ACTA CHEMICA SCANDINAVICA 14 (1960) 1—8

Characterization of Three Different Hog Intestinal Maltases

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Hog intestinal maltase activity was recently separated into three fractions (maltase I—III) with different heat stability and different K_s values. The characterization of these maltases with respect to their optimum pH, transglycosylase activity, and specificity, is now reported.

Generally, *maltase I* showed properties markedly different from those of *maltases II and III*. The two last maltases, on the other side, had very similar properties except their different sensibility to heat.

All three maltases were found to be α-D-*glucopyranosidases* (glucosido-maltases). *Maltase I* hydrolyzed *sucrose* with a rate 1.7 times the rate for maltose hydrolysis. However, it did not hydrolyze *iso*maltose or phenyl α-D-glucopyranoside. *Maltases II and III* hydrolyzed *isomaltose* and *phenyl α-D-glucopyranoside* but not sucrose. All three maltases hydrolyzed *maltosucrose* (α-D-glucopyranosyl(1→4)α-D-glucopyranosyl(1→2) β-D-fructofuranoside).

Hog intestinal maltase activity was recently separated into three fractions by the method of heat inactivation combined with ion exchange chromatography [1,2]. One of these fractions (maltase III) was not inactivated even when heated in 0.01 M phosphate buffer pH 6.0 at 70°C for 1 h. The other two fractions were more heat-labile, and were rapidly inactivated at 60°C. However, a small difference in heat stability was found also between these two fractions (maltases I and II), which was utilized for the purification of the maltase II fraction [2].

The three maltase fractions are all derived from the microsomes of the intestinal mucosa [1]. Each one of them contributes to about one third of the total maltase activity of the mucosa [1].

The three hog intestinal maltases were found to have different K_s values, which supports the theory that they are different enzymes [2]. In the present paper the optimum pH, the transglycosylase property, and the specificity of the three different maltases are recorded, and their characterization as three different enzymes is discussed.

MATERIALS AND METHODS

Hog intestinal maltases

Maltase preparations were the same fractions from mutual displacement chromatography as were used earlier for K_s determinations [2]. In the text these fractions are referred to as *maltase I, II,* and *III* [1,2]. The specific maltase activity (units of maltase per mg of protein [2]) of the preparations used were 175 for maltase I, 100 for maltase II, and 200 for maltase III.

Substrates

Maltose (monohydrate), cryst., was obtained from Merck A. G. (Germany). For maltase determinations the commercial preparation was used without further purification. In paper chromatography, however, it formed some spots which moved more slowly than maltose. For K_s determinations and for transglycosylase activity studies, therefore, maltose was used which had been purified upon carbon-celite columns [3], and which only formed one spot in paper chromatography. *Isomaltose* (6(α-D-glucopyranosyl) D-glucose) was prepared by enzymatic hydrolysis of dextran, as will be described elsewhere [4]. The hydrolysis of maltose and *iso*maltose was determined with acid copper reagent as described earlier for maltose [2].

Sucrose, cryst., was obtained from J. T. Baker Co. and *αα-trehalose (dihydrate)*, chemically pure, from Pfanstiehl Inc. The hydrolysis of these sugars was determined with the 3,5-dinitrosalicylic acid method [3].

Phenyl-α-D-glucopyranoside. The tetraacetate was obtained by condensation of α-pentaacetylglucose (obtained from Nutritional Biochemicals Corp.) and phenol in the presence of $ZnCl_2$ [5,6]. It had $[\alpha]_D^{20}$ +168.0° (7.2 % in $CHCl_3$) and m. p. 113—114°C. Deacetylation was performed as described elsewhere [7], and the product was crystallized from water. Drying at 50°C *in vacuo* over P_2O_5 yielded anhydrous phenyl α-D-glucopyranoside with $[\alpha]_D^{20}$ +186.0° (3 % in water).

The hydrolysis of phenyl α-D-glucopyranoside was measured at 0.1388 M substrate concentration as in the case of the other substrates. The enzyme solution, therefore, was mixed with an equal volume of 0.2776 M phenyl α-D-glucopyranoside solution. Such a concentrated solution, however, crystallizes at room temperature. It was therefore heated in a boiling water-bath until it became clear, and was then placed in a test-tube in a water-bath at 37°C for 3—5 min before it was mixed with the enzyme solution. The amount of glucose produced was determined with the method of Somogyi and Nelson [8,9] after precipitation of the proteins with the Zn-Ba-reagents of Somogyi [10].

Maltosucrose (α-D-glucopyranosyl(1 → 4) α-D-glucopyranosyl(1→2) β-D-fructofuranoside) was prepared as described earlier [3]. The hydrolysis of this sugar, too, was measured with the method of Somogyi and Nelson.

The rate of hydrolysis of all substrates was measured at 37°C at 0.1388 M substrate concentration in the presence of 0.05 M maleate buffer pH 6.5. When the *initial rate of reaction* was measured, the degree of hydrolysis was not allowed to exceed 10 %. One unit of maltase activity during these conditions produces 1 mg of glucose (= 1 % of hydrolysis in 2 ml of reaction mixture) in 1 h. For comparison of the rate of hydrolysis of different substrates the number of molecules of the different substrates that were hydrolyzed per time unit, was calculated. For a trisaccharide, such as maltosucrose, either the number of glycosylic linkages hydrolyzed or the number of molecules totally hydrolyzed may be calculated [11].

Paper chromatography of sugars was performed as described earlier [3].

^{14}C-Labelled glucose was obtained from the Radiochemical Centre (England). The ^{14}C-labelled sugars were localized on paper chromatograms as described earlier [3].

RESULTS AND DISCUSSION

Optimum pH

The pH activity curves for the three different intestinal maltases are seen in Fig. 1. The optimum pH for the *maltase I* activity was 6.5 with a fairly

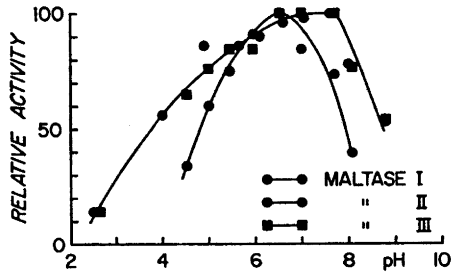

Fig. 1. Influence of pH on the activity of the three different maltases from hog intestinal mucosa. The reaction mixtures contained 5 units of maltase/ml. Buffers: 0.05 M citrate pH 2.5, 0.05 M acetate pH 4.0—5.0, 0.05 M maleate pH 5.5—6.5, 0.025 M veronal pH 7.0—9.0. The pH of the reaction mixtures was measured with a glass electrode.

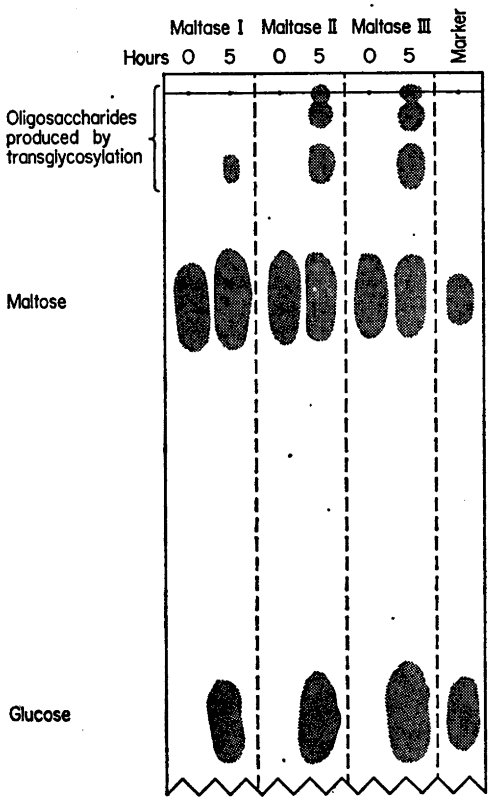

Fig. 2. Formation of oligosaccharides by transglycosylation by the three different hog intestinal maltases. The reaction mixture in all cases contained 50 units of maltase/ml 0.833 M maltose (= 30 % maltose monohydrate), 0.05 M maleate buffer pH 6.5, and a few drops of toluene in each tube. Of the reaction mixtures, 5 µl spots were applied to a paper chromatogram which was run for 60 h. Maltase I produced only one oligosaccharide spot, while maltases II and III produced at least three different oligosaccharide spots.

narrow peak. The shape of this curve coincides with that for the intestinal *invertase* activity [4], which it has not been possible to separate from the maltase I fraction [1,2]. *Maltases II and III* had broader pH activity curves, with optima at pH 6.5—7.5. No difference was found in the shape of the curves for the maltase II and III fractions.

Transglycosylase activity

All three fractions produced slower moving oligosaccharides in a concentrated maltose solution. With *maltase I* only one oligosaccharide spot was found on the paper chromatogram, but with *maltases II and III* a series of at least three different oligosaccharides was formed (Fig. 2).

The transglycosylase activity with ^{14}C-labelled glucose as receptor was also studied. All three maltases incorporated ^{14}C-labelled glucose into the maltose spot (Fig. 3). The rate for this reaction, however, compared with the rate for liberation of glucose, was greater with maltase II and III activities than with maltase I. With maltase I no detectable amount of ^{14}C-labelled glucose was incorporated into the oligosaccharide with slower chromatographic mobility than maltose, but with maltases II and III a great part of the ^{14}C-labelled glucose was incorporated into the oligosaccharides as well (Fig. 3).

The incorporation of ^{14}C-labelled glucose into maltose is *not* caused by the combination of two free glucose molecules. In a 1.65 M (= 30 %) * solution of glucose, under the corresponding experimental conditions, no detectable amount of maltose was formed in 5 h. (When the reaction time was extended to 23 h, however, a faint spot with the same chromatographic mobility as maltose was formed by maltases II and III, but not by maltase I. The reason for the difference is not known. Since the reaction mixture in all cases contained the same number of maltase units per ml, it should have been expected that the reverse reaction (the synthesis of maltose), too, would proceed with the same rate in all three cases. It is well known that the kinetics of the hydrolysis of maltose are such that detectable amounts of maltose are present at equilibrium [12].) In the experiment shown in Fig. 3, therefore, the incorporation of ^{14}C-labelled glucose into maltose (and other oligosaccharides) must be the result of a *transglycosylation*.

Maltases II and III seem to have a stronger transglycosylase activity in relation to their hydrolytic activity than maltase I, since a greater amount of ^{14}C-labelled glucose was incorporated into maltose by maltases II and III than by maltase I under the same experimental conditions. No difference in the transglycosylase activity of maltase II and that of maltase III could be detected.

Rate for the liberation of glucose in concentrated substrate solutions. The amount of glucose liberated (as measured with the acid copper reagent [2]) per time unit by *maltase I* increased with increasing substrate concentration up to more than 5 % (0.1388 M) maltose (monohydrate) (Table 1). With *maltase II and III*, however, the optimal substrate concentration was 1 % (0.0278 M),

* Per cent means gram of solute in 100 ml of solution.

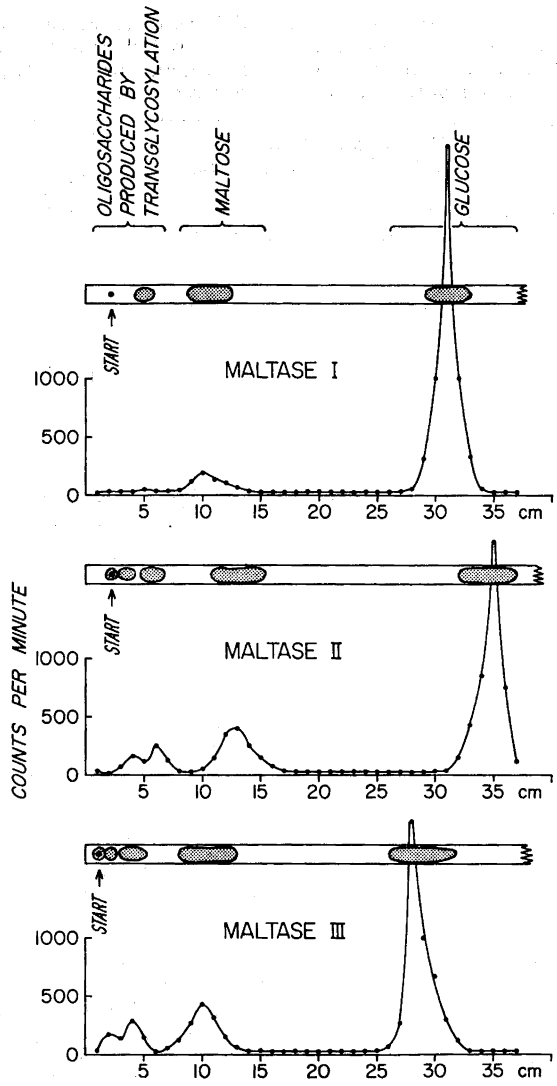

Fig. 3. Transglycosylation by the three different hog intestinal maltases with ^{14}C-glucose as receptor. The reaction mixture contained 50 units of maltase/ml, 0.833 M maltose, 1 mg of ^{14}C-labelled glucose (1 250 000 c.p.m.)/ml, 0.05 M maleate buffer pH 6.5, and one drop of toluene. After 5 h at 37°C the reaction was interrupted by boiling in a water-bath for 2 min, and 5 μl spots of the reaction mixtures were applied to paper chromatograms which were run for 2 days. Each spot contained 6 250 c.p.m. of ^{14}C-labelled sugars. Counting and chemical localization of the sugars were performed on the same paper strip [3]. With *maltase I* 500 c.p.m. (8 % of the total activity) was incorporated into the maltose spot and no detectable amount into the oligosaccharide spot. With *maltase II* 1 250 c.p.m. (20 %) was incorporated into the maltose and 650 c.p.m. (10.4 %) into the other oligosaccharides produced. With *maltase III* 1 250 c.p.m. (20 %) was incorporated into the maltose and 600 c.p.m. (9.6 %) into the other oligosaccharides.

Table 1. The rate of liberation of glucose by three different intestinal maltases in 1 % (0.0278 M) and 5 % (0.1388 M) maltose solutions. The reaction was performed at 37°C in the presence of 0.05 M maleate buffer pH 6.5. The amount of glucose produced was measured with the acid copper reagent.

	Mg of glucose in 1 h per 2 ml of react. mixt.		rate in 1 % maltose / rate in 5 % maltose
	1 % maltose (monohydrate)	5 % maltose (monohydrate)	
Maltase I	6.0	7.5	0.8
Maltase II	6.2	5.3	1.2
Maltase III	11.4	9.5	1.2

and at higher substrate concentration the amount of glucose liberated decreased (Table 1). This effect is possibly caused by the stronger transglycosylase activity of maltases II and III as compared with maltase I.

Specificity of hog intestinal maltases

Sucrose was hydrolyzed by *maltase I* with a rate that was 1.7 times the rate for the hydrolysis of maltose. The invertase and maltase activities of this fraction were not separable by ion exchange chromatography or by heat inactivation, performed in a series of buffers of different pH values [1]. There is strong evidence, therefore, that these two activities are caused by the same enzyme *. *Maltase II* and *maltase III*, on the other hand, did not hydrolyze sucrose. Under the experimental conditions used, a hydrolysis of sucrose with only 1/100 of the rate for maltose hydrolysis would have been detected.

αα-Trehalose (1-(α-D-glucopyranosyl) α-D-glucopyranoside) was *not* hydrolyzed by any of the three maltase fractions. A hydrolysis with only 1/100 of the rate for maltose hydrolysis would have been detected.

Isomaltose (6-(α-D-glucopyranosyl) D-glucose) was *not* hydrolyzed by *maltase I*. A hydrolysis with only 1/200 of the rate for maltose hydrolysis would have been detected. *Maltase II* hydrolyzed iso-maltose with 0.02 times and *maltase III* with 0.05 times the rate for maltose hydrolysis. When heated in the presence of 0.01 M phosphate buffer pH 6.0, the *iso*maltase activity of the maltase II preparation was destroyed below 60°C, while the *iso*maltase activity of the maltase III preparation was not inactivated below 70°C. The inactivation of the *iso*maltase activity of the two preparations ran parallel with that of the maltase activity. It seems probable, therefore, that the *iso*-maltase activity of these two preparations is caused by the same enzyme as the maltase activity.

* Experiments which will be reported in a later paper demonstrate that sucrose and maltose act as competitive inhibitors for each others with this enzyme fraction, which clearly shows that hog intestinal *invertase* is identical with *maltase I*.

Phenyl α-D-glucopyranoside was *not* hydrolyzed by *maltase I*. A hydrolysis with only 1/1 000 of the rate for maltose hydrolysis would have been detected. *Maltase II* hydrolyzed phenyl α-D-glucopyranoside with 0.03, and *maltase III* with 0.05 times the rate for maltose hydrolysis (calculated as the number of molecules hydrolyzed per time unit). As was the case with the *iso*maltase activity of the maltase II and III fractions, phenyl α-D-glucopyranosidase activity had the same sensitivity to heat as had the maltase activity.

Maltosucrose (α-D-glucopyranosyl(1→4)α-D-glucopyranosyl(1→2)β-D-fructofuranoside) was hydrolyzed by all three maltase fractions. By *maltase I* it was hydrolyzed *completely* into glucose and fructose. Calculated as the number of glycosylic linkages hydrolyzed per time unit, the rate for hydrolysis of maltosucrose was 0.8 times the rate for maltose hydrolysis. With the aid of paper chromatography, sucrose was found to be the intermediary product during the hydrolysis of maltosucrose. The trisaccharide is therefore first hydrolyzed into one molecule of glucose and one molecule of sucrose, and then the sucrose molecule is hydrolyzed into glucose and fructose. *Maltase II* and *maltase III* both hydrolyzed maltosucrose into glucose and sucrose, *i.e.* only the *maltose* linkage of the trisaccharide was hydrolyzed. When calculated as the number of glycosylic linkages hydrolyzed per time unit, the rate for hydrolysis of maltosucrose was 0.4 times the rate for maltose hydrolysis for both fractions. The heat inactivation of the maltosucrase activity of these two fractions ran parallel with the inactivation of the maltase activity.

The specificity of *maltase I*, thus, differs markedly from the specificity of *maltase II* and *maltase III*. No difference in specificity was found between the last-mentioned two fractions, however, except that they hydrolyzed *iso*-maltose and phenyl α-D-glucopyranoside at a slightly different rate. All three fractions may be classified as α-D-glucopyranosidases (glucosido-maltases) * since they hydrolyze a number of other α-D-glucopyranosides in addition to maltose.

Possibility of a heat-stabilizing factor

There is no doubt that *maltase I* is an enzyme which differs from the two other fractions. *Maltase II* and *maltase III*, on the other side, are very similar. Except the great difference in their sensitivity to heat [1], the only differences were a small difference in the K_s value for maltose [2], and a slightly different relative rate of hydrolysis of *iso*maltose and phenyl α-D-glucopyranoside. The K_s value as well as the relative rate of hydrolysis of different substrates may be influenced by contaminants in the enzyme preparation, which react with the enzyme. The question therefore arises if the difference in heat sensitivity may be an artifact.

During studies on yeast invertase Myrbäck [14] observed that the course of the heat inactivation did not always follow the kinetics of a first order reaction. The course of the heat inactivation of some preparations should coincide with the existence in them of two different invertases with different

* Leibowitz [13] once postulated the exixtence of *gluco-maltases*, which, in contrast to glucosido-maltases, should have their specificity directed towards the *reducing* component of the maltose molecule. Later workers, however, have not been able to verify the existence of gluco-maltases [12].

heat stability. The K_s value for the invertase activity was not altered, however, during partial heat inactivation, which would have been expected if there really had been two different invertases in the preparation. In order to explain the course of the heat inactivation, therefore, the existence was proposed, not of two different invertases, but of a *heat-stabilizing factor* in a small amount, insufficient to protect the whole enzyme [15].

In order to find out if the maltase III preparation contained a heat-stabilizing factor, an experiment was made for the purpose of showing if the presence of a maltase III preparation, the maltase activity of which had been completely inactivated, could protect maltase II against heat inactivation. A small amount of a *maltase III* preparation, with 216 units/ml of maltase, was heated for 10 min at 100°C. The maltase activity was found to be completely destroyed by this procedure. After cooling, 0.5 ml of the inactivated enzyme preparation was mixed with 0.5 ml of a *maltase II* preparation with 160 units/ml of maltase. When this mixture was heated at 60°C, for 45 min., the maltase activity was found to be completely destroyed. (Before the experiment, both maltase preparations had been dialyzed against 0.01 M phosphate buffer pH 6.0) Thus no heat-stabilizing factor could be demonstrated in the heat-stable maltase preparation.

If maltase II and maltase III are really different enzymes, however, the structural difference between them is probably very small since they are so similar in action and so difficult to separate from each other.

Acknowledgment. The author's thanks are due to Professor Bengt Borgström for his interest in my work and for valuable discussions.

This work has been supported by grants from the *Medical Faculty of the University of Lund.*

The skilful technical assistance of Mrs. K. Hagebris is gratefully acknowledged.

ACTA CHEMICA SCANDINAVICA 14 (1960) 9—16

Characterization of Hog Intestinal Trehalase

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Hog intestinal trehalase is a specific enzyme, separable from the intestinal invertase, maltase, and *iso*maltase activities. In the present paper the partial purification and the characteristics of hog intestinal trehalase will be described.

In contrast to the hog intestinal invertase and maltase activities, hog intestinal trehalase had *no* transglycosylase activity. Nor could any synthesis of trehalose be detected.

Hog intestinal trehalase has very high specificity for *aa*-trehalose. The preparation did not hydrolyze sucrose, maltose, *iso*maltose, phenyl α-D-glucopyranoside, or *ββ*-trehalose. It hydrolyzed *αβ*-trehalose slowly, but heat inactivation revealed that this sugar was *not* hydrolyzed by the same enzyme as *aa*-trehalose.

The high specificity and the lack of transglycosylase activity makes it probable that hog intestinal trehalase acts upon its substrate in a more symmetrical way than do the other glycosidases.

That intestinal mucosa from certain mammals (rabbit, horse, cow) has trehalase activity *, has been known since the end of the 19th century [1–3]. Until recently it has not been known, however, if the intestinal trehalase activity is caused by a specific enzyme, or if it is only one activity of an intestinal α-D-glucopyranosidase which acts on many different substrates, as proposed by Weidenhagen [3,4].

In the course of a study of hog intentinal α-D-glucopyranosidase activities it was recently observed, however, that the hog intestinal trehalase activity was separable from the hog intestinal invertase and maltase activities. The trehalase activity was inactivated by exposure to ethanol, and it appeared as a separate peak in chromatography upon DEAE-cellulose [5]. The hog intestinal trehalase activity could also be separated from the invertase and maltase activities by heat inactivation [6]. Hog intestinal trehalase, therefore, is a specific enzyme, as has earlier been reported in the case of trehalase from fungi (*Aspergillus niger* [7], yeast [3]) and insect larvae (*Galleria mellonella* [8]).

In the present paper the partial purification of trehalase from hog intestinal mucosa and some characteristics of hog intestinal trehalase will be described.

* *Trehalase* activity (without prefix) means hydrolytic activity against the *naturally* occurring trehalose, *aa*-trehalose (1(α-D-glucopyranosyl) α-D-glucopyranoside).

MATERIALS AND METHODS

Hog intestinal mucosa was obtained from the slaughterhouse immediately after slaughter, and was chilled with crushed ice during the transport to the laboratory.

Substrates. *αα-Trehalose* (1-(α-D-glucopyranosyl) α-D-glucopyranoside) (dihydrate) of analytical grade purity, with $[\alpha]_D^{20}$ +178.3°, was obtained from Pfanstiehl Chemical Co. *Sucrose*, cryst., was obtained from J. T. Baker Co. and *maltose* (monohydrate), cryst., from Merck A. G. (Germany).

αβ-Trehalose (1-(α-D-glucopyranosyl) β-D-glucopyranoside, *neo*trehalose) and *ββ-trehalose* (1-(β-D-glucopyranosyl) β-D-glucopyranoside, *iso*trehalose) were obtained as their *octaacetates*, a generous gift from *Professor H. Bredereck* (Technische Hochschule, Stuttgart) [9]. Deacetylation was performed by shaking with excess of NaOH (200 mg of trehalose octaacetate and 40 ml of 0.1 N NaOH) at room temp. for 16 h. The Na-acetate formed and the excess of NaOH were removed by filtration through a column with 2 cm diam., containing 4 g of Dowex 2 (OH-form), 4 g of Dowex 50 (H-form), and 4 g of Dowex 2 (OH-form) as separate layers. The flow rate was 0.5 ml/min. The column was washed with 150 ml of water. The neutral filtrate was evaporated at reduced pressure to a volume of about 10 ml, lyophilized and dried *in vacuo* at 50°C over P_2O_5. About 90 mg of each sugar was obtained.

The sugars obtained did not reduce Somogyi's copper reagent. They had the same mobility as αα-trehalose on the paper chromatogram. $[\alpha]_D^{20}$ was +79.0° for αβ-trehalose (3 % in water) and −41.4° for ββ-trehalose (4.2 % in water).

Phenyl-α-D-glucopyranoside was obtained as its *tetraacetate* by the method of *Helferich* [10] as modified by *Montgomery et al.*[11] $[\alpha]_D^{20}$ of the tetraacetate was +168.0° (7.2 % in $CHCl_3$), m. p. 113−114°C (reported [10] $[\alpha]_D^{20}$ +168°, m. p. 115−116°C). Deacetylation was performed as described above in the case of trehalose octaacetates. The phenyl-α-D-glucopyranoside was crystallized from water and dried *in vacuo* at 50°C over P_2O_5. $[\alpha]_D^{20}$ was +186.0° (anhydrous, 3 % in water).

Isomaltose (6(α-D-glucopyranosyl) D-glucose) was obtained by enzymatic hydrolysis of dextran (kindly supplied by *A. B. Pharmacia*) as described elsewhere [12].

Determination of trehalase activity was performed at 0.1388 M substrate concentration at 37°C in the presence of 0.05 M maleate buffer pH 6.0. 1 ml of enzyme solution (containing 0.5−3 units of trehalase) was mixed with 1 ml of substrate solution (10.5 % * αα-trehalose (dihydrate) in 0.1 M maleate buffer pH 6.0 with a few ml of toluene per litre as a preservative). After 60 min. at 37°C the reaction was interrupted by the addition of 2 ml of Sumner's 3,5-dinitrosalicylic acid reagent [13]. A blank was prepared with the same composition, but the 3,5-dinitrosalicylic acid reagent was added *before* the substrate solution. The tubes were boiled in a water-bath for 10 min, chilled with tap water, and diluted with 20 ml of distilled water. The red colour was measured in a Beckman B spectrophotometer at 530 mμ. The colour was stable for at least 20 h. The amount of glucose produced was calculated from a standard curve with known amounts of glucose. One unit of trehalase is the amount which produces 1 mg of glucose (= 1 % hydrolysis in 2 ml of reaction mixture) during the conditions used.

Determination of K_s for trehalase activity was made by measuring the rate of hydrolysis in 0.0500−0.0007 M trehalose solutions. The degree of hydrolysis was never allowed to exceed 10 %. The amount of glucose produced in these dilute substrate solutions was determined with the method of Somogyi and Nelson [14,15] after deproteinization with Somogyi's Zn-Ba reagents [16]. Calculation of K_s was performed as described earlier [17].

The hydrolysis of sucrose, maltose, isomaltose, and phenyl-α-D-glucopyranoside was measured at 0.1388 M substrate concentration at 37°C in the presence of 0.05 M maleate buffer pH 6.0. The amount of glucose produced from these substrates was determined with the methods described elsewhere [12,18].

The hydrolysis of αβ-trehalose and ββ-trehalose was measured at 0.0139 M substrate concentration at 37°C in the presence of 0.05 M maleate buffer pH 6.0. The amount of glucose produced was determined with the reagents of Somogyi and Nelson [14,15] after deproteinization with the Zn-Ba-reagents [16].

* Per cent means gram of solute in 100 ml of solution.

Determination of protein was made with the method of Lowry et al. [19] by use of human serum albumin (kindly supplied by *A. B. Kabi*) as a standard.

Determination of inorganic phosphate was made with the method of King [20]. The blue colour produced was measured with a Beckman B spectrophotometer at 700 mμ.

Paper chromatography of sugars was performed as described earlier [21].

^{14}C-Labelled glucose was obtained from the *Radiochemical Centre* (England). The distribution of the radioactivity on paper chromatograms was measured as described earlier [21].

Crystalline trypsin (Trypure Novo) was kindly supplied by *A. B. Ferrosan.*

RESULTS AND DISCUSSION

As the source of trehalase hog intestinal mucosa was used. While the mucosa of the duodenum and the proximal jejunum had a strong trehalase activity (trehalase/invertase activity quotient 0.50—0.75), the trehalase activity of the distal part of the small intestine was weak (trehalase/invertase activity quotient about 0.10). For the preparation of trehalase the proximal 100 cm of the small intestine was therefore used.

Solubilization and purification of trehalase. The mucosa and the intestinal contents of the proximal part of the small intestine were squeezed out manually within a few minutes after the slaughter. From 10 pigs (about 10 metres of small intestine) 200 ml of viscous liquid was thus obtained, which yielded 55 mg/ml of protein, 96 units/ml of trehalase, 140 units/ml of invertase, and 210 units/ml of maltase. For solubilization of the glycosidases 30 mg of crystalline trypsin, freshly dissolved in 20 ml of water, was added during stirring [5]. After 4 h at room temperature the solution was centrifuged at 600 *g* for 10 min and the supernatant was filtered through a bed of Solkafloc cellulose powder SW 40 A. The filtrate was dialyzed against 0.01 M phosphate buffer pH 6.0.

The solution was then applied to a 6 × 20 cm column, containing 80 g (dry weight) of DEAE-cellulose [5], equilibrated with 0.01 M phosphate buffer pH 6.0. The column operations were performed at +4°C. The column was first eluted with 4 l of 0.01 M phosphate buffer pH 6.0, which eluted 40 % of the protein applied to the column, but only 8 % of the trehalase activity. This fraction was discarded. The main part (80 %) of the trehalase activity, together with 5 % of the protein, was eluted with 4 l of 0.05 M phosphate buffer pH 6.0. This buffer did not elute the invertase and maltase activities from the column.

For concentration of the enzyme, this fraction was diluted with 4 vol. of distilled water, and filtered through a column containing 10 g (dry weight) of DEAE-cellulose, equilibrated with 0.01 M phosphate buffer pH 6.0. All the trehalase activity was adsorbed to the column. The enzyme was eluted with 200 ml of 0.20 M phosphate buffer pH 6.0, dialyzed against distilled water and lyophilized. Since the powder obtained was found to contain considerable amounts of inorganic phosphate, it was dissolved in 25 ml of distilled water and again dialyzed against distilled water. On lyophilization of the dialyzed solution 160 mg of a white powder, with a trehalase, activity of 34 units/mg, was obtained. This corresponds to 25 % of the trehalase activity of the original solution. The powder had the same absorption coefficient according to Lowry's method for protein determination as pure human serum

Table 1. Hydrolysis of *aa*-trehalose by hog intestinal trehalase. Course of the reaction. The reaction mixture contained 0.1388 M *aa*-trehalose, 0.05 M maleate buffer pH 6.0, 1 mg/ml of purified trehalase containing 1 mg of protein and 34 units of trehalase per mg. The temperature was 37°C. — Up to between 15 and 20 % hydrolysis the reaction followed zero order kinetics.

t Time, h	x per cent of hydrolysis	k_{zero} x/t
0.083	5.3	63.7
0.166	10.6	63.7
0.250	15.9	63.7
0.333	20.5	61.4
0.500	30.5	61.0
0.667	39.3	58.9
0.833	48.3	58.0
1.000	52.9	52.9
2.000	80.3	40.1
3.000	91.7	30.6
4.000	97.3	24.4

albumin. The specific trehalase activity of the powder (trehalase activity/mg of protein) was 20 times that of the original solution.

Stability of hog intestinal trehalase activity. In crude hog intestinal glycosidase preparations the trehalase activity, in contrast to the invertase and maltase activities, was not stable when stored at low temperature. After storage at —16°C for a month, the trehalase activity of a crude preparation had decreased by 25 %. At higher temperatures the decrease was more rapid. After storage at —16°C for 6 months, no more than about 15 % of the trehalase activity remained, while the invertase and maltase activities were unaffected.

The trehalase activity of the purified, lyophilized powder, however, was very stable. After storage at —16°C for 6 months, *no* decrease of the trehalase activity of this preparation could be detected.

Kinetics of hog intestinal trehalase. Hog intestinal trehalase had its optimum pH around 6.0 (Fig. 1). The hydrolysis of *aa*-trehalose by hog intestinal trehalase proceeded to completion with glucose as the only product. Up to 20 % hydrolysis the reaction followed zero order kinetics (Table 1). Within wide limits the initial velocity of the reaction was proportional to the amount of enzyme present (Fig. 2).

The K_s value was determined at 3.0×10^{-3} M *aa*-trehalose (at 37°C in the presence of 0.05 M maleate buffer pH 6.0). The V_{max} was 1.02 times the initial velocity at 0.1388 M substrate concentration.

Influence of inorganic phosphate on hog intestinal trehalase activity. The trehalase activity by extracts from some *insects* is stimulated by the presence of inorganic phosphate, which has led to the conclusion that a phosphorolysis may be involved in the trehalase action by these preparations [23]. Later researchers, however, found that the hydrolysis of trehalose by insect trehalase proceeds to completion with glucose as the sole product. Since their preparations had no activity on glucose-1-phosphate, the cleavage of trehalose by their preparations must be a purely hydrolytic reaction [8].

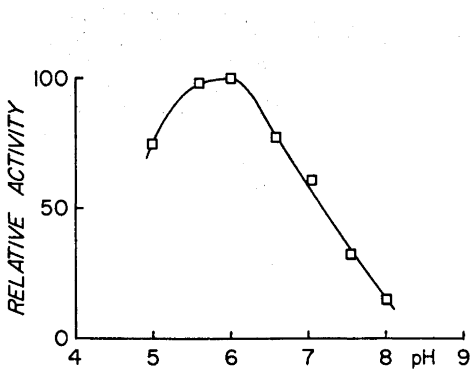

Fig. 1. Influence of pH on the hydrolysis of *aa*-trehalose by hog intestinal trehalase. Buffers: 0.05 M acetate pH 5.0, 0.05 M maleate pH 5.5—6.5, 0.025 M veronal pH 7.0—8.0. Temperature 37°C. Substrate concentration 0.1388 M.

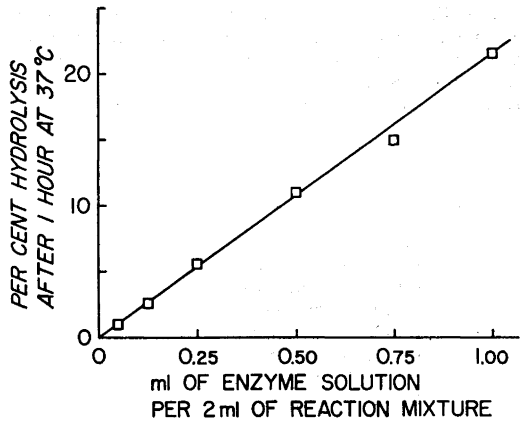

Fig. 2. Proportionality between the degree of hydrolysis after 1 h and the amount of enzyme added. Experimental conditions: 0.1388 M *aa*-trehalose solution in the presence of 0.05 M maleate buffer pH 6.0. The enzyme solution was a purified preparation of hog intestinal trehalase, containing 0.65 mg of protein and 22 units of trehalase per ml. Up to 20 % hydrolysis, the degree of hydrolysis after 1 h was proportional to the amount of enzyme added.

The influence of inorganic phosphate on the hog intestinal trehalase activity was studied with the results seen in Table 2. The reaction mixture contained 25 μg/ml of the lyophilized trehalase preparation, 0.1388 M *aa*-trehalose, and varying amounts of phosphate or maleate buffer pH 6.0. Without addition of phosphate buffer, the reaction mixture was found to contain less than 0.2 μg/ml of inorganic phosphorous. The trehalase activity was *not* stimulated by the addition of phosphate buffer. The presence of concentrated phosphate buffer rather decreased the rate of hydrolysis to some extent.

Transglycosylation properties of hog intestinal trehalase. Most glycosidases are known to have transglycosylase activity, *i.e.* they are able to transfer the glycosyl residue of their substrate to some receptor other than water [24]. In a concentrated substrate solution the substrate may itself act as receptor, which results in the formation of oligosaccharides. Also other compounds, containing a free alcohol group, may act as receptors. If the substrate is a disaccharide, the transfer of the glycosylic residue to a free hexose may lead to the regeneration of the substrate or the production of other disaccharides [21,24].

A reaction mixture, containing 30 % (= g/100 ml) of *aa*-trehalose (dihydrate) and 41 units/ml of hog intestinal trehalase in 0.05 M maleate buffer pH 6.0 with toluene as preservative, was incubated at 37°C for 23 h. When 5 μl spots of the reaction mixture were chromatographed, only glucose and trehalose were found (Fig. 3). Thus no oligosaccharide formation could be

Table 2. Influence of inorganic phosphate on the activity of hog intestinal trehalase. Experimental conditions: 0.1388 M substrate concentration, pH 6.0, temperature 37°C, and time of reaction 60 min. The reaction mixture contained 25 μg/ml of purified hog intestinal trehalase. The degree of hydrolysis was determined with the 3,5-dinitrosalicylic acid reagent. — The presence of phosphate did *not* stimulate the trehalase activity.

Buffer	Degree of hydrolysis, %
No buffer	1.79
0.010 M maleate	1.80
0.025 M maleate	1.85
0.050 M maleate	1.83
0.005 M phosphate	1.86
0.025 M phosphate	1.85
0.050 M phosphate	1.74
0.100 M phosphate	1.59

demonstrated. During the corresponding conditions, hog intestinal invertase and hog intestinal maltases produce a series of oligosaccharides in addition to their hydrolysis products [12,21].

In another experiment 1 mg/ml of ^{14}C-labelled glucose was added to a reaction mixture with the same composition as above. After 5 and 23 h at 37°C 5 μl samples of the reaction mixture were applied to a paper chromatogram. After run for 2 days, the distribution of the radioactivity on the chromatogram was measured as described earlier [21]. Each 5 μl spot contained 6 250 c.p.m. of ^{14}C-labelled sugar as measured with the counter. All the radioactivity was localized in the *glucose* spot. Glucose is therefore *not* incorporated into trehalose or other oligosaccharides by intestinal trehalase. During the corresponding conditions the intestinal maltases form ^{14}C-labelled maltose and other oligosaccharides [12], and intestinal invertase, too, forms a ^{14}C-labelled disaccharide [21].

That hog intestinal trehalase has no transglycosylase activity was also indicated by the fact that the rate of glucose formation (as measured with the 3,5-dinitrosalicylic acid reagent) did not decrease when the substrate concentration was increased to 0.794 M (30 % *aa*-trehalose dihydrate). The

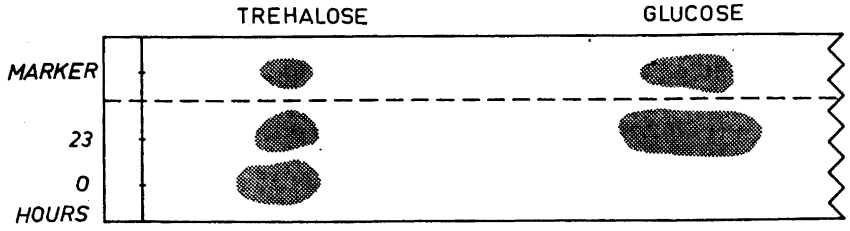

Fig. 3. Hydrolysis of a 30 % solution of *aa*-trehalose (dihydrate) by hog intestinal trehalase. Experimental conditions, see text. The chromatogram was developed for 2 days. In contrast to the other intestinal glycosidases, trehalase did *not* form any oligosaccharides by transglycosylation.

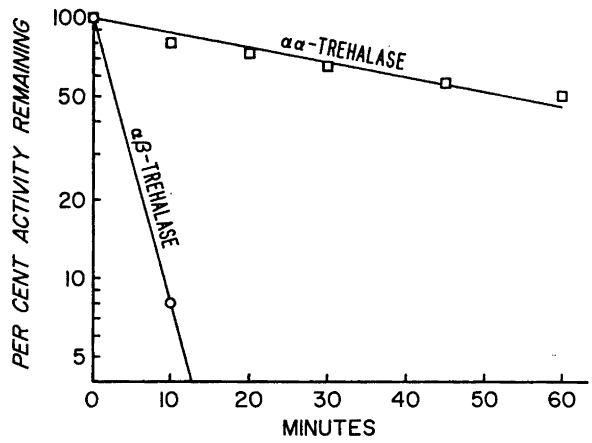

Fig. 4. Separation of $\alpha\beta$-trehalase and $\alpha\alpha$-trehalase activity by heat inactivation. A solution of purified hog intestinal trehalase, containing 5 mg/ml of protein in 0.01 M phosphate buffer pH 6.0, with 165 units/ml of $\alpha\alpha$-trehalase and 1 unit/ml of $\alpha\beta$-trehalase, was heated at 65°C. While the $\alpha\beta$-trehalase activity was rapidly inactivated, the $\alpha\alpha$-trehalase activity only decreased slowly.

hog intestinal invertase and maltase activities decrease in concentrated substrate solutions, probably owing to their transglycosylase activity [12,17,21].

In some cases, the equilibrium for reactions catalyzed by glycosidases has been found to be such that the synthesis of the substrates from the hydrolysis products could be demonstrated [22]. A solution containing 30 % glucose and 41 units/ml of trehalase in 0.05 M maleate buffer pH 6.0 and with toluene as a preservative was incubated at 37°C. After 23h only glucose was found on a paper chromatogram. The equilibrium for the reaction catalyzed, therefore, must be far to the side of hydrolysis.

Specificity of hog intestinal trehalase. The trehalase preparation had no hydrolytic activity on *sucrose*, *maltose*, *isomaltose*, *phenyl* α-D-*glucopyranoside*, or *ββ-trehalose*. The experimental conditions were such that a hydrolysis with a rate only 1/100 of that for the hydrolysis of $\alpha\alpha$-trehalose would have been detected with sucrose, maltose and *iso*maltose as substrates, and only 1/1 000 with phenyl α-D-glucopyranoside and $\beta\beta$-trehalose.

The preparation hydrolyzed *αβ-trehalose* with a rate which was 0.006 times the rate for the hydrolysis of $\alpha\alpha$-trehalose. The hydrolysis of $\alpha\beta$-trehalose proceeded *to completion*. The K_s for the hydrolysis of $\alpha\beta$-trehalose was determined at 9.1×10^{-3} and the V_{max} at 1.65 times the rate of hydrolysis at 0.0139 M substrate concentration. — Heat inactivation at 65°C (performed as described earlier [6]), however, revealed that $\alpha\alpha$-trehalose and $\alpha\beta$-trehalose were hydrolyzed by different enzymes (Fig. 4). The hydrolytic activity on $\alpha\beta$-trehalose was completely destroyed after 20 min while 73 % of the original $\alpha\alpha$-trehalase activity persisted after that time. Hog intestinal trehalase, therefore, has *no* activity on $\alpha\beta$-trehalose. The specificity of the contaminating enzyme, which hydrolyzed $\alpha\beta$-trehalose, is not known.

Mode of action upon the substrate. Glycosidases generally act upon their substrates asymmetrically, *i.e.* they are more firmly bound to the *glycon* component (the glycosyl residue) of their substrates than to the *aglycon*. This appears from their greater specificity for the glycon [4,17,22] and by the phenomenon of transglycosylation [24]. This fact is particularly apparent in the case of invertases. In sucrose either the glucosylic or the fructosylic part may be regarded as glycon and aglycon, respectively. Consequently, there are two kinds of invertases, namely, glucosido- and fructosidoinvertases, with activity on different α-D-glucopyranosides or β-D-fructofuranosides, and with transglucosylase or transfructosylase activity, respectively [4,17,21,24].

Hog intestinal trehalase, on the other hand, has no transglycosylase activity. Nor does it seem to be able to hydrolyze any other α-D-glucopyranoside than αα-trehalose. These facts make it probable that hog intestinal trehalase has a more symmetrical way of attacking its substrate than have the other glycosidases. This property is possibly common to many different trehalases, since trehalases from many different sources seem to have a marked specificity for their substrate [3,8,22].

Acknowledgment. The author's thanks are due to Professor Bengt Borgström for his interest in my work and for valuable discussions.

This work has been supported by grants from the *Medical Faculty of the University of Lund.*

The skilful technical assistance of Mrs. K. Hagebris is gratefully acknowledged.

Preparation of Ursodeoxycholic Acid and 3α,7β,12α-Trihydroxycholanic Acid

Bile Acids and Steroids 94

BENGT SAMUELSSON

Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

The compounds have been prepared through reduction of the corresponding 7-ketoacids with sodium in *n*-propanol. Reversed phase partition chromatography of the reduction products revealed that the epimeric 7β- and 7α-hydroxycompounds are formed in the proportion of about 3:1.

Ursodeoxycholic acid (3 α,7β-dihydroxycholanic acid) is found in the bile of certain bear species [1] and in the coypu [1]. Traces of this acid has recently also been reported to occur in the rat [2] and man [3]. Urxodeoxycholic acid has previously been prepared synthetically through reduction of 7-ketolithocholic acid (3α-hydroxy-7-ketocholanic acid) with sodium ethoxide and through catalytic hydrogenation in acidic medium. The yield of the 7β-epimer was only about 10 % [4]. Sodium borohydride reduction of 7-ketocholanic acids and derivatives produces specifically the corresponding 7α-hydroxycompounds [5-8]. The 7-ketone in the bile acid series has been reported to be almost resistent to reduction with aluminium *iso*propoxide [8,9]. In one case, however, a successful reduction, which gave predominately the axial epimer (7α), has been described [10]. These authors also reported the preparation of ursodeoxycholic acid in 95 % yield by reduction of 7-ketolithocholic acid with sodium in *n*-propanol. When this method was used in the present investigation and the reaction product separated by reversed phase partition chromatography, it appeared that the reduction gives a mixture consisting of the equatorial 7β- and axial 7α-hydroxyepimers in the approximate proportion of 3:1.

3α,7β,12α-trihydroxycholanic acid has never been synthesized or isolated before. Recently, however, an acid with identical chromatographic properties and sulfuric acid spectrum has been isolated as a metabolite of cholic acid-24-^{14}C in the rat [11] and has been detected in samples of human bile [3].

3α,7β,12α-trihydroxycholanic acid was obtained by reduction of 7-ketodeoxycholic acid (3α,12α-dihydroxy-7-ketocholanic acid) by the same method

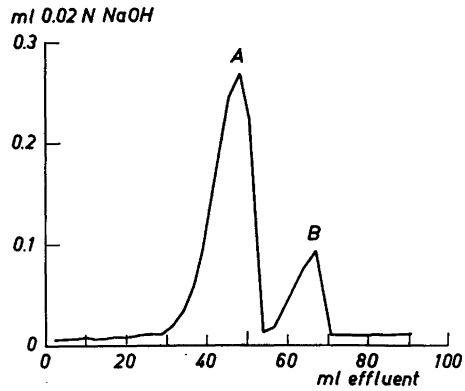

Fig. 1. Chromatography of an aliquot of the reaction product obtained by reduction of 7-ketolithocholic acid with sodium in *n*-propanol. Column: 4.5 g of hydrophobic SuperCel. Moving phase: 55 % (v/v) aqueous methanol. Stationary phase: 10 % (v/v)-heptane in chloroform. A: Ursodeoxycholic acid. B: Chenodeoxycholic acid.

as above. The two epimers, separated chromatographically, were found in the same proportion as in the reduction of 7-ketolithocholic acid. The methyl ester of 3α,7β,12α-trihydroxycholanic acid yielded a tri-*p*-nitrobenzoate on acylation with *p*-nitrobenzoyl chloride in pyridine. Under similar conditions methyl cholate only gives the 3α-mono-*p*-nitrobenzoate [12].

EXPERIMENTAL

Ursodeoxycholic acid. 7-Ketolithocholic acid (m. p. 200—202°) was prepared through sodium dichromate oxidation of methyl 3α-cathyloxy-7α-hydroxycholanate followed by hydrolysis [13,14]. A solution of 0.5 g of the ketoacid in 10 ml of anhydrous *n*-propanol was refluxed with 1 g of sodium for 3 h. The solution was diluted with water, acidified with hydrochloric acid and extracted with ethylacetate. After evaporation to dryness *in vacuo* the residue was chromatographed on hydrophobic Super Cel with 55 % (v/v) methanol as moving phase and 10 % (v/v) heptane in chloroform as stationary phase [15] (Fig. 1).

No unchanged ketoacid could be detected and of the two peaks which appeared, the first one (77 %) was crystallized from ethylacetate/light petroleum. Yield: 0.32 g, m. p. 201—202°. There was no depression of the m. p. on admixture with authentic ursodeoxycholic acid that was kindly supplied by Prof. G. A. D. Haslewood. $[\alpha]_D^{25} = +57 \pm 2°$ (*c* 1.02, dioxane). (Found: C 73.1; H 10.3. Calc. for $C_{24}H_{40}O_4$: C 73.4; H 10.3).

The material in the second peak (23 %) with an elution volume characteristic of chenodeoxycholic acid was crystallized from ethylacetate/light petroleum. M. p. 141—142°, undepressed by authentic chenodeoxycholic acid.

3α, 7β, 12α-trihydroxycholanic acid. Methylcholate was oxidized with N-bromosuccinimide [16] to methyl-7-ketodeoxycholate, purified *via* the diacetate [17] (m. p. 118—118.5°) and saponified. 7-Ketodeoxycholic acid was crystallized according to the directions given by Hoehn and Linsk [18]; m. p. 198—199°. The ketoacid was reduced as described above and the reaction product was separated by reversed phase partition chromatography on hydrophobic Super Cel. Aqueous methanol (50 % (v/v)) was used as the moving phase and *iso*octanol-chloroform (1:1) as stationary phase [19]. (Fig. 2.) The more hydrophilic compound (72 %), 3α,7β,12α-trihydroxycholanic acid (0.2 g), was dissolved in 3 ml methanol, neutralized with 0.1 N NaOH and added slowly to 100 ml of cold

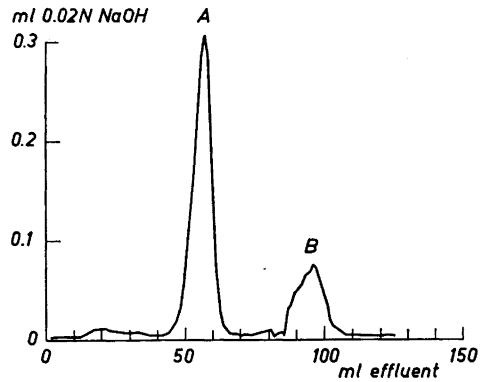

Fig. 2. Chromatography of an aliquot of the reaction product obtained by reduction of 7-ketodeoxycholic acid with sodium in *n*-propanol. Column: 4.5 g of hydrophobic Super Cel. Moving phase: 50 % (v/v) aqueous methanol. Stationary phase: *iso*octanol / chloroform (1:1). A: 3α,7β,12α-trihydroxycholanic acid. B: Cholic acid.

0.05 N HCl, with vigorous stirring. The precipitated acid crystallized after standing 12 h at +4°. 0.155 g (56 % yield calculated on 7-ketodeoxycholic acid) was obtained after filtration, washing with water and drying; m. p. 127—129°. The m. p. was not changed after repeated recrystallizations by this method. $[\alpha]_D^{25} = +62 \pm 2°$ (*c* 1.13, dioxane). (Found C 70.3; H 10.0. Calc. for $C_{24}H_{40}O_5$: C 70.5; H 9.9.)

A sample of this acid was crystallized from ethylacetate/heptane and dried at 130° at 0.001 mm Hg for 24 h; m. p. 157—158° (decomp.). $[\alpha]_D^{25} = +57 \pm 2°$ (*c* 1.06, dioxane). The elemental analysis indicated that the acid had formed a complex with heptane. (Found C 72.7; H 10.4. Calc. for $C_{24}H_{40}O_5 + C_7H_{16}$: C 73.2; H 11.1). Several other organic solvents were tried for recrystallization without success.

Methyl 3α,7β,12α-trihydroxycholanate-tri-p-nitrobenzoate. The method of Borsche [12] was followed. A solution of 75 mg of methyl 3α,7β,12α-trihydroxycholanate, prepared with diazomethane, was dissolved in 2 ml of dry pyridine and cooled to 0°. 180 mg of *p*-nitrobenzoylchloride in 2 ml of pyridine was added. After standing at room temperature for 12 h the reaction mixture was transferred to a mixture of ether, ethylacetate, ice and 2 N HCl. The ether layer was washed successively with 2 N HCl, 5 % aqueous sodium carbonate and water. After evaporation to dryness *in vacuo* the residue was crystallized from ethylacetate/ethanol to yield 121 mg of fine needles, m. p. 188—189°. The concentrated mother liquor gave an additional 24 mg of crystals with the same m. p. Total yield: 94 % $[\alpha]_D^{25} = +140 \pm 3°$ (*c* 1.19, dioxane). (Found C 63.5; H 6.0; N 4.8. Calc. for $C_{46}H_{51}O_{14}N_3$: C 63.5; H 5.9; N 4.8).

The second compound (B in Fig. 2) comprising about 28 % of the two epimers, was eluted at the place of cholic acid. It was crystallized from ethylacetate, m. p. 197—198°, undepressed by authentic cholic acid.

Metabolism of 3α,7β,12α-Trihydroxycholanic Acid in the Rat

Bile Acids and Steroids 95

BENGT SAMUELSSON

Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

Tritium labelled 3α, 7β, 12α-trihydroxycholanic acid has been prepared. The metabolism of this acid after intraperitoneal or intracecal injection into bile fistula rats has been studied. It is not attacked by the liver enzymes but is extensively transformed by the intestinal microorganisms. Deoxycholic- and 12-ketolithocholic acids were identified in the feces and cecum and cholic, deoxycholic and 12-ketolithocholic acids in the bile.

In a recent investigation on the transformation of cholic acid-24-^{14}C in the rat during the enterohepatic circulation a metabolite was isolated with properties identical with 3α, 7β, 12α-trihydroxycholanic acid. Material with the same chromatographic behaviour and sulfuric acid spectrum was also isolated from human bile samples [2]. 3α, 7β, 12α-Trihydroxycholanic acid is probably only formed by reduction of a bacterial metabolite of cholic acid, 7-ketodeoxycholic acid (3α, 12α-dihydroxy-7-ketocholanic acid) in the liver [3].

The metabolism of randomly tritium labelled 3α, 7β, 12α-trihydroxycholanic acid in the rat liver and intestine and the liver metabolism of the intestinal metabolites has been studied in the present investigation.

EXPERIMENTAL

Bile acid samples

Tritium labelled 3α, 7β, 12α-trihydroxycholanic acid. The inactive acid [4] (5 mg) was exposed to tritium gas [5] (2 Curie, 99 % pure, 200 mm Hg. Purchased from Isotope Division, A. E. R. E. Harwell, England) at room temperature for 4 days. The tritium labelled product was purified by chromatography with solvent system C3 after dilution with 30 mg of inactive 3α, 7β, 12α-trihydroxycholanic acid. It was crystallized by acidification of an aqueous solution of the sodium salt, yielding 19 mg, m. p. 126—128°. Specific activity: 20 μC/mg. The radioactivity of this sample was further checked by recrystallizations of the free acid with inactive material and after conversion of the methylester to the tri-*p*-nitrobenzoate [4].

7-Ketodeoxycholic acid was prepared according to the method of Hoehn and Linsk [6], m. p. 197–198°.

12-Ketolithocholic acid (3α-hydroxy-12-ketocholanic acid) was prepared according to the method of Bergström and Haslewood [7], m. p. 160–161°.

Animal experiments

Bile duct cannulated rats (Sprague-Dawley strain, 200–250 g, male) were prepared as described earlier [8]. The sodium salt of the labelled bile acid in 0.9 % aqueous NaCl was injected intraperitoneally 12 h after the bile duct cannulation. The bile was collected in ethanol. The excreted radioactive products represent the pure liver metabolites of the administered acid. In another series of experiments the labelled bile acid was administered by intracecal injection during the operation [1]. The rats were killed after 36 h. Labelled material present in feces and the large intestine of these animals represents transformation products of the injected acid by the intestinal microorganisms. The radioactive compounds excreted in the bile during this period consist of the intestinal metabolites, absorbed from the large intestine as well as the products formed by the action of liver enzymes on these metabolites.

Isolation procedures and chromatographic methods

The bile was filtered, evaporated and hydrolyzed with 2 N NaOH for 8 h at 120° in a closed steel tube. The solution was acidified with hydrochloric acid and extracted with ether.

Feces and intestinal contents were refluxed twice with 80 % aqueous ethanol. After evaporation the residue was hydrolyzed, acidified and extracted with ether. The residue from the ether extracts was distributed between equal volumes of 70 % ethanol and light petroleum by a 3-stage counter-current extraction. The residue from the combined aqueous phases was chromatographed.

Separation of the free bile acids was made by reversed phase partition chromatography as described by Bergström and Sjövall [9] and Norman and Sjövall [1].

Solvent system	Moving phase	(ml)	Stationary phase	(ml)
F (Ref.[9])	Mathanol-water	165: 135	Chloroform-heptane	45 : 5
C3 (Ref.[1])	Methanol-water	140 : 160	Chloroform-isooctanol	15 : 15

4 ml of the stationary phase was supported on 4.5 g of hydrophobic Super Cel. Temperature 23°.

The radioactivity of the fractions collected from the column was determined by counting of an aliquot in an infinitely thin layer on aluminium planchets. A gas flow counter Frieseke Hoepfner FH 51, was used.

RESULTS

Intraperitoneal injection of tritium labelled 3α, 7β, 12α-trihydroxycholanic acid to bile duct cannulated rats. Bile fistulas were made on two rats and tritium labelled 3α, 7β, 12α-trihydroxycholanic acid (0.2 mg) injected intraperitoneally 12 h after the operation. Of the administered ^3H 78–92 % was excreted in the bile within the first 24 h. The hydrolyzed bile was chromatographed with solvent system C3. The only radioactive material, eluted, consisted of unchanged 3α, 7β, 12α-trihydroxycholanic acid as judged by rechromatography together with the inactive acid and by isotope-dilution. The stationary phase retained less than 1 % of the chromatographed ^3H.

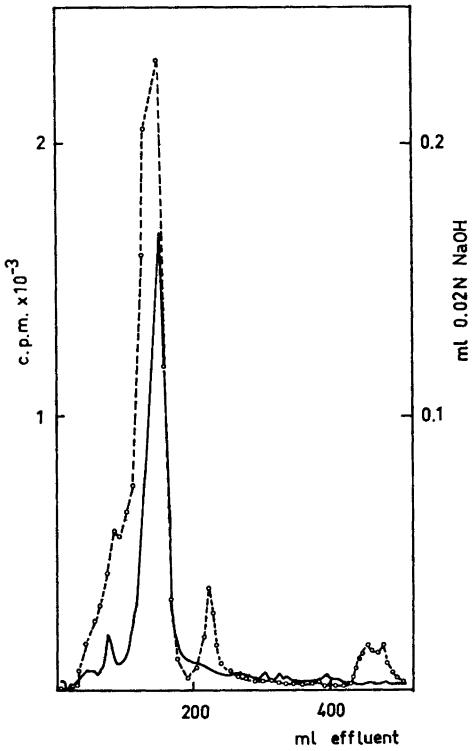

Fig. 5. Chromatographic separation of acids remaining in the stationary phase of the chromatogram shown in Fig. 4. Inactive deoxycholic acid (19 mg) was added. Column: 9 g of hydrophobic Super Cel. Solvent system: F. ——— Titration values; - - - - - - - Radioactivity.

intestine and feces was first chromatographed together with inactive deoxycholic acid with solvent system F. A chromatogram from one of the rats is shown in Fig. 1. (1.5 % of the chromatographed radioactivity remained in the stationary phase). The main peak of radioactivity (B) coincides with the titration peak caused by added inactive deoxycholic acid. The identity was established by recrystallizations with unlabelled deoxycholic acid in different solvents (Table 1). The third radioactive peak (C) was rerun together with unlabelled 12-ketolithocholic acid (Fig. 2). The identity was prooved by isotope dilution (Table 1). The radioactivity being eluted almost with the front (A in Fig. 1) was rechromatographed with the more polar solvent system C3 together with unlabelled 7-ketodeoxycholic acid (Fig. 3). The main part of the radioactivity appeared at the position of 3α, 7β, 12α-trihydroxycholanic

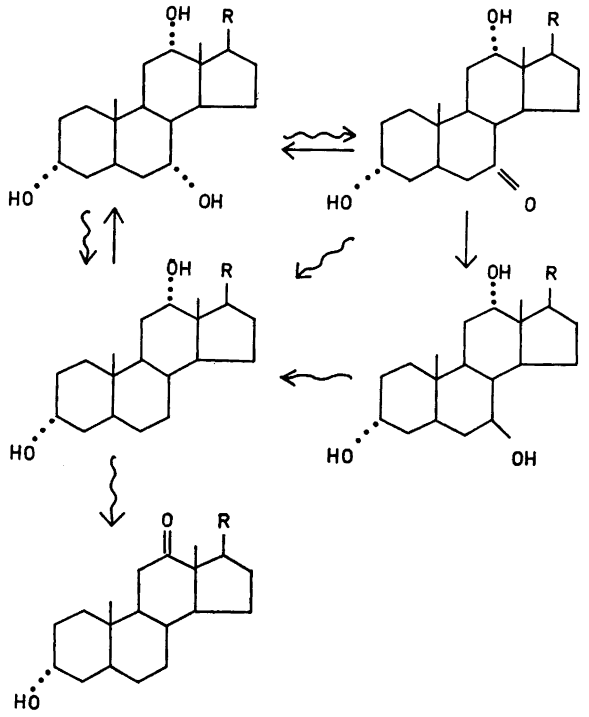

Fig. 6. ——→ Reaction caused by liver enzymes. ~~→ Reaction caused by intestinal microorganisms.

acid as shown by rechromatography with the unlabelled compound. No significant amount of tritium was eluted at the position of 7-ketodeoxycholic acid (160—280 ml effluent) or cholic acid (300—450 ml effluent).

Metabolites excreted in the bile. The hydrolyzed bile (containing 53 % (RI), 44 % (RII) and 38 % (RIII) of the injected ^3H) was chromatographed with solvent system C3 (Fig. 4). The main part of the radioactivity coincides with the titration peak (350—750 ml effluent) of the inactive cholic acid present in the bile. The identity was established by isotope dilution (Table 1). Traces of radioactivity appear at the position of 3α, 7β, 12α-trihydroxycholanic acid. The material remaining in the stationary phase was chromatographed with solvent system F together with unlabelled deoxycholic acid (Fig. 5). The main peak of radioactivity is eluted at the same position as the added inactive deoxycholic acid. At the beginning of this peak, however, contaminating labelled material of unknown nature is eluted. This could be removed by rechromatography with the same solvent system. The identity of labelled deoxycholic acid was established by isotope dilution. The following radioactive band (200—240 ml effluent) was identified as 12-ketolithocholic acid. The structure of the least hydrophilic compound (440—500 ml effluent) has not been determined.

DISCUSSION

When tritium labelled 3α, 7β, 12α-trihydroxycholanic acid was administered intraperitoneally to bile fistula rats it was excreted unchanged in the bile. In the large intestine, however, when administered by intracecal injection it was extensively transformed. The identified metabolites consisted of deoxycholic acid and 12-ketolithocholic acid. The labelled products excreted in the bile in these experiments, were identified as cholic, deoxycholic and 12-ketolithocholic acids. The labelled cholic acid found in the bile is most probably only formed by 7α-hydroxylation of deoxycholic acid absorbed from the intestine.

The numerous possibilities of converting cholic, deoxycholic, 7-ketodeoxycholic and 3α, 7β, 12α-trihydroxycholanic acids into each other are summarized in Fig. 6. Thus, different oxygen functions at C7 (ketone, α- and β-hydroxyl groups) in bile acids with the parent structure of deoxycholic acid are eliminated by microorganisms in the rat. Results available at present are not sufficient to establish whether cholic acid is the common denominator in the microbiological formation of deoxycholic acid by the following reactions:

$$7\alpha\text{-ol} \rightleftharpoons \text{7-ketone} \rightleftharpoons 7\beta\text{-ol}$$

or if the different functions are eliminated *per se*.

From experiments [10] with cholic acid-7-^{3}H-24-^{14}C, it is known that deoxycholic acid is synthesized *in vivo* with a negligibly intermediate formation of 7-ketodeoxycholic acid and that the dehydrogenation of cholic acid to 7-ketodeoxycholic acid is reversible in suspensions of *E. coli* [11].

On Vitamins in Sewage Sludge

XI. Further Studies on the Production of Vitamin B_{12} by Some Enrichment Cultures of Methane Bacteria

HALINA Y. NEUJAHR

Royal Institute of Technology, Division of Food Chemistry, Stockholm 70, Sweden

Fermentations with a methanol-fermenting and vitamin B_{12}-producing enrichment culture of methane bacteria were performed in order to find the most favourable conditions for obtaining high yields of vitamin B_{12}.

Stirring was not favourable for high yields of *E. coli* activity but, on the other hand, it resulted in the formation of only one vitamin B_{12} factor which seems to be the clinically active factor III of Bernhauer [5] or/and factor W[4], which has in earlier investigations been found to be active for *Ochromonas malhamensis*.

The conversion of the different vitamin B_{12} factors formed in non-stirred cultures to cyanocobalamin could not be achieved by adding greater than previously used amounts of 5,6-dimethyl benziminazole at the start or smaller amounts at a later stage of the fermentation. Concentrations of 10 μg benziminazole per ml medium inhibited the growth of the culture.

Under certain conditions, the addition of glucose was found to stimulate both the evolution of gas and the production of vitamin B_{12} activity. As far as could be observed, the carbohydrate had no effect upon the kind of vitamin B_{12} factors formed in synthetic media.

The addition of certain nitrogenous materials, *e. g.* corn steep liquor or casein hydrolyzates together with glucose, or casein hydrolyzates together with glucose and yeast extract, resulted in a greatly diminished synthesis of vitamin B_{12}. The possible reasons for this phenomenon are discussed.

The addition of sterilized sewage to the medium was found to have a favourable effect on vitamin B_{12} synthesis and can successfully replace the Bactopeptone (Difco) used in earlier experiments.

The greatest utilization of methanol was found to take place in media containing sterilized sewage.

It seems that vitamin B_{12} begins to accumulate in the cells when their metabolic activity (juged by gas evolution and methanol utilization) tends to decrease. However, no correlation between the utilization of methanol and the production of gas and vitamin B_{12} activity could finally be concluded, so far.

It has been reported earlier from this laboratory that enrichment cultures of methane bacteria produce varying amounts of vitamin B_{12} activity [1-3]. The enrichment culture producing the highest activity was the one obtained in a methanol-containing medium [3]. The present investigation is concerned with a further study of the conditions under which such a culture should be grown in order to obtain high yields of the vitamin. Fermentations were carried out in two liter vessels. The intensity of gas evolution was used as an indicator for the intensity of growth since other changes in the culture, *e.g.* turbidity, dry solids content, *etc.* were difficult to follow for reasons discussed elsewhere [1]. In one series of experiments, the influence of stirring was studied both with the enrichment culture obtained in the medium containing ethanol and consisting mainly of *Mb. omelianskii* [1], and with the enrichment culture obtained in the methanol-containing medium [3]. In the rest of the experiments, certain modifications of the earlier adopted medium [3] were studied using only the culture obtained in the methanol-containing medium. The following points were studied: 1. addition of greater than earlier used amounts of 5,6-dimethyl benziminazole (DMB) and variation of the time of this addition; 2. addition of organic nutrients, notably casein hydrolyzates, corn steep liquor, sterilized sewage, whey and glucose; 3. adjustment of the pH every day to the optimum value; 4. adjustment of the methanol concentration in the medium several times during the fermentation period.

Using certain modifications of the medium, it has been possible to obtain *E. coli* activities higher than 10 μg/ml calculated as cyanocobalamin in cup plate assay. These high activities represented, however, mixtures of several vitamin B_{12} factors. Attempts to get all these factors converted by the cultures to cyanocobalamin have not yet been successful, even if the yield of cyanocobalamin could be improved. The dominating factor(s) in the cultures was (were) probably factor W[4] earlier isolated from digested sludge in this laboratory and (or) factor III of Bernhauer[5]. The former factor was found to be active for *Ochromonas malhamensis* [4], which indicates that it may also be active for higher animals. The clinical activity of factor III has been proved [6]. It thus seems to be of considerable interest that the enrichment cultures of the methanol-fermenting organism can produce such high amounts of this(these)physiologically active factor(s).

EXPERIMENTAL

The fermentations were carried out in 2 l conical flasks provided with stoppered outlets at the bottom through which samples could be removed by means of a syringe. The tops of the flasks were closed with rubber stoppers provided with glass tubes containing sterile cotton wool filters, by means of which the flasks were connected, using rubber tubing, with devices for collecting and measuring the evolved gas. The gas collecting devices consisted of scaled cylindrical vessels of 1 l capacity, provided with two outlets, one at the bottom and one at the top. The top outlet was connected to the fermentation vessel whereas the bottom outlet was connected to a separating funnel, which functioned as a levelling flask. The gas was collected over a saturated aqueous solution of NaCl. The apparatus is shown schematically in Fig. 1. Up to six fermentations could be run simultaneously. The fermentation flasks were filled with media, only a little space being left above. The basal medium used in all experiments with the methanol-fermenting organism was the one previously used [3] and had the following composition:

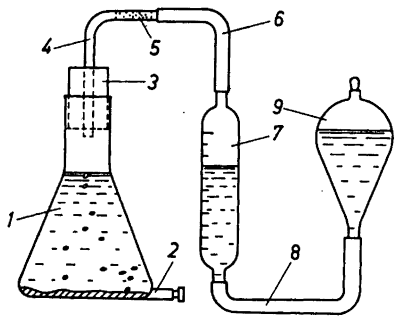

Fig. 1. Apparatus used in fermentations with a methanol-fermenting enrichment culture of methane bacteria. 1 fermentation flask; 2 outlet for taking samples; 3 pierced rubber tap; 4 bent glass tube; 5 cotton wool filter; 6 rubber tubing; 7 calibrated gas collection vessel; 8 rubber tubing; 9 levelling flask.

NH_4Cl	—	1.0 g
K_2HPO_4	—	0.4 g
$MgCl_2 . 6H_2O$	—	0.1 g
$CoCl_2 . 6H_2O$	—	10 mg
CH_3OH	—	10 ml
$CaCO_3$	—	15 g
Asbestos powder	—	5 g
Tap water	—	1 000 ml

Each fermentation flask was filled with 1 600 ml of this medium and, in addition, 160 ml of a separately sterilized solution consisting of 32 ml 1 % $Na_2S . 9H_2O$ solution + 128 ml of 5 % $Na_2CO_3 . 10H_2O$ solution, was added while the medium was still hot after autoclaving. If not otherwise stated, the methanol was autoclaved together with the medium. The pH of the final medium M was adjusted with separately sterilized HCl (1:5) to 6.5—7.5. The flasks were cooled in a nitrogen atmosphere, inoculated with 100 ml of the actively growing enrichment culture and incubated at 37°C for 2—3 weeks. Samples were removed every day and assayed for vitamin B_{12} activity as described elsewhere [7]. The gas evolved and the pH of the medium were also measured daily in all fermentations. The gas evolution is given in the tables and figures as the number of ml evolved from a 2 l vessel in 1 h. The vitamin B_{12} activity is given as the activity for *E. coli* 113-3 calculated as cyanocobalamin in the plate assay. In some experiments, determinations of reducing substances [8] and of methanol according to the *Official Methods of Analysis* [9] were performed. In some experiments, certain fractions of sterilized sewage were used as a substrate after supplementation with the components of medium M.

Further details of the different experiments are given below.

I. *Influence of stirring.* The influence of stirring was studied *a.* with the methanol-fermenting organism, and *b.* with the ethanol-fermenting one. The stirring was achieved by means of a magnete. Media: *a.* (M) supplemented with Bactopeptone, 0.25 %; *b.* Barker's medium (used already in earlier experiments [1]). In some vessels, the fermenting medium was covered with a layer of paraffin oil. The results are given in Tables 1 and 2.

II. *Influence of DMB.* The influence of DMB was studied only with the methanol-fermenting organism.

The purpose of this experiment was to investigate whether concentrations of DMB greater than those previously used or adding the DMB at a later stage of fermentation could lead to greater yields of cyanocobalamin at the expense of the other vitamin B_{12} factors. Medium: M supplemented with 0.25 % Bactopeptone and with *a.* 1 μg or 10 μg DMB/ml medium added at the beginning of the fermentation, or *b.* 1 μg DMB added after 8 days' fermentation. The results are shown in Figs. 2a and 2b.

III. *Influence of carbohydrates.* The influence of carbohydrates was studied only with the methanol-fermenting organism.

a. Glucose (10 g/l) was added to the medium M and its content as well as the pH were readjusted to their initial values four times during the fermentation period. DMB

was present in the medium from the beginning at a level of 1 μg/ml. *b.* Glucose was added to the medium M as in *a*, and its content as well as the pH were readjusted to their initial values every day. Methanol was added aseptically and its content readjusted to 1 % several times during the fermentation period. DMB was added after eight days' fermentation at a level of 1 μg/ml. *c.* Milk whey was mixed with sterilized sewage in the proportion 1:1. Methanol was added aseptically and its content readjusted several times to 1 %. DMB was present in the medium from the beginning.

For comparison parallel fermentations in all three cases, *a*, *b*, and *c*, were performed without the addition of carbohydrate. The results of these experiments are given in Figs. 3a, 3b and in Table 3.

IV. *Influence of organic nitrogen sources and yeast extract.* The influence of these materials was studied only with the methanol-fermenting organism.

In all fermentations of this series, methanol was sterilized separately and its content in the medium adjusted four times during the fermentation period. If not otherwise stated, DMB was added after 8 days' fermentation at a level of 1 μg/ml medium. The different supplements to the medium M were as follows:

a. Bactopeptone (Difco) 0.25 %; DMB.
b. Corn steep liquor added at a level corresponding to 0.4 % total nitrogen or ~0.2 % available nitrogen; DMB added at the beginning of the fermentation.
c. Acid hydrolyzed casein (Casaminoacids Vitaminfree, Difco) added at a level corresponding to 0.11 % total nitrogen; trypsin hydrolyzed casein (Bactogen, Vitrum) added at a level corresponding to 0.16 % total nitrogen; glucose 1 %; DMB added at the beginning of the fermentation.
d. Nitrogen sources and glucose as in *c.*; Yeast Extract (Difco) 0.25 %; DMB.
e. The medium consisted of sterilized sewage supplemented with the components of medium M and with DMB.
f. Medium as in *e*, further supplemented with glucose 1 % and Yeast Extract (Difco) 0.25 %.

The results of this experiment are shown in Figs. 4a, 4b, 4c, 4d, 4e and 4f.

V. *Utilization of methanol.* Fermentations were performed as in the other experiments using the methanol-fermenting organism and six different modifications of the basal medium M. The modifications used are given in Table 4. The amounts of the different materials added to medium M were the same as in corresponding additions applied in

the experimental series III and IV. In all fermentations in this series, DMB was added after 8 days. MeOH was added aseptically to the sterile medium and its content determined three times during the fermentation period. After each determination, the level of the methanol in the medium was readjusted to its initial value (1 %). The results of these experiments can be seen in Table 4.

RESULTS AND DISCUSSION

I. *Influence of stirring.* It seems from Table 1 that stirring is unfavourable for both gas evolution and production of vitamin B_{12} in fermentations with the methanol-fermenting organism. In fermentations with *Mb. omelianskii* (see Table 2) the use of stirring together with a covering oil layer gave higher values for the *E. coli* activity than those obtained with stirring alone. This may be explained by the fact that stirring facilitates the distribution of the oxygen which has diffused in from the surrounding air and which is harmful to the growth and, thus also, to the production of vitamin B_{12}. Since the evolution of gas in this fermentation is very slow, the diffusion of oxygen from the air may be quite important if oil is not used. The *E. coli* activity values obtained in the fermentations with *Mb. omelianskii* are so small that no further conclusions can be made about the influence of stirring.

In the methanol fermentation (see Table 1) an oil layer together with stirring does not give a higher gas evolution than that obtained with stirring alone whereas the stationary fermentation gives the highest gas evolution and vitamin B_{12} activity. Thus the unfavourable effect of stirring upon the production of gas and vitamin B_{12} activity cannot be explained by the distribution throughout the medium of the diffused oxygen. Besides, the evolution of gas is so strong in this fermentation that a diffusion of oxygen into

the medium is not probable since an overpressure in the medium is established very soon after the start of the fermentation. The reasons for the unfavourable effect of stirring could thus not be deduced. Possibly, the stirring causes a disintegration of some complexes or configurations of the medium components which are favourable for the growth of the organism. It would be interesting to investigate whether the same effect is produced at different stirring rates. This, however, could not be done in the present investigation. Still, it cannot be understood why stirring had such distinctly different effects on two different enrichment cultures of methane organisms.

Chromatographic and electrophoretic studies were performed only with the methanol-fermenting culture since the enrichment culture of *Mb. omelianskii* produced such small amounts of *E. coli* activity. The results of these studies indicate that stirring, although not favourable for the production of gas and *E. coli* activity, may cause a different distribution of the activity between the various vitamin B_{12} factors than is the case in a stationary fermentation. Thus stirring seems to favour the formation of vitamin B_{12} substances which upon chromatography and electrophoresis give only one spot. The position of the spot indicates that it may be identical with factor III (Bernhauer) [5] and/or factor W (Neujahr) [4] and possibly other factors with R_c-values in the range 0.6—0.7 (*cf.* Ref.[4]). The phenomenon could be noticed even if DMB (1 μg/ml) was present in the medium. In the stationary fermentations, on the other hand, the *E. coli* activity formed could always be separated by chromatography into three spots if DMB had not been added to the medium and into four spots if it had been added. The four spots corresponded to the following factors: spot 1 - factor B (Ford) [10] spot 2 - cyanocobalamin, spot 3 - factor III (Bernhauer) [5] and/or factor W (Neujahr) [4] and possibly other factors with R_c-values in the range 0.6—0.7 (*cf.* Ref.[4]), spot 4 - factors Z (Neujahr) [4]. The distribution of *E. coli* activity between the different factors

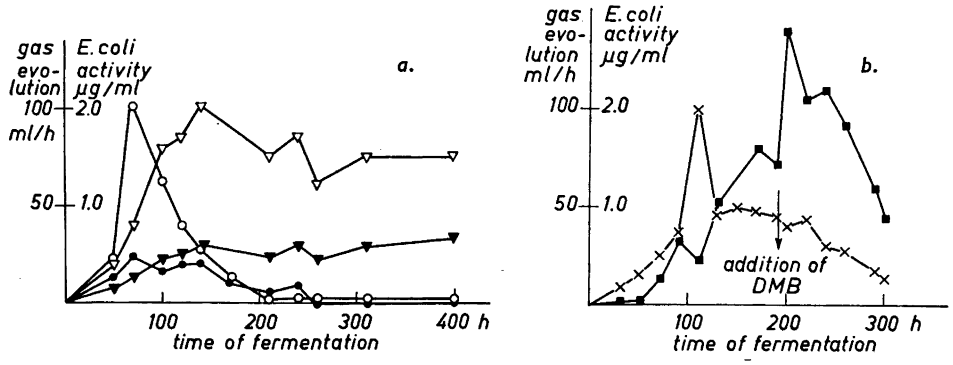

Fig. 2. Influence of 5,6-dimethyl benziminazole (DMB) on the gas production and *E. coli* activity of a methanol fermenting enrichment culture of methane bacteria. a. as found in this experiment is in agreement with previous experience [3]. Since stirring did not seem to give higher yields of vitamin B_{12}, not even when applied together with a covering oil layer, only stationary fermentations were carried out in the following experiments. For convenience no oil layer was employed.

II. *Influence of DMB.* It can be seen in Fig. 2a that the addition of 10 μg instead of 1 μg DMB per ml medium has a strongly inhibiting effect on both evolution of gas and production of vitamin B_{12} activity. A similar inhibitory effect of DMB on the enrichment culture of *Mb. omelianskii* has been reported earlier from this laboratory [1]. The inhibitory effect of benziminazoles upon the growth of several microorganisms is well known and attributed to its competition with adenine or guanine [11]. The inhibitory effect of benziminazoles may be influenced by vitamin B_{12} [12]. On the other hand, Pawelkiewicz [13] has used amounts of 20 μg DMB per ml medium in his fermentations with *Propionibacterium shermannii* for production of vitamin B_{12} without reporting any inhibition of the bacterial growth. Bernhauer [14] reports the use of amounts up to 40 μg DMB per ml medium in similar fermentations without mentioning any inhibitory effect on growth. In fermentations with *Propionibacterium shermannii* carried out in our laboratory [15], in which large additions of DMB (30 μg/ml) were used together with glucose and different modifications of the conventional medium, no such effect could be noticed. Thus it seems that the effect of DMB on cultures of vitamin B_{12}-producing methane bacteria differs from its effect on cultures of vitamin B_{12}-producing propionic acid bacteria. The following conclusions could be made at this point:

1) DMB seems to inhibit the growth of the methanol-fermenting organism, at least when added at a level of 10 μg/ml.

2) In the presence of DMB, on the other hand, cyanocobalamin is formed in preference to other vitamin B_{12} factors [3].

3) In the presence of DMB, several vitamin B_{12} factors could be converted to cyanocobalamin by an enrichment culture of another methane organism, viz. *Mb. omelianskii.*

Starting from the above three statements, a fermentation was made in which the methanol-fermenting culture was allowed to grow without added DMB for 192 h, after which time DMB was added to the medium at a level of 1 μg/ml. It was hoped that the amply formed vitamin B_{12} factors would then be converted to cyanocobalamin. The course of this fermentation can be seen in Fig. 2b. A comparison of Figs. 2a and 2b leads to the following conclusions: Fermentation without added DMB seems to proceed somewhat more slowly than in the presence of 1 μg DMB/ml medium. This is in agreement with previous experience with the methanol-fermenting organism [3]. Adding 1 μg DMB/ml medium after 192 h of fermentation results in a sudden increase of *E. coli* activity to a value which is about 50 % higher than the highest value in the corresponding fermentation with DMB added at the beginning. However, this higher *E. coli* activity decreases again very rapidly contrarily to what is the case in the fermentation with DMB added at the beginning. Chromatographic studies revealed further that the addition of DMB after 192 h results in the formation of a considerably smaller amount of cyanocobalamin than is the case in the fermentation in which DMB is added at the

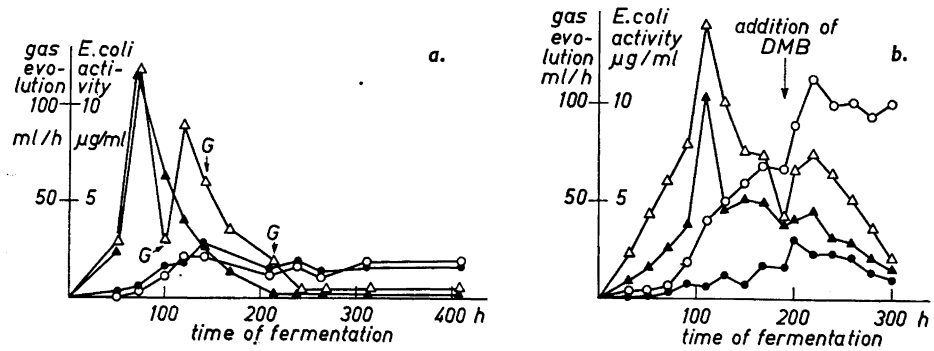

Fig. 3. Influence of glucose on the gas production and *E. coli* activity of a methanol-fermenting enrichment culture of methane bacteria. ▲—▲—▲ gas evolution, ●—●—● *E. coli* activity in the fermentation without glucose; △—△—△ gas evolution, O—O—O *E. coli* activity in the fermentation with glucose. a. DMB added at the beginning, methanol level not adjusted: G readjustment of the glucose level. b. DMB added after 192 h, methanol level adjusted, glucose level and pH readjusted daily.

beginning. Thus the conversion of the different vitamin B_{12} factors to cyanocobalamin cannot be achieved by this method, at least not with the level of DMB used. The factors predominantly produced in such fermentation are again factor III or/and factor W together with only smaller amounts of cyanocobalamin, factor B and factors Z.

It seems from above that smaller amounts of DMB (1 µg/ml) may be favourable for the fermentation, especially in its initial phase, whereas higher amounts of DMB (10 µg/ml) are harmful to the fermentation. This harmful effect depends probably on the known antimetabolic effect of benziminazoles [10,11] whereas the favourable effect of small amounts of DMB may depend on the fact that it is a precursor of cyanocobalamin and at a low concentration — 1 µg/ml — may not produce the antimetabolic effect.

III. *Influence of carbohydrates. a.* The course of two fermentations, in which DMB was added at the beginning and the level of methanol not adjusted during the fermentation time, is shown in Fig. 3a. In one of the fermentations glucose was present and its level adjusted 3 times during the fermentation period. It seems from Fig. 3a that, under the conditions stated above, glucose may stimulate the evolution of gas if added at a relatively early stage of the fermentation. Thus the adjustment of the glucose level (to 1 %) after 100 h results in a considerably increased gas evolution whereas repeated readjustments of glucose after both 140 h and 214 h have no longer such an effect. It should be mentioned that the last two readjustments necessitated the addition of approximately the same amounts of glucose as the first one. The glucose was thus being consumed in the medium all the time.

The production of vitamin B_{12} activity does not seem to be affected by the addition of glucose under the conditions described above.

b. Two other fermentations were performed in which DMB was added after 192 h and methanol added aseptically to the sterilized medium and its

level readjusted to the initial value (1 %) several times during the fermentation. In one of the fermentations, glucose was also present and its level was determined and readjusted to the initial value (1 %) every day. The course of these two fermentations is represented in Fig. 3b. It is evident from Fig. 3b that, under the new and more carefully controlled conditions, the addition of glucose very distinctly stimulates the formation of both gas and vitamin B_{12} activity. The highest *E. coli* activity obtained in this fermentation, *viz.* 11 μg/ml calculated as cyanocobalamin in the plate assay, is higher than any other activity obtained in fermentations of this kind. Moreover, in the fermentation in which the level of glucose was adjusted every day to 1 %, the vitamin B_{12} activity once formed is not destroyed again as is the case in the corresponding fermentation without glucose. Since the favourable effect of glucose appears only when the level of methanol is maintained at a somewhat constant value, it may be assumed that both substances are necessary for the high production of gas and vitamin B_{12}. The favourable effect of low molecular carbohydrates upon the production of vitamin B_{12} in septic methane fermentations of sewage sludge with *Mb. omelianskii* has been reported also by Cserei-Pehany [16].

c. In a separate experiment in this series, an attempt was made to use milk whey instead of glucose as a source of carbohydrate. The results are given in Table 3. It can be seen there that the addition of whey leads to a somewhat lower gas production but a consistently higher production of vitamin B_{12} activity throughout the fermentation than is the case in the corresponding fermentation without added carbohydrate. The highest *E. coli* activity obtained in the fermentation with whey is of the order of 3—4 μg/ml, calculated

as cyanocobalamin in the plate assay. These values are not directly comparable with those of the fermentations with glucose since, as described in Experimental, a different medium was used in the fermentations with whey and only fermentations with DMB added at the beginning were carried out.

Chromatographic and electrophoretic studies of the *E. coli* activity did not reveal any differences between the kind of factors formed in fermentations with and without the addition of carbohydrate to the basal medium. Chromatography gave spots corresponding to the following factors (listed in order of decreasing amounts): factor W[4] and/or III [5], factor B[10], cyanocobalamin, factors Z [4]. In the fermentations performed under more carefully controlled conditions, *i.e.* repeated readjustments of the glucose content, pH and methanol, a certain regularity in the occurrence of factors Z, B and W and/or III could be observed. Thus, during the first two or three days of the fermentation, there occurred a chromatographically almost immobile factor, different from factors Z2 + Z3 [4]. The behaviour of this factor was similar to that of factor C_2[17] (*cf.* Ref.[4]). This factor disappeared simultaneously as factors Z2 + Z3 appeared in the medium. The latter factors could usually be observed for the following two or three days, after which time their content

decreased markedly and they finally disappeared. Simultaneously with the disappearance of factors Z2 + Z3, factor B began to appear. Factors W and/or III were present all the time. A similar sequence for the appearance of factors C_2, C_1[17] (which may possibly be identical with factor Z3) and B has been observed earlier in anaerobically decomposing sewage sludge [18].

IV. *Influence of organic nitrogen sources and yeast extract.* It has been found in an earlier investigation [3] that the addition of Bactopeptone (Difco) stimulated both the production of gas and the vitamin B_{12} activity. An attempt was now made to elucidate whether other nitrogenous sources may have a similar and possibly more pronounced effect since the use of *a.* Bactopeptone, is very expensive. It can be seen in Fig. 4 that the addition of *b.* corn steep liquor (Fig. 4b), *c.* casein hydrolyzates together with glucose (Fig. 4c), and *d.* casein hydrolyzates together with glucose and yeast extract (Fig. 4d) results in a greatly diminished production of gas and vitamin B_{12} activity as compared with the fermentation with Bactopeptone (Fig. 4a). The shape of the gas evolution curves in Figs. 4b, 4c, and 4d is also quite different from the shape of the corresponding curve in Fig. 4a and the corresponding curves in Figs. 2a, 2b, 3a, 3b. Thus, the maximum in the gas evolution, which usually occurs between 70—110 h in the fermentations with the methanol-fermenting organism, is missing in those fermentations in which the above mentioned modifications of the conventional medium were employed. In the fermentations with casein hydrolyzates (Fig. 4c and 4d), the gas evolution curve has instead a "pulsating" character and the maximum gas evolution values are 4—5 times lower than the maximum values in other fermentations of this kind. A suspicion has arisen that, in the fermentations with media modified according to *b*, *c*, and *d*, some other organisms present in the enrichment culture of methane bacteria have developed due to the fact that the modified media might not have been any longer selective for the methanol-fermenting organism. At least in so far as the fermentations with casein hydrolyzates (Figs. 4c and 4d) are concerned, such a suspicion was jutified by the results of microscopic studies, by the putrefactive odour produced in these fermentations and also by the "pulsating" character of the gas evolution. In these fermentations, motile, possibly rod shaped organisms seemed to be present together with the coccoidal forms and the immobile rods usually present in fermentations of this kind [3]. Some of the motile forms may possibly have had the characteristic shape of *Clostridia*. However, the microscopic studies were rendered very difficult by the fact that methane bacteria grow mostly in the sediment [1] (*i.e.* the asbestos powder, calcium carbonate and sediment produced during the fermentation) the particles of which were very difficult to separate from the bacterial cells. Thus, under the microscope, the bacteria always appeared imbedded in a bulky precipitate and no definite conclusions about their shape could be made. There remains, however, the fact that certain motile forms were present in the cultures which was inconsistent with the immobile character of methane bacteria.

Further support for the suspicion that some *Clostridia* developed in the fermentations with casein hydrolyzates came from the results of chromatographic and electrophoretic studies. The *E. coli* activity produced in these fermentations was found to contain ψ-B_{12} together with factors W [4] and/or

III [5], B^{10} and cyanocobalamin. None of the methane bacteria studied so far was found to produce ψ-B_{12}[1,3]. On the other hand, certain strains of *Clostridia* were found, in a separate study, to produce ψ-B_{12}[10].

In the fermentation with corn steep liquor (Fig. 4b), the shape of the gas evolution curve is still more different from the gas evolution curves usually obtained in the fermentations with methane bacteria. Not only are the gas evolution maxima missing — at least during the period investigated — but also the gas evolution is extremely slow (2—3 ml/h) during the first five days of fermentation after which it increases slowly but steadily and, after eighteen days, still shows a tendency to increase. It should further be mentioned that, during the first five days, which were characterized by an extremely slow gas evolution (*cf.* Fig. 4b), the pH of the medium decreased considerably (to 6.5—6.7) after each of the daily readjustments to its optimum value (7.2) whereas, during the following period of time, characterized by a steady increase in gas evolution, the changes of pH were less pronounced and limited to the range 6.7—6.9 even without readjustments which were therefore no longer undertaken after 7 days of fermentation.

Microscopic examinations did not indicate that other organisms than the methanol-fermenting methane bacteria may have developed in the fermentation. Neither could any putrefactive odour be detected in the fermentation flask as was the case in the fermentations with casein hydrolyzates.

Knivett in England who has succeeded in growing a methane organism in a continuous culture [20] suggests that "a starved cell, which has to synthesize cell material from the simplest materials, may need to produce a lot of B_{12} coenzyme to do this whilst a cell adequately supplied with growth factors, amino acids etc., has no need to synthesize them and its coenzyme requirement may be less"[20]. Corn steep liquor is considered to be a source of most essential nutrients. According to the attractive suggestion of Knivett, the addition of corn steep liquor would thus result in a considerably diminished synthesis of vitamin B_{12} until the supply of the nutrients was exhausted in the medium. But can a similar relation apply also to the production of gas? (*cf.* Fig. 4b), *i.e.*, can the adequately supplied cells of the methanol-fermenting methane organism satisfy their growth requirements in a different way than by producing methane gas? (*cf.* also the above mentioned changes of pH!). The results of the present investigation are, however, much too preliminary to permit speculations of this kind. It should further be remembered that an enrichment and *not* a pure culture of the methanol-fermenting organism was used in the experiment. Bactopeptone is also an excellent source of different nutrients but it was found to stimulate both the production of gas and vitamin B_{12} activity in cultures of the methanol-fermenting organism [3]. On the other hand, the mutual relation of gas evolution and vitamin B_{12} activity curves in most fermentations with the enrichment culture can be plausibly interpreted by the suggestion of Knivett [20]. It can be seen for instance in Figs. 2a, 2b, 3a, 3b, 4a that the maximum in *E. coli* activity always comes *after* the maximum in gas evolution. It seems that the vitamin B_{12} content of the cells begins to increase as their metabolic activity — judged by the gas evolution — tends to decrease, probably due to the exhaustion of certain nutrients in the medium.

It can be seen in Fig. 4e that the use of sterilized sewage in the medium greatly stimulates the evolution of gas and production of vitamin B_{12} activity as compared for instance with Bactopeptone. The maximum gas evolution obtained in this fermentation is much greater than with most other modifications of the basal medium and comparable perhaps only with the medium containing glucose, DMB added after 8 days in the fermentation with regularly adjusted pH and methanol content (Fig. 3b). As in the fermentations with casein hydrolyzates (*cf.* Figs. 4c and 4d), the gas evolution curve has three maxima. However, here the second maximum is much smaller than the first and the third much smaller than the second. No indications could be found that other organisms than the methanol-fermenting one had developed in the culture. The curve for *E. coli* activity (Fig. 4e) shows a steady tendency to increase apart from two less pronounced maxima which seem to correspond to the first two maxima of the gas evolution curve. Between the 14th and 16th day of fermentation, the *E. coli* activity remains at the level of 7 μg/ml which is very high compared with the yields obtained in the fermentations in which nitrogenous materials were added (*cf.* Figs. 4a, 4b, 4c and 4d).

A still higher yield of *E. coli* activity, *viz.* 9 μg/ml, was obtained in a similar fermentation with sterilized sewage in which, however, the medium was further supplemented with glucose and yeast extract (Fig. 4f). The maximum value of *E. coli* activity was obtained after only 8 days of fermentation, after which time the activity tended to decrease again.

Chromatographic and electrophoretic studies revealed that the *E. coli* activity produced in the fermentations with sterilized sewage was mainly due to factors W[4] and/or III [5]. Roughly estimated, at least 70 % of the *E. coli* activity was contributed by these factors. Cyanocobalamin was present in much smaller amounts than the above factors. Factors B and Z were present only in trace amounts. In the fermentations with sterilized sewage, in which the medium was further supplemented with glucose and yeast extract, the dominant factors were factor W[4] or/and III[5] and factor B[10]. Cyanocobalamin was present in much smaller amounts than in the fermentations with sterilized sewage only. Thus the higher *E. coli* activity obtained in the further supplemented medium (Fig. 4f), *viz.* 9 μg/ml instead of 7 μg/ml (Fig. 4e) in the medium containing only sterilized sewage, may not reflect a really higher yield of vitamin B_{12} obtained in the richer medium since, according to previous experience [4], factor B gives much greater growth zones than cyanocobalamin when assayed by the plate method. Very small amounts of factors Z[4] and of some not identified factors were also produced in the fermentation with sterilized sewage, glucose and yeast extract.

It seems from the above that sterilized sewage, supplemented in an appropriate way provides a very good medium for obtaining high yields of vitamin B_{12} activity in fermentations with the methanol-fermenting enrichment culture of methane bacteria. It has also been successfully used in this laboratory for the cultivation of other vitamin B_{12}-producing organisms [15]. As described above (*cf.* p. 36), the addition of glucose to the basal medium M may lead to even higher yields of *E. coli* activity (Fig. 3b), *viz.* 11 μg/ml, than is the case in the fermentation with sterilized sewage (Fig. 4e). However, with glucose, greater amounts of factor B are formed and this makes un-

certain, once again, a direct comparison of the *E. coli* activity values obtained in the fermentations with glucose with those obtained in the fermentations with sterilized sewage. It should also be mentioned that the sterilized sewage contained only negligible amounts of reducing sugars.

V. *Utilization of methanol.* It can be seen in Table 4 that the greatest utilization of methanol took place in the fermentations with sterilized sewage in the medium. A somewhat lower utilization of methanol can be noticed in the media to which glucose had been added while the lowest utilization was observed in the media containing Bactopeptone or casein hydrolyzates. The latter finding may provide an interesting contribution to the discussion on p. 39. However, no conclusions concerning the relation between utilization of methanol and an adequate supply of preformed cell material can so far be made for various reasons — *viz.* partly because the values for methanol utilization, given in Table 4, are too few, and also because no sure correlation between utilization of methanol, production of gas and production of vitamin B_{12} activity can be deduced from Table 4 even if in most cases the vitamin B_{12} activity tends to increase when the utilization of methanol begins to decrease.

VI. *Maintainance of optimum pH.* As was described above, certain fermentations were performed with a daily readjustment of the pH to its optimum value for the methanol-fermenting organism (7.2). However, it was found that, in the media not containing glucose, the changes in pH were very small. After a few days of fermentation, these media exhibited in addition a very strong buffering capacity in the range 6.8—7.0. On the other hand, the fermentations in media containing glucose were characterized by considerable daily decreases in pH.

Acknowledgements. The author wishes to thank Professor H. Lundin, Head of the Division, for his encouraging interest in this work and Assistant Professor N. Nielsen, AB Kabi, Stockholm, for the generous gift of corn steep liquor and kind information about its chemical composition. The valuable technical assistance of Ing. Giancarlo Rossi-Ricci is gratefully acknowledged.

On Vitamins in Sewage Sludge

XII. Production of Vitamin B_{12} by Certain *Clostridia*

HALINA Y. NEUJAHR and GIANCARLO ROSSI-RICCI

Royal Institute of Technology, Division of Food Chemistry, Stockholm 70, Sweden

The ability to produce vitamin B_{12} was investigated in three strains of *Clostridia*.

The strains were found to produce amounts of *E. coli* activity ranging from 16—60 mμg/ml medium, calculated as cyanocobalamin in plate assay. These amounts are considerably smaller than those obtained in this laboratory with certain methane bacteria [6,7].

The addition of Co^{2+} was found to have only a negligible effect on the production of *E. coli* activity.

The factors mainly produced by the strains are factor A and ψ-B_{12}. If the medium is supplemented with 5,6-dimethyl benzimidazole, however, cyanocobalamin is produced almost exclusively.

As reported from this laboratory [1] and by several other authors [2–4], digested sewage sludge contains considerable amounts of vitamin B_{12} activity. It has also been reported earlier from this laboratory that the formation of vitamin B_{12} activity during the anaerobic decomposition of sewage sludge proceeds in several stages and seems to be caused by several different microorganisms [5]. The initial stages of the anaerobic sludge fermentation imply the decomposition of high molecular organic matter (proteins, fats and carbohydrates) to low molecular compounds (alcohols and fatty acids). The latter compounds are utilized during the final stages of the anaerobic sludge decomposition by methane bacteria with a simultaneous formation of large amounts of methane and carbon dioxide.

It was found in this laboratory that several of the methane organisms active during the final stages of the anaerobic sludge decomposition produce vitamin B_{12} activity [6]. Some of the methane organisms were found to produce considerable amounts of certain vitamin B_{12} factors when grown in appropriate media [7]. It was therefore considered to be of interest to investigate also whether the organisms active during the initial stages of the anaerobic sludge decomposition produce vitamin B_{12} activity and, if that is the case, which particular vitamin B_{12} factors are synthesized.

According to Enebo [8], the quantitatively most important group of organic materials in municipal sewage are high molecular carbohydrates. The organisms known to decompose such carbohydrates under anaerobic conditions are *Clostridia*. Three available strains of *Clostridia*, which presumably are active also during the anaerobic decomposition of sewage sludge, were grown in a medium containing maize meal, yeast autolyzate and phosphates both with and without the addition of Co^{2+} and 5,6-dimethyl benziminazole. The ability of these strains to produce vitamin B_{12} activity was investigated.

EXPERIMENTAL

The three strains of *Clostridia* investigated were

1. *Clostridium acetobutylicum* Weizmann (AB)
2. *Clostridium butylicum* (B4)
3. *Clostridium butylicum* (B6)

The cultures were maintained in the form of spores in soil.

Basal medium. Maize meal 70 g, yeast antolyzate (12 h at 50–60°C) 25 ml, $NH_4H_2PO_4$ 5 g, KH_2PO_4 1 g, dist. water 1 000 ml. The maize meal was boiled for about 30 min and mixed with the yeast autolyzate and salts. The pH was adjusted to 6 with NaOH and finally with $CaCO_3$ and the medium autoclaved for 1 h at 120°C and steamed the following day.

Preparation of the inocula. 10 ml portions of the sterile medium in test tubes (18 × 200 mm) were inoculated with 2 ml of a soil-spore suspension in a sterile saline solution which had been submitted to a heat shock (2 min in boiling water). The test tubes were incubated at 37°C for 24 h in evacuated vessels containing an alkaline pyrogallol solution. After this time, a considerable gas evolution usually took place.

Fermentations for determining the ability of Clostridia to produce vitamin B_{12}. 20 ml portions of the sterile medium in 50 ml E-flasks were inoculated with 5 ml of inoculum prepared as described above. The flasks were incubated at 37°C for either 7 or 14 days in evacuated vessels containing alkaline pyrogallol solution. Six simultaneous fermentations were performed with each strain according to the following scheme:

No. of flasks	Additions to the basal medium	Time of fermentation days
1	none	7
1	»	14
1	Co^{2+}, 2.5 μg/ml	7
1	» 2.5 »	14
1	Co^{2+}, 2.5 μg/ml + 5,6-dimethyl benziminazole, 1 μg/ml	7
1	—»— —»—	14

The Co^{2+} was supplied as a 0.1 % solution of $CoCl_2 \cdot 6H_2O$.

