibition in the background growth of the *P. cerevisiae* plates made with unsupplemented media or with media containing leucovorin *. Bioautography using four different solvent systems showed that the UV-absorbing spot of deoxyuridine always corresponded to the growth inhibition spot in the *P. cerevisiae* plates and to a dense growth spot in the *Lb. leichmannii* 313 plates. In the *P. cerevisiae* plates, 3—4 μg of deoxyuridine could be detected bioautographically, which was the amount required for detection by in-spection in UV-light.

In the cup plate tests, deoxyuridine formed inhibition zones only when tested at concentrations of 100 μg/ml and above. In typical cup tests made in *P. cerevisiae* plates using unsupplemented media or media supplemented with leucovorin, the almost completely clear inhibition zones with fairly well defined zone edges produced by deoxyuridine (100 and 1 000 μg/ml) measured 17 mm and 27 mm, respectively. The growth inhibition produced by deoxyuridine was reversed by leucovorin or by thymidine, if either of the latter compounds were present in sufficient concentration.

In the *P. cerevisiae* plates with unsupplemented media leucovorin produced zones of heavy growth, whereas thymidine produced somewhat fainter growth zones.

In a series of cup plate experiments several nucleic acid compounds were tested for growth stimulation or growth inhibition using the three types of *P. cerevisiae* media. However, of all the compounds tested, deoxyuridine was the only one that showed strong growth inhibition. Very faint and diffuse inhibition zones were formed by uridine, cytidine, adenosine, and guanosine when these compounds were tested at concentrations of 1 mg/ml. These inhibitions were also reversed by leucovorin or thymidine.

Small zones of growth stimulation were formed by 5-methyldeoxycytidine (500 μg/ml) which was confirmed bioautographically. This finding is under further investigation.

No inhibition zones could be detected in the plates when the following compounds were tested separately at concentrations of 1 mg/ml (if not otherwise stated in brackets): (a) uracil (500 μg/ml), cytosine, 5-methylcytosine, thymine (500 μg/ml), orotic acid (500 μg/ml), dihydrouracil, and dihydrothymine, (b) adenine (500 μg/ml), guanine (200 μg/ml), hypoxanthine (500 μg/ml), and xanthine (200 μg/ml), (c) deoxycytidine, deoxyadenosine, deoxyguanosine, and deoxyinosine, (d) inosine and xanthosine (500 μg/ml), (e) the 5′-monophosphates of thymidine, deoxyuridine, deoxycytidine, 5-methyldeoxycytidine (500 μg/ml), deoxyadenosine, and deoxyguanosine, (f) the 5′-monophosphates of uridine, cytidine, adenosine, guanosine, and inosine, (g) uridylic, cytidylic, adenylic, and guanylic acids (mixtures of the 2′- and 3′-monophosphates), (h) the cyclic 2′,3′-monophosphates of uridine, cytidine, and adenosine, and (i) the 5′-di- and -tri-phosphates of adenosine and inosine. Each of the compounds uracil, adenine, guanine, and xanthine were present in the basal medium at a concentration of 10 μg/ml.

The growth inhibitory activity of deoxyuridine and some other nucleic acid compounds was also studied by turbidimetric tube tests using *P. cerevisiae*. Read-

* In *P. cerevisiae* plates made with media containing thymidine, only faint zones of growth inhibition were formed by deoxyuridine in cup tests or bioautographic tests.

ings were made after 24, 48, and 68 h of incubation. For these tube tests a batch of deoxyuridine free of contaminating thymidine was prepared by chromatography on Whatman No. 3MM filter paper followed by elution with distilled water. We found that the growth promoting effects of suboptimal amounts of leucovorin or thymidine were strongly inhibited by deoxyuridine and to a much lesser extent by uridine and adenosine. Under the same testing conditions cytidine, guanosine, and inosine were only very slightly growth inhibitory, whereas no growth inhibition was caused by deoxycytidine, deoxyadenosine, deoxyguanosine or xanthosine. These findings are in accordance with the plate tests mentioned above.

The growth promoting effect of suboptimal amounts of leucovorin was inhibited noncompetitively by deoxyuridine, the inhibition index * increased as the amount of leucovorin was increased in the tubes. However, the growth promoting effect of suboptimal amounts of thymidine was competitively inhibited by deoxyuridine. An inhibition index of about 30 was obtained after 48 h of incubation when thymidine was present in the medium in amounts of 0.1 to 3 μg per tube. Larger amounts of thymidine increased the inhibition index. No inhibitions occurred in the tube tests when leucovorin or thymidine were present in amounts sufficient to promote optimal growth of *P. cerevisiae*.

Earlier work on the nutritional requirements of *P. cerevisiae* using the tube assay method, have shown that thymidine was the only deoxyribonucleoside which supported growth when substituted for leucovorin [4,5]. However, in these investigations only low concentrations of deoxyribonucleosides were tested. Some synthetic nucleosides of thymine (*e. g.* 1-D-glycosylthymine) have been reported to have a slight inhibitory effect upon the growth of *P. cerevisiae* when cultured in the presence of limiting amounts of thymidine [6].

Further work is needed before any conclusions can be drawn concerning the inhibition mechanism of *P. cerevisiae* by deoxyuridine. Our findings for *P. cerevisiae* are very similar to those obtained by Lansford *et al.*[7] using 2,4-diamino-6,7-diphenylpteridine-inhibited *Lactobacillus arabinosus*. This latter is a microbiological testing system in which the biosynthesis of thymidine is inhibited. Thus, these workers found that deoxyuridine was the only deoxyribonucleoside that showed any growth inhibition. Adenosine, inosine, guanosine, cytidine, and uridine were also found to be growth inhibitory, whereas deoxyadenosine, deoxyguanosine, deoxycytidine, and xanthosine showed neither inhibitory nor stimulatory effects upon growth. However, we found that no inhibition of growth was exerted by kinetin (100, 300, and 1 000 μg/ml) in plate tests with *P. cerevisiae*. This is in contrast to the *Lb. arabinosus* testing system of Lansford *et al.*[7] in which kinetin and related compounds showed growth inhibitory effects.

* The inhibition index was calculated as the molar ratio of deoxyuridine to growth factor, present in the medium at 50 % inhibition of growth.