Vitamin B_{12} activity was determined by the cup plate method using *E. coli 113-3* as described elsewhere [5]. Chromatographic determinations were performed in solvent system I[9] and paper electrophoresis according to Holdsworth [10] using 2 M HAc containing 0.01 % KCN, pH 2.5, 10 V/cm, 18 h at +4°C. In both the chromatographic and electrophoretic determinations, bioautography on *E. coli 113-3* plates was used to reveal the spots obtained.

The results of this investigation are given in Table 1.

* calculated as cyanocobalamin in plate assay.

RESULTS AND DISCUSSION

In all of the flasks, an intensive fermentation must have taken place during the first 4—5 days of incubation judging by the vigorous gas evolution and the decrease of pH from its initial value (6.0) to 4.9—5.0 (see Table 1). It can further be seen in Table 1 that in all flasks, except one, there was a production of *E. coli* activity in amounts ranging from 16 to 60 mμg/ml calculated as cyanocobalamin in plate assay. A prolonged time of fermentation (14 days instead of 7 days) seemed to increase the total *E. coli* activity produced in fermentations with strains B4 and B6 whereas the reverse may be true for strain AB. In one flask, *viz.* the fermentation with strain B6 in the basal medium supplemented with Co^{2+} and interrupted after 7 days, considerable amounts of

methionine seemed to be present instead of vitamin B_{12} activity. The reasons for this discrepancy could not be deduced.

The *E. coli* activity produced in the fermentations of the basal medium, not further supplemented, was due to factor A and ψ-B_{12} as shown by both chromatography and electrophoresis. The situation was the same with all three strains after both 7 and 14 days of fermentation. The addition of Co^{2+} had only negligible effect on the total amount of *E. coli* activity obtained and only a very slight effect on the kind of vitamin B_{12} factors produced which, with all three strains, were once again mainly factor A and ψ-B_{12} together with only trace amounts of a factor neutral on electrophoresis at pH 2.5. After 14 days of fermentation, small amounts of a factor ressembling the factors Z[10] could be detected by chromatography in fermentations with strains AB and B4 but not with strain B6. This factor moved still more slowly, upon chromatography in solvent system I[8], than factor Z3[11]. Its presence could not be confirmed by electrophoresis. The nature of this factor was not further investigated since it was present in much smaller amounts than the other two factors, *viz.* factors A and ψ-B_{12}.

The addition of DMB together with Co^{2+} resulted in a considerable decrease in the values for total *E. coli* activity produced in fermentations with all three strains as compared with the fermentations in the unsupplemented basal medium or this medium supplemented with Co^{2+} alone. The decrease may, however, be only an apparent one since the addition of DMB led the synthesis of vitamin B_{12} activity in all fermentations towards the formation of mainly cyanocobalamin instead of factors A and ψ-B_{12}. As discussed elsewhere [5,12], cyanocobalamin gives much smaller growth zones on *E. coli* plates than several other vitamin B_{12} factors. In certain cases (cf. Table 1), very small amounts of the above mentioned factor Z was formed together with cyanocobalamin as revealed by chromatography but not confirmed by electrophoresis. In other cases, very small amounts of a factor ressembling factor B seemed to be present as judged by the results of paper electrophoresis but not confirmed by chromatography. Again, the nature of these factors was not further investigated since they were present only in very small amounts.

The following conclusions concerning the three strains of *Clostridia* can be made on the basis of the present investigation.

1. *Clostridia* seem to produce amounts of vitamin B_{12} activity which are considerably smaller than those obtained in fermentations with certain methane bacteria [6,7].

2. *Clostridia* seem to produce mainly factor A and ψ-B_{12} in the basal medium not supplemented with 5,6-dimethyl benziminazole. However, with this compound added to the medium they produce almost exclusively cyanocobalamin. It should be mentioned that none of the hitherto investigated methane bacteria was found to produce ψ-B_{12} or factor A[6,13].

3. The presence of centain amounts of ψ-B_{12} and factor A in digested sludge could thus be attributed to ***inter alia*** the activity of *Clostridia*.

Acknowledgements. The authors are greatly indebted to Dr. L. Enebo of the Division of Fermentations, Royal Institute of Technology, Stockholm 70, for providing us with the strains of *Clostridia* and to Dr. C. Carenberg for advice concerning the performing

of the fermentations. The authors wish to thank Professor Harry Lundin, Head of the Division, for his encouraging interest in this work.

Transfer of Triplet State Energy in Fluid Solutions

I. Sensitized Phosphorescence and Its Application to the Determination of Triplet State Lifetimes

HANS L. J. BÄCKSTRÖM and KJELL SANDROS

Institutionen för fysikalisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The photo-luminescence spectra of biacetyl, benzil, and anisil, in oxygen-free benzene solutions at room temperature have been determined, using the mercury line at 366 mμ as exciting light. All three substances show mainly phosphorescence, with a mean lifetime exceeding 5×10^{-5} sec, but also measurable fluorescence. Addition of an efficient phosphorescence quencher makes it possible to study the fluorescence spectra separately.

Measurements on solutions containing both benzophenone and one of the three substances mentioned have shown that the latter may be excited to luminescence also by light primarily absorbed by benzophenone. The spectrum of this sensitized luminescence shows it to be pure phosphorescence. This proves that the sensitization takes place by a transfer of triplet state energy from sensitizer to acceptor.

The triplet energy level of benzophenone lies 4 000 cm^{-1} above that of biacetyl. This difference is sufficiently large to justify the assumption that the transfer of triplet state energy is a diffusion controlled process. On this basis the mean life of benzophenone in its triplet state may be calculated from measurements of the intensity of sensitized biacetyl phosphorescence as a function of the concentration of biacetyl. The following values were obtained: in benzene solution at 20°C, 1.9×10^{-6} sec, in *iso*propanol solution, 5.7×10^{-6} sec at 20°C, and 4.6×10^{-6} sec at 25°C. The latter figure is in satisfactory agreement with a previous value calculated from the kinetics of a photochemical reaction involving triplet state benzophenone.

Comparative intensity measurements of sensitized and unsensitized biacetyl phosphorescence indicated that the internal conversion from the excited singlet state to the triplet state is virtually complete in fluid solution. It is suggested that the low phosphorescence yield in biacetyl vapour is due to radiationless transitions to the ground state from higher vibrational levels of the triplet state.

In a previous paper [1] we presented the results of a study of the quenching effect of different types of compounds on the long-lived fluorescence of biacetyl in solution. As shown by Lewis and Kasha [2], this luminescence accompanies the spin-forbidden transition of an excited biacetyl molecule

from its lowest triplet state to the singlet ground level. In the nomenclature proposed by these authors [3] it should therefore be termed phosphorescence to distinguish it from normal fluorescence, which is a spin-allowed transition (generally singlet → singlet). In the present paper we have adopted this nomenclature.

One result of our study [1] was the discovery of a class of quenchers, consisting of unsaturated and aromatic compounds, that were assumed to act by a transfer of excitation energy resulting in a triplet → singlet transition in the biacetyl molecule and the reverse transition in the quencher. This type of energy transfer has been shown by Terenin and Ermolaev [4] to explain the phenomenon of sensitized phosphorescence observed in solid solutions at liquid air temperature. Broadly speaking, the necessary condition for the transfer to be possible is that the triplet energy level of the sensitizer (donor) must lie above that of the acceptor. As pointed out in our previous paper, the same process of energy transfer may be expected to take place in fluid solutions at ordinary temperatures. Substances with triplet levels lying below that of biacetyl should therefore act as quenchers of biacetyl phosphorescence. This interpretation of our results receives strong support from further work on phosphorescence quenching, to be published shortly.

On the other hand, substances with triplet levels lying *above* that of biacetyl, should be able to function as sensitizers of biacetyl phosphorescence in solution. The present paper gives the results of experiments designed to test this conclusion. The experiments were extended to two other substances showing phosphorescence in solution, namely benzil and anisil.

EXPERIMENTAL

Apparatus

For measuring *luminescence spectra* the optical system of a Beckman DU spectrophotometer was used. The cell compartment mounting block, containing the entrance mirror, was replaced by a similar metal block into which a sealed Pyrex tube (outer diameter 8 mm), containing the degassed solution to be studied, could be introduced from below directly in front of the entrance slit An opening in the metal block permitted the tube to be illuminated from the side. Light from a water-cooled 80-watt A.C. mercury lamp, Hanau S 81, was filtered through a 2 mm Schott UG 2 glass and focused on the tube with a lense. The exciting light was therefore mainly of wavelength 366 mμ. A Sorensen voltage regulator was used to keep the lamp voltage constant.

From the exit slit of the instrument the light beam passed through a hole (diameter 12.5 mm) in the metal block and struck the photocathode of a multiplier phototube of the head-on type. The latter was enclosed in a light-tight housing screwed on to the back of the metal block. Two different multiplier tubes were used, RCA 5819 and RCA 6217. The latter tube has a spectral sensitivity curve extending farther into the red wavelength region, but also a less favourable signal to noise ratio. The tube was connected to a stabilized adjustable voltage supply and the current was read on a sensitive light-spot galvanometer (Norma Model 251 J). The voltage was chosen so as to give satisfactory results with a low slit width. For biacetyl luminescence a slit width of 0.2 mm was used, corresponding to a half-intensity band width of 4 mμ at the wavelength 500 mμ. For benzil and anisil the slit width had to be increased to 0.3 mm owing to the lower luminescence yield.

In determining a spectrum, readings were taken at different settings of the wavelength selector. Repeated readings at the wavelength corresponding to the maximum in the luminescence curve served as a check on the constancy of the exciting light. Using the

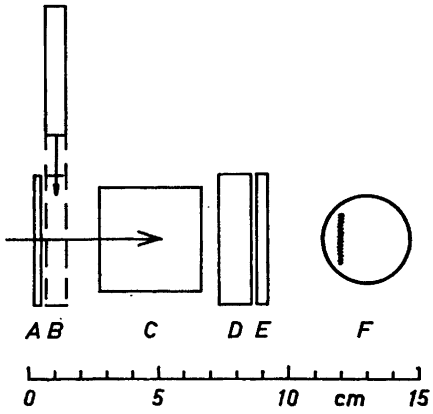

Fig. 1. Schematic diagram of experimental arrangement for measuring relative luminescence intensities. (A) Light filter (Schott UG2, 2 mm). (B) Uranyl glass. (C) Cylindrical glass cell, 4 × 4 cm. (D) Quartz cell with 0.5 M sodium nitrite solution. (E) Light filter (Chance OY3, 4 mm). (F) Multiplier phototube, RCA 931 A. — A light-tight box with an opening for the exciting beam enclosed parts C—F. The measurements were made in a darkened room.

spectral sensitivity curves of the multiplier phototubes, as given by the manufacturers, and the dispersion data for the Beckman spectrophotometer, relative intensity values at different wavelengths were calculated. No correction was made for the variation of reflexion losses with wavelength. The curve thus obtained was finally recalculated to give relative numbers of light quanta emitted at different wave-numbers.

For all three substances studied luminescence curves were determined with both photomultiplier tubes, covering the range from the onset of luminescence at about 470 mμ to the limit (about 610 mμ) where the normal sensitivity of tube 5819 has dropped to 10 % of its maximum value. The results with the two tubes showed no systematic deviations. The curves shown in Figs. 4—6 are based on measurements made with tube 6217 for wavelengths above 600 mμ and with tube 5819 for shorter wavelengths.

The experimental arrangement for measuring *relative luminescence intensities* is shown schematically in Fig. 1. The degassed solution was contained in the cylindrical glass cell C (shown in more detail in Ref.[1], Fig. 2). It was excited to luminescence by a light beam of wavelength 366 mμ from the exit slit of a Bausch and Lomb grating monochromator (1 200 grooves per mm, focal length 500 mm). The light source was an A.C. mercury lamp. Fluctuations in line voltage were eliminated with a Sorensen voltage regulator. The luminescence light reaching the cathode of the photomultiplier tube (F) was limited by the filter combination D + E to wavelengths > approximately 510 mμ. The stabilized voltage applied to the multiplier tube was adjusted to give a current of suitable magnitude within one of the two lowest measuring ranges of a certified high-resistance light-spot galvanometer (Norma Model 251 J). The sensitivity in these ranges was 1.975×10^{-9} and 1.975×10^{-8} A per scale division, respectively.

The fluorescent uranyl glass (B) was used to obtain a measure of the intensity of the exciting light. With C removed and B in the path of the light beam, in an accurately fixed position, the photocurrent produced by the fluorescence light was determined. This current was in the third measuring range of the galvanometer (1.975×10^{-7} A per scale division). Determinations made before and after a luminescence measurement showed that the intensity of the exciting light was constant to better than 1 % during an experiment.

In order to minimize photochemical changes in the solutions they were exposed to light as little as possible.

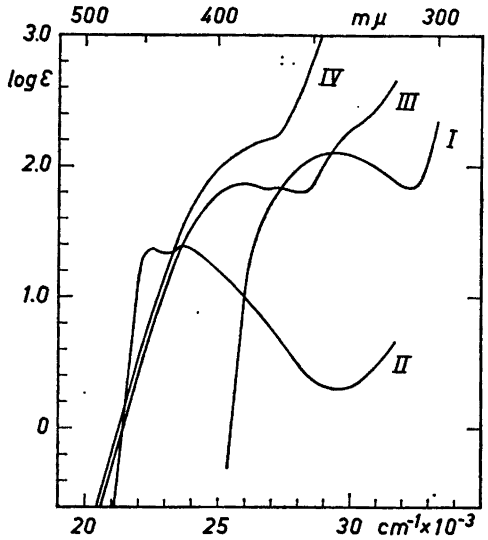

Fig. 2. Absorption spectra in benzene solution, log ε *vs.* wave number in cm^{-1}. (I) Benzophenone. (II) Biacetyl. (III) Benzil. (IV) Anisil.

Materials

Anisil (*p,p'*-dimethoxybenzil) was prepared from anisoin according to the directions of Biltz and Arnd [5]. It was recrystallized three times from ethanol.

All other chemicals were of the highest purity obtainable commercially. *Biacetyl* was further purified and stored as described earlier [1]. *Benzil* was recrystallized three times from ethanol. *Benzophenone* was recrystallized twice from an ethanol-water mixture and once from a methanol-water mixture. *Benzene* and *isopropanol* were fractionally distilled using a column corresponding to 15 theoretical plates.

All solutions were degassed as described earlier [1]. The phosphorescence lifetime for biacetyl in dilute benzene solution at 20°C was generally found to be only about 700 μsec as against 1 000 μsec in our earlier work [1]. This shows that we did not succeed in obtaining the benzene as pure as earlier although the raw-material was from the same source and the method of purification was the same.

RESULTS AND DISCUSSION

Luminescence spectra

The substance used as sensitizer was benzophenone. Its long-wave absorption band in benzene solution at room temperature is shown in Fig. 2, together with the corresponding spectra of the acceptors studied. The molar decadic extinction coefficients at 366 mμ were found to have the following values: benzophenone 67, biacetyl 4.5, benzil 68, anisil 180.

Energy level diagrams for benzophenone and biacetyl are shown in Fig. 3. Only the lowest excited levels are included as being the only ones of interest in the present connection. Since liquid solutions of benzophenone do not show

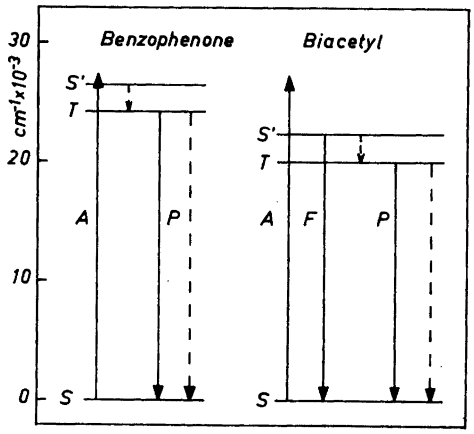

Fig. 3. Electronic energy level diagrams for benzophenone and biacetyl, showing the energy above the ground level (S), expressed in wave numbers, of the first excited singlet level (S') and the lowest triplet level (T). Solid arrows represent transitions involving radiation: (A) absorption of light of wavelength 366 mμ, (F) fluorescence, (P) phosphorescence. Dashed arrows represent radiationless transitions.

measureable phosphorescence, the position of its lowest triplet level is known only from its phosphorescence spectrum in solid solutions at liquid air temperature. For this reason the diagrams are based entirely on absorption and luminescence measurements made under those conditions [4,6-8]. The spectral changes produced by changing the temperature or the solvent are small enough to be unimportant in the present discussion.

Only the zero-point vibrational levels are shown, in order not to complicate the diagrams *. It will be noted that no radiative S' → S transition is indicated in the case of benzophenone. Benzophenone shows no fluorescence, only phosphorescence, which proves [10] that the radiationless transition to the slightly lower lying triplet level is essentially complete. This means that the lifetime of benzophenone in its excited singlet state must be so short that transfer of energy to the acceptor from benzophenone molecules in this state may be ruled out as a possibility. This is one of the advantages of using benzophenone as a sensitizer in the present case.

The value reported [7] for the quantum efficiency of phosphorescence in solid solution at 77°K, 0.84 ± 10 %, shows that under these conditions radiationless transition to the ground state must be of minor importance. The rate of decay of phosphorescence under the same conditions [7] corresponds to a mean life of the triplet state of 0.008 sec. In liquid solution at ordinary temperature, collisional deactivation or chemical reaction with the solvent reduces the lifetime to a small fraction of this value (See p. 59).

* In accordance with the Franck-Condon principle, molecular spectra are largely determined by the higher vibrational levels. See, *e.g.*, Förster [9]. The absorption and luminescence spectra of benzophenone have recently been discussed by Dörr [6].

Biacetyl shows fluorescence as well as phosphorescence, and the same is true of the other two substances studied as acceptors in the present work. As found by Groh [11], irradiation of biacetyl vapour with light of wavelength 366 mμ leads to the emission of a "fast" fluorescence of low intensity and with a spectrum lying mostly between 400 and 500 mμ, in addition to the previously known slow fluorescence (phosphorescence) whose spectrum lies mostly at wavelengths > 500 mμ. Similarly, Sidman and McClure [8] found that the photoluminescence of biacetyl crystals at low temperatures contains a weak blue component. An analysis of its band spectrum showed it to be true fluorescence.

For the purpose of the present investigation, the most important difference between benzophenone and biacetyl is that the latter compound shows strong phosphorescence even in liquid solution in a suitable solvent. No measurements of quantum efficiency either in solid or in liquid solution have been made, but already the existence of fluorescence shows that the internal conversion $S' \rightarrow T$ cannot be complete. However, molecules that have reached the triplet state exhibit remarkable stability toward deactivating influences. This is shown by the fact that the triplet state lifetime in benzene solution at 20°C may amount to [1] as much as 1.0×10^{-3} sec, which is 45 % of the value found in solid solution at liquid air temperature.

As regards the relative positions of the energy levels of the two substances, Fig. 3 shows that the S′ level of benzophenone lies above that of biacetyl. From this point of view an energy transfer: $D_{S'} + A_S = D_S + A_{S'}$ (D donor, A acceptor) would be possible. For the reason mentioned above this possibility may, however, be excluded. That this is not the mechanism of the sensitized luminescence observed is confirmed by the experimental results. As shown below, the sensitized luminescence is pure phosphorescence, whereas raising the acceptor to the S′ level by direct light absorption produces both fluores-

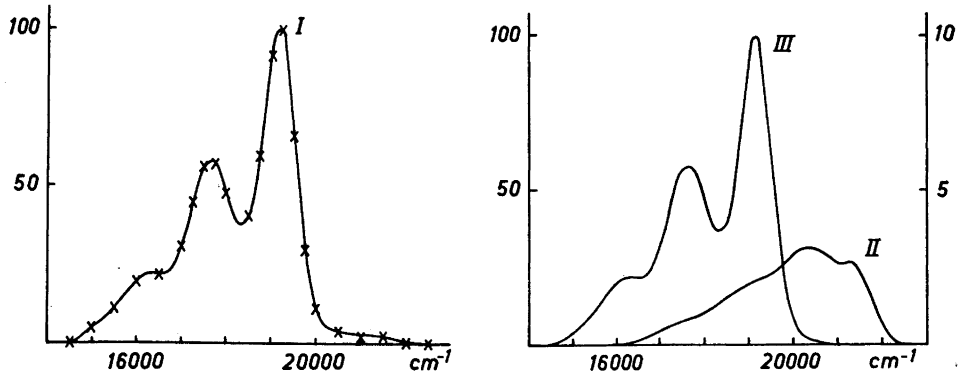

Fig. 4, a and *b*. Luminescence spectra of biacetyl in benzene solution, showing relative numbers of light quanta emitted *vs.* wave number in cm^{-1}. (I) Unsensitized luminescence. Benzophenone 2.64×10^{-2} M, biacetyl 7.0×10^{-3} M.

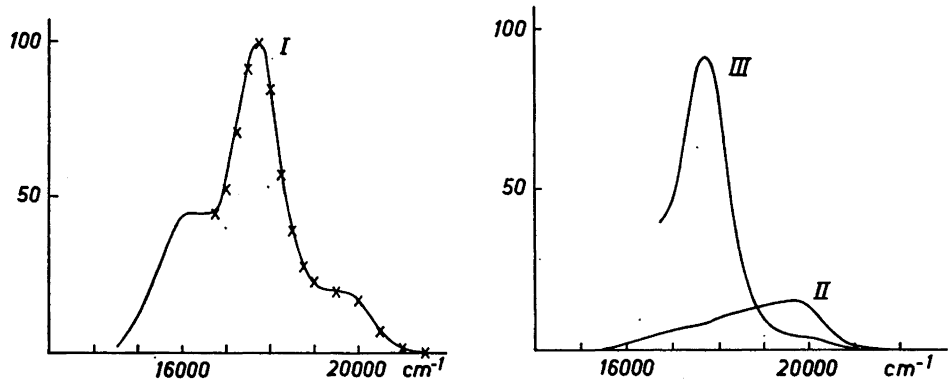

Fig. 5, a and *b*. Luminescence spectra of benzil. (I) Unsensitized luminescence. Benzil 2.14×10^{-2} M, observed values. (X) Calculated values. (II) Fluorescence. Benzil 2.75×10^{-2} M, pyrene 2.7×10^{-4} M. (III) Sensitized luminescence. Benzophenone 3.43×10^{-2} M, benzil 1.49×10^{-2} M. — The measurements represented by curve III met with difficulties and were only pursued as far as shown. Apparently a photochemical reaction took place, leading to a change in the spectrum.

cence and phosphorescence. There can be no doubt, therefore, that the sensitization takes place by a process: $D_T + A_S = D_S + A_T$. That this process is energetically possible is shown by the relative position of the triplet levels.

The results obtained with the three acceptors studied are given in graphical form in Figs. 4—6, the relative number of light quanta emitted being plotted in arbitrary units against the wave-number in cm^{-1}. In each case, curve I represents the spectrum obtained on irradiating a pure solution of the acceptor in benzene with light of wavelength 366 mμ. This spectrum is partly fluorescence, partly phosphorescence. The curves marked II represent the pure fluorescence spectrum as obtained by eliminating the phosphorescence by the addition of a small quantity of pyrene, which is a strong phosphorescence quencher [1]. The fact that pyrene itself shows fluorescence made it necessary to apply a slight correction. The fluorescence of pyrene in very dilute solutions [12] lies mainly in the ultraviolet but extends into the visible with decreasing intensity. The magnitude of the correction was obtained from the observed fluorescence in the region 23 000—25 000 cm^{-1} where the acceptors themselves show no luminescence, as is evident from curves I.

The curves marked III represent the luminescence spectra of solutions containing both benzophenone and a low concentration of acceptor. The concentrations were such that only a small fraction (2—7 %) of the absorbed light went to the acceptor, the rest being absorbed by the benzophenone. Nevertheless, visual comparison showed that the luminescence intensity was much higher than that obtained when the acceptor was present alone in the same low concentration. This was confirmed by quantitative intensity measurements of biacetyl luminescence that will be presented in a later section (p. 60).

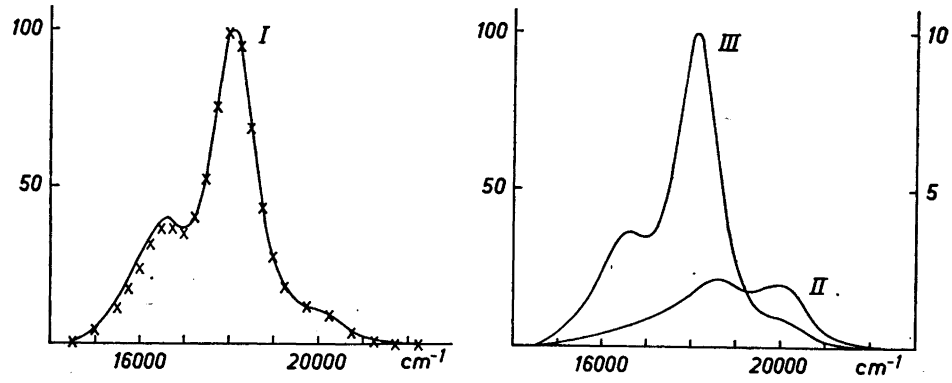

Fig. 6, a and *b*. Luminescence spectra of anisil. (I) Unsensitized luminescence. Anisil 6.9×10^{-3} M, observed values. (X) Calculated values. (II) Fluorescence (scale to the right). Anisil 1.27×10^{-2} M, pyrene 2.7×10^{-4} M. (III) Sensitized luminescence (scale to the left). Benzophenone 2.64×10^{-2} M, anisil 7.8×10^{-4} M.

There is thus no doubt that radiation absorbed by benzophenone gives rise to a sensitized luminescence of the acceptor. The spectrum of this luminescence differs from that obtained on direct excitation of the acceptor. Curve I for benzil shows a hump which coincides with the maximum in the fluorescence spectrum (curve II) and which is absent in curve III. Similarly curve I for biacetyl extends to higher wave-numbers than curve III. In the case of anisil the difference is less apparent which can be connected with the position and low intensity of its fluorescence. The conclusion seems inevitable that fluorescence is absent from the sensitized luminescence, which therefore represents pure phosphorescence. In agreement with this it is found that by multiplying the experimental intensity values for sensitized luminescence and for fluorescence by suitably chosen factors, one for each kind of luminescence, curves are obtained that, when added together, reproduce the directly excited luminescence (curve I) of the acceptor in question. In the figures, curves II and III have been drawn in this manner, and the result of the addition is represented by the crosses in Figs. 4a, 5a and 6a. By determining the areas under the curves it is found that the ratio between the quantum efficiencies of phosphorescence and of fluorescence under our experimental conditions was 20:1 for biacetyl, 4.0:1 for benzil, and 25:1 for anisil.

Obviously, very different values may be expected under other conditions. Thus it has been reported by Ermolaev [13], who studied the luminescence of different carbonyl compounds, including benzil, in solid solutions at −195°C, that their luminescence, within an error of 2—3 %, consisted entirely of long-lived radiation. For benzil he found a mean life of this radiation of 4.4×10^{-3} sec. Under our conditions it was only 7×10^{-5} sec, which shows that the phosphorescence yield had been reduced in the ratio of 60:1. The fluorescence yield, on the other hand, probably changes relatively little with temperature. Our results are therefore not incompatible with those of Ermolaev.

Table 1. Intensity of sensitized biacetyl phosphorescence in benzene solution at 20°C as a function of biacetyl concentration. Sensitizer: benzophenone, 1.65×10^{-2} mole/l.

[A] mole/l	I, scale divisions	τ_A μsec	τ_A/I observed	τ_A/I calculated
2.76×10^{-3}	90.5	489	5.40	5.35
2.73×10^{-4}	71.5	445	6.22	6.28
5.07×10^{-5}	39.5	440	11.1	10.8
2.39×10^{-5}	31.0	528	17.0	17.0
1.64×10^{-5}	21.1	440	20.9	22.4

For benzil and anisil, phosphorescence in fluid solution has not been reported previously. The following values of the phosphorescence mean life were determined as described earlier [1]: Benzil in benzene, 5.9×10^{-3} M, $\tau = 71$ μsec, benzil in carbon tetrachloride, 4.7×10^{-3} M, $\tau = 141$ μsec, anisil in benzene, 1.4×10^{-3} M, $\tau = 60$ μsec.

The intensity of sensitized phosphorescence as a function of the acceptor concentration. The triplet state lifetime of the sensitizer

With benzophenone as sensitizer and biacetyl as acceptor, the intensity of the sensitized phosphorescence was studied as a function of the acceptor concentration, using the method described above. In one series of measurements the solvent was benzene, in two others, *iso*propanol. In each series the voltage applied to the photomultiplier tube was adjusted so that the fluorescence of the uranyl glass always gave the same photocurrent. The phosphorescence photocurrents observed were therefore directly comparable. Before a measurement the solution was brought to the desired temperature. For every solution the phosphorescence mean life was determined at 20°C.

The results for benzene solutions at 20°C are given in Table 1, those for *iso*propanol solutions at 20 and 25°C in Fig. 7. They can be accounted for on the following reaction scheme. In addition to the processes indicated in the energy level diagram, Fig. 2, the scheme includes possible chemical reactions with the solvent (L) (steps 3 and 7).

$$D_S + h\nu \rightarrow D_{S'} \rightarrow D_T \quad (1)$$

$$D_T \rightarrow D_S \text{ (radiationless deactivation)} \quad (2)$$

$$D_T + L \rightarrow \text{Reaction products} \quad (3)$$

$$D_T + A_S \rightarrow D_S + A_T \quad (4)$$

$$A_T \rightarrow A_S + h\nu' \text{ (phosphorescence)} \quad (5)$$

$$A_T \rightarrow A_S \text{ (radiationless deactivation)} \quad (6)$$

$$A_T + L \rightarrow \text{Reaction products} \quad (7)$$

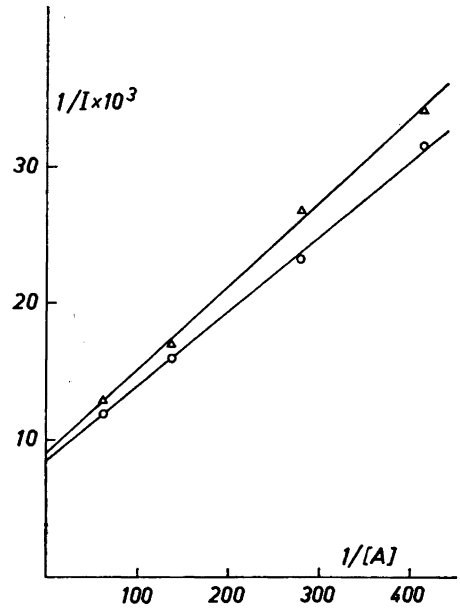

Fig. 7. Sensitized phosphorescence of biacetyl in *iso*propanol solution, $1/I$ *vs.* $1/[A]$. I = phosphorescence intensity in scale divisions, [A] = biacetyl concentration in mole/l. Sensitizer benzophenone, 3.74×10^{-3} M. ⊙ 20°C, △ 25°C.

The assumption that, in the case of benzophenone, step (1) has a quantum efficiency = 1, seems to be supported by all known facts *. Triplet state acceptor molecules will then be formed with the quantum efficiency

$$\varphi_4 = \frac{k_4[A_S]}{k_2 + k_3[L] + k_4[A_S]}$$

The probability for radiative transition of A_T to the ground state is equal to

$$\frac{k_5}{k_5 + k_6 + k_7[L]}$$

The quantum efficiency of phosphorescence therefore becomes

$$\varphi_5 = \frac{k_4[A_S]}{k_2 + k_3[L] + k_4[A_S]} \cdot \frac{k_5}{k_5 + k_6 + k_7[L]}$$

The natural mean lifetime of the acceptor in its triplet state, τ_A^N, its mean lifetime in the solution, τ_A, and the triplet state lifetime of the donor in the absence of acceptor, τ_D°, are given by:

$$\tau_A^N = \frac{1}{k_5}; \quad \tau_A = \frac{1}{k_5 + k_6 + k_7[L]}; \quad \tau_D^\circ = \frac{1}{k_2 + k_3[L]}$$

$$\text{Hence: } \frac{1}{\varphi_5} = \frac{\tau_A^N}{\tau_A}\left(1 + \frac{1}{k_4[A]\tau_D^\circ}\right) \tag{8}$$

where [A] denotes the concentration of the acceptor.

* For a discussion of this point, see Bäckström, H. L. J., Steneryr, A. and Perlmann, P. *This Journal* 12 (1958) 8.

Provided that the experimental conditions are such that the photocurrent (I) may be assumed to be proportional to φ_5, the following relations should hold: $I = a\varphi_5$, where a is a constant, and

$$\frac{\tau_A}{I} = K\left(1 + \frac{1}{k_4[A]\tau_D^\circ}\right), \text{ where } K = \frac{\tau_A^N}{a}$$

The values of τ_A/I given in the last column of Table 1 were calculated from a formula of this type, namely,

$$\frac{\tau_A}{I} = 5.25\left(1 + \frac{1}{1.87 \times 10^4[A]}\right)$$

The high value of the mean lifetime of triplet state biacetyl in benzene solutions makes it very susceptible to deactivation by impurities accidentally present. This is probably the explanation of the variations in τ_A in Table 1. It may easily be shown that eqn (8) should be valid also if a deactivation of this kind is included in the reaction scheme. The necessary condition is only that the impurity should not change the value of τ_D°. However, the much shorter lifetime of benzophenone in its triplet state makes it much less susceptible to deactivating influences.

In *iso*propanol solutions the lifetime of biacetyl in its triplet state is considerably reduced by reaction with the solvent (step 7). Within limits of error the same value of τ_A was found in all cases (21 μsec at 20°C). The results of the intensity measurements are given in graphical form in Fig. 7, $1/I$ being plotted against 1/[A]. The straight lines correspond to the formulas

$$\frac{1}{I} = 8.43 \times 10^{-3}\left(1 + \frac{1}{153\,[A]}\right) \text{ at } 20°C, \text{ and}$$

$$\frac{1}{I} = 9.02 \times 10^{-3}\left(1 + \frac{1}{147\,[A]}\right) \text{ at } 25°C.$$

The reaction scheme rests on the assumption that the light is absorbed exclusively by the sensitizer. This was very nearly the case in the benzene experiments, but less so in the *iso*propanol experiments where the lower value of τ_D° made it necessary to use higher biacetyl concentrations. However, the fraction of the light absorbed by the biacetyl never exceeded 5 %.

Step 4 is a transfer of triplet state energy. The triplet level of biacetyl is 4 000 cm^{-1} lower than that of benzophenone, corresponding to an energy difference of $>$ 11 kcal/mole. The results on phosphorescence quenching given in Ref.[1], Table 2, indicate that this energy difference is sufficient to make the process diffusion controlled, and this is confirmed by later results. The rate constant may therefore be estimated by a formula derived by Debye [14] on the assumption that the molecules may be regarded as spheres. If the molecular diameters of the reacting species are assumed equal the result is:

$$k = \frac{8RT}{3\,000\,\eta} \text{ l mole}^{-1} \text{ sec}^{-1}$$

where η is the viscosity in dyne-sec/cm^2 and $R = 8.31 \times 10^7$ erg/°K. This simplified form of the equation is the one generally used. However, if the diameters (d_1 and d_2) are not equal the result should be multiplied by a factor

$$\frac{1}{4}\left(2 + \frac{d_1}{d_2} + \frac{d_2}{d_1}\right)$$

For benzene solutions at 20°C the simplified formula gives 1.0×10^{10} l mole^{-1} sec^{-1}. Our results in this solvent thus indicate a mean life of benzophenone in its triplet state of about 1.9×10^{-6} sec. The results of the low-temperature work of Gilmore, Gibson, and McClure [7], mentioned on p. 52, show that the natural lifetime is about 0.01 sec. Accordingly the phosphorescence yield under our experimental conditions must have been about 0.02 %. A weak blue luminescence could be seen when an oxygen-free solution of benzophenone in benzene was irradiated with light of wavelength 366 mμ. As was to be expected [15], saturation of the solution with air caused a marked reduction in luminescence intensity.

As regards the measurements in *iso*propanol solution, some results of Forster [16] point to a possible source of error. In a study of the visible absorption spectrum of biacetyl he found that the extinction coefficients of solutions in certain alcohols decrease with time and approach an equilibrium value while the spectral shape is unchanged. This indicates a reaction with the solvent, leading to the formation of a colourless reaction product. In agreement with this we found that the extinctions of a solution of biacetyl in *iso*propanol at wavelengths in the visible and near ultraviolet decreased with time whereas their ratio remained unchanged. At the same time the extinctions at shorter wavelengths ($<$330 mμ) increased. However, the reaction was so slow that the decrease in concentration of unchanged biacetyl during the time required for a measurement of the intensity of sensitized phosphorescence (about 2 h) was of the order of 1 %.

For solutions in *iso*propanol, the rate constant given by the simplified Debye formula is 2.7×10^9 l mole^{-1} sec^{-1} at 20°C and 3.2×10^9 l mole^{-1} sec^{-1} at 25°C. With these values for k_4 the experimental results at the two temperatures give 5.7×10^{-8} sec and 4.6×10^{-8} sec, respectively, for the triplet state lifetime (τ_D°) of benzophenone in *iso*propanol solution. An independent value of the same quantity at 25°C has previously been obtained by an entirely different method [15]. A study of the retarding effect of nitric oxide on the photochemical reaction between nitric oxide and *iso*propanol, sensitized by benzophenone, yielded a value of 252 for the product $k \times \tau^\circ$, where k is the rate constant for the deactivation of excited benzophenone molecules in their triplet state by nitric oxide. There is reason to believe that this is also a diffusion controlled process [15]. Assuming $k = 3.2 \times 10^9$ l mole^{-1} sec^{-1}, τ° becomes 7.9×10^{-8}sec. However, this is a case where the molecules taking part in the diffusion controlled process are very different in size. According to the complete Debye formula this leads to an increase in the rate constant and a corresponding decrease in the calculated value of τ°. Since the molecules are far from spherical it is not possible to calculate the magnitude of this effect. The conclusion seems justified, however, that the results of the two determinations of τ° agree within the probable limits of error. This agreement furnishes a very

direct proof that the biradical state of benzophenone appearing as an intermediate in its photochemical reactions is identical with the triplet state responsible for its phosphorescence at low temperatures [15].

Comparison of the values of τ_D° in benzene and in *iso*propanol shows that the latter value is determined almost entirely by the reaction with the solvent (step 3). The same is true of τ_A in *iso*propanol (21 μsec). Hence $k_3/k_7 \sim 350$, *i.e.*, biacetyl in the triplet state reacts much more slowly with *iso*propanol than does benzophenone.

Intensity measurements on sensitized and unsensitized phosphorescence

The following experiments were made in order to demonstrate the existence of sensitized phosphorescence by intensity measurements, and to compare the quantum efficiencies of sensitized and unsensitized phosphorescence in the case of biacetyl. The sensitizer was benzophenone, the solvent benzene. The experimental arrangements were the same as in the previous section.

1. A 3.07×10^{-3} M solution of biacetyl, with a calculated light absorption at 366 mμ of 12.0 %, gave a galvanometer deflection of 11.5 scale divisions. The phosphorescence decay rate corresponded to a triplet state lifetime of 796 μsec.

2. 3.46×10^{-3} M biacetyl + 7.74×10^{-3} M benzophenone. Calculated total light absorption 99.3 %, 2.9 % absorbed by biacetyl and the rest by benzophenone. Galvanometer deflection 98.0 scale divisions, $\tau = 756$ μsec.

Obviously most of the luminescence in this case must be sensitized phosphorescence.

3. A 0.1226 M solution of biacetyl gave an extinction at 366 mμ of 0.515, corresponding to a light absorption of 99.1 % in a layer thickness of 4 cm. It gave a galvanometer deflection of 21.0 scale divisions, and $\tau = 154$ μsec. The low value of τ is due to the high concentration ("self-quenching") [1].

In experiments 2 and 3, the solutions had very nearly the same extinctions. The galvanometer deflections observed may therefore be assumed to be strictly proportional to the phosphorescence yields.

As will appear from the following, no appreciable error is introduced if the phosphorescence observed in experiment 2 is assumed to be entirely sensitized. Its quantum yield (φ_2) will then be given by eqn (8). As regards the quantum yield in experiment 3 (φ_3), it follows from the reaction scheme that

$$\varphi_3 = \frac{(\tau_A)_3}{\tau_A^N} \cdot P$$

where P denotes the probability under our experimental conditions for the internal conversion of singlet excited biacetyl to the triplet state (*Cf.* Fig. 3). With the value of $k_4\tau_D^\circ$ found above in benzene solution, 1.87×10^4 l mole^{-1}, and with [A] = 3.46×10^{-3} mole/l, the factor within parentheses in eqn (8) becomes 1.015. Hence

$$P = \frac{756}{154} \times \frac{21.0}{98.0} \times \frac{1}{1.015} = 1.04$$

Experiments 2 and 3 were repeated under almost identical conditions but with a fresh sample of biacetyl. The resulting value of P was 1.10.

These results indicate that when biacetyl is excited by light absorption in solution, the internal conversion to the triplet state is practically complete. The fraction of the singlet excited biacetyl molecules returning to the ground state with the emission of fluorescence may be estimated at about 0.22 %. This figure is based on the ratio between phosphorescence and fluorescence found above (p. 55) for a 0.222 M solution, an estimate of the triplet state lifetime in that solution (100 ± 10 μsec), and assuming the natural lifetime to be equal to the phosphorescence lifetime, 2.25×10^{-3} sec, in a solid solution at 77°K [17].

The phosphorescence quantum yield of biacetyl in the vapour state at 27°C has been determined by Almy and Gillette [18]. When the wavelength of the exciting light is 366 mμ the phosphorescence yield rises with pressure, apparently from zero at zero pressure, and seems to approach a value almost as great as that obtained when the mercury lines at 405 or 436 mμ are used as exciting light. This value, 0.145 ± 0.030, is nearly constant in the pressure range investigated (2—45 mm).

Under the same conditions the integrated intensity ratio of phosphorescence to fluorescence has been found by Okabe and Noyes [19] to be 58.4 ± 2.5:1, independent of pressure and incident wavelength. Recalculated to relative numbers of quanta the ratio becomes 64:1, giving a fluorescence quantum yield of $0.145/64 = 0.23$ %, *i.e.* within limits of error the same value as in solution. This indicates that the yield of fluorescence from the low lying vibrational levels of the excited singlet state is determined entirely by the relative rates of light emission and of internal conversion to the triplet state, and that the latter rate is not affected by the presence of the solvent. (*Cf.* Ref.[17], p. 906).

On this basis the efficiency of the internal conversion to the triplet state from the low lying vibrational levels of the excited singlet state should be 99.8 % both in the vapour and in solution. Since the phosphorescence lifetime of biacetyl in the vapour state at 25°C has been found [20] to be 1.80×10^{-3} sec, whereas the natural lifetime may be assumed [17] to be about 2.25×10^{-3} sec, the phosphorescence yield observed by Almy and Gillette corresponds to a conversion efficiency of only about 20 %. This must be due to a radiationless process which originates in the higher vibrational levels of the triplet state and which will therefore be suppressed in solution, where the excess vibrational energy is rapidly removed by collisions with solvent molecules. On the other hand, the process must be sufficiently rapid to compete with collisional deactivation in a gas at low pressures. Dissociation may be excluded as a possibility both on the basis of the photochemical data [21] and because the available energy, 64 kcal/mole, is too low. Probably, therefore, the explanation of the discrepancy is the occurrence of radiationless transitions to the ground state. The theoretical treatment of such processes [22] has shown that they are possible only if the two electronic states differ in some essential way, for instance in multiplicity, as in the present case. Furthermore they may be expected to be favoured by atomic oscillations that cause the molecule to become distorted.

Characterization of Hog Intestinal Invertase as a Glucosido-Invertase

III. Specificity of Purified Invertase

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The specificity of purified hog intestinal invertase has been studied.

Hog intestinal invertase, purified by mutual displacement chromatography on TEAE-cellulose, hydrolyzed *sucrose* and *turanose* (3-(α-D-glucopyranosyl)-D-fructose). Heat inactivation and inhibition experiments indicated that a single enzyme in this preparation hydrolyzed both sucrose and turanose.

Maltose was also hydrolyzed by the purified hog intestinal invertase. Maltose and sucrose inhibited the hydrolysis of each other competitively, and the values of K_i for maltose and sucrose as inhibitors for each other agreed with the values of K_s for each sugar as substrate, indicating the hydrolysis of each of these sugars by the same enzyme.

The purified invertase, however, is responsible for only 1/2 of the total turanase activity and 1/3 of the total maltase activity of crude hog intestinal glycosidase preparations.

Melezitose (α-D-glucopyranosyl (1→3) β-D-fructofuranosyl-(2→1)α-D-glucopyranoside) was *not* hydrolyzed by the purified enzyme preparation. Crude hog intestinal glycosidase preparations have melezitase activity caused by two other α-D-glucopyranosidases, but these enzymes have no invertase activity.

The characterization of hog intestinal invertase as a *glucosido-invertase* (α-D-glucopyranosidase) was recently confirmed by a study of the transglycosylation catalyzed by this enzyme [1]. It may therefore be expected that hog intestinal invertase should hydrolyze, in addition to sucrose, a number of other α-D-glucopyranosides, *e.g. maltose*, *isomaltose* (6-(α-D-glucopyranosyl)-D-glucose), *trehalose* (1-(α-D-glucopyranosyl)-α-D-glucopyranoside), *melezitose* (α-D-glucopyranosyl (1 → 3) β-D-fructofuranosyl (2 → 1) α-D-glucopyranoside), *turanose* (3-(α-D-glucopyranosyl)-D-fructose), *phenyl-α-D-glucopyranoside*, or *methyl-α-D-glucopyranoside*.

Methyl-α-D-glucopyranoside is *not* hydrolyzed by crude hog intestinal preparations [2,3], and is therefore *not* a substrate for hog intestinal invertase.

The hydrolysis of *melezitose* and *turanose* by crude hog intestinal preparations has been reported previously [4]. Since the preparation used contained several different α-D-glucopyranosidases [5-10], however, these findings do *not* prove that melezitose and turanose are hydrolyzed by intestinal *invertase*.

Hog intestinal invertase was recently purified by ion exchange chromatography, and was then separated from all the *trehalase*, *isomaltase* and *phenyl-α-D-glucopyranosidase* activity of the original preparation [5,8,9]. These glucosides are therefore not substrates for hog intestinal invertase. The invertase was also separated from 2/3 of the *maltase* activity of the original preparation [6,7,9]. However, 1/3 of the original maltase activity accompanied the invertase activity during its purification, and was not separable from the invertase activity by heat inactivation at varying pH-values or by ion exchange chromatography [6,7]. The question therefore arises, if this part of the maltase activity is caused by the same enzyme as the invertase activity.

In the present paper will be reported a study of the specificity of purified intestinal invertase. The aim the study was to answer the following two questions:

1) Is the hydrolysis of *melezitose* and *turanose* by crude hog intestinal preparations caused by the same enzyme as is responsible for the invertase activity?

2) Is that part of the *maltase* activity (= 1/3 of the total maltase activity), which it was not possible to separate from the invertase activity, caused by the same enzyme as the invertase activity?

MATERIALS AND METHODS

Enzyme preparations

Purified hog intestinal invertase was obtained by mutual displacement chromatography upon TEAE-cellulose [7]. The preparation had maltase activity which was 0.6 times the invertase activity, and was identical with the *purified hog intestinal maltase I* described in previous papers [7,9]. The specific invertase activity of the preparation was 292 units per mg of protein. One unit of glycosidase activity is the activity which causes 1 % of hydrolysis in 2 ml of reaction mixture in 1 h at 37°C under the conditions used.

Purified hog intestinal maltase II and *purified hog intestinal maltase III* were the same preparations as have been described in previous papers [7,9]. The specific maltase activity of these preparations was 100 and 200 units per mg of protein, respectively. These two maltase preparations had no invertase activity [9].

Crude hog intestinal glycosidase preparation was obtained as described earlier [5]. This preparation contained all the hog intestinal glycosidase activities observed earlier [4-10]. The specific invertase activity of the crude preparation was 20 units per mg of protein. The maltase activity of the crude preparation was 2 times the invertase activity, and it contained maltase I, II, and III in about equal proportions, expressed as number of units per ml.

Substrates

Sucrose, cryst., was obtained from J. T. Baker Co. *Maltose* (monohydrate), cryst., was obtained from Merck A.G. (Germany). Since the commercial maltose was found to contain contaminating sugars, which moved slower than maltose in paper chromatography (higher homologues), it was purified on carbon-celite columns [1,7]. The product was chromatographically pure. *Melezitose* (dihydrate) was obtained from Pfanstiehl Chemical Co., and *turanose* from Nutritional Biochemicals Corporation. All substrates used were chromatographically homogenous.

Activity determination

Determination of glycosidase activity was performed at 0.1388 M substrate concentration in the presence of 0.05 M maleate buffer pH 6.5. The degree of hydrolysis of the different substrates was determined with the methods described earlier [4,7]. (In order to spare enzyme, the 3,5-dinitrosalicylic acid method in some cases was replaced by the more sensitive Somogyi-Nelson method [4] for the determination of the hydrolysis of melezitose. The values obtained by these two methods agreed very well.)

Determination of the hydrolysis of sucrose and maltose in mixture. For the separate determination of the hydrolysis of sucrose and maltose, when the reaction solution contained these two substrates *in mixture*, it was necessary to determine the amounts of glucose and fructose liberated by quantitative paper chromatography. One molecule of sucrose hydrolyzed liberates one molecule of fructose and one molecule of glucose. One molecule of maltose hydrolyzed liberates two molecules of glucose. The number of sucrose and maltose molecules, respectively, which are hydrolyzed in a mixture of these two substrates therefore may be calculated.

The quantitative determination of glucose and fructose on paper chromatograms was performed with 5 μl spots of the reaction mixture as described earlier [1].

RESULTS AND DISCUSSION

Invertase activity

The invertase activity of the purified hog intestinal invertase preparation had the same characteristics as that of a crude hog intestinal glycosidase preparation. The optimum pH was 6.5 (Fig. 3) in accordance with that for a crude preparation [4]. The K_s was determined at 2.6×10^{-2}, which may be compared with the value 2.5×10^{-2} obtained for a crude preparation [4]. It has been demonstrated earlier that the K_s value for the invertase activity was the

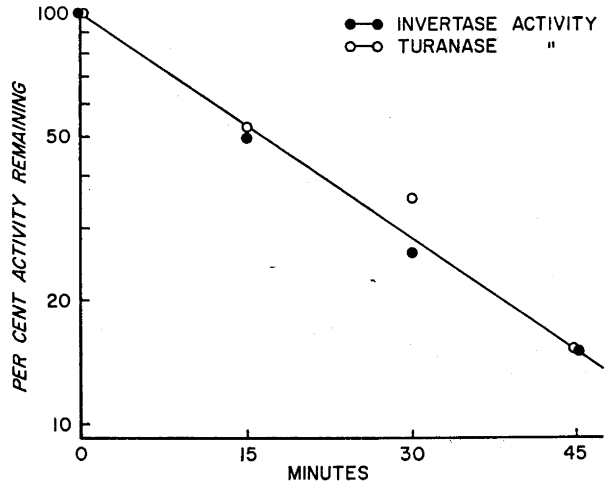

Fig 1. Heat inactivation of purified hog intestinal invertase in 0.01 M phosphate buffer pH 6.0 at 48°C. The solution contained 305 units/ml of invertase, 23 units/ml of turanase and 1.05 mg/ml of protein. The inactivation of the invertase and turanase activities ran parallel.

Table 1. Action of purified hog intestinal invertase upon sucrose and turanose alone and in mixture. The reaction mixture contained 0.01 mg/ml of protein. After incubation at 37°C for 1 h, the amount of glucose liberated was determined with glucose oxidase [4].

Concentration of substrate	Mg of glucose produced in 2 ml of reaction mixture
0.10 M sucrose	3.2
0.05 M sucrose	2.5
0.10 M turanose	<0.5
0.05 M turanose	<0.5
0.05 M sucrose +0.05 M turanose	1.4

same in different fractions of the single invertase peak obtained by anion exchange chromatography of a solubilized hog intestinal glycosidase preparation [7]. These facts indicate that the invertase activity of hog intestinal glycosidase preparations is exerted by one single enzyme.

Turanase activity

The purified invertase preparation had turanase activity which was 7.5 % of the invertase activity, whereas a crude hog intestinal glycosidase preparation had turanase activity which was 15 % of the invertase activity [4].

The K_s for the turanase activity of the purified invertase preparation was determined at 1.0×10^{-2}, which is lower than the value obtained [4] with a crude glycosidase preparation (2.8×10^{-2}). When the purified invertase was inactivated at 48°C in the presence of 0.01 M phosphate buffer pH 6.0, the inactivation of the turanase activity ran completely parallel with the inactivation of the invertase activity (Fig. 1), which supports the theory that the invertase and turanase activities of this fraction are caused by the same enzyme. This theory was also supported by the fact that the amount of monosaccharides produced by a certain amount of the enzyme acting upon the two substrates *in mixture* was less than the sum of the amounts of monosaccharides produced when the same amount of enzyme in separate experiments was acting upon each substrate alone (Table 1).*

* In a later experiment the inhibition of the hydrolysis of a series of sucrose solutions (0.025—0.100 M) by the presence of turanose (0.025 M) was determined. The amount of glucose liberated in the reaction mixtures was determined with glucose oxidase as described earlier for turanose [4]. Since turanose is hydrolyzed considerably slower than sucrose, the approximation was made that all the glucose liberated was produced from sucrose. (This approximation will cause the K_i value measured to be somewhat *too high*. From the relative rates of hydrolysis of turanose and sucrose and the K_s values for these activities the error to be expected was calculated at about 1/3 of the K_i value). It was found that turanose inhibited the hydrolysis of sucrose *competitively* and K_i for turanose as inhibitor was calculated at 1.2×10^{-2} which accords with the K_s value for the hydrolysis of turanose. This strongly supports the theory that sucrose and turanose are hydrolyzed by the same enzyme in the preparation studied. (For definitions and calculations see the experiments with sucrose and maltose described below.).

The remainder of the turanase activity of the crude glycosidase preparation appeared to be present in the *maltase II* and *maltase III* fractions [9]. The turanase activity of these fractions showed the same heat inactivation patterns as did the maltase activity [6,9]. At 72°C, the inactivation of the turanase activity of the maltase III preparation ran parallel to that of the maltase activity (Fig. 2). The turanase activity was 4 % of the maltase activity for maltase II and 6 % for maltase III. This means that the turanase activity of a crude preparation [4] quantitatively fits very well with the sum of the turanase activities of the invertase (= maltase I), maltase II and maltase III in the crude preparation. (In the calculation it is assumed that the activities of the maltase I, II and III in the crude preparation were equal, and that the maltase/invertase activity quotient was 2.0.)

Melezitase activity

The purified invertase had *no measurable melezitase activity.* With the conditions used, this means that the amount of monosaccharides produced from melezitose was less than 0.05 % of that produced from sucrose. All of the melezitase activity of the crude preparation [4] could be shown to reside in the maltase II and maltase III fractions.

The purified *maltase III* hydrolyzed melezitose *to glucose and sucrose* as demonstrated by paper chromatography. Only the turanose link of the trisaccharide was hydrolyzed. *Maltase II*, too, had some melezitase activity (with glucose and sucrose as the hydrolysis products), but this activity was weaker in relation to the maltase activity than that of maltase III. The melezitase activities followed the same heat inactivation patterns as did the maltase activities [9] of these two fractions. At 72°C the inactivation of the melezitase activity of a maltase III preparation ran parallel with that of the maltase activity (Fig. 2). The melezitase activity * was 0.1 % of the maltase activity for maltase II and 0.4 % for maltase III. With the same assumptions as made above in calculating the turanase activity, these enzymes would cause a melezitase activity of the crude preparation 0.17 % of the (total) maltase activity, which is somewhat higher than the value obtained, 0.10 % **, in earlier experiments [4]. Maltase II and III, therefore, are the only

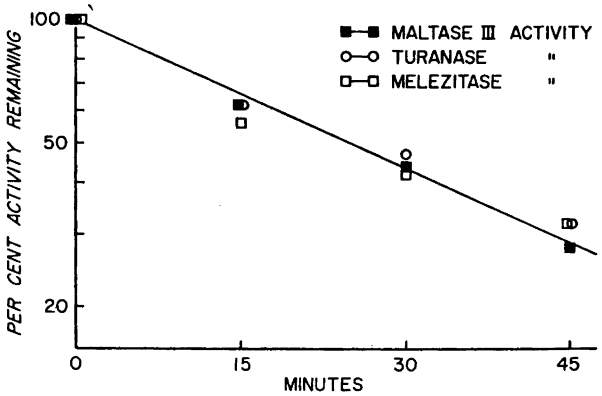

Fig. 2. Inactivation of a purified hog intestinal maltase III preparation at 72°C in the presence of 0.01 M phosphate buffer pH 6.0. The solution contained 235 units/ml of maltase III, 14 units/ml of turanase, 0.9 units/ml of melezitase and 1.18 mg/ml of protein. The inactivation of the maltase, turanase and melezitase activities ran parallel.

* Calculated as number of melezitose molecules hydrolyzed to glucose and sucrose, compared with the number of maltose molecules hydrolyzed by the same amount of enzyme.

** Calculated as number of melezitose molecules *completely* hydrolyzed [4].

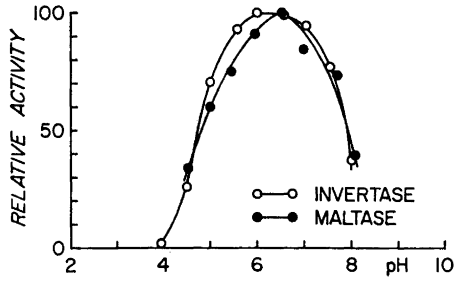

Fig. 3. pH activity curves for the invertase and maltase (I) activities of a purified hog intestinal invertase preparation. Temperature 37°C, 0.1388 M substrate concentration. Buffers: 0.05 M acetate pH 4.0—5.0, 0.05 M maleate pH 5.5—6.5, 0.025 M veronal pH 7.0—8.0. pH was measured with a glass electrode.

enzymes in crude hog intestinal glycosidase preparations which hydrolyze melezitose. When a crude glycosidase preparation was heated at 60°C, in the presence of 0.01 M phosphate buffer pH 6.0, the amount of reducing sugars produced from melezitose per time unit decreased by 70 % within 30 min but was then not further diminished. After heating, the invertase (= maltase I) and maltase II (containing weak melezitase activity) are inactivated, but maltase III (containing the majority of melezitase activity) remains unaffected. This marked decrease in the amount of reducing sugars liberated from melezitose is chiefly caused by the inactivation of *invertase*. Although the invertase has no melezitase activity *per se*, it hydrolyzes the sucrose formed from melezitose hydrolysis to two molecules of reducing sugar. In the absence of invertase, melezitose is hydrolyzed by maltase III only to glucose and sucrose, and one molecule, rather than three, of reducing sugar is released for each melezitose molecule hydrolyzed.

Maltase activity

The purified hog intestinal invertase preparation had maltase activity (= maltase I) which was 0.6 times the invertase activity. This activity represents 1/3 of the total maltase activity of crude preparations. Attempts to separate the maltase (I) activity of the purified invertase preparation from the invertase activity were not sucessful. With rechromatography on ion exchange columns the two activities formed a homogenous peak [6]. When the preparation was exposed to heat, the two activities were inactivated completely similarly, even when such experiments were performed in a series of buffers of varying pH [6]. In frontal analysis the maltase I and invertase activities appeared as one common, homogeneous front [7], and they were not separable by mutual displacement chromatography [7]. The pH activity curve of the maltase I activity was similar to that of the invertase activity (Fig. 3) but differed from those of the maltase II and III activities [9].

All these facts support the theory, that the maltase I activity is caused by same enzyme as the invertase activity. The ability to independently determine the hydrolysis of sucrose and maltose, by quantitative paper chromatography of the hydrolysis products, when these two substrates are mixed with each other, offers one additional method for proving the identity of the maltase I

and invertase activities. If one enzyme catalyzes the hydrolysis of two different substrates, these two substrates must act as competitive inhibitors for each other. The invertase activity should be competitively inhibited by maltose, and the maltase I activity competitively inhibited by sucrose. In addition the inhibitor constant (K_i) for maltose as a competitive inhibitor for the invertase must have the same value as the substrate constant (K_s) for maltose as substrate for maltase I, and vice-versa, if it possible to ascribe the invertase and maltase I activities to the same enzyme.

Definitions. K_s = the dissociation constant for the enzyme-substrate complex (Michaeli's constant). K_s is measured as the substrate concentration at which the initial velocity of reaction is half of the V_{max} (provided no (competitive) inhibitor is present) *.

K_i = the dissociation constant for the enzyme-inhibitor complex. When the inhibition is *competitive*, K_i is calculated from the influence of the presence of the inhibitor upon the *apparent* K_s value for the substrate.

v = the measured initial velocity for the hydrolysis of the substrate.

V_{max} = the initial velocity for the hydrolysis of the substrate when the enzyme is 100 % saturated with substrate.

[s] = the substrate concentration
[i] = the inhibitor concentration.

The constants were obtained graphically by the method of Lineweaver and Burk [11] as modified by Dixon [12,13] (Fig. 4).

Experimental conditions. The reaction mixture contained 0.05 M maleate buffer pH 6.5, and the incubation of the substrate with the enzyme was performed for 60 min at 37°C. After this time the reaction was interrupted by boiling in a water-bath for 2 min.

The enzyme used was the purified invertase preparation. The substrate concentration varied within the range of 0.10—0.01 M, and the inhibitor concentration was 0.0139 or 0.0278 M in the experiments where inhibitor was present. In each experiment the hydrolysis at a series of different substrate concentrations was measured, at a constant concentration of inhibitor. The degree of hydrolysis was never allowed to exceed 20 % at the lowest substrate concentration used in the experiment. The quantitative determination of glucose and fructose, after elution from the paper chromatograms, was made with amounts of 1—8 μg.

It is essential for the accuracy of the results that no transglycosylation [1] occurs. In the experiments with sucrose as substrate, without maltose present, there was no measurable difference between the amount of glucose and the amount of fructose liberated, and this demonstrates that no transglycosylation occurs at the substrate concentrations used.

Inhibition of invertase activity. In one series of experiments *sucrose* was used as *substrate*. One such experiment is illustrated in Fig. 4. Without inhibitor present, the K_s for the invertase activity was determined at 2×10^{-2}

* Measured in this way, the K_s is not the true dissociation constant for the enzyme-substrate complex, but with most enzymes it has probably approximately the same value [13].

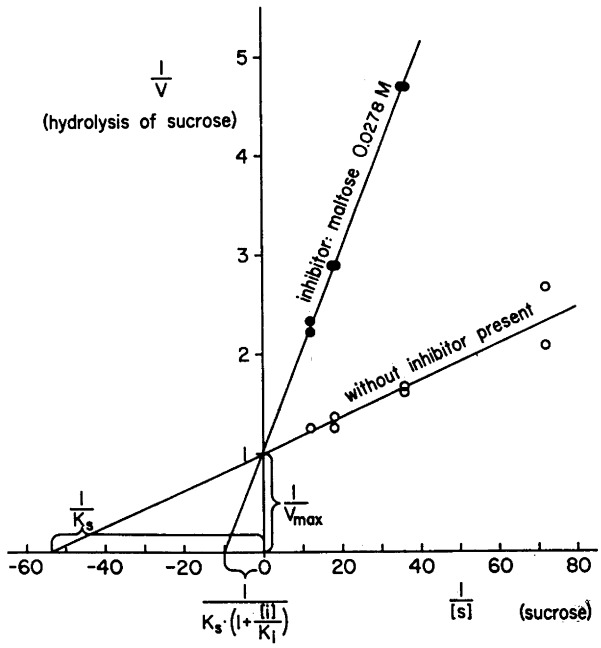

Fig. 4. Inhibition of the invertase activity of a purified hog intestinal invertase preparation by maltose. The V_{max} for the hydrolysis of *sucrose* was unaltered by the addition of inhibitor (maltose) which demonstrates that the inhibition was *competitive*. The K_s (for sucrose) and the K_i (for maltose as inhibitor of the invertase activity) were calculated from the intercept with the abscissa as seen in the figure.

with the chromatographic method, which may be compared with the value 2.6×10^{-2} earlier obtained with the 3,5-dinitrosalicylic acid method [7]. Maltose was found to inhibit the invertase activity competitively with a K_i value at about 1×10^{-2}, which agrees with the value for K_s for maltase I obtained earlier (1.1×10^{-2}) with another method [7].

Inhibition of maltase I activity. In another series of experiments *maltose* was used as *substrate*. Without the presence of sucrose the K_s for the maltase I activity was determined at 1×10^{-2}. Sucrose inhibited the maltase I activity competitively with K_i at 2×10^{-2}, which agrees with the K_s value for the invertase activity obtained earlier.

These results clearly demonstrate that the *maltase I* activity, which represents one third of the total maltase activity of crude preparations, and which closely follows the *invertase* activity during its purification, is exerted by the same enzyme as the invertase activity.

Acknowledgment. The author's thanks are due to Professor Bengt Borgström for his interest in my work and for valuable discussions. This work has been supported by grants from the *Medical Faculty of the University of Lund.* The skillful technical assistance of Mrs. K. Hagebris is gratefully acknowledged.

Hog Intestinal Isomaltase Activity

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Homogenates of hog intestinal mucosa have *isomaltase* activity, caused by at least three different enzymes.

About 3/4 of the total isomaltase activity is caused by an enzyme (or enzymes) which seems to have mainly isomaltase activity. This enzyme has no invertase or maltase activity, but it possibly hydrolyzes phenyl-α-D-glucopyranoside. The name *specific isomaltase* is suggested for this enzyme.

The remainder of the isomaltase activity is caused by two hog intestinal maltases, which hydrolyze isomaltose slowly.

Separation of the specific isomaltase from the other hog intestinal α-D-glucopyranosidases was not successful. It could be stated, however, that the specific isomaltase has transglycosylase properties which clearly differ from those of the isomaltase activity accompanying the two maltases.

The influence of freezing and thawing upon the specific isomaltase activity is complex, and involves a decrease as well as an increase of this activity.

The hydrolysis of *isomaltose* (6-α(-D-glucopyranosyl)-D-glucose) by enzyme preparations from hog intestinal mucosa has recently been studied by Larner, Mc Nickle and Gillespie [1-7]. These authors postulated that isomaltose and maltose were hydrolyzed by two different enzymes in these preparations, although they were able to separate these two activities only partially. A hog intestinal maltase preparation was obtained, which had no demonstrable isomaltase activity, but the isomaltase activity* was never purified from maltase activity [3,6].

More recently, however, it has been demonstrated that hog intestinal *maltase* activity is not caused by a single enzyme, but can be separated into three different fractions (maltase I—III) with different enzymatic properties.[8-10] One of these fractions, maltase I, had no detectable isomaltase activity, while the other two, maltase II and III, hydrolyzed isomaltose slowly [10].

The present investigation was undertaken to elucidate further the relation between the *maltase* and *isomaltase* activities of hog intestinal mucosa.

* Larner *et al.* name this activity *oligo-1,6-glucosidase* (to distinguish it from *amylo*-1,6-glucosidase). It seems more logical to call it *isomaltase* activity in agreement with general nomenclature used for other glycosidase activities.

MATERIALS AND METHODS

Enzyme preparations

Crude hog intestinal glycosidase preparations. Pieces of hog small intestine were cut within a few minutes after slaughter and chilled with crushed ice during the transport to the laboratory. In some experiments the mucosa was scraped off (as done by Larner *et al.*[3]) and homogenized for 2 min in an "Ultra-Turrax" homogenizer with an equal volume of saline or buffer. In other experiments the mucosa was squeezed out manually and solubilized as described earlier [11]. Whichever procedure was used, the relation of the isomaltase activity to the invertase and maltase activity of the preparation obtained was the same.

Purified hog intestinal maltase II and purified hog intestinal maltase III were obtained by mutual displacement chromatography of solubilized hog intestinal glycosidase preparations as described earlier [9].

Substrates

Isomaltose (6-(α-D-glucopyranosyl)-D-glucose) was prepared by enzymatic hydrolysis of dextran as described by Jeanes *et al.*[12] *Dextran* (average molecular weight M_w (end group analysis) 17 600, M_n (light scattering) 40 400) was obtained as a gift from A. B. Pharmacia (Uppsala, Sweden). *Penicillium funiculosum* was obtained from Centraalbureau voor Schimmelkultures (Baarn, Nederland). The mold was cultured on a solution containing 2 % dextran and 3 % yeast extract (from Difco Lab., Detroit, Mich.) at room temp. for 9—10 days during shaking. The culture filtrate had dextranase activity of 18 units/ml (determined essentially as described by Tsuchiya *et al.*[13], but the amount of reducing sugar produced was measured with the 3,5-dinitrosalicylic acid reagent [17] instead of Somogyi's copper reagent).

For preparations of isomaltose 4 g of dextran was dissolved in 40 ml of water. To this solution was added 20 ml of 0.1 N acetate buffer pH 5.1, 20 ml of culture filtrate from *Penicillium funiculosum*, and 5 ml of toluene. After 23 h, at 37°C the reducing power of the solution corresponded to 77 % of hydrolysis to isomaltose. After removing toluene, the solution was boiled for a few minutes to interrupt the enzymatic hydrolysis. The solution was then poured onto a 9 × 25 cm carbon-celite column [14]. The glucose was eluted with 5 l of distilled water, and then the isomaltose was eluted with 5 l of 5 % (by vol.) ethanol. The isomaltose fraction was evaporated at reduced pressure to a volume of about 50 ml and then lyophilized (the sugar was markedly hygroscopic and crystallization was not successful). The powder obtained was dried *in vacuo* over P_2O_5 at 50°C. The yield was 1.75 g of chromatographically homogeneous sugar (when 1 mg of the sugar was run on a paper chromatogram it formed only one spot). The chromatographic mobility was somewhat lower than that of maltose, R_M value (mobility/mobility of maltose) 0.75 in ethyl acetate: acetic acid : water 9:2:2 (v/v). The molecular weight of the sugar was determined at 325 by cryoscopy (calcd. for $C_{12}H_{22}O_{11}$ 342.3). The optical rotation agreed well with that reported for isomaltose, measured $[\alpha]_D^{20}$ +117.5° (10 % in water), reported for isomaltose +122.0° [12], +103.2° (amorphous) [15], +120° (cryst.) [15]. Acetylation with sodium acetate as catalyst yielded the β-octaacetate (amorphous, in spite of several attempts crystallization was not achieved) which had $[\alpha]_D^{20}$ +97.5° (2 % in $CHCl_3$), reported for isomaltose-β-octaacetate +96.9° [12,16].

Phenyl-α-D-glucopyranoside was prepared as described earlier [10]. The other substrates used were commercial preparations of analytical grade purity [11].

Determination of glycosidase activity

The reaction mixture in all cases had 0.1388 M substrate concentration and contained 0.05 M maleate buffer pH 6.5 and small amount of toluene as preservative. The degree of hydrolysis was determined with the methods described earlier [9-10]. One unit of glycosidase activity is the amount which causes 1 % of hydrolysis in 2 ml of reaction mixture in 1 h at 37°C during these conditions. The degree of hydrolysis was not allowed to exceed 10 %.

The hydrolysis of isomaltose was determined with Tauber and Kleiner's acid copper reagent as described earlier for maltose [9]. Since isomaltose had stronger reducing power with this reagent than maltose, the sugar determination was made with 1.0 mg of isomaltose instead of 2.5 mg of maltose. The modified copper reagent (Caputto's reagent) which was used for K_s and optimum pH determinations with maltose could not be used for isomaltase determinations, because isomaltose, itself, reduced this reagent too strongly.

Adsorbents

Cellulose ion exchangers. DEAE-cellulose was prepared from Solkafloc cellulose powder SW 40 A by the method of Peterson and Sober [20]. The product contained 0.8 mequiv. titrable hydroxyl groups per gram dry weight. *TEAE-cellulose* was prepared from DEAE-cellulose by ethylation as described by Porath [21]. CM-cellulose was prepared from Whatman cellulose powder by the method of Peterson and Sober [20]. It contained 0.3 mequiv. titrable acid groups per gram dry weight.

Alumina Cγ-gel was prepared as described by Willstätter and Kraut [22]. The gel was stored, suspended in distilled water, for six months at room temperature before use. The amount of gel used in the experiments will be expressed as mg dry weight, determined after drying to constant weight at 100°C.

Calcium phosphate gel (for column chromatography) was prepared by the method of Tiselius et al.[23]

Paper chromatography of sugars was performed as described earlier [14].

RESULTS AND DISCUSSION

Freshley prepared homogenates of hog small intestinal mucosa hydrolyzed *isomaltose* with a rate which was 8—10 % of the rate for the hydrolysis of maltose. The relation between the isomaltase and maltase activities was the same in all parts of the small intestine. Some different α-D-glucopyranosidase activities of a representative homogenate from hog small intestine are recorded in Table 1.

The separation of several different hog intestinal α-D-glucopyranosidases has been reported previously [8–10,17]. Two of the different α-D-glucopyranosidases separated had *isomaltase* activity, namely maltase II and maltase III.

Table 1. Some α-D-glucopyranosidase activities of a freshly prepared homogenate (1:2 in saline) of hog intestinal mucosa. The protein content of the homogenate was 9.5 mg/ml.

	Units/ml
Invertase	32
Maltase (total)	62
Maltase I *	19
Maltase II	21
Maltase III **	22
Isomaltase	6.8
Phenyl-α-D-glucopyranosidase	3.6

* Calculated as 0.6 times the invertase activity [10].

** Determined after inactivation of maltase I and II by heat [9].

The rate for the hydrolysis of isomaltose by these fractions was 2 and 5 %, respectively, of the rate for the hydrolysis of maltose [10]. Since each of the maltase II and III contributes only 1/3 to the total maltase activity of crude preparations, the isomaltase activity of these purified maltase fractions can contribute only 1/4 of the total isomaltase activity of the crude preparation. The existence therein of a *specific hog intestinal isomaltase* therefore was postulated.

The question then arises, if the isomaltase activity of the purified maltase II and III preparations really is caused by these enzymes *per se*, or if is caused by contamination with the specific isomaltase.

In order to study the properties of the specific hog intestinal isomaltase, attempts were made to separate this enzyme from the other intestinal α-D-glucopyranosidases.

Solubilization. Like the other hog intestinal glycosidase activities, the isomaltase activity is localized to the microsome fraction, obtained by differential centrifugation [6,11]. Like the invertase and maltase activities, the isomaltase activity could be solubilized with trypsin (in the presence of phosphate buffer) and precipitated with ethanol in the same way as described earlier for the other activities [11], without losses of isomaltase activity.

It has been reported that hog intestinal isomaltase is inactivated by high speed centrifugation [6]. This, however, could not be verified. Even when homogenates of intestinal mucosa (in the presence of 0.01 M veronal buffer pH 7.5) were centrifuged at 100 000 × *g* for 3 h (Spinco preparative ultracentrifuge, rotor 40) no losses of isomaltase activity were recorded. All the activity was found in the sediment, when fresh homogenates were used, or in the supernatant, when solubilized preparations were used.

Ion exchange chromatography. Chromatography of the solubilized glycosidase preparations on DEAE-cellulose or TEAE-cellulose, which has earlier been used for the separation of the other hog intestinal α-D-glucopyranosidases [9,11], was associated with losses of more than 50 % of the isomaltase activity. When adsorption to TEAE-columns, however, was performed at +4°C and elution completed within 60 min, 90—100 % of the isomaltase activity was eluted with 0.07—0.15 M phosphate buffer (pH 6.0) together with the invertase and maltase activities. DEAE- and TEAE-cellulose, therefore, were not useful for the purification of hog intestinal iso-maltase.

Neither the isomaltase, invertase or maltase activities were adsorbed to CM-cellulose in 0.01 M phosphate buffer pH 6.5, although 50 % of the protein content of the glycosidase preparation was adsorbed.

Adsorption to alumina Cγ-gel. At pH 5.0 (in 0.02 M acetate buffer) the invertase, maltase and isomaltase activities were adsorbed to alumina Cγ-gel. When pH was increased, the activities were released all together, and at pH 6.0 (0.02 M phosphate buffer) no adsorption occured.

The influence of varying the amount of adsorbent in the presence of 0.02 M acetate buffer pH 5.0 was studied (Table 2). The activities investigated, however, showed no difference in their degree of adsorption during these conditions which was sufficiently great to be used for their separation.

Adsorption to calcium phosphate gel. This adsorbent was used in columns, as described by Tiselius *et al.*[23], and the experiments were performed in the

Table 2. Adsorption of intestinal α-D-glucopyranosidases on alumina Cγ-gel in 0.02 M acetate buffer, pH 5.0. The solution contained 0.8 mg/ml of protein, 10 units/ml of invertase, 21 units/ml of maltase, 2.5 units/ml of isomaltase and 0.9—7.2 mg/ml (dry weight) of alumina Cγ-gel. After shaking for 30 min at room temperatur, the solution was centrifuged and the supernatant analyzed.

Mg/ml of alumina C γ-gel	Per cent adsorbed			
	Protein	Invertase activity	Maltase activity	Isomaltase activity
0.9	35	40	23	40
1.8	53	83	65	75
3.6	66	96	90	95
7.2	70	100	96	95

presence of phosphate buffer pH 6.8. The invertase, maltase and isomaltase activities were weakly adsorbed to calcium phosphate, for the adsorption step it was necessary to use 0.001 M buffer. Whether gradient elution or step-wise elution was used, the invertase, maltase and isomaltase activities were eluted all together with 0.002—0.005 M buffer. Calcium phosphate is therefore no suitable adsorbent for the separation of these activities. (The trehalase activity, however, was not eluted until the buffer concentration exceeded 0.005 M, and was therefore separated from the other activities. The separation of hog intestinal trehalase on ion exchange columns has been reported earlier [11,17]).

Heat inactivation. The isomaltase activities of the purified maltase II and III preparations followed the same heat inactivation patterns as the maltase activities, *i.e.* that of the maltase II fraction was rapidly inactivated at 60°C, while that of the maltase III fraction was not inactivated at temperatures below 70°C (in presence of 0.01 M phosphate buffer pH 6.0) [10].

In one experiment, a crude solubilized glycosidase preparation, after dialysis against 0.01 M phosphate buffer pH 6.0, was heated at 60°C. The preparation had protein content 5.2 mg/ml and contained 38.5 units/ml of invertase, 97 units/ml of total maltase and 7.6 units/ml of isomaltase. During heating, all the invertase activity and 62 % of the total maltase activity were abolished within 20 min. The remaining 38 % of the maltase activity (*i.e.* maltase III [8]) was not affected during heating for 60 min. The isomaltase activity decreased by 74 % within 20 min. but was then not further diminished. Apparently the specific isomaltase was inactivated (together with the weak isomaltase activity of maltase II) within the first 20 min. The quotient between that isomaltase activity which survived heating and the maltase activity which was not abolished, fits well with the isomaltase/maltase activity quotient of a purified maltase III preparation [10].

Transglycosylation properties. The purified maltase II and maltase III as well as a crude glycosidase preparation, formed a number of oligosaccharide spots when acting in a concentrated (30 %*) isomaltose solution. The oligosaccharides formed by the crude preparation were, however, not identical with those formed by the purified maltase preparations.

* Per cent means g of solute per 100 ml of solution.

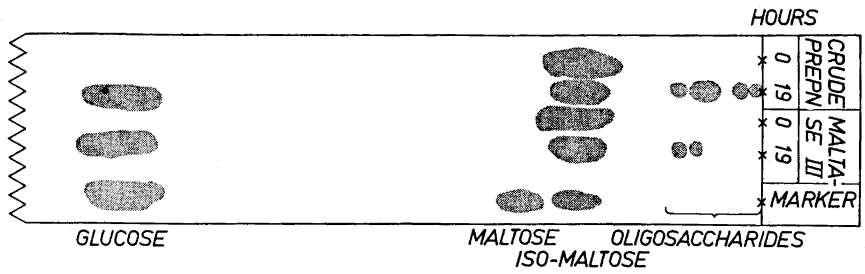

Fig. 1. Oliogosaccharides produced by transglycosylation by hog intestinal isomaltase. The *crude preparation* was a freshly prepared solubilized hog intestinal glycosidase preparation. In this case the reaction mixture contained 12 units of isomaltase, 108 units of (total) maltase and 15 mg of protein/ml. In the other case a *purified maltase III preparation* was used, and the reaction mixture contained 12 units of isomaltase, 263 units of maltase (III) and 1.5 mg of protein/ml. In both cases the reaction mixture containe 30 % isomaltose, 0.05 M maleate buffer and a few drops of toluene/ml. Before incubation and after incubation at 37°C for 19 hours 5 μl spots of the reaction mixture were applied to a chromatogram, which was developed with ethyl acetate: acetic acid: water (v/v) for 3 days.

In Fig. 1. is shown a chromatogram from one such experiment. In one case the reaction mixture contained a crude preparation, yielding 12 units/ml of isomaltase, 108 units/ml of (total) maltase and 15 mg/ml of protein. In the other case it contained a purified maltase III preparation, yielding 12 units/ml of isomaltase, 263 units/ml of maltase and 1.5 mg/ml of protein. In both cases the reaction mixture contained 30 % isomaltose, 0.05 M maleate buffer pH 6.5 and a few drops of toluene/ml. After different time of incubation at 37°C, 5 μl spots were applied to a paper chromatogram, which was developed for 3 days.

After the reaction had proceeded for 19 h, the reaction mixture with the crude glycosidase preparation contained *four* different oligosaccharides, formed by transglycosylation, which were separated on the paper chromatogram. In the reaction mixture with the purified maltase III, however, only *two* oligosaccharides could be detected (Fig. 1), although the reaction mixture in both cases contained equally many units of isomaltase activity per ml. Even when the reaction time was extended to two and three days, only two oligosaccharides could be detected in the reaction mixture which contained purified maltase III. A purified maltase II preparation showed the same behaviour as maltase III. It is therefore apparent that the specific isomaltase which is present in crude preparations, is able to form some oligosaccharides by transglycosylation which cannot be formed by the purified maltase II and III. This indicates that the isomaltase activity precent in the purified maltase II and maltase III preparations is *not* caused by contamination with specific isomaltase.

After a crude preparation had been heated at 60°C for 1 h (inactivating the specific isomaltase and maltase II but not the maltase III) it formed only two oligosaccharides in a 30 % isomaltose solution. These oligosaccharides had

the same mobility as those formed by the purified maltase II and maltase III preparations.

Effect of freezing. It has been reported by Larner *et al.*[6] that freezing and thawing of particulate intestinal glycosidase preparations *increases* the isomaltase and maltase activities by more than 200 %. In another paper [3], however, the same authors state that freezing and thawing *reduces* the isomaltase activity of crude preparations.

The present author has *not* observed any remarkable change of the maltase or invertase activities of either particulate or solubilized intestinal glycosidase preparations, although these preparations usually were stored in the frozen state in order to preserve their activity. Nor was any change of these activities observed when intestinal microsomes were frozen and thawed repeatedly as an attempt to solubilize the glycosidases [11].

For studing the effect of freezing and thawing upon hog intestinal isomaltase activity a solubilized crude glycosidase preparation was used which contained 15 mg/ml of protein in 0.01 M phosphate buffer pH 6.0. About 5 ml of the solution in a test tube was frozen by dipping the tube into a mixture of dry ice and ethanol at −80°C. After freezing, which took less than one min, the tube was held in the freezing mixture for 10 min, and then thawed in a water-bath at 37°C. As is seen in Table 3, the isomaltase activity had decreased by 1/3 after repeating this procedure three times. By further repeating of the freezing and thawing the isomaltase activity was, however, not further decreased, although the isomaltase activity still was three times that which could be caused by the isomaltase activity of maltase II and maltase III in the preparation. It was also found that the preparation after this treatment still formed all the four oligosaccharides in a 30 % isomaltose solution which were formed by the crude preparation before freezing. It is therefore not possible to *completely* inactivate the specific isomaltase by repeated freezing and thawing.

Exactly the same resultes were obtained when the freezing mixture consisted of sodium chloride and ice at −15°C. The temperature used seems therefore to be without importance for the results.

The effect of keeping the preparation in the frozen state for a longer time was also studied. The same enzyme preparation was used, but in this case the preparation was distributed in a series of test tubes, so that the content of each tube was frozen and thawed only once. The tubes were stored at −16°C

Table 3. Effect of repeated freezing and thawing upon some hog intestinal α-D-glucopyranosidase activities. For experimental conditions, see text.

	Activity (units per ml)			
	Isomaltase	Maltase	Invertase	Phenyl-α-D-glucopyranosidase
Before freezing	13.6	130	61	8.3
Frozen and thawed once	11.8	131	62	8.8
Frozen and thawed three times	9.1	115	62	8.2

Table 4. Effect of storage in the frozen state upon some hog intestinal α-D-glucopyranosidase activities. For experimental conditions, see text.

	Activity (units per ml)			
	Isomaltase	Maltase	Invertase	Phenyl-α-D-glucopyranosidase
Before freezing	13.6	130	61	8.3
After 4 days at −16°C	11.0	135	55	8.0
After 12 days at −16°C	8.2	148	55	7.0
After 33 days at −16°C	18.0	165	57	8.5

and each tube was thawed just before analysis. The effect of storage in the frozen state upon the different α-D-glucopyranosidase activities is shown in Table 4. The iso-maltase activity decreased by a little more than 1/3 within the first two weeks, but then *increased* to 1/3 more than its original value. In this experiment the maltase activity, too, increased somewhat, but not so much as reported by Larner *et al.*[6]

The effect of freezing during a still longer time was studied by analysis of a solubilized glycosidase preparation which had been dialyzed against distilled water and kept frozen at −16°C for eight months. This preparation contained 23.5 units/ml of invertase and 45 units/ml of maltase, *i.e.* the maltase/invertase activity quotient was 1.9, which agrees well with that of fresh preparations. The isomaltase activity of the preparation which had been frozen for eight months was 5.5 units/ml, *i.e.* the isomaltase activity was 12 % of the maltase activity, which is somewhat higher than the value usually obtained with fresh preparations (8—10 %). When acting in a 30 % solution of isomaltose, this preparation formed all the four different oligosaccharides which are formed by a fresh crude intestinal glycosidase preparation.

The isomaltase activities of *purified maltase II and maltase III preparations* were not changed by storage in the frozen state.

The procedure of freezing apparently has a complex effect upon the isomaltase activity of hog intestinal mucosa, with an initial *decrease* of the isomaltase activity followed by a more slow *increase* of this activity. A more thorough investigation of this phenomenon must wait until a method has been found for the purification of the specific isomaltase of hog intestinal mucosa. One explanation may be that the specific isomaltase is a mixture of several different enzymes which are influenced in different ways by freezing, but no other indications for such a heterogenity have appeared.

Phenyl-α-D-glucopyranosidase activity was studied in some experiments. Of the different hog intestinal α-D-glucopyranosidases separated earlier, two had phenyl-α-D-glucopyranosidase activity, namely maltase II and maltase III. The phenyl-α-D-glucopyranosidase activity of these fractions was 3 and 5 %, respectively, of their maltase activity (calculated as number of molecules hydrolyzed per time unit) [10]. Fresh mucosa homogenates had phenyl-α-D-glucopyranosidase activity about 6 % of their (total) maltase activity. This means that the phenyl-α-D-glucopyranosidase activity of the maltases II and III in the homogenates can contribute only 1/2 to the total phenyl-α-D-

glucopyranosidase activity. The remainder of the phenyl-α-D-glucopyranosidase activity may be caused by the specific isomaltase.

During heating at 60°C, the major part (about 2/3) of the phenyl-α-D-glucopyranosidase activity of crude preparations was abolished together with the invertase (= maltase I), maltase II and specific isomaltase. After heating the preparation had phenyl-α-D-glucopyranosidase/maltase (III) activity quotient which was the same as that of a purified maltase III preparation.

The effect of freezing and thawing upon the phenyl-α-D-glucopyranosidase activity of crude preparations varied somewhat. In some experiments slightly decreased activity was observed on freezing and thawing (Table 4) while in other cases no change could be stated (Table 3). It can not at present be stated whether that part of the phenyl-α-D-glucopyranosidase activity which is not caused by maltase II and maltase III is caused by the specific isomaltase or by some other enzyme.

Acknowledgment. The author's thanks are due to Professor Bengt Borgström for his interest in my work and for valuable discussions.

This work has been supported by grants from the *Medical Faculty of the University of Lund.*

The skillful technical assistance of Mrs. K. Hagebris is gratefully acknowledged.

The Chemistry of the Natural Order Cupressales

XXIV.* Heartwood Constituents of *Chamaecyparis thyoides* (L) Britt.

C. ENZELL

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The heartwood of *Chamaecyparis thyoides* was found to contain carvacrol methyl ether, α-cedrene, cuparene, thujopsene (widdrene), cedrol, widdrol, cuparenic acid, hinokiic acid (widdrenic acid) and "Widdringtonia acid II"; no tropolones were detected.

The family *Cupressaceae* has been subdivided by botanists into about twenty genera, most of which are monotypic or include only a few species. Both chemical and botanical aspects of the relationship between the different genera and the various species of the larger genera have been discussed in a recent review [1].

The present investigation was undertaken to provide a chemical characterisation of *Chamaecyparis thyoides*, a tree endemic to the south-eastern part of North America. Zavarin and Anderson [2], in a survey of the occurrence of tropolones, have previously examined an extract from this tree by paper chromatography and have reported the presence of α-, β- and γ-thujaplicins.

The heartwood of *Chamaecyparis thyoides*, very kindly provided by Dr. J. P. Bain, Glidden Co., Jacksonville, Florida, was extracted with acetone and the light petroleum-soluble part of this extract was separated into acidic and neutral fractions. The neutral part, after a preliminary distillation, was fractionated through a high efficiency column giving a forerun, which contained mainly carvacrol methyl ether, and three main fractions with practically constant boiling points.

The first fraction was a mixture of sesquiterpene hydrocarbons, which according to gas chromatographic examination contained two main components in about equal amounts. Oxidation of the hydrocarbon mixture with selenium dioxide furnished an oil, from which widdrenal [3] was isolated in crystalline form. The non-crystalline material on further oxidation with silver oxide and chromatography on dimethyl sulphoxide-impregnated silica gel gave cedrene carboxylic acid and hinokiic acid. The oxidation product of widdrenal, "widdrenic acid" [3], has recently been shown [4] to be identical with hinokiic

* Part XXIII. *Acta Chem. Scand.* **13** (1959) 1395.

acid. The hydrocarbon fraction thus contains α-cedrene and thujopsene. The optical rotation and the infra-red absorption (1 647 and 885 cm^{-1}) of this fraction were, however, consistent with the presence of a minor constituent of more positive rotation containing a $RR'C=CH_2$-group, possibly the so-called β-cedrene [5].

Hirose and Nakatsuka [6] have shown that the "thujopsene" originally isolated by Kawamura [7] from *Thujopsis dolobrata* (Linneus, f) Sieb. et Zucc., on oxidation with selenium dioxide furnished a crystalline aldehyde which was identical with the widdrenal previously obtained by Erdtman and co-workers [3,8] from "widdrene", a hydrocarbon isolated from several *Widdringtonia* species and from *Biota orientalis*. Recently Erdtman and Norin [4] obtained pure "widdrene" from *Thujopsis dolobrata* and suggested that the name thujopsene should be retained for this hydrocarbon. Although it was clear that several of the oils containing thujopsene also contained a second component this had not been identified. It now seems probable that many of these oils are mixtures of thujopsene and α-cedrene and that similar mixtures are of frequent occurence.

Sesquichamene (b.p. 122—123°/12 mm, d_4^{28} 0.9277, n_D^{28} 1.5021, $[\alpha]_D^{28}$ —89.85°), isolated by Kafuku and Nozoe [9] from the leaves of *Chamaecyparis obtusa*, Sieb. et Zucc. and later by Katsura [10] from the leaves of *Chamaecyparis formosensis*, Mats. on oxidation with potassium permanganate, gave a glycol $C_{15}H_{26}O_2$, m.p. 89—91°, and a ketoaldehyde, $C_{14}H_{20}O_2$, disemicarbazone m.p. 233°. It has been suggested [11] that sesquichamene is identical with α-cedrene, but the physical constants of sesquichamene and the similarity of the melting points of the oxidation products to those of thujopsene glycol [12] (92—93°) and cedrene ketoaldehyde disemicarbazone (233°) makes it probable that it was in fact a mixture containing mainly thujopsene and α-cedrene.

The main component of the second fraction from *Chamaecyparis thyoides* was the aromatic sesquiterpene hydrocarbon cuparene. The isolation of this compound and the elucidation of its structure have been described in a previous paper [13].

The third fraction was a crystalline mixture of the sesquiterpene alcohols cedrol and widdrol [3], which were separated by chromatography on alumina. Widdrol is apparently frequently associated with cedrol [3,14]; its structure is at present being investigated.

On standing, the acidic fraction from *Chamaecyparis thyoides* deposited crystalline material, which after recrystallisation gave pure "Widdringtonia acid II" [3], m.p. 191—193°. The remainder of the material on distillation gave a small amount of low-boiling forerun and a higher-boiling, crystalline main fraction. According to paper chromatographic results, the low-boiling material contained at least five components, but no tropolones and no carvacrol were detected. The crystalline main fraction gave hinokiic acid on crystallisation and the remaining mixture was separated into hinokiic acid and cuparenic acid [13] by chromatography on dimethyl sulphoxide-impregnated paper.

The absence of tropolones from the sample of wood examined in this investigation is not in accordance with the results obtained by Zavarin and Anderson[2], but this divergence is probably due to the variations not infrequent in biological material.

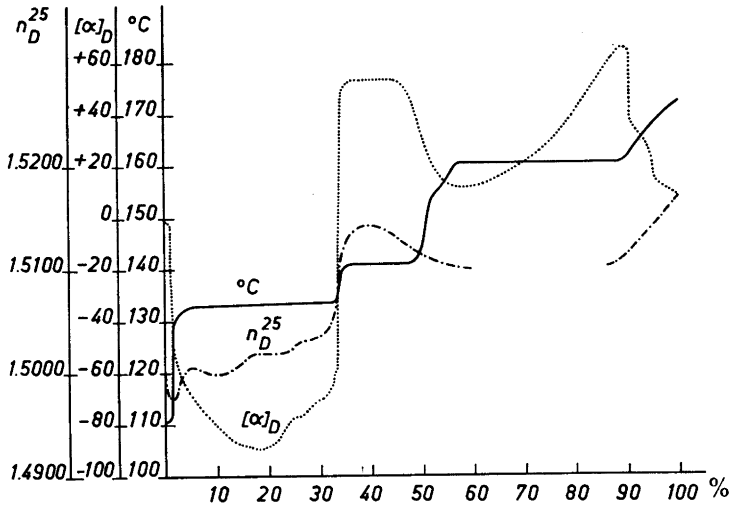

Fig. 1. Distillation of the main neutral fraction, ——— b. p. (°C/20 mm), ····· $[\alpha]_D$, —·—·—·— n_D^{25}.

The results of the present study show a pattern of heartwood constituents which is remarkably similar to that of the Southern hemisphere genus *Widdringtonia* [3]. Any detailed comparison with the patterns of heartwood constituents of other species of *Chamaecyparis* and with those of other genera of the Cupressaceae is however impeded by the lack of sufficient data [1].

EXPERIMENTAL

Melting points were taken on a Kofler micro hot stage (uncorr). Unless stated to the contrary, rotations were measured in chloroform. Infrared spectra were recorded on a Perkin-Elmer No 21 instrument (NaCl-prism; liquids, pure oils in an 0.025 mm NaCl-cell). Light petroleum refers to a fraction b.p. 35—60°, unless otherwise stated. Microanalyses by Dr. A. Benhardt, Mülheim.

Extraction. Finely milled air-dry heartwood of *Chamaecyparis thyoides* (9.9 kg) was extracted with acetone for 48 h. The extract was filtered, concentrated to small volume and poured with vigorous stirring into a tenfold volume of ether. The precipitate (25 g) was filtered off, washed with ether and set aside.

The combined ether solutions were concentrated and poured into light petroleum in the same way. This precipitate (50 g) after extraction with light petroleum was also set aside. The light petroleum solution was concentrated to one litre, extracted successively with aqueous potassium hydroxide (5 % and then 10 %) and washed with water. The alkaline solutions were combined, washed with light petroleum, acidified with dilute sulphuric acid (10 %) and extracted with light petroleum. The combined neutral solution and the acidic solution gave, after drying (Na_2SO_4) and evaporation of the solvent, a neutral fraction, a yellow oil (340 g, 3.5 % of the wood), and an acidic fraction, a redbrown oil (37 g, 0.4 % of the wood).

The neutral oil (340 g) was distilled to give a fraction, b.p. 120°/50 mm-180°/6 mm (260 g). The residue (80 g) gave two crystalline compounds in very small amounts, a "C_{15}-ketone", m. p. 108—109°, $[\alpha]_D$ +73°, 2,4-dinitrophenylhydrazone, m. p. 198—199° (Found: N 14.2. $C_{21}H_{22}N_4O_4$ requires N 14.5), and a substance, m. p. 140—141°, $[\alpha]_D$ +58° (Found: C 68.3; H 10.4. $C_{21}H_{38}O_5$ requires C 68.1; H 10.3), but it has not yet been further investigated.

The main part of the distillate was fractionally distilled through a vacuum-jacketed, packed column and where necessary refractionated through a spinning band column.

Curves for the distillation of the main neutral fraction showing boiling point (20 mm), refractive index and rotation plotted against percentage of material distilled are given in Fig. 1. There were three main fractions and a small forerun.

The forerun (0 → 1 %), according to its infrared absorption, contained mainly carvacrol methyl ether. Demethylation with hydrogen bromide (30 %, 1.5 h) followed by etherification with ethyl chloroacetate and saponification of the ester gave carvacroxyacetic acid (50 %), m. p. and mixed m. p. 152—153°.

The fraction b. p. 131—133° (2 → 32 %) was a mixture of sesquiterpene hydrocarbons. A gas chromatogram on a Perkin-Elmer vapour fractometer model 154 B (two metre column, 2,4-dinitrophenyl-2-naphthyl ether (20 %) on celite; column temp. 156°; flow rate 50 ml/min of helium; charge 5 μl) showed two peaks with elution times of 14 and 15 min and percentage of total area 48 and 52, respectively. This mixture (2.0 g) was oxidised with selenium dioxide (1.2 g) in ethanol (30 ml) for 3 h at reflux temperature. Evaporation of the solvent followed by repeated distillation of the product and recrystallisation from light petroleum gave widdrenal (0.2 g), m. p. and mixed m. p. 75—76°; infrared spectrum identical with that of authentic material. The non-crystalline part of the oxidation product (1.1 g) was added to a suspension of silver oxide (silver nitrate, 1.6 g, and sodium hydroxide 0.8 g) in water (15 ml) and the mixture was stirred vigorously for 2 h at 100°. The reaction mixture was separated into a neutral fraction (0.4 g) and an acid fraction (0.6 g). The chloroform-soluble part (0.2 g) of the acid fraction was chromatographed on dimethyl sulphoxide-impregnated silica gel.

This dimethyl sulphoxide-impregnated silica gel column was prepared by a method developed by Lindberg and Wickberg [15] for the separation of acetylated sugars. Dried, acid-washed silica gel (0.03—0.08 mm, 30 ml) was suspended in a solution of dimethyl sulphoxide in chloroform (5 %, 100 ml). The suspension was kept under reduced pressure in a vacuum desiccator for a short time and then transferred to a separatory funnel fitted on the top of a chromatogram tube that was completely filled with the same chloroform solution. Moderate pressure was applied to the top of the separatory funnel and the taps were opened to allow the suspension to replace the solution in the tube. The silica gel (1.5 × 24 cm) was saturated with dimethyl sulphoxide by passing a solution of dimethyl sulphoxide in ether (5 %, 150 ml). This was followed by a small volume of pure ether (5 ml), to prevent precipitation of dimethyl sulphoxide by the eluant to be used, and finally by the eluant (100 ml).

The acid mixture (0.2 g) was absorbed on the column and eluted with a mixture of light petroleum (b. p. 60—71°) and *iso*propyl ether (2:1, 6 ml fractions). The separation was most conveniently followed by the test chromatograms of the eluate on dimethyl sulphoxide-impregnated paper [18] with light petroleum and using a mixed indicator as spray reagent. The acids were found in fractions 15—18 and 20—26. The first acid (0.1 g) after sublimation had m. p. 122—124°, $[\alpha]_D$ −68° (*c* 2.2) (*cf.* authentic cedrenecarboxylic acid, m. p. 122°). Cedrol (8.4 g) was dehydrated with formic acid, refluxed with methanolic potassium hydroxide (10 %, 0.5 h) and filtered through alumina (200 g) in light petroleum to give α-cedrene [16] (7.0 g), $[\alpha]_D$ −91° (pure oil), d_{20}^{20} 0.9371, n_D^{25} 1.4968. It was gas chromatographically homogeneous (conditions as above, elution time 14 min) and the infrared spectrum indicated that there was no exocyclic methylene group present.

α-Cedrene (4 g) was oxidised with selenium dioxide in ethanol to give cedrenal [17] (3.8 g) and a part (0.6 g) of this aldehyde was treated with an aqueous silver oxide suspension at reflux temperature for 15 h giving cedrene carboxylic acid [17] (0.3 g). The infrared spectra of the two acids were superimposable and the mixed m. p. was undepressed, 122—124°. The second acid (0.1 g), m. p. 169—170°, was identified as hinokiic acid, mixed m. p. undepressed, infrared spectra identical.

The fraction b. p. approx. 141° (34 → 47 %) after purification as described in a previous paper [13] gave pure cuparene (b. p. 138°/19 mm, d_{21}^{21} 0.9374, $[\alpha]_D$ +65°, n_D^{25} 1.5202) in 45 % yield. It was further characterised by oxidation with chromic acid to cuparenic acid, m. p. 158—160°, $[\alpha]_D$ +63° (*c* 2.4).

The fraction b. p. approx. 161° (56 → 89 %) was a crystalline mixture of sesquiterpene alcohols. A sample of this mixture (3.0 g) was separated by chromatography on alumina (200 g); elution with benzene gave cedrol (1.8 g), m. p. and mixed m. p. 87—88°, $[\alpha]_D$ +10° (*c* 2.1); further elution with benzene-ether (9:1) gave widdrol (1.0 g), m. p. and mixed m. p. 97—98°, $[\alpha]_D$ +105° (*c* 2.9).

The acidic fraction (37 g) on standing deposited crystalline material (6 g) which was filtered off, washed with light petroleum and recrystallised from methanol giving pure "Widdringtonia acid II", m. p. and mixed m. p. 191—193°, $[\alpha]_D$ −96° (*c* 1.9), infrared spectrum identical with that of authentic material. A part (12 g) of the remaining oil on quick distillation gave a low-boiling forerun (1.9 g, 90—125°/4 mm), a higher-boiling main fraction (8.3 g, 145—170°/4 mm) and a residue (1.6 g, discarded). The forerun showed five distinct spots when chromatographed on dimethyl sulphoxide-impregnated paper[18], but none of these compounds were obtained in a crystalline state when eluted from a preparative (60 mg) chromatogram and this fraction was not further investigated. The higher-boiling, main fraction crystallised on standing. After repeated crystallisation from light petroleum it gave pure hinokiic acid (1.5 g), m. p. and mixed m. p. 169—171°, $[\alpha]_D$ −85° (*c* 2.1) infrared spectrum identical with that of authentic material. The remaining material, a constant melting mixture (135—138°) was conveniently separated by preparative paper chromatography. A sheet of paper (23 × 50 cm, Whatman 3MM) was impregnated with a mixture of dimethyl sulphoxide and benzene (3:2), dried in an oven (60°, 3 min) and then placed between glass plates to protect it from atmospheric moisture while the acid mixture was being applied. A chromatogram of the acid mixture (70 mg) was run on this paper in light petroleum (b. p. 60—71°) for 7 h. Two bands, at 12 and 20 cm from the starting line, were detected when the chromatogram was sprayed with water. These bands were cut out, extracted with ether and the ether solutions obtained were washed with water, dried (Na_2SO_4) and the ether was evaporated. The slow moving acid (20 mg) was identified as cuparenic acid, m. p. and mixed m. p. 158—160°, $[\alpha]_D$ +63° (*c* 2.1), infrared absorption identical with that of authentic material. The fast moving acid was hinokiic acid which was identified in the same way.

No tropolones could be detected in the total acidic fraction, in the distilled acidic fractions or in the ether or light petroleum-insoluble fractions of the acetone extract when these were chromatographed according to the method of Wachtmeister and Wickberg [19].

Acknowledgements. Thanks are due to Professor H. Erdtman for his interest and encouragement, to Miss Gurli Hammarberg for skilful assistance, to Dr. B. R. Thomas for valuable discussions, to Dr. J. Bain., Jacksonville, Fla, for supplying the wood used in this study and to the *Swedish Technical Research Council* for financial support.

Studies on the Hydrolysis of Metal Ions

26. Application of a Liquid Distribution Method to the Study of the Hydrolysis of Ag^+

P. J. ANTIKAINEN* and D. DYRSSEN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The distribution of silver at 25°C between solutions of quinoline (Q) in benzene and 3 M $Na(ClO_4,OH)$ has been studied as a function of $[Q]_{org}$, $[OH^-]$ and the silver concentration. In these experiments the reaction

$$Ag^+ (aq) + 2\ Q\ (org) + ClO_4^- (aq) \rightleftharpoons AgQ_2ClO_4\ (org)$$

(eq. const. $\log K = 3.23 \pm 0.02$) was used for the study of the hydrolysis of Ag^+ in 3 M $NaClO_4$ at low concentrations of silver. The data provide no evidence for the presence of significant amounts of polynuclear complexes. Furthermore, the data indicate that AgOH is not formed to any large extent in 3 M $Na(ClO_4, OH)$. The value of $\log K_1K_2 = \log[Ag(OH)_2^-][Ag^+]^{-1}[OH^-]^{-2}$ was calculated to be 3.50 ± 0.10 in 3 M $Na(ClO_4, OH)$. No evidence was found for $Ag(OH)_3^{2-}$ in solutions less alkaline than 0.5 M.

These conclusions are supported by measurements of the solubility of Ag_2O in 3 M $Na(ClO_4,OH)$. The value of $\log K_{s2} = \log [Ag(OH)_2^-][OH^-]^{-1}$ was determined to be -3.82 ± 0.06. Together with the solubility product, $K_{s0} = 10^{-7.42 \pm 0.02}$, determined by Hietanen [7] we obtained $\log K_1K_2 = 3.60 \pm 0.08$. The pH of the solubility minimum of Ag_2O is determined by this constant.

In connection with the distribution experiments the distribution constant, K_d, of quinoline between various organic solvents and 3 M $NaClO_4$ has been determined (Table 1).

The hydrolysis of silver ions, Ag^+, has been studied by several people. The data hitherto obtained have been collected together with values of K_{s0}, the solubility product, in Part II of the compilation of stability constants by Bjerrum, Schwarzenbach, and Sillén [1]. Rather different values of the equilibrium constants for the formation of AgOH and $Ag(OH)_2^-$ have been given. Moreover some authors have in addition suggested the hydroxo complexes

* Present address: Institute of Chemistry, University of Helsinki, Helsinki, Finland.

Ag_2OH^+ and $Ag(OH)_3^{2-}$. There seems to be some uncertainty about the existence of AgOH in solution. In a recent paper by Pleskov and Kabanov [2] a trinuclear complex, $Ag_3O(OH)_2^-$, has been claimed from emf data in alkaline solutions of Ag_2O. A critical discussion of available data will be presented in a subsequent paper by Biedermann and Sillén [9].

The purpose of this work was to apply the liquid distribution method to the study of the hydrolysis of Ag^+ in 3 M $Na(ClO_4,OH)$. The method allows the use of very low concentrations of silver in the aqueous phase; this would favor the mononuclear reactions. Also one usually does not obtain slow equilibria as with systems where a solid phase is present. In addition, a few measurements have been made of the solubility of silver oxide in 3 M $Na(ClO_4,OH)$. These solubility data are compared with data obtained from the distribution measurements.

EXPERIMENTAL

Determination of $[Ag]_{tot}$ *and* $[OH^-]$. The experiments were carried out in a room thermostated at 25°C. The Na^+ concentration in the aqueous phase was kept constant at 3 M using $NaClO_4$ and NaOH. The distribution between the organic phase, quinoline in benzene, and the aqueous phase, was measured by liquid counting using ^{110m}Ag as a tracer. 20th Century Electronic M6 liquid counter tubes (volume 10 ml, wall thickness approx. 30 mg/cm^2) and Tracerlab Scalers were used for the radiometric determinations. In the solubility measurements the silver concentration of the aqueous phase was likewise determined radiometrically. Equilibration was attained by slow tilting (20—25 revolutions per min) of the solutions in glass-stoppered Pyrex centrifuge tubes; 1 h in the liquid distribution experiments, at least 2 days in the solubility measurements. The volume of the two phases in the liquid distribution measurements was 15 ml each. For the determination of the solubility of silver oxide, 15—40 ml 3 M $Na(ClO_4,OH)$ was used. After shaking, the phases were separated by centrifugation. Samples for liquid counting were withdrawn with 10 ml pipettes; in the solubility measurements the contamination by solid particles was avoided by sucking the solution through a capillary tube. The correction factor for the effect of the solvent composition on the counting rate was found to be 0.964 for the solvent pair quinoline-benzene/3 M $Na(ClO_4,OH)$; 2.96×10^{-4} M silver from sample 1 gave 19 604 cpm in the quinoline-benzene phase, but only 18 895 cpm in the aqueous phase. The determination of $-\log [OH^-]$ was carried out analytically in most cases; lower concentrations were measured potentiometrically with a Beckman glass electrode (Type 1190-72) using a solution of 0.01 M NaOH + 2.99 M $NaClO_4$ as reference ($-\log [OH^-] = 2.00$).

Choice of extracting system. It has been shown by Dyrssen, Krasovec, and Sillén [4] that Ag^+ can be extracted with chloroform from acid or neutral perchlorate solutions as $Ag(quinoline)_3ClO_4$. As quinoline does not react with alkali, it was thought that a two-phase system with quinoline and perchlorate would be very suitable for the determination of $[Ag^+]$ in an aqueous alkaline solution. However, chloroform is known to react with alkali forming, among other products, chloride ions. (It was found that a 0.1 M NaOH + 2.9 M $NaClO_4$ solution became 0.03 M in Cl^- after contact with chloroform for 24 h). A separate investigation by Mrs. Solweig Ekberg (*cf.* Table 1) showed that benzene could be a good choice as a diluent for quinoline and extracting solvent for $Ag(quinoline)_3ClO_4$. Benzene is a sufficiently stable organic solvent also. A few preliminary experiments with acridine showed that the solubility of its silver perchlorate complex was too low.

Reagents. Some insoluble matter was precipitated when the quinoline-benzene solutions, prepared from pure analytical grade products, were shaken with aqueous solutions containing silver. The quinoline solutions in benzene (0.5—0.8 M) had to be purified therefore by shaking them with a dilute solution of $AgClO_4$ (3×10^{-4} M) in distilled, chloride-free water. Traces of silver in the benzene phase were then removed by shaking with water repeatedly (at least six times). Still we obtained some losses of silver in the distribution experiments in the alkaline range, which were due probably to the collection

Table 1. Distribution constant, K_d, of quinoline between equal volumes of various organic solvents and 3 M $NaClO_4$ (0.001 M in NaOH). The concentration of quinoline in the aqueous phase after equilibration was determined spectrophotometrically at 273–283 mμ (except for hexone) and at the peak value around 312 mμ. 3 M $NaClO_4$ (with 0.001 M NaOH) saturated with the organic solvent were used as blanks. K_d was calculated as $[Q]'_{org}[Q]^{-1}_{aq} - 1$.

Solvent	Initial conc. of quinoline in the organic phase, $[Q]'_{org}$ M	log K_d
Chloroform	0.1	2.784 ± 0.020
Benzene	0.01	2.146 ± 0.002
Tri-n-butyl phosphate	0.02	2.123 ± 0.023
Methyl isobutyl carbinol	0.02	2.104 ± 0.023
Methyl isobutyl ketone	0.02	1.951 ± 0.001
Carbon tetrachloride	0.01	1.887 ± 0.056
*Iso*propylether	0.02	1.537 ± 0.018
n-Hexane	0.01–0.002	1.159 ± 0.018

of insoluble silver in the interphase. Although this seemed not to have any influence on the distribution ratio, it might have been worthwhile to have treated the organic phase with a solution of Ag_2O in, *e. g.*, 0.1 M NaOH in order to remove impurities that might react with silver in alkaline solutions only. The quinoline concentration in the benzene phase was determined spectrophotometrically at 312.5 mμ by Mrs. Ekberg.

The $NaClO_4$ was made from doubly recrystallized Na_2CO_3 p. a. and conc. $HClO_4$ p. a. The $NaClO_4$ was crystallized twice from distilled, chloride-free water according to a technique used by our colleagues at this laboratory [5]. The molarity of the $NaClO_4$ solution was determined from the specific gravity of the solution and the weight of $NaClO_4$ (dried at 110°C) per gram of the solution. The NaOH was of finest Merck quality and contained negligible amounts of chloride.

The radioactive isotope of silver was obtained by thermal neutron irradiation of a weighed piece of pure silver at A.E.R.E., Harwell, England. The silver was dissolved in nitric acid and the silver concentration was checked gravimetrically as AgCl. The initial specific activities of the two silver samples used were 1.2 and 12 mC per gram Ag, respectively. Stock solutions of the radioactive silver were prepared in 3 M $NaClO_4$.

APPLICATION OF THE LAW OF MASS ACTION TO THE DATA

Symbols. The following symbols and definitions are used:

$[\ ]$ concentrations in the aqueous phase
$[\ ]_{org}$ concentrations in the benzene phase
Q quinoline
$K_1 = [AgOH][Ag^+]^{-1}[OH^-]^{-1}$
$K_2 = [Ag(OH)_2^-][AgOH]^{-1}[OH^-]^{-1}$

With two liquid phases:

$K = [AgQ_2ClO_4]_{org}[Ag^+]^{-1}[Q]^{-2}_{org}[ClO_4^-]^{-1}$ (equil. constant)
$q = [Ag]_{total,\ org}[Ag]^{-1}_{total,\ aq}$ (net distribution ratio)
$\varphi = q[Q]^{-2}_{org}[ClO_4^-]^{-1}$ and $y = -\log \varphi\ [OH^-]$ (auxiliary functions)

In equilibrium with Ag_2O:

$K_{s0} = [Ag^+][OH^-]$
$K_{s1} = [AgOH] = K_{s0}K_1$
$K_{s2} = [Ag(OH)_2^-][OH^-]^{-1} = K_{s0}K_1K_2 = K_{s1}K_2$

Distribution measurements. The quantity measured in the distribution experiments is the net distribution ratio

$$q = [Ag]_{total,org}[Ag]^{-1}_{total,\ aq}$$

It may be seen from Table 2 ($[OH^-] \approx 10^{-7}$ M, $[ClO_4^-] = 3$ M) that $q[Q]^{-2}_{org}$ is constant for a range of values of $[Q]_{org}$ and silver concentration in both phases. This is a strong indication that silver is extracted as monomeric AgQ_2ClO_4. As the concentration of quinoline in the aqueous phase was low due to a high value of the distribution constant (*cf.* Table 1), silver complexes with quinoline were not likely to be formed in the aqueous phase in any appreciable amount. Furthermore, it was shown by Dyrssen, Krašovec, and Sillén [4] that the distribution of silver between quinoline in chloroform and perchlorate solutions in the range pH 3—10 was function of $[Q]^2_{org}[ClO_4^-]$ only. Thus we may assume that the extraction of silver takes place by the following reaction (eq. const. K):

$$Ag^+ \text{ (aq)} + 2\ Q \text{ (org)} + ClO_4^- \text{ (aq)} \rightleftharpoons AgQ_2ClO_4 \text{ (org)}$$

In the presence of a complexing ion like OH^- the expression for q will be

$$q = \frac{[AgQ_2ClO_4]_{org}}{[Ag^+] + [AgOH] + [Ag(OH)_2^-] + [\text{other hydroxo complexes}]} \quad (1a)$$

or

$$\log q = \log K\,[Q]^2_{org}\,[ClO_4^-] - \log\,(1 + K_1[OH^-] + K_1K_2[OH^-]^2 + \ldots.) \quad (1b)$$

Other hydroxo complexes would appear in eqn. (1b) as terms with higher powers of $[OH^-]$ (*e.g.* $Ag(OH)_3^{2-}$) or of $[Ag^+]$ (*e.g.* $Ag_2(OH)_2$). Further the equation presupposes that silver is not extracted as AgQ_2OH. In fact, at the silver concentrations used practically no silver was found to be extracted by a solution of quinoline in benzene from a solution of Ag(I) in 0.5 M NaOH as long as no ClO_4^- was present.

Eqn. (1b) may be written as

$$y = \log\,(q^{-1}[Q]^2_{org}[ClO_4^-]\,[OH^-]^{-1}) = -\log\,\varphi\,[OH^-] = \log\,K^{-1}K_1 + \\ + \log\,(K_1^{-1}[OH^-]^{-1} + 1 + K_2[OH^-]) \quad (1c)$$

The curve $y = -\log\,\varphi\,[OH^-]$ against $\log\,[OH^-]$ will have two asymptotes, namely

$$[OH^-] \to 0;\ y = -\log\,[OH^-] - \log\,K;\ \textit{i.e.}\ \varphi = K \quad (2a)$$

$$[OH^-] \to \infty;\ y = \log\,[OH^-] + \log\,K_1K_2 - \log\,K \quad (2b)$$

The intersection of the asymptotes at

$$[OH^-] = [OH^-]_0 \text{ and } y = y_0$$

gives

$$-\,2\,\log\,[OH^-]_0 = \log\,K_1K_2 \quad (3a)$$

and

$$y_0 = \log\,(K^{-1}K_1{}^{1/2}K_2{}^{1/2}) \quad (3b)$$

The point at $[OH^-] = [OH^-]_0$ on the distribution curve is

$$y'_0 = \log K^{-1}K_1(K_1^{-\frac{1}{2}}K_2^{\frac{1}{2}} + 1 + K_1^{-\frac{1}{2}}K_2^{\frac{1}{2}}) \quad (4)$$

The difference between this point and the point of intersection of the asymptotes is

$$y'_0 - y_0 = \log (1 + \log K_1^{\frac{1}{2}}K_2^{-\frac{1}{2}} + 1) \quad (5)$$

i.e., this quantity is determined by $K_1K_2^{-1}$, the ratio between the two consecutive constants. The smallest value of $y'_0 - y_0$ is log 2, which corresponds to the case when AgOH may be neglected ($K_1 = 0$, see Fig. 1).

Solubility measurements. It is not possible to determine from solubility measurements whether silver oxide dissolves in water as polynuclear fractions of the solid phase, *e.g.* $Ag_2(OH)_2$, as the concentrations of such species will not vary with the composition of the solvent. Assuming the same species to exist in the aqueous phase as previously in the distribution experiments, we obtain

$$[Ag]_{total} = [Ag^+] + [AgOH] + [Ag(OH)_2^-] \quad (6a)$$

or

$$[Ag]_{total} = [AgOH](K_1^{-1}[OH^-]^{-1} + 1 + K_2[OH^-]) \quad (6b)$$

[AgOH] is constant ($= K_{s1}$) in the presence of solid Ag_2O.
The curve log $[Ag]_{total}$ against log $[OH^-]$ will have the same form as the curve $y = -\log \varphi$ $[OH^-]$ against log $[OH^-]$ for the distribution data (eqn. 1c). Eqns. 2—5 will be the same except that K_{s1} must be substituted for $K^{-1}K_1$, and

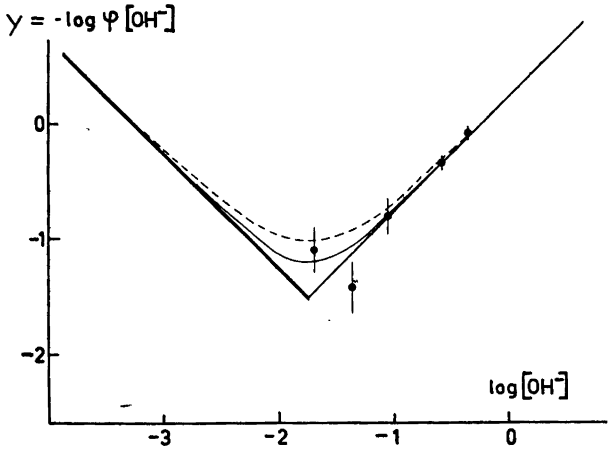

Fig. 1. The distribution of Ag — ^{110m}Ag between solutions of quinoline in benzene and 3 M $Na(ClO_4,OH)$ plotted as $y = -\log \varphi$ $[OH^-]$ against log $[OH^-]$. The data are taken from Table 2. The equations for the curves with their two asymptotes are given in the text. The full-drawn curve has been calculated for $K_1 = 0$ and the dashed curve for $K_1 = K_2$. The position of the asymptote will slope −1 is calculated from values of φ in Table 2, where the hydrolysis of Ag^+ has no influence on the distribution ($[OH^-] \approx 10^{-7}$ M).
The point of intersection of the two asymptotes gives log $K_1K_2 = 3.50 \pm 0.10$.

Table 2. Distribution of Ag-^{110m}Ag between quinoline in benzene and 3 M Na(ClO_4,OH) solutions as a function of the concentrations of quinoline, silver, NaOH, and $NaClO_4$.

log $[Ag]_{total}$ for −log φ $[OH^-]$. The value of $[OH^-]$ of the solubility minimum of Ag_2O is thus given by

$$-2 \log [OH^-]_0 = \log K_1K_2 \qquad (3'a)$$

The constants in these equations may found by fitting normalized curves to the data [3].

RESULTS

Distribution data. The data on the distribution of silver between solutions of quinoline in benzene and 3 M $NaClO_4$-NaOH solutions, with varying amounts of NaOH are given in Table 2 and plotted in Fig. 1. The two curves in Fig. 1

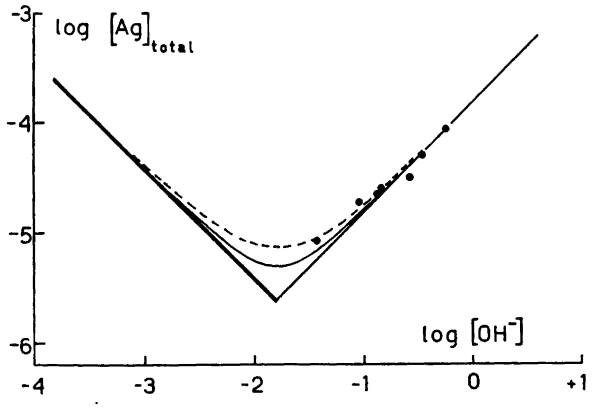

Fig. 2. The solubility of Ag_2O in 3 M $Na(ClO_4, OH)$ as a function of $[OH^-]$. The data are given in Table 3. The equations for the curves are given in the text and are the same as for the curves in Fig. 1. The full-drawn curve has been calculated for $K_1 = 0$ and the dashed curve for $K_1 = K_2$. The position of the left-hand asymptote with slope −1 is given by the solubility product, K_{s0}. The point of intersection of the two asymptotes gives log $K_1K_2 = 2$ (1.80 ± 0.04) = 3.60 ± 0.08.

correspond to the assumptions $K_1 = 0$ (full-drawn curve) and $K_1 = K_2$ (dashed curve). In spite of the rather large limits of error it can be said that $K_1 < K_2$. The point of intersection of the two asymptotes at log $[OH^-] = -1.75 \pm 0.05$ gives

$$\log K_1K_2 = 3.50 \pm 0.10$$

There is no evidence of a third complex below 0.5 M NaOH. The equilibrium constant K for the reaction

$$Ag^+ \text{ (aq)} + 2 \text{ Q (org)} + ClO_4^- \text{ (aq)} \rightleftharpoons AgQ_2ClO_4 \text{ (aq)}$$

can be calculated from Table 1 ($[ClO_4^-] = 3$ M, $[OH^-] \approx 10^{-7}$ M) to be log $K = 3.23 \pm 0.02$. This constant determines the left-hand asymptote in Fig. 1 rather accurately.

It can also be seen from Table 2 that the value of q (or φ) is independent of the silver concentration at the low amounts of silver used in these experiments. As silver certainly is monomeric in the organic phase (*cf.* φ at $[OH^-] \approx 10^{-7}$ M) this proves that no appreciable amounts of polynuclear complexes are present in the aqueous phase.

It was mentioned under "Experimental" that losses of silver occured in the distribution experiments in spite of the purification of the reagents. However, the loss of silver did not seem to correlate with any change in q (or φ). It was also found that the losses could be kept at a minimum using a rather large concentration of quinoline in benzene.

Solubility data. The data in Table 3 are plotted in Fig. 2 as log $[Ag]_{total}$ against log $[OH^-]$. It was shown above that the same curves as in Fig. 1 then apply to the solubility data too. The position of the left-hand asymptote with slope -1 is given by the solubility product, K_{s0}; log $[Ag]_{total} = \log K_{s0} - \log [OH^-]$. A value of this constant, log $K_{s0} = 7.42 \pm 0.02$, was determined from potentiometric determinations of $[Ag^+]$ and $[H^+]$ by Hietanen [7]. The right-hand asymptote is determined by log K_{s2}, which was calculated to be -3.82 ± 0.06 in Table 3. The point of intersection of the asymptotes gives

$$\log K_1K_2 = 3.60 \pm 0.08$$

This value is not very different from the value determined from the distribution data. Nor do the solubility data provide any evidence of appreciable amounts of AgOH or $Ag(OH)_3^{2-}$; we conclude $K_1 < K_2$ and $K_3 \ll K_2$ in 3 M $NaClO_4$ from these experiments too. It might be pointed out that a study of the solubility of Ag_2O in solutions less alkaline than 0.01 M gives rather uncertain values due to the fact that the buffer capacity of such solutions is low.

CONCLUSIONS

The hydrolysis of silver in water, examined at low concentrations of silver in 3 M $NaClO_4$ at 25°C by the distribution and solubility methods described above, can be explained by the following two reactions:

$$Ag^+ + OH^- \rightleftharpoons AgOH \qquad K_1$$

$$AgOH + OH^- \rightleftharpoons Ag(OH)_2^- \qquad K_2$$

The data indicate that $K_1 < K_2$, *i.e.* that in 3 M $Na(ClO_4,OH)$ [AgOH] is never as much as 1/3 of the total silver. The value of $\log K_1K_2$ was determined as 3.6 ± 0.1. The hydrolysis of Ag^+ thus seems to resemble that of Hg^{2+} as determined by Hietanen and Sillén [6]. No evidence is found for the existence of $Ag(OH)_3^{2-}$ below $[OH^-] = 0.5$ M.

The distribution method allows a full variation of the concentration of all silver species. However, no influence of the silver concentration on the distribution ratio could be detected at $[Ag^+][OH^-] < K_{s0}$. This does not preclude the possibility that polynuclear hydroxo complexes can be proved to exist in solutions with higher silver concentrations, *e.g.* 1 M $AgNO_3$ or 5 M KOH saturated with Ag_2O. In the former case titration with HNO_3 in 1 M $AgNO_3$ would reveal any $Ag_m(OH)_n$ and in the second case a potentiometric determination of $[Ag^+]$ (*cf.* Ref.[2]) on dilution with 5 M KOH should reveal any polynuclear species. Results on such solutions will be reported in following papers [7,8].

The composition of the argentate(I) complex formed in alkaline solutions of silver oxide has been studied by emf titrations with constant ionic medium (0.95 and 12.6 M NaOH, 1.15 and 11.5 M KOH) using Ag-AgI electrodes. The data indicate that only mononuclear complexes are formed; from this result, together with the solubility data of other workers, it is concluded that the formula of the complex is $Ag(OH)_2^-$. No evidence has been found for the presence of the polynuclear argentate complexes proposed by some previous workers [5].

The solubility product of $Ag_2O(s)$ in 3 M $Na(ClO_4)$ at 25°C was determined as $\log K_{s0} = \log [Ag^+][OH^-] = -7.42 \pm 0.02$.

Silver oxide is appreciably more soluble in strongly alkaline solutions than in water, which proves that one or more argentate species are formed. The formula of the argentate species is the problem of the present work.

The solubility of Ag_2O in NaOH (0.1 to 5.3 M) was studied by Laue [1] in 1927. The solubility, which we may express as a total concentration of B_s moles Ag/l in a saturated solution, was approximately proportional to $[OH^-]$, more nearly so after an activity correction. Laue concluded that the formula of the complex formed is AgO^-. We shall use instead the equivalent formula $Ag(OH)_2^-$; from equilibrium studies in aqueous solutions it is hard to distinguish between formulas that differ only by the content of H_2O and we shall keep to the convention of writing OH complexes if there is no definite evidence for other formulas.

In 1933, Johnston, Čůta and Garrett [2] published their data on the solubility of Ag_2O in NaOH (0.001 to 6.6 M) and KOH (0.0005 to 5.2 M). Like Laue, whose work they do not seem to have seen, they found a solubility minimum at 0.015 M OH^-, and a linear course of B_s with higher $[OH^-]$. They explained their data assuming the species AgOH and AgO^-; in addition, they found evidence for an unknown species, perhaps Ag_2OH^+, besides Ag^+, in solutions on the acid side of the solubility minimum.

* Present address: Institute of Chemistry, University of Helsinki, Helsinki, Finland.

Their data [2] have later been discussed by Reynolds and Argersinger [3] and by Beck [4], who used the position of the solubility minimum to calculate the equilibrium constants. Neither quotes the work of Laue [1], in spite of its high quality.

The fact that the solubility, B_s, is proportional to $[OH^-]$ may be explained by assuming the predominant complex to be $Ag(OH)_2^-$ (or AgO^-), as was done by the authors quoted [1-4]. However, the same result would be obtained with any argentate complex of the charge -1. For instance, we have, with the general formula:

$$\frac{n}{2}\,Ag_2O(s) + \frac{m}{2}\,H_2O + OH^- \rightleftharpoons Ag_nO_{\frac{1}{2}(n-m)}(OH)^-_{m+1}$$

$$B_s = n[Ag_nO_{\frac{1}{2}(n-m)}(OH)^-_{m+1}] = nKf^{-1}_{cpx}f_{OH}\{H_2O\}^{m/2}[OH^-] \approx \text{const}\ [OH^-] \quad (1)$$

Here K is the equilibrium constant for (1), f_{cpx} is the activity factor of the argentate complex and f_{OH} that of the OH^- ion. The two activity factors may approximately cancel each other out. The "conventional" formula for the complex, $Ag_n(OH)^-_{n+1}$, is obtained by setting $m = n$.

The fact that $B_s/[OH^-]$ must be constant for any value of n in (1) was realized by Pleskov and Kabanov [5], who measured the solubility of Ag_2O in KOH (3 to 15 M). For the logarithm of the ratio, $\log (B_s[OH^-]^{-1}) = \log nK$, at 25°C, Laue gave -3.76, Johnston *et al.* -3.71, and Pleskov and Kabanov ≈ -3.8. From the variation of the solubility with water activity, Pleskov and Kabanov moreover concluded $m = 1$ in eqn. (1)

Pleskov and Kabanov tried to determine the number of Ag atoms, n, in the argentate ion by studying the emf:s of silver concentration cells with various total concentrations, B, of Ag. Applying the Nernst equation (eqn. 3 or 6a below), they concluded that $n = 3$. The complex would then be trinuclear, $Ag_3(OH)^-_4$ or rather $Ag_3O(OH)^-_2$.

Recently, Antikainen and Dyrssen [6] studied the distribution equilibria of silver(I) between 3 M $Na(ClO_4,OH)$, and benzene solutions of quinoline. Their data, however, indicate that the predominant complex is the mononuclear $Ag(OH)^-_2$. Because of this apparent contradiction between the distribution [6] and emf [5] data, it was thought necessary to make a new emf investigation as a check of the Russian work.

The cell used in the present investigation had the following composition:

$$-Ag/I\ M\ M^+OH^-, B_+M\ Ag/I\ M\ M^+OH^-\ \text{with}\ B_0\ M\ Ag/Ag+ \quad (2)$$

In our experiments, M^+ was Na^+ or K^+, and the concentration, I, was about 1 or 12 M. Pleskov and Kabanov used 6 and 16 M KOH.

According to the Nernst equation, the emf of this cell (2) is given by the ratio between the concentrations of free Ag^+ in the two half-cells. Now, B is always very small as compared with I, and so the liquid junction potential in (2) is certainly negligible, and the activity factors may be assumed to be the same on both sides. Thus we have

$$E = 59.15\ \log\ ([Ag^+]_+[Ag^+]_-^{-1}) \quad (3)$$

For any dissolved species, $Ag_n(OH)_{n+r}^{r-}$, the law of mass action gives (β = equilibrium constant):

$$[Ag_n(OH)_{n+r}^{r-}] = \beta[Ag^+]^n[OH^-]^{n+r} \quad (4)$$

Now let us assume that, in the solutions with I M OH^-, one single complex of this type predominates and that the concentrations of all other species, including Ag^+, are much smaller. The concentration of the predominating species, $[Ag_n(OH)_{n+r}^{r-}]$, is then equal to B/n, and so eqn. (4) becomes

$$B/n = \beta[Ag^+]^n I^{n+r} \quad (5)$$

The activity factors are included in the equilibrium constant, β ,in eqns. (4) and (5); this can be done, provided that only experiments at the same I are compared.

In our cell (2) we have on both sides the same values for β and I and so it follows from eqns. (3) and (5)

$$E = \frac{59.15}{n} \log B_+/B_- \quad (6)$$

Here, B_+ and B_- are the total concentrations of silver at the two electrodes.

In the present work, B_+ was kept constant at the value B_0, whereas B_- was varied; it is denoted by B. In practice the two solutions were prepared by mixing the same stock solution — an almost saturated solution of Ag_2O in I M MOH — with various amounts of pure I M MOH; thus the ratio B_0/B is known with better accuracy than the separate values of B_0 and B.

We then have

$$E = \frac{59.15}{n} \log (B_0/B) \quad (6a)$$

EXPERIMENTAL

Sodium hydroxide solutions were prepared as usual here (see, *e.g.*, Ref. [7]), starting from a 50 % solution of the commercial *p.a.* reagent, which was kept in a polythene bottle. To prepare the 12.6 M solution, the 50 % solution (which is 18 M) was filtered through a G4 Jena glass filter funnel into a Büchner flask of Jena glass and diluted. In the making of the 0.957 M NaOH solution, recrystallized $Ba(OH)_2$ was added to the 50 % NaOH to remove the last trace of carbonate before the solution was filtered and diluted as before.

Potassium hydroxide, 11.5 M, was prepared from commercial *p.a.* reagent, which was dissolved in distilled water, after which $Ba(OH)_2$ was added. The 1.15 M KOH solution was prepared by simple dilution.

Silver oxide was prepared from recrystallized $Ba(OH)_2$ and $AgNO_3$. It was first washed carefully with de-aerated water until Ba could not be detected with sulfuric acid. The silver oxide was then washed three times with I M MOH and finally suspended in I M MOH and transferred to a polythene flask. The flask was shaken for 19 — 48 h and the solution so obtained, which may not have been quite saturated ($B_0 \leqq B_S$) was the starting solution of concentration B_0.

Some polythene flasks were found to reduce alkaline argentate(I) solutions, forming metallic silver; usually Polva polythene flasks, which do not seem to reduce silver, were used.

The *total silver concentration*, B_0, in the argentate solutions was determined as follows: the 12.6 M NaOH was diluted, hydrazinium sulfate was added, the metallic Ag was filtered off, washed, dissolved in HNO_3 and titrated with KCNS in the usual way. $B_0 = 0.7 \pm 0.2$

mM was found. To 11.5 M KOH, $HClO_4$ was added, $KClO_4$ was filtered off, and Ag^+ in the filtrate was titrated with KCNS. Result: $B_0 = 0.6 \pm 0.1$ mM. From the diagram of Pleskov and Kabanov we may read the solubility B_s between 0.60 and 0.65 mM Ag in 11.5 M KOH, which indicates that our solutions were close to saturation.

With 1 M NaOH, $B_0 = 0.12 \pm 0.01$ mM was found, which is somewhat less than the solubility ≈ 0.18 mM found from Johnston's, Čůta's and Garrett's data.

For our equation (6a) we do not need an accurate value for B_0 but only for B_0/B which is obtained, with all the accuracy necessary, from the volume ratio of dilution. Even the approximate values for B_0 show that in our experiments we have used the same range of B_0 and B as have Pleskov and Kabanov.

Nitrogen gas was bubbled through 10 % H_2SO_4, 10 % NaOH, and finally through the ionic medium, I M MOH.

Electrodes. Some preliminary experiments were made with Ag, AgCl-electrodes; however, the emf was found to drift as much as 4 mV in 1.5 h, probably because of the dissolution of AgCl. If the AgCl was first washed away with conc NH_3, and then with water, E showed no continous drift but rather small jumps so that the accuracy was not more than $\pm$ 1 mV.

For all the following experiments, Ag, AgI-electrodes were used. Pt coils were covered with Ag and then electrolyzed as anodes in 0.1 M NaI (30 min, 0.3 mA). Even with them a drift around 1 mV/h was noticed, in 1 M NaOH (KOH) solution.

In 12.6 M NaOH, E was more constant and the difference between two Ag, AgI-electrodes in the same solution was at most 0.3 mV in one experiment; between different solutions the deviations were sometimes as high as 1 mV. One had to wait 15—60 min for a stable potential.

In 11.5 M KOH, the emf was somewhat less stable than in 12.6 M NaOH.

The cell (2) consisted of a reference half-cell with $B = B_0$ and the "titration" half-cell with B variable. The reference half-cell, in the final experiments, was always a "Wilhelm" apparatus [9]; for the 1 M MOH experiments it was shortened by leaving out the middle part of the salt bridge. Some attempts were made to use polythene bridges of different constructions, but so great were the difficulties met with — solution was pumped out or in through the flexibility of polythene, silver was reduced — that a glass "Wilhelm" was finally used. Changes within the reference electrode may account for the fact that the line constructed on eqn. (6a) does not always pass through the origin. See especially 0.957 M NaOH, where the reference electrode was Ag, AgCl which had been kept for a day in the "Wilhelm"; in all other experiments the reference electrode was Ag, AgI.

For the titration half cell, a vessel of Jena glass was used with 1 M MOH, and one of polythene with 12 M MOH. To check whether the reduction of Ag made any perceptible difference, a glass vessel was also used in some of the experiments with 12 M MOH. No difference was found.

Table 1 shows, for each titration, the order in which the additions were made. A known amount of I M MOH with B_0 M Ag was added through a pipet and the emf measured. The solution was then diluted by addition of several portions of I M MOH without Ag (denoted as "0") and E was measured after each portion. All additions were made by means of pipets, which were filled with nitrogen before the solution was sucked up into them. In the course of the titration, a certain amount of solution was withdrawn with a pipet (denoted by "—" in the table) to keep the total volume within reasonable limits. At the end, a "back-titration" was made by adding again one or several portions of the B_0 solution.

Two electrodes were used in the titration cell in all experiments with 12 M MOH. The difference between them was in general less than 0.2—0.3 mV (see table and figs.).

The whole cell was kept in a thermostat room at 25 $\pm$ 0.2°C, and the emf was measured with a Cambridge type K potentiometer.

RESULTS

Table 1 gives our data in a short-hand form which we hope will be easily understood. The corresponding graphs, E *versus* log (B_0/B), are given in the four fields of Fig. 1. In each field are also given lines with slopes corresponding to

Table 1. Results of emf measurements. For each experiment ("titration"), first the various additions in ml are given; "0" stands for I M MOH without Ag, "B_0" for the stock solution, I M MOH with B_0 M Ag. The figures given are then $\log(B_0/B)$ and E in mV (sometimes for two different electrodes).

a) 0.957 M NaOH

I. 49.89 ml B_0 + 3 · 9.95 ml 0—49.89 ml + 4 · 9.95 ml 0 + 9.95 ml B_0.

log (B_0/B), E (two electrodes): 0.000 0.9 0.5; 0.067 4.6 4.0; 0.177 9.7 9.1; 0.264 14.0 12.8; 0.302 15.2 15.9; 0.428 20.6 21.4; 0.232 12.4 12.6; 0.190 10.4 10.5.

n = 1, 2, and 3, according to eqn. (6a). Obviously, the slope of the present data is not compatible with n = 2 or n = 3 but agrees fairly well with n = 1.

Admittedly, the silver electrodes do not behave very well in these solutions. It is seen, however, from the "back titrations" that the emfs are fairly reproducible; a small drift of the order of 1 or 2 mV would not affect the general conclusions.

The conclusions are the same for ~1 M and ~12 M alkali, as could be expected from the equilibrium condition, eqn. (1): in a saturated solution, the ratios between the species, say, $Ag(OH)_2^-/Ag_3(OH)_4^-/OH^-$ would be practically independent of $[OH^-]$. Thus, if the trinuclear complex predominates at low I, it should do so at high I too; if it is insignificant (as it seems to be) at low I, one could not increase its importance by increasing I.

One may ask why Pleskov and Kabanov got a so much lower slope, that it would correspond to n = 3. We would think that the main cause is in the electrodes. They seem to have used silver wires (instead of electrolytically

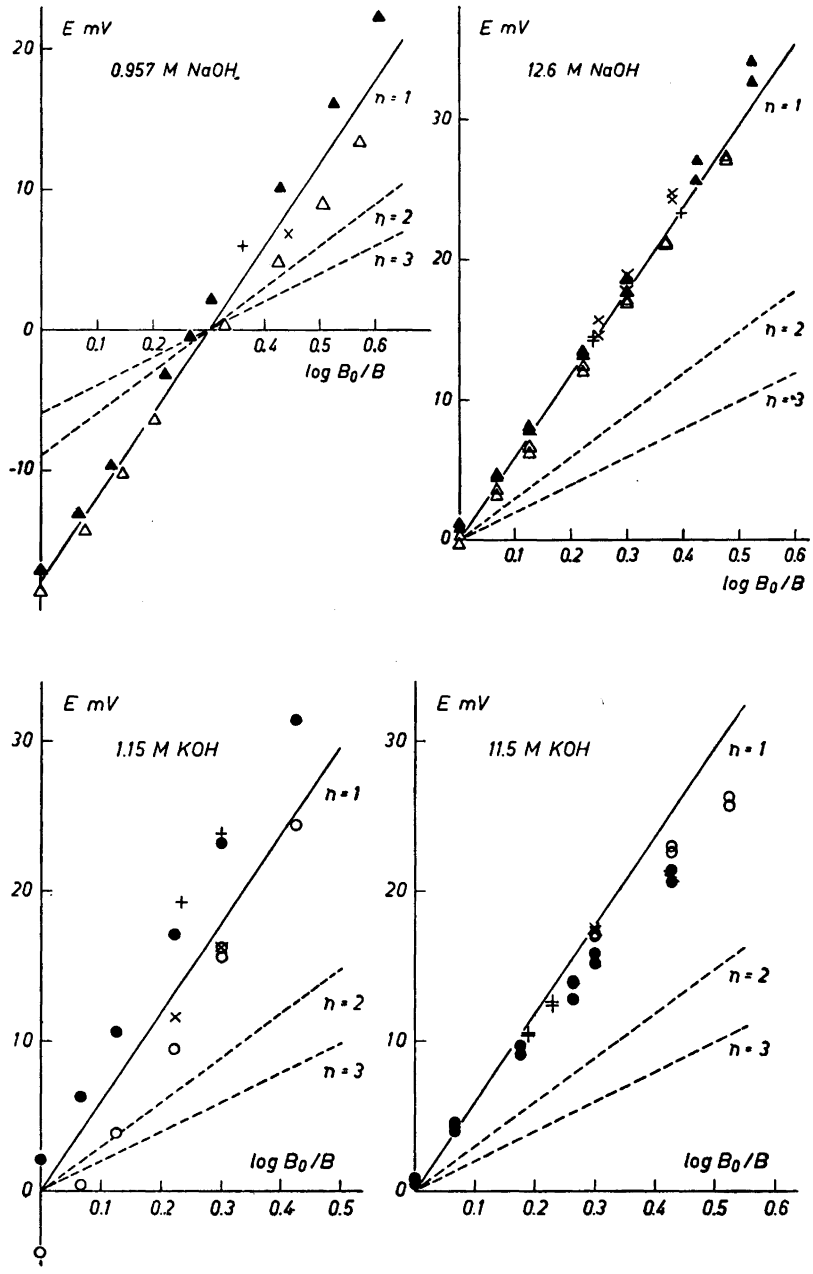

Fig. 1. Experimental results, plotted as E (mV) *versus* $\log(B_0/B)$. Full-drawn line: calculated with eqn. (6a) and $n = 1$; dotted lines calculated with eqn. (6a) and $n = 2$ or 30 Different runs, or electrodes, are denoted by different symbols.

precipitated silver), which, according to our experience, can give rise to emf:s somewhat different from the standard emf:s for pure silver; the deviations are especially great at low $[Ag^+]$. Covering the silver electrolytically with an oxide "Ag_2O_2" layer and then reducing it (method not mentioned) [5], might lead to difficulties. If solid Ag_2O is left on the silver surface, it is likely to dissolve in a unsaturated solution and the actual concentration of Ag^+ would be higher than calculated from the dilution, the emf measured would be less than expected and so would the slope.

It is apparent from the present work how important is the treatment of the electrodes. It should be mentioned that, in a few of our preliminary experiments, the apparent slope would have corresponded to $n \sim 1.5$.

In conclusion, our present data give no reason to assume any polynuclear species in argentate solutions. In the region where the solubility is proportional to $[OH^-]$, the formula of the predominant species can be simply written as $Ag(OH)_2^-$. At very high alkalinities, >5 M OH^-, other species such as $Ag(OH)_3^{2-}$ may perhaps occur; the bend in the solubility curve is however not upward, as would be expected from terms for higher complexes, but downward, presumably because of activity factors.

SOLUBILITY PRODUCT OF Ag_2O

In connection with other work [6], the solubility product of AgOH was determined in the medium 3 M $(Na)ClO_4$. Silver electrodes were used for determining $[Ag^+]$; they were standardized against acid solutions of known Ag^+. Three titrations were carried out, starting with acid silver solution and adding alkali. A glass electrode was used as a check, but $[OH^-]$ was taken from the analytical composition of the solution. The average value obtained was

$$\tfrac{1}{2}Ag_2O(s) + \tfrac{1}{2}H_2O \rightleftharpoons Ag^+ \pm OH^-; \log K_{s0} = -7.42 \pm 0.02 \ (25°C, 3\ M\ (Na)ClO_4)$$

The measurements could have been made more accurate but the precision sufficed for our needs.

Acknowledgements. This work has been supported in part by the *Air Force Office of Scientific Research of the Air Research Development Command, United States Air Force,* through its European Office.

Dr. George Biedermann has given valuable aid in the preparation of very pure Ag_2O. Professor Robert Connick has been kind enough to read the manuscript and to give helpful comments on it.

On the Biosynthesis of the Pigments from *Penicillium islandicum* I

STEN GATENBECK

Institute of Biochemistry, University of Lund, Lund, Sweden

The biochemical interrelationships of the pigments iridoskyrin, islandicin, rubroskyrin, luteoskyrin and skyrin in the mould *Penicillium islandicum* have been investigated. The specific radioactivity / time curves of the pigments have been determined after feeding the mould for a short time with ^{14}C-labelled acetate. Analysis of these curves indicates that the pigments are formed independently of each other.

The mould *Penicillium islandium* Sopp produces a set of various pigments of very close structural relationship to each other when grown on a medium with glucose as the sole carbon source. All the pigments are polycyclic compounds and have furthermore the anthracene structure in common. The dominant compounds are skyrin, rubroskyrin, luteoskyrin, iridoskyrin and islandicin. From the structures of these compounds (Fig. 1) one would anticipate a biological interconversion. Rubroskyrin and luteoskyrin are easily transformed *in vitro* by dehydrating agents or dithionite [1] to iridoskyrin so it is reasonable to assume them to be the biological precursors of iridoskyrin.

As shown in earlier papers [2,3] the actual pigments originate from acetate. In order to investigate their interconvertibility a series of experiments has been carried out on the incorporation of ^{14}C-labelled acetate into these pigments in addition to studying the production sequence of the pigments (expt. A). The variations in time of their specific radioactivities were followed (expt. B). In other experiments (C and D) the specific radioactivities were determined after replacement of the labelled substrate with normal Czapek-Dox medium.

EXPERIMENTAL

Experiment A. A Petri dish (5 × 15 cm) containing 100 ml of Czapek-Dox medium was sterilized and inoculated with a spore suspension of *Penicillium islandicum* Sopp, N.R.R.L. 1036. After two days the whole surface of the medium was covered by a white mycelium. At eight hourly intervals a piece of the mycelium (*ca.* 3 × 3 cm) was cut out and thoroughly extracted with acetone. A portion of the acetone solution was developed on a paper chromatogram in a solvent containing benzene-2 % formic acid (10:1). The

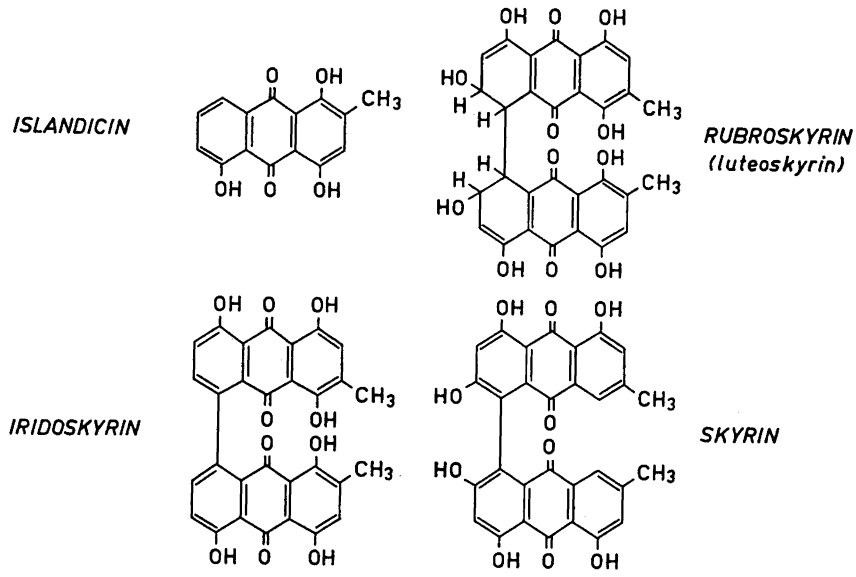

Fig. 1.

different pigments were identified by their R_F-values, color and color reactions with methanolic magnesium acetate solution (Table 1). The pigment that appeared first was skyrin. It was not possible to detect any other pigment until 24 h after the appearance of skyrin. The experiment was repeated with shorter intervals between the withdrawals of the test samples but even with one hourly intervals it was not possible to determine any production order in time of rubroskyrin, luteoskyrin, iridoskyrin and islandicin.

Experiment B. A culture was grown for seven days in the same way as in experiment A. After the addition of 0.25 mC $CH_3{}^{14}COONa$ (5 mC/mmole) samples were taken from the mycelium at different times as described above. Every sample was extracted with acetone, the acetone solution evaporated to dryness and the residue triturated several times with petroleum ether (b. p. 40—60°C) in order to remove the lipids. After dissolving the pigments in acetone, two equal portions were withdrawn, one of which was then developed on a paper chromatogram. The total radioactivity of the iridoskyrin-islandicin spot was measured directly on the paper. The pigments were extracted from the paper with 3 ml of HCl-acidified acetone. Their concentration was measured in a Hilger Uvispek spectrophotometer at 492 mμ. Iridoskyrin and islandicin have their absorption maxima at the same wavelengths but the molar extinction coefficient of iridoskyrin is twice that of islandicin (log ε_{492} 4.09). The molar specific radioactivity of the mixture iridoskyrin-islandicin was calculated, the amount being expressed as islandicin.

The other portion of the acetone solution was evaporated to dryness and 1 ml of concentrated H_2SO_4 added. After keeping at room temperature for 20 h it was diluted with water and exhaustively extracted with ether. The extract was concentrated to a small volume and developed on a paper chromatogram in the same solvent as above. The radioactivity and the amount of the mixture of the natural iridoskyrin-islandicin and the iridoskyrin obtained from rubroskyrin and luteoskyrin by the treatment with H_2SO_4 was measured as above. After subtraction of the radioactivity and the amount of natural iridoskyrin-islandicin, the specific radioactivity of rubroskyrin-luteoskyrin was calculated. The values are given in Fig. 2.

Table 1.

Compound	R_F-value (benzene-formic acid	Color	Color with meth. Mg-acetate
Islandicin	1.00	Pink	Purple
Iridoskyrin	0.95	Pink	Purple
Skyrin	0.15	Yellow	Violet
Rubroskyrin	0.20	Red	Green
Luteoskyrin	0.30	Yellow	—

It was also desirable to know the molar specific radioactivity of skyrin. In the solvent used, skyrin and rubroskyrin overlap on the paper chromatogram and no other solvent could be found which would separate them completely. In order to obtain a true value of the specific radioactivity, skyrin was cleaved to emodin which is easily separated from the other pigments by paper chromatography. The cleavage was performed according to Raistrick [4] by dissolving an aliquot of the acetone extract in 1 N NaOH and treating the solution with sodium dithionite for one hour at room temperature. After acidification with concentrated HCl the solution was extracted with ether and the ether phase developed on a paper chromatogram in benzene-formic acid. The radioactivity and the amount of emodin was then determined as above (log ε_{437} 4.10).

Experiment C. The mould was cultured in a Petri dish as described in experiment A. After seven days an aqueous solution of 0.25 mC of $CH_3{}^{14}COONa$ was added to the medium. The radioactive medium was withdrawn with a pipette after half an hour and fresh Czapek-Dox solution added after washing the mycelium three times with sterilized, distilled water by injecting the water beneath the mycelium. Test samples were taken from the mycelium over a period of 10 h. The pieces of mycelium were extracted with acetone, the lipids removed and the extract developed on a paper chromatogram as above. The molar specific radioactivity of iridoskyrin-islandicin was determined. The region on the paper containing rubroskyrin and luteoskyrin was cut out and the pigment extracted from the paper with acetone. The acetone solution was evaporated to dryness, treated with concentrated H_2SO_4 for 20 h and the molar specific radioactivity determined after further chromatographing as in expt. B. The values are given in Fig. 3.

Experiment D. Expt. C was repeated with the modification that islandicin was separated from iridoskyrin by sublimation in vacuum at 160°C. The residue from the sublimation consisting of iridoskyrin was resublimed in vacuum at 270°C. The molar specific radioactivities of islandicin and iridoskyrin were then determined separately. As the culture in this experiment produced unusally large amount of luteoskyrin this pigment was isolated by paper chromatography and its molar specific radioactivity determined without prior conversion to iridoskyrin. The concentration of luteoskyrin was measured at 447.5 mμ (log ε 4.46). The results of expt. D are shown in Fig. 4.

RESULTS AND DISCUSSION

The values in Fig. 2 show that the molar specific radioactivity of naturally occurring iridoskyrin-islandicin is definitely higher than that of rubroskyrin-luteoskyrin. If rubroskyrin-luteoskyrin were precursors of iridoskyrin-islandicin they should have a higher specific radioactivity than iridoskyrin-islandicin or at least the same. While the results of expt. B immediately exclude this possibility they do not argue against the reverse mechanism.

Although expt. C shows a rather high incorporation of labelled acetate after half an hour, experiment A and repeated experiments of the same type indicate that the radioactivity of the pigments has not reached the steady state within this time.

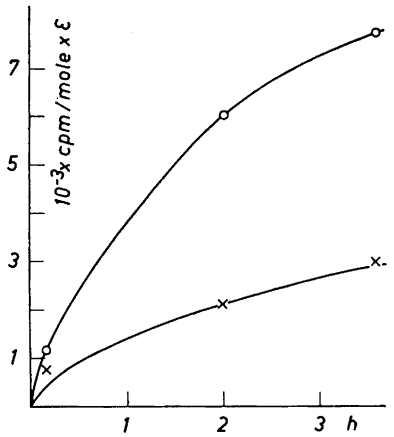

Fig. 2. Specific radioactivity/time curves, iridoskyrin-islandicin O———O, rubroskyrin-luteoskyrin ×———×.

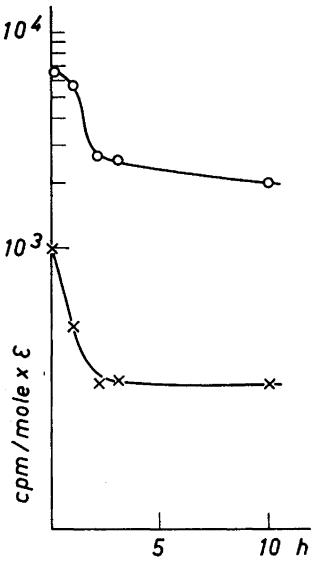

Fig. 3. Specific radioactivity/time curves, iridoskyrin-islandicin O———O, rubroskyrin-luteoskyrin ×———×.

If the iridoskyrin-islandicin mixture was transformed to rubroskyrin-luteoskyrin by a hydration reaction, the specific radioactivity of the former should decrease relative to that of the latter. As seen from Fig. 3 the specific radioactivities of iridoskyrin-islandicin and rubroskyrin-luteoskyrin decrease almost at the same rate and this result has been obtained in several repeated

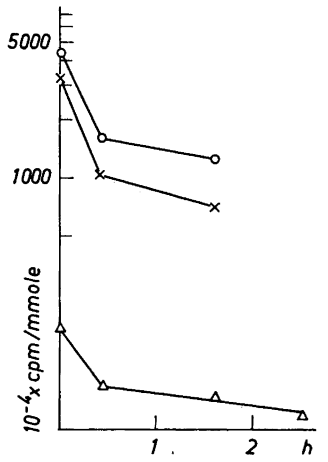

Fig. 4. Specific radioactivity/time curves, islandicin O———O, iridoskyrin ×———×, luteoskyrin △———△.

experiments. This is in accord with the independent formation of these pigments.

Expt. D confirms the conclusions derived from expt. C that there is no interconvertibility of the anthraquinones and their hydrated forms. Furthermore, expt. D gives the surprising result that islandicin is not the immediate precursor of its dimer, iridoskyrin. The parallel specific radioactivity/time curves of these compounds in Fig. 4 indicate that the biosynthesis of one pigment is wholly independent of the production of the other one.

Emodin, which is equivalent to skyrin, has about the same specific radioactivity as rubroskyrin-luteoskyrin and is consequently not a precursor of iridoskyrin-islandicin. The early formation of skyrin indicates that it has a separate position in the biosynthesis of the pigments. As skyrin occurs in other strains of *Penicillium islandicum*[4] and in other moulds, *e.g. P. rugulosum*[5], *P. wortmanni*[5], *Endothia parasitica* and *E. fluens*[6], which do not produce rubroskyrin or luteoskyrin, it is assumed, that skyrin has no connection with these pigments.

On Observable Discontinuities and Coherence in the Kinetics of Enzymically Reacting Systems

J. A. CHRISTIANSEN

Sundvænget 9, Hellerup, Denmark

It is shown that there are thermodynamic arguments for the belief, that the cyclic transformations which the individual molecules of an enzyme in a macroscopic reacting system are forced to run through during their action as catalysts are in phase, are coherent. A necessary consequence of this behaviour is, that the reaction proceeds in observable jumps, whose magnitude is determined by the amount of enzyme present in the system. Experimental evidence, which seems to support this view is quoted.

This paper contains an extension of considerations from former papers of the author [1-3].

In most mechanical or even quantum-mechanical pictures of an elementary chemical reaction the process is considered to be a continuous one. The picture may be more ore less refined, but the fundamental assumption is always the one due to Arrhenius, that a molecule or a complex of molecules to react must pass a state in which its energy is maximum.

Arrhenius [4] called this state the active one. Later on R. Marcelin [5] denoted it as the critical state, while J. N. Brønsted [6] in a paper in German used the name "Übergangszustand". The corresponding name in English "transition state" was used by M. Polanyi and M. G. Evans [7], and this name has since been used exclusively by H. Eyring and his school.

But even if the single elementary reaction be described as proceeding continuously, it is evident that statistically an elementary reaction must be considered as practically speaking discontinuous. This is so, because the life times of the reactants and the resultants are immensely much larger than that of the intermediate complex. Therefore we commit only a very small error if we state that a molecule or a complex of molecules is either in the reactant state or in the resultant state. Or we may say, that the reaction takes place in a jump from one state to the other through the transition state. However, in a macroscopic system, containing an immense number of reacting molecules

the jumps are randomly distributed in time, and the discontinuity is therefore not observable. But this statement may not be true in the case where a reaction is catalyzed, *e.g.* by an enzyme.

Let a reaction, which has a positive affinity from the left to the right

$$B_1 + B_2 + B_3 = A_2 + A_3 + A_1 \qquad (B)$$

be catalyzed by an enzyme in three elementary steps:

$$\begin{array}{ll} B_1 + X_1 = X_2 + A_2 & (+1) \\ B_2 + X_2 = X_3 + A_3 & (+2) \\ B_3 + X_3 = X_1 + A_1 & (+3) \end{array} \qquad (A)$$

X_1, X_2, and X_3 being three different forms or compounds with the substrates (B_i, A_i) of the enzyme.

The sequence (A) means, that the reaction (B) forces the enzyme to undergo a cyclic transformation in the order 1231. What we observe is the occurrence or the disappearence of one species of the resultants or the reactants respectively. To fix our ideas let us assume, that we observe the occurrence of A_1 which may be, *e.g.*, a (hydrated) hydrogen ion.

The liberation of this takes place in the moment when X_3 is transformed into X_1 which, according to the foregoing, is a sudden event, so long as only one molecule of the enzyme is considered. Or in other words, we may state that the enzyme molecule must be at a certain time in one of its three possible states.

Consider now the realistic case, where there are many molecules of the enzyme within a certain volume element. May we then assume that the different molecules are simultaneously in the same state or may we not? Or expressed in another way, is the instantaneous distribution of the enzyme on its different states the same everywhere in the reacting system?

According to thermodynamics it seems, that the answer to the latter question must be yes, because we know that, to change the state of the whole system from one in which the distribution is the same everywhere to one in which it is not, requires work. Therefore the former state of the system is more probable than the latter and, as usual in statistical thermodynamics, so much more so that it is, practically speaking, the only possibility. We may therefore say that the cyclic transformations of the individual enzyme molecules must always be in phase or, that the system is coherent in respect of transformations of the enzyme.

This coherence would have an important consequence: As mentioned above the transformation of an X_3 into an X_1 is accompanied by a liberation of A_1. If now coherence exists this means, that all the enzyme molecules X_3 react simultaneously that is, an amount of A_1 which is stoichiometrically equivalent to the amount of enzyme in the system is suddenly released. If, therefore, the liberation of A_1 in our system is observed and taken as a measure of the extent of the overall reaction (B) it is evident, that we observe a discontinuous progress of the reaction. Or, in other words, the reaction is observed to proceed in consecutive jumps, each representing the same number of individual reactions according to (B). It must be added, however, that the author is not

able at present to indicate a mechanism, by means of which the coherence is maintained. It is evidently a question of great importance whether or not the peculiar behaviour described above of a reaction catalyzed by an enzyme has ever been found, and the answer seems to be in the affirmative: It is an experimental fact [8], that certain (by no means all) nerves in their endings spontaneously generate electrical impulses which are transmitted through the nerve and which can be observed oscillographically by means of electrodes connected to the nerve in a suitable way. The signals as we may call them appear periodically, the period, which is often of the order of 0.01 to 0.1 s, being constant so long as the corresponding sense organ is not stimulated. Furthermore, and this is what mostly interests us here, the duration of the signal is only a small fraction of the distance in time between two consecutive signals. We thus get the impression, that periodically an outburst of "something" takes place which causes the electrical disturbance. Evidently this phenomenon might be understood on the lines described above if an enzyme catalyzing a chemical (metabolic?) reaction were located in the nerve ending, the substrates being supplied from its surroundings. This again would be a corroboration of the widely accepted assumption, that everything which happens in a living organism is caused by chemical reactions. It may be added that it is a fact that chemical reactions go on in nerves as in other cells of the living organism.

Besides this to a certain extent direct evidence for the existence of discontinuities in the course of an enzymic reaction, evidence of a more indirect nature seems to exist: In most (not in all) cases of enzymic reactions it can be shown that steady state is arrived at in the course of an exceedingly short time. In such cases a function φ of the extent of reaction ξ can always be found, which obeys the equation

$$t = \varphi(\xi)$$

where t is the time at which the extent of reaction has reached the value ξ. If now, as hitherto assumed, ξ increases continuously with time, it must be possible to determine the rate of the reaction with an accuracy which is only limited by the inaccuracy of the experiments. If, however, the reaction proceeds in observable jumps it may well happen, that the accuracy obtained is less than that estimated from the properties of the experimental procedure. We have had in the institute of physical chemistry of the university of Copenhagen indications of such a situation. However, as we might have overestimated the accuracy of our measurements, the results were not published. Then a Russian colleague, S. E. Shnoll, referring to the present authors paper [2], sent him a paper in Russian [9], in whose English summary Shnoll explicitly states, that his determinations of the rate of a certain reaction show deviations, which certainly cannot be explained by inaccuracies in the experimental procedure.

The different pieces of evidence mentioned above may not seem sufficiently convincing when they are taken separately. But when taken together they seem to point out that reactions of the types mentioned show discontinuities which are macroscopically observable. Or as we may say, the single cyclic transformations in the macroscopic system are in phase, are coherent.

The Bacteriostatic Action of Benzoic and Salicylic Acids

II. The Effect on Acetate Metabolism

INGMAR BOSUND*

Swedish Institute for Food Preservation Research, Gothenburg, Sweden, and State Dairy Research Station, Alnarp, Sweden

The effect of benzoic and salicylic acids on the acetate metabolism of resting cells of *Proteus vulgaris* was investigated by the Warburg technique.

The oxidation of acetate by washed cells previously grown in a medium containing glucose and amino acids was inhibited by both acids. Small amounts of succinate added simultaneously with the acetate in these respiration studies decreased the inhibition caused by benzoic acid considerably.

In similar experiments with cells previously grown in a medium with acetate as the sole carbon source, the effect of benzoic acid on the rate of acetate oxidation was much less, while that of salicylic acid was as before.

Both inhibitors had a tendency to increase the total amount of CO_2 evolved per mole of substrate added in experiments with washed cells previously grown in the acetate medium. Such an increase in CO_2 output from acetate induced by benzoic acid was further investigated in experiments with labelled acetate and shown to be derived mainly from the methyl group of the acetate molecule.

Neither of the acids had any appreciable effect on pyruvate dismutation with cell-free extracts of *Escherichia coli*.

In a previous investigation [1] the oxidation of glucose and pyruvate by resting cells of *Proteus vulgaris* was found to be completely inhibited at the oxidation level of acetate by 0.01 M benzoic acid or 0.003 M salicylic acid at pH 6.0. It was further shown that these concentrations of the two acids are necessary for complete suppression of growth of this organism at the pH mentioned. It was considered that the inhibition of acetate oxidation might have something to do with the bacteriostatic effect.

This paper is concerned with the influence of benzoic and salicylic acids on the oxidation of acetate by resting cells of *P. vulgaris* and with the effect of these acids on acetyl phosphate formation with extracts of *Escherichia coli*.

* Present address: State Dairy Research Station, Alnarp, Sweden.

EXPERIMENTAL

Organisms. The same strain of *Proteus vulgaris* was used as before. The extract in the experiments on acetyl phosphate formation was prepared from cells of *Escherichia coli*.

Growth conditions. Cell suspensions for respiration studies with *P. vulgaris* were prepared from cultures grown either in a fairly rich medium containing glucose and amino acids (medium A) or in a poor medium with acetate as the sole carbon source (medium B). In the case of medium B the inoculation was made with cells previously adapted to growth in this medium. Medium A: glucose, 10.0 g; casein hydrolysate (Difco vitamin-free casamino acids), 1.0 g; NH_4Cl, 1.0 g; nicotinamide, 0.2 mg; K_2HPO_4, 9.5 g; KH_2PO_4, 1.5 g; $MgSO_4 \cdot 7H_2O$, 0.1 g; distilled water to 1 l; adjusted to pH 7.0. Medium B: $CH_3COONa \cdot 3H_2O$, 1.0 g; NH_4Cl, 1.0 g; nicotinamide 0.2 mg; $Na_2HPO_4 \cdot 2H_2O$, 6.0 g; KH_2PO_4, 3.0 g; $MgSO_4 \cdot 7H_2O$, 0.1 g; distilled water to 1 l; adjusted to pH 7.0. The cultures were grown at 37°C in Kluyver flasks with sufficient aeration to ensure maximum growth rate or, in some experiments using medium A, in Erlenmeyer flasks without aeration or shaking. In some experiments the cells were harvested early in the logarithmic growth phase, and then the medium was inoculated with a heavy suspension of washed cells. When necessary, growth was followed by turbidity measurements in a Beckman spectrophotometer at 425 mμ.

Methods. Oxygen consumption and production of carbon dioxide was measured by the conventional Warburg technique as described in the first paper of this series. The data recorded in the figures and tables have been corrected for endogenous respiration. In the experiments with labelled acetate the oxidation was terminated by addition of 0.3 ml of 5 N H_2SO_4 when the rate of oxygen consumption had decreased to the value of the endogenous respiration. The cells were collected by centrifugation, washed three times with distilled water and dried at 110°C. The media and the washings were pooled, neutralized with 2 N NaOH and evaporated to dryness over night by freeze drying. The total amount of carbon in the cells and in the media was then converted into CO_2 by the wet decomposition method of van Slyke and Folch [2]. The CO_2 was collected as $BaCO_3$ in centrifuge tubes containing a saturated solution of $Ba(OH)_2$ in water. The precipitates were washed twice with distilled water, dried at 125°C and weighed. The respiratory CO_2, which was absorbed during the experiment in 10 % KOH in the center wells of the Warburg flasks was carefully transferred, together with the KOH, into a flask containing a known amount of K_2CO_3 dissolved in distilled water. The carbonate was collected as $BaCO_3$ by addition of 0.2 M $BaCl_2$, and the precipitate was washed, dried and weighed in the way described. The total amount of radioactivity in the three samples of $BaCO_3$, from cells, media and respiratory CO_2 was then determined by plating the carbonate on aluminium dishes and counting in a Geiger-Müller counter. In each experiment it was checked that the sum of the radioactivities recovered in the three samples of $BaCO_3$ corresponded to the amount added with the acetate.

Preparation of E. coli extract. The soluble enzyme system used in the experiments on acetyl phosphate formation was prepared from cells of *E. coli* grown in a medium containing lactose, meat extract, yeast extract, trypton and phosphate. The cells were harvested by use of a Sharples centrifuge, washed twice with 0.9 % KCl-solution and freeze dried. The extract was prepared from the dry powder in the way described by Korkes *et al.*[3]

Reagents. The reagents used were commercial preparations with the exception of acetyl phosphate, which was synthesized from *iso*propenyl acetate and phosphoric acid by the method of Stadtman and Lipmann [4]. DPN * and CoA were supplied by Pabst Laboratories; DPT and lactic dehydrogenase, by Sigma Chemical Company; and methyl and carboxyl labelled samples of sodium acetate, by The Radiochemical Centre, Amersham, England.

RESULTS

The effect of benzoic acid on acetate oxidation by washed cells previously grown in medium A. Preliminary respiration studies showed that the acetate oxidiz-

Each vessel contained 5—10 mg dry weight of washed cells, 133 μmoles of potassium phosphate, 7 μmoles of sodium acetate and 0.2 μmoles of sodium succinate (when present). Temp. 37°C; pH 6.0. In these experiments the rate of oxygen consumption generally became constant about 20 min after addition of substrate. The Q_{O_2} values recorded are based on measurements made after this initial period. In all experiments the oxygen consumption due to succinate oxidation was completed about 15 min after addition of substrate as determined in separate flasks where only succinate was added. This oxygen uptake could thus have no influence on the Q_{O_2} values shown in the table. Moreover, the theoretical amount of oxygen for complete oxidation of 0.2 μmole of succinate is only 15.7 μl (generally about 10 μl was consumed in these experiments) whereas the total oxygen consumption due to acetate oxidation during the experimental period was more than 200 μl.

ing capacity of *P. vulgaris* cells, isolated from the growth medium by centrifugation and washed as described in the experimental part, varies with the growth conditions and with the physiological age of the cells at the time of harvesting. The influence of such factors in the pre-history of the cells on the rate of oxygen consumption after addition of acetate to washed cell suspensions is shown in Table 1 (see also Table 6). In these tables the increase in the rate of acetate oxidation, caused by the addition of small amounts of succinate together with the acetate is clearly demonstrated. It is probable that this stimulating

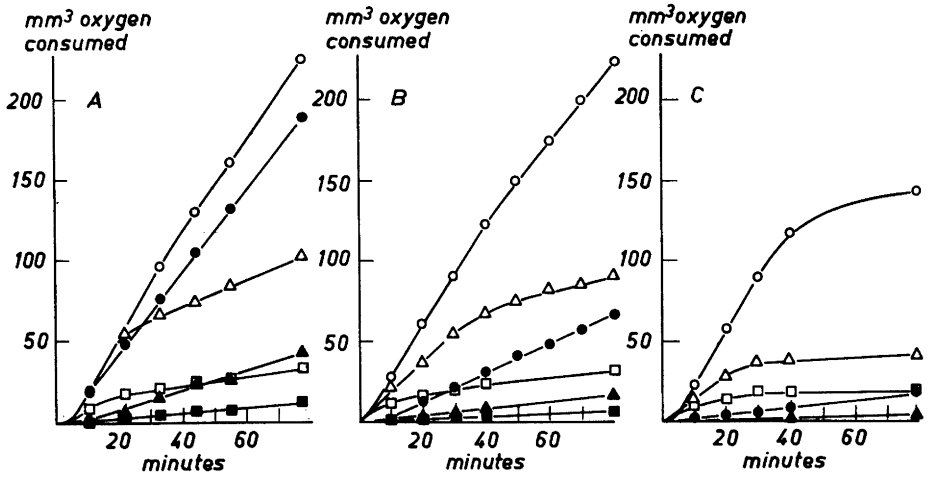

Fig. 1. Influence of benzoic acid on acetate oxidation by washed *P. vulgaris* cells previously grown with aeration in medium A. A — cells harvested in the logarithmic growth phase, B — cells harvested early in the stationary phase, and C — cells harvested after 8 h in the stationary phase. The vessels contained besides 7 mg dry wt. of cells, 133 μmoles of potassium phosphate and 10 μmoles of sodium acetate: ●———● no further additions; ▲———▲ 3.5 mM sodium benzoate; ■———■ 7.0 mM sodium benzoate; ○———○ 0.2 μmoles of sodium succinate; △———△ 0.2 μmoles of sodium succinate and 3.5 mM sodium benzoate; □———□ 0.2 μmoles of sodium succinate and 7 mM sodium benzoate. Temp. 37°C; pH 6.0. The values recorded have been corrected for the oxygen uptake attributable to the succinate oxidation (10—15 μl).

effect is due either to conversion of succinate to oxalacetate, which serves as a condensing partner for oxidation of acetate through the Krebs cycle or to the functioning of succinate as a readily utilizable source of energy for the ATP-generated activation of acetate.

It is evident from the table that only cells pre-grown with adequate aeration oxidize acetate to any appreciable extent and at a rate decreasing with increasing age of the cells when harvested (Expts. Nos. 3—7). Cells, harvested after growth without aeration, or with aeration for only one or two generations, did not oxidize acetate (Expts. Nos. 1—2). The great acetate oxidizing capacity of washed cells pre-cultivated in medium B is apparent from Expt. No. 8.

For the cultivation of cells in medium B, the Kluyver flasks were inoculated with cells previously adapted to the growth medium employed, but unaccustomed to excessive aeration. Therefore, in order to obviate any consequent delay in growth (Dagley, Dawes and Morrison [5] or Lwoff and Monod [6]), the medium was inoculated with a fairly large amount of cells.

In some experiments *P. vulgaris* was studied with regard to its ability to oxidize other fatty acids, such as propionic and butyric acids. No oxygen consumption attributable to such an oxidation was, however, noticed, not even in the presence of succinate.

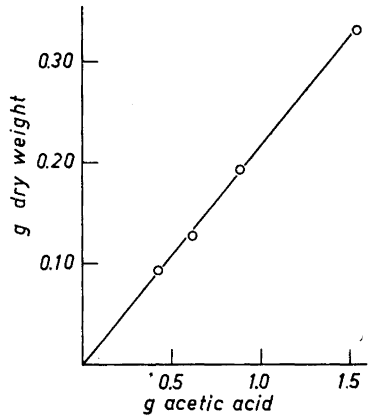

Fig. 2. Total growth of *P. vulgaris* in medium B as a function of the amount of acetic acid available.

As is shown in Fig. 1 A, B and C benzoic acid completely inhibited acetate oxidation by washed *P. vulgaris* cells, pre-grown in medium A, at concentrations previously found not to influence the initial rate of glucose and pyruvate oxidation by this organism. The degree of inhibition was approximately the same whether the cells were harvested in the logarithmic or in the stationary phase. Simultaneous oxidation of a comparatively small amount (0.2 μmole) of succinate markedly reduced the inhibitory effect of 3.5 mM benzoic acid for the first 20—30 min. In parallel experiments with omission of acetate the same amount of succinate was oxidized with consumption of 10—15 μl of oxygen during this period, after which the rate of the oxygen uptake decreased to that of the endogenous respiration (see the text to Table 1). The succinate oxidation was not inhibited by benzoic acid in the concentrations used.

In a similar study (unpublished) with salicylic acid, which in a concentration of about 1—2 mM completely inhibited any acetate oxidation, addition of succinate did not markedly reduce the inhibition produced. Salicylic acid in the same concentration range was previously found [1] to block glucose and pyruvate oxidation at the acetate level in experiments where the initial rate of glucose oxidation was actually stimulated.

Adaptation of P. vulgaris to growth on acetate as the sole carbon source. The comparatively strong inhibitory effect of benzoic acid on acetate oxidation as revealed by the experiments discussed above was further investigated, but now with cells grown on acetate as the sole carbon source (apart from CO_2). The same strain of *P. vulgaris*, but acetate-adapted, was used as before. The strain was adapted to acetate by successive inoculation in test tubes with medium B containing decreasing amounts of glucose or some other readily utilizable carbon source. pH values above 6.5 proved best for the adaptation process which resulted in a rather slow growth, even of fully adapted cells, owing to lack of aeration. The adapted cells behaved in the same way as the original cells in bacteriological standard tests and were, as before, dependent on addition of nicotinamide for growth. Cells for respiration studies were cultured in Kluyver flasks inoculated with adapted cells and adequately

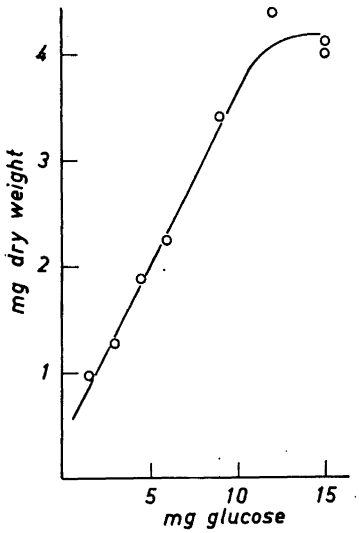

Fig. 3. Total growth of acetate adapted *P. vulgaris* in medium B containing butyrate instead of acetate and supplemented with varying amounts of glucose. When growth had ceased in the different flasks the content of volatile acids in the culture media was determined by steam-distillation and paper chromatography of the distillates. Butyric acid was quantitatively recovered from all the distillates. In flasks where relatively much glucose had been added, additional amounts of volatile acids (probably acetic and formic) were found.

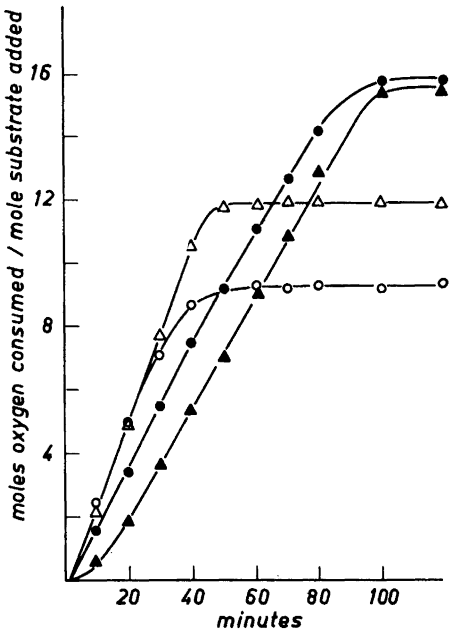

Fig. 4. Effect of benzoic acid on pyruvate and acetate oxidation by washed *P. vulgaris* cells previously grown in medium B. Each vessel contained 2.2 mg dry wt. of cells and 133 μmoles of potassium phosphate. O——O 7 μmoles of sodium pyruvate; ●——● 7 μmoles of sodium pyruvate and 8 mM sodium benzoate; △——△ 7 μmoles of sodium acetate; ▲——▲ 7 μmoles of sodium acetate and 8 mM sodium benzoate. Temp. 37°C; pH 6.0; final volume 2.5 ml.

aerated. As mentioned above, it was necessary to start with heavy inoculation to avoid unduly long lag phases. The cells were therefore allowed to multiply for 24—48 h before aeration was started.

During these conditions the total yield of bacterial growth obtained varied with the amount of acetate added as shown in Fig. 2. The mean generation time during aeration was 3—4 h. Attempts to adapt the strain to growth on butyrate as the sole carbon source proved unsuccessful. Fig. 3 shows an experiment demonstrating the inability of acetate adapted cells to utilize butyrate when grown in a butyrate medium containing various amounts of glucose to support growth.

The effect of benzoic acid and salicylic acid on acetate and pyruvate oxidation by washed cells pre-grown in the acetate medium. The highest rate of oxygen

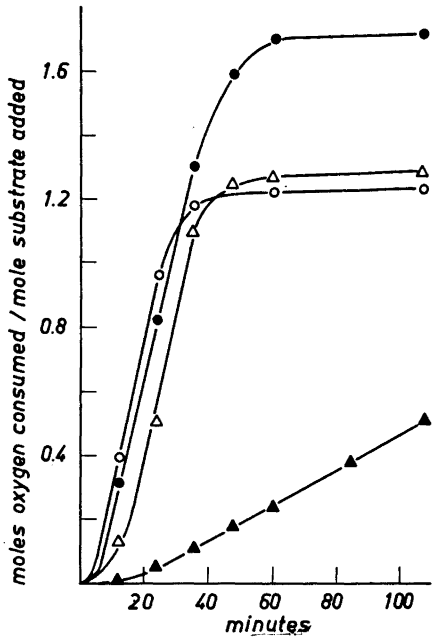

Fig. 5. Effect of salicylic acid on pyruvate and acetate oxidation by washed *P. vulgaris* cells previously grown in medium B. Each vessel contained 3.6 mg dry wt. of cells and 133 μmoles of potassium phosphate. O——O 7 μmoles of sodium pyruvate, ●——● 7 μmoles of sodium pyruvate and 2 mM sodium salicylate, △——△ 7 μmoles of sodium acetate, ▲——▲ 7 μmoles of sodium acetate and 1 mM sodium salicylate. Temp. 37°C; pH 6.0; final volume 2.5 ml.

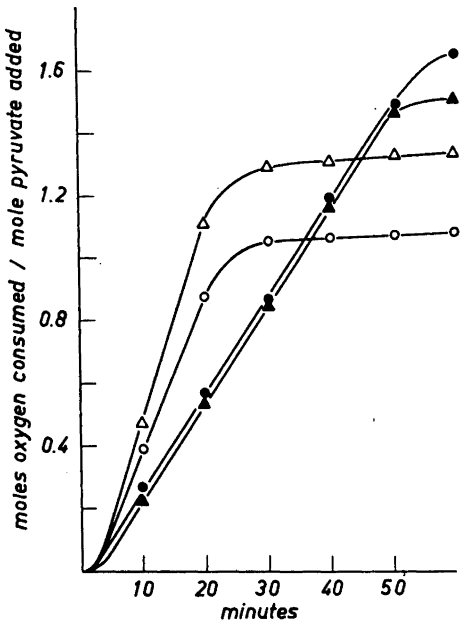

Fig. 6. Effect of benzoic acid on pyruvate oxidation in presence and absence of ammonium ions by washed *P. vulgaris* cells previously grown in medium B. Each vessel contained 3.2 mg dry wt. of cells, 133 μmoles of potassium phosphate and 7 μmoles of sodium pyruvate. O——O no further additions, ●——● 8 mM sodium benzoate, △——△ 20 μmoles of ammonium chloride, ▲——▲ 20 μmoles of ammonium chloride and 8 mM sodium benzoate. Temp. 37°C; pH 6.0; final volume 2.5 ml.

consumption during acetate oxidation with washed cells previously grown on glucose and amino acids was about 30 μl oxygen per mg dry weight and hour (Table 1). The corresponding values found in similar experiments in which the cells had been grown on acetate and harvested in the logarithmic phase generally ranged between 100 and 200. These latter experiments also showed (Figs. 4 and 5) that the rate of oxygen consumption was approximately the same whether acetate or pyruvate was used as substrate; the total amount of oxygen taken up per mole substrate was somewhat greater for acetate.

Figs. 4 and 5 illustrate the effect of benzoic and salicylic acids on acetate and pyruvate oxidation by washed cells previously grown on acetate. The most striking feature in these results compared with those obtained in a previous study is the absence of any specific inhibiting effect on the pyruvate

Table 2. Influence of benzoic and salicylic acids on the extent and rate of pyruvate and acetate oxidation by washed *P. vulgaris* cells previously grown in medium B. The experiments were similar to those in Figs. 4 and 5.

Substrate	Benzoate experiments			Salicylate experiments			
	Moles of oxygen consumed per mole substrate (4 experiments)		Benzoate conc. giving 50 % inhibition of oxidation rate, mM	Moles of oxygen consumed per mole substrate (2 experiments)			Salicylate conc. giving 50 % inhibition of oxidation rate, mM

oxidation at the oxidation level of acetate in the presence of benzoic or salicylic acid. On the contrary these acids considerably increase the *total amount* of oxygen consumed per mole of substrate. The magnitude of this increase is shown in Table 2 together with the approximate concentrations at which the two acids produced 50 % reduction in the *rate* of oxygen consumption. These figures show that the rate of acetate oxidation by washed cells grown in medium B is much more sensitive to salicylic acid than is that of pyruvate oxidation. The difference is also apparent from the experiment illustrated in Fig. 5 where 2 mM salicylic acid produced no demonstrable effect on the rate of pyruvate oxidation, whereas half this concentration caused 90 % inhibition of the rate of acetate oxidation. The influence of salicylic acid on the amount of oxygen consumed per mole of acetate could thus be studied only at rather low concentrations. At these concentrations no significant increase was observed.

The above effects of benzoic acid on the pyruvate and acetate oxidations were further studied in some experiments in which ammonium ions were added to the cell suspension simultaneously with the substrate. The presence of ammonium ions caused the oxygen consumption per mole pyruvate to decrease in the presence of benzoic acid and to increase in the absence of inhibitor (Fig. 6). A similar tendency, though less marked, was also noticed in some experiments with acetate.

The results suggested an enhanced release of CO_2 from pyruvate and acetate in the presence of benzoic acid and from pyruvate in the case of salicylic acid. This was demonstrated more directly by actual measurement of CO_2 production and furthermore in experiments with labelled acetate, which were carried out in Warburg vessels in the same way as those with unlabelled substrates. The total amount of radioactivity in cells, medium and respiratory CO_2 after oxidation of the same amounts of methyl and carboxyl labelled acetate was measured in the way described in the experimental part. Table 3

Table 3. Effect of benzoic acid on radioactivity of CO_2, medium and cells after oxidation of methyl and carboxyl labelled acetate by *P. vulgaris*.

Fraction	$^{14}CH_3COOH$ experiment Distribution of radioactivity in per cent of total		$CH_3{}^{14}COOH$ experiment Distribution of radioactivity in per cent of total

shows the result of a typical experiment with washed cells harvested from an actively growing culture in medium B. From the values of the distribution of radioactivity recorded in this table it can be calculated that the amount of CO_2 evolved per mole of acetate increased from 1.24 to 1.56 in the presence of benzoic acid. These values are in excellent agreement with those obtained by direct measurement of the CO_2 evolved. Such measurements, performed in separate experiments, showed that the molar amount of CO_2 evolved per mole of acetate increased from 1.25 in the absence to 1.60 in the presence of benzoic acid. It is noteworthy that the additional CO_2 production caused by benzoic acid originates almost entirely from the methyl group of the acetate molecule, and that the incorporation of both the methyl and carboxyl carbon in the cells is almost uneffected by benzoic acid.

Table 4 shows the distribution of methyl carbon in cells, media and respiratory CO_2 after acetate oxidation with and without addition of ammonium ions and the effect of benzoic acid on this distribution. In the absence of ammonium ions the quantitative values differ somewhat from those in Table 3, but the tendency is the same. Addition of ammonium ions resulted in increased incorporation of carbon in the cell, both in the presence and in the absence of benzoic acid. However, this increase was somewhat larger when the oxidation

proceeded without inhibitor and the additional amount incorporated in this case was balanced by a decrease in the radioactivity of the medium.

Growth experiments with acetate adapted cells. * The results set forth above prompted investigations of the effect of benzoic and salicylic acids on the growth of *P. vulgaris* in medium B, in which all cell material must be synthesized from the acetyl group. Unfortunately these experiments had to be carried out at neutral pH values, at which the effect of benzoic and salicylic acids is rather low, since, as mentioned, the adapted strain did not grow rapidly in the acetate medium at pH values lower than 6.5. The experimental arrangement consisted of a battery of equally aerated Kluyver flasks containing 400 ml of the acetate medium at pH 7.0. The flasks were inoculated with adapted cells in the presence of varying amounts of inhibitor and the growth was followed turbidimetrically. Readings were taken continually for the first seven hours during which the pH rose from 7.0 to 7.3 in the absence of inhibitor. As might be expected from the experiments on acetate oxidation with adapted cells reported above, in acetate medium salicylic acid proved to be a much stronger inhibitor than benzoic acid. In this connection it was considered worthwhile to test the efficiency of some aliphatic fatty acid with growth inhibiting effect in the simple acetate medium under investigation. For this reason some experiments with sorbic acid were performed. As shown in Fig. 7, benzoic acid and sorbic acid seemed to be equally strong inhibitors, at least when compared without considering the difference in the dissociation constants, while salicylic acid proved much stronger.

In another series of experiments the effect of benzoic acid was studied on growth in medium A inoculated either with washed cells previously grown in this medium or with washed cells adapted to medium B. Since adaptation to acetate medium had strongly improved the ability of the cells to oxidize acetate in the presence of benzoic acid, it was tempting to imagine that the growth of such cells might be less sensitive to this inhibitor than the growth of unadapted cells, but no such difference could be demonstrated.

* This investigation was carried out in close collaboration with Miss Inger Erichsen, Swedish Institute for Food Preservation Research, who actually performed most of the experiments. For this valuable help I am greatly indebted.

The effect of benzoic and salicylic acids on pyruvate dismutation in extracts from E. coli. The preparation of extracts from *E. coli* and *Streptococcus faecalis* catalyzing the dismutation of 2 molecules of pyruvate to acetyl phosphate, carbon dioxide, and lactate in the presence of ortho-phosphate was described by Korkes *et al.* [3] The soluble enzyme system involved in this process seemed to be suitable for further investigation of the effect of benzoic and salicylic acids on pyruvate and acetate oxidation. The first preparations were made from cells of the *P. vulgaris* strain used in this investigation and resulted in extracts with much lower activity than those obtained by Korkes *et al.* from *E. coli.* However, since experiments (to be published) with resting cells of *E. coli*, similar to those with *P. vulgaris* previously reported, showed essentially the same effects of benzoic and salicylic acids on this organism, the present experiments on pyruvate dismutation could be performed equally well on extracts from *E. coli.* On the whole, there seems to be great similarities between the pyruvate metabolism in *E. coli* and in *P. vulgaris* (Razzell and Gunsalus [7]). The extracts were prepared in the way described above and assayed for activity in the system proposed by Korkes *et al.* The activity of our preparations ranged between 230 and 260 units per ml of dialyzed extract (1 unit = 1.0 mm^3 of CO_2 per hour at pH 6.0 and 25°C), compared with 270 units for that of Korkes *et al.* The influence of benzoic and salicylic acids on the evolution of CO_2 and the formation of acetyl phosphate during pyruvate dismutation was studied at pH 6.0. The enzyme activity at this pH was only about 60 % of that obtained at pH 7.4, but the lower pH was nevertheless preferred because of the known increase of metabolic activity of weak acids with decreasing pH.

Table 5 shows the influence of rather large amounts of benzoic and salicylic acids on pyruvate dismutation in cell free extracts. It is evident that the effect is weak, especially since the bacterial cell membrane usually believed

Table 5. Effect of benzoic and salicylic acids on pyruvate dismutation in cell free extracts of *E. coli.*

Additions of inhibitor	μmoles of CO_2 formed a	μmoles of acetyl phosphate formed b	b/a
—	4.54	1.58	0.35
3.5 mM benzoate	3.89	1.42	0.36
7.0 mM benzoate	3.33	1.33	0.40
14.0 mM benzoate	3.22	1.15	0.36
3.5 mM salicylate	3.34	1.49	0.45
7.0 mM salicylate	2.28	1.49	0.65
14.0 mM salicylate	2.31	1.85	0.80

Each vessel contained: 500 μl dialyzed extract, 50 μmoles of potassium phosphate, 2.4 μmoles of $MgCl_2$, 1.6 μmoles of $MnCl_2$, 0.1 μmoles of DPT, 50 μg of CoA, 0.15 μmoles of DPN and 2 μl of lactic dehydrogenase in the main compartment and 50 μmoles of sodium pyruvate together with the inhibitor in the side arm. Final volume 1.22 ml. Temp. 30°C; pH 6.0; gas phase, nitrogen. CO_2 evolution was measured 20 and 40 min after addition of pyruvate and inhibitor to the enzyme extract.

to prevent penetration of the inhibitors studied had been removed. The evolution of CO_2 from pyruvate in nitrogen atmosphere with intact cells at pH 6.0 is much more sensitive to benzoic and salicylic acids as revealed by experiments (not shown here) with washed cells identical with those from which the extracts were prepared. It is further clear from Table 5 that benzoic acid had no influence on the amount of acetyl phosphate formed per mole of CO_2 produced. On the other hand, salicylic acid seemed to increase this value. This effect was not further investigated because of the relatively high concentrations of inhibitor required.

Experiments with acetyl phosphate and intact cells. The sensitivity of acetate oxidation (at least by intact cells) to benzoic and salicylic acids and the protective effect of small amounts of succinate suggested that the inhibition might be overcome by simultaneous energy producing reactions. With this in mind, acetyl phosphate, in itself an energy-rich compound, should be a better starting point for acetate oxidation than the acetate molecule. However, when acetyl phosphate was added to intact cells of *P. vulgaris* or baker's yeast, the rate of oxygen consumption was very slow. Parallel experiments showed that the oxygen consumed could be ascribed to oxidation of acetate after chemical decomposition of the acetyl phosphate added.

DISCUSSION

Addition of acetate to a suspension of washed *Proteus vulgaris* cells in phosphate buffer is followed by increased oxygen consumption due to oxidation of the acetate. The rate of this oxygen consumption is determined by the pre-history of the cells. In the present work the influence of three factors in this pre-history on the acetate oxidizing ability has, to some extent, been investigated: 1. the composition of the growth medium employed in cultivating the cells, 2. aeration during growth, and 3. the physiological age of the cells at the time of harvesting. It is important to note that the term "acetate oxidizing ability" used above, refers to the rate of the oxygen consumption following the addition of acetate to cells isolated from the growth medium by centrifugation and washing. A survey of the experiments discussed is shown in Table 6.

This investigation shows that the rate of acetate oxidation by washed *P. vulgaris* cells varies considerably with the conditions prevailing during cultivation of the cells. The ability to oxidize acetate, at least by cells grown in a glucose-casein hydrolysate medium (medium A), thus seems to be dependent upon aeration during growth. When such a medium is inoculated with a small amount of cells and aerated, a lag phase occurs before growth begins. It is possible that the ability to oxidize acetate at any appreciable rate is acquired during this period. If large inocula are used, the lag phase is almost completely abolished and no acetate oxidizing power seems to be acquired, at least not by the first generation (Table 6:II).

The rate of acetate oxidation by washed cells previously grown in medium A decrease steadily with increasing age of the cells at the time of harvesting and becomes insignificant after some hours in the stationary phase (Table

6:III and Table 1). If the cultures are not too old when harvested, most of the activity can, however, be restored by adding a small amount of succinate together with the acetate in the respiration experiments. This seems to indicate that the decreasing oxidation rate is due either to lack of Krebs cycle intermediates or to a low level of energy-rich compounds in the cells. The latter explanation would be consistent with the marked increase in the rate of acetate oxidation observed after addition of succinate in the presence of benzoic acid if, as suggested in the first part of this series, this inhibitor interferes with the ATP-generated acetate activation. The absence of an equally marked effect in the case of salicylic acid may be due to the specific uncoupling of oxidative phosphorylation produced by this acid [8].

So far, only experiments with cells cultivated in medium A have been discussed. In such a fairly rich medium much of the energy requirements for growth can be met by ATP-generation at the substrate level. In medium B where acetate is the sole carbon source oxidative phosphorylation is of prime importance especially since the acetate molecule must be activated in an ATP-requiring process before it can be metabolized. It is therefore highly probable that the enzyme systems involved both in the acetate activation and in the generation of ATP from the acetate oxidation exist in larger amounts in cells grown in medium B than in cells grown in medium A. It may further be assumed that cells grown in medium B contain only small amounts of the acetate generating pyruvate oxidase (Stumpf [9], Moyed and O'Kane [10]), which significance in relation to the results previously obtained with cells grown in medium A was discussed in the first paper of this series.

It is consistent with this view that the characteristic feature of the action of benzoic and salicylic acids on cells grown in the glucose-casein hydrolysate medium, *i.e.* the blocking of pyruvate oxidation at the oxidation level of acetate, is not observed in experiments with cells grown in the acetate medium. Furthermore, the sensitivity of acetate oxidation to benzoic acid when the acetate is added directly as substrate is similarly less in experiments with cells grown in the acetate medium (the concentration of benzoic acid required for complete inhibition is increased 4—5 fold). It is noteworthy that this is true only with benzoic acid; salicylic acid in a concentration of 1—2 mM completely inhibits acetate oxidation by both kinds of cells although, as mentioned above, the blocking of pyruvate oxidation at the oxidation level of acetate is abolished, even in this case, by growing the cells in the acetate medium.

The most characteristic effect of benzoic and salicylic acids on acetate-adapted cells is the increased substrate breakdown induced in the presence of these acids. A stimulation of oxygen consumption and CO_2 production is generally observed in the presence of substances impairing the formation of energy-rich compounds and such an effect by salicylic acid agrees with the action of this substance on oxidative phosphorylation [8]. The similarity between the effects of benzoic and salicylic acids in the present experiments is noteworthy, though the inhibition of oxidative phosphorylation by benzoic acid is weak, at least in experiments with rat liver mitochondria [11].

Salicylate has for some years been known [12, 13] to produce effects on carbohydrate metabolism in the rat, which agrees well with the present find-

ings. In recent experiments with salicylate [14] an increased output of total CO_2 and $^{14}CO_2$ was observed in rats given acetate-2-^{14}C and a corresponding inhibition of isotope incorporation into liver glycogen and liver fatty acids.

The increase in the output of CO_2 from acetate observed in the presence of benzoic acid was further investigated in respiration studies with labelled acetate (Tables 3 and 4). These studies confirm the results obtained in the experiments in which the CO_2 evolution was actually measured and indicate that the increase in CO_2 production induced by benzoic acid is derived mainly from the methyl group of the acetate molecule. When acetate is oxidized in absence of inhibitor, a corresponding amount of methyl carbon accumulates in the medium. The incorporation of ^{14}C-compounds into the cells is largely uninfluenced by benzoic acid. The results could tentatively be explained by assuming that a keto acid, derived mainly from the methyl group of the original acetate molecule accumulates in the medium in the absence of benzoic acid. If the acetate oxidation occurs in the presence of ammonium ions, as in the experiment showed in Table 4, such a keto acid may be incorporated in the cell material after conversion to the corresponding amino acid. Further research is, however, necessary before any valid interpretation can be made on this point.

Acknowledgements. This work is part of an investigation supported by the *Swedish Natural Science Research Council* and the *Swedish Technical Research Council.*

I am greatly indebted to Professor G. Lindeberg, Agricultural College of Norway, Vollebekk, Norway, and to Professor E. Adler, Chalmers University of Technology, Gothenburg, Sweden, for continued and encouraging interest in this work. I also wish to express my sincere gratitude to Professor G. Ehrensvärd and his collaborators at the Institute of Biochemistry, Lund, Sweden, for stimulating discussions and valuable help with the isotope technique.

Studies on the Hydrolysis of Metal Ions

25. The Hydrolysis of Lead(II) in Perchlorate Medium

ÅKE OLIN

Department of inorganic chemistry, the Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of lead(II) has been studied at 25°C by the inert medium method using 3 M or 0.3 M $(Na)ClO_4$ and the cells

– Pb-Hg / S / ref. +
– glass / S / ref. +

S had the general composition
B M Pb(II), H M H^+, $(I-2B-H)$ M Na^+, I M ClO_4^-

The experimental data Z (average number of OH^- bound per lead (II)) and η (log $[Pb(II)]_{tot}$ / $[Pb^{2+}]_{free}$) as functions of log h can be explained by the following reactions and equilibrium constants.

		Equilibrium constants	
		3 M $(Na)ClO_4$	0.3 M $(Na)ClO_4$
$Pb^{2+} + H_2O \rightleftharpoons PbOH^+ + H^+$	$\log \beta_{11}$	-7.9 ± 0.1	-7.8 ± 0.1
$4Pb^{2+} + 4H_2O \rightleftharpoons Pb_4(OH)_4^{4+} + 4H^+$	$\log \beta_{4,4}$	-19.25 ± 0.1	-19.90 ± 0.1
$3Pb^{2+} + 4H_2O \rightleftharpoons Pb_3(OH)_4^{2+} + 4H^+$	$\log \beta_{4,3}$	-22.87 ± 0.1	-23.35 ± 0.1
$6Pb^{2+} + 8H_2O \rightleftharpoons Pb_6(OH)_8^{4+} + 8H^+$	$\log \beta_{8,6}$	-42.14 ± 0.1	-42.66 ± 0.1

SURVEY OF PREVIOUS WORK

The two most complete investigations on the hydrolysis of Pb(II) hitherto published are those of Pedersen [1] and Faucherre [2]. Pedersen carried out potentiometric titrations of $Pb(NO_3)_2$ solutions to which NaOH was added and log h followed with a glass electrode. The experimental data could be explained by the formation of the complexes Pb_2OH^{3+}, $PbOH^+$ and $Pb_4(OH)_4^{4+}$. However, the nitrate is not very suitable for this type of investigation since the basic lead nitrates have so low solubility that only one percent of the total Pb(II) was hydrolysed before precipitation started.

This led Faucherre to study lead(II) perchlorate solutions instead, which allow the addition of 4/3 OH^- per Pb(II) before precipitation starts. Potentiometric titrations, where NaOH was added and log h followed with a glass

electrode, were interpreted as follows. In solutions where less than one OH^- per lead(II) had been added the complex $Pb_4(OH)_4^{4+}$ was formed. On further addition of alkali the complex $Pb_9(OH)_{12}^{6+}$ started to form. When 4/3 OH^- per lead(II) had been added precipitation started. Spectrophotometric and cryoscopic measurements on solutions containing less than one OH^- per lead(II) indicated the complex $Pb_4(OH)_4^{4+}$ also. Faucherre followed the change in log h of $Pb(NO_3)_2$ solutions upon dilution. These measurements also indicated the complex $Pb_4(OH)_4^{4+}$. In addition $PbOH^+$ was indicated in dilute solutions.

Most of the other previous works on the hydrolysis of Pb(II) have been done with so called pure salt solutions, notably with solutions of $Pb(NO_3)_2$. Kullgren [3] measured the acidity of $Pb(NO_3)_2$ kinetically at 100°C and 85.5°C. He could explain his data by the reaction $Pb^{2+} + H_2O \rightleftharpoons PbOH^+ + H^+$ ($\beta_{11} = 1.02 \times 10^{-6}$). Denham and Marris [4] measured the acidity of $Pb(NO_3)_2$ and $PbCl_2$ solutions with the quinhydrone electrode but did not attempt to explain their findings in terms of a hydrolysis reaction. Cranston and Brown [5] made similar experiments with the glass electrode and assuming only the first mononuclear step, calculated from their data $\beta_{11} = 1.7 \times 10^{-8}$ at 15°C and from the earlier data by Denham and Marris $\beta_{11} = 3.8 \times 10^{-8}$ at 25°C. Guiter [6] followed colorimetrically the change of log h in a $Pb(NO_3)_2$ solution on dilution. He suggested that the ions $Pb_2(OH)_2^{2+}$, $PbOH^+$ and their nitrato complexes were formed, but apparently some of his results contradict the law of mass action.

Reiff and Müller [7] suggested the complex $Pb_2(OH)_2^{2+}$. Their measurements of the concentration of Pb^{2+} by lead amalgam in solutions of analytical composition $PbOHClO_4$ showed that $[Pb^{2+}]$ was not negligibly small. Therefore they suggested that the complex was partly dissociated to Pb^{2+}, $PbOH^+$ and $Pb(OH)_2$. From a study of the solubility of $Pb(IO_3)_2$ in $HClO_4$-$NaClO_4$ mixtures and PbO in $HClO_4$, Misra and Pani [8] and Pattanaik and Pani [9] claimed the existence of $PbOH^+$. They interpreted the increase of the solubility of the iodate with increasing acidity as due to the formation of $PbOH^+$ which contradicts the law of mass action; a more reasonable explanation is the formation of undissociated iodic acid. See also Ref. [10] where the increase of the solubility of $Cu(IO_3)_2$ with acidity was used to determine the dissociation constant for iodic acid. The fact that they were able to dissolve PbO in $HClO_4$ in a 1:1 ratio is not very convincing evidence for the formation of $PbOH^+$ since any species $(PbOH^+)_n$ would give the same result. The formation of $PbOH^+$ and $Pb(OH)_2$ has been suggested by Goward [11] from polarographic measurements.

Finally we might cite a report on ultracentrifuge work on lead perchlorate solutions by Johnson and Kraus [12]. "Preliminary ultracentrifugation studies of Pb(II) in perchlorate solution indicate that low-molecular weight polymers are formed in the range of hydrolysis studied, between hydroxyl numbers (n) about 0.5 and 1.4. Interpretation by a simple monomer-tetramer equilibrium does not seem adequate, however, since degrees of polymerization higher than 4 are found for $n = 1.4$. Near $n = 1$ the weight average degree of polymerization is about 4, but existence of a predominant tetrameric species has not yet been established".

From the above survey we might conclude that there is good evidence for the complexes $PbOH^+$ and $Pb_4(OH)_4^{4+}$ but comparatively little quantitative work has been done on solutions with a $OH^-/Pb(II)$ ratio > 1. The electrometric measurements have been done almost exclusively with log h-sensitive electrodes. It was therefore considered worthwhile to reinvestigate the hydrolysis of Pb(II) in perchlorate solution using both the glass electrode and the amalgam electrode.

SYMBOLS

The commoner symbols used in the text are defined below for reference.

B total Pb(II) concentration
b concentration of Pb^{2+}
H analytical hydrogen ion concentration
h actual hydrogen ion concentration
Z average number of hydrogen ions split off by one Pb(II)
ν average number of OH^- groups bound to one Pb(II) in a complex (5)
η log B/b
$\beta_{p,q}$ formation constant of $Pb_q(OH)_p^{(2q-p)+}$ from Pb^{2+} and H_2O.

$$q\ Pb^{2+} + p H_2O \rightleftharpoons Pb_q(OH)_p^{(2q-p)+} + p H^+$$

$$BZ = h - H = \Sigma\, p\beta_{p,q}\, b^q h^{-p}$$

$$10\eta = 1 + \Sigma\, q\beta_{p,q}\, b^{q-1} h^{-p}$$

$y(x)_v$ y as a function of x at constant v

Other symbols used are defined where they appear in the text. All concentrations in tables and figures are expressed in M (moles/l) and equilibrium constants are given on the M scale. In the text, however, the more convenient unit mM will be used frequently.

In the following we shall describe in detail only the experiments done with 3 M $(Na)ClO_4$ as medium and their interpretation. The interpretation of the data with 0.3 M $(Na)ClO_4$ will be discussed briefly at the end of the chapter dealing with the calculations on the 3 M $(Na)ClO_4$ data.

METHOD OF INVESTIGATION

The experiments have been carried out as potentiometric titrations. The analytical hydrogen ion concentration of lead(II) perchlorate solutions with 3 M $(Na)ClO_4$ as the ionic medium was varied by adding sodium hydroxide or perchloric acid. The total lead concentration, B, was kept constant in each run and the hydrogen ion concentration, h, and the concentration of Pb^{2+}, b, were measured with the cells

— glass/equilibrium solution/ ref. + (I)

$$E = E_g^\circ - 59.15 \log h - E_j \quad (1)$$

— Pb-Hg/equilibrium solution/ ref. + (II)

$$E = E_{am}^\circ - 29.58 \log b - E_j \quad (2)$$

Eqns. (1) and (2) have been written on the assumption that the activity factors keep constant so that they may be included as constants in the E°'s. However, this is only approximately correct since E°_{am} is not independent of the total lead concentration, B, for B larger than 10 mM. The change in E°_{am} when b was lowered from 80 mM to 5 mM was -0.3 mV but from 5 mM down to 0.5 mM no further change in E°_{am} was observed. No similar trend in E°_{g} was noted. This may be due to the fact that E°_{g} cannot be determined with sufficient accuracy (± 0.2 mV). A thorough investigation of these changes in the activity factors has been omitted deliberately since such an investigation by G. Biedermann is now under way at this Institute.

The composition of the solutions measured can be written

$$[\mathrm{Pb(II)}] = B \text{ M}, [\mathrm{H^+}] = H \text{ M}, [\mathrm{Na^+}] = (3-2B-H) \text{ M}, [\mathrm{ClO_4^-}] = 3 \text{ M}$$

where H is the analytical hydrogen ion concentration. In the present case H is usually a negative number, so that the solutions are deficient in hydrogen ions.

Apparatus

The measurements were performed in an oil thermostat at 25° ± 0.1°C using the salt bridge described by Forsling, Hietanen and Sillén [13]. The reference half-cell was

$$3 \text{ M } \mathrm{NaClO_4}/3 \text{ M } \mathrm{ClO_4^-}, 2.99 \text{ M } \mathrm{Na^+}, 0.01 \text{ M } \mathrm{Ag^+}/\mathrm{AgCl}, \mathrm{Ag} \qquad \text{(III)}$$

Much trouble was experienced before we found a glass electrode which could be used without too large corrections in the log h range (-2 to -8.5) studied. The glass electrodes were tested against the hydrogen electrode in a series of buffers made up by gradually adding NaOH in 3 M $\mathrm{NaClO_4}$ to a solution, S, containing 0.005 M $\mathrm{HClO_4}$, 0.005 M HAc, 0.005 M $\mathrm{H_3PO_4}$, 0.005 M $\mathrm{H_3BO_3}$, 3 M $\mathrm{NaClO_4}$. The emfs of the cells

$$-\ \mathrm{Pt}/\mathrm{H_2}/\mathrm{S}/\ \mathrm{ref}\ +\ (E_H) \qquad \text{(IV)}$$

$$-\ \mathrm{glass}\ /\mathrm{S}/\ \mathrm{ref}\ +\ (E_g) \qquad \text{(V)}$$

were measured. Actually the glass and $\mathrm{H_2}$ electrodes were kept in the same solution. The difference $\Delta E = E_H - E_g$ was thus obtained for different log h values, which were calculated from E_g and eqn. (1) using an E°_{g} determined with mixtures of $\mathrm{HClO_4}$ and 3 M (Na)$\mathrm{ClO_4}$. The glass electrode finally selected for the measurements was a Beckman electrode (No. 1190—808) which gave a constant ΔE down to log $h \simeq -7.5$, thus behaving like a hydrogen electrode. From log $h \simeq -7.5$ to -8.5 ΔE gradually increased and the corresponding change in ΔE was applied as a correction to the glass electrode. The largest correction (at log $h = -8.5$) was + 0.5 mV.

The emf of cell (I) was recorded to ± 0.2 mV on a Radiometer valve potentiometer (PHM4). The amalgam emf was measured to ± 0.01 mV by a Cambridge potentiometer.

Experimental details of the emf measurements and titration procedure

The liquid junction potential, E_j, and an estimate of the beginning of the hydrolysis of Pb(II) was obtained in a titration, where standard NaOH was added to a solution containing 10 mM Pb^{2+} and 100 mM $HClO_4$ in 3 M $(Na)ClO_4$. Treating the data as an ordinary acid-base titration using Gran's extrapolation method [14] a straight line was obtained almost the whole way down to the equivalence point. This indicates that the hydrolysis of Pb(II) at moderate concentrations is small until an excess of OH^- has been added.

The amalgam and glass electrode potentials were also used to determine E_j by the procedure described by Biedermann and Sillén [15]. The results obtained were in complete agreement with their findings and E_j has been calculated as $-16.7\ h$ mV in subsequent titrations.

E_g^o and E_{am}^o were determined from the potentials in acid solution inserting the analytical concentrations for h and b in eqns. (1) and (2), which is permissible since the hydrolysis is negligible for $H > 2$ mM. For $B > 5$ mM the titrations were started from $H \simeq 20$ mM and the $E^{o\prime}$s calculated from the first points of each titration. This procedure becomes less satisfactory for lower values of B since then most of the alkali added is consumed to neutralize the acid added for the determination of the $E^{o\prime}$s, which is undesirable when Z is to be determined accurately. When B was 5 mM or less the titration was started from the H^+ concentration ($\simeq 0.3\ B$) associated with the lead perchlorate stock solution, NaOH gradually added and the hydrolysis followed till precipitation started. Afterwards a strong perchloric acid solution was introduced to give H values between 5 and 20 mM and E_g^o and E_{am}^o determined from the potentials. In one of the 2.5 mM titrations both methods were used as a check. The values for E_g^o agreed to $\pm$ 0.1 mV and those for E_{am}^o to $\pm$ 0.05 mV which is as good as can be expected.

In general after each addition of alkali the glass and amalgam emfs took about 20 min to attain a constant value. The time increased somewhat as the degree of hydrolysis increased. Also it was somewhat longer at the lowest B (1.25 mM) measured. A local excess of OH^- could not be avoided upon addition of the alkali and a precipitate was formed. The precipitate dissolved rapidly and completely at the beginning of a run but in the most hydrolysed solutions small amounts remained undissolved. This small residue apparently dissolved very slowly, since the potentials remained constant. It may consist of basic lead carbonates formed from the inevitable carbonate content (*ca.* 0.1 % of total OH^-) of the sodium hydroxide.

In general, the titrations had to be discontinued when Z had reached $\simeq 1.3$ since the solutions became permanently turbid owing to the precipitate of basic lead perchlorates. In the 80 and 40 mM titrations, where rather strong alkali had to be used, the amount of precipitate formed was appreciable when Z had reached 1 and the hydrolysis could not be followed further. The lowest B value that could be used satisfactorily was 1.25 mM. When 0.625 mM was tried reproducible values could not be obtained. When the same lead solution was titrated with the same alkali different results were obtained on different

days. The nonreproducibility occured with 0.625 mM Pb(II) only and in hydrolysed solution. In acid solution the agreement between different titrations was still good.

The measurements on $B = 0.625$ mM revealed an impurity in the sodium perchlorate. When the very weak NaOH solution used for this titration was standardized potentiometrically against $HClO_4$, both solutions containing 3 M $(Na)ClO_4$, it was found that the Gran extrapolation was not linear near the equivalence point. The 3 M $(Na)ClO_4$ behaved as if it contained a weak acid (concentration $\simeq 3 \times 10^{-5}$ M). By making the same standardization in 0.3 M $(Na)ClO_4$, it was established that the disturbance was connected with the $NaClO_4$. In this medium the disturbance almost disappeared. The Z measurements in 3 M $(Na)ClO_4$ have been corrected for this buffer capacity of the ionic medium on the assumption that it is a function of log h only and not affected by the presence of lead. With the exception of the last few points of the 1.25 and 2.5 mM titrations the correction is less than 1 % in Z. This impurity was not detected until the measurements in 3 M $(Na)ClO_4$ were almost completed. It was therefore decided to extend the measurements to 0.3 M $(Na)ClO_4$ to avoid the uncertainty in the Z values for small values of B caused by the impurity.

The reversibility of the hydrolysis reactions was tested by carrying out some back titrations. The results from these titrations in general agreed to better than $\pm$ 0.005 in Z and η with those from the forward titrations, thus indicating that true equilibria were measured.

Materials and analysis

Sodium perchlorate was prepared and analysed as described previously [16]. The determination of free, strong acid or base in the product has been somewhat modified. Since the method employed can also be advantageously used to determine the analytical hydrogen ion concentration in solutions of metal salts, which do not hydrolyse too strongly, it may be worth a short description. The following solutions are employed

S_1 Metal salt solution of concentration B M and ionic medium I M
S_2 Metal salt solution of concentration $2B$ M and ionic medium $2I$ M
S_3 Solution containing acid or base of known concentration H M

When the acidity of the ionic medium is determined S_1 and S_2 of course, do not contain the metal salt. To a known volume (V_0) of solution S_1 are added equal volumes (V) of solutions S_2 and S_3, and log h is measured as a function of V. If the acidity of solution S_1 is δ, it is 2 δ in solution S_2, so that the acidity in each point is given by;

$$h = \frac{V_o\delta + 2V\delta + VH}{V_o + 2V} = \delta + \frac{VH}{V_o + 2V} \quad (3)$$

From the measured emf we get;

$$E = E^o + 59.15 \log h + E_j;\ 10^{(E-Ej)/59.15} = h\ 10^{E^o/59.15} = \text{const} \cdot h = \text{const} \cdot \left(\delta + \frac{VH}{V_o + 2V}\right) \quad (4)$$

If we plot $10^{(E-Ej)/59.15}$ as a function of $VH/(V_o + 2V)$ a straight line is obtained which, when extrapolated to $10^{(E-Ej)/59.15} = 0$ gives $-\delta$ on the horizontal axis. The method is a version of the usual Gran extrapolation [14], and a special case of a more general expression derived by Berecki-Biedermann [17].

Perchloric acid solutions were prepared and analysed as described previously [16].

Sodium hydroxide was prepared either from 50 % NaOH by dilution or by the method described by Han and Chao [18] adding $Ba(OH)_2$. No difference was observed between titrations carried out with NaOH prepared in either way. Base solutions stronger than *ca.*

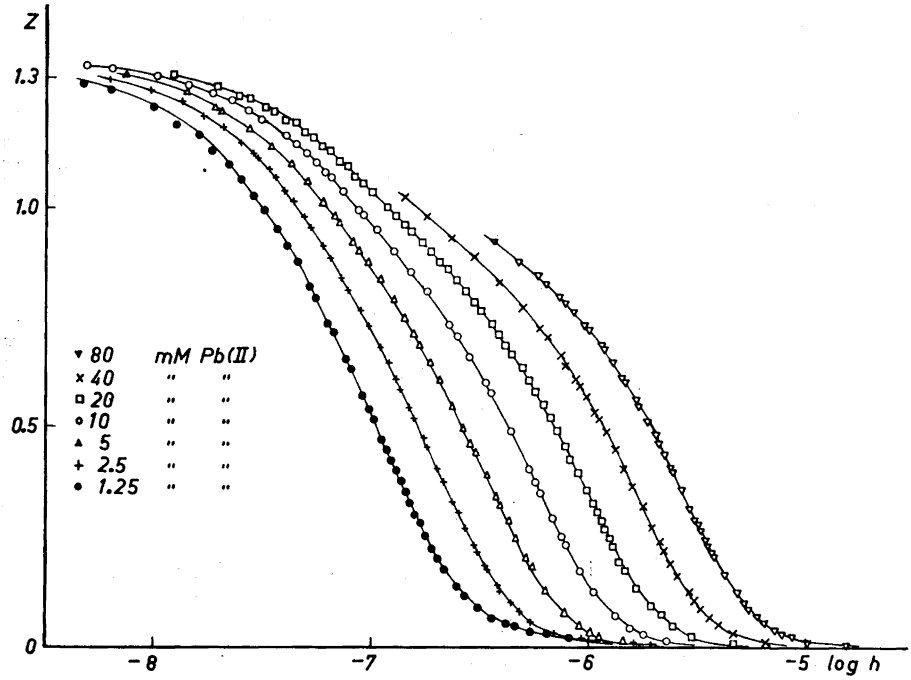

Fig. 1. Average number, Z, of OH^- bound per Pb(II) as a function of log h with 3 M $(Na)ClO_4$ as medium. The curves are calculated with the equilibrium constants given in the text.

25 mM were standardized visually against standard acid. Less strong solutions were standardized potentiometrically using Gran's method to determine the end point.

Lead (II) perchlorate solutions were prepared from two different lead sources. One solution was prepared from PbO (Baker p.a.) which was dissolved in perchloric acid and small amounts of tetravalent lead present in the oxide destroyed by H_2O_2. The other solution was prepared from lead metal (Merck silberfrei) which was dissolved in nitric acid and the nitric acid dispelled by fuming with perchloric acid. Due to the very great solubility of lead perchlorate, this salt could not be satisfactorily recrystallised from water but had to be used without further purification. The Z and η data obtained from solutions made up from the two stock solutions were consistent which would indicate that no impurities were present. Lead was determined as lead sulfate [19] or as lead iodate [20]. Both methods gave the same results to ± 0.1 %. The analytical hydrogen ion concentration was determined potentiometrically using a Gran extrapolation to obtain the equivalence point.

Lead amalgam was prepared by dissolving lead metal (Merck silberfrei) in mercury. The amalgam was stored under 25 mM $HClO_4$ in a N_2 atmosphere and the lead concentration in the amalgam was *ca.* 0.7 % (weight).

RESULTS AND CALCULATIONS

The experimental data are presented in Figs 1, 2, 3 and 4 and in Tables 1 and 2 giving Z and η as functions of log h and B. $Z = (h-H)/B$, *i. e.* the average number of OH^- groups bound per lead(II), and $\eta = \log B/b$.

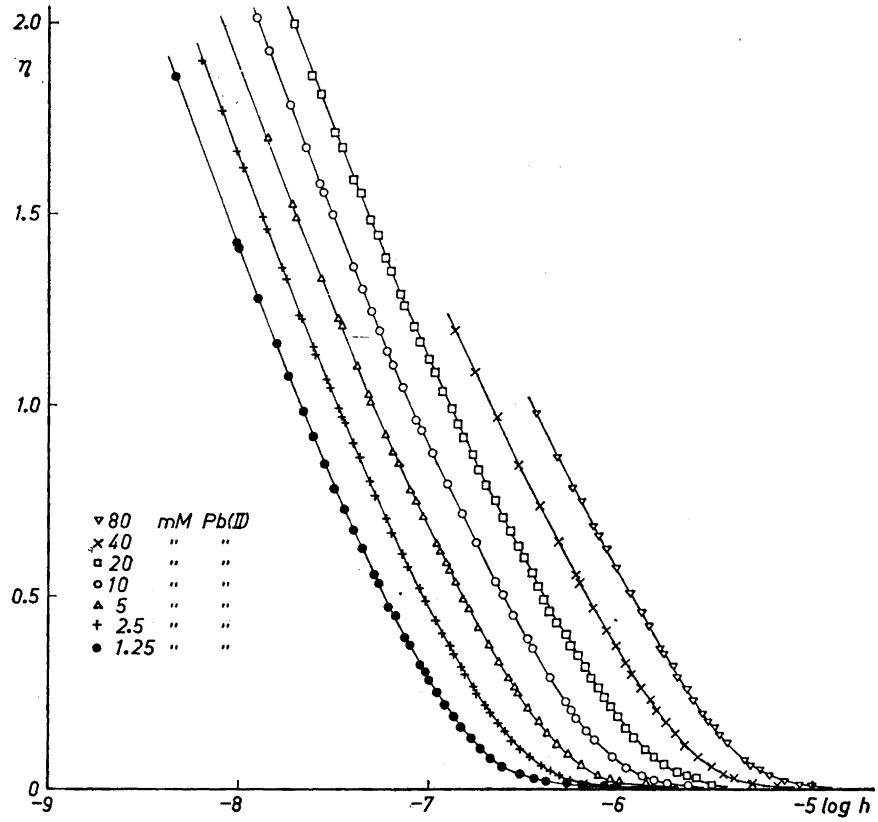

Fig. 2. η = log B/b as a function of log h with 3 M (Na)ClO_4 as medium. The curves are calculated with the equilibrium constants given in the text.

In those earlier studies, published from this Institute, where it has been possible to determine experimentally both η and Z, these have been treated separately to find the formulas of the hydrolysis products and their formation constants (see for example Ref. [21]). The fact that the two sets of data have given the same results may be taken as additional evidence for the correctness of the hydrolysis mechanism proposed.

With lead(II), such a procedure certainly would give the main complexes formed, but it is somewhat more difficult to establish the minor products with certainty. When deriving the composition of the complexes formed, we shall prefer to combine the two sets of data. This mode of approach greatly simplifies our task, although we lose the double-check of the previous method. As a check on systematic errors in either set of data the equilibrium constants will be determined from the Z and η data separately.

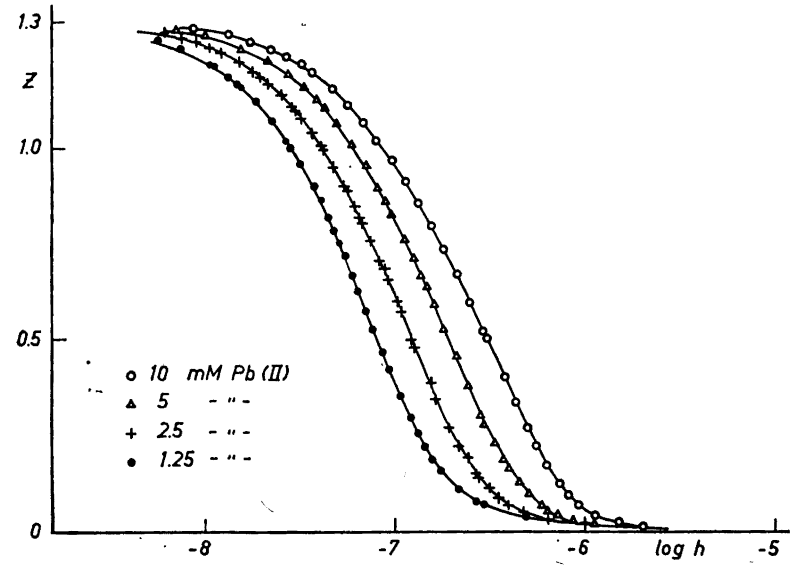

Fig. 3. Z as a function of log h with 0.3 M $(Na)ClO_4$ as medium. The curves are calculated with the equilibrium constants given in the text.

It is apparent that polynuclear complexes are formed since Z and η are functions of both B and log h. It is also apparent that more than one complex is formed. The lower the value of B is, the steeper are the Z and η curves. This would indicate that when B is lowered, complexes with a higher OH^-/Pb(II) ratio are formed at increasingly early stages of the hydrolysis. The limiting value of this ratio is 4/3 as indicated by the $Z_{lim} \simeq 1.3$ and $\lim_{b \to 0} (\Delta\eta/\Delta\log h)_B \simeq -1.3$.

Determination of the products of hydrolysis in the region where $\nu = 1$. By combining the Z and η data we can calculate the number of OH^- groups bound per hydrolysed Pb(II), ν,

$$\nu = \frac{h-H}{B-b} \tag{5}$$

This quantity gives an average value of the ratio OH^-/Pb(II) in the complexes formed. On calculation from Tables 1 and 2, ν is found to have the value 1.00 ± 0.02 in the initial stages of hydrolysis for B values larger than 2.5 mM. After the halt at 1.0, ν steadily increases with -log h and the largest value of ν registered was 1.33.

For the two lowest concentrations, however, the initial ν values showed irregularities indicating that the data from these concentrations are less reliable at small values of Z. Usually ν started from a value of *ca.* 1.2 and then decreased to *ca.* 1.05. Afterwards it steadily increased again in a regular manner. These irregularities are probably connected with the impurity in the $NaClO_4$, since they are less pronounced with 0.3 M $(Na)ClO_4$. But even with this medium the values for the lowest concentrations do not show the

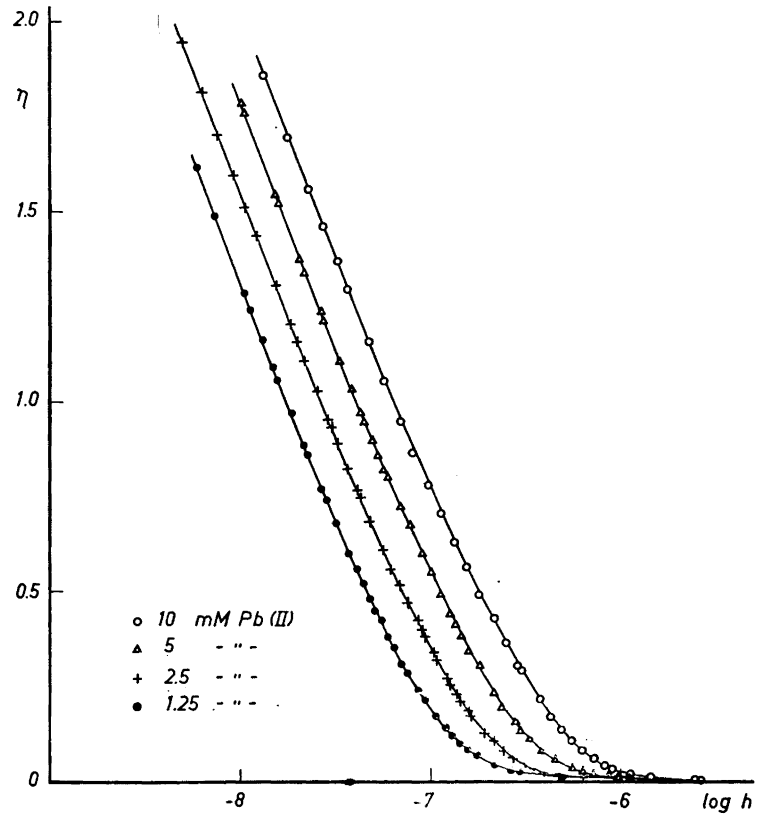

Fig. 4. η as a function of log h with 0.3 M $(Na)ClO_4$ as medium. The curves are calculated with the equilibrium constants given in the text.

regular behaviour of those found for the higher values of B. However, it must be pointed out that ν is very sensitive to experimental errors since H and $(B-b)$ are both obtained as differences between numbers which are about equal in magnitude. It is reasonable to assume that even for the two lowest values of B, complexes with a OH^-/Pb(II) ratio = 1 are formed in the initial stages of hydrolysis.

We shall start with a determination of the formulas of the complexes formed in the region where $\nu = 1$. In this region complexes with the general composition $(PbOH^+)_n$ apparently predominate. However, their range of predominance varies greatly with B. For $B = 80$ mM it extends to $Z \simeq 0.8$. but for $B = 5$ mM ν deviates significantly from 1 when $Z > 0.3$. An inspection of the curves for $B \geq 5$ mM shows that they are parallel and that the spacing along the log h axis

$$\left(\frac{\Delta \log B}{\Delta \log h}\right)_\eta \simeq \left(\frac{\Delta \log B}{\Delta \log h}\right)_z = 1.33 \pm 0.03 \qquad (6)$$

in the range where $\nu = 1$. This means that the complexes formed can be written as $Pb(Pb(OH)_{1.33 \pm 0.03})_n$ (Ref. [22]), where n is variable and unknown and may assume any value which fulfills the requirements that $n(1.33 \pm 0.03)$ are whole numbers. The restriction that the complexes should give a value $\nu = 1$ gives as the only possibility $n = 3$, from the relation $n(1.33 \pm 0.03)/(n + 1) = 1$. Hence the complex formed is $Pb_4(OH)_4^{4+}$.

In this derivation we have not made use of the shapes of the Z and η curves for the complex. It is therefore necessary to make a comparison with theoretical curves for $Pb_4(OH)_4^{4+}$ to see if the experimental $Z(\log h)_B$ and η $(\log h)_B$ curves are of the correct shapes. At the same time the equilibrium constant for the reaction

$$4\,Pb^{2+} + 4\,H_2O \rightleftharpoons Pb_4(OH)_4^{4+} + 4\,H^+ \qquad (7)$$

is determined.

This is accomplished in the following way. We start from the equations

$$B = b + 4\beta_{4,4}b^4h^{-4} \tag{8}$$

$$BZ = 4\beta_{4,4}b^4h^{-4} \tag{9}$$

$$10\eta = B/b = 1 + 4\beta_{4,4}b^3h^{-4} \tag{10}$$

and introduce

$$\beta^3 = 4\beta_{4,4} \text{ and } v = \beta\ B\ h^{-4/3} \tag{11, 11a}$$

We find after elimination of b

$$\log v = \log B - 4/3 \log h + \log \beta =$$
$$= \eta + 1/3 \log (10\eta - 1) = 1/3 \log Z - 4/3 \log (1 - Z) \tag{12}$$

According to these equations plots of Z and η as functions of (log B — 4/3 log h) should give single curves independent of B. Then these are compared with the theoretical η (log v) and Z(log v) curves and examined for a fit. The difference on the log v and (log B — 4/3 log h) axes in this position gives log β and from eqn. (11) log $\beta_{4,4}$.

For $B \geq 5$ mM the experimental points in the region with $v = 1$ fell on single curves, which had the shape required by the theoretical curves. The value of the equilibrium constant found from the Z and η data was the same

$$\log\beta_{4,4} = -19.25 \pm 0.03$$

The 2.5 and 1.25 mM curves showed deviations in a direction which indicated that species smaller than $Pb_4(OH)_4^{4+}$ were also present. However, the deviations are not very large.

In order to obtain information about the cause of these deviations the terms for the $Pb_4(OH)_4^{4+}$ ion were subtracted from B and BZ. The following quantities were calculated and plotted as functions of log h

$$\eta_c = \log \frac{B_c}{b} \quad \text{and} \quad Z_c = \frac{BZ - 4\beta_{4,4}b^4h^{-4}}{B_c} \qquad (13,\ 13a)$$

where B_c, a corrected B, is defined by

$$B_c = B - 4\beta_{4,4}b^4h^{-4} \qquad (14)$$

These plots showed that η_c and Z_c were independent of B_c and were functions of log h only, which indicates that the mononuclear complex $PbOH^+$ is formed. In fact a satisfactory fit was obtained with normalized curves according to Sillén [23]. The equilibrium constant for the reaction

$$Pb^{2+} + H_2O \rightleftharpoons PbOH^+ + H^+ \qquad (15)$$

was found to be

$$\log \beta_{11} = -7.90 \pm 0.05$$

The equilibrium constants $\beta_{4,4}$ and β_{11} were also determined simultaneously from projection maps by the method described by Biedermann and Sillén [24] with (log B — 4/3 log h) and log h as variables on the axes. This approach gave the same values for the equilibrium constants as before, but indicated that the uncertainty in log β_{11} should be increased to ± 0.1 logarithmic unit.

Determination of the products of hydrolysis in the region where $v > 1$. Now we turn to the upper parts of the Z(log h)$_B$ and η (log h)$_B$ curves. The calculations to be described in the following were made on the Z and η data for $B < 40$ mM. (In the 40 and 80 mM titrations $Pb_4(OH)_4^{4+}$ is so predominant that little information can be found about the other species present). As has already been mentioned both the Z and η data indicate that complexes with a OH^-/Pb(II) ratio = 4/3 are formed. By calculating the concentrations of $Pb_4(OH)_4^{4+}$ and $PbOH^+$ for each experimental point and subtracting the terms for these

ions we can find the average number of OH^- groups bound to each Pb(II) in the unknown complexes. This quantity remained constant at 1.33 ± 0.03 in the region where it could be calculated with sufficient accuracy. This region covered more than one log h unit for each value of B. It is therefore apparent that the complexes predominating in the upper parts of the curves are of the form $(Pb(OH)_{4/3}^{2/3+})_n$ and the formulas of the complexes have been determined on this assumption.

Approach I. Information about possible species written as $Pb(Pb(OH)_t)_n$ is found from the difference quotient $(\Delta \log B/\Delta \log h)_\eta = t$. If one only of the above complexes predominated, we would have $t = 2.0$ for $Pb_3(OH)_4^{2+}$, $t = 1.6$ for $Pb_6(OH)_8^{4+}$, $t = 1.5$ for $Pb_9(OH)_{12}^{6+}$, *etc.* The spacing along the log h axis between the experimental η (log h)$_B$ curves for $B = 20$, 10 and 5 mM gave a t value close to 1.6, but for the two lower concentrations t was somewhat higher. Since the presence of $PbOH^+$ could be expected to cause such an effect, it was considered possible that the data could be explained by the formation of $Pb_6(OH)_8^{4+}$ only. To test the hypothesis the following equations were used. We start from

$$B = b + \beta_{11} b h^{-1} + 4\beta_{4,4} b^4 h^{-4} + 6\beta_{8,6} b^6 h^{-8} \quad (16)$$

$$BZ = \beta_{11} b h^{-1} + 4\beta_{4,4} b^4 h^{-4} + 8\beta_{8,6} b^6 h^{-8} \quad (17)$$

$$B/b = 10\eta = 1 + \beta_{11} h^{-1} + 4\beta_{4,4} b^3 h^{-4} + 6\beta_{8,6} b^5 h^{-8} \quad (18)$$

and introduce the corrected dependent variables B_c, η_c and Z_c by

$$B_c = B - \beta_{11} b h^{-1} - 4\beta_{4,4} b^4 h^{-4} = b + 6\beta_{8,6} b^6 h^{-8} \quad (19)$$

$$B_c Z_c = BZ - \beta_{11} b h^{-1} - 4\beta_{4,4} b^4 h^{-4} = 8\beta_{8,6} b^6 h^{-8} \quad (20)$$

$$B_c/b = 10\eta_c = 1 + 6\beta_{8,6} b^5 h^{-8} \quad (21)$$

With the parameters

$$6\beta_{8,6} = \alpha^5 \text{ and } 8\beta_{8,6} = \gamma^5 \quad (22, 22a)$$

and the variables

$$\alpha B_c h^{-1.6} = v \text{ and } \gamma B_c h^{-1.6} = u \quad (23, 23a)$$

we get

$$\log v = \log B_c - 1.6 \log h + \log \alpha = \eta_c + 0.2 \log (10\eta_c - 1) \quad (24)$$

and

$$\log u = \log B_c - 1.6 \log h + \log \gamma = 0.2 \log Z_c - 1.2 \log (1 - 0.75 Z_c) \quad (25)$$

If the hypothesis is valid each of the Z_c and η_c according to eqns. (24) and (25) should give a single curve when plotted as a function of (log B_c − 1.6 log h). The terms for $PbOH^+$ and $Pb_4(OH)_4^{4+}$ were calculated with the equilibrium constants already determined.

The plots showed that $Pb_6(OH)_8^{4+}$ alone did not suffice to explain the data. The data for the three highest concentrations fulfilled the requirements for the formation of $Pb_6(OH)_8^{4+}$ at large values of Z_c and η_c well, but the t value used was too small to bring the data from the 2.5 and 1.25 mM titrations on to the η_c, $Z_c(\log B_c - 1.6 \log h)$ curves formed at the higher concentrations. Moreover at low Z_c and η_c the shapes of the experimental and theoretical curves were a little different. The fact that we have to use a larger t value for the lower concentrations to bring the data on to the same curve indicates the presence of $Pb_3(OH)_4^{2+}$. $Pb_3(OH)_4^{2+}$ is the only complex with $\nu = 4/3$ and a t value > 1.6.

From the above discussion it may be considered likely that the data could be explained by the formation of $Pb_6(OH)_8^{4+}$ and $Pb_3(OH)_4^{2+}$. However, we shall start with the more general assumption that all members of the series $(Pb(OH)_{4/3}^{2/3+})_n$ may be present. In order to determine the equilibrium constant for the first member of the series, $Pb_3(OH)_4^{2+}$, two methods were used.

Approach II. We start from the equations

$$B = b + [PbOH^+] + 4[Pb_4(OH)_4^{4+}] + 3[Pb_3(OH)_4^{2+}] + 6[Pb_6(OH)_8^{4+}] + - \quad (26)$$

$$B_c = B - b - [PbOH^+] - 4[Pb_4(OH)_4^{4+}] = 3\beta_{4,3}b^3h^{-4} + 6\beta_{8,6}b^6h^{-8} - - - =$$

$$= 3\beta_{4,3}x + 6\beta_{8,6}x^2 + - - - \quad (27)$$

$$b^3h^{-4} = x \quad (28)$$

We can calculate $[Pb_4(OH)_4^{4+}]$ and $[PbOH^+]$ for each experimental point from the potentials and the equilibrium constants already determined. In addition we can find $b^3h^{-4} = x$. With this quantity as the independent variable, B_c becomes a function of x only.

$$B_c = 3\beta_{4,3}x + 6\beta_{8,6}x^2 + - - - \text{ or } B_cx^{-1} = 3\beta_{4,3} + 6\beta_{8,6}x + - - - \quad (27, 27a)$$

The first two coefficients of the above series are found by plotting B_cx^{-1} as function of x. If the first two complexes only are present a straight line should be obtained. The presence of higher complexes should give the line a curvature for the higher x values. The plot is shown in Fig. 5. The points fall with good approximation on a straight line and there appears to be no indication of the presence of $Pb_9(OH)_{12}^{6+}$ or higher complexes. The intercept and the slope of the line give the following equilibrium constants.

$$\log \beta_{4.3} = - 22.89 \pm 0.1$$
$$\log \beta_{8.6} = - 42.13 \pm 0.1$$

corresponding to the equilibria

$$3\ Pb^{2+} + 4H_2O \rightleftharpoons Pb_3(OH)_4^{2+} + 4\ H^+$$
$$6\ Pb^{2+} + 8\ H_2O \rightleftharpoons Pb_6(OH)_8^{4+} + 8\ H^+$$

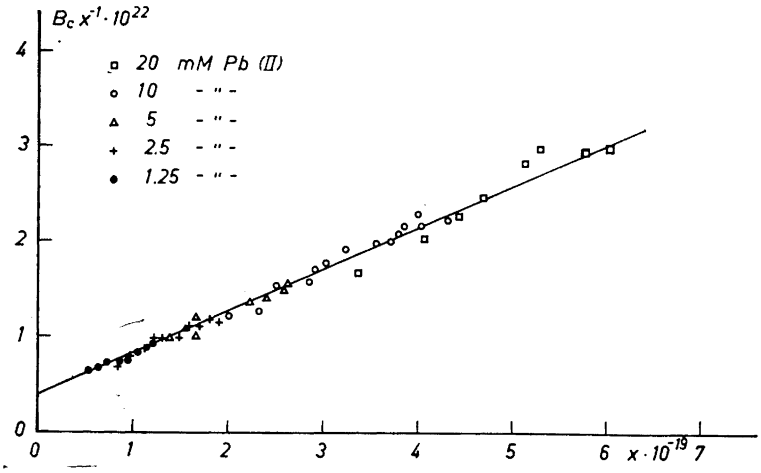

Fig. 5. Determination of log $\beta_{4,3}$ (and log $\beta_{8,6}$) from eqn. (27). B_c; terms for $Pb_4(OH)_4^{4+}$ and $PbOH^+$ have been subtracted. The drawn line yields log $\beta_{4,3} = -22.89$ (and log $\beta_{8,6} = -42.13$).

Approach III. The above calculations were made on the assumption that $Pb_4(OH)_4^{4+}$ and $PbOH^+$ were formed in the initial stages of hydrolysis. If we combine the amalgam data with the Z data the members of the series can be found on the more general assumption, which is strongly supported by the initial ν values, that only complexes of the general type $(PbOH)_n^{n+}$ occur beside $(PbOH_{4/3})_n^{2/3n+}$ species. The following equations are valid.

$$B = b + \Sigma\, n\beta_{n,n}b^n h^{-n} + 3\beta_{4,3}b^3h^{-4} + 6\beta_{8,6}b^6h^{-8} + - - - \qquad (29)$$

$$BZ = \Sigma\, n\beta_{n,n}b^n h^{-n} + 4\beta_{4,3}b^3h^{-4} + 8\beta_{8,6}b^6h^{-8} + - - - - - \qquad (30)$$

Subtracting and rearranging we get

$$(BZ + b - B)\, x^{-1} = \beta_{4,3} + 2\,\beta_{8,6}x + - - - \qquad (31)$$

The plot $(BZ + b - B)x^{-1}$ versus x yields a straight line (Fig. 6) and the equilibrium constants are found to be

$$\log \beta_{4,3} = -22.85 \pm 0.1$$

$$\log \beta_{8,6} = -42.15 \pm 0.1$$

From Figs. 5 and 6 we find that the data for each total lead(II) concentration are gathered in different parts of the lines and do not overlap to any great extent, nor do they cover a broad range in x. This is due to the nature of the functions used. They are based on the concentrations of the $(Pb(OH)_{4/3}^{2/3+})_n$ species obtained from the difference between B and the concentrations of the other species present. Of course, when the latter predominate this difference

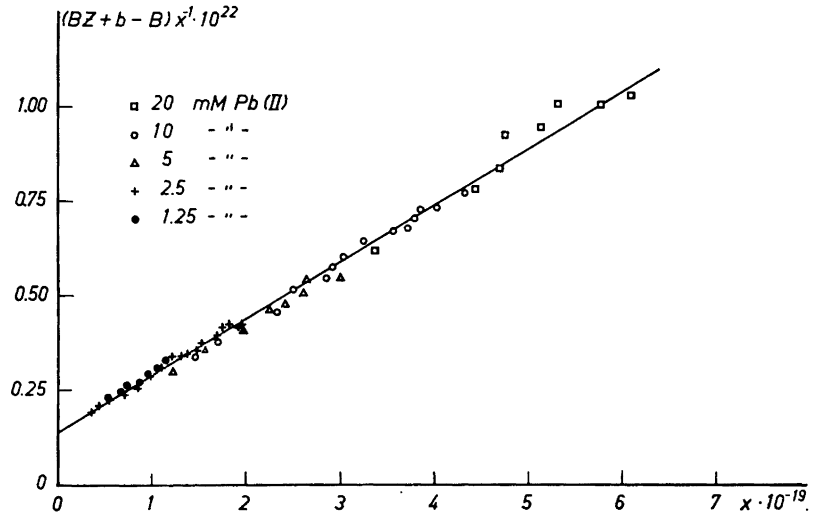

Fig. 6. Determination of log $\beta_{4,3}$ (and log $\beta_{8,6}$) from eqn. (31). The drawn line yields log $\beta_{4,3} = -22.85$ (and log $\beta_{8,6} = -42.15$).

is not very accurate. This leads to a quite narrow x range where the difference is of sufficient accuracy. Therefore any curvature of the lines may not show up. The value found for log $\beta_{4,3}$ will be accepted as being correct, but we shall still doubt the value found for log $\beta_{8,6}$ since higher complexes may also be present.

Now we can subtract the term for $Pb_3(OH)_4^{2+}$ in eqns. (19,20,21) and obtain

$$B_c Z_c = \Sigma\, p\beta_{p,q} b^q h^{-p} \tag{32}$$

$$10^{\eta_c} = 1 + \Sigma\, q\beta_{p,q} b^{q-1} h^{-p} \tag{33}$$

where the sums represent the terms for the unknown complexes. Since the plots in Figs. 5 and 6 strongly indicated that the term for $Pb_6(OH)_8^{4+}$ predominates in the sums above we started with the assumption that $p = 8$ and $q = 6$ and eqns. (24) and (25) were used to test it. From Figs. 7 and 8 it is seen that Z_c and η_c are functions of (log B_c — 1.6 log h) only as required by the hypothesis. The agreement between the experimental and normalized curves is also good. Hence there is no reason to introduce more new complexes other than $Pb_3(OH)_4^{2+}$ and $Pb_6(OH)_8^{4+}$ to explain the upper parts of the η (log $h)_B$ and Z(log $h)_B$ curves. Log $\beta_{8,6}$ was found from eqns. (24, 25) and the difference between the coordinates on the (log B_c — 1.6 log h) and the log v and log u axes when the experimental and normalized curves overlap.

$$\log \beta_{8,6} = -42.15 \pm 0.1\ (\eta \text{ data}) \text{ and } -42.13 \pm 0.1\ (Z \text{ data})$$

Final values for $\beta_{4,4}$ and β_{11}. Thus having established the complexes which predominate in the low log h region and their equilibrium constants it must be remembered that these findings were based partly on the hypothesis that

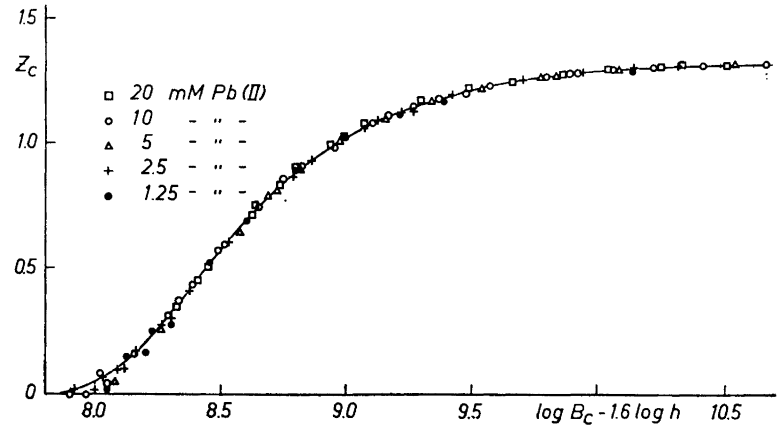

Fig. 7. Z_c as a function of (log B_c −1.6 log h) according to eqn. (25). Z_c, B_c; terms for $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$ and $PbOH^+$ have been subtracted. Drawn curve represents normalized curve, calculated from eqn. (25), in position of best fit and giving log $\beta_{8,6} = -42.13$.

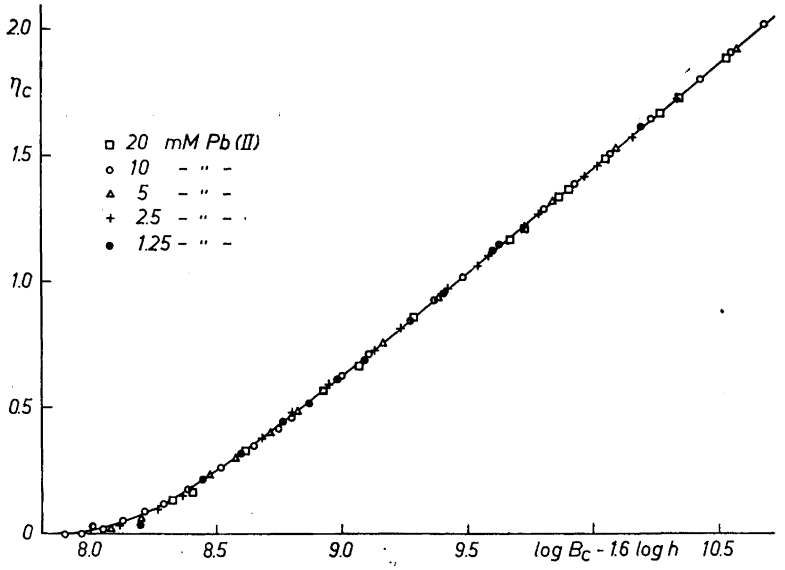

Fig. 8. η_c as a function of (log B_c −1.6 log h) according to eqn. (24). η_c, B_c; terms for $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$ and $PbOH^+$ have been subtracted. Drawn curve represents normalized curve, calculated from eqn. (24), in position of best fit and giving log $\beta_{8,6} = -42.15$.

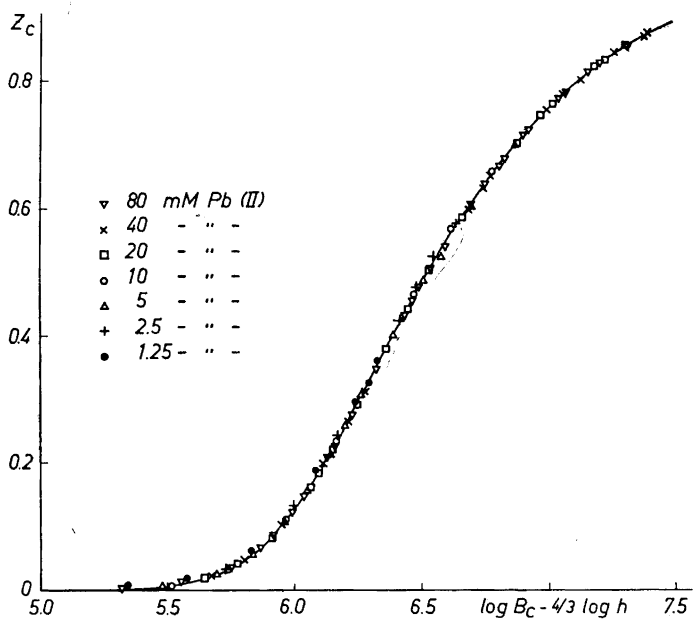

Fig. 9. Z_c as a function of (log B_c −4/3 log h) according to eqn. (12). Z_c, B_c; terms for $Pb_6(OH)_8^{4+}$, $Pb_3(OH)_4^{2+}$ and $PbOH^+$ have been subtracted. Drawn curve represents normalized curve, calculated from eqn. (12), in position of best fit and giving log $\beta_{4,4} = -19.26$.

$Pb_4(OH)_4^{4+}$ and $PbOH^+$ were formed as the initial hydrolysis products. Therefore it was considered necessary to recalculate the data in the high log h region to see that this hypothesis in not upset by disturbances from the new complexes. A calculation of the concentrations of $Pb_3(OH)_4^{2+}$ and $Pb_6(OH)_8^{4+}$ showed that they give only a small contribution in this region.

In order to follow, separately, the formation curve of $Pb_4(OH)_4^{4+}$ at low B values and into the region where the contribution of $Pb_3(OH)_4^{2+}$ and $Pb_6(OH)_8^{4+}$ is not negligible the following equations were derived

$$B_cZ_c = BZ - \beta_{11}bh^{-1} - 4\beta_{4,3}b^3h^{-4} - 8\beta_{8,6}b^6h^{-8} = 4\beta_{4,4}b^4h^{-4} \quad (34)$$

$$10^{\eta_c} = (B - \beta_{11}bh^{-1} - 3\beta_{4,3}b^3h^{-4} - 6\beta_{8,6}b^6h^{-8})\, b^{-1} = 1 + 4\beta_{4,4}b^3h^{-4} \quad (35)$$

By subtracting the terms for the other complexes, calculated with the equilibrium constants already determined, we have arrived at equations identical to (9, 10) and the equilibrium constant is determined as described there (Figs. 9, 10). The value found was

$$\log \beta_{4,4} = -19.25 \pm 0.03 \ (\eta \text{ data}) \text{ and } -19.26 \pm 0.03 \ (Z \text{ data})$$

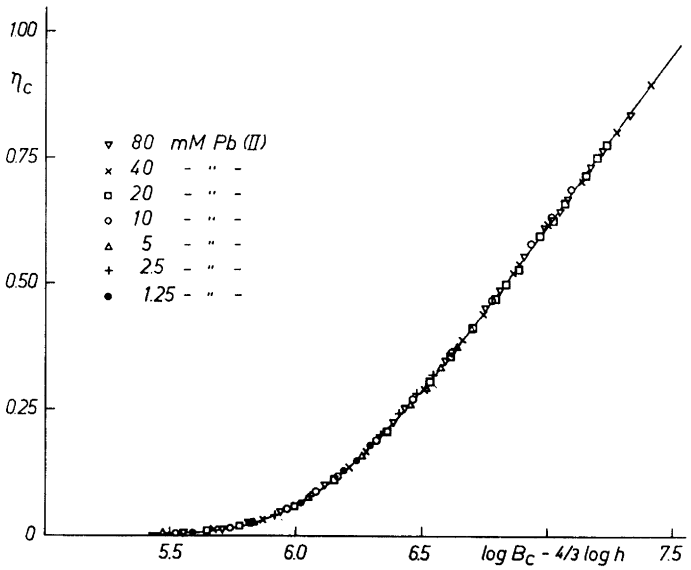

Fig. 10. η_c as a function of (log B_c $-4/3$ log h) according to eqn. (12). η_c, B_c; terms for $Pb_6(OH)_8^{4+}$, $Pb_3(OH)_4^{2+}$ and $PbOH^+$ have been subtracted. Drawn curve represents normalized curve, calculated from eqn. (12), in position of best fit and giving log $\beta_{4,4} = -19.25$.

Determination of the equilibrium constants in 0.3 M (Na)ClO_4. With 0.3 M (Na)ClO_4 as medium the Pb(II) concentrations 10, 5, 2.5 and 1.25 mM were investigated. The interpretation of the data has not been carried out independent of the results which were obtained from the 3 M (Na)ClO_4 data. We have tested only to see if they could be explained by the same mechanism. The calculations were started from eqn. (31) which gave a good straight line from which the equilibrium constants were found as

$$\log \beta_{4,3} = -23.35 \pm 0.1$$

$$\log \beta_{8,6} = -42.66 \pm 0.1$$

Knowing these constants the quantities

$$B_cZ_c = BZ - 4\beta_{4,3}b^3h^{-4} - 8\beta_{8,6}b^6h^{-8} \quad (36)$$

$$10^{\eta_c} = (B - 3\beta_{4,3}b^3h^{-4} - 6\beta_{8,6}b^6h^{-8})b^{-1} \quad (37)$$

were calculated and Z_c and η_c plotted as functions of (log B_c $-$ 4/3 log h). The data from the 10 and 5 mM titrations fell on the same curve as required by the formation of $Pb_4(OH)_4^{4+}$, but the data for the other two values of B were slightly off the curve. This is not unexpected since the Z and η curves

for these concentrations clearly indicate the presence of mononuclear species. Log $\beta_{4,4}$ was determined from the 10 and 5 mM titrations by curve-fitting according to eqn. (12) and found to be

$$\log \beta_{4,4} = -19.89 \pm 0.05 \ (\eta \text{ data}) \text{ and } -19.91 \pm 0.05 \ (Z \text{ data})$$

With these values for log $\beta_{4,4}$, new $B_c Z_c$ and η_c functions were calculated where the terms for $Pb_4(OH)_4^{4+}$ had also been subtracted. Plots of Z_c and η_c as functions of log h gave single curves, which fitted the normalized curves for $PbOH^+$ well. Log β_{11} was found to be

$$\log \beta_{11} = -7.75 \pm 0.1$$

Log β_{11} was estimated also from the lower parts of the Z and η curves of the 2.5 and 1.25 mM titrations. The value found was log $\beta_{11} = -7.8 \pm 0.1$. With this value for log β_{11} the terms for $PbOH^+$ were also subtracted in eqns. (36) and (37). The new plots of Z_c and η_c as functions of (log B − 4/3 log h) fell on the same curves for all concentrations and the plots gave good agreement with the normalized curves for the formation of $Pb_4(OH)_4^{4+}$.

With the help of the equilibrium constants thus found theoretical Z $(\log h)_B$ and η $(\log h)_B$ curves were calculated for all values of B both in 3 M and 0.3 M (Na)ClO_4. In general very good agreement was found between the experimental and theoretical curves as is seen from Figs. 1, 2, 3 and 4. However, there are two questions that need some discussion.

The first question is concerned with the Z data from the titrations at low values of B. As has been mentioned already the 3 M (Na)ClO_4 contained an acidic impurity. The Z data used in the previous calculation have been corrected for this impurity. If for the moment we assume that the correction is not valid, ν values as high as 1.37 are found for $B = 1.25$ mM. Thus complexes with a OH^-/Pb(II) ratio $> 4/3$ must also be present. It is likely that these complexes contain only a few Pb atoms since otherwise the deviations could be expected to be most pronounced at the highest values of B. The simplest explanation that might be suggested is the formation of $Pb(OH)_2$. We have

$$BZ' - (\beta_{11} b h^{-1} + 4\beta_{4,4} b^4 h^{-4} + 4\beta_{4,3} b^3 h^{-4} + 8\beta_{8,6} b^6 h^{-8}) = p\beta_{p,q} b^q h^{-p} \qquad (38)$$

Z' is the Z value which is obtained if no correction is applied for the acidity in the $NaClO_4$. The quantity in the parenthesis was calculated as a function of log h using the previously determined equilibrium constants and neglecting the term $q\beta_{p,q} b^q h^{-p}$ in B. This approximation was employed since exact calculations would be very time-consuming. Using eqn. (38) log $\beta_{2,1}$ ($p = 2$, $q = 1$) was estimated from the 1.25 and 2.5 mM titrations. The value found was log $\beta_{2,1} \simeq -16$. No other hypotheses were tested.

A value of $\beta_{2,1}$ around 10^{-16} would make the acidity constants of Pb^{2+} and $PbOH^+$ about equal. This unusual situation has been observed for other metal

ions including Hg^{2+} (Ref. [27]), Tl^{3+} (Ref. [25]), Fe^{3+} (Ref. [26]), In^{3+} (Ref. [28]) and Sc^{3+} (Ref. [29]). The η data do not show any deviation from the calculated curves either in 3 M or 0.3 M (Na)ClO_4. In 0.3 M (Na)ClO_4 medium, where no correction has been applied for the acidity in the $NaClO_4$, there is almost no discrepancy between the experimental and calculated Z (log $h)_B$ curves, which would indicate the validity of the correction applied to the measurements with 3 M (Na)ClO_4 as medium. Since the presence of $Pb(OH)_2$ in the investigated log h region is dubious it has not been included in the explanation of the data.

The second question is concerned with the data at low Z for the 80 and 40 mM titrations. In this region ν is found to be < 1. It starts from *ca.* 0.9 and increases to 1.00 ± 0.02. The deviations from $\nu = 1$ for the first points appear to be outside the limits of the experimental error and would indicate the presence of complexes with a OH^-/Pb(II) ratio < 1, for instance Pb_2OH^{3+}. This is not unlikely since a high value of B and log h favours the formation of such complexes. The disturbance might be caused by the complex Pb_2OH^{3+}, for which Pedersen [1] found evidence in concentrated $Pb(NO_3)_2$ solutions. A search for this complex is now being made by studying the hydrolysis in concentrated $Pb(ClO_4)_2$ solutions.

To sum up we propose the following reactions and equilibrium constants to explain the data.

		Equilibrium constants	
		3 M (Na)ClO_4	0.3 M (Na)ClO_4
$Pb^{2+} + H_2O \rightleftharpoons PbOH^+ + H^+$	log β_{11}	-7.9 ± 0.1	-7.8 ± 0.1
$4Pb^{2+} + 4H_2O \rightleftharpoons Pb_4(OH)_4^{4+} + 4H^+$	log $\beta_{4,4}$	-19.25 ± 0.1	-19.90 ± 0.1
$3Pb^{2+} + 4H_2O \rightleftharpoons Pb_3(OH)_4^{2+} + 4H^+$	log $\beta_{4,3}$	-22.87 ± 0.1	-23.35 ± 0.1
$6Pb^{2+} + 8H_2O \rightleftharpoons Pb_6(OH)_8^{4+} + 8H^+$	log $\beta_{8,6}$	-42.14 ± 0.1	-42.66 ± 0.1

DISCUSSION

The present investigation agrees with the earlier works by Pedersen [1] and Faucherre [2] in so far as they also found evidence for the complexes $Pb_4(OH)_4^{4+}$ and $PbOH^+$. The numerical values of the equilibrium constants seem to agree less satisfactorily. However, they have often been determined in different media and are therefore not directly comparable.

Faucherre's values for $\beta_{4,4}$ were obtained from his measurements on $Pb(NO_3)_2$ solutions, which also contained $Ba(NO_3)_2$ to make the ionic strength, I, 0.6 or 0.06. Pedersen also determined $\beta_{4,4}$ in mixtures of $Pb(NO_3)_2$ and $Ba(NO_3)_2$ at different I and has given a formula from which log $\beta_{4,4}$ can be calculated knowing I. In the table below the results of these authors are compared.

I	log $\beta_{4,4}$ (Faucherre)	log $\beta_{4,4}$ (Pedersen)
0.6	-18.75	-20.81
0.06	-18.05	-20.61

In perchlorate medium Faucherre did not determine $\beta_{4,4}$ directly. He calculated theoretical Z curves for $Pb_4(OH)_4^{4+}$ with $\log \beta_{4,4} = -18.75$ obtained with nitrate medium, and from the fact that these curves satisfactorily pass through his experimental points in 1 M $NaClO_4$ the value in this medium must be close to -18.75. This value differs by 0.5 units from our value in 3 M $NaClO_4$.

The lower value for $\beta_{4,4}$ in nitrate medium, found by Pedersen, is reasonable considering the complex formation between Pb^{2+} and NO_3^-. The values found by Faucherre with the same medium, therefore, seem to be somewhat in error.

The discrepancy between the results obtained by Faucherre and us from measurements on solutions with $Z > 1$ is probably due mainly to his mode of calculation. His calculations were based on the assumption that the lead(II) at $Z = 1$ is present solely as $Pb_4(OH)_4^{4+}$, which is not correct.

The values for $\log \beta_{11}$ found in the literature range between -6.2 and -8.7. There is, however, no value from perchlorate solutions.

The complexes found probably have closed structures but we shall at the present stage refrain from any structure proposals.

Acknowledgements. The author is indebted to Professor Lars Gunnar Sillén for his continual interest in this work and to Professor Robert E. Connick, Univ. of Calif., for valuable criticism of the manuscript. He also wishes to thank Dr. George Biedermann for discussions on practical aspects of the research and for comments in the manuscript. Thanks are also due to Mr. György Patzauer for skilful help with some of the measurements and calculations and to Mr. Frans Eriksson for construction of the apparatus. The English of this paper has been corrected by Mr. David Martin. Conjugate Additions of Grignard Reagents to alpha,beta-Unsaturated Esters

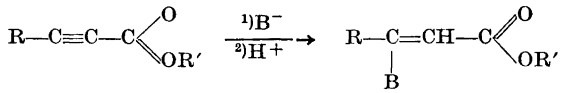
VII. Additions to Acetylenic Esters

CLAUS BRETTING, JON MUNCH-PETERSEN, PEER MØLLER JØRGENSEN and SUSANNE REFN

Organisk-kemisk Laboratorium, Polyteknisk Læreanstalt, Copenhagen, Denmark

The reactions of *n*-butylmagnesium bromide with esters of phenylpropiolic, tetrolic and acetylenedicarboxylic acids have been investigated. With *sec*-butyl phenylpropiolate and tetrolate conjugate addition takes place if the reaction is catalyzed by cuprous chloride; otherwise tertiary acetylenic alcohols are formed. Diethyl acetylenedicarboxylate gave a small yield of conjugate addition product when the reaction was uncatalyzed and the reaction time very short. The ethyl ester of phenylpropiolic acid gave unsatisfactory results. The general reactivity of the triple bond is considered.

Isolated carbon-carbon triple bonds are in general more reactive towards nucleophilic reagents than are double bonds. Thus, alcohols are added, in the presence of the corresponding alkoxides, to alkynes but not to alkenes. Sometimes electrophilic catalysts, such as certain metallic salts, must be present in order to secure addition, *e.g.* the additions of water and hydrogen cyanide to acetylene in the presence of mercuric sulfate and cuprous chloride, respectively. As in the case of the ethylenic bond, a carbonyl group in conjugation with the multiple bond will enhance the reactivity towards nucleophilic reagents and, conversely, reduce the reactivity towards electrophilic reagents. Thus, α,β-acetylenic esters are known to add nucleophilic reagents without the presence of a catalyst:



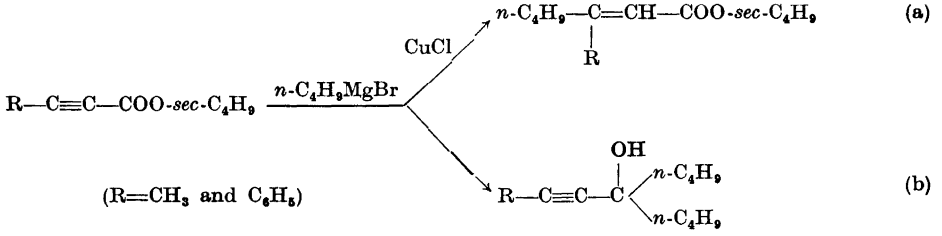
Several Michael-type condensations with malonic and cyanoacetic esters are described in the literature [1] for the cases of phenylpropiolic, tetrolic, propiolic and acetylenedicarboxylic esters. Other nucleophilic reagents, such as

ammonia [2] and phenylhydrazine [2,3], have also been added to the triple bond of α,β-acetylenic esters. Recently, the addition of methyl thioglycolate to dimethyl acetylenedicarboxylate has been described [4]. In this, as well as some of the above cases, the primarily formed products undergo further reactions under certain conditions.

Also reactions of Grignard reagents with α,β-acetylenic esters are described in the literature. Wilson and Hyslop [5] found that only normal tertiary alcohols were formed from ethyl phenylpropiolate and methyl- and phenylmagnesium bromides. No yields were reported. Hurd and Cohen [6], however, were able to obtain the ketone (phenylpropiolophenone) from ethyl phenylpropiolate and phenylmagnesium bromide in 85 % yield. Thus in these as well as in some other cases [7] only 1,2-additions (to the carbonyl group) have been encountered.

With acetylenic ketones Kohler [8] has found that benzoyl-phenylacetylene with phenylmagnesium bromide gives exclusively 1,2-addition under conditions where the corresponding ethylenic compound, benzalacetophenone, gives chiefly 1,4-addition. However, Fuson and Meek [9] have found that with mesitoyl-phenylacetylene, in which the carbonyl group is sterically hindered, 1,4-addition of methyl- and mesitylmagnesium bromides takes place in good yields, although the yield with phenylmagnesium bromide is only 20 %.

In the present investigation certain α,β-acetylenic esters have been subjected to the action of *n*-butylmagnesium bromide under conditions which have previously been found favourable for conjugate addition to α,β-ethylenic esters, uncatalyzed [10] as well as catalyzed by cuprous chloride [11]. The results are given in Table 1.



In the uncatalyzed reactions (*b*) *sec*-butyl tetrolate and phenylpropiolate, in contrast to the corresponding ethylenic compounds, do not give conjugate addition products but carbonyl addition products (*i.e.* tertiary alcohols) *. These results prove the triple bond of acetylenic esters to be less reactive towards Grignard reagents than the double bond in ethylenic esters.

This is in agreement with other evidence that a triple bond to a much less degree than a double bond is able to participate in conjugation with other multiple bonds [12]. For example, the methyl group of ethyl tetrolate does not

* The yield of tertiary alcohol from phenylpropiolic ester (also the ethyl ester, *cf.* below) is diminished by the formation of varying quantities of a lower boiling (106—107°/5 mm) product with higher refractive index (n_D^{25} 1. 5392). This compound, which rather quickly turns into a viscous yellow syrup, may be an elimination product from the tertiary alcohol. It contains oxygen, but shows no infra-red absorption for either carbonyl or hydroxyl groups.

Table 1. Type of products and yields from reactions of α,β-acetylenic esters with *n*-butylmagnesium bromide.

	No catalyst	CuCl-catalyst
sec-Butyl phenylpropiolate	Tertiary alcohol [a] (1,2-addition) 28–47 % [b]	Ethylenic ester [c] (1,4-addition) 55 %
Ethyl phenylpropiolate	Tertiary alcohol [a] (1,2-addition) 21–37 % [b]	High-boiling, non-destillable product
sec-Butyl tetrolate	Tertiary alcohol [d] (1,2-addition) 63 %	Ethylenic ester [e] (1,4-addition) 73 %
Di-*sec*-butyl acetylenedicarboxylate (crude)		High-boiling, non-distillable product. Tar
Diethyl acetylenedicarboxylate [f]	Diethyl di-*n*-butylsuccinate [g] 15 % Mostly high-boiling residue	High-boiling, non-distillable product [h]

[a] Phenylethynyl-di-*n*-butylcarbinol, b.p. 131°/0.9 mm, n_D^{25} 1.5213. (Found: C 83.50; H 9.69. Calc. for $C_{17}H_{24}O$ (244.36): C 83.55; H 9.90). [b] *cf.* foot-note, page 152. [c] *sec*-Butyl β-*n*-butylcinnamate, b.p. 124.5°/0.8 mm, n_D^{20} 1.5072. (Found: C 78.40; H 9.19. Calc. for $C_{17}H_{24}O_2$ (260.36): C 78.42; H 9.29). [d] 1-Propynyl-di-*n*-butylcarbinol, b.p. 108°/11 mm, n_D^{20} 1.4562. (Found: C 79.15; H 12.07. Calc. for $C_{12}H_{22}O$ (182.30): C 79.06; H 12.16). [e] *sec*-Butyl 3-methylhept-2-enoate (β-*n*-butylcrotonate), b.p. 104–105°/13 mm, n_D^{20} 1.4478. (Found: C 72.65; H 10.96. Calc. for $C_{12}H_{22}O_2$ (198.30): C 72.68; H 11.18). [f] Ester added during ½ h only, and worked up immediately. [g] B.p. 97–102°/0.7 mm, n_D^{25} 1.4379. (Found: C 67.15; H 10.30. Calc. for $C_{16}H_{30}O_4$ (286.40): C 67.09; H. 10.56). [h] This result was obtained also when the addition time for the ester was reduced to ½ h.

show any reactivity towards carbonyl groups in condensation processes of the aldol or Claisen types as compared with ethyl crotonate, which is the vinylog of ethyl acetate [13]. Furthermore, it has been found by G. Østrup of this department [14] that, in the preparation of tetrolyl chloride from the acid and thionyl chloride, addition of hydrogen chloride to the multiple bond takes place to a considerable degree, whereas this is not the case in the analogous preparation of crotonyl chloride, in which the reactivity of the double bond towards electrophilic reagents is strongly reduced by conjugation with the carbonyl group.

The mechanism which has been proposed for conjugate addition af Grignard reagents to α,β-ethylenic systems [15] involves a cyclic synchronous electron

shift within a six-membered ephemeral ring, the energy of activation thereby being especially low. In the corresponding reaction with acetylenic esters, however, the conditions for such a mechanism is much less favourable, since the linearity of the triple bond prevents the formation of a regular hexagon.

The presence of cuprous chloride (*a*, above) has the drastic effect of changing completely the direction of addition from 1,2- to 1,4-addition, the sole products now being the *sec*-butyl esters of *β*-*n*-butyl-*α*,*β*-ethylenic acids. This is in agreement with the above-mentioned catalytic effect of metallic salts on additions to the triple bond, and also with the previously described general effect of cuprous chloride that the presence of this compound promotes conjugate additions of Grignard reagents to *α*,*β*-unsaturated esters in competition with carbonyl addition reactions [11].

Diethyl acetylenedicarboxylate was used besides the *sec*-butyl ester, since the latter proved to be difficult to obtain in a pure state, probably due to elimination and decarboxylation during the distillation. Both esters were found to give only tarry or high-boiling products when the standard cuprous chloride catalyzed procedure was followed. A similar result has apparently been obtained by Gilman and Robinson [16] in the uncatalyzed reaction of diethyl acetylenedicarboxylate and phenylmagnesium bromide. On the other hand, Michael [17] has reported the formation in 20—25 % yield of diethyl ethylfumarate by treating diethyl acetylenedicarboxylate for a long period with ethyl iodide in the presence of zinc. No details are given.

We have found that when the addition of *n*-butylmagnesium bromide was uncatalyzed and performed quickly a small yield of a well-defined product could be obtained. This proved to be a di-*n*-butylsuccinic ester, which was presumably formed by two 1,4-additions to the triple bond. For sterical reasons one would expect the product to be an *α*,*α*′-isomer, but previous investigations of conjugate additions to citraconic and mesaconic esters [18] have shown that in such cases mixtures of isomers may be formed. No attempts were made during the present work to determine the structure of the dibutylsuccinic ester.

In the above-mentioned addition of methyl thioglycolate to dimethyl acetylenedicarboxylate [4], the use of piperidine as a catalyst likewise resulted in two 1,4-additions, the *α*,*α*′-product presumably being formed.

Apparently acetylenedicarboxylic esters are far more reactive than the mono-carboxylic esters, and in the presence of cuprous chloride polymerisation takes place. This was also the case with ethyl phenylpropiolate, when cuprous chloride was present, whereas the *sec*-butyl ester under these conditions did give the 1,4-addition product. The uncatalyzed reaction with ethyl phenylpropiolate gives the same products as does the *sec*-butyl ester.

EXPERIMENTAL

Microanalyses are by Mr. Preben Hansen, Microanalytical Division, The Chemical Laboratory, The University of Copenhagen. Fractional distillations were through a simple 45 cm × 8 mm Podbielniak type column with a tantalum wire spiral, a heated jacket and a partial reflux head.

Preparations of α,β-acetylenic acids

Phenylpropiolic acid [19] and *acetylenedicarboxylic acid* [20] were obtained according to the directions in *Organic Syntheses*.

Tetrolic acid. But-2-yn-1-ol was prepared as described in *Organic Syntheses* [21]: 1,3-dichlorobut-2-ene (Eastman, technical) * was hydrolyzed to 3-chlorobut-2-en-1-ol and from this hydrogen chloride was eliminated by means of sodium amide in liquid ammonia. The butynol, dissolved in acetone, was oxidized with chromic anhydride in sulfuric acid as described for the preparation of propiolic [22] and γ-chlorotetrolic [23] acids. The yield of of tetrolic acid, b. p. 93—98°/15 mm, m. p. 72—73° (from ligroin) was 40 %. The overall yield from 1,3-dichlorobut-2-ene was about 20 %, but could probably be improved.

Preparations of α,β-acetylenic esters

sec-*Butyl esters* were prepared by esterification of the acids as previously described [24]: sec-*Butyl phenylpropiolate*, b. p. 112—113°/1 mm, n_D^{20} 1.5368, yield 58 %. (Found: C 77.10; H 6.80. Calc. for $C_{13}H_{14}O_2$ (202.34): C 77.20; H 6.98.) sec-*Butyl tetrolate*, b.p. 72—73°/12 mm, n_D^{25} 1.4392, yield 59 %. (Found: 68.70; H 8.66. Calc. for $C_8H_{12}O_2$ (140.18): C 68.54; H 8.63.) *Di*-sec-*butyl acetylenedicarboxylate;* by the distillation gas-evolution took place, and the pressure and boiling point were fluctuating. The main fraction passed over at 110—113°/1.4—1.8 mm, n_D^{20} 1.4479; the yield was only about 20 % and the analysis was slightly incorrect (about 1 % in carbon).

Diethyl acetylenedicarboxylate was prepared by an esterification procedure similar to that described in *Organic Syntheses* for the dimethyl ester [25]; b. p. 63—64°/1 mm, n_D^{25} 1.4418. (Found: C 56.50; H 5.92. Calc. for $C_8H_{10}O_4$ (170.16): C 56.46; H 5.92.)

Ethyl phenylpropiolate was obtained by sulfuric acid catalyzed esterification of the acid with excess of ethanol under reflux for 8 h; b. p. 87—89°/0.8 mm (rep.[5] 104°/1.5 mm), n_D^{20} 1.5534, yield 76 %. (Found: C 75.90; H 5.86. Calc. for $C_{11}H_{10}O_2$ (174.19): C 75.84; H 5.79).

Addition reactions

These were carried out as previously described [10,11], except in one case with diethyl acetylenedicarboxylate (see Table 1).

The identity of the reaction products were further checked by *infra-red spectroscopy*. The spectra were measured with a Beckman IR2 spectrophotometer with sodium chloride prisms, using 5 % solutions in carbon tetrachloride. The alcohols were identified by their hydroxyl band in the 3 μ regicn and by the absence of a carbonyl absorption. The spectra of the esters showed an absorption at 1 715 cm^{-1} within the carbonyl region for α,β-unsaturated esters, as well as a somewhat weaker band around 1 650 cm^{-1} (C=C stretching vibration). Furthermore, the *sec*-butyl esters also showed the group of absorption bands around 1 111 cm^{-1}, which has previously been found in the spectra of other *sec*-butyl carboxylates [18]. The diethyl di-*n*-butylsuccinate (from diethyl acetylenedicarboxylate) showed the normal carbonyl band for saturated ester at 1 730 cm^{-1}, but no absorption for conjugated C=O, C=C or OH.

The authors want to express their gratitude towards *Otto Mønsteds Fond* and *Det Teknisk-Videnskabelige Forskningsraad* for financial support.

* The authors are indebted to *Dansk Esso A/S*, Copenhagen, for the generous gift of this chemical.

Least Squares Calculations of Equilibrium Constants for some Metal Complexes *

JAN RYDBERG**

Chemistry Division, Argonne National Laboratory, Lemont, Illinois, U.S.A.

The least squares technique demonstrated in an earlier paper [1] has been applied to complexes formed between a number of different organic ligands and rare earth and actinide metals. The consequences of various weighing procedures are discussed and demonstrated in the examples. A comparison is carried out between the results of the least squares calculations and the results of earlier (usually graphical) computations, and the reasons for the discrepancies are discussed.

In a recent paper [1] it was demonstrated how equilibrium constants could be calculated from solvent extraction data by the methods of least squares and using high-speed digital computers. These calculations rapidly yielded the maximum number of equilibrium constants and their precision. On the other hand it was also indicated that — in the absence of very precise experimental data — the earlier graphical methods gave equilibrium constants, which cannot be supported by the results of the least squares calculations.

It was therefore felt to be of value to make a more comprehensive comparison between various methods of calculating equilibrium constants from solvent extraction data. For that purpose, a series of papers by Bernström, Dyrssen, Rydberg, *et al.* [2–14] was selected, in which a number of different graphical computations of equilibrium constants have been used.

The principles of the various computational methods are briefly outlined below, together with the relation between the primary parameters obtained and the equilibrium constants calculated from them. The least squares method will not be described in any detail, because its use in this kind of investigations has been fully treated in earlier papers [1,15]. The result of this investigation is summarized in Table 1, where equilibrium constants computed by the least squares method can be compared with the constants determined by earlier methods.

* Based on work performed under the auspices of the U. S. Atomic Energy Commission.

** On leave from the University of Stockholm, and the Research Institute of National Defense, Stockholm, Sweden.

OUTLINE OF VARIOUS COMPUTATIONAL PROCEDURES

The most commonly used methods for calculation of equilibrium constants from solvent extraction data are the ligand number method (sometimes called the Bjerrum method; *e.g.* Refs.[2,16,17]) the limiting value method (sometimes called the Leden method; *e.g.* Refs.[2,17,18]) and the two-parameter method (sometimes called the Dyrssen-Sillén method [14]).

The basic equation for all the solvent extraction work discussed here is [2]

$$Q = \frac{\lambda_\nu \beta_\nu [\mathrm{A}]^\nu}{\sum_0^N \beta_n [\mathrm{A}]^n} \qquad (1)^*$$

where Q is the distribution ratio between the organic and aqueous phases of all mononuclear forms of the metal (charge $+\nu$) at constant activity factors for all species involved, [A] is the concentration of free (uncomplexed) ligand ion (here assumed to be monovalent), λ_ν is the partition constant of the uncharged MA_ν complex between the two solvents, and β_n is the gross complexity constant as defined by

$$\beta_n = \frac{[\mathrm{MA}_n]}{[\mathrm{M}]\ [\mathrm{A}]^n} = \prod_0^n k_n \qquad (2)$$

where by definition $\beta_0 = k_0 = 1$, and k_n is the stepwise complexity constant. For simplicity the charges of the ions have been omitted. N is the maximum coordination number of A for M.

1. *The ligand number method.* It has been shown [2] that

$$\frac{\mathrm{d} \log Q}{\mathrm{d} \log [\mathrm{A}]} = \nu - \bar{n} \qquad (3)$$

where $\bar{n}$ is the mean ligand number defined by [16]

$$\bar{n} = \frac{\sum_1^N n[\mathrm{MA}_n]}{\sum_0^N [\mathrm{MA}_n]} \qquad (4)$$

Since ν is known, the graphical derivation of the curve log Q *versus* log [A] will yield $\bar{n}$. Eqn. 4 can be rearranged to

$$\sum_0^N (\bar{n} - n)\ \beta_n\ [\mathrm{A}]^n = 0. \qquad (5)$$

* The symbols used here conform with those in Refs. [1,15], and differ slightly from those in Refs. [2-14]

By choosing N number of points $\bar{n}_i([A]_i)$ on the curve $\bar{n}$ *versus* log [A], preferably at $\bar{n}_i = 0.5, 1.5, \ldots\ldots N-0.5$, a set of N equations are obtained. The solution of this set of equations by determinants using Cramer's rule is straightforward.

2. *The limiting value method.* Equation 1 can be rearranged to

$$Q^{-1} = \frac{1}{\lambda_\nu} \sum_{N}^{0} \varphi_{\nu-n}[A]^{n-\nu} \tag{6}$$

If, *e.g.* for $\nu = N$, Q^{-1} is plotted against $[A]^{-1}$, the limiting value when $[A]^{-1} \to 0$ of the resulting curve will yield

$$\lim_{[A]^{-1} \to 0} Q^{-1} = \frac{\psi_0}{\lambda_\nu} + \frac{\psi_1}{\lambda_\nu} [A]^{-1} (+ \ldots.)$$

Since $\psi_0 = 1$, the intercept on the Q^{-1} axes will be $1/\lambda_\nu$, and the slope at the intercept will be ψ_1/λ_ν. By then setting $F_1 = \left(\frac{\lambda_\nu}{Q} - 1\right)[A]$ and taking the limiting value of F_1 when $[A]^{-1} \to 0$, the new intercept value will be ψ_1 and the corresponding slope ψ_2; similarly all ψ_n and λ_ν can be determined. The relation between ψ and β is given by

$$\psi_{\nu-n} = \beta_n/\beta_\nu \tag{7}$$

3. *The two-parameter method.* It is assumed [14] that the relation between the equilibrium constants can be approximated to

$$\log \beta_N = Np_1 \tag{8}$$

and

$$\log k_n/k_{n+1} = 2p_2 \tag{9}$$

Here 10^{p_1} is called the mean complexity constant, and 10^{2p_2} is called the mean spreading factor.

When these relations are introduced into eqn. 1, it becomes

$$Q = \frac{\lambda_\nu [A]^\nu \, 10^{\nu[p_1+p_2(N-\nu)]}}{\sum_{0}^{N} [A]^n 10^{n[p_1+p_2(N-n)]}} \tag{10}$$

It is seen that in addition to λ_ν this equation only contains two unknown parameters, p_1 and p_2. For a given combination of ν and N (which are known parameters) a family of curves log Q/λ_ν as a function of log ([A] + p_1) can be constructed, each curve representing a specific p_2 value. By placing this family of curves (*e.g.* suitably etched on a clear plastic ruler) over the experimental points log Q *versus* log [A], the curve with the best fit can be found; from the curvature and intercepts on the two axes, the parameters λ_ν, p_1 and p_2 are obtained.

4. *The least squares method.*
Eqn. 1 can be rearranged to

$$z = \sum_{0}^{N} a_n [\mathrm{A}]^n \tag{11}$$

where

$$z = [\mathrm{A}]^p/Q \tag{12}$$

and

$$a_n = \beta_n/\lambda_p\beta_p \tag{13}$$

Eqn. 11 can be solved by the method of weighted least squares using high speed digital computers [1,15] to cut down on the computation time. It will then yield $a_n \pm \sigma_{a_n}$, where σ_{a_n} is the standard deviation in a_n. The weight, which has to be assigned to the z_i values, depends on the precision of the measurements of Q_i.

Several kinds of standard errors in Q have been tested here for solvent extraction data: (1) errors in Q (or in I_{org} and I_{aq}, which represent measured standardized radioactivities of the organic and aqueous phases) given in the original paper, (2) a counting error in Q, called $\sigma_Q(I)$, based on the assumption that the number of measured counts is 5 times that given for the intensities (5 min. measurement if I is given in counts per min., cpm) and that the background error is ± 1 (thus, *e.g.* $\sigma(I_{aq}) \approx 1 + \sqrt{I_{aq}/5}$), (3) a constant percentage (**P**) error, called $\sigma_Q(\%)$, making $\sigma_Q(\%) = \mathbf{P}\ Q$, (4) errors in Q caused by errors in the determination of the free ligand concentration. These kinds of errors are more extensively discussed elsewhere [1].

Since the weight of a point $z_i(x_i)$ is defined here as one over the variance σ_i^2 of the z_i value, *i.e.* $\omega_i = 1/\sigma_i^2$, the weight of all points can be changed by multiplying the variance with a constant factor. This will not change the $a_n \pm \sigma_{a_n}$ values, *cf.* Ref.[15], but will alter the χ^2 values (*e.g.* Ref.[20]), which also are calculated in the computer program [1,15]. Since the ratio χ^2/k should be within the range 0.5—1.5 for a reasonable consistency between the experimental data and the equations used for computing a_n, χ^2/k can be brought into this range by changing the weights of the data. This procedure is used all through this investigation to see what size of standard error should have been assigned to the original data. The k value is the number of degrees of freedom in the computations and is equal to $L-N-1$ for eqn. 11; L is the number of experimental points.

It is obvious that when $\sigma_{a_n} > a_n$, the a_n value is of little statistical significance. If such an a_n value is obtained, it is omitted from eqn. 11 and the least squares computations are repeated without it. Though this means mathematically that the particular a_n value is put equal to zero, it should be interpreted only as a way of removing parameters from the calculations which can only be determined very inaccurately; this usually causes only small changes in the remainning parameters (see paragraphs a and d below). Similarly, negative a_n values are omitted, because in the deductions of the basic solvent extraction equations only positive concentrations of the complexes are assumed to exist.

Table 1. Survey of the investigated systems.

RESULTS

The solvent extraction systems investigated here are given in alphabetical order of the ligand in Table 1, which contains the computed primary parameters and the equilibrium constants obtained from them. Sometimes only the primary parameters are given in the original papers and usually without any indication of the sizes of the standard deviations. In order to facilitate a comparison between the least squares calculations and the results of the other methods in these cases, equilibrium constants have been computed from the parameters and standard deviations estimated when possible; those values which are not found in the original paper are given within parenthesis in the table.

In all systems, the least squares parameters a_n have been used to calculate log Q as a function of log [A] according to

$$Q = [A]^p / \sum_0^N a_n [A]^n. \qquad (14)$$

If nothing particular is said in the text accompanying the Tables, it is understood that the curve thus obtained goes smoothly through the experimental points with about equally many points on both sides of the curve (see also Discussion).

a. *The Th(IV)-acetylacetone-benzene-0.01 M $NaClO_4$ system* [2]. The least squares computations on this system have been discussed before [1]. Regardless of the kinds of errors tested for the primary data, the parameter a_1 came out negative. Omitting a_1 and using a certain combination of counting and pH error (see Ref.[1]), the a_n values in Table 1a were obtained. (The corresponding a_n values with *all* parameters are: a_0 $10^{30} = 6.4 \pm 1.7$, a_1 $10^{22} = -1.3 \pm 1.3$, a_2 $10^{14} = 1.94 \pm 0.15$, a_3 $10^8 = 2.34 \pm 0.29$ and a_4 $10^3 = 3.53 \pm 0.49$; omitting a_1, the changes in the remaining parameters are rather small, see Table 1a).

Though the requilibrium constants of the two computational procedures are in good agreement, the spread of the experimental data (an average standard deviation of about 25 %) prevents a separation of k_1 from k_2. With the limiting value method more constants have been calculated than are justifiable. The precision of the equilibrium constants of the limiting value method is based on graphical estimates and are obviously in good agreement with the corresponding least squares data.

b. The Th(IV)-acetylacetone-chloroform-0.1 M $NaClO_4$ system.[3] In the original paper, the standard deviations of the primary data I_{org} and I_{aq} are given. Using these deviations, the least squares procedure yields a negative value of a_0 and with a standard deviation of > 100 %. Omitting this parameter, a χ^2/k value of 39 is obtained, indicating that the weights assigned from the errors in the primary data are incorrect (*cf.* Ref.[1]).

Following the procedure discussed in Ref.[1] for the Th-acetylacetone-benzene case, both a counting error (σ_Q(I)) and a ligand error (σ_Q(A)) was tried, separately as well as combined. With a weighing factor of 6 times the original counting error, and a ligand error corresponding to $\pm$ 0.01 log units,

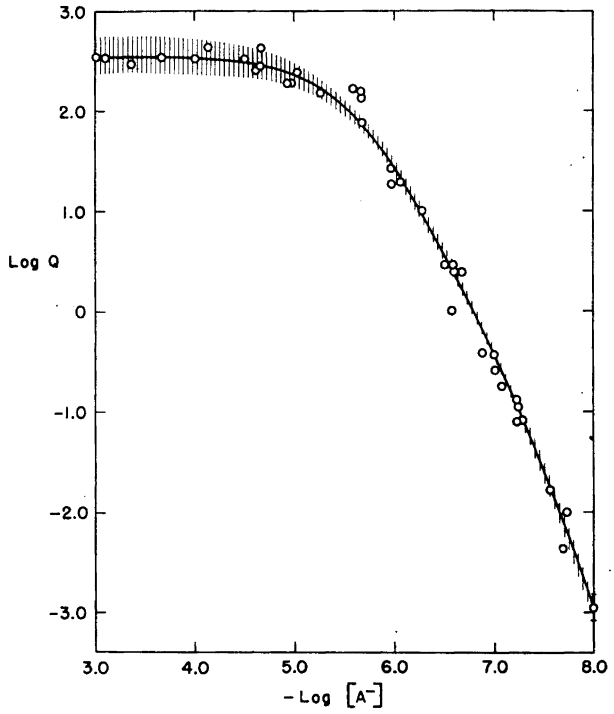

Fig. 1. The Th(IV)-acetylacetone-chloroform-0.1 M $NaClO_4$ system. The curve is computed from the least squares parameters in Table 1 b. The shaded area indicates the precision of the curve.

$\chi^2/k = 1.5$ was obtained; the a_n values for this combination are given in Table 1b. The fact that so much larger errors had to be assigned to the data indicates that the solvent extraction procedure may involve large errors, which were not originally accounted for.

Table 1b shows that though the numerical values of the equilibrium constants obtained with the two computational methods agree fairly well, the least squares method indicates that the experimental data do not allow a calculation of k_1. This is also clear from Fig. 1, where the curve computed without k_1 obviously fit the data very well. The broad band around the curve in Fig. 1 gives the precision of the curve as obtained with the least squares method. From Table 1b it is also seen that the estimated errors given for the equilibrium constants of the ligand number method are far too small.

c. The U(IV)-acetylacetone-benzene-0.1 M $NaClO_4$ system [4,19]. The least squares treatment of this system has recently been described [19]. The results are summarized in Table 1c, where comparison is made only with the results of the two-parameter method, though the ligand number method was also used in the original paper [4].

Table 2. Comparison between a_n parameter values obtained by the least squares calculations and those computed from graphically obtained equilibrium constants for the Pu(IV) acetylacetone system.

Method	Parameter values					
	χ^2/k	$a_0 \times 10^{37}$	$a_1 \times 10^{26}$	$a_2 \times 10^{17}$	$a_3 \times 10^{9}$	$a_4 \times 10^{3}$
limiting value	—	2.8	1.7	6.9	2.8	2.8
ligand number	—	1.0	1.0	1.3	4.0	3.2
two-parameter	—	3.6	2.9	5.8	2.9	3.6
least squares (5 parameters)	0.91	-17 ± 10	1.9 ± 0.8	-0.046 ± 0.53	3.3 ± 0.6	2.9 ± 0.4
least squares (3 parameters)	1.07	—	0.61 ± 0.15	—	3.6 ± 0.5	2.9 ± 0.5
Parameters refer to the following equilibria (no index means aqueous phase):		$\frac{[M]\,[A]^4}{[MA_4]_{org}}$	$\frac{[MA]\,[A]^3}{[MA_4]_{org}}$	$\frac{[MA_2]\,[A]^2}{[MA_4]_{org}}$	$\frac{[MA_3]\,[A]}{[MA_4]_{org}}$	$\frac{[MA_4]}{[MA_4]_{org}}$

This system is the only one in the present investigation where significant values have been obtained for all possible parameters using the least squares method. The agreement between the results of the two computational methods is fair. The precision of the equilibrium constants of the two parameter method is based on graphical estimates [19].

d. The Pu(IV)-acetylacetone-benzene-0.1 M $NaClO_4$ system [5]. From the spread of the experimental points, the standard deviations in Q were assumed to be 20 %. With the least squares method this produced a χ^2/k value of 0.91 and the parameter values in Table 2. Omitting the negative parameters, a χ^2/k of 1.07 was obtained, indicating that the 20 % error is a reasonable estimate.

Table 1d contains the primary parameters and the equilibrium constants computed from them, including those of all three different methods given in the original paper. The precision values given within parenthesis are, for the limiting value and ligand number methods, estimates from the differences in β_n-values obtained with these two methods. In the two-parameter method, the precision in the primary parameters are here assumed to be $\pm$ 0.1.

It is seen from Table 2 that a_0 is negative with $\sigma_{a_0} < |a_0|$, which should mean that negative concentrations of either Pu^{4+} or $PuAa_4$ exist. Since this cannot be true, a_0 had to be omitted with the consequences that no k_1 value can be calculated. The difficulty encountered in calculating k_1 with the limiting value method also supports that the calculation of such a value (as has been done with the ligand number and two-parameter methods) is dubious. Thus in contradiction to the graphical methods, the least squares result clearly indicates that the experimental data do not permit a calculation of k_1, the reason probably being that the concentration of Pu^{4+} in the experiments is too low to have any serious influence on the measurements. (It is obvious that the omission of a_0 does not mean that Pu^{4+} does not exist! *cf.* p. 160).

Since a_2 was negative and was associated with a very large standard error it was also omitted. Of the a_2 values computed from the graphically obtained equilibrium constants (see Table 2), it is seen that the ligand number value is much smaller than those of the other two methods. In the original paper [5], a plot of $\bar{n}$ against log [A] for Pu(IV) showed a steeper slope at $\bar{n} = 2$ than was the case for the similar Th(IV) and U(IV) systems [2-4], thus indicating an unexpectedly low concentration of the PuA_2^{2+} complex. The numerically low and highly uncertain value of a_2 obtained by the least squares calculation agrees well with these more visual findings on the $\bar{n}$ curve. It must therefore be concluded that in the Pu(IV) acetylacetone system the formation of the second complex, PuA_2^{2+}, seems to be hindered. A "regular" behaviour of the system would give an a_2 value of about 6×10^{-17} (the two-parameter value), while its real value probably is $< 0.5 \times 10^{-17}$. A use of the a_2 value obtained by the two-parameter or limiting value methods is therefore probably very misleading.

On the other hand, it should be mentioned that both Th(IV) and U(IV) show an unusually high stability for their second acetylacetonate complex, as judged by the regular principles of the two-parameter method. The only explanation that would remove the conclusions above about the PuA_2^{2+} complex is that systematic errors are involved in the Pu(IV) system which do not appear in the Th(IV) and U(IV) systems, or vice versa. Investigations by other methods than solvent extraction may settle this question; such experiments are being planned.

e. The Th(IV)-cinnamicacid-hexone-0.1 M $NaClO_4$-system.[6] As pointed out in the original paper, the data are badly scattered which makes accurate calculations of the equilibrium constants difficult. By choosing $\sigma_Q(\%) = 0.7\ Q$, $\chi^2/k = 0.99$ was obtained with two negative parameters (a_0 and a_3) and two parameters having standard deviations > 100 % (a_2 and a_3). Omitting these three parameters, $\chi^2/k = 1.03$ is obtained with the a_n values in Table 1e.

Thus the least squares method only yields two parameters, while the two-parameter method yields three parameters, that is one parameter more than the experimental data permit. Though the $k_1k_2k_3$ values of the two computations agree, the λ_4 values show a rather large discrepancy.

f. The Th(IV)-cinnamic acid-chloroform-0.1 M $NaClO_4$ system.[6] In the least squares treatment, the parameters a_0, a_2, and a_4 came out negative. With these parameters omitted and $\sigma_Q(\%) = 0.7\ Q$, a $\chi^2/k = 0.85$ was obtained; the corresponding a_n values are given in Table 1f.

In the original paper [6], three parameters are obtained: p_1, p_2, and λ_4. Fig. 2 shows the curve in the original paper given with these three parameters and also the curve computed with the a_1 and a_3 parameters. It is obvious that the equilibrium constants calculated from the least squares parameters give all the information which can be obtained from the experimental data.

g. The La(III)-cupferron-hexone-0.1 M $NaClO_4$ system.[7] Two kinds of errors were tested on this system: a counting error $\sigma_Q(\mathrm{I})$ and a percentage error $\sigma_Q(\%)$. With 1 "$\sigma_Q(\mathrm{I})$" the least squares method gave $\chi^2/k = 412$, and of the four parameters a_0 came out negative, and a_0 and a_2 with standard deviations > 100 %; $\chi^2/k = 2\,791$ was obtained when only a_0 was omitted. Reasonable value of χ^2/k (0.95) was obtained from a weighing factor corresponding

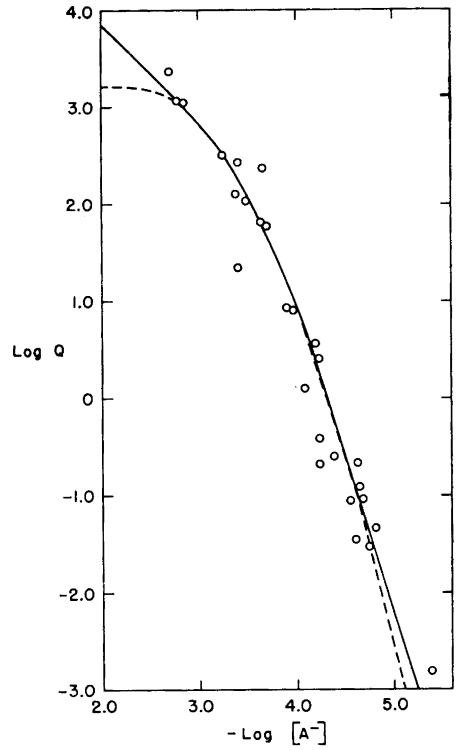

Fig. 2. The Th(IV)-cinnamic acid-chloroform-0.1 M $NaClO_4$ system. The solid curve (———) is computed with the least squares parameters in Table 1 f. The dashed curve (- - - - -) was obtained with the parameters of the two-parameter method.

to 20 times "σ_Q(I)", indicating that the experiments involved much larger than the estimated counting errors.

When tested with the σ_Q(%) error, a_0 came out negative, and both a_0 and a_2 had standard deviations > 100 %. However, omitting a_0 only, a_2 came out with only a 75 % standard deviation. Thus there is some support in the data for significance of the a_2 parameter. Reasonable $\chi^2/k = (0.91)$ was obtained for $\sigma_Q(\%) = 0.4\ Q$.

In Fig. 3 is plotted the experimental data and two curves, one obtained with the counting error and 2 parameters, and the other with the percentage error and 3 parameters. The shaded areas are the standard deviations in Q due to the standard deviation in a_n. The two areas overlap each other. Since the curve with 3 parameters seems to fit the experimental data somewhat better, its parameter values are given in Table 1g together with the equilibrium constants calculated from them. Within parenthesis, the a_n values for the "σ_Q(I)" computation are also given; it is seen that the two pairs of a_1 and a_3 values overlap each other.

h. The Sm(III)-cupferron-hexone-0.1 M $NaClO_4$ system.[7] Both with a counting and a percentage error the least squares computations yielded a negative a_0 with a standard deviation > 100 %. A weight corresponding to 7 "σ_Q(I)" produced $\chi^2/k = 0.82$, and a 20 % σ_Q(%) error produced $\chi^2/k = 1.29$,

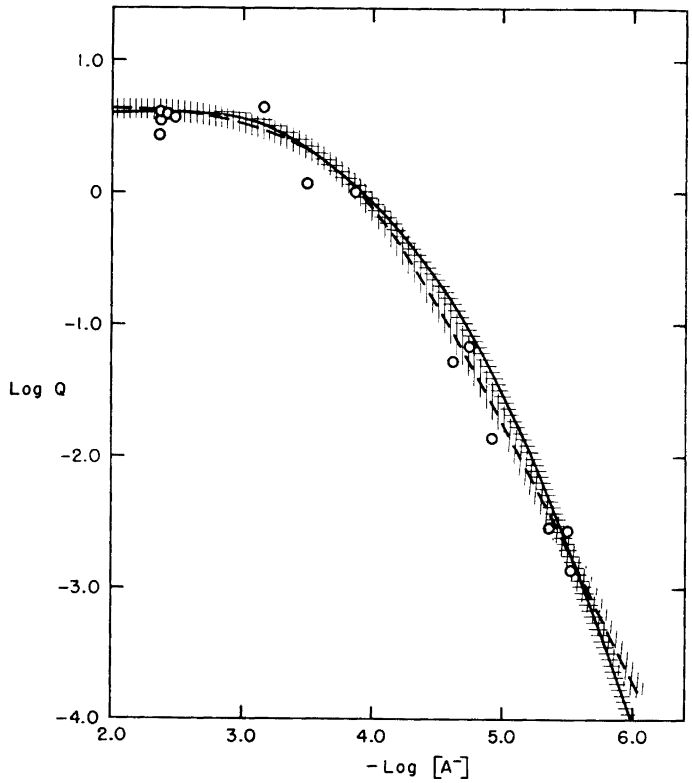

Fig. 3. The La(III)-cupferron-hexone-0.1 M $NaClO_4$ system. The solid curve (———) is obtained for a σ_Q(I) error and 2 parameters, and the dashed curve (- - - - -) for a σ_Q(%) error and 3 parameters; see Table 1 g. The shaded areas indicate the precision of the curves.

both cases with a_0 omitted. In Table 1h the parameters for the counting error are given with those for the percentage error within parenthesis; the differences between the two sets of parameters is negligible.

The least squares calculations indicate (in contradiction to the two-parameter method) that the experimental data do not allow a calculation of a k_1 value.

i. The Th(IV)-cupferron-chloroform-0.1 M $NaClO_4$ system. [8] The least squares calculations were performed only with a counting error. A 10 "σ_Q(I)" weight * gave $\chi^2/k = 1.66$ with the parameter a_1 negative, and a_1 and a_3 having standard deviations > 100 %. With a_1 and a_3 omitted, χ^2/k became 1.50; the corresponding a_n values are given in Table 1i.

A comparison between the results of the two computational methods shows that more equilibrium constants than the data permit are calculated with the

* With 10 "σ_Q(I)" weight, we mean a weight of $1/(10\ \text{"}\sigma_Q\text{(I)"})^2$.

two-parameter method, and also that the precision of the λ_4 constant is overestimated.

j. The Th(IV)-dichlorooxine-hexol-0.1 M $NaClO_4$ system. [9] Using a counting error in the least squares treatment, the parameters a_0 and a_2 came out with standard deviations > 100 %. For a 6"σ_Q(I)" weight, χ^2/k became 1.06. The parameters obtained are given in Table 1j. The comments in paragraph h about the k_1 value are applicable also to this case.

k. The Th(IV)*-methoxybenzoic acid-chloroform-0.1 M $NaClO_4$ system.* [6] The least squares procedure using a 1 "σ_Q(I)" weight gave $\chi^2/k = 1.6 \times 10^6$ and all parameters with standard deviations in excess of 100 %. Therefore the weight of the points was decreased to correspond to a 40 "σ_Q(I)" weight, where $\chi^2/k = 4.5$ was obtained. With this weight all parameters except a_4 were negative or had standard deviations > 100 %. All combinations of 2, 3, and 4 parameters were tested; in no case was it possible to obtain a combination of only positive parameters with standard deviations < 100 %.

Since it was unreasonable to decrease the weight of the points further with this kind of error, the system was further investigated with a constant percentage error in Q. For $\sigma_Q(\%) = 0.7\ Q$, $\chi^2/k = 1.4$ was obtained; of the five parameters only 2 were positive, but had standard deviations > 100 %. Again all possible combinations were run, and again no combination with only positive parameters with standard deviations < 100 % could be obtained.

Obviously the experimental data are too poor to make possible *any* calculation of equilibrium constants with the least squares procedure and the present methods of weighing the data.

l. The Th(IV)-methoxybenzoic acid-hexone-0.1 M $NaClO_4$ system. [6] The least squares procedure with a 30 "σ_Q(I)" weight produced a $\chi^2/k = 1.24$ with one parameter (a_1) negative and one with a standard deviation close to 100 % (a_3). The system was therefore run, first with a_1 omitted, and then with all possible combinations of 2 and 3 omitted parameters. As a result, a number of possible combinations were obtained, all with a 30 "σ_Q(I)" weight as shown in Table 3.

From this table it is seen that χ^2/k increases with decreasing number of parameters. Though the χ^2/k values in the last three cases is > 1.5, they could rather easily be brought down to < 1.5 by a slight decrease in weight; they are therefore worth being included in the Table.

Table 3. Possible parameter combinations for the Th(IV)-methoxybenzoic acid-hexone-0.1 M $NaClO_4$ system when tested with a 30 "σ_Q(I)" weight (see paragraph l).

χ^2/k	$a_0 \times 10^{13}$	$a_1 \times 10^9$	$a_2 \times 10^6$	$a_3 \times 10^4$	$a_4 \times 10^2$	Average stand. dev. in a_n
1.21	1.04 ± 0.39	–	1.25 ± 0.34	5.39 ± 0.21	3.9 ± 1.8	38 %
1.35	–	0.87 ± 0.17	–	8.63 ± 1.51	2.7 ± 1.8	35 »
1.62	0.80 ± 0.44	–	1.94 ± 0.25	–	7.4 ± 1.4	29 »
1.65	–	–	1.61 ± 0.37	4.07 ± 2.35	4.5 ± 2.1	43 »
1.83	–	–	2.10 ± 0.25	–	7.2 ± 1.5	17 »

Considering both the χ^2/k values and the average standard deviations of all the a_n values, some slight preference may be given to the combination yielding $\chi^2/k = 1.35$. A plot of the curves obtained with the various parameter combinations will show that the curves for 3 and 4 parameters fit the experimental points about equally well. In view of the scatter of the data, the least squares method and the χ^2 test cannot in this case distinguish between different functional models, and therefore no reliable equilibrium constants can be computed.

m. The Th(IV)-1-nitroso-2-naphtol-hexone-0.1 M $NaClO_4$ system.[10] Using a counting error with the least squares method, a_0 was obtained with a standard deviation > 100 %. With the other 4 parameters and a 5 "σ_Q(I)" weight, $\chi^2/k = 1.1$ was obtained. The corresponding parameter values are given in Table 1m.

In this case, like in some of the earlier ones, it is possible to omit an additional parameter and still obtain real values for the remaining parameters. The result, using the same weight is: $\chi^2/k = 3.2$, $a_1 \times 10^{26} = 19.1 \pm 3.5$, $a_3 \times 10^9 = 6 \pm 1$, and $a_4 \times 10^3 = 6.4 \pm 3.7$. Since χ^2/k is considerably increased and the average standard deviation in the parameters is here 31 % compared to 13 % for the case with 4 parameters, it is concluded that, from a statistical point, the system is most correctly described with 4 parameters.

n. The Th(IV)-2-nitroso-1-naphtol-hexone-0.1 M $NaClO_4$ system.[10] In all least squares tests, some parameters came out negative or with standard deviations > 100 %. The only possibly significant combination was obtained with the omission of a_0 and a_1, which gave $\chi^2/k = 0.7$ for a 6 "σ_Q(I)" weight. The parameters are given in Table 1n.

If also a_3 is omitted, one obtains for the same weights $\chi^2/k = 2.9$ and the parameter values $a_2 \times 10^{16} = 2.12 \pm 0.21$ and $a_4 \times 10^3 = 10.1 \pm 3.9$. Since χ^2/k as well as the average standard deviation in a_n is greater with this parameter combination, the earlier results with 3 parameters are of greater statistical significance. However, a detailed analyses of the data shows that a higher statistical significance can be obtained using two parameters, a_2 and a_4, if the weight of one single point (at -log [A] = 6.41) is considerably decreased. The least squares method does not allow a calculation of k_1 (*cf.* paragraph h).

o. The Sr(II)-oxine-chloroform-0.1 M $NaClO_4$ system.[11] In the original paper it is assumed that the organic phase only contains the complex $SrA_2.2HA$. On this assumption the following polynomial is developed:

$$\frac{[A]^2}{Q}[HA]^2_{org} = \frac{1}{\beta_2\lambda_2''} + \frac{\beta_1}{\beta_2\lambda_2''}[A] + \frac{\beta_2}{\beta_2\lambda_2''}[A]^2$$

Using this expression in the least squares treatment, the parameters will become $a_0 = 1/\beta_2\lambda_2''$, $a_1 = \beta_1/\beta_2\lambda_2''$ and $a_2 = 1/\lambda_2''$, where λ_2'' is the partition constant for the $SrA_2.2HA$ complex. For $\sigma_Q(\%) = 0.3\,[HA]^2_{org}/Q$, χ^2/k is 0.89 and the following parameter values are found: $a_0 \times 10^3 = 3.6 \pm 0.7$, $a_1 = 1.7 \pm 0.2$ and $a_2 \times 10^3 = 1.0 \pm 6.0$. Since the standard deviation in a_2 is > 100 %, runs were made with a_2 omitted, yielding $\chi^2/k = 0.86$ and the a_1 and a_0 values in Table 1o; the a_0 and a_1 values are almost identical to those obtained with three parameters.

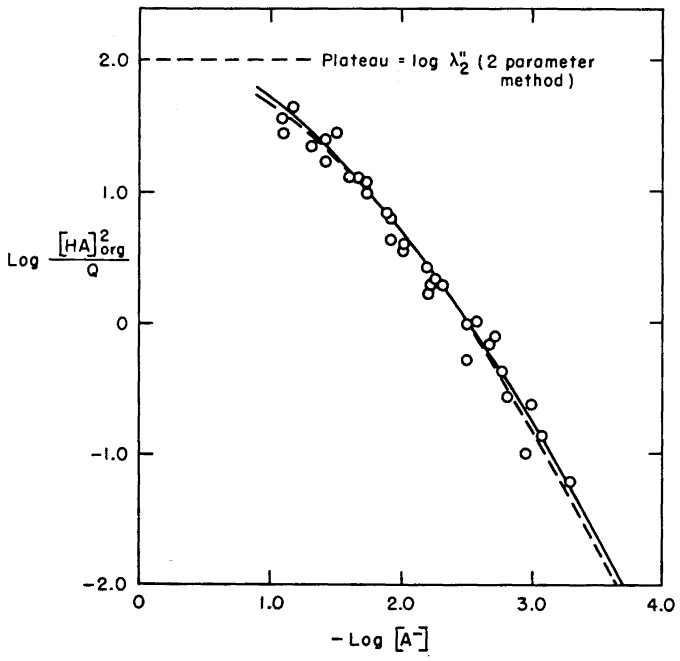

Fig. 4. The Sr(II)-oxine-chloroform-0.1 M $NaClO_4$ system. The solid curve (———) is obtained with the least squares parameters in Table 1 o, and the dashed curve (- - - - -) with the parameters of the two-parameter method.

From a_0 and a_1 only two equilibrium constants can be computed k_1 and $k_2\lambda_2''$. With these 2 parameters, the solid curve in Fig. 4 is calculated. Since the curve goes smoothly through the experimental points, with about equally many points on both sides and without any tendency to level out into a sort of plateau, it is obvious that the data do not allow a separate calculation of the λ_2'' value, as has been done with the two-parameter method.

p. The La (III)-oxine-chloroform-0.1 M $NaClO_4$ system.[7] All least squares computations using counting as well as percentage errors gave negative a_0, and a_0 and a_2 having standard errors > 100 %. Omitting these parameters, $\chi^2/k = 1.08$ was obtained for a 20 "σ_Q(I)" weight; the same χ^2/k value was obtained for a 70 % error in Q. The parameters are given in Table 1p. A comparison with the results of the two-parameter computation shows considerable discrepancies.

Fig. 5 gives the curves calculated with the parameters of the two computational methods. It is seen that the two-parameter curve has about equally many points on each side, while the least squares curve has about twice as many points below as above the curve. However, with badly scattered data the log scale is misleading, because in such a plot the average value will always be closer to the higher points (*e. g.* $y_1 = 5$, $y_2 = 15$ and thus $\bar{y} = 10$; therefore log $y_1 = 0.7$, log $y_2 = 1.18$, and log $\bar{y} = 1.0$ and not $(0.7 + 1.18)/2 = 0.94$).

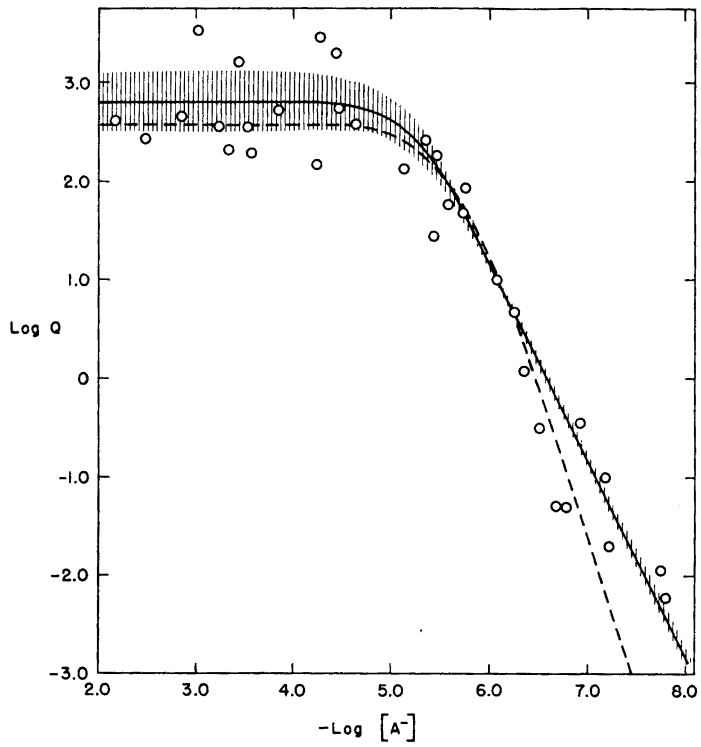

Fig. 5. The La(III)-oxine-chloroform-0.1 M $NaClO_4$ system. The solid curve (———) is obtained with the least squares parameters of Table 1 p (using 2 parameters), and the dashed curve (- - - - -) with the parameters of the two-parameter method (using 3 parameters). The shaded area indicates the precision of the least squares curve.

When the higher values are given a less weight than the lower ones the average curve will move closer to the lower points; this effect of weighing is not sufficiently pronounced in Fig. 5 to move the least squares curve down to the two-parameter curve (the author of the original paper has obviously weighted the higher points still less than the present author).

q. The Sm(III)-oxine-chloroform-0.1 M $NaClO_4$ system. [7] Using percentage and counting errors for the least squares treatment, the parameters a_0 and a_2 came out negative and with standard deviations > 100 %. Omitting these parameters, the standard deviation in a_3 turned out to be > 100 % when the counting error was used, but not with the percentage error. With $\sigma_Q(\%) = 0.5Q$, a χ^2/k value of 1.35 was obtained. The corresponding a_n values are given in Table 1q. The discrepancies between the results of the two-parameter method and the least squares method are again quite large.

r. The Th(IV)-oxine-chloroform-0.1 M $NaClO_4$ system. [8] Because of the big range of free ligand concentration ($10^{-1} \gtrsim [A] \gtrsim 10^{-11}$), the GEORGE computer could not handle the whole problem for $N = 6$. It was therefore decided

to split it into two parts and run these two separately with overlapping [A] values (the same principle of splitting was used in the original paper with the two-parameter method). This splitting can be justified, because the Q values are almost independent of [A] in the range $10^{-4} > [A] > 10^{-8}$, which means that in the presence of negatively charged complexes one can neglect the positively charged ones, and vice versa. Considering the experimental data in the original paper, the problem was divided in the two following parts:

Split I: $z = \sum_{0}^{4} a_n x^n$, run on the IBM 704 for $x < 10^{-3}$.

Split II: $z = \sum_{0}^{2} a_{n+4} x^n$, run on the GEORGE for $x > 10^{-9}$.

Using a percentage as well as a counting error in the Split I case, a_1 came out negative. Omitting this parameter, a_0 was obtained with a standard deviation > 100 % (this a_0 is given within parenthesis in Table 1r; it is used for computing an approximate k_1k_2 value). Omitting both a_0 and a_1, the parameters in Table 1r were obtained; the 70 % error in Q yielded a $\chi^2/k = 0.83$, and the 17 "σ_Q(I)" weight $\chi^2/k = 0.98$.

Only a 70 % error was tested in the Split II case, which first yielded a negative a_6 value with standard deviation > 100 %. With this parameter omitted, the a_4 and a_5 values in Table 1r were obtained with a $\chi^2/k = 0.73$. The good agreement between the χ^2/k and a_4 values of Split I (σ_Q(%)) and Split II (σ_Q(%)) indicates consistency between the two split cases.

The equilibrium constants in Table 1r are computed from the σ_Q(%) data, λ_4 being taken from a_4 of Split I (σ_Q(%)). A comparison between the results of the two computational methods indicates that more parameters (and more equilibrium constants) are given by the two-parameter method than the experimental data justify. Particularly dubious is the calculation by that method of a k_1 value, because in the concentration range where the first complex, MA^{3+}, is supposed to exist, the scatter of the experimental data is tremendous (*e. g.* for $-\log [A^-] = 10.53 \pm 0.01$ the spread in log Q is 1.75, *i. e.* over a factor of 50 in Q).

Because of the generally very great scatter of experimental data in this system, the comments in § p about the distortion of the log scale is particularly applicable to this case.

s. The Th(IV)-N-phenylbenzohydroxamic acid-chloroform-0.1 M $NaClO_4$ system. [12] With a counting error, the least squares calculations yielded a negative a_1, and a_1 and a_3 with standard deviations > 100 %. Omitting these parameters, a $\chi^2/k = 0.91$ was obtained with a 20 "σ_Q(I)" weight; the resulting parameters are given in Table 1s.

The average standard errors given for p_1 and p_2 is somewhat above 12 %, while for a_0 and a_2 it is about 40 %. Similarily, for λ_4 the two-parameter method gives a standard error of about 7 %, while the least squares method gives about

33 %. The high precision given for the two-parameter method seems therefore overestimated.

t. The Th(IV)-salicylic acid-hexone-0.1 M $NaClO_4$ system. [6] Whith the functional form given for this system in the original paper, the same equations as before can be used in the least squares treatment, provided Q is replaced by $Q/[H_2A]_{aq}$ and the partition constant λ_4 is replaced by

$$\lambda_4' = \frac{[Th(HA)_4H_2A]_{org}}{[Th(HA)_4]_{aq}[H_2A]_{aq}}$$

where H_2A stands for undissociated salicylic acid. With the least squares treatment using a percentage error in Q, the parameters a_1 and a_3 came out with standard deviations > 100 %. Omitting them and using $\sigma_Q(\%) = 0.3.Q$, a χ^2/k value of 0.94 and the parameter values in Table 1t were obtained. The table indicates that more equilibrium constants have been computed from the two-parameter results than the experimental data permit.

u. The Th(IV)-tropolone-chloroform-0.1 M $NaClO_4$ system. [13] With this system the same mathematical difficulties were encountered as with the Th(IV)-oxine system in § r, and the same splitting procedure was used to get around these difficulties; Split I was used for $[A] < 10^{-2}$, and Split II for $[A] > 10^{-7}$.

Using a percentage and a counting error, a_0 and a_3 came out negative, and a_3 with a standard deviation > 100 %. Omitting a_0 and a_3, the parameters a_1, a_2 and a_4 given in Table 1u were obtained; for a 70 % error in Q, $\chi^2/k = 0.51$ was obtained, while a counting error corresponding to 15 "$\sigma_Q(I)$" gave $\chi^2/k = 0.73$. It is seen in the table that the equilibrium constants k_2 and k_3k_4 computed from the two Split I data agree well (the values within parenthesis are computed from the Split I ($\sigma_Q(\%)$) data), while the precision of the k_3k_4 and λ_4 values obtained from the Split I ($\sigma_Q(I)$) data is less good.

The Split II case was only run with a percentage error in Q, which gave an a_5 value with a standard deviation > 100 %. Omitting a_5 and using a $\sigma_Q(\%) = 0.7\ Q$ error, a χ^2/k value of 0.56 and the parameters a_4 and a_6 in Table 1u were obtained; log k_5k_6 in the table is computed from these a_4 and a_6 values. It is seen that the 70 % error in Q used in both Split I ($\sigma_Q(\%)$) and Split II ($\sigma_Q(\%)$) give approximately identical $a_n \pm \sigma_{a_n}$ and χ^2/k, demonstrating good consistency between the two treatments.

With the equilibrium constants of the least squares procedure, a curve $Q([A])$ can be computed which goes smoothly through the experimental points. Thus, with the present spread in the experimental data, the Th(IV)-tropolone system can be completely explained by only 4 equilibrium constants.

DISCUSSION

With good data, the ligand number and limiting value methods should give the same equilibrium constants as the least squares method; *cf.* Ref. [15] This is also true for the two-parameter method as long as only two complexes are present in the system studied.

Though only the least squares method yields true standard deviations of the constants, rather good estimates of precision can be made with the limiting value method; these two methods are the only ones here discussed where the experimental data are used directly for computing the parameters. On the other hand, precision estimates are very hard to make with the ligand number method, because the calculation of the complexity constants are based on points $\bar{n}$ ([A]) taken from a smoothed curve through the experimental points (*cf.* discussion in connection with eqn. 5). This is rather pointedly illustrated by comparing the dissertations of J. Bjerrum [16] (ligand number method and few estimates of precision) and I. Leden [18] (limiting value method and almost all constants with precision estimates). Good estimates of precision are also hard to make with the two-parameter method.

With very scattered data, as has been the case in the solvent extraction work here investigated, different results may be anticipated with different computational methods.

In the ligand number method, the graphical differentiation of the smooth curve through the experimental points may introduce errors which in the later computations cannot be detected; this method may therefore sometimes lead to the calculation of more constants than the original data would permit (see Tables 1b and d, and Ref. [1]).

The limiting value method is sensitive to large spread of the experimental data. With poor data it is extremely hazardous to extrapolate curves through the measured or calculated points to zero. Further, the errors obtained in one constant propagates to the successive constants. If the computations are not carried out carefully, such a propagated error may in a later step turn up as a "constant". Though the limiting value method makes more direct use of the experimental data than any of the other graphical methods, its use should be limited to rather good data.

With very poor data, the visual judgement of the two-parameter method may be the only way to get information about the system. In such a case one should realize that the method is entirely qualitative (see paragraphs k and l in the experimental part).

The two-parameter method is based on the assumption that the experimental data fall on a curve with two asymptotes, one with slope zero (when the aqueous phase contains almost only the uncharged complex MA_ν) and one with slope ν (when the aqueous phase contains almost only uncomplexed metal ions $M^{\nu+}$).* When this method is carelessly applied to data which do not closely approach these asymptotes, dubious results may be obtained. This is demonstrated in a great number of tables above, where from the two-parameter results partition constants (q's) and k_1 or $k_1k_2.....k_N$ have been calculated, while the least squares method shows that there is no support in the experimental data for significant values of these constants. ** Thus improper application of the two-parameter method may produce more parameters than the experimental data allow (Tables 1e, f, o, p, q, r and u); on the other hand,

* The principles of the two-parameter method can be used with the assumption that the first measurable complex is MA_r, giving an asymptote of slope $\nu - r$; however, this has never been done.

** By definition (see equations 2 and 8) $k_1k_1 ..... k_N = 10^{N\rho_1}$.

with very good data the method does not always permit the evaluation of all parameters involved (Tables 1c and m).

A draw-back of the two-parameter method is also the difficulty in relating the parameters to any specific equilibrium constants (*cf.* Tables 1i, s and t, where the two different computational methods have produced the same number of parameters, and k_1 and λ_ν both exist). Though there is some experimental support for the existence of a constant spreading factor, *cf.e.g.* Ref. [16,18], certainly not all systems are of the regular type indicated by eqn. 9. The calculation of step-wise equilibrium constants from the parameters of the two-parameter method must therefore be based on additional information about the system than the experimental data alone provide. In fact, such a calculation is in contradiction to the original purpose of the two-parameter method [14].

The simultaneous consideration of all experimental data in the least squares method leads to the computation of the maximum number of significant equilibrium constants and their precision; in this respect this method is superior to any of the graphical methods.

However, graphical plots must be made before the least squares calculations are begun, in order to see if any curve at all can be fitted to the experimental points; it is also advisable to check the results of the computations with the input data, so that errors in making up the programs, *etc.* are disclosed, *cf.* Ref. [15]

When parameters are omitted in the least squares calculations (because they are negative or their standard deviations exceed the parameter value) this does not necessarily mean that the corresponding complexes do not exist, but only that the equilibrium constants cannot be calculated because of uncertanties in the experimental data (*cf.* paragraph d).

Since the laborius manual computations of the least squares method are now overcome by the use of high speed digital computers, it is hoped that this method will be more used in the future.

The present investigation also indicates the need for more refined technique in solvent extraction work.

Acknowledgement. The author wishes to thank Drs. J. C. Hindman and J. C. Sullivan of the Chemistry Division, and Dr. W. Miller, Mr. W. Greenhow and Mrs. M. Hanson of the Applied Mathematics Division, for their extensive cooperation in this investigation. He is also most grateful to Dr. W. M. Manning, Head of the Chemistry Division, for his interest in this work and for the research appointment which made it possible.

Heats of Combustion of Butanal and Some Related Compounds

JAN TJEBBES

*Thermochemistry Laboratory *, University of Lund, Sweden*

Heats of combustion values have been determined and from these, heat of formation data at 25°C calculated in kcal.mole^{-1} for the following six carbon-hydrogen-oxygen compounds: 2-butenal ($\Delta H_f^\circ = -34.45 \pm 0.09$), butanal ($\Delta H_f^\circ = -57.06 \pm 0.17$), butanol-1 ($\Delta H_f^\circ = -79.55 \pm 0.10$), 2-ethyl-2-hexenal ($\Delta H_f^\circ = -62.46 \pm 0.17$), 2-ethyl-hexanal ($\Delta H_f^\circ = -83.32 \pm 0.18$), 2-ethyl-hexanol-1 ($\Delta H_f^\circ = -103.46 \pm 0.19$).

Precise data on heats of combustion of aliphatic aldehydes are lacking in the literature, and since the appearance of Kharasch's compilation [1] no further determinations have been published. Therefore it was judged of interest to study a number of aliphatic aldehydes, the choice of compounds being mainly governed by an interest in the aldol condensation reaction and associated processes for butanal.

Verkade and Coops [2] have accurately determined the heats of combustion of the lower 1-alkanols. However, a redetermination for butanol-1 was performed in order to ascertain the internal consistency within this investigation **. No value of the heat of combustion of 2-ethyl-hexanol-1 has been found in the literature.

SAMPLE PURITY

It was found difficult to obtain the aldehydes in a very pure state. Before describing the special problems met with in handling the aldehydes, the general procedure for preparing the samples for combustion will be given.

* Sponsored by the *Swedish Natural Science Research Council* and the *Swedish Technical Research Council*.

** Verkade and Coops' value recalculated [3] to present day units is ΔH_c°(butanol-1) = − 638.25 ± 0.32 kcal.mole^{-1}, and the value given in this paper is ΔH_c°(butanol-1) = − 638.25 ± 0.10 kcal.mole^{-1}.

Table 1. Density of butanal *versus* water content.

Water %	d_4^{25} g · ml^{-1}
x	$0.7966_0 \pm 0.0000_2$
$x + 0.275$	$0.7976_1 \pm 0.0000_5$
$x + 0.551$	$0.7988_3 \pm 0.0000_5$

Procedure. All six substances used in this investigation were prepared and carefully purified by the Research Laboratory, Mo och Domsjö AB, Örnsköldsvik, Sweden. After the final distillation in a Podbielniak column with 50—70 theoretical plates, samples of the main fraction were enclosed in sealed Pyrex-glass ampoules in an atmosphere of carbon dioxide or helium. The purity was established using gas-liquid chromatographic technique on the contents of one of these ampoules, and a number of ampoules were sent to our laboratory. Immediately upon arrival (2—3 days later) a distillation was performed at room temperature under reduced pressure. All samples were handled in a nitrogen atmosphere and great care was taken to exclude air. The middle fraction from this distillation (about one third of the total sample) was collected in a receiver where *ca.* 10 combustion ampoules (made from soft glass) had been placed in advance, and then the ampoules were filled [4] immediately. At the same time ampoules were filled with samples for gas-liquid chromatographic analysis and for density determination. The combustions were made as soon as possible, and in no case did more than six days elapse between ampoule filling and combustion. In the case of butanal all experiments were carried out within two days. Analysis (by Mo & Domsjö) and density determination were performed so as to coincide in time with the middle experiment in the combustion series.

The gas-liquid chromatographic analysis was done in order to determine the amount of impurities, especially water. For all substances except butanal the area under the water peak of the chromatogram was proportional to the water content of the sample, which was found from calibration experiments with known amounts of water added to the sample. The linearity implies that no reaction leading to the formation of water occurred on the column. In the

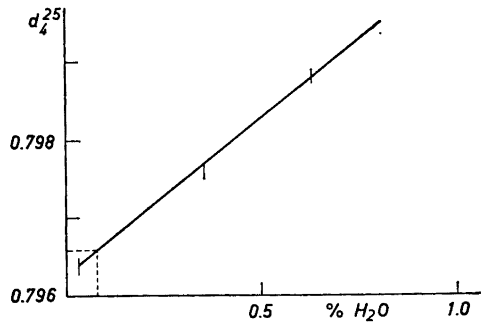

Fig. 1. Density of butanal *versus* water content.

case of butanal, however, a reaction took place on the column forming water and organic impurities.

The water content of the butanal sample was evaluated using the observation that the density of a sample of this compound was found to vary linearly with the water content, at least within a small interval. A sample of butanal was prepared exactly as the material for combustion. This sample was divided into three parts and water was added to two of them, increasing the amount of water by 0.275 resp. 0.551 %. The densities of the three parts were determined, Table 1. The slope of the line, density *versus* per cent water, was calculated, and the line was drawn (Fig. 1) using the value of Smith and Bronner[5]: $d_4^{25} = 0.7964$ at 0.03 % water. As indicated by dotted lines in the diagram the density 0.7966 then corresponds to a water content of 0.08 ± 0.02 %.

Special problems. The unsaturated aldehydes studied were found to be stable during storage in Pyrex-glass ampoules for two weeks. However, distillation at temperatures higher than *ca.* 50°C caused rapid decomposition. These compounds were found to be very sensitive to oxidation; and it was therefore necessary to exclude all traces of air in handling them.

Butanal was found to be unstable even when every precaution was taken in storing the samples. The decomposition was followed by measuring the density, and an increase in d_4^{25} of 0.00003 per day was observed. Distillation of butanal above room temperature caused an increase in water content and in amounts of other impurities. When distillation was performed at room temperature with the receiver kept at −40 to −80°C, the distillate showed a marked tendency to polymerize to solid products. A few successful distillations were performed with the receiver kept at −20°C and the distilling flask at 35°C (pressure 40—50 mm Hg).

In a number of cases condensation of butanal took place within the sealed combustion ampoule, which then invariably burst *. This was shown by the following series of experiments. Twelve ampoules (of the combustion type) were filled with butanal and left to stand for some days. During this time several ampoules burst and now and then one of the intact ampoules was opened. The refractive index ** of the content was immediately determined for both cases and was found unchanged for all intact ampoules, but altered for every broken ampoule, usually about 0.002 units.

The handling of 2-ethyl-hexanal offered the same kind of difficulties as did butanal but to a much smaller extent. Distillation could be performed at 85°C and 35 mm Hg, and gas-liquid chromatography was successfully run at 150°C. With the alcohols of this investigation no special problems were met, and the analyses showed that perfect purity was obtained in both cases.

Results of purity determinations. In Table 2 values of densities and amounts of impurities have been summarized. As a comparison, density values found in the literature have also been given.

* In a few cases the ampoule burst in the bomb during filling with oxygen. The butanal then exploded, and in a separate experiment it was found that oxygen caused the butanal to explode at a pressure of 12 atm.

** The small amount of substance in an ampoule made a density determination impossible, and therefore refractive indices were chosen as an aid to follow the purity.

Table 2. Sample purity.

Substance	d_4^{20} g · ml^{-1}	d_4^{25} g · ml^{-1}	H_2O %	Org.matter %	Literature
2-Butenal	0.8526	0.8475	0.02	0.05	$d^{17.3}$ = 0.8557 [6]
Butanal	—	0.7966	0.08	—	d_4^{25} = 0.7964/0.03 % H_2O [5]
Butanol-1	0.8099	0.8059	0	0	d_4^{25} = 0.8057 [7]
2-Ethyl-2-hexenal	0.8522	0.8461	0.014	0.4	d_4^{25} = 0.8528 [8]
2-Ethyl-hexanal	0.8201	0.8156	0.03	0.7	d_4^{18} = 0.8231 [9]
2-Ethyl-hexanol-1	0.8332	0.8291	0	0	d_4^{20} = 0.8328 [10]

The organic impurity of 2-butenal was small enough to be neglected, but this was not the case with 2-ethyl-2-hexenal. Three organic impurities gave traces on the chromatogram, but one of them made up for 75 % of the total amount. This one was isolated with the aid of a preparative column and examined by infrared spectroscopy. The spectrogram was compared with that of 2-ethyl-2-hexenal and differences were found on three frequencies, namely 979 cm^{-1} had changed to 969 cm^{-1}; 1 202 cm^{-1} to 1 180 cm^{-1} and at 1 730 cm^{-1} a new absorption peak appeared. The impurity was most certainly 2-ethyl-3-hexenal, and its presence would not affect the heat of combustion value to a noticeable extent. The organic impurity found in 2-ethyl-hexanal was thought to be formed during analysis. The peak on the chromatogram corresponding to this impurity was always found when analysing samples from different steps of the purification process and was always of the same relative size, while all other impurity-peaks gradually disappeared. As the purification involved distillations at different pressures, the presence of an azeotropic mixture was not likely.

COMBUSTION CALORIMETRY

All calorimetric quantities are expressed in terms of the defined calorie which is equal to 4.1840 absolute joules. All weighings have been reduced to mass. The molecular weight for each compound has been given in the Tables and is based upon the 1954 International Atomic Weights.

In this work the symbols introduced by Hubbard, Scott and Waddington [11] have been used.

Apparatus and method. The calorimetric system of Bjellerup [12] was used with the difference that his rotating bomb was replaced by a static one of the same construction. The aldehydes showed a marked tendency for splashing upon ignition, and therefore a platinum baffle was used together with a platinum shield [4]. Paraffin oil of known heat of combustion [13] was used as an ignition aid. The amount of HNO_3 formed was determined by titration with NaOH.

In each experiment the calorimeter vessel was filled with water until a fixed total weight of calorimeter with mounted bomb was reached, and the energy equivalent of the system was calculated using the following principles [12]. The result of the calibration (see below) is reported as ε° which is the theoretical energy equivalent (in cal.deg^{-1}) of the calorimeter with mounted, empty,

Table 3. Calibration.

t_h = 25.0°C, t_i = 24.1°C, P^i(Gas) = 30.0 atm, V(Bomb) = 0.2751 l, V^i(water) = 0.000820 l, $\Delta E_c/M$ (Benzoic acid) = −6 317.83 ± 0.62 cal · g^{-1}, m(Pt) = 29.790 g, $\Delta E_c^\circ/M$(Fuse) = 3 971 ± 4 cal · g^{-1}

bomb and filled with water until the fixed total weight. In an actual experiment m^i(Cont) grams (total substance, oxygen, ampoule, water and loose platinum parts) are introduced into the bomb, and the amount of calorimeter water must be reduced accordingly in order to maintain the fixed total weight. The energy equivalent of the system is thus diminished by $C_p(H_2O)\cdot m^i$ (Cont) cal.deg^{-1}, and at the same time the energy equivalent ε^i (Cont) of the added bomb content must be taken into account. The total energy equivalent of the calorimetric system will therefore be:

$$\varepsilon^\circ(\text{calor}) \; - \; C_p(H_2O)\cdot m^i(\text{Cont}) \; + \; \varepsilon\,(\text{Cont}) \quad \text{cal.deg}^{-1}$$

Calibration. The calorimetric system was calibrated by burning benzoic acid (National Bureau of Standards Standard Sample 39 g) under specified conditions [14], and the calibration combustions are reported in Table 3.

Heats of combustion and formation. The six combustion series are reported Tables 4 to 9. The found heat of combustion value for a sample containing x % water was called $\Delta E_c'/M$ (in cal.g^{-1}) and the heat of combustion of the pure compound has been calculated thus:

$$\Delta E_c^\circ/M = \frac{100}{100 - x} \cdot \Delta E_c'/M \;\; \text{cal.g}^{-1}$$

Washburn corrections were applied as described by Hubbard, Scott and Waddington [11]. No accurate information concerning the heat capacities of the substances was available. For butanol-1 the value 0.7 cal.g^{-1}.deg^{-1} was used and for the other five compounds 0.5 cal.g^{-1}.deg^{-1}. Anticipating an error in these values of 0.2 cal.g^{-1}.deg^{-1} a value of the uncertainty introduced into the heat of combustion determinations was found to be 0.05 cal per combustion, *i.e.* 0.1 cal.g^{-1} in the $\Delta E_c^\circ/M$ values. This uncertainty could therefore be neglected in the calculations.

$\Delta E_c^\circ/M$ = −8 203.4 cal · g^{-1}

* Another series using less pure substance gave the same precision, so it was felt permissible to use only three values for obtaining the standard deviation.

ΔH_c° values were computed from the ΔE_c° values. If the combustion reaction is:

$$C_aH_bO_c(l) + (a + b/4 - c/2)\, O_2(g) \rightarrow a\, CO_2(g) + b/2\, H_2O(l)$$

this relation holds:

$$-\Delta H_c^\circ = -\Delta E_c^\circ - (b/4 - c/2)\cdot 0.592 \text{ kcal.mole}^{-1}$$

Polymorphs and Conformations of the Cytidylic Acids

S. FURBERG

Institute of Chemistry, University of Oslo, Blindern-Oslo, Norway

Unit cell dimensions and space groups have been determined for three polymorphs of cytidylic acid "a" and two polymorphs of cytidylic acid "b". The conformations of the molecules are discussed.

It was shown by Harris *et al.*[1] that cytidylic acid "a" (cytidine-2-phosphate) and cytidylic acid "b" (cytidine-3-phosphate) both exist in two stable crystalline forms called the alc-form and the H_2O-form. The different polymorphs were characterized by their infra-red spectra, but crystal data were not given. In connection with other X-ray crystallographic studies of nucleic acid components, we have determined unit cell dimensions of the polymorphs, thus providing an additional method for their identification. A third polymorphic form of the "a"-isomer, which is metastable, was also examined.

Crystal data were derived from oscillation and Weissenberg diagrams taken with Cu radiation ($\lambda = 1.542$ Å). The cell dimensions given are believed to be accurate to within 1 %. The space groups were determined from systematic absences and the densities measured by the flotation method. None of the crystal forms contain water of crystallization [1].

Cytidylic acid "b". Following the procedure described by Harris *et al.*, the two polymorphs were obtained together by letting a saturated aqueous solution evaporate on a watch-glass.

The *alc-form* crystallizes in the monoclinic system, with $a = 5.94$ Å, $b = 16.96$ Å, $c = 6.89$ Å and $\beta = 118°$. The space group is $P2_1$ and the unit cell contains two molecules. The observed density is 1.73 g/cm^3, the calculated value 1.75 g/cm^3. This polymorphic form was found to occur in a variety of different crystal habits. Short polar needles elongated along b with c lying in the predominant face were observed, but usually the crystals are elongated along the diagonal [101], being either rod-like, or developed as flat plates (010). The length of this diagonal is 6.66 Å.

The *H_2O-form* is readily obtained as big flat plates several mm of extension. In general, they are somewhat elongated along c, with (010) as the dominating face. Forms {011}, {001}, {100}, and {110} were also observed. The crystals are biaxial positive with (001) as the optic axial plane. They crystallize in the

orthorhombic system, with unit cell dimensions $a = 8.80$ Å, $b = 21.7$ Å and $c = 6.85$ Å. The space group is $P2_12_12$, and there are four molecules in the unit cell. The density was found to be 1.66 g/cm³ (calculated 1.64 g/cm³).

Cytidylic acid "a". A sample of the *alc-form* was kindly supplied by Dr. R.J.C. Harris of the Central Laboratories, Imperial Cancer Research Fund. It consisted of very small needles with b as the needle axis. On the basis of a number of weak oscillation diagrams taken around the needle axis it was concluded that the crystals are monoclinic, with $a = 16.97$ Å, $b = 7.50$ Å, $c = 11.80$ and $\beta = 119°$. The space group is $C2$, as reflexions with $h + k$ odd are absent and the molecules are optically active. The calculated density assuming four molecules per unit cell, is 1.68 g/cm³.

By letting a saturated aqueous solution evaporate on a watch-glass, two other polymorphic forms were obtained, one as a crust at the edge and one deposited from the middle of the solution. The latter is probably the H_2O-form of Harris *et al.* The former is metastable and is transformed into the alc-form described above in the course of a few days. The transformation is made evident by the loss of extinction and by changes in the X-ray diagrams.

The *metastable* form yields needle-shaped crystals elongated along the c axis. The crystals grow either together in spherulitic formations of needles, or alternatively well-developed crystals with (100) as the dominating face are formed. They give straight extinction and may be recognized under the microscope by the angle of 57° between (010) and (021). The crystals are monoclinic, with $a = 9.32$ Å, $b = 22.8$ Å, $c = 7.38$ Å and $\beta = 95°$. Space group $P2_1$. Four molecules in the unit cell give a calculated density of 1.38 g/cm³. This density is much lower than that of the four other crystalline cytidylic acids, for which values between 1.64 and 1.75 g/cm³ are found. The packing of the molecules must be a very loose one and it is not surprising that the crystals are less stable than those of the other polymorphs.

The crystals of the *H_2O-form* were extremely small, and only feeble diffraction patterns were obtained. These show that the crystals probably are orthorhombic, with $a = 7.35$ Å, $b = 25.2$ Å and $c = 6.66$ Å. The extinctions indicate the space group $P2_12_12_1$ or $P2_12_12$. The calculated density is 1.74 g/cm³. The crystals have the shape of flat prisms elongated along c. Faces (100), (001) and (010) were observed, the latter being predominant.

Identification. The data given above provide a method for identification of extremely small quantities of the different polymorphs and isomorphs of of cytidylic acids. One single crystal of dimensions greater than say 0.05 mm will suffice with ordinary cameras and X-ray sources.

In general, the crystals are more or less elongated along one direction and the crystals may be identified by taking an oscillation diagram around this axis. The polymorphs are distinguishable by the length of the corresponding crystallographic axis, and by the symmetry, where some of them give diagrams with a plane of symmetry perpendicular to the axis of oscillation, others not (denoted "plane" and "no plane", respectively, in Table 1). Table 1 may serve as a key for the identification.

All the crystals give straight extinction when lying on the predominant face, except some of the habits of "b" alc and the metastable form.

Table 1. The characteristics of oscillation diagrams of crystals of cytidylic acid.

Length of axis, Å	Symmetry	Polymorph
6.66	No plane	"b" alc.
6.66	Plane	"a" H_2O
6.85	Plane	"b" H_2O
7.38	No plane	"a" metastable
7.50	Plane	"a" alc.
16.96	Plane	"b" alc.

Molecular shape. The molecular structure of nucleotides is a problem of considerable interest because of its relation to the structure of nucleic acids. We have carried out a complete structure analysis of the "b" H_2O polymorph and determined the molecular structure [2]. In the crystals the NH_2-group in one molecule is connected by hydrogen bonds to PO_4-groups in neighbouring molecules and the molecular axis is roughly parallel to *b*, the longest cell edge. It seems reasonable to assume that the amino and phosphate groups are linked together by hydrogen bonds also in the other polymorphic forms. Taking also the unit cell dimensions and the space group into account, this permits some conclusions to be drawn about the general shape of the molecules and their orientation in the crystals.

Considering first the "b"-isomer the molecular dimensions in the known structure ("b" H_2O) are roughly 4.5 × 7 × 11 Å, whereas in the "b" alc form the molecule probably extends only about 8.5 Å in the *b* direction. This indicates a considerably shorter molecule, and it seems likely that the molecule exhibits different shapes in the two polymorphic crystal forms.

Two main factors govern the general shape of the cytidylic acid molecule, namely (i) at the conformation of the ribose ring and (ii) the orientation of the phosphate group. From the crystal structure analysis of cytidine and cytidylic acid "b" H_2O two different ribose conformations are known to occur, one with $C_{2'}$ out of the plane of the four other atoms, and one with $C_{3'}$ out of the plane [2]. As for the orientation of the phosphate group, one would expect a staggered arrangement of the bonds around the $C_{3'}—O_{3'}$ linkage. There are three such orientations, but one of these corresponds to a *cis* relation between phosphate and ribose and would seem to be less favourable than the other two. Thus the molecule may be expected to occur in four general shapes:

(1) $C_{2'}$ out of the plane; $P—O_{3'}$ nearly parallel to $C_{2'}—C_{3'}$
(2) » » » » » » » » » $C_{3'}—C_{4'}$
(3) $C_{3'}$ » » » » » » » » $C_{2'}—C_{3'}$
(4) » » » » » » » » » $C_{3'}—C_{4'}$

Conformations (1) and (2) are shown in Fig. 1. The length of the molecule, as measured by the distance $P—N_6$, is about 9.8 Å, 8.8 Å, 9.1 Å and 8.5 Å in the four conformations, respectively. These values are based on bond lengths and angles derived by the X-ray analysis of cytidylic acid "b" H_2O. Minor

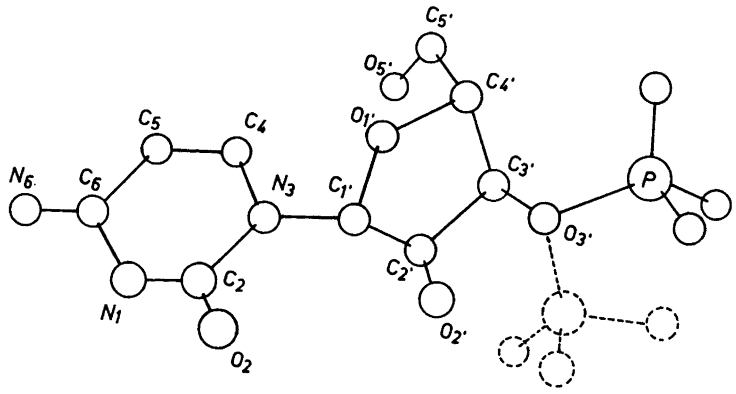

Fig. 1. Conformations of cytidylic acid "b" with atom $C_{2'}$ out of the ring plane.

variations in molecular shape may also be obtained by rotation around the bonds $N_3—C_{1'}$ and $P—O_{3'}$, but these changes do not alter the length of the molecule and need not be considered in this connection.

In the known structure of the H_2O polymorph the molecule has conformation (1), the most extended one. As stated above, the molecule would seem to be less extended in the alc polymorph and one of the other three conformations occurs. It may also be mentioned that current models of DNA are based on a nucleotide conformation of type (4).

Turning now to cytidylic acid "a", there are also in this case four stable conformations. It is seen from models, however, that the molecule is less extended than that of the "b" isomer, the amino and phosphate groups being in closer proximity. The $P—N_6$ distances are 7.5 Å and 5.8 Å, respectively, with $C_{2'}$ out of the plane, and 7.3 Å and 8.0 Å with $C_{3'}$ out of the plane. In the three first-mentioned conformations the molecule is very roughly equally extended in all directions, in agreement with the cell dimensions of the H_2O form, which may be interpreted as indicating four molecules of dimensions $7 \times 7 \times 6$ Å along the *b* axis. Similar molecular dimensions may be derived from the data obtained for the alc-form. On the basis of the data given above it is not possible to decide whether or not the molecule has the same conformation in the two cases. As for the unstable modification, the low density of this form makes a comparison with the other polymorphs difficult.

Finally, it may be remarked that the discussion of the conformations of the cytidylic acids given above is valid also for other 2' and 3' nucleotides. For each isomer there should be four conformations as far as variations in ribose puckering and orientation of the phosphate group are concerned. In the case of the 5' -nucleotides, there are more conformations because of the additional single bond $C_{4'}—C_{5'}$.

The author wishes to thank Dr. W. E. Cohn of the Oak Ridge National Laboratories and Dr. R. J. C. Harris of the Central Laboratories, Imperial Cancer Research Fund, for supplying samples of the isomers. The investigation was supported by *Norsk Hydros fond.*

Association of Zn-free Insulin

KJELD MARCKER

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

In this investigation the association of Zn-free insulin in dependence on concentration and pH has been investigated by means of osmometry. The minimum molecular weight at acid pH has been found to 12 000, and at basic pH to 6 000. The association monomer to dimer seems to proceed by a reaction which is different from the one leading to association of dimers to higher degrees of association.

Molecular weights for insulin determined by several methods have already been published.[1–6] In these investigations it has been observed that the molecular weight of insulin is dependent upon pH, temperature, ionic strength and protein concentration of the solution.

The insulin used in these experiments was crystalline Zn-insulin and therefore it seemed worth while to investigate the association of Zn-free insulin in aqueous solution. Fredericq [5] has found indications of association of insulin molecules by means of Zn-ions. On account of this finding it was therefore expected that a difference between crystalline Zn-insulin and Zn-free insulin would exist, and this was found to be the case.

The insulin used was Zn-free pig insulin prepared from crystalline Zn-insulin by precipitation at pH 2 with NaCl. The colloid osmotic pressures were measured by means of the inverted micro-osmometer described by Christiansen and Jensen [7]. The semipermeable membranes were made according to Adair [8]. The membranes prepared by this method have proved to be impermeable to molecules with molecular weights as low as five to six thousands. The collodion solution used was made in the following way: 4 g of completely dry pyroxolin (Parlodion Mallinckrodt) were dissolved in a mixture of 50 ml of anhydrous alcohol and 50 ml of anhydrous ether; to this mixture were added 6 ml of anhydrous ethylene glycol. The preparation of the semipermeable membranes turned out to be a difficult problem. In the drying process the membranes shrink, thus giving rise to tensions in the membranes. Besides the membranes lose their elasticity which makes it very difficult to place them on the capillary. In order to avoid these difficulties smaller modifications in the membrane making procedure have been tried, but unfortunately without success. On account of the above mentioned irregularities about 50 % of the membranes had to be discarded. The tension in the membranes could easily be detected, because in the case of tension it was impossible to obtain a straight line in the interpolation diagram.

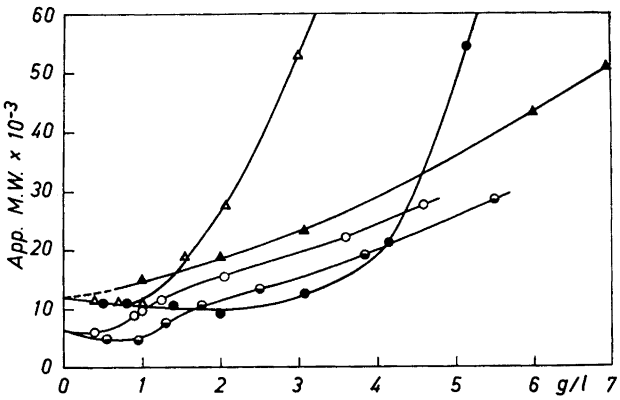

Fig. 1. Association of Zn-free insulin: Ordinate: Apparent molecular weight; Abscissa: Concentration in g/l. △ pH = 2.10; ● pH = 2.98; ▲ pH = 7.70; ○ pH = 8.31; ◒ pH = 9.10. Temp. 20°C.

Fredericq [5] and Gutfreund [3] have observed a specific anion effect upon the association of crystalline Zn-insulin. In this investigation no attempt has been made to evaluate a possible anion effect upon the association of Zn-free insulin.

The buffers used were: HCl-KCl, citrate-HCl and veronal-HCl. All buffers were adjusted to the ionic strength 0.2 with KCl. According to our experience the influence of the Donnan-effect is then negligible. The results are shown in Fig. 1.

It should be mentioned that the points in the diagram refer to apparent molecular weights and not to the true molecular weights. On account of the association it is impossible to extrapolate to infinite dilution in order to obtain the true molecular weight. The difference, however, between the true and the apparent molecular weight is probably not great, because of the relatively small electrical charge on the insulin molecule.

The surprisingly high degree of association in the acid region might be explained as a "salting out" effect. At pH 2 and 3 insulin is easily precipitated by KCl. At acid pH Fredericq [5] has obtained evidence for the existence of the insulin monomer in very dilute solution. In the present investigation there is no indication for the existence of the monomer at acid pH. On the contrary the results strongly support the generally accepted view that the minimum molecular weight in acid solution is 12 000 which corresponds to the dimer. In nearly neutral solution crystalline zinc insulin is reported to have a molecular weight of 36 000. The results of this investigation show that this is not the case with zinc-free insulin. The results reported here indicate a molecular weight of 12 000 at a pH about 7.7. Schlichtkrull [9] has shown that the minimum amount of zinc in crystalline zinc insulin is two atoms pr 36 000. It therefore seems reasonable to assume that three molecules having a molecular weight of 12 000 are associated by means of two zinc ions. Until recently it was generally accepted that the monomer insulin molecule did not exist in aqueous solution. By sedimentation experiments at pH 9 and 10 Fredericq [4],

however, demonstrated the presence of the monomer in dilute aqueous solution. The results reported here are in agreement with the findings of Fredericq as they clearly show that in dilute basic solution insulin molecules exist as monomers. By closer examination of the curves representing the results obtained at pH 8.31 and pH 9.10, a difference in the course of the curves in the concentration range 0 to 1.5 g/l compared to that from 1.5 g/l to higher values is apparent. This might indicate that the reaction of monomers to dimers is different from the reaction of dimers to higher association compounds.

Alkaline Hydrolysis of Some Local Anaesthetic Esters

BO KARLÉN and ALLAN ÅGREN

Department of Chemistry, Royal Pharmaceutical Institute, Stockholm, Sweden

The alkaline hydrolysis of the following local anaesthetic esters has been studied: benzocaine, butyl benzocaine, tetracaine, procaine, panthesine and *o*-hydroxyprocaine.

The velocity constants are determined photometrically in water solution at 25.0, 35.0 and 45.0°C. The influence of substituents on the activation energy and the frequency factor is discussed.

A knowledge of the behaviour of the local anaesthetics on alkaline hydrolysis is of interest not only from a theoretical point of view but also practically. For example the deterioration of pharmaceutical preparations may be estimated and the possibility of heat sterilization predicted. Further, the duration and toxicity of intravenous injected preparations is said to be connected with the speed of hydrolysis by blood serum [1]. In the thesis of Terp [2] the hydrolysis of procaine influenced by procaine esterase is discussed. Obviously, other physical and chemical factors will also affect the physiological effect of local anaesthetics, *e.g.* their solubility. However, this property has not been studied in this work.

Some of the substances which we have studied have also been investigated by other authors. The purpose of most of the earlier investigations published has been to make clear the stability of pharmaceutical preparations under special conditions and the authors have not been interested in the kinetic problems from a theoretical point of view. Among these publications the following may be mentioned [3–8]. Only a few investigations have been found in the literature, where the kinetic aspects on the alkaline hydrolysis of local anaesthetic esters have been thoroughly studied. In Table 1 a survey of the results from other authors is found. The authors all have found, that the process in strongly alkaline solution is a bimolecular reaction and thus can be written

$$\text{ester} + \text{OH}^- \rightarrow \text{alcohol} + \text{acid}$$

and the velocity constant, k_2, is defined by the equation

$$\mathrm{d}x/\mathrm{d}t = k_2\,(\text{OH}^-)\,(\text{ester})$$

Table 1. Previous work.

Compound	k_2 lit/mole/min	Temp. °C	Medium	E kcal	A lit/mole/min	Ref.
Benzocaine	7.53×10^{-4}	25	85 % ethanol	20.00	11.50	9
	5.04×10^{-3}	25	56 % acetone	16.70	10.00	10
	1.14×10^{-3}	30	88 % ethanol	—	—	13
	2.52×10^{-1}	30	water	—	—	15
	1.85×10^{-1}	25	water	12.6	8.5	this work
Procaine	4.8×10^{-2}	40	60 % acetone	—	—	11
	6.6×10^{-1}	40	water	13.80	9.38	12
	7.84×10^{-1}	37	water	—	—	14
	3.14×10^{-1}	25	water	14.2	9.9	this work

In the table all the values of k_2 are given in litre/mole/min. In some of the investigations the hydrolysis has been studied at several temperatures so that the activation energy, E, and the frequency factor, A, could be calculated. In the calculations the Arrhenius formula has been used

$$k_2 = PZ \times e^{-E/RT}$$

and

$$\log (PZ) = A$$

A great number of investigations have been published, where esters of different kinds have been studied in this respect. To be mentioned are the following authors, namely Tommila [16], Tommila and Hinshelwood [10], Newling and Hinshelwood [17], Kindler [13], Jones and Robinson [18], Ingold and Nathan [9] *etc.*

Among the many local anaesthetic esters only benzocaine and procaine seem to have been kinetically studied, and thus the present work will elucidate the properties of some other of the most used local anaesthetic esters.

Many of the authors mentioned have studied the end products of the hydrolysis. Some have found that the first produced acid is later on broken down by decarboxylation, but this has only been found in acidic solutions. In the present work no further decomposition of the acid has been found, at least during the relatively short time the process has been followed. Hydroxy procaine is hydrolyzed to *p*-amino salicylic acid. Not even this rather unstable acid has been decomposed under the conditions and short time used by us.

METHODS

Some authors [1-3,6] have followed the ester hydrolysis by a chemical separation of one of the hydrolysis products, and then the amount of this substance or the ester left has been estimated, for instance photometrically. Another method being used is a titration of the hydroxyl ion. In order to make this method possible the amount of the reacting species must be rather great and this gives a rather high velocity. Further, the investigation has to be made in a suitable solvent as the water solubility of the esters is small. As solvent, acetone-water has been used by Tommila [16] and Armstrong [11], ethanol-water by Ingold [9] and Kindler [13].

We have preferred to use a direct method also used by Higuchi [12,15] and others. All the esters studied in this work have a strong absorption in the UV. The acid formed has the maximum absorption shifted to another wavelength and the molecular extinction at this wavelength is lower than for the ester. Thus the concentration of the ester may be measured photometrically without separating it from the acid. The alcohol has a very low extinction in the same wavelength region. Thanks to the strong absorption, very low concentrations can be used, and thus water is suitable as a solvent.

Figs. 1—6 show the extinction curves of the esters and the corresponding acids. In the hydrolysis experiments all measurements are made at the wavelength where the extinction of the ester has its maximum. We have used the method given by Higuchi [12]:

A 0.1000 % water solution of the ester or its salt was warmed up to the temperature at which the hydrolysis was to be made. (Butyl benzocaine is sparingly soluble in water and in this case a saturated solution was made.) From this stock solution a certain volume was added to a solution of sodium hydroxide in water free from carbon dioxide. The volumes were so chosen that the concentration of the ester was 0.01000 % and the pH of the solution was exactly 12.00. This mixture was kept in one bottle in a water bath, the temperature of which was known within 0.1°. At different times samples were

taken from the mixture and added to a borate buffer solution with a pH = 9.5, which was made according to the Swedish Pharmacopeia Ed. XI. The extinction of the resulting solution was measured with a Beckmann photometer model DU in 1 cm cuvettes.

In order to avoid the influence of the carbon dioxide of the air, some experiments were made in a slightly different manner. The reaction mixture was dispensed in a number of bottles closed with glass stoppers. The content of each bottle was used only for one measurement. However, it was found that the results from these experiments agreed with the other ones.

The reaction mixture contained about 30 times the theoretically necessary amount of sodium hydroxide to hydrolyse the total amount of ester. This means that the concentration of hydroxyl ions is hardly changed during the experiment. It was found that the pH of the solutions was diminished by 0.02 units at the end of the experiments. Thus, the reactions could be treated as monomolecular.

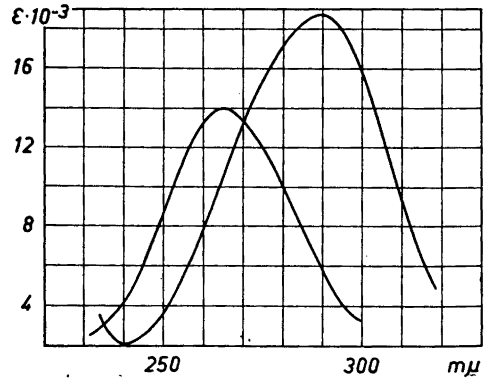

Fig. 5. Molecular extinction *vs.* wave length. Panthesine (ε_{max} = 18 680 at 289 mμ) and *p*-amino benzoic acid (ε_{max} = 13 980 at 265 mμ). pH = 9.5

All the esters studied in this investigation were examined at 25.0, 35.0 and 45.0°C.

Chemicals. Commercial benzocaine, tetracaine hydrochloride, procaine hydrochloride, and panthesine methane sulfonate were used without any further purification.

Hydroxy procaine hydrochloride was synthesized from *p*-amino salicylic acid and β-chloroethyl diethylamine hydrochloride. The latter was synthesized according to Gough and King [20]. The acid was suspended in acetone and then β-chloroethyl diethylamine hydrochloride was added. The mixture was refluxed for 20 h. *Iso*propyl alcohol containing 10 % hydrogen chloride was then added to the filtered solution [19]. The precipitate was washed with acetone and recrystallized from ethanol. The melting point was 153.5—154°C. The water content was determined by K. Fischer titration to be 1.8 %.

Butyl benzocaine was synthesized from butyl bromide and benzocaine [21]. Its melting point was 68°C. The other chemicals used were of analytical grade.

RESULTS

The results of the experiments are reported in Tables 2—7. E_t is the extinction of the reaction mixture when added to the buffer solution. E_o, the extinction at the beginning of an experiment, was determined by measuring the ester in the same buffer solution but without any alkali. E_s, the extinction after "infinite" time, was determined by measuring the corresponding acid dissolved in the buffer solution.

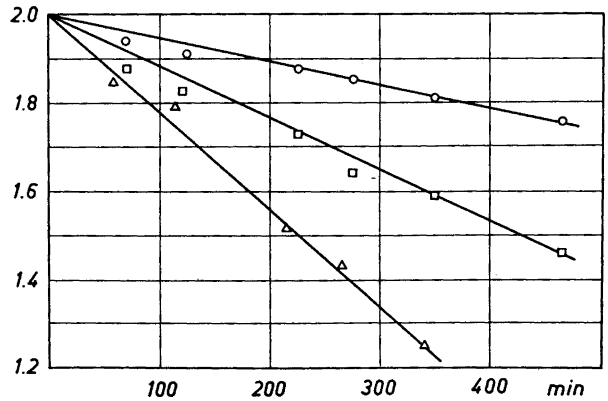

Fig. 8. Hydrolysis of butyl benzocaine. log (% ester left) *vs.* time.

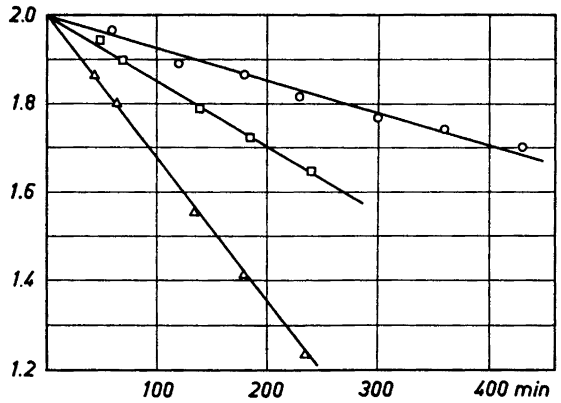

Fig. 9. Hydrolysis of tetracaine. log (% ester left) *vs.* time.

If the logarithm of this number is plotted against the time, straight lines should be obtained. These are found in Figs. 7—12. From the slope of the lines the velocity constant, k_1, may be calculated. k_1 refers to the "monomolecular" reaction:

$$k_1 \cdot t = \ln \frac{E_o - E_s}{E_t - E_s}$$

or

$$\frac{k_1 \cdot t}{2.303} = 2 - \log (\% \text{ ester left})$$

However, the reaction rate is

$$dx/dt = k_1 (\text{ester}) = k_2 (\text{ester}) (OH^-)$$

where k_2 is the bimolecular reaction rate constant. Thus the following equations are valid

$$k_2 = k_1/(OH^-)$$

or when pH = 12.00 and $(OH^-) = 0.01$

$$k_2 = 100\, k_1$$

k_2 is given in litre/mole/min. The results are surveyed in Table 8.

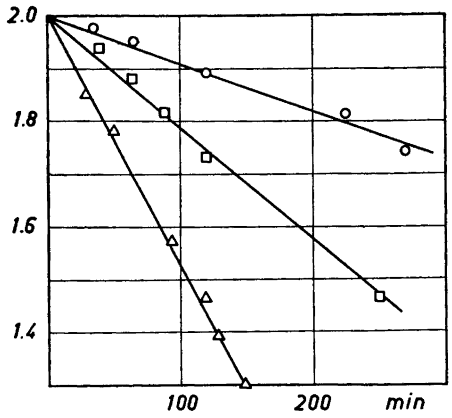

Fig. 11. Hydrolysis of panthesine. log (% ester left) *vs.* time.

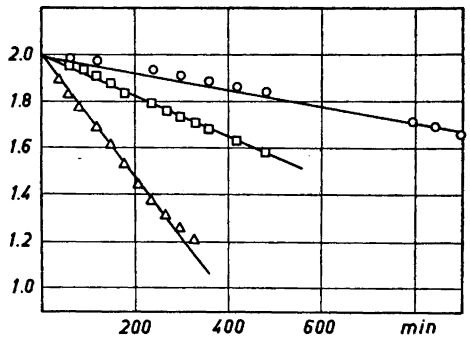

Fig. 12. Hydrolysis of hydroxy procaine. log (% ester left) *vs.* time.

The equation of Arrhenius is transformed to

$$\ln k_2 = \ln (PZ) - E/RT$$

or, when $\log (PZ) = A$

$$\log k_2 = A - \frac{E}{2.303\ RT}$$

Thus, if $\log k_2$ is plotted against $1/T$ a straight line should be obtained. The slope of the line, multiplied by 2.303 R, is the activation energy, E, and the intercept the frequency factor, A. In Fig. 13 these straight lines are shown. Table 9 shows the values obtained in this manner. The numbers are calculated by means of the method of least squares.

DISCUSSION

In alkaline medium the ester hydrolysis is due to the action of the nucleophilic reagent OH^- upon the carbon atom of the carbonyl group. This carbon atom has a partial positive charge due to the electrophilic character of the oxygen atom:

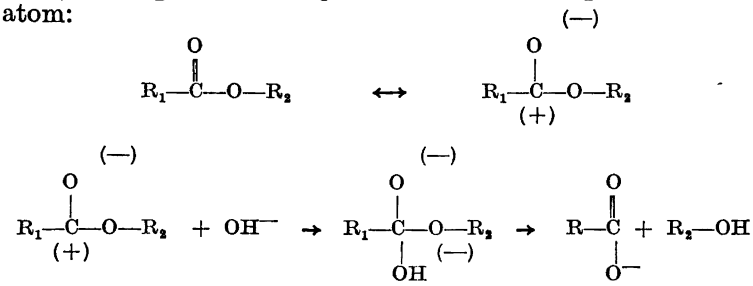

Table 8. Survey of results.

Name	k_2 lit/mole/min.		
	25.0°	35.0°	45.0°
Benzocaine	0.185	0.352	0.701
Butyl benzocaine	0.122	0.269	0.509
Tetracaine	0.173	0.344	0.743
Procaine	0.314	0.631	1.416
Panthesine	0.206	0.482	1.080
Hydroxy procaine	0.0825	0.204	0.613

By substitution in the acidic or the alcoholic part of the ester molecule the positive charge of the carbonyl carbon may be increased or decreased, which leads to a faster or slower hydrolysis. The ease with which the hydrolysis takes place may be expressed by the activation energy, E, of the process. A high value of E means a slow reaction and a low value of E means a fast reaction (provided that the value of the frequency factor A is unchanged).

The facts presented in this work are still too few to draw definite conclusions. However, it seems to be possible to make some preliminary observations.

The introduction of a butyl group causes, as expected, an electron releasing effect. This is apparent by a comparison of the activation energies of benzocaine and butyl benzocaine. Here the butyl group diminishes the positive charge of the carbonyl carbon and thus the activation energy is increased by

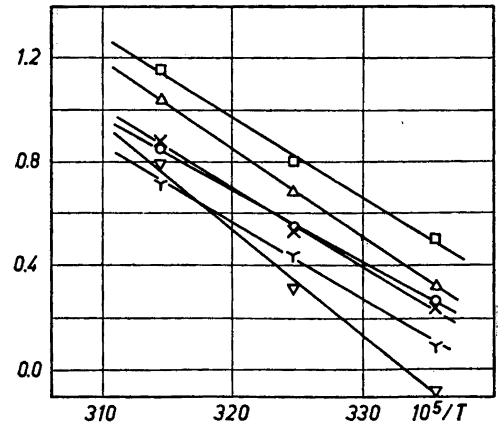

Fig. 13. (1 + log k_2) *vs.* 1/T.

Benzocaine	O	Procaine	□
Butyl benzocaine	Y	Panthesine	△
Tetracaine	×	Hydroxy procaine	▽

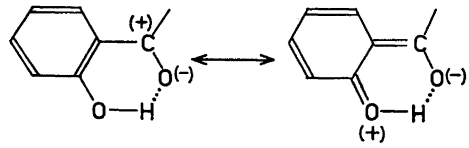
Table 9. Survey of results calculated from Fig. 13.

No.	Name	Formula	*E* kcal.	*A* lit/mole/min.
1	Benzocaine		12.6	8.5
2	Butyl benzocaine		13.5	9.0
3	Tetracaine		13.8	9.3
4	Procaine		14.2	9.9
5	Panthesine		15.7	10.8
6	Hydroxy procaine		18.9	12.8

0.9 kcal. A comparison of procaine and panthesine shows that the butyl group, when placed in the β-position of the alcohol, increases the E value by 1.5 kcal. In both cases the frequency factor is increased at the same time.

The introduction of a tertiary amino group in the alcoholic part of the ester has a rather vague effect. By comparing benzocaine and procaine it can be seen that the amino group increases E by 1.6 kcal, but by comparing butyl benzocaine and tetracaine it is found that there is an increase by only 0.3 kcal. At the same time there is a change in the frequency factor.

However, the introduction of a hydroxy group in the *ortho*-position in the benzene ring has the most striking effect. By a comparison of procaine and hydroxy procaine it is found that the OH group causes an increase in E by 4.7 kcal and in A by 2.9 units. The increase of the activation energy may be understood by the resonance effect, which is followed by an *o*-hydroxy group and which is visualized by the formula



(The dotted line represents a hydrogen bond.) By this resonance the charge on the carbonyl carbon is diminished.

The increase in A is opposite to the effect which is found in other cases of *ortho* substitution of esters of benzoic acid [9]. This effect may be understood by the following reasoning.

In esters of benzoic acid and *p*-amino benzoic acid there is a free rotation of the bond between the benzene ring and the carboxylic group. The reagent OH^- may rather easily attack the carbonyl carbon, which leads to hydrolysis. When there is an *ortho* group such as CH_3, Cl or NO_2 the carboxyl group will prefer to be in a plane which is perpendicular to the plane of the benzene ring. This means that the hydroxyl ion must attack from that side of the molecule which is opposite to the *ortho* substituent, and this fact makes the attack more difficult from steric reasons. This is indicated by a low value of A.

Ortho substitution by the hydroxy group seems to have an opposite effect. The hydroxy group is bound to the carbonyl group with a hydrogen bond, and thus the carboxyl group is held in the same plane as the benzene ring. The reagent OH^- will attack in a direction which is perpendicular to the benzene ring plane. From a steric point of view this attack seems to be easier than from another angle and this is indicated by a high value of A. However, at the same time there is a decrease in E.

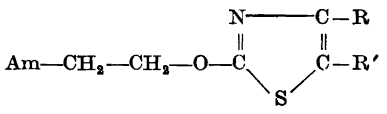
Short Communications

The Structure of the Products Formed in the Reaction of β-Dialkylaminoethyl Chlorides with 2-Hydroxythiazoles

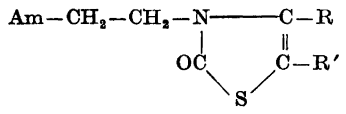
RICHARD DAHLBOM

Research Laboratories, AB Astra, Södertälje, Sweden

In a paper from these laboratories some years ago [1] a series of compounds were described, which were prepared by the reaction of a β-dialkylaminoethyl chloride with the sodium salt of a 2-hydroxythiazole (thiazol-2-one). The reaction products were thought to be 2-(β-dialkylaminoethoxy)-thiazoles (I).



I



II

Am = $(CH_3)_2N-$, $(C_2H_5)_2N-$, 
R = CH_3, C_6H_5 R′ = H, CH_3, C_6H_5

However, later work in this field [2,3] has indicated that in alkylations of this type the alkyl residue enters the 3-position in the thiazole nucleus, the reaction product being an N-substituted thiazol-2-one (II). The structure of the products formed in the above reaction was therefore reinvestigated using infrared spectroscopy.

It was found that all compounds in this series showed a very strong absorbtion band in the range 1 655 – 1 640 cm^{-1}, which can only be due to a carbonyl group. No absorbtion bands were observed near 1 250 cm^{-1} and in the 1 150 – 1 060 cm^{-1} region which are characteristic for aryl ethers [4] and which are found in the infrared spectrum of 2-methoxythiazole [2].

It can therefore be concluded that the products formed in the reaction of β-dialkylaminoethyl chlorides with the sodium salt of a 2-hydroxythiazole are 3-(β-dialkylaminoethyl)-thiazol-2-ones (II) and not 2-(β-dialkylaminoethoxy)-thiazoles (I).

The infrared spectra were recorded in KCl discs on a Perkin-Elmer No. 21 instrument with an NaCl prism.

A New Apparatus for Separation of Chemical Compounds by Liquid-Liquid Extraction

PENTTI K. HIETALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Partition between two immiscible or partially miscible solvents has in recent years become a very valuable tool for the isolation, determination and characterization of chemical substances. The first apparatus for "countercurrent" extraction was the one described by Jantzen [1]. Other workers have subsequently built apparatus on the same principle. The first laboratory-scale device with continuous flow of solvents was the column of Cornish *et al.* [2] The excellent work of Craig and his associates [3,4] has made the counter-current distribution technique a useful routine method. Another apparatus working on the same principle is that described by v. Metzsch [5]. For the large number of other works reference should be made to more comprehensive reviews on the subject [6,7].

In this laboratory there has been a need for methods for the isolation, determination and characterization of different chemical substances of plant origin. For this purpose I have developed a new type of counter-current apparatus with 100 distribution tubes, using continuous solvent flow. This may be regarded as an improved modification of an apparatus developed by Weygand *et al.* [8] The new apparatus is intended for the separation of one substance from a mixture by solvent distribution. It has the following advantages:

1) The construction is extremely simple. There are no complicated mechanical or glass parts. This makes the operation very reliable. The building of the apparatus is not very costly.

2) The apparatus works precisely according to theoretical calculations. This has usually not been true of earlier apparatus with continuous solvent flow, which has been a serious objection by comparison with apparatus functioning after the "decanting" principle.

3) There are no limiting factors in the use of different solvent systems. The apparatus has been loaded with large amounts of raw unpurified plant extracts without stable emulsions being produced.

4) The apparatus has 100 tubes, but in principle the number of tubes is unlimited.

5) It is possible to run the apparatus with either flowing upper phase or flowing lower phase, these flowing in opposite directions. This can be done with successively smaller amounts of both phases, which increases considerably the effective number of tubes in the isolation of a substance. In this way the apparatus corresponds theoretically to about 1 100 distribution tubes without recycling for a 99.7 % yield and approximately 2 500 tubes for a 95.5 % yield. In practice, distributions corresponding to some hundred "transfers" can be conveniently made.

An important defect is that work with this apparatus is somewhat more time-consuming than with apparatus using the "decanting" principle.

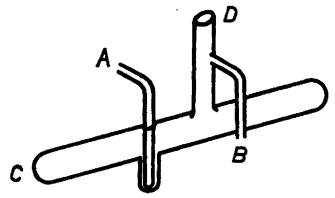

Fig. 1. See text.

The design of one distribution unit is seen in Fig. 1. Tube A is the inlet tube for the upper phase, tube B corresponds to tube A in the next cell. Ten such units are fused together into one piece, and these are connected to each other with suitable plastic tubing. In runs where lower phase flows in the reverse direction, it enters through tube B and leaves the unit through A. The equilibration is made by a continuous swinging movement of the main tube C in its length-wise direction through an angle of $\pm 30°$. The tubes are filled through D. Tubes D are closed with stoppers. In the two end tubes there are stopcocks for changing the solvent and the direction of flow. The whole row of 100 tubes is mounted on a suitable bar and made to swing by an electric motor. The frequency and amplitude of the strokes can be adjusted. The flow rate of solvents is controlled with Mariotte's flasks at both ends of the apparatus. The apparatus is used with a fraction collector having a moving center arm. The fraction collector is shifted from one end to the other if the solvent and direction of flow are changed.

Table 1. Distribution constants and recoveries in the distribution of oxalic, succinic and glutaric acid mixture presented in Fig. 2.

Acid	K, determined in separatory funnels	Conc. in the upper phase, normality	K, calc. from distr. curves	Substance weighed mequiv.	Substance found from distribution	Recovery %
Oxalic	0.24—0.22	0.02—0.002	0.23	5.85	5.89	100.8
Succinic	1.09—1.02	0.05—0.004	1.08	4.95	4.91	99.3
Glutaric	2.05—1.80	0.06—0.002	1.90	4.91	4.96	101

The volume of one tube is 86 ml. The relative amounts of the upper and lower phases can be varied over at least the ratios 3—0.33.

The theory of the apparatus cannot be presented here in detail. Stene [9] *e. g.* has made theoretical calculations concerning distribution in apparatus functioning after this principle. The distribution, presented as a function of tube number, of the mass of a solute A introduced into the first tube at the beginning of the distribution, forms a Poisson distribution curve known from statistics. When the tube number is large, it can be approximated by a standard error curve. In this apparatus the standard deviation δ of the normal error curve is $\delta = \sqrt{x}$, where x is the number of those tubes through which the maximum of the solute A has passed. When the solute A has passed through the whole apparatus and has been collected in fractions, the amount of effluent corresponding to δ is approximately $\sqrt{x(v + KV)}$, where v is the amount of the flowing phase and V the amount of the stationary phase in one distribution unit. K is the distribution coefficient of the substance.

Fig. 2 shows the distribution of a known mixture of oxalic, succinic and glutaric acids in the solvent system *n*-butanol-water. These acids are known to have distribution coefficients which are relatively concentration-independent. Table 1 shows numerical values concerning the distribution.

As an example of the fractionation of substances of biological origin Fig. 3 shows distribution of three sulfur-containing glucosides from turnip seeds.

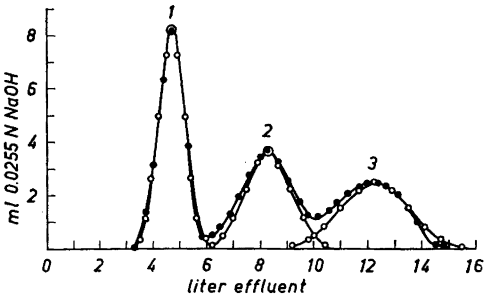

Fig. 2. Distribution of oxalic, succinic and glutaric acids in a solvent system *n*-butanol-water at 20°C. Run in one direction only with the lower phase flowing. Volume ratio 1:1. Flow speed 6 ml/min. ●———● experimental curve by titration O———O calculated curves, 1, oxalic acid, 2, succinic acid, 3, glutaric acid.

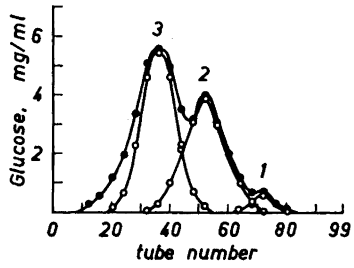

Fig. 3. The distribution of three sulfur-containing glucosides from turnip seeds in a solvent system *n*-butanol-ethanol-water (4:1:4) at 20°C. Volume ratio 46:40. The points of the curve represent samples from the tubes of the apparatus after 22.5 liters of the upper phase had flown through with a speed of 10—15 ml/min. Ordinate: Glucose as determined quantitatively by the anthron method. Abscissa: Tube number. ●———● experimental curve. Curve 1: Gluconapin, K 0.148; Curve 2: Gluconasturtin, K 0.104; Curve 3: Progoitrin, K 0.066. The deviation of the last curve depends on dissociation-association phenomena of the last substance in the unbuffered solvent system. The whole amount of substance was about 8 g dry weight.

The exact mathematical and theoretical treatment and technical details omitted from this preliminary note will be presented in a further paper.

I wish to thank Professor Artturi I. Virtanen, Director of the Biochemical Institute, for his encouragement, for valuable suggestions during this work and for the excellent facilities put at my disposal in the laboratory of the Foundation for Chemical Research. I also wish to thank Dr. Matti Kreula for his valuable help and suggestions in planning and building the mechanical parts of this counter-current apparatus.

This work has been supported partly by the *Rockefeller Foundation* and partly it belongs to the research project under U. S. Public Law No. 480, 83rd Congress.

Ozonisation of 3-Methyl*cyclo*pent-2-en-2-ol-1-one

JOHAN B.SON BREDENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland

In a previous paper[1] it was shown by physical methods that 3-methyl*cyclo*penta-1,2-dione exists as the enol 3-methyl*cyclo*pent-2-en-2-ol-1-one. This structure should be readily attacked by ozone to yield laevulic acid. The other possible enol structure for the compound, 5-methyl*cyclo*pent-2-en-2-ol-1-one, should, on the other hand, give methylsuccinic acid. The enol structure can therefore be confirmed also by ozonisation of the compound.

The compound was ozonised in aqueous solution at room temperature and the water evaporated. The evaporation residue, which had an infrared spectrum of almost pure laevulic acid, but with a small amount of starting material, was distilled and gave a high yield of pure laevulic acid, b.p. 103 —105°/1 mm, identified by its infrared spectrum and its phenylhydrazone, m.p. 105—106°, and 2,4-dinitrophenylhydrazone, m.p. 207—208°. The result consequently corroborated the evidence obtained by physical methods.

Experimental. 3-Methyl*cyclo*pent-2-en-2-ol-1-one (Fluka A.-G.) (3.73 g) was dissolved in water (150 ml) and ozonised at room temperature for 2 h (5.1 % O_3, 15.7 mg O_3/min). The solution was left to stand for two days, after which the water was evaporated under diminished pressure at 20°. The evaporation residue, an almost colourless oil, was distilled under reduced pressure and gave two fractions. The first fraction, b.p. 80—103°/1 mm, (0.53 g) which partly crystallised, consisted, according to the infrared spectrum, of the starting material and laevulic acid. The second fraction, b. p. 103—105°/1 mm, (2.94 g) had the infrared spectrum of pure laevulic acid. The fraction yielded a phenylhydrazone, m. p. 105—106°, and a 2,4-dinitrophenylhydrazone, m. p. 207—208°, both prepared in the usual way[2,3]. Neither derivative gave any m. p. depression with authentic material from pure laevulic acid.

Ozonisation of 3-Methyl*cyclo*pent-2-en-2-ol-1-one

JOHAN B.SON BREDENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland

In a previous paper[1] it was shown by physical methods that 3-methyl*cyclo*penta-1,2-dione exists as the enol 3-methyl*cyclo*pent-2-en-2-ol-1-one. This structure should be readily attacked by ozone to yield laevulic acid. The other possible enol structure for the compound, 5-methyl*cyclo*pent-2-en-2-ol-1-one, should, on the other hand, give methylsuccinic acid. The enol structure can therefore be confirmed also by ozonisation of the compound.

The compound was ozonised in aqueous solution at room temperature and the water evaporated. The evaporation residue, which had an infrared spectrum of almost pure laevulic acid, but with a small amount of starting material, was distilled and gave a high yield of pure laevulic acid, b.p. 103 —105°/1 mm, identified by its infrared spectrum and its phenylhydrazone, m.p. 105—106°, and 2,4-dinitrophenylhydrazone, m.p. 207—208°. The result consequently corroborated the evidence obtained by physical methods.

Experimental. 3-Methyl*cyclo*pent-2-en-2-ol-1-one (Fluka A.-G.) (3.73 g) was dissolved in water (150 ml) and ozonised at room temperature for 2 h (5.1 % O_3, 15.7 mg O_3/min). The solution was left to stand for two days, after which the water was evaporated under diminished pressure at 20°. The evaporation residue, an almost colourless oil, was distilled under reduced pressure and gave two fractions. The first fraction, b.p. 80—103°/1 mm, (0.53 g) which partly crystallised, consisted, according to the infrared spectrum, of the starting material and laevulic acid. The second fraction, b. p. 103—105°/1 mm, (2.94 g) had the infrared spectrum of pure laevulic acid. The fraction yielded a phenylhydrazone, m. p. 105—106°, and a 2,4-dinitrophenylhydrazone, m. p. 207—208°, both prepared in the usual way[2,3]. Neither derivative gave any m. p. depression with authentic material from pure laevulic acid.

*iso*Thiocyanates XXXVII *. Rotatory Dispersion Studies of Optically Active Sulphoxides Derivable from *iso*Thiocyanates of Natural Origin

W. KLYNE and JANET DAY

Postgraduate Medical School, University of London, England

ANDERS KJÆR

Organic Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark

Within the group of naturally occurring sulphoxides, in which optical activity can be partly or wholly attributed to the presence of an asymmetric sulphur atom (*cf. e.g.* Refs. [1,4]), a homologous series of *iso*thiocyanates presents an interesting stereochemical problem. In 1948, Schmid and Karrer [2] assigned the structure $CH_3SOCH=CHCH_2CH_2NCS$ to sulphoraphen, a strongly *laevo*rotatory mustard oil, isolated from radish seed. This finding was soon followed by the isolation by Schultz and Gmelin [3] of the glucoside, glucoiberin, enzymically hydrolyzed to another sulphoxide-mustard oil, for which the structure $CH_3SO(CH_2)_3NCS$ was suggested [3] and later proved [4]. More recently, Kjær *et al.* [4,6-8] reported the isolation of additional sulphoxide-mustard oils, subsequent to enzymic hydrolysis of glucosides present in various crucifers. Thus, alyssin [4,5] ($CH_3SO(CH_2)_5NCS$), hirsutin [6] ($CH_3SO(CH_2)_6NCS$), arabin [7] ($CH_3SO(CH_2)_9NCS$) and camelinin [8] ($CH_3SO(CH_2)_{10}NCS$) were encountered as species of natural provenance. Lately, Procházka [9] added sulphoraphan, (−)-$CH_3SO(CH_2)_4NCS$, the saturated compound corresponding to sulphoraphen [2], to the above series (*cf.* also Ref. [6]).

Identical configuration around the asymmetric sulphur atom in the homologous series of naturally derived sulphoxide-mustard oils was suggested by the fact that the optical rotations at 589 mμ [4] of the *iso*thiocyanates measured, as well as of various thiourea derivatives*, were all negative and of comparable magnitude.

In order to substantiate this conclusion, a rather unusual and extensive series of homologous, naturally derived sulphoxides of the general structural type (I) was subjected to rotatory dispersion studies in methanol solution.

$$CH_3S(CH_2)_nNHCXNHY$$
$$\downarrow$$
$$O$$

I

X = O, or S
Y = H, C_6H_5, or $C_6H_5CH_2$
n = 3, 4, 5, 8, 9, or 10

In all cases the rotation becomes *more negative* as one moves to shorter wave lengths (negative plain curves; for nomenclature, see Djerassi and Klyne [10]). Except

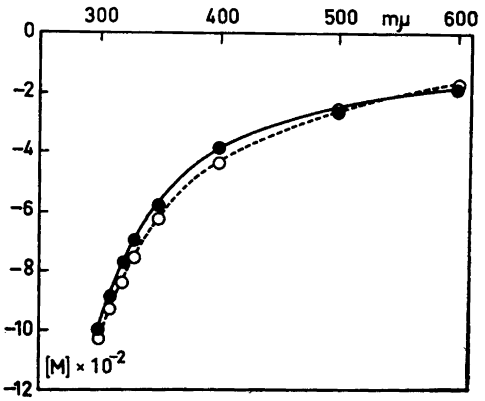

Fig. 1. Rotatory dispersion curve of straight-chain N-(ω-methylsulphinylalkyl)-thioureas, $CH_3SO(CH_2)_nNHCSNH_2$, in methanol. - - - - : n = 5; ——— : n = 10.

* Part XXXVI of this series: *Acta Chem. Scand.* 13 (1959) 1575.

* No rotation was reported for the aromatic thiourea-derivatives employed in the characterisation of sulphoraphan [9]. A small specimen of the phenylthiourea, kindly placed at our disposal by Dr. Procházka, Prague, was measured in the laboratory of one of the authors (A.K.) and gave: $[\alpha]_D^{25}$ −54° (*c* 1.8, 96 % EtOH, microtube).

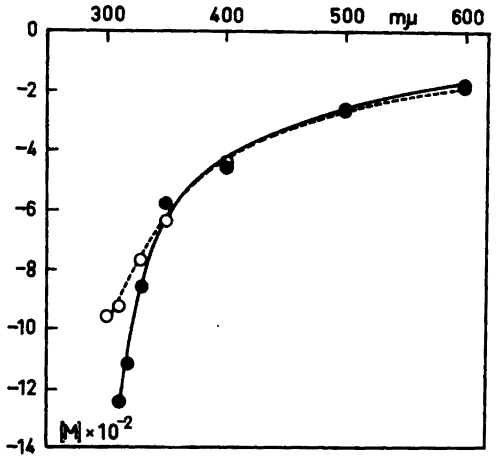

Fig. 2. Rotatory dispersion curve of straight-chain, N-substituted N′-(ω-methylsulphinylalkyl)-thioureas, $CH_3SO(CH_2)_nNHCSNHR$, in methanol. ———: n = 5, R=C_6H_5 - - - -: n = 10, R=$C_6H_5CH_2$.

for a few points in the region of 300 mμ, the curves, when plotted as molecular rotations, are very closely similar, and some are almost superimposable. Representative examples are reproduced in Figs. 1 and 2. In Table 1, the values determined at 600 mμ, 500 mμ, 400 mμ and 300 mμ, are listed for all the compounds investigated.

Clearly, the rotatory dispersion curves provide a much better means of allotting configuration at the asymmetric sulphur atom of the compounds (I), than do "monochromatic" rotation analogies. From the present results it seems safe to conclude that all sulphoxide-*iso*thiocyanates encountered in Nature thus far, possess identical configurations. Their spatial relationship to (+)-*S*-methyl-L-cysteine sulphoxide, the sole sulphoxide of established absolute configuration [11], remains to be determined.

From the present rotatory dispersion curves it is evident that the presence of an aromatic nucleus at a considerable distance from the asymmetric sulphur atom in eleven of the compounds apparently has a negligible effect on the dispersion curve down to 300 mμ. In the phenylthiourea-derivative of sulphoraphen, with a double bond located αβ to the sulphur atom, a slight deviation in the rotatory dispersion curve is noticed at about 300 mμ, compared with those of the saturated series.

Table 1. Molecular rotations in methanol at various wave lengths of compounds represented by formula (I).

Formula	Mol. weight	Concn. (mg/ml)	Molecular rotations at λ 300 mμ	400 mμ	500 mμ	600 mμ

Purification of Human Plasminogen on DEAE-cellulose

PER WALLÉN and KURT BERGSTRÖM

Kemiska Institutionen II, Karolinska Institutet, Stockholm, Sweden

In a recent communication a method for the purification of human plasminogen was outlined [1]. The most important step of this method was an adsorption of a partially purified plasminogen preparation on columns of DEAE-cellulose equilibrated with an ammonium acetate buffer, pH 9.0, containing lysine to a concentration of 0.01 M. Under these conditions about 80 % of the protein was adsorbed, whereas 60—80 % of the plasminogen passed through the column in the frontal fraction together with about 20 % of the protein. We were prompted to use lysine in this connection by the observation of Alkjaersig, Fletcher and Sherry [2], who found that ε-aminocaproic acid and lysine increased the solubility of plasminogen and plasmin preparations at neutral reaction, probably due to a dissolution of a protein complex.

As starting material we used a plasminogen preparation obtained from Cohn's fraction III by dialysis against a phosphate buffer of pH 7.0 and low ionic strength. The specific activity ranged from 8 to 20 times that of fraction III. This variability was shown to be caused by the poor reproducibility of the first step. Therefore we now have excluded this step.

Plasminogen is easily adsorbed on DEAE-cellulose, previously equilibrated with ammonium acetate buffer, pH 9.0, but if lysine is added to the buffer it is not adsorbed. Thus it was near at hand first to adsorb plasminogen to DEAE-cellulose from a weakly alkaline buffer without lysine and then to try to elute the activity with the same buffer to which lysine had been added. In the following a method based on this principle is outlined.

A preparation obtained from Cohn's fraction II + III by precipitating the plasminogen at low ionic strength and pH 5.3 was used as starting material. Preparations of this type have almost the same specific activity as fraction III and the yields are higher. About 35 g DEAE-cellulose (Brown Comp. New Hampshire, U.S.A.) were suspended in 0.04 M ammonium acetate buffer pH 9.0. The slurry was poured in a column with a diameter of 4 cm and packed with

Purification of Human Plasminogen on DEAE-cellulose

PER WALLÉN and KURT BERGSTRÖM

Kemiska Institutionen II, Karolinska Institutet, Stockholm, Sweden

In a recent communication a method for the purification of human plasminogen was outlined [1]. The most important step of this method was an adsorption of a partially purified plasminogen preparation on columns of DEAE-cellulose equilibrated with an ammonium acetate buffer, pH 9.0, containing lysine to a concentration of 0.01 M. Under these conditions about 80 % of the protein was adsorbed, whereas 60—80 % of the plasminogen passed through the column in the frontal fraction together with about 20 % of the protein. We were prompted to use lysine in this connection by the observation of Alkjaersig, Fletcher and Sherry [2], who found that ε-aminocaproic acid and lysine increased the solubility of plasminogen and plasmin preparations at neutral reaction, probably due to a dissolution of a protein complex.

As starting material we used a plasminogen preparation obtained from Cohn's fraction III by dialysis against a phosphate buffer of pH 7.0 and low ionic strength. The specific activity ranged from 8 to 20 times that of fraction III. This variability was shown to be caused by the poor reproducibility of the first step. Therefore we now have excluded this step.

Plasminogen is easily adsorbed on DEAE-cellulose, previously equilibrated with ammonium acetate buffer, pH 9.0, but if lysine is added to the buffer it is not adsorbed. Thus it was near at hand first to adsorb plasminogen to DEAE-cellulose from a weakly alkaline buffer without lysine and then to try to elute the activity with the same buffer to which lysine had been added. In the following a method based on this principle is outlined.

A preparation obtained from Cohn's fraction II + III by precipitating the plasminogen at low ionic strength and pH 5.3 was used as starting material. Preparations of this type have almost the same specific activity as fraction III and the yields are higher. About 35 g DEAE-cellulose (Brown Comp. New Hampshire, U.S.A.) were suspended in 0.04 M ammonium acetate buffer pH 9.0. The slurry was poured in a column with a diameter of 4 cm and packed with

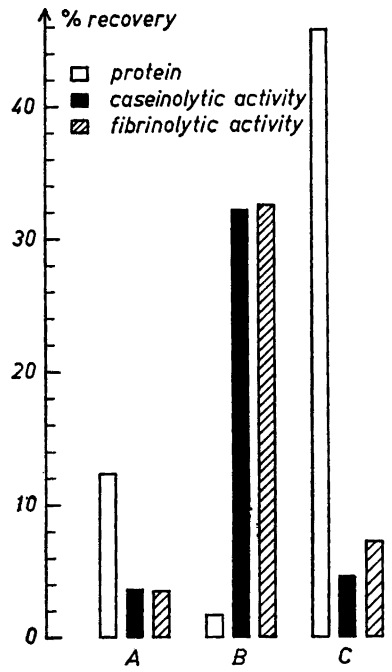

Fig. 1. Adsorption and step-wise elution of human plasminogen on DEAE-cellulose. The buffers are:

A) 0.04 M ammonium acetate, pH 9.0.
B) 0.04 M ammonium acetate, pH 9.0 containing lysine to a concentration of 0.01 M.
C) 0.04 M ammonium acetate, pH 4.0 containing lysine to a concentration of 0.01 M.

an excess air pressure of about 50 mm Hg. The column was equilibrated with the same buffer. 10 g of the starting material was suspended in 500 ml of the equilibration buffer and dialysed against the same buffer during 6—8 h. Some of the material did not dissolve and was removed by centrifugation. The opalescent supernatant was applied to the column, which was then developed with about 1 000 ml of the equilibration buffer. The elution was then performed stepwise with 0.04 M ammonium acetate buffer, pH 9.0 and 4.0, both buffers containing lysine to a concentration of 0.01 M. The protein concentration in the effluent was followed by measuring the optical density at 280 mμ in a Beckman DU photometer.

The fractions were acidified with hydrochloric acid to pH 3.5, dialysed against distilled water and precipitated with cold acetone at a concentration of 40 % at −15°C. The precipitates were lyophilized and the fractions tested with the caseinolytic method of Müllertz [3] and the fibrinolytic method of Christensen [4].

The result of such an experiment is shown in Fig. 1, where the amount of lyophilized protein, caseinolytic and fibrinolytic activity in the fractions are expressed as per cent of the starting material. In the frontal peak appears about 12 % of the protein but only 4 % of the plasminogen. The main part of the plasminogen thus has been adsorbed to the ion exchanger. When the column is eluted with the same buffer, to which lysine has been added, a small peak appears containing only about 1—2 % of the protein but about 30—35 % of the activity, which means a purification of about 20 times as compared to the starting material. With the acidic buffer, finally, 40 % of the protein material and 5 % of the plasminogen is eluted. Five preparations have been made according to the method outlined. The increase in specific activity in the second fraction (B in Fig. 1) has ranged from 20 to 30 times as compared to the starting material and the yield has ranged from 30 to 35 %.

Influence of Steric Hindrance on the Isotope Effect in Aromatic Substitution

PHILIP C. MYHRE*

Nobel Institute of Chemistry, Stockholm 50, Sweden

As part of an investigation of the effect of steric hindrance on the mechanism of aromatic substitution, isotope effects in the nitration and bromination reactions of the highly hindered hydrocarbon, 1,3,5-tri-*t*-butylbenzene, have been measured. No isotope effect could be detected when this hydrocarbon was nitrated in acetic acid — acetic anhydride solution in the presence or absence of sulfuric acid catalyst. However, a "full" isotope effect ($k_T/k_H \sim 0.1$) is observed when the same tritium labeled hydrocarbon is brominated in acetic acid — dioxane solution with bromine, silver perchlorate and perchloric acid. The brominating agent in this reaction is believed to be "positive" bromine or a "positive" bromine carrier [1]. Hydrogen exchange was shown to be absent during these reactions.

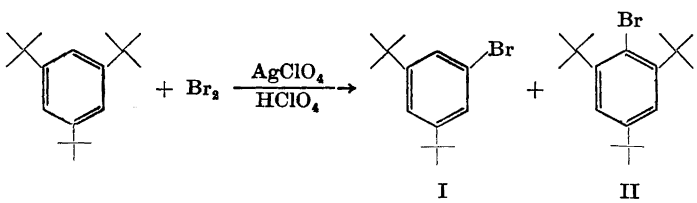
The nitration of tri-*t*-butylbenzene was effected in essentially quantitative yield using the method of Wepster, Verkade *et al.* [2] Possible fractionation of tritium in the reactant as well as the derivative was investigated in some experiments by using less than the stoichiometric amount of nitric acid and recovering both the nitro derivative and the unreacted hydrocarbon.

Normal bromination of tri-*t*-butylbenzene apparently proceeds only in the presence of a "positive" brominating agent. When the classical catalyst, iron powder, is used, it is reported that only the dealkylated 1-bromo-2,5-di-*t*-butylbenzene (I) is isolated in 70 % yield [3]. Barclay and Betts [4] report a 67 % yield of 1-bromo-2,4,6-tri-*t*-butylbenzene (II) by bromination in aqueous acetic acid with silver nitrate and nitric acid. The brominating conditions used in the present measurements yield a mixture of the desired product (II) and the dealkylated product (I). These compounds were identified by comparison of their infrared spectra with the spectra of known samples.

A typical reaction was performed by adding bromine (2.4 g, 15 mmole) to a well stirred solution of tri-*t*-butylbenzene [5] (2.4 g, 10 mmole), silver perchlorate (3.0 g, 15 mmole) and perchloric acid (1.0 ml, 11 mmole) in 60 ml of acetic acid-dioxane (5:1 by volume) and allowing the mixture to stand with stirring for about 16 h. The product was isolated by filtration of the silver salts, addition of water to the filtrate and extraction of the organic product with pentane. The following material balance was obtained by infrared analysis of the crude product: I, 21 %; II, 68 %; unreacted hydrocarbon, 8 %. The infrared spectrum of a synthetic mixture of pure components compounded in this ratio agreed well with the spectrum of the crude reaction product. II was isolated by repeated crystallization from ethanol and sublimation *in vacuo*, m. p. 173—174°.

Activity measurements were made in the usual manner [6] by inside counting of hydrogen obtained from the combustion water of the reactants and derivatives.

A general expression [6,7] for aromatic substitution in compounds possessing a symmetry similar to tri-*t*-butylbenzene which relates the molar activity in the derivative and that in the initial reactant to the kinetic isotope effect (k_T/k_H), the extent of reaction and the relative rate of side reactions is



* U. S. National Science Foundation Postdoctoral Fellow, 1958—1960.

$$\frac{d}{r_0} = \frac{2 + 2q}{2 + \beta + 3q} \cdot \frac{1}{x}\left[1 - (1 - x)^{(2+\beta+3q)/(3+3q)}\right]$$

where d is the molar activity in the derivative measured after separation from the by-product, r_0 is the molar activity in the initial reactant, β is the ratio k_T/k_H, q is the ratio of the specific rates of dealkylation and substitution and x is the extent of reaction. It is assumed that isotopic hydrogen only influences the reaction rate at its own position.

where r is the molar activity in the unconsumed reactant. The other symbols retain their previous meanings. For nitration q vanishes since no evidence of side reactions can be detected. On the basis of product analysis q is assigned a value of 1/3 for the bromination reaction.

All experimentally determined values of the isotope effect for the nitration of tri-*t*-butylbenzene, as shown in Table 1, fall within the interval 1.0 ± 0.1.

Table 1. Isotope effects in nitration of 2,4,6-tri-*t*-butylbenzene in acetic acid — acetic anhydride solution at about 25°.

	Number of experiments	% Yield derivative	Calculated mean k_T/k_H with maximum experimental deviations
Uncatalyzed nitration (nitro derivative)	3	>97 %	$0.98 \begin{matrix}+ 0.05 \\ - 0.06\end{matrix}$
Catalyzed nitration [a] (nitro derivative)	2	80–83 %	$1.04 \begin{matrix}+ 0.06 \\ - 0.06\end{matrix}$
(recovered reactant)	2	80–83 %	$1.04 \begin{matrix}+ 0.01 \\ - 0.02\end{matrix}$

[a] H_2SO_4 concentration, 0.02 % by weight; mole ratio acid to hydrocarbon, 1:100.

The function relating the molar activity in the unconsumed reactant and the molar activity in the initial reactant to the kinetic isotope effect is

$$\log \frac{r}{r_0} = \frac{1 - \beta}{3 + 3q}\left[-\log(1 - x)\right]$$

In Fig. 1 the average value of d/r_0 obtained from duplicate counting of two separate bromination runs is compared with the theoretical function $f(x,\beta,q)$ where $q = 1/3$. The experimental data

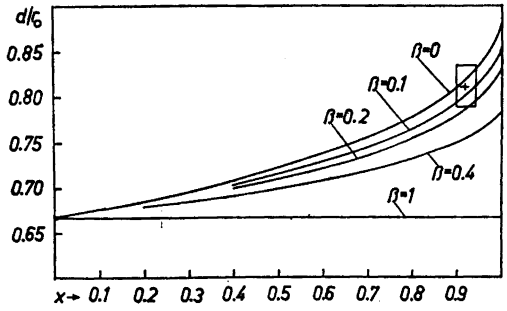


Fig. 1. Tritium content of 1-bromo-2,4,6-tri-*t*-butylbenzene relative to initial hydrocarbon. Curves show the function $f(x,\beta,q)$ for certain values of β.

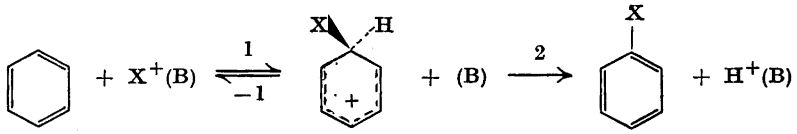
indicate that β is less than 0.2. The most probable value appears to be 0.1 or less. More experimental work is necessary in order to ascertain the value of β with greater accuracy.

The isotope effect investigations made by Zollinger [8,9] of the azo coupling reaction and Schubert *et al.* [10,11] of the acid-catalyzed decarbonylation of 2,4,6-trialkylbenzaldehydes clearly show that in these reactions steric hindrance around the site of electrophilic substitution increases the kinetic importance of the aromatic C—H bond breaking. Their observations are readily explicable in terms of the generally accepted two-step reaction mechanism of aromatic substitution, and, in fact, constitute very strong evidence in favor of this mechanism. Analysis



of the general rate equation of this mechanism reveals that step 2 will be rate-controlling and a hydrogen isotope effect will be observed when the velocity ratio (v_{-1}/v_2) is large. Such a condition should be facilitated when bulky substituents are located *ortho* to the reaction site since the contribution to the total energy of the transition state due to steric repulsion should be larger for step 2 than for step -1. If other factors affecting v_{-1}/v_2 do not counterbalance the steric effects, step 2 should become rate-controlling when a highly hindered compound is subjected to an electrophilic substitution even though an isotope effect is not observed when an unhindered compound is allowed to undergo the same reaction.

The absence of an isotope effect in the nitration of relatively unhindered aromatic compounds is well documented [1,6]. The present work shows this effect is absent even under conditions approaching maximum hindrance. It is concluded that for aromatic nitration other energetic considerations are of far greater importance than steric factors in determining the velocity ratio (v_{-1}/v_2).

There appears to be no isotope effect in the bromination of benzene by hypobromous acid [12] or bromine with iodine catalyst [6]. These results may be contrasted with the strong isotope effect found in the bromination of tri-*t*-butylbenzene and the previously reported isotope effects in the bromination of 2-naphthol-6,8-disulphonic acid ($k_D/k_H = 0.50$)[8] and dimethylaniline ($k_D/k_H = 0.53$)[13]. Although the situation at present is not altogether clear-cut, it would appear that in the aromatic bromination reaction steric hindrance is able to profoundly influence the velocity ratio (v_{-1}/v_2).

Further discussion will be deferred until investigations concerning the isotope effects in the bromination of aromatic hydrocarbons possessing intermediate hindrance and the importance of basic and solvent species on the isotope effect have been completed. The investigations reported here will be published in full detail at a later date.

The UV-Absorption of some 1α, 5α-Epidithio-steroids

GÖRAN BERGSON and BERNDT SJÖBERG

Chemical Institute, University of Uppsala, Sweden

ROBERT C. TWEIT and R. M. DODSON

The Chemical Research Division of G. D. Searle & Co. Chicago, Illinois, USA.

Recently Tweit and Dodson [1] isolated a disulfide from the reaction of 1,4-androstadiene-3,17-dione with hydrogen sulfide and sulfur in pyridine. For various reasons the disulfide linkage was proposed to be between carbon atoms one and five, and the disulfide bridge was placed on the α-side of the molecule. The compound is thus 1α, 5α-epidithioandrostane-3,17-dione (I) which implies that the molecule contains the five-membered 1,2-dithiolane ring.

From a study of molecular models it appeared that the dihedral angle of the disulfide group in I, as in other dithiolane derivatives, cannot be very far from zero. In 1,2-dithiolane-4-carboxylic acid the dihedral angle has been found [2] to be 27°. Furthermore it can be concluded, that the sulfur-sulfur bond distance is certainly larger than the usual (2.08 ± 0.03 Å) since otherwise a large departure from the principle of maximum overlap for the carbon-sulfur bonds must be assumed. Since 1,2-dithiolane and many of its derivatives have an absorption band in the ultraviolet with maximum at about 330 mμ and since Bergson [3] has shown that an increase in the sulfur-sulfur bond distance might be expected to decrease the excitation energy, the thiosteroid I might have

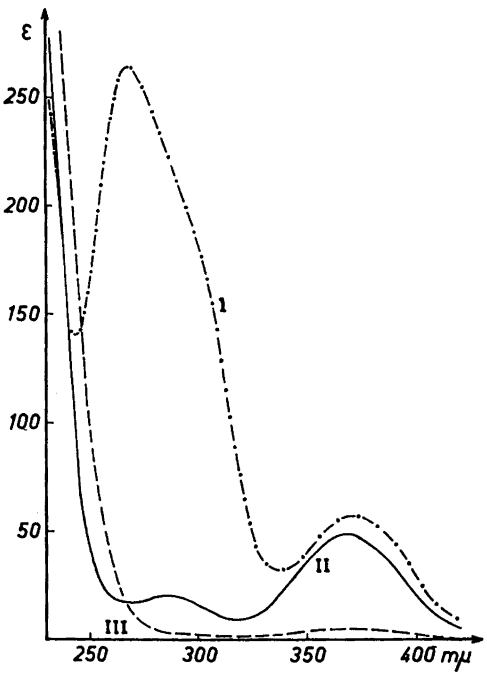

Fig. 1. Ultraviolet absorption in methanol of:
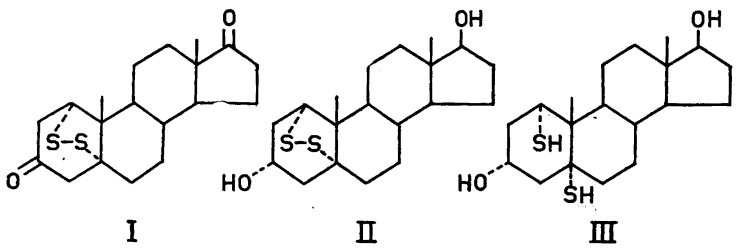
I: 1α,5α-epidithioandrostane-3,17-dione.
II: 1α,5α-epidithioandrostane-3α,17β-diol.
III: 3α,17β-dihydroxyandrostane-1α,5α-dithiol.

an absorption band at longer wavelengths than 330 mμ. The ultraviolet spectrum of 1α,5α-epidithioandrostane-3,17-dione (I) and its reduction products 1α,5α-epidithioandrostane-3α,17β-diol (II) and 3α,17β-dihydroxyandrostane-1α,5α-dithiol (III) have therefore been reinvestigated in



I II III

detail. The results are given in Fig. 1. The disulfides I and II have a maximum at 371 mμ ($\varepsilon_{max} = 58$) and 369 mμ ($\varepsilon_{max} = 49$), respectively. We think that this band is due to a transition from the antibonding 3pπ-orbital to the antibonding σ-orbital of the disulfide group [3,4]. This is in harmony with its almost complete disappearance in the dithiol III; the very small remaining absorption is certainly due to the precense of a trace of II formed by the unavoidable oxidation of III. We cannot at present give a precise interpretation of the absorption at the shorter wave-lengths. Remarkable is the strong absorption maximum at 268 mμ for the keto-compound (I). This cannot be due solely to the keto-groups. It may possibly be due to a trans-annular interaction of the 3-keto-group and the disulfide bridge (*cf.* Leonard *et al.* [5])

Studies on the Zirconium-Aluminium and Hafnium-Aluminium Systems

LARS-ERIK EDSHAMMAR and STEN ANDERSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The following phases have been observed in the zirconium-aluminium system: Zr_3Al, Zr_2Al, Zr_5Al_3, Zr_3Al_2, Zr_4Al_3, ZrAl, Zr_2Al_3, $ZrAl_2$ and $ZrAl_3$[1]. The crystal structures have been reported for Zr_3Al[2], Zr_5Al_3[3], $ZrAl_2$[4] and $ZrAl_3$[5].

In the present investigation, metals of high purity were used, *viz.* aluminium (99.99 %) and zirconium (iodide zirconium 99.9 %, oxygen 260 ppm, Foote Mineral Company). The alloys were prepared by melting in an electric arc furnace under an argon atmosphere and heat-treated in sealed evacuated silica tubes. Tantalum foils protected the alloys from reacting with the silica.

The phase analyses were performed by means of X-ray powder patterns taken in a Guinier camera, potassium chloride being added to the specimens as an internal standard [6]. Single crystal data were obtained in a Weissenberg camera with Cu*K* radiation.

While the crystal structures of Zr_5Al_3 and $ZrAl_2$ were being studied at this Institute, Wilson *et al.*[3,4] published the structures of these compounds. Thus, Zr_5Al_3 was reported to have the **D8*s*** type of structure while $ZrAl_2$ was found to be of the **C14** type. The data given for $ZrAl_2$ are in perfect agreement with our results but this is, however, not the case with Zr_5Al_3.

Single crystals of Zr_5Al_3 could be obtained from a melt of the approximate composition $ZrAl_{0.50}$. The single crystal and powder data showed the structure to be tetragonal with the following unit cell axes:

$$a = 11.049 \text{ Å}, \qquad c = 5.396 \text{ Å}.$$

The Patterson projections along[001] and [100] were calculated and the following structure was derived:

Unit cell content: 4 Zr_5Al_3.

Space-group: *I*4/*mcm* (No. 140)

		x	*y*	*z*
16 Zr in	16 (*k*)	0.077	0.218	0
4 Zr in	4 (*b*)	0	½	1/4
8 Al in	8 (*h*)	0.16	0.66	0
4 Al in	4 (*a*)	0	0	1/4

This structure of the **D8*m*** type is represented by W_5Si_3 (Aronsson [7]). It may be that the occurrence of the **D8*s*** and the **D8*m*** structures depends on the heat-treatment of the sample. It has, however, been suggested that the Me_5X_3 phases with the **D8*s*** type of structure are stabilized by the prescence of impurities such as boron, carbon, nitrogen and oxygen [8-10]. This interesting hypothesis seems to be supported by the observation that a mixture of zirconium, aluminium and aluminium oxide with a composition close to the formula $Zr_{10}Al_6O$ upon melting gave a product with a pure **D8*s*** structure. The powder pattern was found to give the following parameters for the hexagonal unit cell:

$$a = 8.177 \text{ Å}, \qquad c = 5.674 \text{ Å}.$$

The axes reported by Wilson *et al.*[3] for the **D8*s*** phase are 8.184 and 5.702 Å, respectively.

detail. The results are given in Fig. 1. The disulfides I and II have a maximum at 371 mμ ($\varepsilon_{max} = 58$) and 369 mμ ($\varepsilon_{max} = 49$), respectively. Studies on the Zirconium-Aluminium and Hafnium-Aluminium Systems

LARS-ERIK EDSHAMMAR and STEN ANDERSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The following phases have been observed in the zirconium-aluminium system: Zr_3Al, Zr_2Al, Zr_5Al_3, Zr_3Al_2, Zr_4Al_3, ZrAl, Zr_2Al_3, $ZrAl_2$ and $ZrAl_3$[1]. The crystal structures have been reported for Zr_3Al[2], Zr_5Al_3[3], $ZrAl_2$[4] and $ZrAl_3$[5].

In the present investigation, metals of high purity were used, *viz.* aluminium (99.99 %) and zirconium (iodide zirconium 99.9 %, oxygen 260 ppm, Foote Mineral Company). The alloys were prepared by melting in an electric arc furnace under an argon atmosphere and heat-treated in sealed evacuated silica tubes. Tantalum foils protected the alloys from reacting with the silica.

The phase analyses were performed by means of X-ray powder patterns taken in a Guinier camera, potassium chloride being added to the specimens as an internal standard [6]. Single crystal data were obtained in a Weissenberg camera with Cu*K* radiation.

While the crystal structures of Zr_5Al_3 and $ZrAl_2$ were being studied at this Institute, Wilson *et al.*[3,4] published the structures of these compounds. Thus, Zr_5Al_3 was reported to have the **D8*s*** type of structure while $ZrAl_2$ was found to be of the **C14** type. The data given for $ZrAl_2$ are in perfect agreement with our results but this is, however, not the case with Zr_5Al_3.

Single crystals of Zr_5Al_3 could be obtained from a melt of the approximate composition $ZrAl_{0.50}$. The single crystal and powder data showed the structure to be tetragonal with the following unit cell axes:

$$a = 11.049 \text{ Å}, \qquad c = 5.396 \text{ Å}.$$

The Patterson projections along[001] and [100] were calculated and the following structure was derived:

Unit cell content: 4 Zr_5Al_3.

Space-group: *I*4/*mcm* (No. 140)

		x	*y*	*z*
16 Zr in	16 (*k*)	0.077	0.218	0
4 Zr in	4 (*b*)	0	½	1/4
8 Al in	8 (*h*)	0.16	0.66	0
4 Al in	4 (*a*)	0	0	1/4

This structure of the **D8*m*** type is represented by W_5Si_3 (Aronsson [7]). It may be that the occurrence of the **D8*s*** and the **D8*m*** structures depends on the heat-treatment of the sample. It has, however, been suggested that the Me_5X_3 phases with the **D8*s*** type of structure are stabilized by the prescence of impurities such as boron, carbon, nitrogen and oxygen [8-10]. This interesting hypothesis seems to be supported by the observation that a mixture of zirconium, aluminium and aluminium oxide with a composition close to the formula $Zr_{10}Al_6O$ upon melting gave a product with a pure **D8*s*** structure. The powder pattern was found to give the following parameters for the hexagonal unit cell:

$$a = 8.177 \text{ Å}, \qquad c = 5.674 \text{ Å}.$$

The axes reported by Wilson *et al.*[3] for the **D8*s*** phase are 8.184 and 5.702 Å, respectively.

The powder pattern of Zr_4Al_3 was obtained from a sample annealed at 850°C for several days. It was possible to index it it with the following hexagonal unit cell dimensions:

$$a = 5.430 \text{ Å}, \qquad c = 5.389 \text{ Å}.$$

The observed density, 5.32 g cm^{-3}, is in good agreement with the value, 5.37 g cm^{-3}, calculated for a cell content of one formula unit Zr_4Al_3. The intensity data suggest that the structure contains chains of zirconium atoms (Zr—Zr = $\frac{1}{2}$ c) similar to those present in the Zr_5Al_3 phase.

Further studies on these structures are in progress.

In connection with the investigations on the zirconium-aluminium system, the aluminium-rich region of the hafnium-aluminium system has also been studied. Thus, three compounds, *viz.* Hf_2Al_3, $HfAl_2$ and $HfAl_3$, have been prepared so far. The X-ray powder patterns demonstrate clearly that they are all isomorphous with the corresponding phases in the zirconium-aluminium system.

$HfAl_3$ has a hexagonal **C14** type of structure with the unit cell axes:

$$a = 5.288 \text{ Å}, \qquad c = 8.739 \text{ Å}$$

$HfAl_3$ has a tetragonal $\mathbf{D0_{23}}$ type of structure with the unit cell axes:

$$a = 4.010 \text{ Å}, \qquad c = 17.310 \text{ Å}$$

Ozonolysis of *p*-Benzoquinone. III. Counter-current Ozonisation

ERLING BERNATEK and KRISTIAN VALEN

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

On two previous occasions [1,2] we have reported on the ozonolysis of *p*-benzoquinone and discussed some of the possible reaction paths. Anomalous ozonolysis and/or rearrangement of normal ozonides occurred to a large extent. This was to be expected since in quinone two carbonyl groups are conjugated with the double bonds attacked by ozone.

The experimental procedure employed — being a batch procedure — had the drawback that the primary reaction products were in contact with ozone for a comparably long time. Consequently some of the isolated products could have been formed by further oxidation. In order to avoid this and especially to investigate closer the formation of a monozonide and its decomposition products, we adopted a counter-current procedure similar to that of Pummerer and Richtzenhain [3] which allowed a brief contact between the quinone solution and ozone, rapidly followed by hydrolysis.

Previous experiments with the batch procedure has shown that even if quinone was present in excess to the amount of ozone required for mono-ozonolysis only minor amounts of reaction products originating from cleavage of one double bond were found. It thus seems that secondary reactions proceed about as fast as the initial ozonolysis.

In Table 1 is summarised some of the relationships between the amount of applied ozone per mole of quinone, % reacted quinone and consumed ozone as found by the counter-current method. Finally the theoretically possible amount of monozonide (or products from mono-ozonolysis) in moles per mole of quinone is calculated.

When about one mole of ozone is applied per mole of quinone 65 % of the latter is attacked. A substantial part of the quinone must therefore have consumed two molecules of ozone. From the last column it is clear that mono-ozonolysis occurs in increasing amounts with decreasing ozone-quinone ratio.

The powder pattern of Zr_4Al_3 was obtained from a sample annealed at 850°C for several days. It was possible to index it it with the following hexagonal unit cell dimensions:

$$a = 5.430 \text{ Å}, \qquad c = 5.389 \text{ Å}.$$

Ozonolysis of *p*-Benzoquinone. III. Counter-current Ozonisation

ERLING BERNATEK and KRISTIAN VALEN

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

On two previous occasions [1,2] we have reported on the ozonolysis of *p*-benzoquinone and discussed some of the possible reaction paths. Anomalous ozonolysis and/or rearrangement of normal ozonides occurred to a large extent. This was to be expected since in quinone two carbonyl groups are conjugated with the double bonds attacked by ozone.

The experimental procedure employed — being a batch procedure — had the drawback that the primary reaction products were in contact with ozone for a comparably long time. Consequently some of the isolated products could have been formed by further oxidation. In order to avoid this and especially to investigate closer the formation of a monozonide and its decomposition products, we adopted a counter-current procedure similar to that of Pummerer and Richtzenhain [3] which allowed a brief contact between the quinone solution and ozone, rapidly followed by hydrolysis.

Previous experiments with the batch procedure has shown that even if quinone was present in excess to the amount of ozone required for mono-ozonolysis only minor amounts of reaction products originating from cleavage of one double bond were found. It thus seems that secondary reactions proceed about as fast as the initial ozonolysis.

In Table 1 is summarised some of the relationships between the amount of applied ozone per mole of quinone, % reacted quinone and consumed ozone as found by the counter-current method. Finally the theoretically possible amount of monozonide (or products from mono-ozonolysis) in moles per mole of quinone is calculated.

When about one mole of ozone is applied per mole of quinone 65 % of the latter is attacked. A substantial part of the quinone must therefore have consumed two molecules of ozone. From the last column it is clear that mono-ozonolysis occurs in increasing amounts with decreasing ozone-quinone ratio.

Table 1.

Run	Moles O_3 / quinone	% Reacted quinone	% Reacted O_3	Moles monozonide / quinone
1	2.17	95.4	86.8	0.06
2	1.74	83.8	88.2	0.17
3	1.43	79.4	97.7	0.24
4	1.05	67.2	~ 100	0.44
5	1.01	65.0	100	0.45
6	0.98	60.3	100	0.37
7	0.82	56.9	100	0.56
8	0.80	57.5	100	0.61

Oxidation of the aqueous decomposition solution with hydrogen peroxide and analysis for maleic acid constituted another method to determine the degree of mono-ozonolysis. For run 7 and 8 it was found *ca.* 0.20 moles of maleic acid per mole of reacted quinone, the calculated amount of mono-ozonolysis products being *ca.* 0.6 mole. This large difference must have significance and is most likely due to the inability of some mono-ozonolysis products to form maleic acid on oxidation with hydrogen peroxide. It must be remarked, however, that maleic acid is not entirely stable towards hydrogen peroxide under the prevailing conditions and the obtained results are therefore probably rather low.

In the later runs we always kept the ratio between ozone and quinone close to 0.80. The aqueous decomposition solution had an acidic reaction, gave a precipitate with 2,4-dinitrophenylhydrazine and reduced Tollens reagent. Oxalic and maleic acids could not be detected. Formic acid was produced in an amount of 0.78 moles per mole of reacted quinone. Some fractionation of the carbonyl compounds could be achieved by means of a weakly basic ion-exchange column. Neutral components were eluted with water and acidic components with 5 % aqueous formic acid.

The neutral eluate contained glyoxal as identified through its *p*-nitrophenylhydrazone. Mesoxalic dialdehyde was not present in detectable amounts.

From the acidic eluate was precipitated a complex mixture of dinitrophenylhydrazones. This could be separated into three fractions: Glyoxylic acid dinitrophenylhydrazone (from one run only), some red crystals (DNP I) and yellowish crystals (DNP II). The infra-red solid-state spectra of DNP I and II were very similar differing mainly in the relative intensities of some bands. Absorptions at 1 720 cm^{-1} and 1 425 cm^{-1} probably represent a free carboxyl group while the presence of an unreacted carbonyl group seems less probable but cannot be entirely excluded. In composition, however, the two derivatives differ somewhat and none of them corresponds very closely to a rational formula. Closest comes DNP II to the formula $C_{17}H_{12}N_8O_{10}$ which could represent a bis-dinitrophenylhydrazone of a conceivable mono-ozonolysis product $CHO-CH=CH-CO-COOH$. Our only possible conclusion for the present is therefore that in the acidic eluate there are carbonyl compounds resulting from mono-ozonolysis and of a rather complicated nature.

Experimental. Ozonisation procedure. The ozonisation apparatus was essentially that of Pummerer and Richtzenhain [3] with only minor modifications. The reaction column proper was 60 by 2 cm and filled with Fenske helices. Surrounding this was a cooling mantle, during the runs filled with ice. *p*-Benzoquinone in chloroform was trickled down the reactor while ozone was let in at the bottom. After ozonisation the reaction mixture passed into a flask containing continously agitated water. A liquid seal prevented ozone from entering the decomposition vessel. After completion of the ozonisation the apparatus was rinsed briefly with chloroform.

Ozone in the oxygen from the ozone generator and in the effluent gases from the counter-current reactor was determined by absorption in neutral potassium iodide and titration with standard thiosulphate after acidification.

In all the experiments the rate of flow of ozonised oxygen was kept constant at 20 l/h which gave 1.68 g O_3/h. Variations in experimental procedure was therefore effected through varying the concentration of *p*-benzoquinone in chloroform and the flow of this solution.

After ozonisation and decomposition the liquid layers were separated and the chloroform phase exhaustively extracted with water. Some unreacted *p*-benzoquinone went into the water and the combined aqueous extracts were therefore extracted with a small amount fresh chloroform. The unreacted quinone was determined iodometrically in the combined chloroform solutions.

Maleic acid. The aqueous decomposition solution was evaporated to a small volume and barium chloride added. In none of the runs thus investigated any barium maleinate separated. Due to a slight solubility of this salt a minor amount of maleic acid may have escaped detection.

Decomposition solutions from runs 7 and 8 were mixed with 3 ml 30 % hydrogen peroxide and evaporated to dryness on a water-bath. The residues consisted of white, somewhat sticky crystals which were indentified as maleic acid. In the runs 0.935 g and 1.153 g *p*-benzoquinone reacted with ozone and gave 199 mg and 228 mg maleic acid, respectively. Controls by precipitating the dissolved residues with barium chloride were satisfactory.

Formic acid. Aliquots of the decomposition solutions were distilled *in vacuo* to dryness. The distillate was taken up in standard sodium hydroxide and backtitrated with hydrochloric acid. The capillary was connected to a sodium hydroxide-asbestos tube to prevent the entrance of carbon dioxide. Substituting the air in the distilling apparatus with nitrogen did not alter the titration values significantly.

Ion-exchange chromatography. The decomposition solution was passed through a column of De-acidite G and washed with water. The neutral washings which reduced ammoniacal silver solution were combined and precipitated with *p*-nitrophenylhydrazine. This precipitate was extracted with glacial acetic acid and recrystallised from nitrobenzene m. p. *ca.* 270° (decomp.). Through its infra-red spectrum it was identified as glyoxal *p*-nitrophenylosazone. Further elution was performed with 5 % formic acid when more aldehydic material appeared. The acidic eluate was precipitated with 2,4-dinitrophenylhydrazine and the material extracted with boiling water. In one case there separated yellow needles from the aqueous extracts, m. p. 190°, identified as glyoxylic acid dinitrophenylhydrazone. The residue from the extraction was partially soluble in hot glacial acetic acid. From the acetic acid separated red crystals, m. p. 226° (decomp.). (Found: C 43.9; H 3.2; N 20.6.) The insoluble part was recrystallised from nitrobenzene. Yellowish crystals, m. p. 255° (decomp.). (Found: C 41.6; H 2.7; N 22.4. Calc. for $C_{17}H_{12}N_8O_{16}$: C 41.8; H 2.5; N 22.9.)

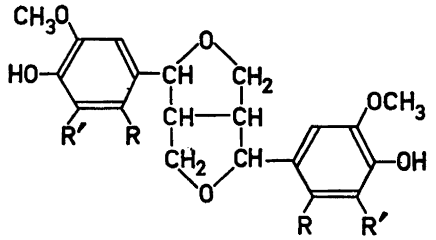
The Structure of Dinitropinoresinol

JARL GRIPENBERG and INGEGERD PETRELL

Department of Chemistry, Finland Institute of Technology, Helsingfors, Finland

Some years ago the preparation of dinitropinoresinol was reported [1]. Its structure was not determined, but it was assumed to be I in analogy with dinitropinoresinol dimethylether. Dinitropinoresinol gives, however, upon treatment with nitric acid 4,6-dinitroguaiacol, m.p. 122°, and must therefore have structure II



I R = NO_2; R′ = H
II R = H ; R′ = NO_2

The aim of the earlier work [1] was the degradation of the aromatic rings of pinoresinol to carboxylic groups. We have now attempted to achieve this by ozonolysis (*cf.* Ref.[2]), but the desired acid could not be obtained. The only products that could be identified were oxalic acid and in some experiments where the reaction time was kept very short, maleic acid.

In connection with this work we had to prepare relatively large amounts of pinoresinol and we found that when the crude pinoresinol from the potassium salt [3] was treated with dioxan it immediately crystallised. The crystals contain 1 molecule of dioxan, which can readily be removed by heating under vacuum on a boiling water bath. This method of purification is more convenient than the customary one *via* the acetate [3].

The Inverse Relationship between Tryptophan and Hydroxyproline in Animal Tissues

OLLE DAHL

Scan's Centrallaboratorium, Malmö, Sweden

During recent years several contributions have increased our knowledge of the amino acid composition of proteins and in particular their content of essential amino acids.

Tryptophan is an essential amino acid typical of high-quality animal proteins and may often, although not always, be considered a special feature of this kind of protein. Blood protein is an example of a protein high in tryptophan but low in the essential amino acid methionine [1]. This is in contrast to, for instance, striated muscular tissue, milk, and egg protein.

An amino acid typical of the low-quality protein present in connective tissue is hydroxyproline, the assessment of which has acquired increased importance over the past few years. Since connective tissue is practically devoid of tryptophan and, on the other hand, striated muscular tissue contains very little hydroxyproline, there is an indication of an inverse relationship between tryptophan and hydroxyproline. The present study was undertaken to assess, whether this relationship is a general characteristic of animal tissues or is subject to limitations. In particular, unstriated muscular tissue, *i.e.* the tissue found in stomach, intestine etc., was investigated.

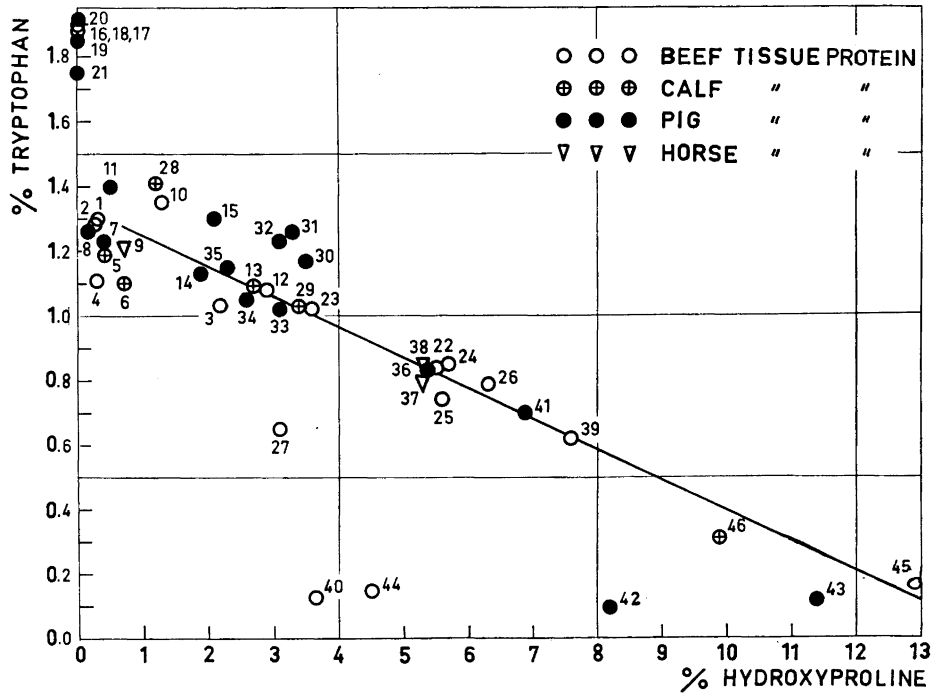

Fig. 1. Relation between the content of tryptophan (T) and hydroxyproline (H) in various animal tissues. The proportions of the two amino acids are given as percentages of total protein (N × 6.25).

The regression line drawn, T = −0.0950 · H +1.345 has been calculated on the basis of all the data except those indicated in the text; coefficient of correlation −0.949, significant at more than the 99.9 % level.

(1) From the last rib to the second lumbar vertebra.
(2) From the last dorsal vertebra to the second lumbar vertebra.
(3) Between the last three (12th to 14th) dorsal vertebra.
(4) Residue after separation of blood into plasma and corpuscles [proportion of plasma to corpuscles 7:3 (beef blood) and 6:3 (pig blood), respectively].
(5) Commercial fatty raw material containing intestinal glands.

This kind of tissue, which is of a considerable interest from a nutritional and also physiological point of view, has not been previously investigated for its tryptophan and hydroxyproline contents.

Tryptophan was determined on the minced tissue without previous hydrolysis according to the widely used method of Bates essentially as described by Graham *et al.*[3] Hydroxyproline was assessed according to the method of Neuman and Logan as modified by Stegemann [3]. This was compared with the modification of Lollar [4] for different kind of tissues. The agreement between the methods was good. The results appear in Fig. 1.

With a few exceptions a close linear, negative correlation was found to exist between the contents of tryptophan and hydroxyproline. The regression line was calculated on the basis of all the data except those of the blood and blood fractions (samples Nos. 16—21), which are very high in tryptophan but contain no hydroxyproline, and the samples No. 27 (glands), Nos. 40 and 42 (cracklings from fatty tissue), and No. 44 (*ligamentum nuchae*).

The inverse relationship between tryptophan and hydroxyproline could best be explained by assuming tryptophan to be related to true cellular, and hydroxyproline to connective tissue content. This point is being investigated, as is the unforeseen difference in hydroxyproline between young and old animals (*cf.* samples Nos. 45 and 46).

The contents of tryptophan and hydroxyproline in unstriated tissues (Nos. 28—38) are intermediate. This is, among other

things, of interest from a nutritional point of view, since stomachs, intestines, and udders are used by some food manufacturers either alone or mixed with other ingredients in various chopped meat products.

The Solubility and the Salt Sensitivity of Yeast D- and L-Lactic Cytochrome c Reductase

AGNAR P. NYGAARD

Johan Throne Holst's Institutt for Ernæringsforsking, Blindern, Oslo, Norway

Homogenates of aerobic yeast have been found to contain D- and L-lactic cytochrome c reductase in the ratio 1:2 [1,2]. Using our extraction method / (15—30°), mainly the L-enzyme was solubilized. At low temperatures (0—5°) both enzymes were obtained in the particulate fraction. Half or more of the L-activity was readily extracted from the particles at 30° with 0.2 M disodium phosphate, whereas the D-enzyme remained insoluble. The extracted particles contained D- and L-lactic cytochrome c reductase in the ratio 1:1. Further mechanical desintegration with ballotini beads gave rise to soluble D-lactic cytochorme c reductase; very little of the L-enzyme was obtained. Complete extraction was not achieved for any of the two enzymes. It is concluded that one part of the L-activity was more firmly bound to the particulate fraction than the other.

Following the described method [3], three fractions of lactic cytochrome c reductase were obtained [2,4]. Fractions I, II, and III were eluted in that order from a N,N-diethylaminoethyl-cellulose column. Fractions I and II were specific for L-lactic acid. Fraction III was D-specific (D-LDH III). However, small amounts of a L-specific enzyme has now been found in some of the fractions III (L-LDH III).

The D- and the L-enzyme of the cell homogenate were both salt sensitive. The D-enzyme was more salt sensitive than the isolated D-LDH III [2]. The L-enzyme was inhibited 50 % when the phosphate concentration (pH 7.1) was increased from 0.01 to 0.08 μ.

The activity of fractions I and II, which represented most of the L-LDH activity of the purified solution, was quite the same in phosphate of ionic strength 0.01 and 0.08. In contrast, both D- and L-LDH III were inhibited 70—90 % when the buffer concentration was increased from μ 0.01 to 0.08. The inhibition of L-LDH III was the same with low and high concentrations of cytochrome c, whereas the inhibition of D-LDH III was less at high concentrations of the acceptor [2].

The strong effect of salt on L-LDH of the cell homogenate suggests that fair amounts of the salt sensitive enzyme is present in the cell. In this connection it is interesting that L-LDH obtained by the method of Boeri *et al.*[6] is very salt sensitive.

To the authors' knowledge, the effect of salts on D- and L-LDH III is stronger than for any other enzymes described. From other relationships D-lactic cytochrome c reductase has been proposed as intermediate in the formation of the L-enzyme [1,5].

D- and L-LDH III were eluted together with ribonucleic acids [7]. Furthermore, the enzymes precipitated together with nucleic acids when the eluate was dialyzed against water. A charge aggregate between protein and nucleic acid might explain both the salt sensitivity and the high negative charge which these two enzymes have available to the anion exchanger.

On the Biosynthesis of the Pigments of *Penicillium islandicum* III

STEN GATENBECK

Institute of Biochemistry, University of Lund, Sweden

PETER BARBESGÅRD

Institute of Genetics, University of Copenhagen, Denmark

In the studies of the biosynthesis of anthraquinones, approximately 50 UV-induced mutants of *Penicillium islandicum* Sopp N.R.R.L. 1036 have been isolated, in the hope that some of the mutants would accumulate an intermediate metabolite because a step in the reaction chain leading to the formation of anthraquinones had been blocked by mutation. The mutants investigated were selected on the basis of their visually abnormal pigment production as compared with the wild type, and a series of strains was obtained varying in colour from pigment-free to dark brown. Paper chromatographic analysis of the pigments of the mycelia and of the aromatic substances occurring in the culture media showed that only variations with respect to the quantities of the normally produced individual substances had been induced by the UV treatment. In the pigment-free mutants no aromatic compounds were detectable with the reagents used.

The principal anthraquinone pigments produced by *P. islandicum* as skyrin, rubroskyrin, iridoskyrin and islandicin, are formed from acetate units by head to tail couplings [1,2] and, despite their close structural relationships, they are not interconvertible *in vivo* but seem to be derived from a common prearomatic stage. The failure to block the formation of any one of these pigments by mutation is in accordance with related findings, published elsewhere [3]. Evidently, the only way to effect a change of the aromate production is to interfere with the acetate condensing enzyme(s) resulting in a general blocking of the aromate production. Consequently, the biogenesis of the anthraquinones should not take place by stepwise formations of defined intermediates such as benzene derivatives, but be dependent throughout on the participating of activated acetate. The increased production of individual pigments has been utilized in investigations published previously [4,5].

Experimental. *Preparation of the mutants.* The culture media used were Czapek-Dox solution (minimal medium) and Czapek-Dox solution supplemented with hydrolyzed casein, B-vitamins, nucleic acid hydrolyzate, Difco malt extract and yeast extract (complete medium). Both media were adjusted to pH 4.5 and 2.5 % Difco agar was added. A suspension of condiaspores in sterile, distilled water was irradiated with a Westinghouse steril-lamp, and then filtered through sterilized filter paper to remove spore clusters and mycelia fragments. The irradiation was done in a small, open petri dish with 5 ml of spore suspension with 10^5 spores per ml. The distance from the UV-lamp was 11.5 cm and the spores were irradiated for 90 sec. After dilution to 10^4 spores per ml, 0.1 ml of the suspension was plated on each of 50 petri dishes containing complete medium. The untreated control was plated on 10 petri dishes, 50 spores per plate. After having grown for 6 days at 28°C, the colonies on the plates were counted, and it was found that the irradiated plates showed, on the average, 1 % survival of the conidiaspores. Among the treated colonies, 50 were selected, which on visual inspection showed an abnormal pigmentation as compared with the wild type. They were transferred to slants of complete medium and each strain was re-isolated by plating on complete medium. From a single colony, spores were transferred to minimum as well as to complete medium to decide whether some of the strains showed different pigmentation when cultivated on the two media. This was not the case.

All the re-isolated strains were grown in culture flasks containing 150 ml of Czapek-Dox liquid medium, two flasks for each strain. These cultures were utilized in the chemical investigations described below.

Chemical analysis of the mutants. The cultures were harvested after two and three weeks' growth, respectively, and the mycelia were separated from the media by filtration. Each mycelium was mechanically disintegrated in 25 ml of acetone, and after centrifugation, 0.5 ml of the supernatant was developed on a paper chromatogram with benzene-formic acid (2 %) (10:1) as the solvent. The pigments were recognized by their R_F values and colour reactions with alcoholic magnesium acetate.

The relative quantities of the different pigments were visually estimated by a direct comparison with the amounts produced by the wild type.

The culture medium was extracted with ether, the residue after evaporation redissolved in acetone, and one third of the solution used for paper chromatographic analysis. After running in a solvent consisting of chloroform-methanol-formic acid (4 %) (10:1:1) the paper was sprayed with alcoholic ferric chloride, dibromoquinone chloroimide, diazotized sulfanilic acid and phosphomolybdic acid. The culture media of the mutants, with the exception of the pigment-free ones, contained in varying amounts the aromatic compounds normally produced by the wild type.

The only difference observed between the cultures grown for three weeks and two weeks, respectively, was a higher production of the substances investigated in the former.

A Note on Proton Magnetic Resonance Spectra of Alcohols in Carbon Tetrachloride

STURE FORSÉN*

Research Group for NMR, Division of Physical Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

In the high resolution proton magnetic resonance (PMR) spectra of the pure forms of most primary and secondary alifatic alcohols, the signal from the OH-protons are obtained as multiplets. When such an alcohol, *e.g.* ethanol, is diluted with a nonpolar solvent such as *cyclo*hexane or *per*--deuterocyclohexane, the OH-triplet is found to persist down to concentrations where the noise level no longer permits observations. The addition of small amounts of carbon tetrachloride to pure ethanol, however, changes the triplet into a sharp singlet [1]. This is rather unexpected since carbon tetrachloride is generally assumed to be about as nonpolar as *cyclo*hexane. We have, however, found that if commercially available carbon tetrachloride of *pro analysi* quality, which in mixtures with ethanol produces OH-singlets, was first washed with a 0.01 M solution of sodium hydroxide and then with three or four portions of water and thereafter kept away from direct or indirect sunlight, the addition of this product to a purified alcohol, *e.g.* ethanol, did not affect the splitting of the OH-signal, *i.e.* this signal was displayed as a triplet down to concentrations where the noise level no longer permitted direct observations (mole fraction alcohol *ca.* 0.02). In Fig. 1 the PMR spectrum at mole fraction alcohol 0.1 is shown (*cf.* PMR spectrum in Ref.[1], p. 3).

Exposure of a mixture of ethanol and purified carbon tetrachloride (mole fraction alcohol 0.8) to ultraviolet light or sunlight 5—30 sec. was, however, found to be sufficient to produce a sharp OH-singlet from the triplet. The extreme sen-

sitivity towards hydrochloric acid of the shape of the OH-signal from ethanol, as shown by Arnold [2], would indicate that small amounts of hydrochloric acid are formed photolytically in the solution and that this is the cause of the observed alteration in the OH-signal. Further evidence for this assumption is the fact that careful addition of minute amounts of alkali to a irradiated mixture of ethanol and carbon tetrachloride brought back the OH-triplet which, upon further irradiation of the mixture, again turned to a singlet.

In addition, another observation of interest was made. When a small amount of water was added to a mixture of ethanol and carbon tetrachloride (mole fraction ethanol 0.85; water 0.05) a separate water line could be seen in the PMR spectrum to the high field side of the OH-triplet. The mixture was then irradiated for a few seconds in ultraviolet light and the PMR spectrum now revealed a complete coalescence of the water and OH-signals into one broad signal. This coalescence is normally only observed at much higher concentrations of water (mole fraction water 0.40—0.50) [3]. Careful addition of a small amount alkali made the coalesced line again separate into a OH-triplet and a separate water line. Repetition of the procedure revealed the coalescence and the separation to be completely reversible. The observation is clearly in line with the suggestion that hydrochloric acid accelerates the proton exchange in ethanol.[2]

From the observation in Ref.[1] and our own dilution experiments with commercial, unwashed carbon tetrachloride, it would appear that small amounts of hydrochloric acid are usually present in the commercial product (for an exception see Ref.[4]).

Carbon tetrachloride purified according to above should be a convenient nonpolar solvent when spin-coupling effects are to be studied in dilute solutions in which the effect of the proton exchange between the OH-groups is reduced.

The spectrometer used in this work is a Varian 4300 B NMR Spectrometer operated at 40 Mc and equipped with a V-K 3506 Flux Stabilizer.

Adenosine Triphosphatase Activity in Chloroplasts

J. S. C. WESSELS

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

and

HERRICK BALTSCHEFFSKY

Wenner-Gren Institute, University of Stockholm, Sweden

The ATP-ase * activity of isolated spinach chloroplasts has been studied. Two distinct systems with ATP-ase activity are observed in this material. They are different in their pH optima and their response to $MgCl_2$ and chlorpromazine.

At pH 7.5 the ATP-ase activity is rather constant in different chloroplast preparations. It is strongly stimulated by $MgCl_2$ and inhibited by chlorpromazine. The pyrophosphatase activity at pH 7.5 is very low under the conditions of the ATP-ase activity measurements. Thus it can be excluded that the release of phosphate from ATP at pH 7.5 involves a liberation and a subsequent hydrolysis of inorganic pyrophosphate. Dinitrophenol does not stimulate the ATP-ase activity, either in intact or in broken chloroplasts.

At pH 5.5 a variable ATP-ase activity is found. It is unaffected by $MgCl_2$ and chlorpromazine and parallels the pyrophosphatase activity at this pH.

Results of kinetic experiments on the Mg^{++}-stimulated ATP-ase activity of spinach chloroplasts are given.

It is discussed whether the ATP-ase activity of chloroplasts has a functional relationship to the enzymatic mechanism by which phosphorylation of ADP is coupled to electron transport during light-induced phosphorylation.

ATP-ase activity becomes evident in rat liver mitochondria when either DNP is added or their structure is disrupted in some way, *e.g.* by making the mitochondrial suspension hypotonic, by ageing, or by treatment with detergents [1–7]. Addition of Mg^{++}-ions stimulates the ATP-ase activity of disrupted mitochondria. DNP-induced ATP-ase activity is obtained in mito-

* Abbreviations: AMP, adenosine monophosphate; ADP, adenosine diphosphate; ATP, adenosine triphosphate; ATP-ase, adenosine triphosphatase; FMN, flavin mononucleotide; FAD, flavinadenine dinucleotide; DNP, 2,4-dinitrophenol; P, inorganic phosphate; PP, inorganic pyrophosphate; Tris, tris(hydroxy-methyl)-aminomethane.

chondria when they are in an "intact" state and disappears when the mitochondria lose their structural integrity. The disappearance of the "intact" mitochondrial structure, involving a loss of the capability to carry out oxidative phosphorylation and of the stimulation of ATP-ase activity with DNP, is concomitant with the development of Mg^{++}-stimulated ATP-ase activity [7].

ATP-ase activity of animal mitochondria is supposed to be a reversal of part of the reaction sequence involved in ATP formation by oxidative phosphorylation [5, 7-15]. The Mg^{++}-activated ATP-ase may involve a one-step transfer of phosphate from ATP to an unknown carrier, followed by a hydrolysis of the compound so formed, whereas the DNP-activated ATP-ase may consist of two consecutive transfer steps, one identical with that involved in the Mg^{++}-activated ATP-ase, and a second yielding a high-energy compound which is subsequently split due to the presence of DNP [7].

Arnon [16] has reported that chloroplasts seem to be rather free of ATP-hydrolyzing enzymes. Avron and Jagendorf [17-18] did not observe any ATP-ase activity in chloroplasts under a large variety of conditions. Baltscheffsky [19], on the other hand, has recently shown that chloroplasts exhibit ATP-ase activity in the presence of added Mg^{++}-ions.

In this paper detailed results of our studies on the ATP-ase activity of spinach chloroplasts are presented. Attention has been directed towards the possibility that this activity is an expression of reversed reactions in light-induced phosphorylation and that information may be obtained about a possible similarity between the mechanisms for generation of ATP in oxidative phosphorylation and in light-induced phosphorylation.

METHODS

Broken spinach chloroplasts were prepared according to the method of Wessels [20]. As no significant difference in ATP-ase activity was found between once washed and four times washed chloroplasts (the activity decreased only 10 % after four washings), they were washed only once. The chlorophyll content of the chloroplast suspension was determined by the method of Arnon [21].

ATP-ase activity was measured by estimating colorimetrically the inorganic phosphate liberated from ATP. The incubation medium, containing ATP and $MgCl_2$ as indicated in the individual experiments, and distilled water to bring the volume up to 1.5 ml, was warmed to 30°. Then 1 ml of a suspension of chloroplasts in 0.1 M Tris buffer, previously warmed rapidly to 30°, was added with stirring. The contents of the tube were incubated in the dark at 30°. The reaction was stopped by the addition of 2 ml of the reaction mixture to 4 ml of ice-cold 9 % trichloroacetic acid. After filtering an aliquot (3 ml) was taken for the estimation of inorganic phosphate by the method of Fiske and Subbarow [22]. The amount of phosphate split from ATP was determined by subtracting (from the values obtained) the phosphate content of a reaction mixture of the same composition, in which the reaction had been quenched directly after the mixture had been made up.

In the pyrophosphatase activity measurements, ATP was replaced by sodium pyrophosphate. Both the ATP and the pyrophosphate solutions were brought to the pH desired in the experiment before being added to the reaction mixture.

ATP, ADP, AMP, FMN and FAD were products of the Sigma Chemical Company.

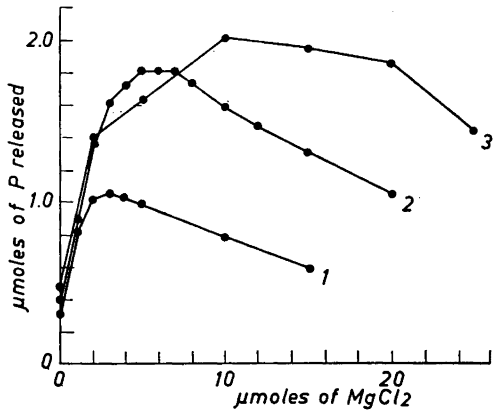

Fig. 1. ATP-ase activity as a function of $MgCl_2$ concentration. The reaction mixture contained, in addition to $MgCl_2$, 5 µmoles of ATP (1), 10 µmoles of ATP (2) or 20 µmoles of ATP (3), and 1 ml of a suspension of chloroplasts in 0.1 M Tris buffer pH 7.5, containing 0.5 mg chlorophyll. Reaction time, 20 min at 30°.

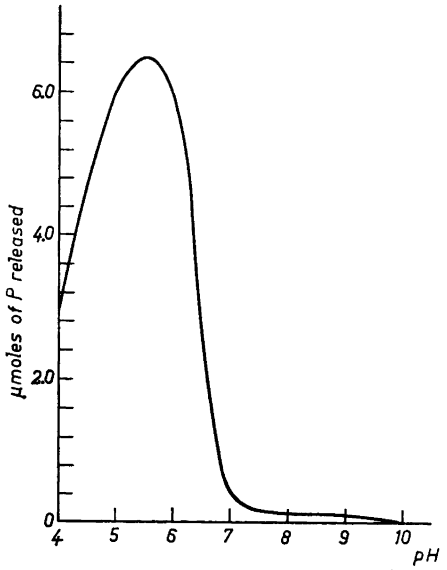

Fig. 2. Effect of pH on ATP-ase activity in the absence of $MgCl_2$. Reaction mixture: 10 µmoles of ATP and 1 ml of a suspension of chloroplasts in 0.1 M buffer, containing 0.5 mg chlorophyll. Reaction time, 15 min at 30°.

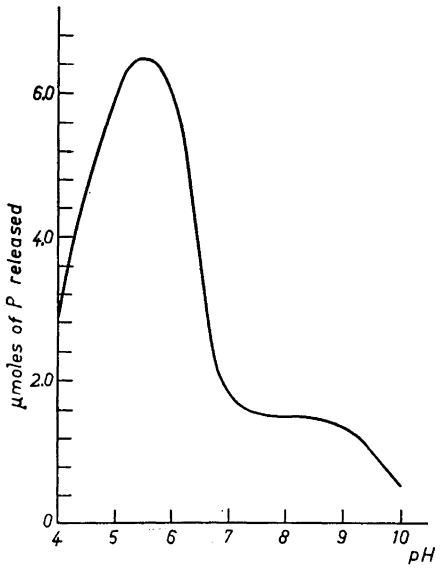

Fig. 3. Effect of pH on ATP-ase activity in the presence of $MgCl_2$. Reaction mixture: 10 µmoles of ATP, 5 µmoles of $MgCl_2$ and 1 ml of a suspension of chloroplasts in 0.1 M buffer, containing 0.5 mg chlorophyll. Reaction time, 15 min at 30°.

RESULTS

Fig. 1 confirms the finding of Baltscheffsky [19] that isolated spinach chloroplasts exhibit a Mg^{++}-dependent ATP-ase activity at pH 7.5. The optimal $MgCl_2$ concentration is 0.5—0.7 times the concentration of ATP.

Figs. 2 and 3 show the dependence of ATP-ase activity on pH in the absence and in the presence of added $MgCl_2$. As buffers we used glycine-NaOH (pH 8.5—10), Tris-HCl (pH 7—9), Tris-maleate-NaOH (pH 5.2—8.6) and phthalate-NaOH (pH 4—6). If possible, measurements were performed with two or more different buffers at each pH so as to prevent errors due to the effect of the buffer on the ATP-ase activity.

It must be stressed that the height of the maximum at pH 5.5 was found to be variable, ranging from one to six times the activity at pH 7.5. The amount of ATP split per unit time per unit chlorophyll at pH 7.5, on the other hand, was nearly constant, *viz.* 8—12 μmoles/h/mg chlorophyll. The ATP-ase activity at pH 5.5 was particularly high in chloroplasts from spinach grown in a greenhouse. The maximum at pH 5.5 cannot be ascribed to an impurity of the particular chloroplast preparation, because it did not disappear either after more washings or after digitonin treatment of the chloroplasts. In the latter case the chloroplasts were suspended in a 1 % digitonin solution. The suspension was allowed to stand for 30 min at 0°, and was then centrifuged for 7 min at 1 000 × *g*. The residue was discarded and the supernatant centrifuged for 30 min at 20 000 × *g*. The precipitated chloroplast fragments

Table 1. ATP-ase activity of two chloroplast preparations having extremely high (A) and extremely low (B) activity at pH 5.5 as compared to the ATP-ase activity at pH 7.5.

Chloroplast preparation	Additions (μmoles), unless otherwise indicated	pH	μmoles of P released
A	10 ATP	5.5	8.4

Chlorophyll concentration, 0.5 mg per sample. Reaction time, 15 min at 30°.

were resuspended in buffer and diluted to a concentration of 0.5 mg of chlorophyll/ml.

The ATP-ase activities at pH 5.5 and pH 7.5 differed with respect to their response to $MgCl_2$ and chlorpromazine. At pH 5.5 both $MgCl_2$ and chlorpromazine had only a slight effect, especially when the activity was high. At pH 7.5, on the other hand, the ATP-ase activity could be raised 4—10 fold by adding $MgCl_2$ to the reaction mixture. Addition of chlorpromazine resulted in inhibition at pH 7.5, which could not be reversed by FMN or FAD. In Table 1 two extreme types of results obtained with various chloroplast preparations are given:

a) High ATP-ase activity at pH 5.5, showing low response to $MgCl_2$ and chloropromazine as compared to the ATP-ase activity at pH 7.5.

b) Low ATP-ase activity at pH 5.5, showing stimulation by $MgCl_2$ and inhibition by chlorpromazine in the presence of $MgCl_2$.

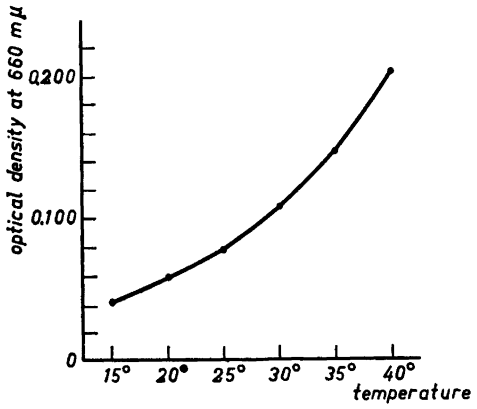

Fig. 4. Effect of temperature on ATP-ase activity (expressed as optical density at 660 mμ). The reaction mixture contained: 10 μmoles of ATP, 5 μmoles of $MgCl_2$ and 1 ml of a suspension of chloroplasts in 0.1 Tris buffer pH 7.5, containing 0.5 mg chlorophyll. Reaction time, 20 min.

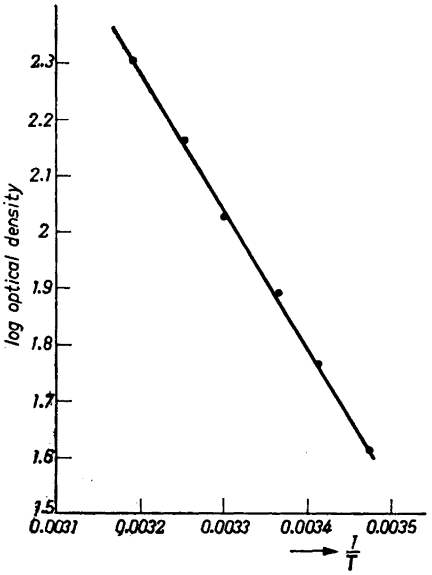

Fig. 5. Arrhenius plot of data of Fig. 4.

Other chloroplast preparations gave results intermediate between those represented in Table 1. The results indicate that chloroplasts contain two enzymes (or enzyme systems) having ATP-ase activity. One enzyme (system) is present in chloroplasts in a rather constant amount, has a broad pH optimum, is strongly stimulated by $MgCl_2$ and inhibited by chlorpromazine. The content of the other enzyme (system) varies in different chloroplast preparations. This enzyme (system) has a pH optimum of 5.5, is not stimulated by $MgCl_2$ and is resistant to chlorpromazine.

As shown in Table 2, ATP-ase activity at pH 7.5 is inhibited by AMP, fluoride, *p*-chloromercuribenzoate, azide, atebrin, arsenate and phosphate. The inhibition by ADP is variable. $(NH_4)_2SO_4$, DNP and KCN had no effect, whereas addition of FMN caused a slight stimulation. A marked stimulation of the ATP-ase activity was observed upon addition of dithionite to the reaction mixture.

Chloroplasts were found to release inorganic phosphate from ADP, but not from AMP. The liberation of inorganic phosphate from ADP at pH 7.5, like the splitting of ATP, was stimulated by $MgCl_2$ and inhibited by chlorpromazine. The release of inorganic phosphate from ADP, the rate of which varied between 20 and 80 % of that of the splitting of ATP, is probably due to the myokinase activity of the chloroplasts. Mazelis [23] has shown that spinach chloroplasts have a high myokinase activity.

It should be noted that with whole chloroplasts similar results were obtained as with broken ones, and that no stimulating effect of DNP could be observed.

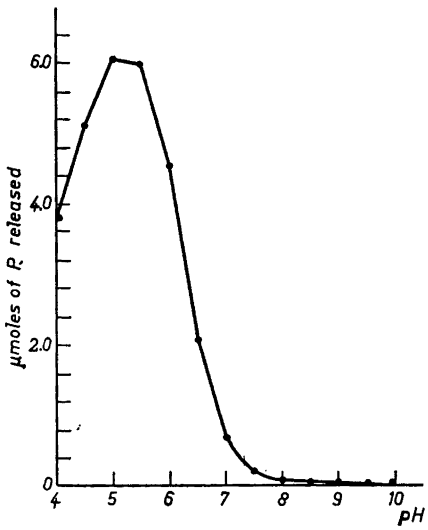

Fig. 6. Effect of pH on pyrophosphatase activity in the absence of $MgCl_2$. Reaction mixture: 10 µmoles of sodium pyrophosphate and 1 ml of a suspension of chloroplasts in 0.1 M buffer, containing 0.5 mg chlorophyll. Reaction time, 15 min at 30°.

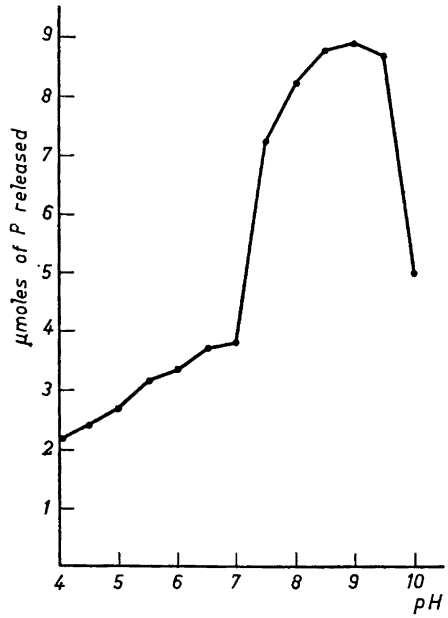

Fig. 7. Effect of pH on pyrophosphatase activity in the presence of $MgCl_2$. Reaction mixture: 10 µmoles of sodium pyrophosphate, 50 µmoles of $MgCl_2$ and 1 ml of a suspension of chloroplasts in 0.1 M buffer, containing 0.5 mg chlorophyll. Reaction time, 10 min at 30°.

An increase in temperature resulted in an acceleration of ATP-ase activity (Fig. 4). Fig. 5 shows that a straight line is obtained on plotting the logarithm of the reaction velocity against the reciprocal of the absolute temperature. The value of the activation energy was calculated from the slope and was found to be about 11 500 cal over the temperature range studied.

In order to test whether the cleavage of ATP could be due to apyrase activity, we have investigated the pyrophosphatase activity of spinach chloroplasts at different pH's. Chloroplasts were found to contain two pyrophosphatases which can be distinguished by pH optima and response to $MgCl_2$. One enzyme has a pH optimum of 5.0—5.5 and does not require Mg^{++}. The other enzyme has a pH optimum of 8.5—9.0 and a requirement for high concentrations of added $MgCl_2$ (Figs. 6 and 7; Table 3). These results resemble those of Naganna *et al.*[24] who have reported that green leaves contain both an acid pyrophosphatase and an alkaline pyrophosphatase, the latter being active only in the presence of $MgCl_2$. The pyrophosphatases were found to be insensitive to 5×10^{-4} M chlorpromazine.

The pyrophosphatase activity at pH 5.5 was sufficient to account for the ATP-ase activity of chloroplasts at this pH. This possibility is supported by

Table 3. Pyrophosphatase activity of spinach chloroplasts.

Additions (μmoles), unless otherwise indicated	pH	μmoles of P released
10 ATP	5.5	6.1

10 PP *	5.5	6.5

Chlorophyll concentration, 0.5 mg per sample.

our finding that there exists a correlation between pyrophosphatase activity and ATP-ase activity at pH 5.5 in different chloroplast preparations. As a rule the amount of inorganic phosphate released from pyrophosphate was found to be about twice that split from ATP at pH 5.5. As shown in Table 3, addition of ATP did not increase the release of inogranic phosphate from pyrophosphate at pH 5.5.

At pH 7.5, however, the pyrophosphatase activity of spinach chloroplasts in the presence of 5 μmoles of $MgCl_2$ is much lower than the ATP-ase activity. The amount of inorganic phosphate formed by cleavage of pyrophosphate was found to be 10—20 % of the amount split from ATP by the same chloroplast preparation. This indicates that the splitting of ATP at pH 7.5 does not proceed by way of an apyrase, but is caused by a true ATP-ase activity.

KINETICS OF THE ATP-ase ACTIVITY AT pH 7.5

Fig. 8 represents the increase of inorganic phosphate as a function of time in a medium containing 10 μmoles of ATP, 5 μmoles of $MgCl_2$ and 1 ml of a suspension of chloroplasts in 0.1 M Tris buffer, pH 7.5, (0.5 mg chlorophyll). It

* 0.2 mg of chlorophyll per sample. Reaction time, 15 min at 30°.

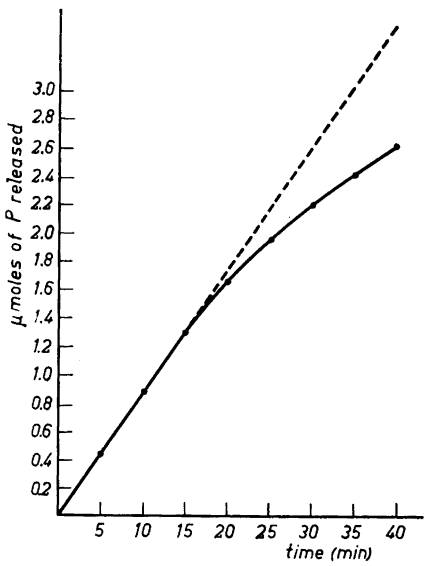

Fig. 8. ATP-ase activity as a function of time. The reaction mixture contained: 10 μmoles of ATP, 5 μmoles of $MgCl_2$ and 1 ml of a suspension of chloroplasts in 0.1 M Tris buffer pH 7.5, containing 0.5 mg chlorophyll. Temperature 30°.

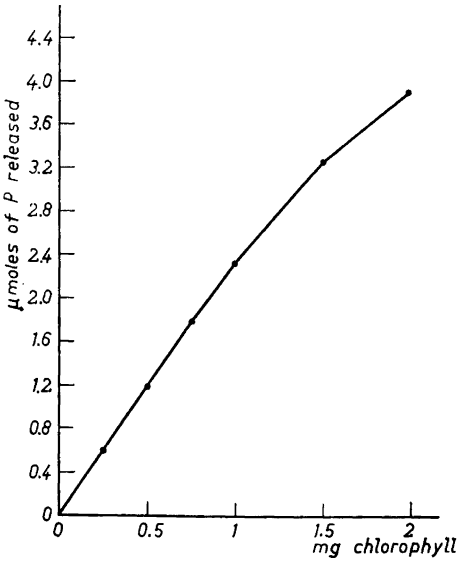

Fig. 9. Effect of varying the amount of chloroplast preparation on the ATP-ase activity. The reaction mixture contained: 10 μmoles of ATP, 5 μmoles of $MgCl_2$ and 1 ml of a suspension of chloroplasts in 0.1 M Tris buffer pH 7.5. Reaction time, 15 min at 30°.

is seen that the reaction rate is constant during the first 15 min of the reaction. In some preparations constancy has been obtained for more than 30 min. As shown in Fig. 9, the rate of ATP cleavage is proportional to the chlorophyll concentration up to 1 mg chlorophyll per sample.

In Fig. 10 the effect of ATP concentration on the velocity of ATP-ase activity is presented, showing the general type of curve obtained with enzyme reactions. For each concentration of ATP the optimal concentration of $MgCl_2$ was added, *viz.* μmoles ATP: μmoles $MgCl_2$ = 2:1. In Fig. 11 the reciprocal of the ATP concentration was plotted against the reciprocal of the rate of production of inorganic phosphate (expressed as optical density at 660 mμ) according to the method of Lineweaver and Burk [25]. The Michaelis constant was calculated from the intercept on the extended 1/S axis and was found to be 1.2×10^{-3} M.

Fig. 12 illustrates the effect of temperature on the maximum velocity (V_{max}) of ATP cleavage, which was calculated from the intercept on the $1/v$ axis of Lineweaver-Burk plots at different temperatures. When log V_{max} is plotted against the reciprocal of the absolute temperature ($1/T$) a straight line is obtained (Fig. 13). The value of the activation energy was calculated from the slope and was found to be 12 800 cal over the temperature range studied. We were unable to study the inhibition of ATP-ase activity by ADP

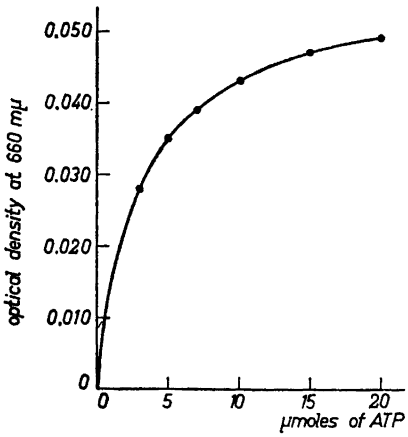

Fig. 10. Effect of ATP concentration on ATP-ase activity (expressed as optical density at 660 mμ). The reaction mixture contained, in addition to ATP, $MgCl_2$ (μmoles $MgCl_2$: μmoles ATP = 1:2) and 1 ml of a suspension of chloroplasts in 0.1 M Tris buffer pH 7.5, containing 0.5 mg chlorophyll. Reaction time, 10 min at 30°.

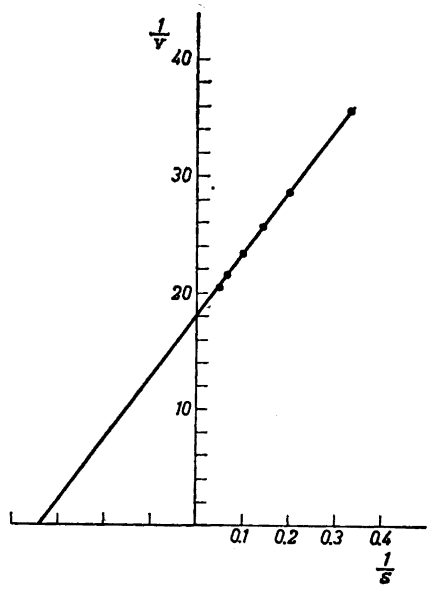

Fig. 11. Lineweaver-Burk plot of the data of Fig. 10. Reciprocal of ATP concentration (1/S) *vs.* reciprocal of optical density at 660 mμ (1/*v*).

kinetically, because of the myokinase activity of the chloroplasts. A kinetic investigation of the inhibition by AMP, on the other hand, was quite possible. Fig. 14 represents the rate of ATP cleavage as a function of ATP concentration in the presence and in the absence of 10 μmoles of AMP. When these data are plotted as 1/*v* against 1/S, as illustrated in Fig. 15, the slope but not the intercept with the 1/*v* axis is found to increase upon addition of AMP. This indicates that AMP inhibits the ATP-ase activity competitively.

DISCUSSION

Lehninger *et al.*[26] have postulated the following reaction scheme for oxidative phosphorylation in mitochondria:

$$\text{Carrier}_{red} + X \longrightarrow \text{Carrier}_{ox} \sim X + 2\ e \quad (1)$$

$$\text{Carrier}_{ox} \sim X + P \rightleftharpoons \text{Carrier}_{ox} + P \sim X \quad (2)$$

$$P \sim X + ADP \rightleftharpoons ATP + X \quad (3)$$

X is an enzyme capable of undergoing reversible phosphorylation. This type of scheme is rather widely accepted, at least as a framework for a general reaction mechanism (recently, however, the necessity of an X-compound between the electron carrier and P has been questioned by Löv *et al.*[27]). The DNP-induced ATP-ase reaction is assumed to involve the splitting of ATP

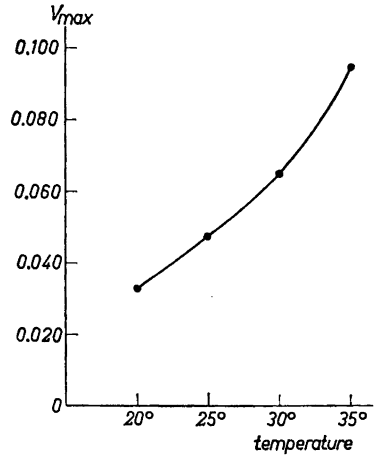

Fig. 12. Effect of temperature on the maximum velocity of ATP cleavage (expressed as optical density at 660 mμ). V_{max} was calculated from Lineweaver-Burk plots at 20, 25, 30 and 35°. The reaction mixture contained, in addition to ATP and $MgCl_2$ in a ratio of 2:1, 1 ml of a suspension of chloroplasts in 0.1 M Tris buffer pH 7.5, containing 0.7 mg chlorophyll. Reaction time, 10 min.

by reversal of reactions (3) and (2), followed by a rapid hydrolytic decomposition of $carrier_{ox} \sim X$. Siekevitz *et al.*[7] obtained data supporting the conclusion that the mitochondrial Mg^{++}-activated ATP-ase reaction constitutes a part of the reaction sequence involved in the DNP-induced ATP-ase and is not due to a separate enzyme. The finding by Kielley and Bronk [28] that DNP stimulates ATP-ase activity in phosphorylating fragments of rat liver mitochondria only in the presence of Mg^{++} is in agreement with this view. The Mg^{++}-activated ATP-ase reaction may be a reversal of reaction (3), followed by decomposition of $P \sim X$.

Our results indicate that chloroplasts exhibit two systems with ATP-hydrolyzing activity, one of which is dependent on added Mg^{++}. Contrary to the results obtained with "intact" liver mitochondria, the phosphorylating whole spinach chloroplasts isolated by us consistently show Mg^{++}-stimulated ATP-ase activity. In this respect they resemble phosphorylating heart muscle mitochondria, which are isolated according to Holton *et al.*[29] and are reported to always have a moderately high ATP-ase activity. It is an open question whether the Mg^{++}-stimulated ATP-ase activity should be regarded as an expression of damage in the isolated chloroplasts or as an inherent property of the system. In liver mitochondria the development of Mg^{++}-stimulated ATP-ase activity is paralleled by a loss of the capability to carry out oxidative phosphorylation. In chloroplasts, on the other hand, the Mg^{++}-

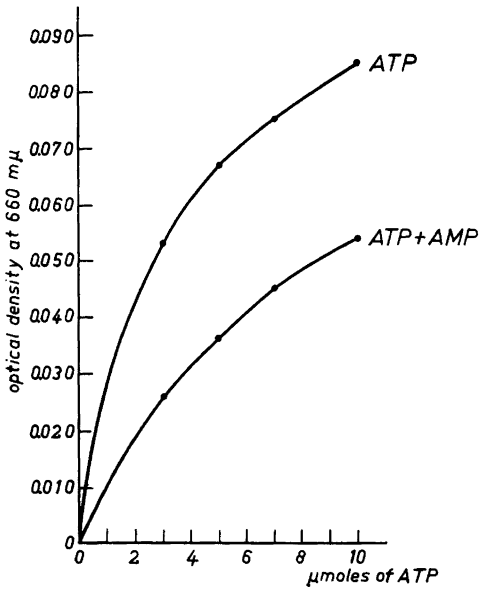

Fig. 14. Inhibition of ATP-ase activity by AMP. Reaction rate (expressed as optical density at 660 mμ) as a function of ATP concentration in the absence and in the presence of 10 μmoles of AMP. stimulated ATP-ase activity does not increase as light-induced phosphorylation falls off.

Light-induced phosphorylation is not much inhibited by low concentrations of DNP, in contrast to oxidative phosphorylation [30-33]. In fact it was found that DNP can catalyze the generation of ATP by illuminated chloroplasts in the absence of exogenous eletron carriers [34]. The mechanisms of light-induced and respiratory generation of ATP thus seem different in at least one respect. The finding that DNP does not induce ATP-ase activity in spinach chloroplasts may be another reflection of the same difference.

The reported lack of ATP-ase activity and of an exchange reaction between ATP and ^{32}P are according to Avron and Jagendorf [18] confirmatory evidence for the view that the last step in ATP formation in light-induced phosphorylation is an irreversible one. Löw *et al.*[27] have shown that a close relationship seems to exist between the P—ATP exchange and the DNP-induced ATP-ase reactions in isolated mitochondria. Our finding that no DNP-induced ATP-ase reaction could be obtained in chloroplasts may be interpreted to mean, by

comparison, that a P—ATP exchange reaction should not be expected in isolated chloroplasts.

Though the amount of inorganic phosphate released in the ATP-ase reaction of the isolated chloroplasts is rather low (8—12 μmoles/h/mg chlorophyll) as compared to the rate of light-induced phosphorylation in the particular chloroplast preparations (60—80 μmoles ATP formed/h/mg chlorophyll, anaerobic conditions, cofactor 2×10^{-4} M vitamin K_3), there are two reasons to believe that the Mg^{++}-stimulated ATP-ase activity is not due to mitochondrial contamination. First, the chloroplast preparations showed no measurable respiratory activity and second, repeated washings of the chloroplasts did not significantly affect the ATP-ase activity. Arnon's [16] statement that chloroplasts seem to be rather free of ATP-hydrolyzing enzymes has not been supported by any published experiments. The failure of Avron and Jagendorf [17,18] to detect any ATP-ase activity may have been due to the combined effect of short reaction time, low concentration of chloroplasts (*cf.* Ref.[18] Table I), high concentration of $MgCl_2$ and low temperature, as compared to our conditions.

The Mg^{++}-activated ATP-ase activities in spinach chloroplasts and in liver mitochondria were found to be similar in their response to azide, *p*-chloromercuribenzoate, fluoride, AMP, ADP, chlorpromazine and atebrin, which were inhibitory and also to dithionite, which had a stimulating effect (*cf.* Refs.[7,10,35,36]). In spinach chloroplasts KCN had no significant effect, whereas in mitochondria a small but significant stimulation of the Mg^{++}-activated ATP-ase reaction has been reported [35]. $(NH_4)_2SO_4$, which recently was found to be an uncoupler of light-induced phosphorylation in chloroplasts [37], did not influence the ATP-ase activity.

Löw [35,36] has shown that the flavin antagonists atebrin [38-40] and chlorpromazine [41] affect the DNP-induced ATP-ase activity of "intact" liver mitochondria as well as the Mg^{++}-stimulated ATP-ase activity of structurally disorganized mitochondria. He concluded that both of these ATP-ases involve the participation of diaphorase flavin. In chloroplasts, those concentrations of chlorpromazine (3×10^{-4} M) and atebrin (5×10^{-3} M), which inhibited the Mg^{++}-stimulated ATP-ase activity by 50 % also caused a precipitation of chloroplast material. In chloroplasts light-induced phosphorylation in the presence of vitamin K_3 or FMN, as well as the phosphorylation coupled to the reduction of ferricyanide were found to be inhibited by much lower concentrations of chlorpromazine and atebrin (50 % inhibition by 5×10^{-5} M chlorpromazine and 5×10^{-5} M atebrin) than the ATP-ase activity. Thus we are not certain that these agents inhibit chloroplast ATP-ase by a specific action towards flavin.

Summarizing it may be said that the Mg^{++}-stimulated ATP-ase reaction of chloroplasts in several respects is similar to that of disrupted liver mitochondria. Our data do not permit, however, to draw a definite conclusion as to whether the Mg^{++}-stimulated ATP-ase reaction is a reversal of ATP forming reactions in light-induced phosphorylation in chloroplasts.

Preparation and Some Properties of Sub-Mitochondrial, Reduced Diphosphopyridine Nucleotide Oxidizing Particles from Isolated Mitochondria

HERRICK BALTSCHEFFSKY, MOLLY FUDGE and BARBRO ARWIDSSON

Wenner-Gren Institute, University of Stockholm, Sweden

A simple method for preparation and isolation of sub-mitochondrial particles from isolated rat or guinea-pig liver mitochondria is described. It consists of grinding the mitochondria with Al_2O_3 in a mortar and subsequent differential centrifugation. Some properties of a fraction, which is centrifuged down at 100 000 *g* (60 min centrifugation), are described.

The fraction oxidizes reduced diphosphopyridine nucleotide at a much higher rate than reduced triphosphopyridine nucleotide, both with oxygen and with cytochrome c as electron acceptors. The oxidation of succinate with cytochrome c is strongly stimulated by phenazine methosulfate. Antimycin A inhibits the oxidation of succinate in the absence of phenazine methosulfate, which can mediate electron transport from succinate to cytochrome c around the antimycin A-sensitive site. When a catalytic amount of diphosphopyridine nucleotide is added, β-hydroxybutyrate is oxidized by added cytochrome c in the presence of the sub-mitochondrial fraction whereas glutamate oxidation occurs only when also the final supernatant is added. This indicates that mitochondrial dehydrogenases are differently distributed in the sub-mitochondrial fractions.

The methods employed for preparation of sub-mitochondrial particles from isolated animal mitochondria [1–10] are of two kinds with respect to the disruption of the mitochondrial structure, chemical [1–6] and physical or mechanical [7–10]. Three physical methods have been reported: use of a Waring blendor[7], sonic vibration [8–9] and grinding with alumina [10]. This paper describes the method of preparation and some properties of sub-mitochondrial DPNH-oxidizing * particles obtained from isolated liver mito-

* Abbreviations: ATP, adenosine triphosphate; ATP-ase, adenosine triphosphatase; DPN, diphosphopyridine nucleotide; DPNH, reduced diphosphopyridine nucleotide; TPN, triphosphopyridine nucleotide; TPNH, reduced triphosphopyridine nucleotide; DNP, 2,4-dinitrophenol; PMS, phenazine methosulfate; HOQNO, 2-*n*-heptyl-4-hydroxyquinoline-N-oxide; M, moles per liter.

chondria by grinding with alumina. Earlier communications on this method have been in note or abstract form [10-13].

MATERIALS AND METHODS

The pyridine nucleotides, PMS, cytochrome c and antimycin A were obtained from Sigma Chemical Co., St. Louis, Mo., U.S.A. HOQNO was obtained from Dr. J. W. Cornforth, National Institute for Medical Research, London, England, this gift is gratefully acknowledged. Antimycin A and HOQNO were dissolved in ethanol. The stock solutions were kept in a deep-freeze. The molecular weight of antimycin A was taken as 548, in agreement with the formula $C_{28}H_{40}O_9N_2$ [14] (*cf.* Ref.[15]).

Liver mitochondria were prepared in 0.25 M sucrose, essentially according to the method of Schneider and Hogeboom [16] as modified by Ernster and Löw [17]. For one preparation 4—8 white male rats, each weighing 200—300 g or 2—4 male guinea-pigs, each weighing 300—400 g were used. After decapitation of an animal, the liver was removed, weighed, cut into small pieces and rinsed once or twice with sucrose. The homogenization was carried out on a 30—40 % tissue suspension as rapidly as possible (in between 15 and 30 sec) in a Potter-Elvehjem homogenizer with a loosely fitting Teflon Pestle. When all the livers were homogenized a dilution to a 15—20 % suspension was made. The material was centrifuged 10 min at 800 *g* * in an International Refrigerated Centrifuge, model PR-1, head no. 840. The pellet was discarded and the supernatant centrifuged 20 min at 4 100 *g*. The mitochondrial pellet was suspended in sucrose to the same volume as before the centrifugation and recentrifuged at 4 100 *g*, now for 15 min. The supernatant was discarded and the mitochondrial pellet suspended in a small volume of sucrose (1—2 ml per 5 g of liver). The material was centrifuged 8 min at 20 000 *g* in a Spinco Ultracentrifuge, model L, head no. 40, which was also used for the subsequent centrifugations. In this centrifugation the resulting pellet was sharply divided into two parts. The upper part, small in volume, was the remaining "fluffy layer" [18] which was thoroughly swirled off from the densely packed mitochondrial layer and discarded. The remaining layer contained mitochondria of high ("intact") quality, as judged by the criteria of P/O ratios and respiratory control. It was used for preparation of the sub-mitochondrial particles, according to one of the following two methods.

Method I: The mitochondrial layer was suspended in a small volume of 0.03 M phosphate buffer, pH 7.0, and centrifuged 5 min at 25 000 *g*. The supernatant was discarded. The pellet was mixed in a mortar with 20 mg Al_2O_3 (Alcoa A-301) per gram liver and ground for 6 min. The mixture was transferred to a centrifugation tube with small volumes of the phosphate buffer and centrifuged 10 min at 25 000 *g*. The pellet contained Al_2O_3 and "heavier fragments". The supernatant was centrifuged 60 min at 100 000 *g*. The pellet from this centrifugation was suspended in a small volume of the phosphate buffer. The resulting yellow, translucent suspension contained "DPNH-oxidase particles".

Method II: The mitochondrial layer was mixed in a mortar with 20 mg Al_2O_3 (Alcoa A-301) per gram liver and ground for 6 min. The mixture was transferred to a centrifugation tube with small volumes of 0.25 M sucrose. From this on, the method was the same as method I, except that 0.25 M sucrose was used throughout.

The "heavier fragments" could be separated from the alumina with a glass rod. This fraction was obtained by transfer to an empty tube with the aid of phosphate or sucrose medium, 10 min centrifugation at 25 000 *g* and suspension of the pellet in the medium desired.

All operations were carried out at as near to 0°C as possible. Delays between the individual steps were avoided.

The solutions were made with deionized water and kept at 0°C.

Method II has also been used for preparation of sub-mitochondrial particles from isolated rat- or guinea pig-heart-muscle mitochondria [12].

---

* The *g* values are given for the bottom of the tubes with the International Refrigerated Centrifuge and for the middle of the tubes with the Spinco Ultracentrifuge.

Electron micrographs were taken of the isolated mitochondria, the "heavier fragments" fraction and the "DPNH-oxidase particles" *. The majority of the mitochondria appeared to be "intact" with clearly visible internal double membrane structures. Some, however, appeared to be swollen, with diminished integrity of the internal membranes. The microsomal contamination appeared to be low. Both the "heavier fragments" fraction and the DPNH-oxidase particles appeared to be more or less round vesicles with no interior structures. No "intact" mitochondria were observed in these fractions.

Measurements. Protein was determined by the biuret method. Phosphorylation was measured by the ^{32}P method recommended by Lindberg and Ernster [19], ATP-ase activity by the method of Martin and Doty [20] as described by Lindberg and Ernster [19].

Oxidase activities were measured with the Warburg technique or, for DPNH and TPNH by following the disappearance of the absorption of reduced nucleotide at 340 mμ in a Beckman Recording Spectrophotometer, model DK 2. Cytochrome c reducing activities were measured at 550 mμ, in the presence of mM KCN. The following values were used for the extinction coefficients: DPNH minus DPN and TPNH minus TPN at 340 mμ = 6.2 $cm^{-1} \times mM^{-1}$, reduced cytochrome c minus oxidized cytochrome c at 550 mμ = 19.1 $cm^{-1} \times mM^{-1}$.

RESULTS

A method similar to method I where the mitochondria were treated with 0.03 M phosphate, pH 7.0, before the grinding, was outlined in the first note [10] about this work. This medium had earlier been used for preparation of submitochondrial particles by sonic treatment of liver mitochondria [21]. Method II gave a higher yield than method I (Table 1), as was previously noted [11]. Preparations made according to method II have been used for the experiments reported below, unless otherwise indicated.

Table 1. Yield of "DPNH-oxidase particles".

Material	Method	Number of preparations	mg protein/g liver		
			lowest value	highest value	mean value
Rat liver	I	3	0.1	0.2	0.1
» »	II	9	0.5	0.9	0.7
Guinea pig liver	I	3	0.2	0.3	0.2
» » »	II	4	0.8	1.4	1.1

The higher yield obtained with method II allowed some experiments to be done in order to confirm the visual observation that 6 min was a suitable grinding time. Mitochondria were isolated from 80 g of liver. During the grinding, which was extended to 15 min, samples were removed from the mixture at suitable time intervals, weighed and put into centrifuge tubes. Two variables of the "DPNH-oxidase particles" obtained from these samples were determined: the amount of protein recovered and the DPNH-oxidase activity. Fig. 1 shows that 6 min grinding was suitable with respect to the yield of

* Thanks are due to Dr. Fritiof S. Sjöstrand of the Department of Anatomy, Karolinska Institutet, for carrying out the studies with the electron microscope.

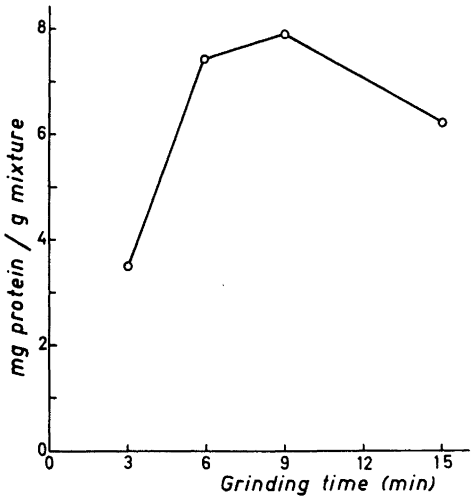

Fig. 1. Yield of protein as a function of grinding time (guinea pig).

protein. Table 2 shows that this was true also with respect to the yield of DPNH-oxidase activity. Parallel values are given in Table 2 to show that the experimental error was satisfactorily small for the purpose of the experiment.

The recovery of mitochondrial protein is shown in Table 3. With both methods of preparation the bulk of the protein was in the supernatant after the centrifugation at 100 000 *g*. Whereas method II gave a better yield of "DPNH-oxidase particles" than method I, the opposite was true for the "heavier fragments" fraction. A considerable amount of protein (6 %) was dissolved by the treatment of the "intact" mitochondria with phosphate. As was to be expected, the amount of protein was low (2 %) in the corresponding fraction from a similar centrifugation in 0.25 M sucrose.

The efficiency of the oxidative phosphorylation obtained was very low, as was shown in a note [10]. It was true both with preparations made according to method I and method II, and likewise when versene was added or a mixture of sucrose and phosphate was used. Shortening the reaction time to

Table 2. DPNH-oxidase activity as a function of grinding time. The oxidation of DPNH was measured spectrophotometrically at 340 mμ, in 25 mM phosphate buffer pH 7.0, in the presence of 1 % serum albumin. Material: "DPNH-oxidase particles". Each given value is the mean value of two determinations from a separate sample. Reaction volume 3 ml (guinea pig).

Grinding time min	DPNH-oxidase activity μmoles DPNH oxidized/min/g mixture	
0.2	0.1	0.3
3	1.7	1.6
6	2.0	2.5
9	2.5	2.6
15	2.3	2.2

Table 3. Recovery of mitochondrial protein (rat).

Fraction	Recovery per 100 mg mitochondrial protein	
	Method I	Method II
	mg protein	mg protein
"DPNH-oxidase particles"	7	23
"Heavier fragments"	15	11

Supernatant$_{100\,000\ g}$ *	59	55
Total recovery	87	91

* Supernatant $_{25\,000\ g}$ and Supernatant $_{100\,000\ g}$ = supernatant from the centrifugation at 25 000 *g* which was performed immediately before the grinding and the centrifugation at 100 000 *g*, respectively.

2 min (measuring the rate of oxidation of DPNH at 340 mμ and at 20°C), did not result in higher P/O ratios.

The ATP-ase activity of isolated liver mitochondria is related to their state and capacity for oxidative phosphorylation. A parallel relationship exists between disappearance of mitochondrial integrity, oxidative phosphorylation and DNP-induced ATP-ase activity. When these decrease, the Mg^{++}-stimulated ATP-ase activity, on the other hand, increases [22]. Fig. 2 shows that the Mg^{++}-stimulated ATP-ase activity of the "DPNH-oxidase particles" is very high as compared to the DNP-induced ATP-ase and the endogenous ATP-ase activities.

In early preparations of "DPNH-oxidase particles" with the alumina grinding-method, DPNH was oxidized at a much higher rate than succinate with either oxygen or cytochrome c as electron acceptor [10,11]. It has been

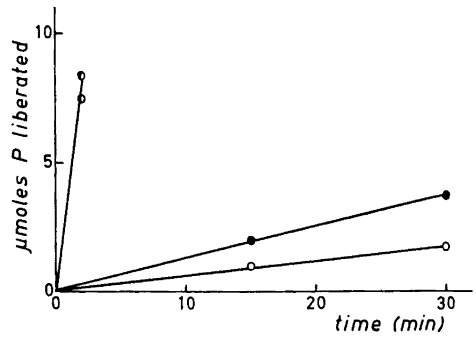

Fig. 2. Effects of Mg and DNP on the ATP-ase activity. ◐ = Mg added, ● = DNP added, O = no addition. The reaction medium contained: 0.015 M tris(hydroxymethyl)-aminomethane, pH 7.6, and 0.01 M ATP. Where added: 4 mM $MgCl_2$ or 10^{-4} M DNP. Final volume 2.0 ml. Temperature 30°C (guinea pig).

Table 4. Cytochrome c reductase activities. Spectrophotometric measurement at 550 mμ. In the reaction cuvette: "DPNH-oxidase particles", 1 mM KCN, 5×10^{-5} M cytochrome c and 30 mM phosphate buffer, pH 7.0. Where added: 6.7 mM succinate or 0.1 mM DPNH (final concentrations are given throughout). The final volume was 3 ml. Temperature 22°C. The values are given as μM cytochrome c reduced/min/mg protein (rat).

* Experiments made on preparations according to method I.

** As PMS is autoxidizable the data with PMS may be quantitative only with respect to the reduction of cytochrome c (and not indicate an equivalent oxidation of succinate).

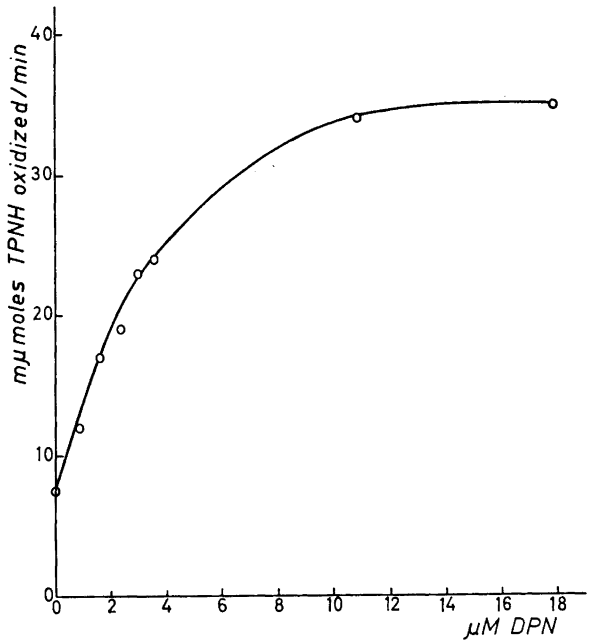

Fig. 3. Stimulation of TPNH-oxidase by DPN. The oxidation of TPNH was measured spectrophotometrically at 340 mμ. Initial concentration of phosphate buffer pH 7.0, was 27 mM. Protein content 1.9 mg. Successive additions of DPN were made. Final volume before the additions 3.0 ml. Note the rate of oxidation of TPNH (that of DPNH was, in a separate experiment, 120 mμmoles DPNH oxidized/min). (Variation of the concentration of phosphate buffer over a wide range did not influence the rate.) Temperature 20°C (rat).

found, however, that both method I and method II may give preparations where the oxidase activities were of the same order of magnitude with succinate and with DPNH as substrates. On the other hand, the difference between the rates with DPNH and succinate as substrates has constantly been great for the cytochrome c reductase activities (Table 4).

Different cytochrome c-reducing activities are shown in Table 5. The low rate of oxidation of succinate with cytochrome c is stimulated by phenazine methosulfate, which is known to accept electrons from a purified and solubilized succinic dehydrogenase preparation [23]. Antimycin A (or HOQNO) inhibits the succinate-cytochrome c reductase activity, but the stimulation due to phenazine methosulfate is unihibited. These agents have previously been reported to provide a by-pass for electrons around the antimycin A- and HOQNO-sensitive step in bacterial light-induced phosphorylation [24,25], and recently also in mitochondrial electron transport [26]. The present results demonstrate that electrons which, through the action of phenazine methosulfate, have passed around the antimycin A sensitive step may be brought back to the respiratory chain at the cytochrome c-level. Mitochondrial substrates,

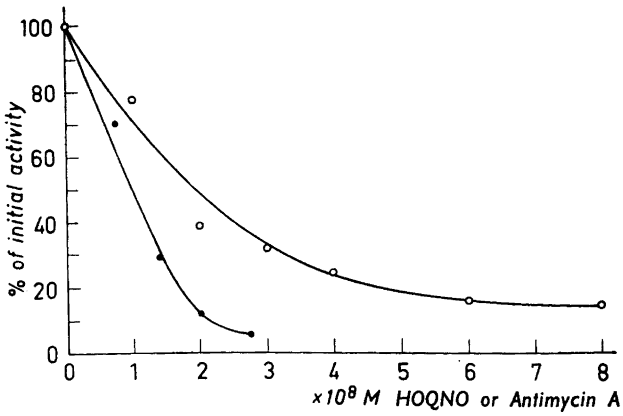

Fig. 4. Inhibition by antimycin A and HOQNO of DPNH-oxidase activity. ○ = HOQNO, ● = antimycin A. The oxidation of DPNH was measured spectrophotometrically at 340 mμ. The reaction medium contained: 25 mM phosphate buffer pH 7.0 and "DPNH-oxidase particles" containing 0.62 mg protein. Final volume 3.0 ml. Temperature 22°C (rat).

which are linked to DPN over specific dehydrogenases, may be oxidized after addition of catalytic amounts of DPN (*e.g.* β-hydroxybutyrate), or they may need addition of both DPN and the final supernatant from the preparation (*e.g.* glutamate). Mitochondrial dehydrogenases thus seem to be distributed in different sub-mitochondrial fractions. This may be a reflection of a corresponding compartmentation in the structure of the mitochondrion. The low initial rate of oxidation of TPNH can be markedly stimulated by DPN in catalytic amounts. This is shown in more detail in Fig. 3 and indicates that pyridine nucleotide transhydrogenase [27] is present in the particles.

It has been shown earlier [12] that amytal *, antimycin A, and HOQNO in "DPNH-oxidase particles" from liver inhibit only that part of the respiration which is not due to the addition of cytochrome c. Fig. 4 shows the inhibition curves for antimycin A and HOQNO in a system where no cytochrome c had been added.

DISCUSSION

Isolated "intact" mitochondria have been disrupted into smaller fragments by various chemical and mechanical means. The new, simple method described in this paper, grinding with alumina, was originally used for disruption of bacterial cells [28]. After the grinding the various sub-mitochondrial fractions are separated by differential centrifugation performed in a similar manner to that after sonic disruption [8]. The recovery of mitochondrial protein in different fractions (Table 2), with a high amount in the final supernatant, resembles the distribution shown by Kielley and Bronk [8] in the fractions obtained from sonicated mitochondria.

* 5-Ethyl-5-*iso*amylbarbiturate.

The fraction which has been termed "DPNH-oxidase particles" oxidized DPNH in previously described preparations at a much higher rate than succinate [10]. As many preparations, both with method I and method II, have given rather similar rates with the two substrates and as a marked variation between different preparations has been found, it can be stated that the alumina grinding as such does not constantly give low succinoxidase activity in the "DPNH-oxidase particles" and the absolute DPNH-oxidizing activities are governed by factors which are difficult to control. Two possible sources for this difficulty should be considered, the postulated "external" mitochondrial pathway for oxidation of DPNH [29,30], and influence of microsomes. The fact that amytal, antimycin A and HOQNO virtually completely inhibit the DPNH-oxidase activity in the absence of cytochrome c [11,12] shows that this respiration is of a mitochondrial, and not microsomal, origin. The additional respiration, which is initiated by external cytochrome c, may originate from either of the two sources mentioned above, or from both. A low microsomal contamination in the mitochondria would be percentagewise increased in the fraction containing the "DPNH-oxidase particles" because of similar sedimentation characteristics. DPNH-cytochrome c reductase activity of the microsomes may then be linked to the mitochondrial oxidase at the cytochrome c-level and by-pass a rate-limiting step between DPNH and cytochrome c. The effect would be the same as that of the postulated "external" mitochondrial pathway. A vague indication that microsomes may be responsible for at least part of the stimulating effect of added cytochrome c in preparations from liver is found from experiments with "DPNH-oxidase particles" from heart muscle [12]. In this material the increased DPNH-oxidase activity, which is due to addition of cytochrome c, is sensitive to the above-mentioned inhibitors, and the ratio DPNH- to succinate-cytochrome c reductase activity is lower than the corresponding ratio in liver material. The amount of microsomes which can be obtained from heart muscle homogenates is very low.

Glutamate was not oxidized by the DPNH-oxidase particles unless both DPN and the final supernatant were added. Thus no glutamic dehydrogenase was active in the particles. The same was reported for sub-mitochondrial particles obtained by Kielley and Bronk [8] (but not by McMurray, Maley and Lardy [9]) after sonic disruption of liver mitochondria. On the other hand, β-hydroxy-butyric dehydrogenase was present (Table 5).

Inhibitor Studies on Light-Induced Phosphorylation in Extracts of *Rhodospirillum rubrum*

HERRICK BALTSCHEFFSKY and MARGARETA BALTSCHEFFSKY

Wenner-Gren Institute, University of Stockholm, Sweden

Light-induced phosphorylation in extracts of the photosynthetic bacterium *Rhodospirillum rubrum* is strongly inhibited not only by 2-*n*-heptyl-4-hydroxyquinoline-N-oxide [1] and antimycin A[2] but also by gramicidin and oligomycin A in concentrations which are similar to those necessary to inhibit the reactions involved in oxidative phosphorylation in animal mitochondria. Amytal, azide and cyanide [3] have only a weak inhibitory effect. Dicumarol and especially 2,4-dinitrophenol, which both "uncouple" phosphorylation from electron transport in animal mitochondria, have a much less pronounced inhibitory effect on the light-induced phosphorylation.

The similarities between the two different electron transport phosphorylation * systems in response to various kinds of inhibitors indicate that the investigated mechanism for bacterial light-induced phosphorylation has properties similar to the mechanism for mitochondrial oxidative phosphorylation. This is true with respect not only to electron transport but also to the mechanism of coupling between electron transport and phosphate esterification and to the nature of a reaction involved in phosphate transfer. The differences show that reactions near the oxidizing and the reducing ends of the mitochondrial respiratory chain are not shared by the bacterial system for light-induced phosphorylation.

Studies with inhibitors and stimulators have provided information about the system for respiration and oxidative phosphorylation in animal mitochondria. Experimental evidence for the assumption that light-induced phosphorylation (LIP) in photosynthetic bacteria is dependent upon electron transport was first obtained with the electron transport inhibitor HOQNO [1] **. Current concepts about the electron transport system in LIP in the facultative

* The term "electron transport phosphorylation" is used to denote "phosphorylation linked to electron (or hydrogen) transport".

** Abbreviations: P, orthophosphate; ATP, adenosine triphosphate; DPN, diphosphopyridine nucleotide; DPNH, reduced diphosphopyridine nucleotide; HOQNO, 2-n-heptyl-4-hydroxyquinoline-N-oxide; DNP, 2,4-dinitrophenol; % P_{org}, percentage orthophosphate esterified; M, moles per liter.

phototroph *Rhodospirillum rubrum* are largely based on results obtained with electron transport inhibitors and stimulators [1-4]. Further results obtained with inhibitors of electron transport and phosphorylation are given and discussed in this paper.

MATERIALS AND METHODS

ATP, DPNH, PMS and antimycin A were obtained from Sigma Chemical Co., St. Louis, Mo., U.S.A. Gramicidin D was obtained from Mann Research Laboratories, New York, N.Y., U.S.A. HOQNO was obtained from Dr. J. W. Cornforth, National Institute for Medical Research, London, England, and oligomycin A from Dr. F. M. Strong, Department of Biochemistry, University of Wisconsin, Madison, Wisc., U.S.A. These gifts are gratefully acknowledged. Hexokinase was prepared and stored as in Ref.[5] Antimycin A, HOQNO, gramicidin and oligomycin A were dissolved in ethanol. The stock solutions were kept in a deep-freeze. In the reaction medium for LIP the ethanol content was kept below 1 % in order not to inhibit the LIP. The molecular weight of antimycin A was taken as 548 (*cf.* Ref.[6]).

Rhodospirillum rubrum, van Niel strain S1, was grown and harvested as has been described [4]. The method which was used for disruption of the bacteria, grinding with alumina, was first employed on bacteria by McIlwain [7]. It has been described in a previous paper [4], as well as the procedures employed for preparation of "chromatophores" and "chromatophore fragments" and for measuring yield and efficiency of LIP, and the medium used in the LIP experiments. The results reported here have been obtained with the "chromatophore fragments" fraction unless otherwise indicated. The two fractions were equally efficient in LIP but the "chromatophores" fraction showed a higher DPNH-oxidase activity than the "chromatophore fragments" fraction.

Aerobic conditions were used throughout. In all experiments 3.3×10^{-4} M * succinate was added in accordance with the finding of Frenkel [8,9] that a reducing agent in catalytic amounts is necessary to elicit full LIP activity in "purified" extracts of *R. rubrum*. Frenkel [9] has shown that the LIP process is inhibited by molecular oxygen in the absence, or at very low concentrations, of hydrogen donor. Under our conditions, with an added excess of succinate, anaerobiosis obtained with N_2 *via* a pyrogallol solution did not result in higher LIP values. In fact, a slight inhibition of the LIP as compared with aerobiosis was obtained (10 and 15 % in two separate experiments with different preparations).

RESULTS

Fig. 1 shows that the rate of LIP is a linear function of the concentration of the chromatophore extract. A time curve for LIP is given in Fig. 2.

Amytal gives only a weak inhibition of LIP, even at concentrations several times higher than those which strongly inhibit the oxidation of DPN-linked substrates in animal mitochondria [10] (Fig. 3).

Fig. 4 shows the inhibition curves for antimycin A and HOQNO, which have been shown [11] to inhibit electron transport in animal mitochondria between cytochrome b and cytochrome c_1. Fig. 5 shows that the inhibition obtained with antimycin A was by-passed by phenazine methosulfate [2,12], even at high concentrations of the inhibitor. However, with increasing concentrations of antimycin A the amount of phosphate esterified decreased.

As shown in Table 1, no marked inhibition was obtained with high concentrations of KCN and NaN_3. Mitochondrial electron transport is strongly inhibited by 5×10^{-4} M concentrations of these agents.

* Final concentrations are given throughout.

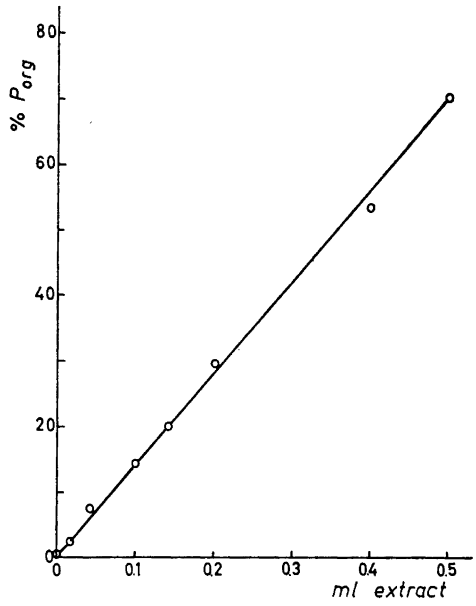

Fig. 1. LIP as a function of the amount of added "chromatophore fragments". The tubes contained 1.5 ml 0.2 M glycylglycine pH 7.4, 8 μmoles $K_2H^{32}PO_4$, 10 μmoles ATP, 1 μmole succinate, 30 μmoles $MgCl_2$, 60 μmoles glucose and an excess of yeast hexokinase. "OD_{800}" = 0.20 for a sample with 0.1 ml "chromatophore fragments" per 3.0 ml (reaction volume 3.0 ml). 20 min experiment at 30°C.

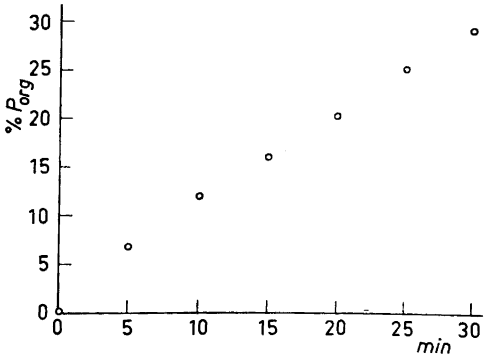

Fig. 2. Time curve for LIP. Experimental details as in Fig. 1. "OD_{800}" = 0.20.

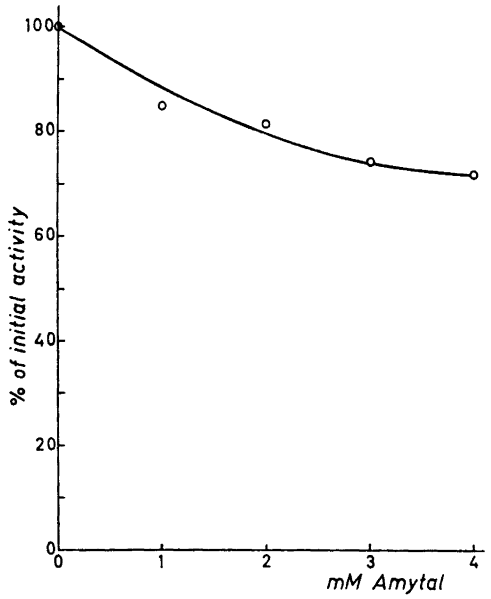

Fig. 3. Effect of amytal on LIP. Experimental details as in Fig. 1. "OD_{800}" = 0.20. 30 min experiment. 100 % initial activity = 39.4 % P_{org}.

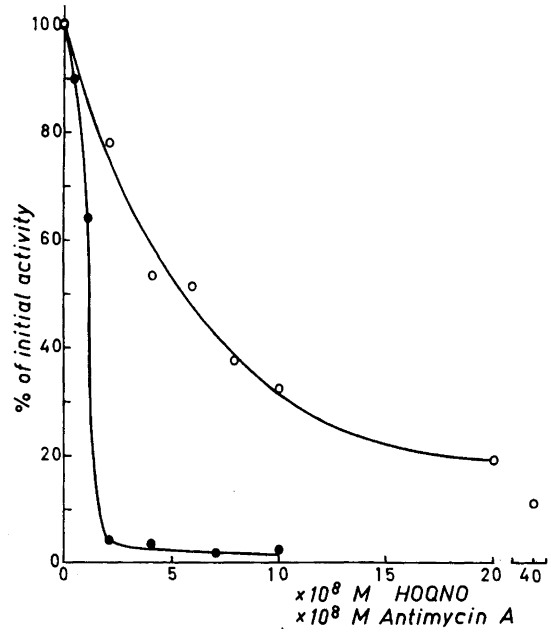

Fig. 4. Effect of antimycin A and HOQNO on LIP. Experimental details as in Fig. 1. ● = antimycin A, ○ = HOQNO. For ●, "OD_{800}" = 0.28, 100 % initial activity = 56.3 % P_{org}. For ○, "OD_{800}" = 0.32, 100 % initial activity = 62.0 % P_{org}. 30 min experiment. "Chromatophores" fraction.

The effect of two well known agents that uncouple oxidative phosphorylation in mitochondria, DNP and dicumarol, is shown in Fig. 6. Comparatively high concentrations were required to obtain an inhibitory effect on LIP. Dicumarol was much more efficient than DNP in this system.

Oligomycin A and gramicidin, which inhibit oxidative phosphorylation in animal mitochondria, also strongly inhibit LIP in extracts of *Rhodosprillium rubrum* (Figs. 7 and 8). LIP in spinach chloroplasts is inhibited by gramicidin [13,14] but not by oligomycin A in the concentrations tested [14].

DISCUSSION

A certain similarity between the mitochondrial system for oxidative phosphorylation and the system for LIP in *R. rubrum* has been indicated by the work of several investigators [1-4]. It is in the flavin and cytochrome regions that common denominators in the electron carrier systems have been suggested [3,4]. The nature of the reactions at both the reducing and the oxidizing ends of the mitochondrial electron transport chain is, however, not shared by the chromatophore system. This is shown by the fact that amytal, which inhibits electron transport in phosphorylating mitochondria between DPNH

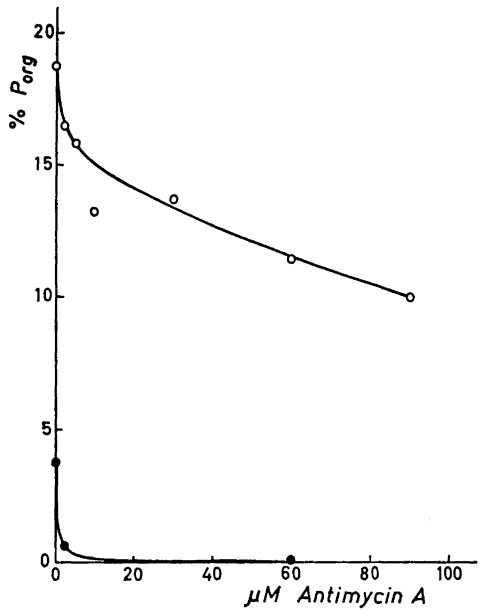

Fig. 5. Effect of antimycin A on PMS-stimulated LIP. Experimental details as in Fig. 1. O = PMS-stimulated, ● = without PMS, which curve is given as a comparison. The PMS-concentration, where added, was 3.3×10^{-4} M. "OD_{800}" = 0.50. 6 min experiment with PMS, 20 min without PMS (the values given are recalculated for 6 min assuming linearity).

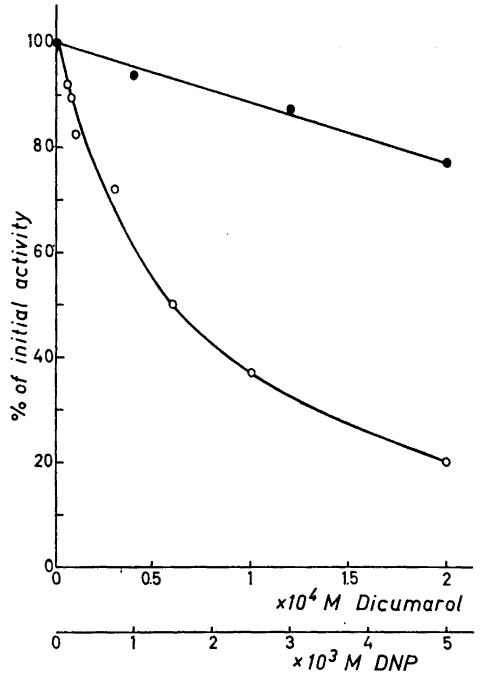

Fig. 6. Effects of dicumarol and DNP on LIP. Experimental details as in Fig. 1. O = dicumarol, ● = DNP. For O, "OD_{800}" = 0.47, 100 % initial activity = 47.5 % P_{org}, 30 min experiment. For ●, "OD_{800}" = 0.20, 100 % initial activity = 10.9 % P_{org}, 20 min experiment.

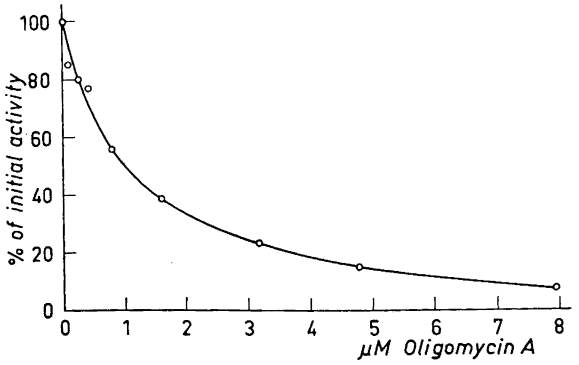

Fig. 7. Effect of oligomycin A on LIP. Experimental details as in Fig. 1. "OD_{800}" = 0.48, 100 % initial activity = 18.8 % P_{org}, 20 min experiment. "Chromatophores" fraction.

Table 1. Effects of NaN_3 and KCN on LIP. Experimental details as in Fig. 1. "OD_{800}" = 0.54, 20 min experiment.

KCN or NaN_3 concentration M	% P_{org} KCN	% P_{org} NaN_3
—	34.8	34.8
$\times 10^{-4}$	33.0	34.9
$\times 10^{-3}$	35.5	36.1
3×10^{-3}	33.1	39.9
5×10^{-3}	31.9	34.0

and flavin [15], as well as cyanide and azide, which both inhibit at the cytochrome a_3-level, have no similar effect on LIP in *R. rubrum* (Fig. 3 and Table 1).

The concentrations of antimycin A and HOQNO which were needed to inhibit LIP in *R. rubrum* (Fig. 4) were found to be almost the same as those inhibiting electron transport in mitochondrial systems [16,6]. This supports the previously formulated concept [12] that an identical or at least very similar electron carrier is acted upon in both systems.

DNP and dicumarol are "uncoupling agents" in mitochondrial oxidative phosphorylation, *i.e.* they inhibit the phosphorylation but not the respiration. In order to inhibit LIP in extracts of *R. rubrum* much higher concentrations of dicumarol and especially DNP were required than those necessary for uncoupling of the mitochondrial system [17]. It is therefore doubtful whether the inhibitory effect in the bacterial system is due to a similar mechanism as that in mitochondria. It may be appropriate to mention that at high concentration of DNP [18] and dicumarol [19] electron transport itself is inhibited in mitochondrial systems.

Also gramicidin and oligomycin A interfere with oxidative phosphorylation in animal mitochondria. Gramicidin is an "uncoupling agent" [17] and oligomycin A an inhibitor of both phosphorylation and oxidation reactions [20]. The effect of oligomycin A on respiration is especially strong with DPN-linked substrates and has been assumed to involve the inhibition of a phosphoryla-

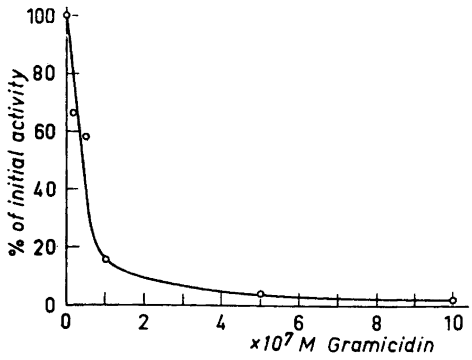

Fig. 8. Effect of gramicidin on LIP. Experimental details as in Fig. 1. "OD_{800}" = 0.20, 100 % initial activity = 13.3 % P_{org}, 20 min experiment.

tion reaction to which the respiration is obligatorily coupled [20]. The fact that both gramicidin and oligomycin A inhibited the LIP is an indication that the phosphorylation reactions proper in bacterial LIP share qualities with those of the oxidative phosphorylation reactions in animal mitochondria with respect to the mechanism of coupling between electron transport and phosphate esterification and to the nature of a reaction involved in phosphate transfer.

Inhibitor Studies on Light-Induced Phosphorylation in Isolated Spinach Chloroplasts

HERRICK BALTSCHEFFSKY

Wenner-Gren Institute, University of Stockholm, Sweden

Light-induced phosphorylation in isolated chloroplasts is greatly stimulated by the addition of several types of compounds capable of undergoing reduction and oxidation [1-3], among them flavin nucleotides. Whether the stimulatory agent is a flavin or not, 4×10^{-5} M atebrin * completely or almost completely inhibits the phosphorylation, indicating that endogenous chloroplast flavin is an obligatory participant in this system. The inhibition is not reversed by high concentrations of flavin nucleotide. In fact, flavin adenine dinucleotide (2×10^{-3} M) gives nearly complete and flavin mononucleotide (5×10^{-3} M) partial inhibition of phosphate esterification.

Amytal ** gives only slight inhibition.

Low concentrations of antimycin A, 2-*n*-heptyl-4-hydroxyquinoline-N-oxide and oligomycin A have no inhibitory effect on light-induced phosphorylation in isolated spinach chloroplasts comparable to the effects on light-induced phosphorylation in a bacterial *(Rhodospirillum rubrum)* extract and respiration and phosphorylation in animal mitochondria. The hypothesis [2] that added compounds effective as cofactors, such as FMN, menadione and phenazine methosulfate, may bridge over a gap in electron transport of the chloroplasts as they are presently isolated, is discussed.

Light-induced phosphorylation † (LIP) in isolated spinach chloroplasts is stimulated by both physiological electron carriers and non-physiological redox-compounds [1-3]. This and other evidence indicates that the phosphorylation process is linked to electron transport. Several schemes for the electron transport have been suggested [4-8]. In the present paper results of inhibitor studies on LIP in isolated spinach chloroplasts are presented and discussed.

Some data have already been given in an abstract [9].

* 3-Chloro-7-methoxy-9-(1-methyl-4-diethylamino-butylamino) acridine.

** 5-Ethyl-5-*iso*amylbarbiturate.

† This term as used here is equivalent to "cyclic photophosphorylation" [4].

MATERIALS AND METHODS

ATP *, FAD, FMN, PMS and antimycin A were obtained from Sigma Chemical Co., St. Louis, Mo., U.S.A. The FAD was of the 80–90 % pure type. Gramicidin D was obtained from Mann Research Laboratories, New York, N.Y., U.S.A. HOQNO was obtained from Dr. J. W. Cornforth, National Institute for Medical Research, London, England, and oligomycin A from Dr. F. M. Strong, Department of Biochemistry, University of Wisconsin, Madison, Wisc., U.S.A.; these gifts are gratefully acknowledged. Hexokinase was prepared and stored as in Ref.[10]. Antimycin A, HOQNO, gramicidin and oligomycin A were dissolved in ethanol. The stock solutions were kept in a deep-freeze. In the reaction medium for LIP the ethanol content was kept below 1 % in order not to inhibit the LIP. In such a medium, antimycin A occasionally did not keep solubilized when used in high concentrations, in which case the medium was discarded. The molecular weight of antimycin A was taken as 548 (*cf.* Ref.[11]).

Spinach was obtained as whole spinach plants from local growers. The chloroplasts were isolated according to Allen, Whatley and Arnon [12], with one washing and subsequent fragmentation of the whole chloroplasts by addition of hypotonic (0.035 M) NaCl. The chlorophyll content was determined according to Arnon [13]. All experiments were performed immediately after the preparation was finished. The medium employed for the phosphorylation experiments contained, unless otherwise noted, 1.0 ml 0.08 M tris-(hydroxymethyl)-aminomethane pH 8.3, 8 μmoles $K_2H^{32}PO_4$, 10 μmoles ATP, 30 μmoles $MgCl_2$, 60 μmoles glucose and an excess of yeast hexokinase. The final volume was 3.0 ml. The experiments were performed under aerobic conditions in test tubes which were immersed in a water-bath of 20°C. The light source consisted of a row of incandescent 150 W Philips lamps, adjusted to give a light intensity of about 30 000 lux at the reaction tubes. The reaction was stopped with 1 ml of 2 M perchloric acid.

Phosphorylation was measured by the ^{32}P method recommended by Lindberg and Ernster [14]. In all experiments two controls were run. In one of them the reaction was stopped at zero time. The other one was a dark control which was wrapped in aluminium foil and run parallel with the other tubes. The low amount of phosphate esterified in the dark was used as a zero for the LIP values.

Ascorbate gives a very low stimulation of LIP under aerobic conditions [15] but has nevertheless been used as a stimulatory agent in some of the experiments with inhibitors. It is also a stabilizer for the isolated chloroplasts [2,6] and has thus been added in some experiments along with other stimulating agents.

RESULTS

To obtain conveniently measurable rates of LIP in isolated spinach chloroplasts it is necessary to add one of a number of suitable stimulatory agents to the reaction medium. The following stimulatory agents have been employed in the present work: phenazine methosulfate [3], FMN [15], FAD, menadione [1], DNP [16] and ascorbate [15].

In Fig. 1 a typical time curve for LIP is given. It shows that 6 min, which has also been used by Jagendorf and Avron [3], is a suitable reaction time.

Amytal gave only a weak inhibition of LIP in chloroplasts with any of the stimulating agents used, even at concentrations several times higher than those which strongly inhibit the oxidation of DPN-linked substrates in animal mitochondria [17] (Fig. 2).

* Abbreviations: P, orthophosphate; ATP, adenosine triphosphate; FAD, flavinadenine dinucleotide; FMN, flavin mononucleotide; PMS, phenazine methosulfate; HOQNO, 2-*n*-heptyl-4-hydroxyquinoline-N-oxide; DNP, 2,4-dinitrophenol; M, moles per liter; % P_{org}, percentage ortophosphate esterified.

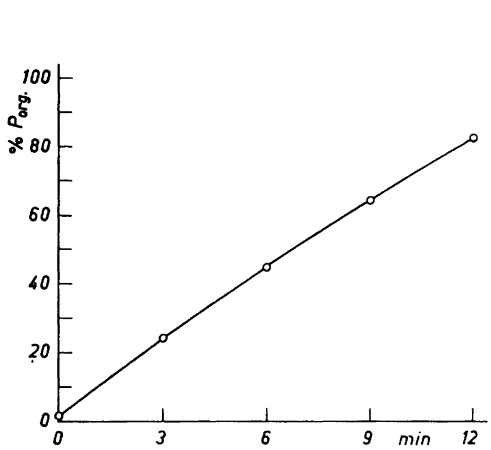

Fig. 1. Time curve of LIP stimulated by FMN. All tubes contained 30 μmoles ascorbate, 0.4 μmoles FMN and 0.16 mg chlorophyll.

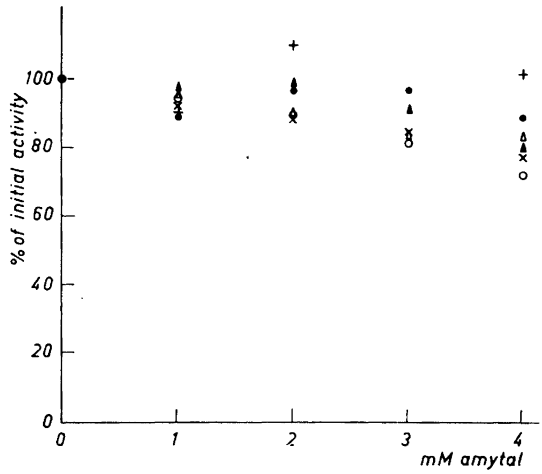

Fig. 2. The effect of amytal on LIP in the presence of various stimulatory agents. × = FMN, △ = PMS, ▲ = DNP, ○ = FAD, ● = menadione and + = ascorbate. The PMS- and menadione-series represent mean values of three, respectively two, different experiments. With the exception of the PMS-series all tubes contained 30 μmoles of ascorbate.

Atebrin, a flavoenzyme antagonist [18], inhibited LIP strongly (Fig. 3) regardless of the stimulatory agent used. The inhibition occured at concentrations of atebrin which were of the same order of magnitude as those required for inhibition of LIP in extracts of *Rhodospirillum rubrum* [19].

In extracts of *R. rubrum* the inhibition obtained with atebrin could be overcome completely with FAD and partially with FMN [19]. With chloroplasts such an effect did not appear. On the contrary it was found that the corres-

Table 1. Effects of FMN and FAD on LIP. All tubes contained 30 μmoles ascorbate. The chlorophyll content in each tube was with FAD 0.066 mg., with FMN 0.072 mg. (Repeated experiments confirmed the inhibition at 2×10^{-3} and 5×10^{-3} M FMN.)

Concentration of FMN or FAD M	% P_{org} FMN	FAD
—	5	5
5×10^{-5}	53	30
1.5×10^{-4}	51	29

2×10^{-3}	47	7
5×10^{-3}	44	5

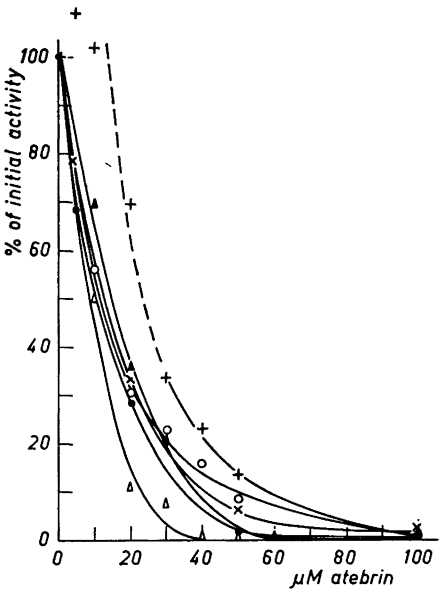

Fig. 3. The effect of atebrin on LIP in the presence of various stimulatory agents. × = FMN, △ = PMS, ▲ = DNP, O = FAD, ● = menadione and + = ascorbate. With the exception of the FAD- and PMS-series all tubes contained 30 μmoles of ascorbate.

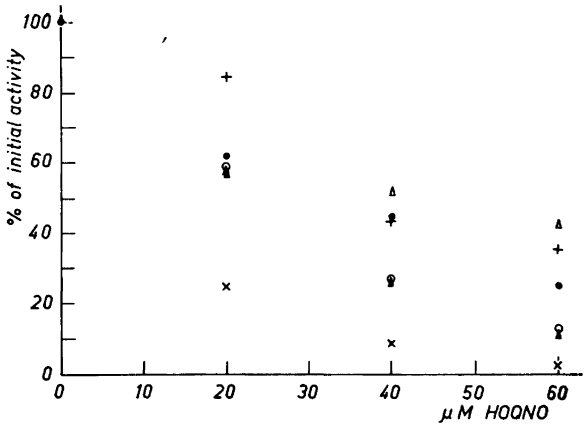

Fig. 4. The effect of HOQNO on LIP in the presence of various stimulatory agents. × = FMN, △ = PMS, ▲ = DNP, O = FAD, ● = menadione and + = ascorbate.

ponding concentrations of the flavin nucleotides inhibited the LIP in chloroplasts, the inhibition due to FAD being very strong (Table 1). The strong inhibitory effect of 2 mM FAD (Table 1) was obtained also when the LIP had been stimulated with PMS or menadione. The inhibition in one experiment was more than 95 % in the former and more than 75 % in the latter case.

Table 2. Effect of antimycin A on LIP, stimulated by FMN, PMS or menadione. With the exception of the PMS-series all tubes contained 30 μmoles ascorbate. Where added: 0.4 μmoles FMN, 0.06 μmoles PMS or 0.3 μmoles menadione. In the FMN-, PMS- and menadione-series, respectively, values for 100 % initial activity was 18, 33 and 56 % P_{org} and the chlorophyll content 0.044, 0.044 and 0.105 mg.

Concentration of antimycin A M	Percentage of initial activity		
	FMN	PMS	menadione
—	100	100	100
2×10^{-5}	83	78	—
5×10^{-5}	24	19	32

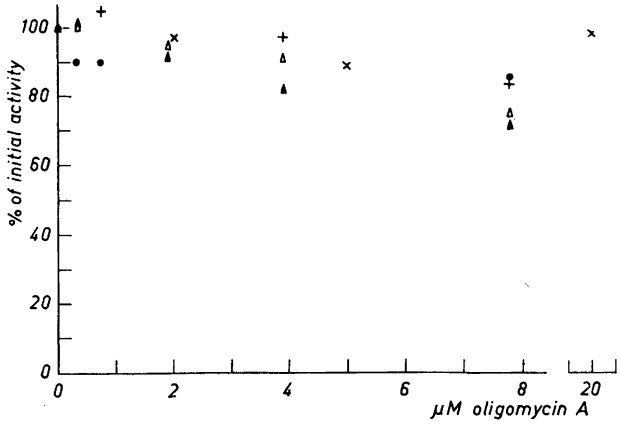

Fig. 5. The effect of oligomycin A on LIP in the presence of various stimulatory agents. △ = PMS, ▲ = DNP, ● = menadione, X = FMN and + = ascorbate. With the exception of the PMS-series all tubes contained 30 μmoles ascorbate. The chlorophyll content in each tube was for the different series taken in the above order, 0.12, 0.28, 0.10, 0.13 and 0.35 mg. The 100 % initial activity was, in the same order, 42, 48, 54, 57 and 9 % P_{org}. These values are included as examples of the rates of LIP obtained and may be regarded as representative, although the rate with menadione was unusually high and although considerable variations occured. (FAD gave rates similar to or somewhat lower than FMN.)

Antimycin A and HOQNO have been shown to inhibit LIP in extracts of *R. rubrum* [20] at similar concentrations as they inhibit electron transport in mitochondrial systems [21,11]. According to Arnon, Allen and Whatley [22] antimycin A does not inhibit LIP in spinach chloroplasts (in anaerobic experiments). No studies with HOQNO have been reported. Also under aerobic conditions LIP was unaffected by low concentrations of antimycin A as well as of HOQNO. As Table 2 and Fig. 4 show, both antimycin A and HOQNO inhibited LIP in chloroplasts at concentrations only as high as between 10^{-5} and 10^{-4} M.

Oligomycin A, which inhibits oxidative phosphorylation in animal mitochondria and the respiration connected with it, but not the respiration induced by addition of DNP [23], gave no significant inhibition of LIP in spinach chloroplasts (Fig. 5). As has been reported, oligomycin A inhibits LIP in extracts of *R. rubrum* [20].

Whatley, Allen and Arnon [24] have shown that gramicidin, which is an uncoupler of oxidative phosphorylation, strongly inhibits LIP under anaerobic conditions. Table 3 shows that inhibition occurs also under aerobic conditions.

DISCUSSION

The path of electron transport in LIP of plant chloroplasts is still essentially unknown. A comparison of various schemes which have been proposed [4-8] shows that no general agreement has been reached in this field. In a recent scheme for LIP in green plants Arnon [4] proposes three different electron trans-

Table 3. The inhibition of LIP by gramicidin. All tubes contained 30 μmoles ascorbate. Where added: 0.4 μmoles FMN or 0.3 μmoles menadione. The chlorophyll content in each tube and the values for 100 % initial activity were as follows: In the FMN-series, experiment 1, 0.090 mg chlorophyll, 46.5 % P_{org}; experiment 2, 0.116 mg chlorophyll, 36.3 % P_{org}. In the menadione-series, experiment 1, 0.089 mg chlorophyll, 15.7 % P_{org}; experiment 2, 0.116 mg chlorophyll, 16.3 % P_{org}.

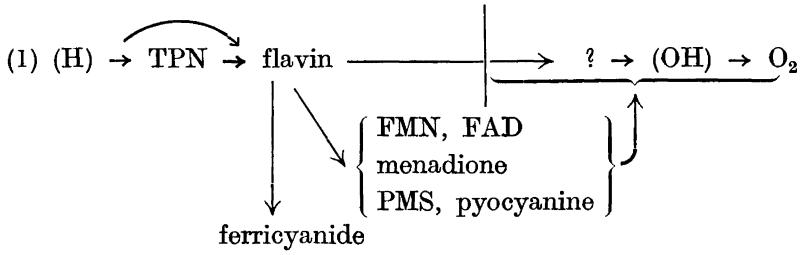
port pathways, all coupled to phosphorylation: (1) the cyclic electron transport system involving vitamin K and a cytochrome, (2) the cyclic electron transport system involving TPN, FMN and cytochromes and (3) the "open" non-cyclic mechanism, which transports electrons from chlorophyll to TPN. According to Wessels [6] TPN is not a member of the cyclic electron carrier chain(s). Both Wessels [25] and Whatley, Allen and Arnon [24] have reported that FMN and menadione are involved in separate pathways of electron transport in LIP under aerobic conditions. Marré, Servettaz and Forti [7] have presented a scheme with five electron carriers, among them cytochrome c, in a single electron transport chain joining the oxidizing and reducing equivalents produced by the photolysis of water. Jagendorf and Avron [3] have pointed out that FMN and menadione as well as PMS may act by bridging a gap in electron transport of the chloroplasts as they are presently isolated.

The absence of a strong inhibition by amytal indicates that no electron transport step identical with that in phosphorylating mitochondria between DPNH and flavin exists in the system studied. A similar lack of inhibition by amytal has been found for bacterial LIP [20]. Arnon, Whatley and Allen [2] have earlier shown that DPN does not seem to be involved in LIP of chloroplasts.

The fact that atebrin inhibited LIP not only when FMN or FAD were added but also when menadione, PMS, DNP or ascorbate were used indicates that chloroplast flavin participated in the electron transport regardless of the nature of the stimulatory agent. When considered together with other results listed below, this finding supports scheme (1) for representation of electron transport in LIP of isolated spinach chloroplasts:



Cyclic electron transport in LIP is in this paper written in its classical form, combining reducing (H) and oxidizing (OH) equivalents from the Hill-reaction (cf Ref.[4]). The stimulatory agents in this scheme may be reoxidized by (OH) or, at least under aerobic conditions, O_2, or by any agent between these and the indicated block in the electron transport chain. Differences between the response of LIP towards various inhibitors when different stimulatory agents are employed may be due to different sites of reoxidation of the stimulatory agents (*cf.* Ref.[4]).

The following information is relevant for the scheme presented. (a) Light induces a phosphorylation concomitantly with the reduction of TPN, or of ferricyanide [26]. In both cases one molecule of ATP is reported to be formed during the transport of two electrons. For the reduction of TPN (but not for that of ferricyanide) an enzyme, photosynthetic pyridine nucleotide reductase [27,28], is necessary. This enzyme is isolated and purified from the supernatant of the chloroplast preparation. (b) Oxidation of photo-reduced TPN in chloroplasts is accomplished when any of the compounds FMN, menadione and pyocyanine is added [29]. (c) A TPNH-specific diaphorase, containing FAD [30], has been isolated from spinach chloroplasts [31]. Electrons from this diaphorase may be accepted by compounds such as potassium ferricyanide, menadione and FMN [32]. (d) High rates of LIP in spinach chloroplasts are obtained by addition of a stimulatory agent with oxidation-reduction properties, such as FMN, FAD, menadione, PMS or pyocyanine [32].

If electron transport between flavin and (OH) is blocked immediately on the oxidizing side of flavin in the isolated chloroplasts, then any physiological electron carrier between the point of inhibition and the point at which the added stimulatory agent is oxidized will remain undetected by inhibitor or spectrophotometric experiments. Four electron carriers which could be so situated have been found in chloroplasts: cyctochrome b_6[33], cytochrome f[34] (with a cytochrome c-like spectrum), vitamin K_1[35] and plastoquinone (Q_{254})[36,37] which is a quinone closely related to coenzyme Q. It is possible that such a by-pass might explain the resistence of LIP in isolated chloroplasts towards antimycin A and HOQNO. Another possibility is that the compound on which these inhibitors act in mitochondria and chromatophores is lacking in chloroplasts or has a structure modified so as to make it less sensitive to the inhibitors. They appear to act in the b-type cytochrome or coenzyme Q region in mitochondria and chromatophores, where they are effective in concentrations of less than one thousandth of what is needed to inhibit LIP in chloroplasts.

Hill [33] has reported an experiment which may support the concept of a block in electron transport of isolated chloroplasts on the reducing side of cytochrome b_6. With illuminated leaves of the "golden varieties" of certain plants he could observe the sharp absorption band of reduced cytochrome b_6 at 563 mμ. With chloroplasts prepared from such leaves, however, no reduced cytochrome b_6 was found, until the preparation was reduced with sodium dithionite.

It is to be observed that not only with respect to the effect of the electron transport inhibitors antimycin A and HOQNO does the electron transport phosphorylation system in isolated chloroplasts show differences from those

of bacterial chromatophores and of animal mitochondria. Low concentrations of oligomycin A, which is reported to block a reaction involved in phosphate transfer in mitochondrial oxidative phosphorylation [23] and inhibit LIP in bacterial chromatophores [20], have no or very small influence on LIP in isolated chloroplasts. These facts are the more remarkable as the two former systems have a similar sensitivity to these inhibitors. On the basis of present evidence it is not possible to decide whether the findings reflect inherent differences between the systems, or whether the sensitivity towards the inhibitors is lost in spinach chloroplasts during the preparation. However, the fact remains that the system for LIP in isolated plant chloroplasts differs in its response to inhibitors both of electron transport and of phosphate transfer from the system for LIP in bacterial chromatophores and the system for oxidative phosphorylation in animal mitochondria. It still seems necessary to strongly consider the possibility that the system for LIP in spinach chloroplasts is partially destroyed, as they are presently prepared.

Acknowledgements. Thanks are due to Professor Olov Lindberg for his active and supporting interest in this work, and to Dr. Lars Ernster, Dr. Thomas Conover and Mrs. Margareta Baltscheffsky for valuable help.

Stereochemical Studies

IX *. The Relationship between Optical Rotatory Dispersion and Configuration for Some Carboxylic Acids

BERNDT SJÖBERG

Department of Organic Chemistry, Chemical Institute, University of Uppsala

The optical rotatory dispersion of several series of arylsubstituted mono- and dicarboxylic acids, and acid derivatives, has been investigated. The utility of plain dispersion curves for establishing configurational relationships has been demonstrated. Attention is called to the high rotation and the steepness of the dispersion curves of anilides in these series. The advantage, and at times the necessity, of using dispersion curves instead of measurements at the D-line, when applying Freudenberg's displacement rule, has been demonstrated.

A knowledge of the configurational relationships between different types of optically active compounds is important in many branches of chemistry. Several chemical and physical methods have been developed for correlating relative configurations [1,2]. From the X-ray crystallographic investigations on sodium rubidium tartrate by Bijvoet, Peerdeman and van Bommel [3] it follows that for compounds with a configuration related to glyceraldehyde even the absolute configuration is known. Most of the methods referred to [1–3] are laborious and require a fairly large amount of optically active substance. Studies of the optical rotatory dispersion, (*i.e.* the change of optical rotation with wavelength), can be performed on as little as 0.1—2 mg of a compound, and with a modern spectropolarimeter a simple dispersion curve from 700 to 275 mμ can be produced in less than half an hour.

Measurements of optical rotatory dispersion have been made by various scientists since the phenomenon was discovered in 1817 by Biot [4]. These investigations have mainly been concerned with physico-chemical aspects of rotatory dispersion [5–7], but some workers, (for instance Tschugaeff, Rupe, Freudenberg, Kuhn and Levene), also tried to relate the observed optical rotation to molecular structure, (for reviews and references see Refs.[1,6,8–13]). It was not until Djerassi started in 1954 extensive studies of the optical rotatory

* Part VIII, *Arkiv Kemi* 15 (1960) 419.

dispersion of ketones and aldehydes that it was proved that spectropolarimetry was an extremely valuable tool for the chemist in solving structural and stereochemical problems. The work by Djerassi and collaborators has been published in the series "Optical Rotatory Dispersion Studies I[14]—XXXIV [15]", and has also been reviewed [16–18].

In order to facilitate further discussion of the application of optical rotatory dispersion in this paper, a brief description will be given of some of the physical background and of the nomenclature used. A compound possesses optical rotatory power in an isotropic medium only when the mirror images of the molecule cannot be superimposed. When plane polarized light, (which is the superposition of right and left circularly polarized components), is transmitted through an optically active medium, the two components travel with unequal velocities. A phase difference between the right and the left circularly polarized components will thus arise, producing a rotation of the plane of polarization. The angle of rotation per unit length, α, is given by the expression,

$$\alpha = \frac{\pi}{\lambda_{vac}} (n_l - n_r) \qquad (1)$$

where λ_{vac} is the wavelength of the light *in vacuo* and n_l and n_r are the refractive indices of the left and right circularly polarized waves, respectively.

Simultaneously with the optical activity produced by the difference in velocity of propagation of right and left circularly polarized waves, there is a second effect referred to as circular dichroism, arising from unequal absorption of the two waves. This is due to differential absorption of the two components of the incident linearly polarized wave so that they have different amplitudes after traversing the medium. They thus combine to give elliptically polarized light. The difference between the absorption coefficients for left and right circularly polarized light is only a small fraction of the mean absorption coefficient, and as a consequence the ellips is very elongate. Any medium that exhibits circular birefringence will simultaneously show circular dichroism and the light will then not be plane polarized, but the effect is only apparent in the immediate vicinity of an absorption band. The variation of rotation and ellipticity in the neighbourhood of an absorption band has been called the *Cotton effect.*

Several physical theories have been developed which attempt quantitatively, to relate molecular structure to optical rotatory power, examples are those based on classical mechanics by Drude [19], Born [20,21] and Kuhn [7,22,23], and based on quantum-mechanical treatment of dispersion by Rosenfeld [24]. Further theories employing quantum-mechanical considerations have been put forward by Kirkwood [25], Condon, Altar, Eyring [26,27] and by Moffitt and Moscowitz [28–30]. A clear account of some of the theories of optical rotatory power has been given by Schellman [31].

The system of nomenclature used in this context by organic chemists is outlined in Fig. 1 [32,33]. It is somewhat different from that used by physical chemists [5,34]. The term *plain* curve is used if the curve shows no maximum, (peak), or minimum, (trough), directly related to a Cotton effect. They are

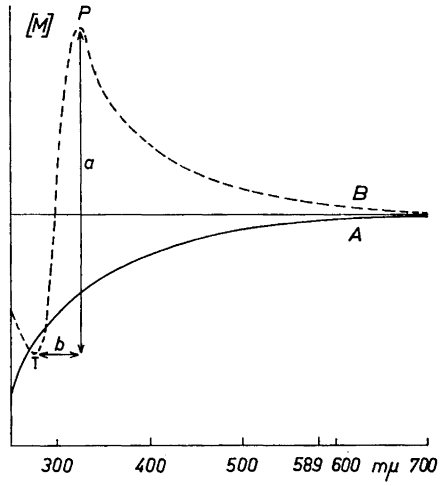

Fig. 1. Examples of a plain negative dispersion curve (A), and of a positive Cotton effect curve (B); (P, peak; T, trough; a, amplitude; b, breadth.)

called *positive* or *negative* respectively if they rise or fall towards shorter wavelengths. Other types of curves are called *anomalous* and in Fig. 1, this type is represented by a *positive single Cotton effect* curve. The Cotton effect is *positive* if the peak occurs at a longer wavelength than the corresponding absorption maximum, and the trough at a shorter wavelength.

The variation of the partial specific rotation $[\alpha]_{px}$ with wavelength outside the range of optically active absorption, can be expressed according to Drude [19]

$$[\alpha]_{px} = \frac{A_x}{\lambda^2 - \lambda_x^2} \tag{2}$$

where A_x is a molecular parameter, and λ_x is the centre of the single optically active absorption band. If more than one absorption band contributes to the rotation within the given spectral range, the general Drude equation [19] must be used:

$$[\alpha] = \sum \frac{A_i}{\lambda^2 - \lambda_i^2} \tag{3}$$

A numerical evalution of the unknown constants in eqn. 3 is extremely time-consuming even for its abbreviated forms [35].

The optical rotatory dispersion work performed recently by organic chemists has mainly been concerned with anomalous dispersion curves, and rotations have been measured in the regions of maximum absorption for the low intensity bands of, for example, ketones and aldehydes. With these compounds it is often unnecessary to calculate λ_i in the Drude equation because comparison of the rotatory dispersion curve and the electronic absorption spectrum of the substances, directly gives λ_i. It has been clearly shown that the sign, shape, and amplitude of these anomalous dispersion curves can be correlated empirically to certain structural and steric features of the compounds [16-18]. Only when more information is sought about the quantitative contributions of the

various optically active chromophores must the molecular parameters A_i, (which are related to the rotational strength [30]), be calculated.

The present paper deals with the optical rotatory dispersion of some carboxylic acids. As the carboxyl group absorbs in a region which is at present inaccessible for rotatory dispersion measurements, it was expected that only the plain part of the curves could be experimentally determined. With the compounds investigated by Djerassi [16-18] the useful information had been obtained mainly from the anomalous part of the dispersion curves. Thus two different problems arose: (a), What information can be obtained from plain dispersion curves, and (b), how can compounds with plain curves be transformed into derivatives possessing anomalous dispersion curves. Both problems are being investigated and some aspects of the second one have already been published [36]; further studies will follow. The first problem will now be discussed in more detail.

GENERAL EXPERIMENTAL PROCEDURE

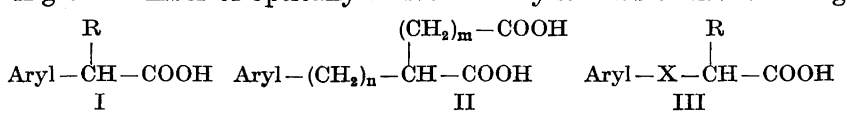
The optical rotatory dispersion curves in this paper have been obtained with a Rudolph photoelectric spectropolarimeter with the exception of a few cases (the measurements were made at Wayne State University, Detroit, Michigan, USA). A detailed description of the instrument as well of its operation, scope and limitations has been given elsewhere [37], and so will only be briefly mentioned here. The spectropolarimeter unit consisted of a light source, monochromator, polarimeter with photomultiplier tube, and photometer. The light source was a glass-jacketed concentrated-arc zirconium lamp in the spectral region 700—320 mμ. For shorter wavelengths a quartz-jacketed xenon high pressure arc lamp was used. The monochromatic light was produced by means of a Beckman DU quartz monochromator. Readings were taken by the method of symmetrical angles [37,38], and the polarimeter equipped with a polarizer drive which automatically changed a chosen symmetrical angle from positive to negative to positive at four seconds periods. One photomultiplier tube was used over the spectral range covered.

The polarimeter tubes were of the centre-filling type with permanently fastened fused silica end windows. The length of the tubes was either 10 cm or 5 cm and the capacity 1.9 ml. The substance to be investigated, 1—4 mg, was weighed out in a 2.00 ml volumetric flask on a microbalance. Solutions were made up in spectro grade solvents, most measurements being made in methanol. Readings were usually performed at 700, 650, 589, 550, 525, 400—330 mμ at 10 mμ intervals, and below 330 mμ at 5 mμ intervals. Blank readings using pure solvent were taken daily. Temperatures were recorded (see experimental) for each run, but no special temperature control was used. The temperature fluctuations were those encountered in the isolated room employed only for polarimetric studies. The errors inherent in the present rotatory dispersion measurements are of such an order of magnitude, that ordinary variations of the room temperature are not significant.

The maximum error in the readings was of the order of ± 0.02° which, for a concentration c = 0.2 g/100 ml, is equivalent to a specific rotation of ± 10° (10 cm tube). This error could have been substantially decreased in the visible region by using a much higher concentration, but for the measurements at shorter wavelengths a concentration c = 0.2 g/100 ml, or even less, had to be used due to the encreased absorption both by the optical system and the compounds. For the purpose of the present investigation, information about the dispersion curves in the ultraviolet region is more important than in the visible.

RESULTS AND DISCUSSION

A great number of optically active carboxylic acids of the following types,



where X is CH_2, NH, O, S or Se, have previously been made in Uppsala [39-42]. The steric relationships have been established, usually by means of the Fredga quasi-racemate method [43,44]. The optical rotatory dispersion of some series of these compounds has now been studied to see if the relative configurations of compounds in special series could be derived from the dispersion curves. The investigations on compounds related to type III will be discussed in a separate paper [45]. Information about the position of the optically active absorption bands can be obtained from the Drude equation. However, it was thought likely that the same type of empirical approach as has been used by Djerassi [16-18] would be more successful, with a large number of compounds, than using a detailed analysis of the Drude equation. All the ivestigated compounds have only one asymmetric centre, and the problem of determining the configuration is thus simplified in distinguishing between the two possibilities. When the region of the Cotton effect can not be quite reached, it is of course not possible to observe all the features — sign, shape and amplitude — which have been used in the correlation of optical rotatory dispersion and molecular structure. Nevertheless, it seemed likely that for the simple compounds of types I—III, dispersion curves and configuration could be correlated if measurements were made close to the first anisotropic absorption band.

α-Aryl monocarboxylic acids and derivatives

The compounds in this series can all be derived from type I, and they may be divided into three sections. In the first, the alkyl group is methyl and the aryl group varies. Most of the dispersion curves have been produced on the D-enantiomers, and even when the actual measurements in some cases were made on the L-forms, the curves throughout this paper will refer to compounds of D-configuration.

According to the Kuhn-Freudenberg theory [1,6] each group attached to the asymmetric centre contributes to the total rotation in two ways — (a), by its own rotatory contribution and (b), by its vicinal action on the other substituents. Weak absorption bands located in the near ultraviolet region often furnish strong partial rotations. The rotation in the visible region will be particularly influenced by these absorption bands due to their proximity. The rotatory contribution from absorption bands in the far ultraviolet will not be so apparent in the visible wavelength range, even if these absorption bands have high anisotropy factors.

The compounds of type I have their aromatic nuclei directly attached to the asymmetric centre. The first absorption in the region 270 to 230 mμ will come from the aromatic group, and if any of these benzenoid absorption bands are anisotropic, the aromatic group will be dominant for the rotation in the visible and near ultraviolet region. Investigations by Kuhn and Biller [12] clearly showed that the phenyl group is highly anisotropic in mandelic acid, atrolactic acid, and some derivatives of these acids, while the anisotropy of the phenyl bands was shown to be very small for phenyl substituted carbinols and halides [12,46]. Rothen and Levene [47] studied the optical rotatory dispersion of some phenyl substituted carboxylic acids, and they found no anomaly in the 250 mμ region. Numerical evaluation of the unknown constants in the Drude

XVI

equation indicated that the first optically active absorption band should be somewhere between 205 and 235 mμ, and so these authors concluded that the phenyl absorption in the 250 mμ region is not anisotropic for phenyl substituted fatty acids.

The rotatory dispersion curve of hydratropic acid (IV) is found in Fig. 2. The rotation rapidly increases towards the region of phenyl absorption. In this way the dispersion curve of hydratropic acid resembles that of mandelic acid [12]. Measurements with a recording Rudolph spectropolarimeter could be extended further into the ultraviolet region (dotted curve), and a peak was found in the experimental dispersion curve at about 270 mμ. An anomalous dispersion curve was also obtained with a Perkin-Elmer spectropolarimeter [37]. This anomaly, however, which was found close to the limiting range of the instruments may not be real. When the direct monochromatic light is almost completely absorbed a small fraction of scattered light of higher wavelengths will result in an effectively higher wavelength than that read on the monochromator. This circumstance may have caused the decreased rotation in the experimental curve below 270 mμ. Even though Rothen and Levene explicitly stated that no anomaly had been found in the 250 mμ region, it can be seen from their own measurements that the rotation of (+)-ethylphenylacetic acid was considerably less at 241 mμ than at 275 mμ (Ref.[46], Table II), *i.e.* the dispersion curve must have had a peak between 275 and 241 mμ.

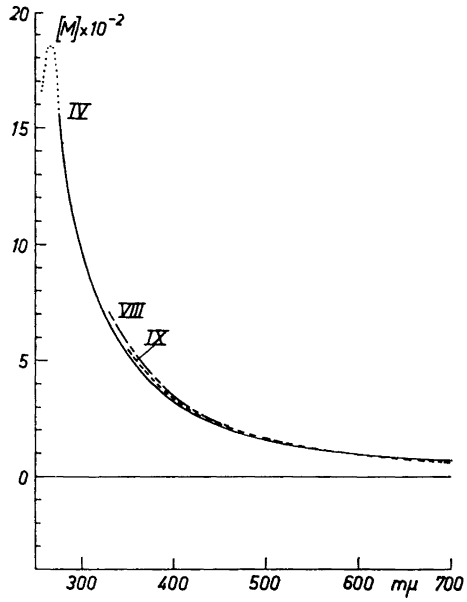

Fig. 2. Optical rotatory dispersion curves of (+)-hydratropic acid (IV), (+)-*p*-amino-hydratropic acid (VIII) and (+)-*p*-nitro-hydratropic acid (IX).

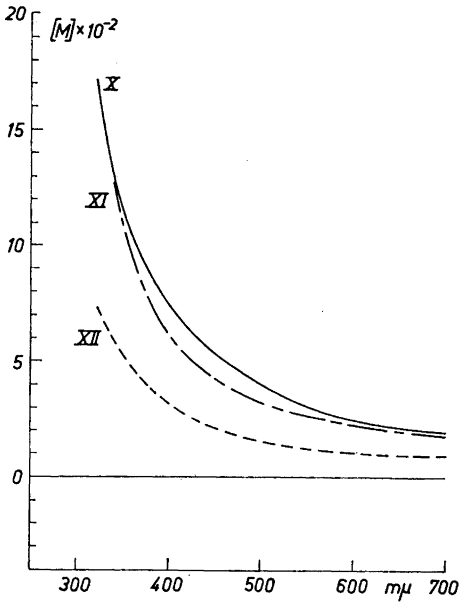

Fig. 3. Optical rotatory dispersion curves of (+)-α-(1-naphthyl)-propionic acid (X), (+)-α-(4-methyl-1-naphthyl)-propionic acid (XI) and (+)-α-(2-naphthyl)-propionic acid (XII).

The present author finds it likely that the phenyl absorption in the 250 mμ region is anisotropic and that the anisotropy factor of this absorption band has the same sign as that of the absorption at about 200 mμ, which may be the second absorption region of the phenyl group, or the first absorption region of the carboxyl group. The values of λ_i, found by Rothen and Levene may be unreliable. Heller [35] pointed out that it is easy to have a fortuitous agreement between calculated and observed [α]-values, and therefore unreliable constants in the two-term Drude equation. It is particularly difficult to calculate the constants, when two absorption bands with the same sign for the anisotropy factors are close together.

For the purpose of the present investigation it is not absolutely necessary to know if a certain absorption band is anisotropic, but it is important that the analogous compounds to be compared have similar groups which are dominant in the rotation. A certain group, for example an aromatic one, may have anisotropic bands or it may have strong vicinal action on the other groups.

The effects on the rotatory power of substitution in different aromatic systems have been studied by several investigators, by Betti [48], Nerdel *et al.*[49,50] and Singh *et al.*[51,52]. The optical rotatory dispersions of hydratropic acid (IV), *p*-aminohydratropic acid (VIII) and *p*-nitrohydratropic acid (IX) have previously been investigated by Nerdel and Würgau [53] in the visible region,

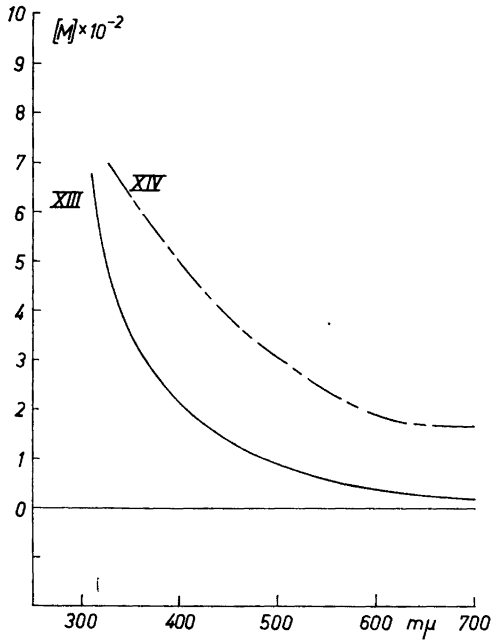

Fig. 4. Optical rotatory dispersion curves of (+)-α-(2-thianaphthenyl)-propionic acid (XIII) and (+)-α-(3-thianaphthenyl)-propionic acid (XIV).

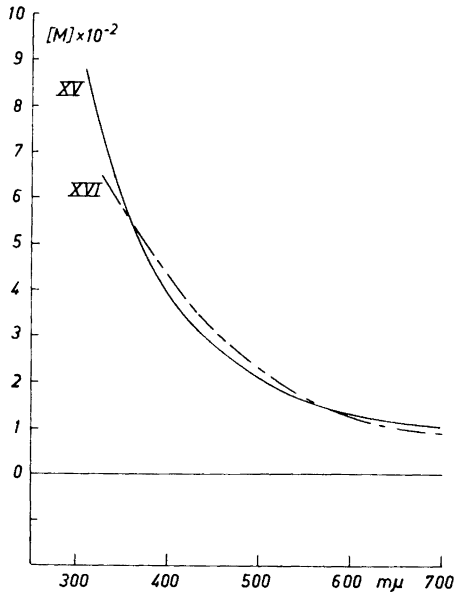

Fig. 5. Optical rotatory dispersion curves of (+)-α-(3-indolyl)-propionic acid (XV) and (+)-α-(1-methyl-3-indolyl)-propionic acid (XVI).

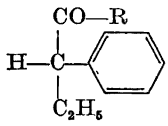
and now repeated and extended to the ultraviolet region, by the author. The curves are found in Fig. 2.

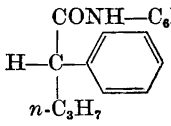
Introduction of an amino or a nitro group alters the benzenoid absorption bands considerably. The principal peak is displaced about 25 mμ towards longer wavelengths, and the intensity of this band is greatly increased [54]. Hydratropic acid *p*-aminohydratropic acids have almost the same molecular rotation in ethanol at the D-line, while that of *p*-nitrohydratropic acid is somewhat lower [55]. The dispersion curves are similar for the three acids; the amino and the nitro compounds having slightly higher molecular rotations towards shorter wavelengths. The dispersion curves of *p*-chlorohydratropic acid and *p*-hydroxihydratropic acid seem also to be positive for the D-forms [53].

The dispersion curves of (+)-α-(1-naphthyl)-propionic acid (X), (+)-α-(4-methyl-1-naphthyl)-propionic acid (XI) and (+)-α-(2-naphthyl)-propionic acid (XII) are found in Fig. 3. The three curves are similar and correspond well with the dispersion curve of hydratropic acid. Other aromatic systems which have been studied are the thianaphthenyl and the indolyl (Figs. 4 and 5). Phenyl, naphthyl, thianaphthenyl and indolyl groups apparently have similar influences on the rotation with this type of compound.

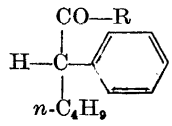
The second series derived from type I has been obtained by keeping the aryl group constant and varying the alkyl group. The following compounds have been investigated:



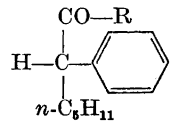
XVII R = OH
XVIII R = NH_2
XIX R = NH—C_6H_5



XX



XXI R = NH_2
XXII R = NH—C_6H_5



XXIII R = NH_2
XXIV R = NH—C_6H_5

The configurational relationship between hydratropic acid (IV) and ethylphenylacetic acid (XVII) has been established by Levene *et al.* from optical rotatory measurements at the D-line [56], and also from rotatory dispersion measurements [47]. Pettersson [57,58] related the compounds XVII—XXIV by applying the quasi-racemate method to the amides. The relationship between hydratropic acid and glyceraldehyde has been established in several ways [41,55,59] (for references to earlier work see Ref.[55]). The configuration of allylphenylacetic acid (XXV) was established by Fredga and Westman [60].

The dispersion curves of (+)-ethylphenylacetic acid (XVII) and (+)-allylphenylacetic acid (XXV) are given in Fig. 6. These curves, are plain positive, and correspond well with the dispersion curve of hydratropic acid (Fig. 2). Changing the alkyl group from methyl to ethyl or allyl does not appreciably alter the rotatory dispersion of the acids in this series.

Fredga [61] investigated 1-indanecarboxylic acid and proved that the (—)-form belongs to the D-series. It was concluded from the higher auxin activity that (—)-1-indanecarboxylic acid (XXVI) and (—)-1,2,3,4-tetrahydro-1-naphthoic acid (XXVII), (which also shows higher activity than its enantiomer [62]), have the same configuration. More evidence was obtained from the similar shifts in rotation when the rotatory power of the acids was measured in different solvents [63]. Levorotatory 1,2,3,4-tetrahydro-1-naphthoic acid was also shown to belong to the D-series by Westman [63], who synthesized it from (+)-*a*-phenylglutaric acid *cf.* formulas XXVII and XXXIX. The optical rotatory dispersion curves of (—)-1-indanecarboxylic acid and (—)-1,2,3,4-tetrahydro-1-naphthoic acid are to be found in Fig. 7; both curves being plain negative, and show the same order of rotation.

In the series of alkylphenylacetic acids, the compounds of D-configuration have plain positive dispersion curves in the region 700—275 mμ with high rotation at lower wavelengths. However, when the acids have the alkyl

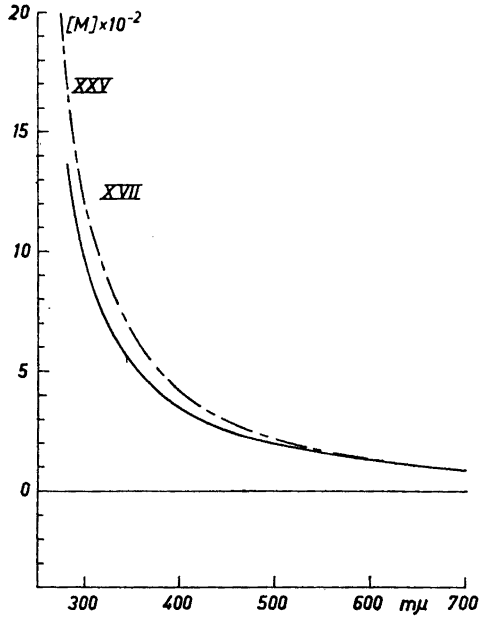

Fig. 6. Optical rotatory dispersion curves of (+)-ethylphenylacetic acid (XVII) and (+)-allylphenylacetic acid (XXV).

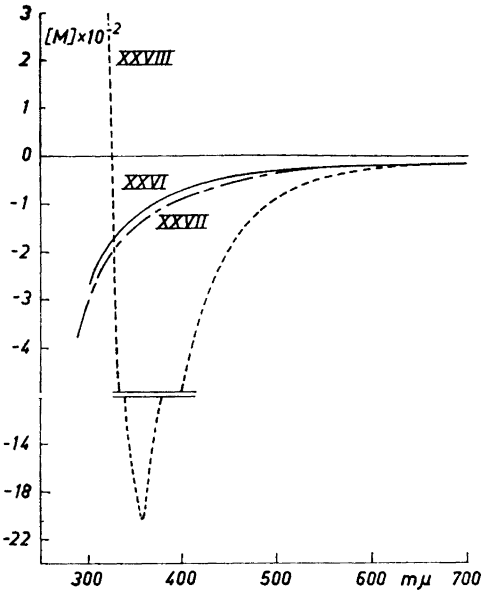

Fig. 7. Optical rotatory dispersion curves of (−)-1-indanecarboxylic acid (XXVI), (−)-1,2,3,4-tetrahydro-1-naphthoic acid (XXVII) and (−)-4-keto-1,2,3,4-tetrahydro-1-naphthoic acid (XXVIII).

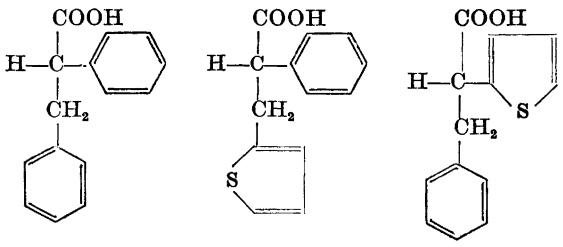
group ring closed to the *ortho* position, so as to form a five or six membered ring, the D-compounds have plain negative dispersion curves of comparatively low rotation in the same wavelength region. The "ring closed forms" have only been investigated in two cases in this series; it is unlikely that the same relation between configuration and sign of the dispersion curve will be found for compounds with small, medium and large rings. Parallels to these "open and closed forms" have also been studied for phenoxy acids and phenylthio acids [45].

The third section of compounds derived from type I has been obtained by varying both the aryl and alkyl groups. The diarylpropionic acids, previously studied by Pettersson [64-66], belong to this group. The optical rotatory dispersion curves of three of the acids (XXIX—XXXI) have been investigated. The curves of benzylphenylacetic acid (XXIX) and of 2-thenylphenylacetic acid (XXX) are almost identical throughout the investigated wavelength region, while benzyl-2-thienylacetic acid (XXXI), which has a thiophene nucleus attached to the asymmetric carbon instead of a benzene nucleus, has a lower rotation in the visible region, and a somewhat steeper curve below 300 mμ (Fig. 8).

Analogous benzene and thiophene compounds are closely similar in many respects [42], and so it was expected that the three compounds XXIX—XXXI



XXIX XXX XXXI

of the same configuration should have the same type of dispersion curves. The first series of ultraviolet absorption bands of thiophene is displaced by about 20 mμ towards shorter wavelengths compared to benzene [67]. Pettersson [40] investigated the optical rotation at the D-line of some 2-thienyl substituted acids; he pointed out that it was not possible to decide from these measurements if the lower rotation of the 2-thienyl compounds compared to the phenyl analogs depends on the shorter wavelength of absorption, or on a lower anisotropy of the band. The greater steepness of the dispersion curve of benzyl-2-thienylacetic acid at lower wavelengths compared to the curve of benzylphenylacetic acid, suggests instead a higher anisotropy of the 2-thienyl absorption

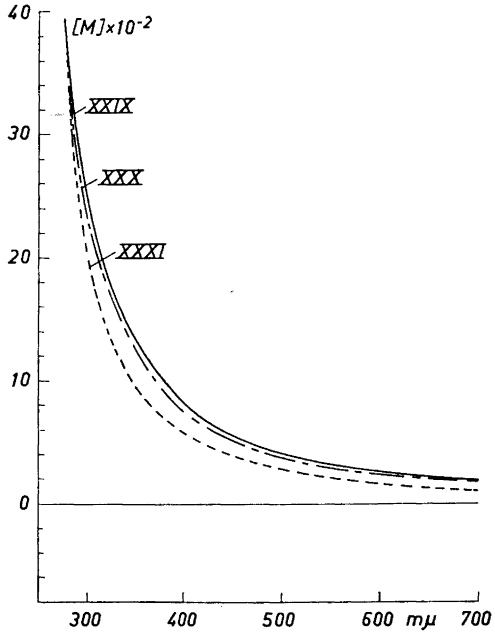


Fig. 8. Optical rotatory dispersion curves of (+)-benzylphenylacetic acid (XXIX), (+)-2-thenylphenylacetic acid (XXX) and (+)-benzyl-2-thienylactic acid (XXXI).

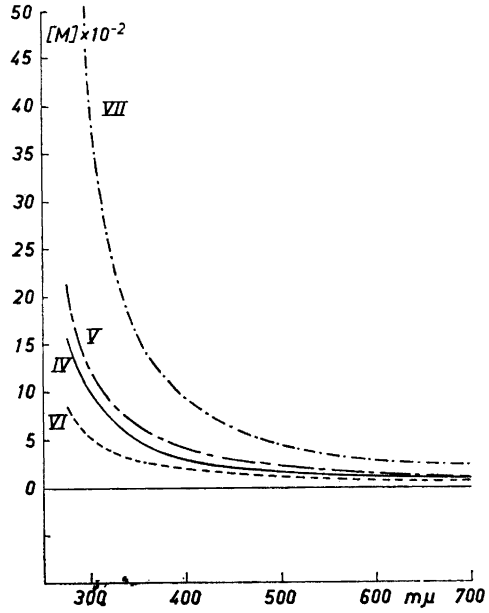

Fig. 9. Optical rotatory dispersion curves of (+)-hydratropic acid (IV), (+)-methyl hydratropate (V), (+)-hydratropamide (VI) and (+)-hydratropanilide (VII).

band, and the lower rotation in the visible region should be due to the shorter wavelength of absorption. Definite answers regarding the anisotropy of an absorption band can only be obtained from careful calculation of the rotational strength [30], or experimentally from measurements of the circular dichroism [5,7].

The displacement rule

Optical rotation data from the sodium D-line has often been used for correlation of configurations within series of similar compounds; (for reviews see Mills and Klyne [2], and Klyne [68]). This approach is based on the application of different rules, for instance the *rule of optical superposition* and the *distance rule*. Another qualitative rule which has been more generally used is *Freudenberg's displacement rule* [11], which can be formulated: "If two similar asymmetric molecules A and B are altered in the same way to give A' and B', then the differences in molecular rotation (A'—A) and (B'—B) are of the same sign" [68]. The displacement rule follows from Kuhn's *vicinal rule* [6] which says that when a small change is made in one of the groups attached to the asymmetric centre, the anisotropy of this group suffers the most change, while the vicinal action is less affected.

The displacement rule is best used when the shifts are large. As the rotational shifts at the sodium D-line for a given structural change are nearly

always less than in the ultraviolet region, it is better to apply Freudenberg's displacement rule on data obtained as far into the ultraviolet region as possible, but without losing accuracy in the measurements. Series of similar carboxylic acids are usually converted to esters, amides or anilides, and the shifts compared. The dispersion curves of hydratropic acid (IV), its methyl ester (V), amide (VI) and anilide (VII), are compared in Fig. 9, and those of ethylphenylacetic acid (XVII), its amide (XVIII) and anilide (XIX) are given in Fig. 10. The rotations of the amides at the D-line are slightly lower than those of the corresponding acids, while the rotations of the anilides are higher; the differences in molecular rotation are enhanced in the ultraviolet region. The calculated shifts for methylphenylacetic acid (hydratropic acid) and ethylphenylacetic acid at 589 mμ (sodium D-line) and 290 mμ, are found in Table 1.

Table 1. Molecular rotational shifts for methylphenylacetic acid and ethylphenylacetic acid; Δ_1 for (amide—acid); Δ_2 for (anilide—acid).

Acid	589 mμ		290 mμ	
	Δ_1	Δ_2	Δ_1	Δ_2
Methylphenylacetic	− 30°	+ 190°	− 480°	+ 4 880°
Ethylphenylacetic	− 30°	+ 160°	− 450°	+ 4 660°

Just as the optical rotatory dispersion curves for a series of acids were compared above, the curves for (+)-methylphenylacetamide (VI), (+)-*n*-butylphenylacetamide (XXI) and for (+)-*n*-amylphenylacetamide (XXIII) are compared in Fig. 11. In Fig. 12 are the curves of (+)-*n*-propylphenylacetanilide (XX), (+)-*n*-butylphenylacetanilide (XXII) and (+)-*n*-amylphenylacetanilide (XXIV). The three amides in Fig. 11, have all plain positive dispersion curves with comparatively low rotations even in the ultraviolet region, while the anilides have very high rotations at lower wavelengths.

From the examples discussed above it can be concluded, that the configurational relationships between different members in the series of alkylphenylacetic acids can be obtained with certainty, directly from the rotatory dispersion curves of the acids, as well as from the dispersion curves of the anilides. The amides are not very suitable for comparison due to the lower rotation throughout the investigated wavelength region.

Solvent effects. The influences of external conditions, such as solvent, temperature and concentration, on optical activity has been observed, and its importance recognized, ever since Biot's early investigations on tartaric acid [69,70]. These factors produce complicated results since both chemical and physical changes may occur from the alteration in external conditions [71]. It is quite obvious that the rotatory power will usually be greatly affected by changes in solvent or temperature, if the solute constitutes an equilibrium mixture of two or more distinct molecular species. The optical rotation is also very sensitive to conformational changes, and inversion of the Cotton effect has been observed [72] on altering the polarity of the solvent. The dipole-dipole interaction between solvent and solute will not only influence the conformation of

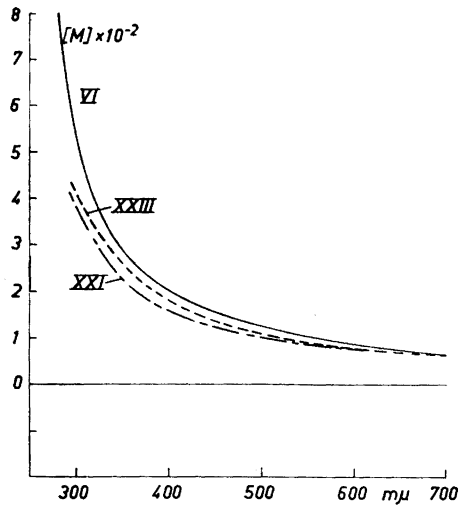

Fig. 11. Optical rotatory dispersion curves of (+)-methylphenylacetamide (VI), (+)-*n*-butylphenylacetamide (XXI) and (+)-*n*-amylphenylacetamide (XXIII).

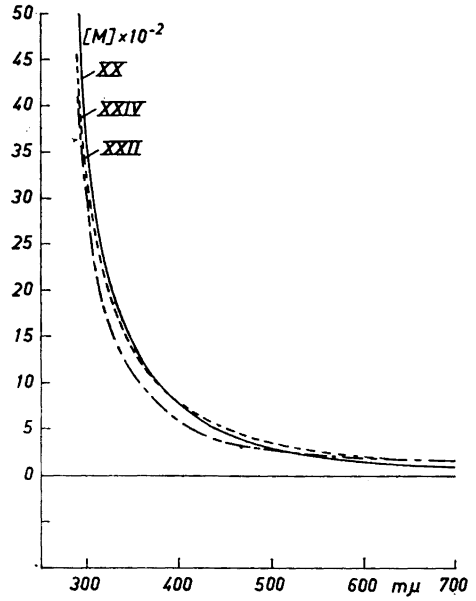

Fig. 12. Optical rotatory dispersion curves of (+)-*n*-propylphenylacetanilide (XX), (+)-*n*-butylphenylacetanilide (XXII) and (+)-*n*-amylphenylacetanilide (XXIV).

the molecules, but will also affect the local field, and in that way exert direct vicinal action on the chromophores of the optically active compounds. Furthermore, if strong bonds are formed between solvent and solute, the chromophores of the optically active molecule will change; sometimes even the solvent molecules can act as chromophoric groups.

Solvent influence on the rotation in the visible region was extensively studied by Pickard and Kenyon [73] and by Rule *et al.*[74,75] The solvent effect is especially noticeable in rotatory dispersion work [76,77], and thus when the dispersion curves of different compounds are compared, they should be made with the same solvent and at about the same concentration and temperature. Nevertheless, the solvent effect can be utilized, and comparison of the effect on similar compounds may give information regarding their steric relationship. Such investigations at the sodium D-line have been made on several compounds [39–41,78]. These studies of the rotational shifts can be considered as a special way of applying Freudenberg's displacement rule, and from the discussion above it is evident that information which is more reliable will be obtained if the rotatory dispersion curves are studied in different solvents, and not only the rotational shifts at the D-line in this way.

Pettersson [40] investigated the solvent effect on several α-arylcarboxylic acids at the D-line. Large negative shifts were observed for compounds of D-configuration when the rotation was measured in dilute sodium hydroxide solution. The rotatory dispersion curves in sodium hydroxide solution of some

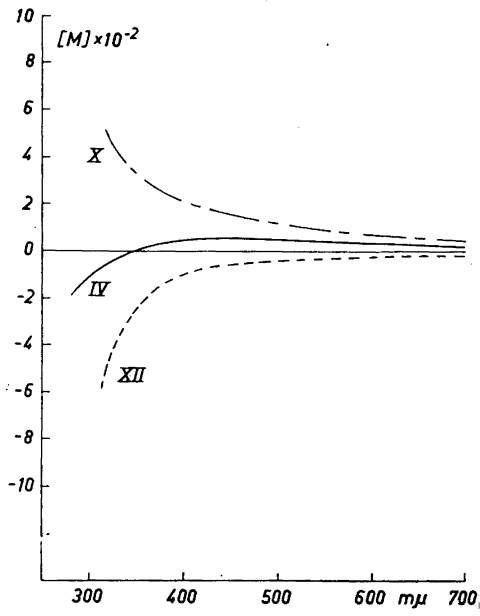

Fig. 13. Optical rotatory dispersion curves in 0.1 N sodium hydroxide of (+)-hydratropic acid (IV), (+)-α-(1-naphthyl)-propionic acid (X) and (+)-α-(2-naphthyl)-propionic acid (XII).

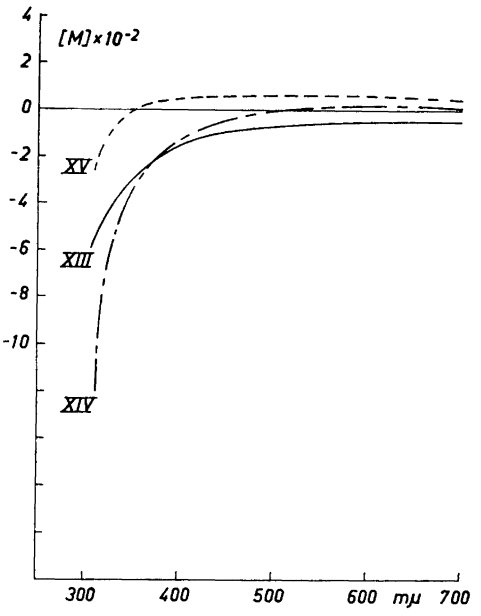

Fig. 14. Optical rotatory dispersion curves in 0.1 N sodium hydroxide of (+)-α-(2-thianaphthenyl)-propionic acid (XIII), (+)-α-(3-thianaphthenyl)-propionic acid (XIV), and (+)-α-(3-indolyl)-propionic acid (XV).

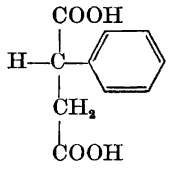
of these acids are given in Figs. 13 and 14. It can be seen that the negative shifts are very prominent in the ultraviolet region, and for all the compounds, except α-(1-naphthyl)-propionic acid (X), even the sign of the dispersion curves is reversed compared to that in methanol.

Aryl dicarboxylic acids

Oxidative degradation of natural products often yields alkyl substituted dicarboxylic acids; for example alkylsuccinic and alkylglutaric acids have been key substances in stereochemical studies on terpenes. Alkylsuccinic acids have also proved to be valuable substances in connecting aromatic compounds to the steric system of glyceraldehyde. Analogous benzene and thiophene derivatives can often be sterically related by the quasi-racemate method, and the thiophene compounds desulphurized with Raney nickel to the corresponding aliphatic compounds without racemisation [79].

In order to see if the steric relationships between different dicarboxylic acids could be found directly from their optical rotatory dispersion curves, an investigation of a large number of dicarboxylic acids was undertaken. The results on the alkylsubstituted acids will be published in a separate paper [80], and only the acids which are derived from type II will be discussed here.



XXXII

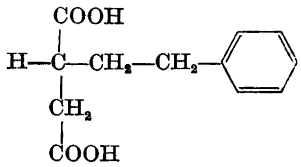
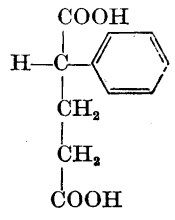
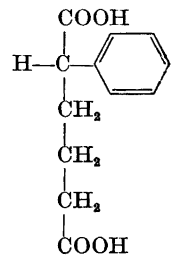
XXXVII



XXXVIII



XXXIX



XL

The configurations of these acids have previously been determined and the dextrorotatory compounds all belong to the D-series, (references are given below). The optical rotatory dispersion curves of (+)-phenylsuccinic acid (XXXII) [81], (+)-2-thienylsuccinic acid (XXXIII) [82] and (+)-3-thienylsuccinic acid (XXXIV) [83] are shown in Fig. 15. The dispersion curves are very similar for all these compounds being plain and positive with high rotation at lower wavelengths. It is interesting to compare the dispersion curve of phenylsuccinic acid to that of hydratropic acid (Fig. 2). Substitution of a hydrogen atom in the methyl group of hydratropic acid with a carboxyl group, gives phenylsuccinic acid. It can be seen that such a substitution does not change the main character of the curve, but only causes a higher rotation. The higher rotation may either be due to the vicinal action of the carboxymethyl group on the phenyl and carboxyl groups attached to the asymmetric centre, or (and) to a positive rotatory contribution from the carboxymethyl group. It has been shown by Levene and Rothen [47,48] that a carboxymethyl group has an opposite sign for its rotatory contribution to that of a carboxyl group in some series of compounds. For example, α-phenylpropionic acid, (hydratropic acid), of D-configuration is dextrorotatory, while β-phenylbutyric acid is levorotatory. Similarly a change in sign due to the partial rotation of the carboxyl group occurs when going from α-methylbutyric acid to β-methylvaleric acid. The

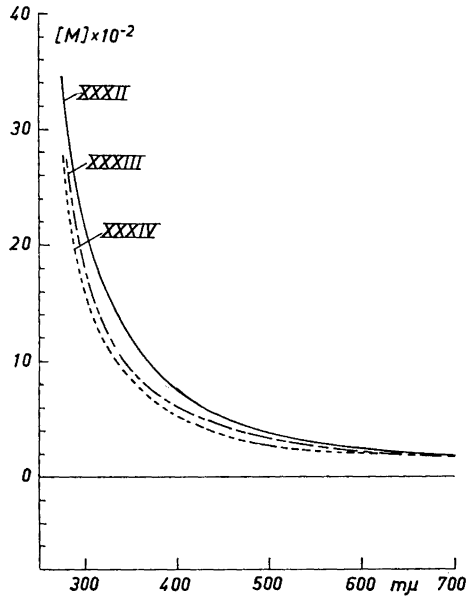


Fig. 15. Optical rotatory dispersion curves of (+)-phenylsuccinic acid (XXXII), (+)-2-thienylsuccinic acid (XXXIII) and (+)-3-thienylsuccinic acid (XXXIV).

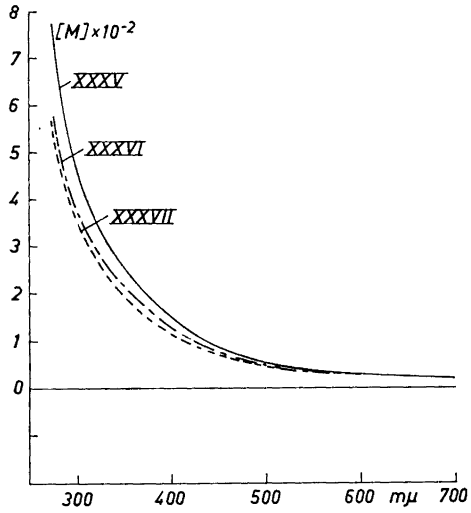

Fig. 16. Optical rotatory dispersion curves of (+)-benzylsuccinic acid (XXXV), (+)-2-thenylsuccinic acid (XXXVI) and (+)-3-thenylsuccinic acid (XXXVII).

reason that the same type of inversion is not found when going from hydratropic acid to phenylsuccinic acid, must be connected with the mutual influence of a phenyl and a carboxyl group attached to the same asymmetric centre.

The variations in the rotatory dispersion curves of some compounds belonging to type II, when n increases from 0 to 1, can be seen from a comparison of Figs. 15 and 16. Benzylsuccinic acid (XXXV) [79], 2-thenylsuccinic acid (XXXVI) [79], and 3-thenylsuccinic acid (XXXVII) [85] of D-configuration have plain positive dispersion curves, but the rotation is considerably lower than for the corresponding compounds with the aryl group directly attached to the asymmetric centre.

According to the distance rule a smaller change in rotation will be expected when n increases from 1 to 2 compared to that for an increase of n from 0 to 1. That this is so can be seen from Fig. 17, where the dispersion curves of (+)-phenylsuccinic acid (XXXII), (+)-benzylsuccinic acid (XXXV) and (+)-phenylethylsuccinic acid (XXXVIII) [86] are reproduced.

The influence on the rotatory dispersion curves of compounds belonging to type II, when n is kept constant (n = 0) and m is varied from 1 to 3, has been studied on the series (+)-phenylsuccinic acid (XXXII), (+)-α-phenylglutaric acid (XXXIX) [87] and (+)-α-phenyladipic acid (XL) [88]. The dispersion curves for these compounds, all of D-configuration, are found in Fig. 18;

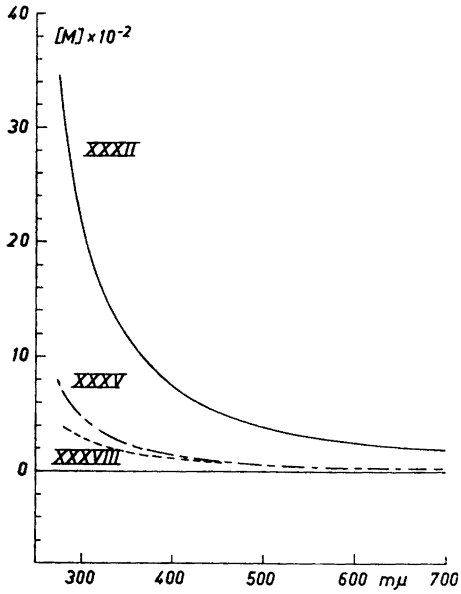

Fig. 17. Optical rotatory dispersion curves of (+)-phenylsuccinic acid (XXXII), (+)-benzylsuccinic acid (XXXV) and (+)-phenylethylsuccinic acid (XXXVIII).

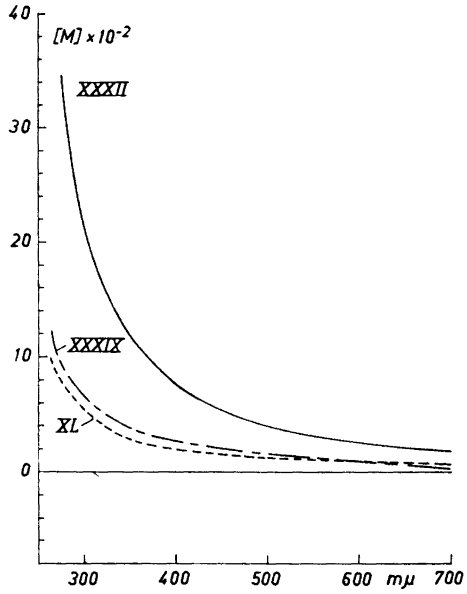

Fig. 18. Optical rotatory dispersion curves of (+)-phenylsuccinic acid (XXXII), (+)-α-phenylglutaric acid (XXXIX) and (+)-α-phenyladipic acid (XL).

the curves are all plain and positive. In the series of alkyl dicarboxylic acids the D-alkylsuccinic acids are dextrorotatory with plain positive dispersion curves, while D-α-alkylglutaric acids are levoratory with plain negative dispersion curves [80].

In the present paper all dispersion curves refer to compounds of D-configuration. All the curves, except the three of the "ring closed" compounds XXVI, XXVII and XXVIII, are plain and positive in the investigated wavelength region. It may be fortuitous, of course, that such different compounds have the same type of rotatory dispersion curves for analogous configuration, but nevertheless, the relative configurations of compounds within some series of types I and II can be obtained with great certainty using these curves. In the Aryl—$\underset{\displaystyle R}{\underset{|}{CH}}$—COOH series, where R is alkyl, an analogous configuration will give a similar dispersion curve if the aryl group is kept constant, and the alkyl group varies. If the alkyl is the same and the aryl group varies, the magnitude of the rotation may change considerably, but the dispersion curves are still of the same general type and especially sign. The last statement is probably not of unrestricted validity, as the aryl group has a dominant influence on the rotation, and very great variations in this group may be expected to reverse the sign of the dispersion curves. However, the following variations in the aryl group have not resulted in any major rotatory dispersion changes:

phenyl, *p*-aminophenyl, *p*-nitrophenyl, *p*-chlorophenyl, *p*-hydroxiphenyl, 1-naphthyl, 4-methyl-1-naphthyl, 2-naphthyl, 2-thianaphthenyl, 3-thianaphthenyl, 3-indolyl and 1-methyl-3-indolyl.

$$\text{Aryl-(CH}_2)_n\text{-CH(-(CH}_2)_m\text{-COOH)-COOH}$$

In the Aryl-$(CH_2)_n$-CH(-$(CH_2)_m$-COOH)-COOH series, the relative configuration of compounds with different aryl groups can be obtained directly from the dispersion curves if n and m are kept constant, (n equal to 0). The aryl group can probably be varied in the same way as for compounds belonging to type I (see above). It may not always be safe to compare compounds belonging to the series with m = 1 to that with m = 2, even if phenylsuccinic and *α*-phenylglutaric acid of the same configuration have the same type of dispersion curves. However, a change of m from 2 to a higher integer will have a smaller influence on the rotation, and a comparison of different acids with n = 0, m = 2 with acids having n = 0, m = 3, 4 . . . is fairly sound. When m is constant (equal to 1), and n varies from 0 to 2, as with the investigated compounds phenylsuccinic, benzylsuccinic, phenylethylsuccinic acids, the disperison curves are of the same type for analogous configuration. When m is greater than 1, these dicarboxylic acids are more similar to the series of *α*-alkyl-*ω*-phenylcarboxylic acids investigated by Levene and Rothen [47,48], which had an alternating change in the rotation at the D-line, but still had the same type of dispersion curves on movement of the phenyl group away from the asymmetric centre. The effect of separation distance of an aliphatic carbonyl function (ketone, aldehyde) on an asymmetric centre has been investigated by Djerassi and Geller [89], and they found that the sign of the Cotton effect curve is reversed when either one, or no carbon atoms are interposed.

The extensive investigations of the anomalous optical rotatory dispersion of ketones and aldehydes by Djerassi *et al.*[16–18] have clearly shown the advantages of using dispersion curves instead of only sodium D-line rotations. Compounds, such as carboxylic acids, which have their ultraviolet absorption in a presently inaccessible region for rotatory dispersion measurements, give only plain dispersion curves, but nevertheless the configurational relationship between compounds belonging to certain series of simple compounds can be obtained directly from their dispersion curves. Occasionally the plain dispersion curves cross the zero rotation line somewhere below 589 mμ [18,45,47] and then configurational assignmentes based on a single measurement at the D-line may be impossible. The displacement rule applied using D-line rotations often gives valuable information about configurational relationships, but even when this rule is used it is more reliable to make a comparison of the dispersion curves of the different derivatives. Freudenberg and Biller [90] pointed out that when the displacement rule is used, the nature of the optical activity has to be considered. Comparisons should be made with great caution if the rotational shifts, when going from one derivative to another, are more dependent on changes in the vicinal action than on changes in the direct contribution from the altered group. For example the rotatory contribution of the phenyl group in the methyl ester of mandelic acid methyl ether is negative, but positive in the dimethylamide. On the other hand, the phenyl contribution is positive in

the corresponding derivatives of atrolactic acid (α-methylmandelic acid)[12,90]. Similar changes in the rotatory contributions cannot be detected from measurements of only D-line rotations, but can at least qualitatively be observed directly in the optical rotatory dispersion curves.

Acknowledgement. The author wishes to express his sincere gratitude to Professors Arne Fredga, Carl Djerassi, and to Dr. E. J. Eisenbraun for many valuable discussions as well as for all the facilities put at his disposal. He is also indebted to Drs. Salo Gronowitz, Magnus Matell, Kurt Skagius (Pettersson) and Lars Westman for specimens of many of the optically active substances.

Financial support from, the *Swedish Natural Science Research Council*, the *Sweden-America Foundation, Smålands nation (A. M. Lundins stipendiefond)*, and the *National Cancer Institute* (grant No. CY-2919) *of the National Institutes of Health, U.S. Public Health Service*, is gratefully acknowledged.

EXPERIMENTAL

The experimental results are recorded in the manner outlined in Ref. [32]. If not otherwise stated the rotatory dispersion curves were taken in methanol. The samples were purified, usually by recrystallization, and the D-line rotations were checked to be in accordance with the literature values. As these measurements were taken in various solvents and at high concentrations, the rotations are not directly comparable with those obtained in the rotatory dispersion (R.D.) measurements, and the results are not reported. The molecular rotation values at the D-line and the previous configurational determinations can be found in the references given.

R.D. (Fig. 13) in 0.1 N sodium hydroxide (*c* 0.100), temp. 27°: $[M]_{589}$ + 30°, $[M]_{400}$ + 40°, $[M]_{350}$ + 10° $[M]_{300}$ −100°, $[M]_{280}$ −290°.

(+)-Methyl hydratropate (V) Prepared from (+)-hydratropic acid using diazomethane. R.D. (Fig. 9) in methanol (*c* 0.225), temp. 25°: $[M]_{589}$ + 170°, $[M]_{400}$ + 440°, $[M]_{350}$ + 650°, $[M]_{300}$ + 1 200°, $[M]_{275}$ + 2 120°.

(+)-Hydratropamide (VI)[57] R.D. (Fig. 9) in methanol (*c* 0.120), temp. 27°: $[M]_{589}$ + 80°, $[M]_{400}$ + 200°, $[M]_{350}$ + 290°, $[M]_{300}$ + 530°, $[M]_{280}$ + 780°.

(+)-Hydratropanilide (VII) [57] R.D. (Fig. 9) in methanol (*c* 0.167), temp. 27°: $[M]_{589}$ + 300°, $[M]_{400}$ + 920°, $[M]_{350}$ + 1 600°, $[M]_{300}$ + 4 250°, $[M]_{290}$ + 5 680°.

(+)-p-Aminohydratropic acid (VIII) [55] R.D. (Fig. 2) in methanol (*c* 0.122), temp. 27°: $[M]_{589}$ + 110°, $[M]_{400}$ + 330°, $[M]_{350}$ + 540°, $[M]_{330}$ + 710°.

(+)-p-Nitrohydratropic acid (IX) [55] R.D. (Fig. 2) in methanol (*c* 0.150), temp. 29°: $[M]_{589}$ + 130°, $[M]_{400}$ + 330°, $[M]_{390}$ + 340°.

(+)-α-(1-Naphthyl)-propionic acid (X) [91] R.D. (Fig. 3) in methanol (*c* 0.094), temp. 30°: $[M]_{589}$ + 260°, $[M]_{400}$ + 740°, $[M]_{350}$ + 1 240°, $[M]_{320}$ + 1 710°.

R.D. (Fig. 13) in 0.1 N sodium hydroxide (*c* 0.090) temp. 26°: $[M]_{589}$ + 60°, $[M]_{400}$ + 230°, $[M]_{350}$ + 360°, $[M]_{315}$ + 520°.

(+)-α-(4-Methyl-1-naphthyl)-propionic acid (XI) [92] R.D. (Fig. 3) in methanol (*c* 0.096), temp. 27°: $[M]_{589}$ + 210°, $[M]_{400}$ + 590°, $[M]_{350}$ + 1 100°, $[M]_{340}$ + 1 240°.

(+)-α-(2-Naphthyl)-propionic acid (XII) [93] R.D. (Fig. 3) in methanol (*c* 0.096), temp. 27°: $[M]_{589}$ + 110°, $[M]_{400}$ + 310°, $[M]_{350}$ + 510°, $[M]_{320}$ + 720°.

R.D. (Fig. 13) in 0.1 N sodium hydroxide (*c* 0.100), temp. 24°: $[M]_{589}$ −30°, $[M]_{400}$ −90°, $[M]_{350}$ − 260°, $[M]_{315}$ − 580°.

(+)-α-(2-Thianaphthenyl)-propionic acid (XIII) [94] R.D. (Fig. 4) in methanol (*c.* 0.060), temp. 27°: $[M]_{589}$ + 40°, $[M]_{400}$ + 210°, $[M]_{350}$ + 340°, $[M]_{310}$ + 680°.

R.D. (Fig. 14) in 0.1 N sodium hydroxide (*c* 0.100), temp. 25°: $[M]_{589}$ − 60°, $[M]_{400}$ − 130°, $[M]_{350}$ − 330°, $[M]_{305}$ − 600°.

(+)-α-(3-Thianaphthenyl)-propionic acid (XIV) [95] R.D. (Fig. 4) in methanol (*c* 0.092), temp. 28°: $[M]_{589}$ + 190°, $[M]_{400}$ + 480°, $[M]_{350}$ + 650°, $[M]_{330}$ + 710°.

R.D. (Fig. 14) in 0.1 N sodium hydroxide (*c* 0.105) temp. 25°: $[M]_{589}$ + 10°, $[M]_{400}$ − 80°, $[M]_{350}$ − 300°, $[M]_{310}$ − 1 170°.

(+)-α-(3-Indolyl)-propionic acid (XV) [96] R.D. (Fig. 5) in methanol (*c* 0.120), temp. 27°: $[M]_{589}$ + 130°, $[M]_{400}$ + 390°, $[M]_{350}$ + 600°, $[M]_{310}$ + 880°.

R.D. (Fig. 14) in 0.1 N sodium hydroxide (*c* 0.179), temp. 24°: $[M]_{589}$ + 50°, $[M]_{400}$ + 50°, $[M]_{350}$ − 10°, $[M]_{310}$ − 270°.

(+)-α-(1-Methyl-3-indolyl)-propionic acid (XVI) [97,98] R.D. (Fig. 5) in methanol (*c* 0.100), temp. 23°: $[M]_{589}$ + 140°, $[M]_{400}$ + 440°, $[M]_{350}$ + 580°, $[M]_{325}$ + 630°.

(+)-Ethylphenylacetic acid (XVII) [57] R.D. (Fig. 6) in methanol (*c* 0.575), temp. 27°: $[M]_{589}$ + 130°, $[M]_{400}$ + 350°, $[M]_{350}$ + 530°, $[M]_{315}$ + 790°; (*c* 0.115): $[M]_{315}$ + 780°, $[M]_{300}$ + 970°, $[M]_{280}$ + 1 370°.

(+)-Ethylphenylacetamide (XVIII) [57] R. D. (Fig. 10) in methanol (*c* 0.130), temp. 27°: $[M]_{589}$ + 100°, $[M]_{400}$ + 240°, $[M]_{350}$ + 330°, $[M]_{300}$ + 620°, $[M]_{280}$ + 810°.

(+)-Ethylphenylacetanilide (XIX) [57] R.D. (Fig. 10) in methanol (*c* 0.170), temp. 27°: $[M]_{589}$ + 290°, $[M]_{400}$ + 890°, $[M]_{350}$ + 1 560°, $[M]_{300}$ + 4 170°, $[M]_{290}$ + 5 700°.

(+)-n-Propylphenylacetanilide (XX) [58,59] R.D. (Fig. 12) in methanol. (*c* 0.140), temp. 27°: $[M]_{589}$ + 190°, $[M]_{400}$ + 780°, $[M]_{350}$ + 1 360°, $[M]_{305}$ + 3 010°; (*c* 0.028): $[M]_{305}$ + 3 100°, $[M]_{300}$ + 3 640°, $[M]_{290}$ + 5 200°.

(+)-n-Butylphenylacetamide (XXI) [58,59] R.D. (Fig. 11) in methanol (*c* 0.142), temp. 27°: $[M]_{589}$ + 80°, $[M]_{400}$ + 160°, $[M]_{350}$ + 200°, $[M]_{320}$ + 300°; (*c* 0.071): $[M]_{320}$ + 310°, $[M]_{300}$ + 380°, $[M]_{290}$ + 420°.

(+)-n-Butylphenylacetanilide (XXII) [58,59] (Fig. 12) in methanol (*c* 0.115), temp. 27°: $[M]_{589}$ + 220°, $[M]_{400}$ + 600°, $[M]_{350}$ + 1 020°, $[M]_{310}$ + 2 210°; (*c* 0.023): $[M]_{310}$ + 2 250°, $[M]_{300}$ + 3 060°, $[M]_{290}$ + 4 100°.

(+)-n-Amylphenylacetamide (XXIII) [58,59] R.D. (Fig. 11) in methanol (*c* 0.127), temp. 27°: $[M]_{589}$ + 80°, $[M]_{400}$ + 180°, $[M]_{350}$ + 270°, $[M]_{300}$ + 420°, $[M]_{290}$ + 450°.

(+)-n-Amylphenylacetanilide (XXIV) [58,59] R.D. (Fig. 12) in methanol (*c* 0.235), temp. 28°: $[M]_{589}$ + 220°, $[M]_{400}$ + 770°, $[M]_{350}$ + 1 320°, $[M]_{300}$ + 3 240°, $[M]_{290}$ + 4 570°.

(+)-Allylphenylacetic acid (XXV) [60] R.D. (Fig. 6) in methanol (*c* 0.263), temp. 28°: $[M]_{589}$ + 150°, $[M]_{400}$ + 420°, $[M]_{350}$ + 660°, $[M]_{300}$ + 1 220°, $[M]_{275}$ + 1 980°.

(−)-1-Indanecarboxylic acid (XXVI) [61] R.D. (Fig. 7) in methanol (*c* 0.098), temp. 27°: $[M]_{589}$ − 20°, $[M]_{400}$ − 70°, $[M]_{350}$ − 120°, $[M]_{300}$ − 270°.

(−)-1.2.3.4-Tetrahydro-1-naphthoic acid (XXVII) [63] R.D. (Fig. 7) in methanol (*c* 0.257), temp. 28°: $[M]_{589}$ − 20°. $[M]_{400}$ − 90°, $[M]_{350}$ − 140°, $[M]_{310}$ − 270°; (*c* 0.0514): $[M]_{310}$ − 260°, $[M]_{300}$ − 330°, $[M]_{290}$ − 360°.

(−)-4-Keto-1,2,3,4-tetrahydro-1-naphthoic acid (XXVIII) [63] R.D. (Fig. 7) in methanol (*c* 0.105), temp. 24°: $[M]_{589}$ − 30°, $[M]_{400}$ − 470°, $[M]_{357.5}$ − 2 050° (T), $[M]_{327}$ ± 0°, $[M]_{305}$ + 1 770°.

(+)-Benzylphenylacetic acid (XXIX) [40,65] R.D. (Fig. 8) in methanol (*c* 0.125), temp. 28°: $[M]_{589}$ + 290°, $[M]_{400}$ + 800°, $[M]_{350}$ + 1 310°, $[M]_{310}$ + 2 040°; (*c* 0.0125): $[M]_{310}$ + 2 140°, $[M]_{300}$ + 2 600°, $[M]_{275}$ + 4 060°.

(+)-2-Thenylphenylacetic acid (XXX) [40,64] R.D. (Fig. 8) in methanol (*c* 0.133), temp. 27°: $[M]_{589}$ + 270°, $[M]_{400}$ + 770°, $[M]_{350}$ + 1 210°, $[M]_{310}$ + 2 020; (*c* 0.0133); $[M]_{310}$ + 2 100°, $[M]_{300}$ + 2 440°, $[M]_{275}$ + 3 950°.

(+)-Benzyl-2-thienylacetic acid (XXXI) [40,64] R.D. (Fig. 8) in methanol (*c* 0.121), temp. 28°: $[M]_{589}$ + 190°, $[M]_{400}$ + 590°, $[M]_{350}$ + 940°, $[M]_{310}$ + 1 640°; (*c* 0.0242): $[M]_{310}$ + 1 800°, $[M]_{300}$ + 2 150°, $[M]_{275}$ + 4 000°.

(+)-Phenylsuccinic acid (XXXII) [81,99] R.D. (Fig. 15) in methanol (*c* 0.120), temp. 24°: $[M]_{589}$ + 250°, $[M]_{400}$ + 750°, $[M]_{350}$ + 1 170°, $[M]_{300}$ + 2 160°, $[M]_{275}$ + 3 460°.

(+)-2-Thienylsuccinic acid (XXXIII) [82] R.D. (Fig. 15) in methanol (*c* 0.130), temp. 24°: $[M]_{589}$ + 220°, $[M]_{400}$ + 610°, $[M]_{350}$ + 950°, $[M]_{300}$ + 1 750°, $[M]_{280}$ + 2 700°.

(+)-3-Thienylsuccinic acid (XXXIV) [83] R.D. (Fig. 15) in methanol (*c* 0.143), temp. 25°: $[M]_{589}$ + 200°, $[M]_{400}$ + 530°, $[M]_{350}$ + 840°, $[M]_{300}$ + 1 560°, $[M]_{275}$ + 2 800°.

(+)-Benzylsuccinic acid (XXXV) [79,100] R.D. (Fig. 16) in methanol (*c* 0.163), temp. 24°: $[M]_{589}$ + 30°, $[M]_{400}$ + 160°, $[M]_{350}$ + 260°, $[M]_{300}$ + 440°, $[M]_{275}$ + 780°.

(+)-2-Thenylsuccinic acid (XXXVI) [79,100] R.D. (Fig. 16) in methanol (*c* 0.110), temp. 25°: $[M]_{589}$ + 20°, $[M]_{400}$ + 150°, $[M]_{350}$ + 230°, $[M]_{300}$ + 340°, $[M]_{275}$ + 570°.

(+)-3-Thenylsuccinic acid (XXXVII) [85] R.D. (Fig. 16) in methanol (*c* 0.171), temp. 25°: $[M]_{589}$ + 30°, $[M]_{400}$ + 110°, $[M]_{350}$ + 190°, $[M]_{300}$ + 330°, $[M]_{275}$ + 580°.

(+)-Phenylethylsuccinic acid (XXXVIII) [86,101] (Fig. 17) in methanol (*c* 0.100), temp. 24°: $[M]_{589}$ + 30°, $[M]_{400}$ + 100°, $[M]_{350}$ + 180°, $[M]_{300}$ + 280°, $[M]_{270}$ + 450°.

(+)-α-Phenylglutaric acid (XXXIX) [87] R.D. (Fig. 18) in methanol (c 0.100), temp. 21°: $[M]_{589}$ + 100°, $[M]_{400}$ + 230°, $[M]_{350}$ + 390°, $[M]_{300}$ + 650°, $[M]_{265}$ + 1 220°.

(+)-α-Phenyladipic acid (XL) [88] R.D. (Fig. 18) in methanol (c 0.100), temp. 21°: $[M]_{589}$ + 90°, $[M]_{400}$ + 190°, $[M]_{350}$ + 320°, $[M]_{300}$ + 550°, $[M]_{265}$ + 1 010°.

On the Biosynthesis of the Pigments of *Penicillium islandicum*. II

STEN GATENBECK

Institute of Biochemistry, University of Lund, Lund, Sweden

The acetate origin of islandicin from *P. islandicum* is shown by degradation after feeding the mould with ^{14}C-carboxyl labelled acetate, resulting in a strict alternate labelling of the anthracen structure.

By feeding the mould with ^{18}O-labelled acetate, three hydroxyl groups in islandicin and four in emodin are shown to be derived from the carbonyl group of acetic acid. Furthermore, the incorporation of ^{18}O in the secondary alcoholic groups of rubroskyrin indicates their formation from keto groups, originating from acetate, by hydrogenation.

The acetate origin of skyrin from *Penicillium islandicum* has been demonstrated by the incorporation of ^{14}C-labelled acetate in the molecule[1]. The ^{14}C-distribution in skyrin was experimentally established by reductive cleavage of the dianthraquinone to emodin. Oxidation of emodin to acetic acid according to Kuhn and Roth and hypobromite degradation of tetranitroemodin to bromopicrin left the radioactivities of six C-atoms out of fifteen to be measured directly. The isotope distribution of the remaining C-atoms was calculated by means of the acetate theory and the experimentally determined localizations of ^{14}C-atoms. In spite of the agreement with the theory it was desirable to complete the experiment with an investigation of a genuine anthraquinone and to make a more extensive degradation of the molecule.

Islandicin, which occurs in dominant amounts in the pigments of *P. islandicum*, was chosen as starting material. The degradation of islandicin, isolated from the mould after growing on a Czapek-Dox medium containing ^{14}C-carboxyl labelled acetate, was made according to the reaction series outlined in Fig. 1.

In the reaction series I, ring A of islandicin was obtained as 3-hydroxyphthalic acid by oxidation with hydrogen peroxide in alkali. Decarboxylation of 3-hydroxyphthalic acid yielded *m*-hydroxybenzoic acid, and the carboxyl group in position 2 as carbon dioxide. The radioactivity of the carbon dioxide, measured as barium carbonate, was 1/4 of the total radioactivity of 3-hydroxyphthalic acid. The carboxyl group in position 1 of 3-hydroxyphthalic acid

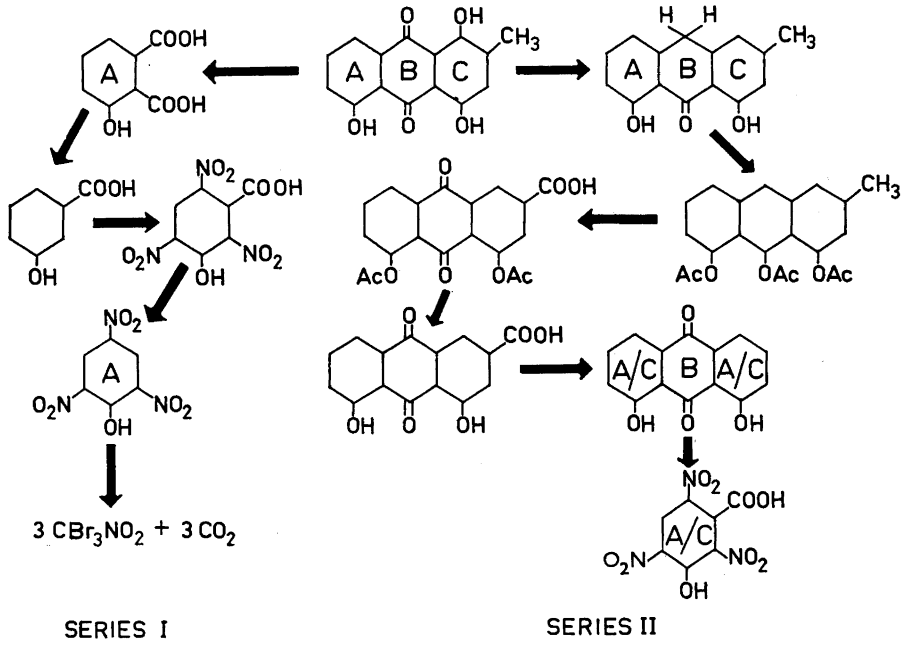

Fig. 1. Scheme of degradation of islandicin.

obtained as carbon dioxide by decarboxylation of the trinitro derivative of *m*-hydroxybenzoic acid, was shown to be nonradioactive. By treating the remaining picric acid with a barium hypobromite solution, the carbon atoms in the 2-, 4-, and 6-positions of the 3-hydroxyphthalic acid were obtained as bromopicrin which was nonradioactive. However, the barium carbonate formed during the reaction, and representing the carbon atoms in the 1-, 3-, and 5-positions, contained the other 3/4 of the total radioactivity of 3-hydroxyphthalic acid.

The ^{14}C-isotope distribution in 3-hydroxyphthalic acid obtained by oxidative cleavage of islandicin is apparently the same as that in the 3-hydroxyphthalic acid formed *in vivo* by *P. islandicum* [2].

On the presumption that the methyl group of islandicin is nonlabelled, which is later confirmed by the experiment, the specific radioactivities of the 3-hydroxyphthalic acid and the islandicin (2.37×10^4 cpm/mg C and 2.23×10^4 cpm/mg C, resp.) indicate that the radioactivity is equally distributed between the A and C rings of islandicin.

In the reaction series II, islandicin was reduced with hydriodic acid to chrysophanol anthron according to Howard and Raistrick [3]. Oxidation of the triacetyl derivative of chrysophanol anthron with chromic anhydride left diacetylrhein. After hydrolysis of the acetyl derivative, the rhein formed

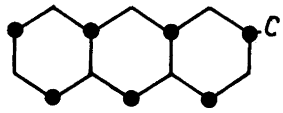

Fig. 2. ^{14}C-Distribution in anthraquinones derived from ^{14}C-carboxyl labelled acetate.

was decarboxylated and the evolved carbon dioxide shown to be nonradioactive. The symmetrical anthraquinone, chrysazin, obtained during the decarboxylation was oxidized with fuming nitric acid to trinitro-*m*-hydroxybenzoic acid. The benzene ring of this substance represents a statistical mixture of the A and C rings of islandicin. The further degradation of trinitro-*m*-hydroxybenzoic acid was performed with the same procedures as described for the degradation of 3-hydroxyphthalic acid. The ^{14}C-distribution in the benzene ring, *i.e.* the rings A + C of islandicin, was identical with that of ring A.

Combination of the ^{14}C-distributions obtained from the two reaction series gives a strict alternate labelling of the carbon atoms all over the molecule of islandicin, as shown in Fig. 2.

As shown in an earlier paper [4] ^{18}O-labelled acetic acid is an available tool for confirmation of the acetate origin of phenolic substances produced by moulds. In some cases it should also be possible to distinguish in the phenolic compound between the oxygen atoms derived from the carbonyl groups of the acetyl units and the oxygen atoms secondarily introduced.

To obtain some information of the character of the oxygen atoms in the polyhydroxyanthraquinone derivatives produced by *P. islandicum*, the mould was grown as above with acetic acid labelled with ^{14}C and ^{18}O in the carboxyl group as the tracer substrate.

Islandicin, skyrin and rubroskyrin were isolated from the mycelium. The radioactivity and the ^{18}O-content of islandicin and emodin, obtained by cleavage of skyrin, were determined.

As seen from Table 3, islandicin and emodin have approximately the same radioactivity, indicating a steady state of the ^{14}C metabolism. Under this condition the ^{18}O-content of the oxygen containing groups originating from the carboxyl group of acetic acid should be the same in islandicin and emodin.

Guided by the acetate theory, the positions of the ^{18}O-labelled groups in phenolic substances could be deduced. Islandicin will theoretically contain three ^{18}O-labelled positions (4, 5 and 10); emodin four labelled positions (4, 5, 7 and 10).

The average amounts of ^{18}O in emodin and islandicin were 0.82 atom% and 0.64 atom%, resp. By calculating the ^{18}O-content in the expected labelled positions, 1.02 atom% (emodin) and 1.07 atom% (islandicin) are obtained. The coincidence of these two values is a support of the validity of the theoretically calculated number of labelled positions in the two substances.

The localization of the labelled oxygen in emodin and islandicin is not established by the ^{18}O-analysis. Emodin anthron and chrysophanol anthron were prepared from the anthraquinones by refluxing with hydriodic acid. The two anthrons should theoretically contain only the labelled oxygen groups but ^{18}O-analysis of the two compounds, however, showed that the ^{18}O groups were interchanged with the nonlabelled aqueous medium during the reaction.

The isolated rubroskyrin was thermally decomposed at 270°C whereby the secondary alcoholic groups of rubroskyrin are split off as water. The ^{18}O-analysis of the water (0.54 atom%) indicated that the alcoholic groups originate from acetic acid and are formed from carbonyl groups by hydrogenation at some stage during the biosynthesis of rubroskyrin. The rather low value of ^{18}O compared with the expected value (1.05 atom%) taken from the ^{18}O-analysis of the anthraquinones, could be explained with a faster exchange of a secondary alcoholic group than of a phenolic hydroxyl group.

In column 7 of Table 3 are given the dilution ratios of ^{18}O and ^{14}C in the substances studied. The ratios 1 obtained for emodin and islandicin show that the activation of exogenous acetate and the formation of these anthraquinones are extremely rapid processes in *P. islandicum*.

Degradation of islandicin

EXPERIMENTAL

The culture conditions and the isolation of the islandicin used are described elsewhere [2].

Reaction series I. 104.5 mg of labelled islandicin were dissolved in 25 ml of 1 N sodium hydroxide. The solution was heated on a steam bath and an aqueous solution of 30 % hydrogen peroxide added dropwise until the islandicin solution was colourless. After cooling, the solution was acidified with hydrochloric acid and extracted exhaustively with ether. The residue, after evaporation of the ether solution, was developed on a paper chromatogram with chloroform-methanol-formic acid (4 %) (10:1:1) as the solvent. The

Table 1. ^{14}C-Distribution in 3-hydroxyphtalic acid obtained by oxidation of islandicin.

Material	Numbers of C-atoms from 3-hydroxy-phthalic acid	Radio-activity cpm	Total radio-activity of the material cpm	Number of ^{14}C-labelled positions	
				Found	Calculated
1	2	3	4	5	6
3-Hydroxyphthalic acid (total comb.)	8	483	3 864	3.99	4
COOH-Group (2-position)	1	960	960	1	1
m-Hydroxybenzoic acid (total comb.)	7	405	2 835	3.06	3
COOH-Group (1-position)	1	61	61	0.06	0
Bromopicrin (C-atoms from 2,4,6-positions)	3	0	0	0	0
CO_2 from the hypobromite degradation (C-atoms from 1,3,5-positions)	3	920	2 760	2.89	3

The numbers of ^{14}C-labelled positions in column 5 are obtained by taking the radio-activity of the COOH-group from 2-position as the basis for the calculations. This COOH-group is supposed to be derived directly from the COOH-group in acetic acid.

region of the paper containing 3-hydroxyphthalic acid (R_F *ca.* 0.15) was cut out and the phthalic acid extracted with ethanol. The yield of 3-hydroxyphthalic acid, determined spectrophotometrically (ε_{333} 1 665) was 60 %. The ethanolic solution was evaporated to dryness at room temperature and the specific radioactivity of the 3-hydroxyphthalic acid determined (2.37×10^4 cpm/mg C). To the labelled compound was added 1.5 g of non-labelled 3-hydroxyphthalic acid and the mixture recrystallized to constant radioactivity from water.

The degradation of the 3-hydroxyphthalic acid and the radioactivity measurements (Table 1) were performed as described in a previous paper [2].

Reaction series II. A mixture of 150 mg of islandicin, 3 ml of glacial acetic acid, 150 mg of red phosphorus and 0.6 ml of hydriodic acid (*d*, 1.67) was refluxed, with stirring, for 5 h. After filtration of the hot solution, chrysophanol anthron crystallized on cooling. Recrystallization from glacial acetic acid yielded 53 mg (40 %) of chrysophanol anthron, m. p. 206°C.

A mixture of the labelled anthron and 705 mg of nonlabelled chrysophanol anthron was recrystallized to constant radioactivity. After combustion of the anthron according to van Slyke and Folch [5], the radioactivity of the carbon dioxide was measured as barium carbonate (the same amount of barium carbonate (15 mg) was used throughout this work for the radioactivity measurements).

Acetylation of the anthron was made with the method described by Naylor and Gardner [6]. A mixture of 500 mg of the chrysophanol anthron, 11 ml of acetic anhydride, and 560 mg of anhydrous sodium acetate was boiled for 5 h and then poured onto crushed ice, and the precipitate formed filtered off and recrystallized from glacial acetic acid. Yield of triacetylchrysophanol anthron: 360 mg (47 %), m. p. 237°C.

The triacetylchrysophanol anthron was oxidized to diacetylrhein according to Hesse [7] by dissolving in a solution of 4 ml of glacial acetic acid and 4 ml of acetic anhydride, and heating with a solution of 750 mg of chromic anhydride in 5 ml of glacial acetic acid at 70°C for 4 h. After addition of water and boiling for a while in order to decompose the acetic anhydride, the precipitate formed was filtered off and redissolved in 1 N sodium carbonate without further purification and the unreacted triacetylchrysophanol anthron separated by filtration. The sodium carbonate solution was acidified with hydrochloric acid and the diacetylrhein sucked off and hydrolyzed with 1 N sodium hydroxide by

Table 2. ^{14}C-Distribution in islandicin.

Material	Number of C-atoms	Radio-activity cpm	Total radio-activity of the material cpm	Number of ^{14}C-labelled positions	
				Found	Calculated
1	2	3	4	5	6

The numbers of ^{14}C-labelled positions in column 5 are obtained by placing seven theoretically labelled positions in chrysazin as basis for the calculations.

Table 3. ^{18}O and ^{14}C analysis.

Material	Radio-activity (total) cpm	Radio-activity of labelled C cpm	Average ^{18}O-content atom %	Theoretical number of ^{18}O-labelled positions	Calculated ^{18}O-content of labelled positions	Dilution ^{18}O *versus* ^{14}C
Sodium acetate	47 600	95 200	21.6			1
Islandicin	2 375	5 089	0.64	3	1.07	1.08
Emodin	2 300	4 928	0.82	4	1.02	1.09
Rubroskyrin			0.54 (the alcoholic group)			

boiling for 15 min. The rhein was isolated after acidification of the solution and recrystallized from glacial acetic acid. Yield 160 mg (57 %), m. p. 320°C.

The rhein was decarboxylated by heating with 5 ml of pure quinoline and 100 mg of copper chromite (prepared according to the method of Adkins and Connor [8]) at 220°C for 2 h. The radioactivity of the carbon dioxide evolved was measured as barium carbonate. After cooling, the reaction mixture was treated with excess of dilute hydrochloric acid, boiled for a few minutes and extracted with ether. The residue, after evaporation of the ether, consisting of chrysazin, was recrystallized from dilute acetic acid. Yield 128 mg (95 %), m. p. 196°C.

The labelled chrysazin was recrystallized together with 2.0 g of nonlabelled chrysazin from glacial acetic acid and the radioactivity determined after combustion as above.

The chrysazin was refluxed with nitric acid (*d*, 1.52) for 7 h and then evaporated to dryness on the steam bath. A filtered water solution of the residue was exhaustively extracted with ether after acidification with hydrochloric acid. Evaporation of the ether phase, containing trinitro-*m*-hydroxybenzoic acid and very small amounts of picric acid, and recrystallization of the residue from dilute sulfuric acid yielded 700 mg of trinitro-*m*-hydroxybenzoic acid, m. p. 186°C.

The ^{14}C-distribution in the trinitro-*m*-hydroxybenzoic acid was experimentally established with the same methods used for the degradation of 3-hydroxyphthalic acid.

The values of the radioactivities in Table 2 are transformed to the same level of dilution.

Analysis of ^{18}O-incorporation

^{18}O-Labelled sodium acetate was prepared by the reaction of 294 mg of water (containing 90 atom% ^{18}O) with an equivalent amount of acetyl chloride at 0°C. The acetic acid and the remaining hydrochloric acid formed were neutralized with 1 N sodium hydroxide. 16.8 mg (0.1 mC) of ^{14}C-carboxyl labelled sodium acetate were added and a small volume withdrawn for isotope analyses. The radioactivity of the dried substance was made after combustion as above, and the ^{14}O content measured after cracking as described earlier [4].

The culture conditions were the same as previously mentioned but with the doubly labelled acetate as the tracer substrate.

After drying at room temperature, the mycelium was extracted in a Soxhlet apparatus with petroleum ether (b. p. 40—60°C) for 3 h, and then with acetone until the extraction solvent was almost uncoloured. The acetone solution was evaporated to dryness, and the pigments separated in a column of silica gel with chloroform as solvent. Islandicin and iridoskyrin together with small amounts of lipids followed the front and a mixture of skyrin and rubroskyrin was eluted by the addition of 10 % acetone to the chloroform.

The islandicin was isolated from its evaporated fraction by sublimation at 150—160°C in vacuum and recrystallization from chloroform. Yield 115 mg, m. p. 218°C.

Skyrin and rubroskyrin were separated in a second silica gel column with ether as the solvent. Emodin, obtained by cleavage of skyrin with sodium dithionite according to Howard and Raistrick [9], was purified by sublimation at 180—190°C in vacuum and recrystallization from toluene. Yield 55 mg, m. p. 257°C.

The radioactivities and ^{18}O contents of islandicin and emodin were determined by the methods described above.

The fraction containing rubroskyrin was developed on a paper chromatogram (Whatman 3 MM) with *iso*propylether, saturated with water, as the solvent. The region containing rubroskyrin (R_F 0.40) was cut out and extracted with acetone. Evaporation of the acetone yielded 30 mg of chromatographically pure rubroskyrin, m. p. 275—280°C (decomp.).

The rubroskyrin was thermally decomposed at 270°C in the apparatus used for the preparation of carbon dioxide for ^{18}O-analysis. Special precautions were taken and test samples run to secure that no decomposition product other than water entered the cracking oven during the process.

Chromatography on ECTEOLA * of Sulfate Containing Mucopolysaccharides

NILS R. RINGERTZ and PETER REICHARD

Department of Cell Research and Department of Chemistry I, Karolinska Institutet, Stockholm 60, Sweden

The chromatographic behaviour at different pH of hyaluronic acid, chondroitinsulfuric acid and heparin on ECTEOLA cellulose columns was studied. At acid pH good separations of the three polysaccharides from each other were obtained either by step-wise or gradient elution chromatography. Heparin preparations could be fractionated into subfractions of different anticoagulant activity. When the chromatography was carried out at +4°C no detectable inactivation of heparin occurred. The recovery of polysaccharides from the columns was close to 100 %.

A great number of different methods have been used for the preparation and fractionation of acid mucopolysaccharides (see *e.g.* Ref.[1-3]). Most of these methods have involved salt or alcohol fractionation, or electrophoresis. These methods are not easily adapted for a rapid preparation of small quantities of polysaccharides, as is often desired in tracer studies and enzyme experiments. An exception in this respect is the cetylpyridinium method of Scott [2,4,5].

Paper chromatography has not been used to any large extent, probably because of difficulties in finding a system where the polysaccharides give reproducible R_F values.

Ion exchange chromatography on Dowex 1 was used by Davidson and Meyer [6] for the preparation of chondroitin.

We have previously described briefly the use of the cellulose anion exchanger ECTEOLA for the fractionation of acid mucopolysaccharides [7]. This paper reports these experiments in full and describes some further extensions from them.

ECTEOLA was originally introduced by Peterson and Sober [8] for the chromatography of proteins. So far, however, it has been used mainly in the fractionation of nucleotides and polynucleotides [9,10].

* For brevity, this anion exchanger will be referred to here simply as ECTEOLA. This designation is derived from a contraction of the words epichlorohydrin and triethanolamine.

MATERIALS AND METHODS

Polysaccharides. Several batches of polysaccharides prepared according to different methods were used in this investigation *. However, the experiments shown in Tables 2—4 were all performed with the same polysaccharides. Some analytical data for the main polysaccharide preparations studied are shown in Table 1. It can be seen that hyaluronic acid was contaminated with materials containing galactosamine and sulfate. It is likely that this was due to the presence of a small quantity of chondroitin sulfuric acid.

Packing of columns. ECTEOLA cellulose (commercial grade, 0.39 meq/g) prepared according to Peterson and Sober [9], was obtained from Brown Company, Berlin, New Hampshire, USA. Before use, about 50 g of ECTEOLA cellulose was suspended in 0.5 M NaCl and packed in a large glass column. The column was then washed with 5 liters of 0.5 M NaOH, 5 liters of 3 M NaCl and 3 liters of 0.1 M NaCl—HCl (1:1). These washings were essential, otherwise materials giving various reactions for sugars were eluted in the chromatograms. The washed resin was then resuspended in 0.1 M NaCl—HCl (1:1) and packed into smaller columns for chromatography.

Polysaccharide solutions in water were adjusted to the pH used for chromatography by the addition of small quantities of the salt solution used for starting the chromatogram. The final solutions, containing 0.5—2 mg polysaccharide/ml with a salt concentration of less than 0.05 M, were allowed to drain into the column by gravity.

Elution of columns: Four different systems were used for elution of the columns:

A. 0.1—3.0 M HCl.
B. 0.1—3.0 M NaCl—HCl (1:1), pH 1.3 **.
C. 0.1—2.5 M NaCl in 0.05 M Glycine-HCl-buffer, pH 2.9 **.
D. 0.1—2.5 M NaCl in 0.05 M Sodium acetate buffer, pH 5.0 **.

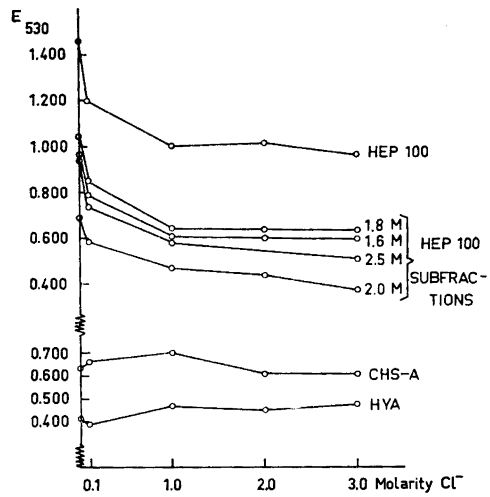

Fig. 1. Effect of different concentrations of HCl—NaCl (1:1) on the development of color in the carbazol reaction.

In a few exceptional cases when the polysaccharide was not completely eluted in these systems, the columns were at the end eluted with 0.5 M NaOH.

The columns were either eluted step-wise or by a gradient elution system which gave a linear increase in chloride concentration [11]. During step-wise elution a total of 100—150 ml of solution was used in each step with 1 × 10 cm ECTEOLA columns containing 10—15 mg of polysaccharide. The columns were eluted with the same eluent until the effluent contained less than 10 μg uronic acid/ml. In most cases 10—20 ml fractions were collected with an automatic fraction collector. The rate of elution during both gradient and step-wise chromatography was 10—20 ml/hour for a 10 × 1 cm column.

Analysis of fractions. The polysaccharides were localized in the different chromatographic fractions with the carbazol method [12]. For keratosulfate the anthrone reaction [13] was used. Salt concentration of the effluent was determined by conductivity measurements.

The influence of salt concentration on the results obtained by the carbazol method was studied in model experiments (Fig. 1). It is seen that, with heparin, increasing salt concentration (HCl—NaCl, 1:1) depressed the color development by about 40 %. No similar effect was observed for hyaluronic acid or chondroitin sulfuric acid. Instead, with hyaluronic acid a slight increase in color was observed at higher salt concentrations, while the effect on chondroitin sulfuric acid was negligable. Since high salt concentrations depressed the color development with heparin, it was considered necessary to investigate whether subfractions of heparin gave the same results. This was found to be the case (*cf.* Fig. 1), although minor quantitative differences could be observed.

The different heparin fractions were eluted at salt concentrations between 1.5 and 3.0 M Cl^- (system A), where no changes took place in the influence of salt on color development. Consequently no correction for the salt effect between different heparin fractions was necessary.

For heparin the carbazol reaction normally gives uronic acid values that are about 60 % higher than the theoretical ones [12]. The depression in color formation observed for heparin in the presence of chloride almost abolishes this anomaly and makes possible a more accurate quantitative interpretation of the carbazol reaction in the effluent. The errors in the quantitative estimation of chondroitin sulfuric acid and hyaluronic acid due to the presence of salt were found to be less than 8 %.

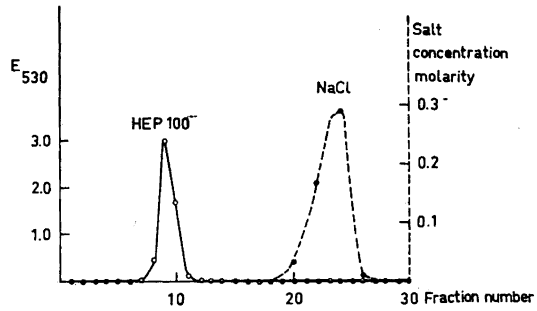

Fig. 2. Separation by gel-filtration on a Sephadex column (14 × 2 cm) of 2.5 mg of HEP 100 from 110 mg of NaCl.

Removal of salt. It was necessary to remove salts before more detailed analysis of the polysaccharide fractions could be made. This was done by dialysis at 0°C for 24 h against distilled water in tubing obtained from Visking Corporation, Chicago, Ill., USA. The solution was then neutralized to pH 7 with NaOH and evaporated under vacuum to a small volume. The polysaccharides were precipitated with 3—4 volumes of ethanol. The precipitate was then washed with 75 % ethanol, dried in a vacuum, weighed and analyzed.

When it was expected that an appreciable amount of polysaccharide would be lost during dialysis, a gel filtration technique was used [14]. This is illustrated by Fig. 2 which shows the separation of 2.5 mg of heparin (HEP 100) and 110 mg of NaCl by gel filtration on Sephadex G 25 (Pharmacia, Uppsala, Sweden). The materials were dissolved in 1 ml of water and introduced into the column by gravity. Elution was carried out with distilled water. Fractions were collected by a fraction collector (1.5 ml/30 sec). The polysaccharide could be completely separated from salt, the whole procedure being completed in less than 10 min.

Analytical methods. The total amino sugar content of the polysaccharides was determined by a modification of the Elson-Morgan procedure [15]. Glucosamine and galactosamine were separated and determined according to Gardell [16], uronic acid according to Tracey [17]. Sulfate was analyzed by the benzidine method [18] as modified by Balazs [19]. In this last modification the benzidine sulfate precipitate was collected on bacterial filters (Ra. Millipore Filter Comp., Bedford, Mass., USA.). Nitrogen was determined according to Kjeldahl. For moisture determinations the polysaccharides were dried under vacuum over P_2O_5 for 22 h at 90°C. Anticoagulant activity * was determined according to Studer and Winterstein [20].

RESULTS AND DISCUSSION

Tables 2, 3 and 4 give a survey of the chromatographic behaviour of hyaluronic acid (HYA), chondroitinssulfuric acid (CHS-A) and heparin (HEP 100) in four different chromatographic systems (*cf.* material and methods).

Hyaluronic acid (Table 2) was found to be very loosely or not at all bound to the ion exchanger in systems A and B. At the higher pH values of systems C and D it was adsorbed to the exchanger. In a gradient chromatogram with system D hyaluronic acid was eluted as a sharp peak between 0.4—0.5 M chloride.

* We wish to thank Prof. E. Jorpes, mrs Sohlberg and Vitrum Company for help with the determination of anticoagulant activities.

Table 2. Chromatographic behaviour of hyaluronic acid on ECTEOLA.

Fraction (Molarity Cl^-)	Amount of polysaccharide in % of total quantity eluted in different fractions	
	System B (and A)	System C (and D)
0.1	92	0
0.7	0	92
0.9	0	0
1.1	8	8

The calculations are based on the carbazol reaction applied directly to the eluted fractions.

The data in Tables 2—4 were obtained from chromatograms of 10—15 mg of polysaccharide on ECTEOLA columns, 1 × 10 cm.

For experimental data see Table 2.

The different behaviour of hyaluronic acid in systems A and B on the one hand and systems C and D on the other hand was probably due to the fact that the pK of the carboxyl groups of hyaluronic acid is 3.2 [21]. The polysaccharide therefore contains hardly any negative charge at a pH below 1.5 (systems A and B). At pH values of 3 and 5 (systems C and D, respectively) the carboxyl group can be expected to be at least partially dissociated and to cause the binding of the polysaccharide to the basic groups of the ECTEOLA column.

The two sulfated polysaccharides studied showed a different behaviour. Chondroitin sulfuric acid A (Table 3) was retained by the exchanger in all four systems. For complete elution of CHS-A the highest chloride concentration was required with system A (HCl), the lowest chloride concentration with system D.

Heparin showed a behaviour similar to chondroitin sulfuric acid A with the four chromatographic systems. In system A heparin was only partially eluted even at 3.0 M HCl. Complete elution of heparin was only obtained by raising the pH (Table 4).

The behaviour of the two sulfated polysaccharides is at first sight rather unexpected. Because of the dissociation of carboxyl groups the polysaccharides would be expected to contain a higher negative net charge at pH values of 3 and 5 (systems C and D, respectively) than at pH-values below 1.5 (systems A and B). Thus one would expect that the polysaccharides would be eluted with a lower chloride concentration at the more acid pH. The reverse was found to be the case.

The sharpest separations of hyaluronic acid, chondroitin sulfuric acid and heparin from each other could be obtained with systems A and B. Since heparin was not completely eluted from the resin with 3 M HCl in system A, it was considered that system B was more suitable for elution of the polysaccharides. System B was therefore studied further.

Fig 3 shows a separation of an artificial mixture of HYA, CHS-A and Hep 120 by step-wise elution. It can be seen that a clear separation of the three polysaccharides into three main peaks was obtained. As demonstrated in

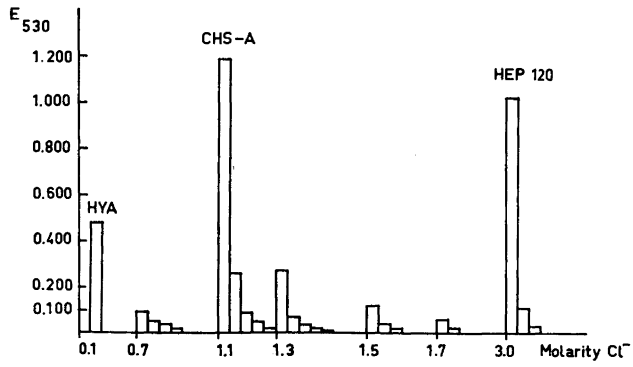

Fig. 3. Fractionation on an ECTEOLA column (1 × 12 cm) of a polysaccharide mixture containing 6 mg HYA, 14 mg CHS—A and 13 mg HEP 120. Fractions 12—15 ml/30 min.

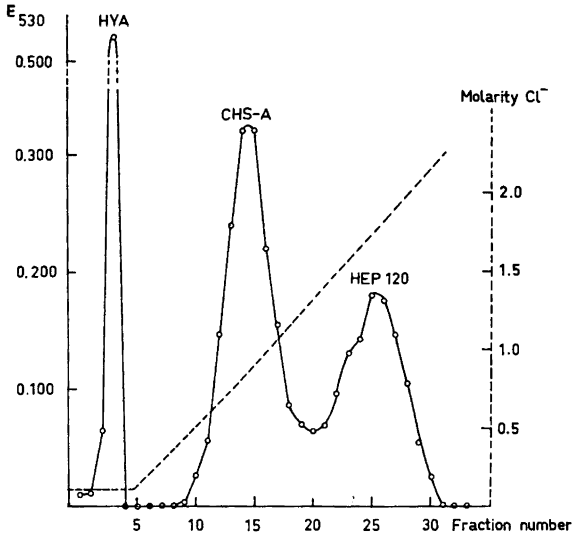

Fig. 4. Gradient chromatogram of the same mixture as in Fig. 3. Reservoir: 400 ml of 3.0 M NaCl—HCl (1:1), mixing vessel: 400 mg of 0.1 M NaCl—HCl (1:1). Fractions ca 20 ml/h. Dotted line = salt concentration.

separate experiments, materials eluted at 0.7, 1.1 and 1.3 M Cl^- originated from the CHS-A preparation, while the HEP 120 contained the material eluted in the 1.5, 1.7 and 3.0 M Cl^- fractions.

A gradient chromatography of a similar mixture of the three polysaccharides is shown in Fig. 4. Again three main peaks, correspondig to HYA, CHS-A and HEP 120 were obtained. The latter two polysaccharides were not separated completely. This behaviour was expected from the behaviour of CHS-A and HEP 120, on individual columns, and from the results obtained in the experiment shown in Fig. 3. The gradient chromatograms clearly demonstrate that the separations obtained by step-wise elution were not due to chromato-

2.0 M »	35	130
2.5 M »	20	140

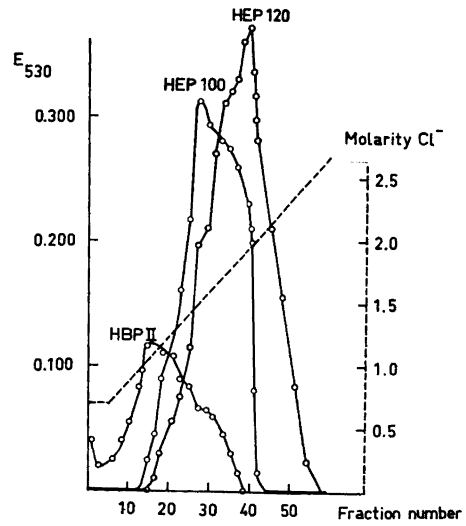

Fig. 5. Chromatography on three separate columns of "heparin" preparations of different anticoagulant activity. The three columns (1 × 5 cm) were eluted simultaneously from the same mixing vessel. Reservoir: 400 ml of 3.0 M NaCl—HCl (1:1), mixing vessel: 400 ml of 0.7 M NaCl—HCl (1:1). Fractions 3 ml/20 min, 12 mg of polysaccharide on each column.

graphic artefacts. However, step-wise elution allowed more clearcut separations and was therefore used in most experiments.

In the experiments described so far, no special attempts were made to obtain subfractions of heparin. However, it was thought of interest to see whether a commercial preparation of this polysaccharide could be further fractionated by chromatography. Such an experiment is described in Table 5.

The fractions obtained differed from each other as regards anticoagulant activity. The most active fractions were those eluted at the highest ionic strength. Fractionation of heparin into materials of different anticoagulant activity has been obtained by several authors [22], the earliest studies in this field being those of Jorpes [23].

In another set of experiments a comparison was made of the chromatographic behaviour of three "heparins" of different anticoagulant activity during gradient elution. HBP II, HEP 100 and HEP 120 were chromatographed on three separate columns of the same dimensions. The three columns were connected with the same gradient system. The results (Fig. 5) indicate that, even though considerable overlapping did occur, the three polysaccharides nevertheless showed distinct differences in their chromatographic behaviour. More material was eluted at higher salt concentrations from the HEP 120 preparation than from HEP 100. A similar difference existed between HEP 100 and HBP II. Thus in general the materials with the highest anticoagulant activities tended to show the highest affinity to the column.

As reported earlier [7] chromatography on ECTEOLA in system B was not found to cause demonstrable inactivation of heparin or loss of sulfate groups from this polysaccharide. It was also found that the recovery of polysaccharides (hyaluronic acid, chondroitin sulfuric acid A and B, and heparin) was close to 100 %. On the other hand losses of some polysaccharides occurred when salts were removed by dialysis.

Chromatography on ECTEOLA with system B has been used for the preparation from mast cell tumors of polysaccharide fractions of different chemical and biological properties [24]. The method was also easily adapted to a microscale which has permitted the fractionation of the polysaccharide from normal peritoneal mast cells in quantities less than 500 μg [25]. When used with the orcinol reaction for the demonstration of polysaccharides in the effluent the separation of 20 μg of HYA, 20 μg of CHS-A and 20 μg of HEP 120 could be followed without difficulty.

Acid Polysaccharides of two Mast Cell Tumors in Mice

NILS R. RINGERTZ

Department of Cell Research and Genetics, Karolinska Institutet, Stockholm 60, Sweden

Polysaccharides prepared from two mast cell tumors in mice were fractionated by chromatography on ECTEOLA cellulose. Both tumors contained heparin and also large quantities of other polysaccharides. These were present in both solid and ascites sublines of the tumors. Polysaccharide fractions from one of the tumors were analyzed and found to differ from each other in sulfate content, anticoagulant activity, and type of amino sugar present.

The first indication of the chemical nature of the metachromatic component of the mast cell granules came from the findings of Jorpes [1] that heparin contained sulfate groups and gave a strong metachromatic reaction with toluidine blue. Subsequent chemical and histological studies by Jorpes, Holmgren and Wilander [2] disclosed a close relationship between the heparin content of various tissues and the number of mast cells found therein indicating that heparin was present in the mast cells.

The histochemical significance of the metachromatic staining reaction was also pointed out by Lison [3], who showed that high molecular polysulfuric acid esters gave such a reaction.

The observations made by Jorpes, Holmgren and Wilander [2] received further support by the finding of Oliver *et al.*[4] in 1947 that a dog mast cell tumor of dermal origin contained large quantities of heparin. During the last decade the heparin content of mast cells has been further substantiated by the work of a number of authors [5,6].

In spite of the fact that several authors [7–9], have advanced theories about the participation of mast cells in the production of the metachromatic ground substance of connective tissue, little is known if other polysaccharides are present in mast cells.

Data obtained by Magnusson and Larsson [10] on a dog mastocytoma and by Korn [11] and Rodén [12] on mast cell tumors in mice, indicate that besides heparin these neoplastic mast cells also contain other polysaccharides with lower sulfate content, similar to heparin monosulfuric acid [13] and chondroitin sulfuric acids.

The aim of the present investigation was to study the total polysaccharide content of two types of mast cell tumors in order to obtain a basis for further studies on the biosynthesis of heparin in the tumor mast cells.

MATERIAL AND METHODS

Tumors. Two mast cell tumors of independent origin were used in the present investigation. One tumor was obtained in July 1957 in its 23rd transplant generation from Dr. Thelma Dunn [14], National Cancer Institute, Bethesda, Maryland, USA. It has been maintained in this laboratory by routine transplantation every 14—20 days to inbred dba, dba F_1, or dba back cross mice as a subcutaneous tumor (DMS). The tumor yield was 1—2 g (wet weight)/mouse. The tumor was easily transformed to the ascites form (DMA) upon intraperitoneal inoculation. A maximum of 1.5 ml ascites was obtained from each mouse. In these fluids 85 % of the cell population were tumor cells.

The second tumor was obtained in March 1958 from Dr. J. Furth [15], Children's Cancer Research Foundation, Harvard Medical School, Boston, Mass., USA. It has been kept in our laboratory as a solid, subcutaneous tumor in LAF_1 mice (FMS). When grown as a subcutaneous tumor a maximum of 8—17 g (wet weight) of tumor/mouse was obtained 4—8 months after inoculation. Often, however, these large tumors showed central necrotic areas and the tumors were therefore usually taken at the size of 4—6 g (*i. e.* 2—4 months after inoculation). When grown intraperitoneally 0.5—1.5 ml of ascites containing 60—80 % tumor cells was obtained from each mouse (FMA). This tumor also produced large solid infiltrates in the peritoneum and in the mesenteries. The intraperitoneal solid tumor mass thus obtained could to a large degree be dissected free from other tissues. The histology of the tumors was studied by routine examination of toluidine blue stained sections and smears.

Preparation of polysaccharide. The tumors were cut into small pieces and homogenized in 2—3 volumes of 0.1 M phosphate buffer, pH 7.8. The homogenate was boiled for 5 min and then digested with a pancreatic extract [16] (Pankreatin, Merck, Darmstadt, Germany). The digestion was performed with 10 mg of enzyme/g wet tissue for 24—48 h.

In some experiments, where a higher degree of purity of the polysaccharide material was desired, the homogenate was first digested with a crude papain preparation (10—30 mg/g wet tissue) for 16 h at 65° in 0.1 M phosphate buffer pH 6.2 containing 0.3 M NaCl, 0.005 M cysteine hydrochloride and 0.0005 M versene [17]. After digestion the preparation was precipitated with 3—4 volumes of ethanol. The precipitate was washed twice with 75 % ethanol and then dried at 50°C in a vacuum. After this the material was digested over night with a pancreatic extract as described above.

After digestion the material was boiled for 5—10 min and centrifuged. The precipitate was washed with distilled water and the combined supernatants were precipitated with 3—4 volumes of ethanol. The precipitate was washed with 75 % ethanol, redissolved in water and acidified at 0°C by the addition of 4 N perchloric acid. The precipitate was washed repeatedly with cold 0.1 N perchloric acid. The combined supernatants were neutralized with KOH and after standing for 1 h the precipitate was removed by centrifugation. The supernatant was then made 0.05 M with respect to Cl^- by the addition of HCl—NaCl (1:1).

Chromatography on ECTEOLA cellulose [18,19]. For the separation of 400 mg of polysaccharide, an ECTEOLA column 4 × 7 cm was used. For smaller quantities a correspondingly thinner column was used. Step-wise chromatography was performed with 250—300 ml of eluent for each step with a 4 × 7 cm column. Fractions were collected at 50 ml/30 min. For elution of the columns, chloride buffers containing equimolar amounts of HCl and NaCl were used. The chloride concentrations in the different elution steps were 0.1, 1.1, 1.4, 1.7 and 2.5 M, respectively. The columns were finally washed with 0.5 M NaOH. This sometimes eluted materials giving a positive carbazol reaction. The absorption spectra for these materials in the carbazol reaction, however, were not those expected for uronic acid containing compounds. These fractions were not studied further.

The chloride concentrations in the different elution steps were chosen on the basis of previous model experiments with known polysaccharides. The fractions were analyzed by the carbazol reaction [20]. Salt was removed from the effluent either by dialysis or by gel filtration on Sephadex G-25 (Pharmacia, Uppsala, Sweden) [21].

Analytical methods. Total amino sugars were determined by the Elson-Morgan reaction [22] after hydrolysis for 8 h in 6 N HCl at 100°C. Glucosamine and galactosamine were determined separately by the method of Gardell [23]. The identity of the amino sugars was checked by paper chromatography according to Gardell *et al.* [24] as modified by Stoffyn and Jeanloz [25]. Uronic acid was estimated by the carbazol reaction [20] using glucuronic acid

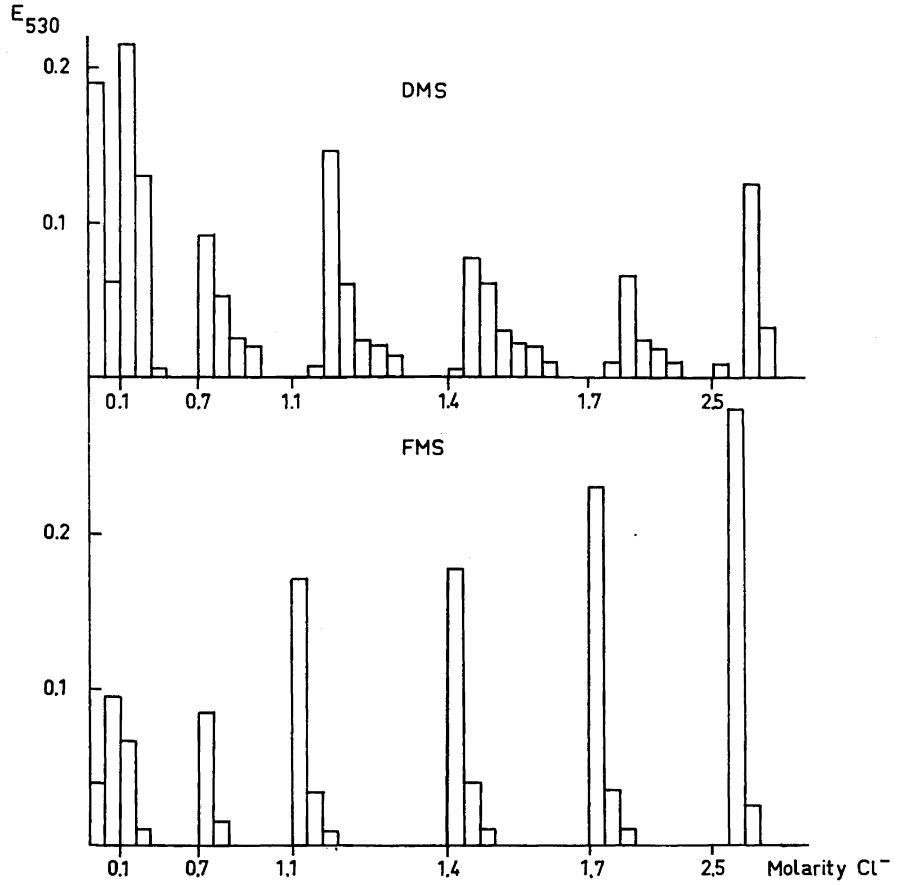

Fig. 1. Stepwise chromatography on ECTEOLA columns of polysaccharides from "pankreatin"-digested DMS and FMS subcutaneous tumors.

as standard. Nitrogen was determined according to Kjeldahl and sulfate by a benzidine method [26,27]. Optical rotation was measured on 1 % solutions in a Zeiss poalrimeter using 10 cm cuvettes.

RESULTS AND DISCUSSION

Chromatographic patterns. Fig. 1 shows the chromatograms obtained with polysaccharides from subcutaneous DMS and FMS tumors. It can be seen, that when the chloride concentration of the eluent was changed, carbazol reacting material was eluted in both chromatograms. The elution steps were chosen so that hyaluronic acid was expected to be completely eluted with the 0.1 M fraction, chondroitin sulfuric acid A and B mainly with the 1.1 M fraction, and heparin mainly with the 2.5 M fraction. From both tumors, carbazol

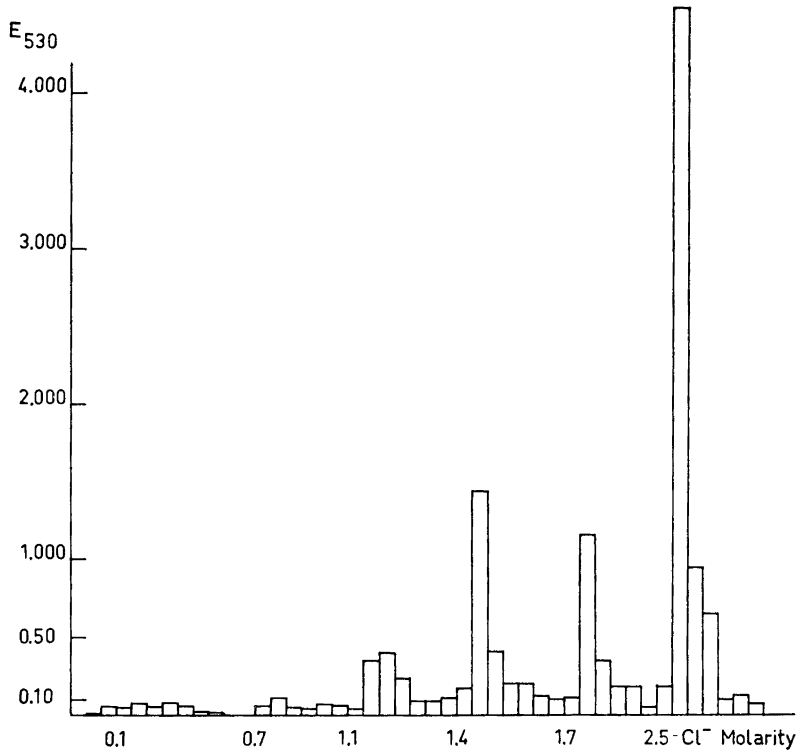

Fig. 2. Stepwise chromatography on an ECTEOLA column (4 × 8 cm) of 450 mg of polysaccharide from "pankreatin" digested solid intraperitoneal FMS tumors. Fractions: 50 ml/30 min.

reacting materials were eluted at the position of heparin, but it was also obvious that both tumors contained large quantities of other polysaccharides. The maximum total quantity of polysaccharides obtained from the FMS tumor was 3—4 mg/g wet weight of tumor tissue. The corresponding value for the DMS tumor was only about 0.5—1.0 mg.

The chromatographic patterns obtained with polysaccharide from the DMS and FMS tumors differed somewhat as to the relative quantity of carbazol reacting material eluted in the different fractions but otherwise showed great similarity. With the FMS tumor the chromatographic patterns varied with the site of growth. With intraperitoneal solid tumors relatively more polysaccharide was eluted at higher chloride concentrations than with the subcutaneous tumors (*cf.* Figs. 1 and 2).

In order to investigate whether the main part of the polysaccharides found in the solid tumors originated from the tumor cells and not from blood vessels and connective tissue, the polysaccharide content of ascites sublines of the two tumors was studied. The chromatogram obtained during the separa-

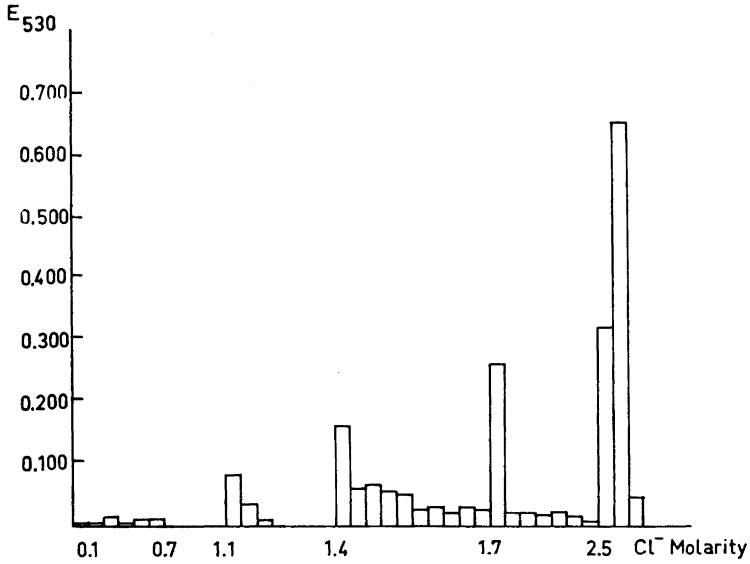

Fig. 3. Stepwise chromatography on an ECTEOLA column (2 × 8 cm) of 70 mg of polysaccharide from "pankreatin" digested FMA ascites tumor. Fractions: 8 ml/30 min.

tion of polysaccharide from the ascites line of the FMS tumor, (FMA), (Fig. 3) was closely similar to that obtained from the solid intraperitoneal tumors in the same animals (Fig. 2).

The same results were obtained with the DMS and DMA tumors except for the 1.1 M fraction, which in the DMA tumor was practically free from carbazol reacting material.

Analyses of the amino sugar type present in the unfractionated FMS and DMS polysaccharides showed that 20—40 % and 24 %, respectively, of the total amino sugars was galactosamine, the remainder being glucosamine. In the unfractionated FMA polysaccharides < 10 % of the amino sugars was galactosamine.

The results indicate that a major part of the non-heparin polysaccharides come from the tumor mast cells while the polysaccharide quantity contributed by the blood vessels and connective tissue in the solid tumors is small.

In order to obtain some information on the chemical nature of the polysaccharides prepared from the mast cell tumors the fractions obtained from the FMS tumor were analyzed. It was found difficult to obtain enough material from the DMS line because of the small size of the tumors and their low polysaccharide content.

Analysis of the 0.1 M fraction. This fraction showed a strong ultraviolet absorption at 260 and 280 mμ and gave an absorption spectrum in the carbazol reaction which was not typical of uronic acids (Fig. 4).

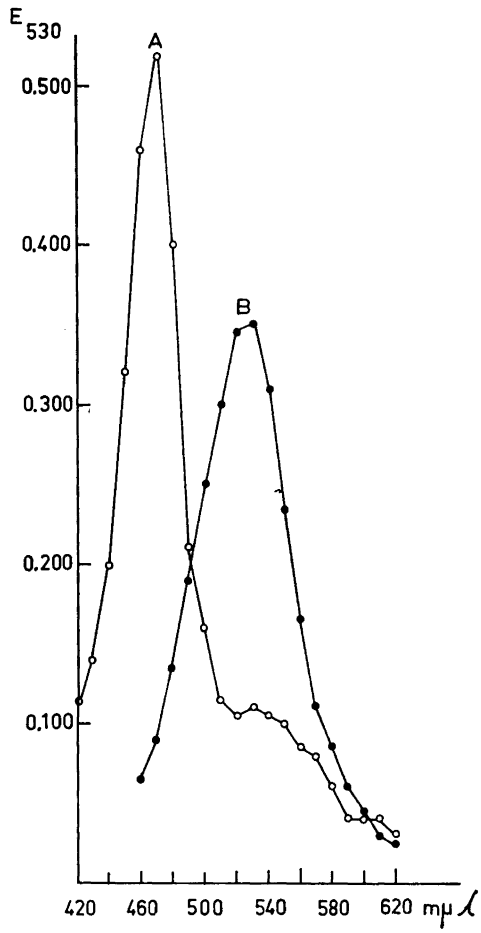

Fig. 4. Carbazol spectra for the 0.1 M fraction (A) and for the 1.1 M fraction (B) obtained in an ECTEOLA chromatogram of the type shown in Fig. 1 (FMS). Curve B is the spectrum obtained for hexuronic acid-containing polysaccharides.

In order to obtain further information about the carbazol reacting material eluted in the 0.1 M fraction, the material obtained from a chromatogram of about 400 mg of FMS tumor polysaccharide (120 g wet tumor tissue) was neutralized to pH 7 with 1 N NaOH and concentrated to 58 ml. From this material, 2 ml were added to a 2 × 14 cm Sephadex column [21]. The column was eluted with distilled water, 1.5 ml fractions being collected at 30 sec intervals. Two components giving carbazol reactions were found (Fig. 5). The main component was eluted after the void volume of the column and gave a typical uronic acid spectrum in the carbazol reaction. A smaller component was eluted close to the salt peak. In its last fractions it contained material giving a maximum at 470 mμ in the carbazol reaction. The main component contained amino sugar and traces of sulfate. The smaller component was not studied further.

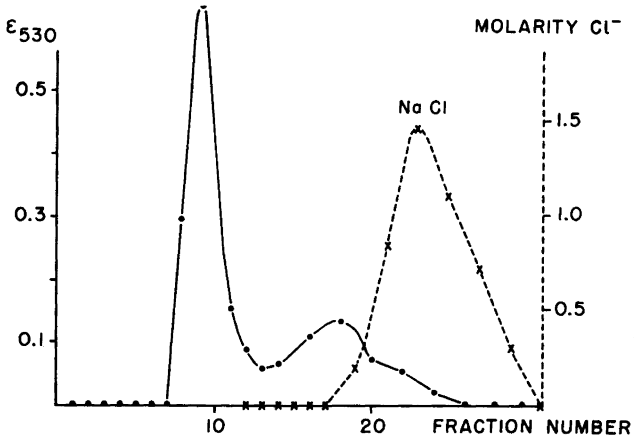

Fig. 5. Fractionation on a Sephadex gel column (2 × 14 cm) of material (= 0.7 mg of glucuronic acid) from the 0.1 M ECTEOLA fraction. The main component is eluted after the void volume of the column indicating a high molecular weight.

A similar separation into two components was obtained also by gradient chromatography on ECTEOLA at pH 5.0 [19]. The major component was eluted between 0.20 and 0.33 M Cl^- and the smaller component between 0.40 and 0.55 M Cl^-. In this chromatographic system, hyaluronic acid, prepared by different methods from cock's comb, bovine vitreus and a human mesothelioma was eluted as sharp peaks between 0.40 and 0.50 M Cl^-.

The results indicate the presence in the 0.1 M fraction of a high molecular polysaccharide with little or no sulfate and with a chromatographic behaviour different from that of high molecular hyaluronic acid.

Analysis of the 0.7—2.5 M fractions. Table 1 shows some analytical data for FMS polysaccharides eluted at higher salt concentrations. The results show that all fractions contained uronic acid, amino sugar and varying quantities of sulfate. The analytical data indicate that the fractions were contaminated with non-polysaccharide material. The nitrogen analyses are in excess of what can be expected from the amino sugar determinations suggesting that in the 1.1—2.5 M fractions 1—5 %, and in the 0.7 M fraction about 17 % of the dry weight may be due to contaminating protein.

The method used for the estimation of uronic acid is known to give values deviating from those obtained by decarboxylation methods. Heparin is thus known to give values about 50 % higher than theory [20]. As the nature of the uronic acid moiety of the different polysaccharide fractions is not known, exact calculations of the ratio of uronic acid to amino sugar is impossible. The values in Table 1, calculated on the basis of glucuronic acid standards indicate, however, that the 1.1—2.5 M fractions contained equimolar quantities of amino sugar and uronic acid.

The amino sugars in the different fractions were isolated by ion exchange chromatography according to Gardell [23]. Glucosamine and galactosamine were identified by their effluent volumes in ion exchange chromatography

Table 1. Analytical data for FMS tumor polysaccharide fractions. The values are for dry polysaccharides.

	Fraction				
	0.7 M	1.1 M	1.4 M	1.7 M	2.5 M

$[\alpha]_D^{22}$	—	+ 1°	+ 1°	+ 39°	+ 35°

and by paper chromatography after degradation with ninhydrin to arabinose and lyxose, respectively [25].

The 1.1 and 1.4 M fractions contained glucosamine and galactosamine in about equal quantities. In the 1.7 M and 2.5 M fractions glucosamine dominated over galactosamine. In the 0.7 M fraction paper chromatography indicated the presence of both amino sugars.

The fractions eluted at lower salt concentration in the chromatogram contained less sulfate than the fractions eluted later in the chromatogram. The 1.1 and 1.4 M fractions contained about 1 mole of sulfate per amino sugar molecule. The 2.5 M fraction regularly contained more than 2 sulfate groups per molecule of amino sugar. The 1.7 M fraction gave intermediate values varying between 1.4 and 1.6 sulfate groups per amino sugar.

The 1.7 and 2.5 M fractions showed marked anticoagulant activity when tested according to Studer and Winterstein [28]. These fractions also showed a strong positive optical rotation while the 1.1 and 1.4 M fractions showed no optical activity.

The analytical data show that the 2.5 and 1.7 M fractions contain heparin. The absolute value for the anticoagulant activity must, however, be interpreted with great caution as the *in vitro* assay system is based on bovine plasma and the polysaccharides tested derive from another species.

The nature of the polysaccharides eluted in the 0.7—1.4 M fractions is not altogether clear, but the results strongly suggest that these fractions may contain mixtures of heparin-like polysaccharides with a low sulfate content, and chondroitin sulfuric acid.

The finding of other polysaccharides than heparin in mast cell tumors raises the question whether these polysaccharides are present in normal mast cells. The results obtained by Schiller and Dorfman [29] indicate that heparin is the only major polysaccharide present in peritoneal mast cells in the rat. Using a micromodification of the ECTEOLA method, we [30] have obtained data on the same material which support the results of Schiller and Dorfman. The polysaccharide content of mouse mast cells is being studied.

* Identified by paper chromatography only.

Studies on Local Anesthetics XIX *

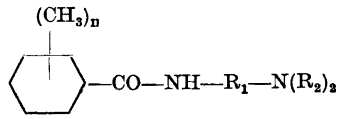
Local Anesthetic Acitivity of N-(Dialkylaminoalkyl)benzamides. Physicochemical Measurements on N-(Dialkylaminoalkyl)benzamides and Benzoic Acids

BJÖRN LÜNING

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden

Local anesthetic properties and LD50 values were evaluated for 22 N-(dialkylaminoalkyl)benzamides. Ionization constants were determined for 26 N-(dialkylaminoalkyl)benzamides, for benzoic acid and all mono-, di-, and trimethylbenzoic acids. Ultraviolet spectra were measured on 15 N-(dialkylaminoalkyl)benzamides, 5 dimethyl-, and all trimethylbenzoic acids. The oscillator strength of these compounds for the absorbtion band at 220–240 mμ was determined and a correlation between these values and the ionization constants was found. Infrared spectra were recorded for the two racemates of N-(2-diethylamino-1,2-dimethylethyl)-2-methylbenzamide.

In a previous paper [1] the syntheses of sixty-five N-(dialkylaminoalkyl)-benzamides were reported. Variations were achieved by introducing one, two, or three methyl groups in the benzene nucleus, by using different alkylene chains (R_1) between the nitrogen atoms, and by attaching methyl or ethyl groups to the terminal nitrogen atom, the general structure being defined by the formula:



n=0, 1, 2, or 3.

A representative selection of these benzamides has been subjected to pharmacological tests, *i.e.* toxicity measurements and determinations of their local anesthetic properties. Further, a report is given on the thermodynamic ionization constants of these compounds. Since it is of interest to compare the ionization constants of the amides and the corresponding benzoic acids,

* For paper XVIII of this series see Lüning [1].

the latter compounds were also included in the measurements. Further, an investigation, *i.e.* determination of the oscillator strength, was made on the ultraviolet spectra of the amides and the acids. Infrared spectra of the two racemates of a compound containing two asymmetric carbon atoms are presented. Finally, a comparison is made between the ionization constants and the oscillator strengths.

EVALUATION OF LOCAL ANESTHETIC ACTIVITY AND LD50

The compounds were tested for their local anesthetic action on the rabbit cornea, and compared with Xylocaine ®, the technique of Wiedling [2] being followed (*cf.* also Löfgren and Tegner [3]). Xylocaine and all the other compounds were used as solutions of their hydrochlorides, made isotonic by the aid of sodium chloride. As a measure of the potency, *relative activity* (RA) was used, *i.e.* the quantity which is obtained by dividing the molarity of a standard Xylocaine solution by the molar concentration of the compound in question which gives the same duration of anesthesia as that of the Xylocaine standard. The molarity of the latter was 0.0738 (= 2 % Xylocaine · HCl solution). Before measuring the duration of anesthesia, both the solution of the actual compound and that of Xylocaine, were adjusted to the same pH, *i.e.* 6.5 *. In the toxicity investigations the LD50 values were obtained from subcutaneous injections in white mice and calculated (a) as grams of the base per kilogram of body weight and (b) as moles per kilogram of body weight ("molar" LD50 value). For these determinations, the bases were dissolved in a mixture of 1,2-propylene glycol and water (1:1, vol/vol) and the "pH" adjusted to about 6.5 by the addition of hydrochloric acid.

The ratio of the *molar* LD50 value of Xylocaine to the corresponding value for one of the other compounds is called the *relative toxicity* (RT) of the compound. For the quotient RA/RT the term *anesthetic index* (Q) will be used (*cf.* Löfgren *et al.*[5]). The *relative latency* (RL) is obtained by dividing the latency time for a solution of the compound to be tested by the latency time for a standard Xylocaine solution having the same duration of anesthesia as the test solution. To determine the RA value of a compound, 10—30 animals were used. In general, the maximum error in the RA values is about 20 %. The error in the RT values is less. The results of the pharmacological measurements are collected in Table 1. The numbering of the compounds is the same as that in the previous paper [1] where the chemical properties of the compounds are presented. The following observations can be made on the relationship between the chemical constitution and the pharmacological properties of the material.

A. From Table 1 is found that no systematic correlation can be detected between the local anesthetic activity or the toxicity and the number and positions of methyl groups in the aromatic residue of N-(dialkylaminoalkyl)-benzamides.

* Because of the low buffering effect of the solution of the hydrochloride at the pH used, and the relatively high buffering capacity of the body fluids, the pH value of the solution need not be very accurately measured.

Table 1. Pharmacolocical properties of N-(dialkylaminoalkyl)-benzamides.

Compound		LD50		RT [e]	RA [e]	RL [e]	Q[e]=RA/RT

[a] The numbering is chosen in accordance with that given for the same compounds in Lüning [1].
[b] The values given for these compounds are taken from Löfgren *et al.*[4]
[c] These are racemates of the same compound, *cf.* Lüning [1].
[d] Measurements made on mixtures of racemates obtained in the synthesis.
[e] Regarding definitions of these quantities see p. 322.
[f] The compounds, the RA-values of which are denoted as 0, give no measurable anesthesia at a concentration of 0.0738 mole/litre.
[g] See Löfgren [8].

Table 2. Change in relative anesthetic activity (RA), relative toxicity (RT), and anesthetic index for variations in the "intermediate chain" R_1 and positions of methyl groups in Ar (*cf.* formula).

$$Ar-CO-NH-R_1-N(C_2H_5)_2$$

Ar = 2,6-dimethylphenyl or 3,5-dimethylphenyl.

$$R_1{}^a = \begin{cases} -CH_2-CH_2- & (1), \\ -CH_2-CH_2-CH_2- & (2), \\ -CH(CH_3)-CH_2- & (3), \\ -CH_2-CH(CH_3)- & (4), \\ -CH(CH_3)-CH(CH_3)- & (5), \\ \text{or } -CH_2-C(CH_3)_2-CH_2- & (6). \end{cases}$$

Factor f_A, f_T and f_Q indicate the change in RA, RT, and Q respectively.

XL	»	(6)	1.6		2.1		0.8	

[a] The formulas of the radicals R_1 must be read in the same direction as the total formula above.

[b] The values given for these compounds are taken from Löfgren *et al.*[4]

B. The effect of variations in the intermediate chain, R_1, (*cf.* formula above) upon anesthetic activity and toxicity is surveyed in Table 2. If Ar is 2,6-dimethylphenyl, and one methyl group is attached to the intermediate chain (transitions A → C and A → D) the increase in anesthetic activity is three to fourfold. The toxicity increases about three times [4]. The corresponding structural change, when Ar is 3,5-dimethylphenyl (XXXVI → XXXVII and XXXVI → XXXVIII), is accompanied by a smaller increase (f_A* = 1.4) or even a small decrease (f_A = 0.9). The toxicity is increased by about 20—50 %.

When one methyl group is attached to each of the carbon atoms of an ethylene radical constituting the intermediate chain R_1, the anesthetic activity is increased approximately seven times if Ar is 2,6-dimethylphenyl (A → E). The toxicity is increased eight to nine times [4]. On the other hand, if Ar is 3,5-dimethylphenyl, the corresponding change (XXXVI → XXXIX) is accompanied by a doubling of the anesthetic activity. The toxicity increases only about 40 %.

The replacement of ethylene by 2,2-dimethyltrimethylene in the intermediate chain is accompanied by a six to sevenfold increase in anesthetic activity when Ar is 2,6-dimethylphenyl (A → XXXI). The toxicity increases about three times. Ar being 3,5-dimethylphenyl, the corresponding change (XXXVI → XL) is followed approximately by a doubling of the anesthetic activity. The increase in toxicity is about the same.

If R_1 is extended by one carbon atom from ethylene to trimethylene and Ar is 2,6-dimethylphenyl (A → B) [4], the activity is lost, whereas it is increased (f_A = 1.3) when Ar is 3,5-dimethylphenyl (XXXVI → F).

C. If the alkyl group (R_2) at the terminal nitrogen atom is changed from ethyl to methyl the anesthetic activity is lost (LVIII → LX).

D. N-(2-Diethylamino-1,2-dimethylethyl)-2-methylbenzamide appears as two separable racemates V*a* and V*b*. They do not differ significantly regarding toxicity or duration of anesthesia. However, the latency time of V*a* is about half of that of V*b*.

DETERMINATION OF THERMODYNAMIC IONIZATION CONSTANTS

The thermodynamic ionization constants in aqueous solution at 25°C were determined for twenty-six N-(dialkylaminoalkyl)benzamides, benzoic acid and all mono-, di-, and trimethylbenzoic acids. For the benzoic acids the equilibrium

$$BH + H_2O \rightleftharpoons B^- + H_3O^+ \qquad (1)$$

is valid. For the basic amides the corresponding expression is

$$BH^+ + H_2O \rightleftharpoons B + H_3O^+ \qquad (2)$$

From equilibrium (1) the expression

$$pK_a = pH - \log \frac{C_{cat} - C_{an} + C_{H^+} - C_{OH^-}}{C_{tot} - C_{cat} + C_{an} - C_{H^+} + C_{OH^-}} + pf_{B^-} \qquad (3)$$

* The *factor* f_A indicates the change in RA.

Table 3. Ionization constants of benzoic acid and methyl substituted benzoic acids in aqueous solution at 25°C.

* $\log \dfrac{C_{tot} - C_{Cl^-} + C_{Na^+} - C_{OH^-}}{C_{Cl^-} - C_{Na^+} + C_{OH^-}}$

[a] The base was dissolved in an excess of HCl, and then neutralized with NaOH.
[b] V *a* and V *b* are racemates of the same compound.
[c] Because of the low solubility of the base in water, it was necessary to make the measurements under conditions where the concentration of base was kept low.
[d] Since in this measurement the ratio between the acid BH^+ and the free base B is great, the accuracy is somewhat lower.

can be derived (*cf.* Lövgren [6]), whereas equilibrium (2) gives

$$pK_a = pH - \log \frac{C_{tot} - C_{an} + C_{cat} - C_{OH^-} + C_{H^+}}{C_{an} - C_{cat} + C_{OH^-} - C_{H^+}} - pf_{BH^+} \qquad (4)$$

In equation (3) C_{tot} is $C_{BH} + C_{B^-}$, whereas in equation (4) this quantity is equal to $C_{BH^+} + C_B$. The quantities C_{cat} and C_{an} represent the concentrations of cations and anions of strong electrolytes. Further,

$$pf_{B^-} = -\log f_{B^-} \; ; \qquad pf_{BH^+} = -\log f_{BH^+} \qquad (5)$$

where f_{B^-} and f_{BH^+} are the activity coefficients of the ions B^- and BH^+ respectively.

The pH values were measured by the aid of a cell of the type:
(—) Glass electrode / H^+(aq) // KCl (satd) / Hg_2Cl_2, Hg (+)

For this cell we have

$$pH = \frac{E - E'}{k} \tag{6}$$

where E is the e.m.f. of the cell and E′ is the standard potential of the cell including the liquid junction potential (assumed to be constant). At 25°C, k is 59.16 mV. Kielland [7] has calculated activity coefficients for a large number of ions at different concentrations in water at 25°C by use of the Debye-Hückel formula

$$-\log f_i = pf_i = \frac{0.358 \cdot z_i^2 \cdot \Gamma^{1/2}}{1 + 10^8 d_i \cdot 0.2325\ \Gamma^{1/2}} \tag{7}$$

where f_i is the activity coefficient of the i-th ion with valence z_i and effective diameter d_i. Γ is the ionic concentration, given by $\Gamma = \Sigma C_i z_i^2$ with C_i in moles per litre.

According to measurements by Löfgren [8], the effective diameter of the BH^+ ions was evaluated to 8×10^{-8} cm. For the B^- ions no determination of the effective diameter was made. A change in d from 5×10^{-8} to 10^{-7} alters pf_i negligibly in comparison with other errors. The values of pf_i for $d = 6 \times 10^{-8}$, $d = 7 \times 10^{-8}$, and $d = 8 \times 10^{-8}$ were plotted against $1/2\ \Gamma$ in a diagram from which pf_{BH^+} and pf_{B^-} were read off directly at any concentration *.

Since it is difficult to obtain a clear survey of the systematic errors, (above all, errors caused by liquid junction potentials) the pK_a values are given to two decimals. For mutual comparison, however, the values can be given with greater accuracy; particularly for the salts of the N-(dialkylaminoalkyl)-benzamides the maximum errors seldom exceed $\pm$ 0.005, whereas for the benzoic acids the errors are somewhat greater.

When calculating pK_a values from (3) or (4), these expressions, for special conditions, can be simplified. Thus, when working at an ionic concentration $> 2 \times 10^{-3}$ mole per litre, C_{H^+} can be neglected at pH > 5, and C_{OH^-} at pH < 9.

Experimental data from the measurements of the thermodynamic ionization constants of benzoic acids in aqueous solution at 25°C are found in Table 3. The ionization constants of the benzoic acids have been measured earlier; good surveys have been presented by Shorter *et al.*[9] and Dippy *et al.*[10,11]. The most accurate determinations given by these authors have, however, been made by conductivity measurements. Since it is essential to obtain a uniformly measured series for mutual comparison, benzoic acid, all mono-, di-, and trimethylbenzoic acids were remeasured. In Table 4 the data from the pK_a determinations of N-(2-diethylaminoethyl)benzamides are given, and in Table

* The three curves did not deviate from each other by more than 0.001 in pf below a value for $\frac{1}{2}\Gamma$ of 8×10^{-3} mole/litre.

5 pK_a values of ten N-(dialkylaminoalkyl)benzamides of different structure have been collected. In a later chapter, a few considerations upon the relationship between chemical structure and the ionization constant will be given.

ULTRAVIOLET AND INFRARED SPECTRA

Ultraviolet spectra have been recorded for methyl substituted benzoic acids and N-(2-diethylaminoethyl)benzamides in the wavelength region 218—310 mμ. In this region two bands are found, one at 220—240 mμ with $\varepsilon_{max} \simeq 10^4$, and one at 260—285 mμ with $\varepsilon_{max} \simeq 300-600$. A band with a higher extinction at about 200—210 mμ is positioned beyond the limits of proper measuring with the solvents used (the benzoic acids in ethanol, and the benzamides in cyclohexane). However, Moser *et al.*[12] have been able to measure the spectrum of benzoic acid and a few methyl substituted benzoic acids between 200 and 220 mμ in other solvents (*e.g.* a mixture of 99.5 % of water 0.5 % of ethanol). According to Hedden *et al.*[13] the band at 260—285 mμ will here be designated as the B-band (B for benzene ring absorption) and that at 220—240 mμ as the C-band (C for conjugation). Particular interest will be focussed on the intensity of the C-band.

Table 6. Wavelengths, wave numbers (ν), and oscillator strengths of maxima and inflexions of benzoic acids and N-(2-diethylaminoethyl)-benzamides for the ultraviolet absortion band at 220—240 mμ.

A quantity which may give some information on the conjugation in a benzoic acid or N-(2-diethylaminoethyl)benzamide is the *oscillator strength f* (of the C-band) which is defined by [14,15]

$$f = \frac{0.1028 \cdot m \cdot c^2}{\pi \cdot e^2 \cdot n} \int_{-\infty}^{+\infty} \varepsilon_\nu d\nu = 4.32 \cdot 10^{-9} \int_{-\infty}^{+\infty} \varepsilon_\nu d\nu \qquad (8)$$

There m and c are the mass of the electron and the velocity of light respectively; and n is the number of molecules in one cm^3, e being the electronic charge,

* For designation of the curves see note to Figs. 1—6.

and $\int_{-\infty}^{+\infty} \varepsilon_\nu d\nu$ the integrated molar extinction over a whole band. Because of overlapping, the band under consideration often occurs as a slight inflexion only. Since intensities in spectra are additive, the integrated molar extinction for a given band can be defined as $\int_{-\infty}^{+\infty} \Delta\varepsilon_\nu d\nu$ in which $\Delta\varepsilon$ is the difference in extinction between the measured curve and a constructed hypothetical curve. The nature of the latter depends on adjacent bands in the spectrum and may be calculated by Fourier analysis, or — as has been done here — be visualized by arbitrary drawing * (see for instance Figs. 1—28).

* The error in the determination of the oscillator strength would of course be smaller by employing Fourier analysis to calculate the integrated extinction. However, this requires that the measurements be extended down to 190 mμ.

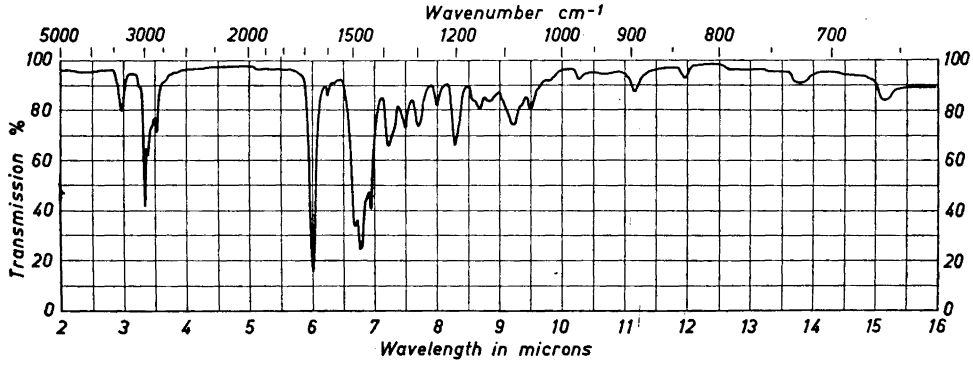

Fig. 29. Infrared spectrogram of V *a*; 4.5 % solution in CCl_4.

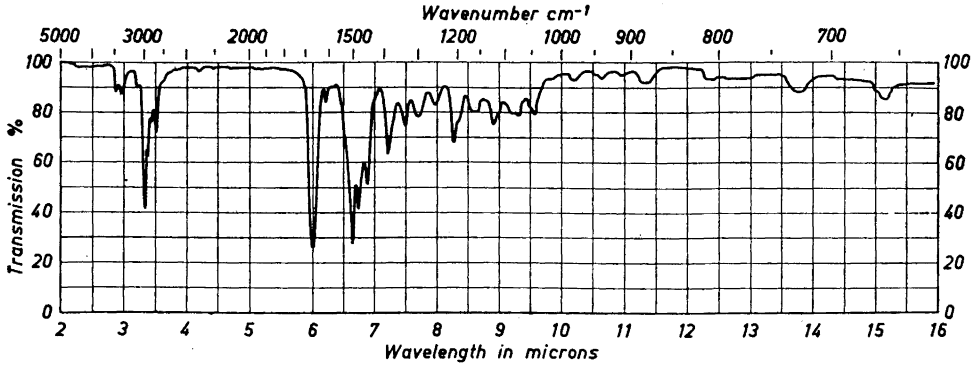

Fig. 30. Infrared spectrogram of V *b*; 4.5 % solution in CCl_4.

The experimental data from the measurements on the ultraviolet absorbtion spectra are found in Table 6 and Figs. 1—28.

Infrared spectra recorded for the two racemates of N-(2-diethylamino-1,2,-dimethylethyl)-2-methylbenzamide in CCl_4 are shown in Figs. 29 and 30. Spectra of the two racemates were also taken up in CS_2 (no diagram shown here). Both racemates showed a relatively strong band at 737 cm^{-1}.

DISCUSSION ON IONIZATION CONSTANTS AND OSCILLATOR STRENGTHS

When attaching a methyl group to the benzene nucleus of a benzoic acid or a N-(2-diethylaminoethyl)benzamide, the pK_a-value is altered in a systematic way. The introduction of a methyl group *para* to the carboxyl group of a benzoic acid is always accompanied by a decrease in acid strength (Table 7). Methyl groups in the positions *ortho* to the carboxyl group cause a marked increase in the acid strength (Table 11). Smaller effects in both directions are brought about by methyl groups in the *meta* positions (Table 9). The influence of methyl groups on the strength of a conjugate acid of the corresponding N-(2-diethylaminoethyl)benzamide is essentially the same as that of the benzoic acid (Tables 8, 10, and 12). — The present results support earlier observations on the strength in aqueous solution of simple alkyl substituted benzoic acids [10,11].

The introduction of a methyl group to the *para* position of acids which do not contain *ortho* methyl groups results in a ΔpK_a equal to $+ 0.18 \pm 0.05$ * (mean of three cases, *cf.* Table 7). This is consistent with the observations by Dippy [10] who compared the ionization constants of benzoic acid and *p*-toluic acid. However, the effect of a *para* methyl group in the presence of one or two *ortho* methyl groups is noticeably increased, *i.e.* ΔpK_a is then equal to $+ 0.31 \pm 0.02$ ** (mean of four cases).

* Maximum error.
** Probable error of the mean.

Table 7. Change in pK_a on the introduction of *p*-methyl groups into benzoic acids.

Structural change Y → Z		ΔpK_a
Y	Z	
Benzoic acid	4-methylbenzoic acid	+ 0.197
2-Methylbenzoic acid	2,4-dimethylbenzoic acid	+ 0.368

[a] For the error, see note, Table 7.

The values of ΔpK_a for the introduction of *ortho* methyl groups into benzoic acids vary within wide limits (*cf.* Table 11). Exceptionally high numerical values are obtained when introducing methyl groups into the 6-position of 2-methyl substituted benzoic acids. The effect of a methyl group in the *ortho* position of a benzoic acid is also increased by the presence of a neighbouring *meta* methyl group. On the other hand, a *para* methyl group in most cases diminishes the acid strengthening effect of an *ortho* methyl group. This tendency is especially manifest in the difference in ionization constant of *p*-toluic acid and 2,4-dimethylbenzoic acid ($\Delta pK_a = -0.11$) or 3,4-dimethylbenzoic acid and 2,4,5-trimethylbenzoic acid ($\Delta pK_a = -0.12$), where no steric interactions can occur between the *ortho* methyl group and other methyl groups present in the molecule.

[a] For the error, see note, Table 7.

A methyl group introduced in the *meta* position of a benzoic acid will cause a small decrease in acid strength ($\Delta pK_a = + 0.09 \pm 0.02$ *; mean of seven cases), provided that no methyl group is located in the *ortho* position between the entering methyl group and the carboxyl. A *meta* methyl group adjacent to an *ortho* methyl is often acid strengthening (*cf.* Table 9).

The effect of *meta* and *para* methyl groups in the N-(2-diethylaminoethyl)-benzamides is about 10 % of that in the corresponding benzoic acids, whereas the effect of *ortho* methyl groups in the basic amides is about 40 % of that in the benzoic acids. The variation in ΔpK_a when introducing methyl groups into the *ortho* positions of benzoic acids (*cf.* above) has not been observed in the benzamide series.

An extensive critical survey of current ideas dealing with the influence of substitution in the benzene nucleus on the ionization constant of benzoic acids has been given by Brown *et al.*[16] The acid strength of benzoic acid is governed by two factors acting in opposite directions. The inductive effect

* Probable error of the mean.

of the benzene nucleus (being electron-attracting) is acid-strengthening, and the resonance between the carboxyl group and the benzene nucleus is acid-weakening. *Para* and *meta* alkyl groups are acid-weakening by means of an electron-repelling * effect [16]. The actual observations in many cases support these theories. Deviations will be discussed below. Brown *et al.*[16] consider the effect of alkyl substituents in the *ortho* positions to be *mainly* of a steric nature. This is ascribed to a twisting of the carboxyl group out of the plane of the ring. An *ortho* methyl should be acid weakening by means of its electron-repelling effect. This is, however, outweighed by the strong effect of resonance inhibition. The more bulky the *ortho* alkyl groups, the more pronounced is the steric inhibition of resonance. Thus, *o-tert*-butylbenzoic acid is three times stronger than *o*-toluic acid, despite the electron-repelling effect of *tert*-butyl being greater than that of methyl [10,11,16].

This theory may explain the abnormal acid-strengthening effect of a *meta* methyl group adjacent to an *ortho* methyl group. The crowding of bulky substituents may enhance the twisting of the carboxyl group out of the plane of the ring. The resulting increase in acid strength is apparently large enough to compensate for the acid weakening effect of the *meta* methyl group. A similar explanation of this *ortho-meta*-effect is given by Dippy *et al.*[11]

The surprisingly large effect of *ortho* methyl groups on the pK_a of the benzamides may be due to steric interference between the bulky dialkylamino-alkyl group and the *ortho* methyl groups. The concept of steric hindrance would also explain the observation (*cf.* above) that a *para* methyl group diminishes the acid strengthening effect of an *ortho* methyl group. The effect may also be expressed as an increase in the acid weakening property of the *para* methyl group in presence of *ortho* methyl groups. Considering the influence of the *para* methyl group on the effect of the *ortho* methyl group, it seems reasonable to assume that the *para* methyl, by virtue of its electron repelling effect, counteracts the twisting of the carboxyl group out of the plane of the ring (*cf.* Dippy [11]).

As a general rule, the introduction of a *para* methyl group is accompanied by an increase in oscillator strength (f) of the ultraviolet absorption band at 220—240 mμ. Hedden *et al.*[13] give a value of + 0.04 for the change in f when a methyl group is introduced in the *para* position of acetophenones. The corresponding value in the present determinations is + 0.06 for the benzoic acids, and + 0.05 for N-(2-diethylaminoethyl)benzamides (*cf.* Tables 13 and 14). The surprisingly low f value for 2,4,6-trimethylbenzoic acid as compared with that of 2,6-dimethylbenzoic acid is consistent with the values for the corresponding acetophenones as reported by Braude [18], but not with those given by Schwartzman *et al.* [25]

When introducing a methyl group into a *meta* position of a benzoic acid or N-(2-diethylaminoethyl)benzamide, f is in most cases slightly decreased. The average change in f is −0.02 for the acids and −0.03 for the basic amides (Tables 15 and 16).

* Throughout this paper no differentiation has been made between the inductive effect of alkyl groups and the so called hyperconjugation which has recently been brought into question (*cf.* for instance Ref.[17]). Thus, when discussing the electron-repelling effect of an alkyl group, the true inductive effect and a possible "hyperconjugation" effect are included.

[a] For the error, see note, Table 7.

The introduction of a methyl group in an *ortho* position is accompanied by a strong decrease in oscillator strength (Tables 17 and 18). The change in f — associated with the introduction of the first methyl group in the benzoic acids — had a value of −0.10. The corresponding value in the benzamide series was found to be −0.09. In the acetophenones the change of f is −0.07 when methyl groups are introduced in the *ortho* positions [13]. On introducing a methyl group in the 6-position of a 2-methyl substituted benzoic acid or N-(2-diethylaminoethyl)benzamide, the change is smaller, being −0.03. From Table 6 is seen that for most amides, *one ortho* methyl group is sufficient to diminish the oscillator strength almost to zero. For the benzoic acids, even *two ortho* methyl groups do not give such a strong effect.

The absorption band studied is considered to be associated with the conjugation between the aromatic nucleus and the carbonyl group [13,18]. The oscillator

strength gives a measure of the probability for a given transition, and hence also of the degree of conjuagtion. The low value of f when *ortho* methyl groups are present is probably due to the out-of-plane twisting of the carbonyl group (*cf.* above and Refs.[13,18,26,27]). This theory is supported by UV spectra of the benzonitriles, which do *not* show any *ortho* effect. Thus, benzonitrile [19], *o*-tolunitrile [19], and 2,6-dimethylbenzonitrile (see Fig. 28) for the actual band have about the same ε_{max} value, *i.e.* $\sim 9.5 \times 10^3$.

The effect of *meta* and *para* methyl groups upon the intesities of spectra is not yet fully understood.

Since the degree of conjugation between the carbonyl group and the benzene nucleus influences both the ionization constant and the oscillator strength,

a certain parallellism might occur between ΔpK_a and Δf. Hence, in Table 19 ΔpK_a and Δf for the various structural changes studied, have been listed side by side.

EXPERIMENTAL

The *N-(dialkylaminoalkyl)benzamides* and their *hydrochlorides* were analytical samples of high purity. Regarding the preparation and purification of these, see Lüning [1].

N-(2-Diethylaminoethyl)benzamide was obtained from benzoyl chloride and 1-amino-2-diethylaminoethane by the general method described by Lüning [1]. The hydrochloride was prepared and recrystallized several times from a mixture of *iso*propyl ether and methyl ethyl ketone m. p. 88°−89°. (Found: Cl 13.8. Calc. for $C_{13}H_{21}ClN_2O$: Cl 13.8.) The melting point of the hydrochloride does not agree with that given for the same compound by Hazard *et al.*[20] who give neither an acceptable method of synthesis nor any proof of the composition. The base was liberated from the hydrochloride and taken up in ether, which was evaporated, leaving the base as an oil; $n_D^{25} = 1.5281$. (Found: Equiv. wt. 223. Calc. for $C_{13}H_{20}N_2O$: Equiv. wt. 220.3.)

Concerning the preparation of *benzoic acids* see Lüning [1]. Each benzoic acid was recrystallized several times from ethanol; all the melting points agreed with those given by Smith and Stanfield [21]. The melting points of 2,3,5-trimethylbenzoic acid and 3,4,5-trimethylbenzoic acid, which were not reported by these authors, were in accordance with those given by Jannasch and Weiler [22].

[a] The first and the second *ortho* methyl group often give rise to different variations of f and pK_a values, see also text p. 338.
[b] For the error, see note, Table 7.

2,6-Dimethylbenzonitrile was prepared from 2,6-dimethylaniline by a Sandmeyer reaction, and purified by means of sublimation.

The duration and latency time of anesthesia were measured on rabbit cornea according to the method given by Wiedling [2] *. The LD50 values were calculated by the method of Kärber [23]. For each toxicity determination, at least 60 male white mice were used. The compound, in the form of a 3 "per cent" solution (weight/volume), was injected under the dorsal skin. The base was dissolved in 1,2-propylene glycol, the equivalent amount of hydrochloric acid was added, followed by water to give the proportion propylene glycol: water equal to 1:1 (v/v). The "pH value" was adjusted to 6.5 before injection.

The solutions for pK_a determinations were prepared in four different ways: (1) Benzoic acids were dissolved in water by gentle heating for a short period, and the solutions neutralized to about 50 % with NaOH. (2) Benzoic acids were dissolved in a slight excess of carbonate-free NaOH which was then titrated back to about 50 % with HCl. (3) Hydrochlorides of bases were dissolved in water and neutralized to 30—60 % with NaOH. (4) Bases were dissolved in a slight excess of HCl which was then titrated back to about 50 % with NaOH. The pH values given in Tables 3—5 are the means of two measurements, obtained by the aid of different glass electrodes. For details in the measurements, and a diagram of the cell used, see Löfgren [8] and Lindström [24].

The ultraviolet absorbtion spectra were measured with the aid of a Beckman DK2 recording quartz spectrophotometer, using a hydrogen lamp as a light source. The wavelength scale is logarithmic. The values of $\int_{-\infty}^{+\infty} \Delta\varepsilon_\nu d\nu$ were obtained by calculation of $\sum_{-\infty}^{+\infty} \Delta\varepsilon\Delta\nu$ of the area between the recorded curve and an arbitrary reference curve, as is demonstrated in Figs. 1—28. $\Delta\varepsilon$ is the difference in molar extinction between the measured curve and the reference curve. The reference curves are included in the figures as dashed lines.

The infrared spectra were measured with the aid of a Beckman IR 5 double beam Infrared Recording Spectrophotometer, using a sodium chloride cell (0.1 mm).

The toxicity determinations were made at the *Battelle Institute*, Frankfurt, Germany, with the aid of a grant from *Aktiebolaget Astra*, Södertälje, Sweden. The measurements of the local anesthetic activity were performed in the research laboratories of *Aktiebolaget Astra*.

I wish to express my sincere gratitude to *Aktiebolaget Astra* for the invaluable help with the pharmacological measurements, and for financial support during the course of this work.

On the Oxidation of 3α,7α,12α-Trihydroxycoprostane by Mouse and Rat Liver Homogenates

Bile Acids and Steroids 97

HENRY DANIELSSON

Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

3α,7α,12α-Trihydroxycoprostane has been found to be hydroxylated to 3α, 7α, 12α, 27-tetrahydroxycoprostane in whole homogenates as well as washed mitochondria of rat liver. The same reaction occurs also in mouse liver homogenates, which in addition transform 3α, 7α, 12α-trihydroxycoprostane into acidic material, part of which has been identified as 3α, 7α, 12α-trihydroxycoprostanic acid. Mouse liver mitochondria alone effect mainly the 27-hydroxylation, while addition of 100 000 × *g* supernatant increases the formation of acidic material 3- to 4-fold. 3α, 7α, 12α, 27-Tetrahydroxycoprostane is a more efficient precursor of the coprostanic acid than 3α, 7α, 12α-trihydroxycoprostane.

The intermediate steps in the degradation of cholesterol to bile acids are not wholly known. The probable sequence of reactions has been proposed by Bergström and Lindstedt [1–4] on basis of their studies on the formation of cholic acid in bile-fistula rats from different possible intermediates. According to these investigations the steroid nucleus is hydroxylated prior to the completion of the side-chain oxidation, and one of the earliest steps appears to be the introduction of the hydroxyl-group of C_7 of the steroid molecule.

The use of *in vitro*-systems seems a reasonable approach to further investigations on the individual steps in the degradation of cholesterol to bile acids. Horning *et al.* [5,6] and Gurin *et al.* [7,8] studied the oxidation of 26-^{14}C-cholesterol to $^{14}CO_2$ in mitochondrial preparations of mouse and rat liver and characterized the cofactor requirements for maximal $^{14}CO_2$-production. Gurin *et al.* [7] also provided evidence for the formation of labeled 25-dehydrocholesterol together with a labeled C_{27}-steroid aldehyde and acid from 26-^{14}C-cholesterol in these experiments. Using the above-mentioned mitochondrial system Fredrickson [9] investigated the products formed from 4-^{14}C-cholesterol and was able to isolate labeled 25- and 26-hydroxycholesterol, neither of which was converted to cholic acid in the bile-fistula rat [10]. In addition there were formed several acidic products not identical with cholic or deoxycholic acid.

Currently the metabolism of 4-^{14}C-cholesterol in mouse and rat liver mitochondrial systems is being studied in this laboratory. With the use of reversed phase partition chromatography [11] some 10 compounds formed from cholesterol in these systems have been isolated and partly identified [12,13]. Some of these substances undoubtedly arise through autoxidation of the added cholesterol, but at least two enzymically formed labeled products have been isolated. Both these compounds, which are transformed into normal bile acids in the bile-fistula rat, are neutral steroids retaining the C_{27}-side-chain, but the detailed structures are as yet not known. In these experiments *in vitro* with 4-^{14}C-cholesterol very limited degradation of the side-chain has so far been obtained.

To study the oxidation of the side-chain we then turned to 3α,7α,12α-trihydroxycoprostane. Bergström *et al.* [14] have shown, that when this compound is injected into a bile-fistula rat, it is rapidly excreted in bile mainly as cholic acid. We have found that both rat and mouse liver homogenates are able to oxidize this compound in good radiochemical yield (50—70 %).

EXPERIMENTAL

White male mice (Danish State Serum Institute strain) weighing approx. 25 g and white male rats (Sprague-Dawley strain) weighing approx. 150 g were used. Homogenates (33 % w/v) were prepared in 0.25 M sucrose containing 3.6 mg nicotinamide/ml using a tight-fitting Potter-Elvehjem pestle. Fractionations of homogenates were carried out in a Spinco preparative ultracentrifuge in the usual manner. The mitochondrial and microsomal pellets were resuspended in the above-mentioned sucrose medium by homo-

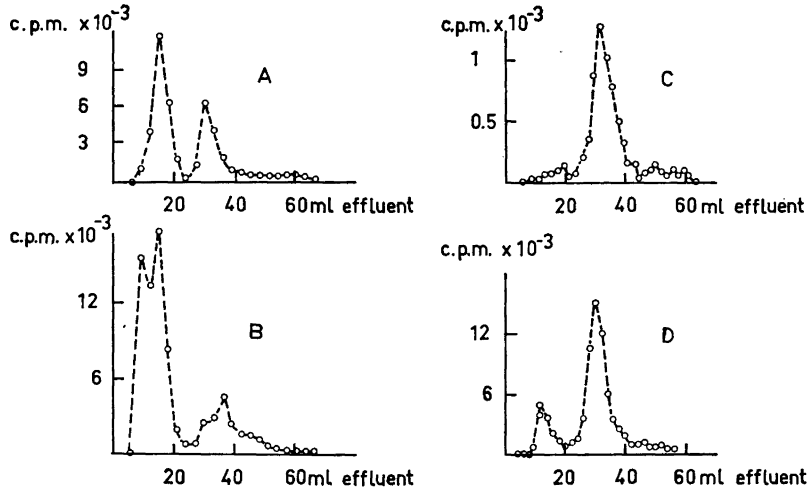

Fig. 1. Chromatograms of incubations of 3α,7α,12α-trihydroxycoprostane with mouse liver mitochondria (curve A) and with ditto plus supernatant (curve B). 4.5 g Hostalene columns. Phase system III. Curves C and D show the rechromatograms of 9—21 ml of effluent of the corresponding chromatograms (curves A and B) with phase system IV. 4.5 g hydrophobic Hyflo columns.

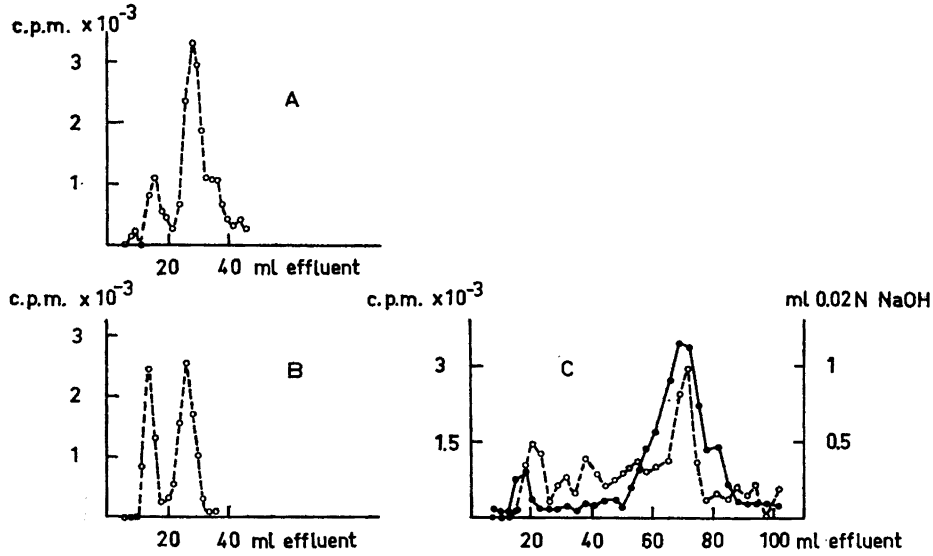

Fig. 2. Chromatograms of incubations of 3*a*,7*a*,12*a*,27-tetrahydroxycoprostane with mouse liver mitochondria (curve A) and with ditto plus supernatant (curve B). 4.5 g hydrophobic Hyflo columns. Phase system IV. Curve C shows the chromatogram of the saponified acidic material of the previous columns together with unlabeled 3*a*,7*a*,12*a*-trihydroxycoprostanic acid. 4.5 g hydrophobic Hyflo column. Phase system: 50 % aqueous methanol as moving phase, 10 % heptane in chloroform as stationary phase.

genization with a loose-fitting pestle for 10—20 sec. Incubations were run aerobically for 1 h at 37° with constant shaking.

The 3*a*,7*a*,12*a*-trihydroxycoprostane used was randomly labeled with tritium according to the method of Wilzbach [15] in the apparatus described by Bergström and Lindstedt [16]. The tritium-labeling was kindly carried out by Dr. B. Samuelsson of this laboratory. To each incubation there were added 0.8—2 μC (60—150 μg) of the labeled 3*a*,7*a*,12*a*-trihydroxycoprostane as an emulsion prepared by dissolving the compound in 0.1 ml of ethanol and diluting with 0.9 ml of a 1 % solution of bovine serum albumin in water.

The following amounts of unfractionated and fractionated homogenate were used per incubation: 3 ml whole homogenate (corresponding to approx. 1 g of liver), 3 ml mitochondria (from approx. 4 g of liver), 3 ml microsomes (from approx. 4 g of liver) and 3 ml 100 000 × *g* supernatant (from approx. 1 g of liver). To each incubation 1 ml of 0.1 M Tris-HCl buffer, pH 7.6, was added.

Incubations were terminated by addition of ethanol and after filtration and evaporation the aqueous solution was acidified and extracted twice with ether. The ether-extracts were chromatographed in the reversed phase systems described previously [11]. In addition a modification of system III was employed using 45 % aqueous *iso*propanol as moving phase (phase-system IV). Hostalene [17] or hydrophobic Hyflo Supercel [11] were used as supporting material for the stationary phase.

RESULTS AND DISCUSSION

Incubations with whole homogenates of mouse liver resulted in the conversion of about 50 % of the 3*a*,7*a*,12*a*-trihydroxycoprostane into more polar material, that could be separated into one acidic fraction and one neutral

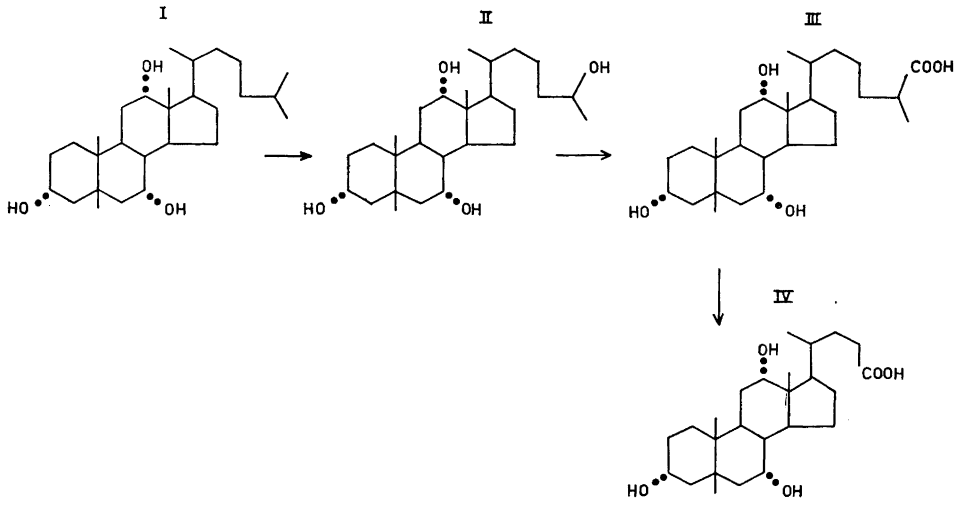

Fig. 3. Postulated sequence for the oxidation of the C_{27}-side-chain: 3α,7α,12α-trihydroxycoprostane (I), 3α,7α,12α,27-tetrahydroxycoprostane (II), 3α,7α,12α-trihydroxycoprostanic acid (III) cholic acid (IV).

tetrahydroxyl compound. Use of the whole homogenate of rat liver resulted in the formation of the tetrahydroxy fraction only. Washed mitochondria of mouse and rat liver effected mainly the formation of the tetrahydroxy compound and addition of 100 000 × *g* supernatant (hereafter called supernatant) to mouse liver mitochondria but not to rat liver mitochondria resulted in the additional formation of acidic material. Hardly any change (0—5 % conversion to more polar material) of the 3α,7α,12α-trihydroxycoprostane was observed in presence of microsomes and/or supernatant from either species.

Fig. 1 shows chromatograms using phase system III of incubations with mouse liver mitochondria (curve A) and with mouse liver mitochondria plus supernatant (curve B). The peak at 30 and 36 ml of effluent, respectively, represents unchanged 3α,7α,12α-trihydroxycoprostane. The material eluted between 9 and 21 ml of effluent in both chromatograms was rerun with phase system IV (curves C and D, Fig. 1). In the presence of mitochondria alone (curve C, Fig. 1) there is one main peak at 31 ml of effluent appearing at the position of a neutral tetrahydroxylated C_{27}-steroid and a small amount of isotope (5 % of total isotope eluted) is eluted earlier representing the acidic fraction. The addition of supernatant (curve D, Fig. 1) increases considerably the amount of isotope in the acidic fraction (18 % of total isotope eluted). The labeled material in the main peak was identified as 3α,7α,12α,27-tetrahydroxycoprostane by cocrystallization to constant specific activity with unlabeled material (m.p. 204°), obtained by $LiAlH_4$-reduction of 3α,7α,12α-trihydroxycoprostanic acid (m.p. 170—171°, reported 172—174° [18]) isolated from frog bile.

Incubation of labeled 3α,7α,12α,27-tetrahydroxycoprostane, biosynthesized *in vitro* from 3α,7α,12α-trihydroxycoprostane, with mouse liver mitochondria demonstrated that this compound was a more efficient precursor of the acidic fraction than 3α,7α,12α-trihydroxycoprostane. Fig. 2 shows the chromatograms with phase system IV of the products of these incubations. There was a 15 % conversion to acidic material by mouse liver mitochondria (curve A, Fig. 2); the addition of supernatant increased the yield of acidic material to 50 % (curve B, Fig. 2). The acidic peaks from these experiments were combined, saponified and chromatographed with unlabeled 3α,7α,12α-trihydroxycoprostanic acid (curve C, Fig. 2). Part of the radioactivity coincides with the titration peak of the added carrier and the identity was confirmed by isotope dilution. The peaks appearing earlier in the chromatogram were not identified, but it is known from the work of Bergström *et al.*[19], that 3α,7α,12α-trihydroxycoprostanic acid is converted to cholic acid also *in vitro*.

A preliminary scheme for the oxidation of the C_{27}-steroid side-chain would then entail hydroxylation of one of the terminal methylgroups and subsequent oxidation of this hydroxyl to a C_{27}-acid, which in turn is oxidized to the C_{24}-acid (*cf.* Fig. 3). It cannot be stated at present, whether the C_{24}-acid is formed by direct oxidation of the C_{27}-acid or whether a series of C_{26}-intermediates occur.

Acknowledgments. The author is very grateful to Prof. T. Kazuno for a generous gift of 3α,7α,12α-trihydroxycoprostanic acid.

The skillful technical assistance of Miss Birgitta Holmberg and Miss Electra Pascalides is gratefully acknowledged.

The Chemistry of the Natural Order Cupressales

XXV *. Heartwood Constituents of *Juniperus chinensis L.*

CLAES PILO (in part) and JARL RUNEBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

From the heartwood of *Juniperus chinensis* there were isolated: thujopsene, cuparene, cedrol, widdrol, hinokiic acid, "widdringtonia acid II", carvacrol, thymohydroquinone, 3-hydroxy-thymoquinone and 3,6-dihydroxy-thymoquinone. Paper chromatographic evidence was obtained for the presence of nootkatin, α-, and β-thujaplicin and gas chromatographic evidence for the presence of α-cedrene.

Most of the genera into which the family Cupressaceae has been divided botanically are small or monotypic. The largest genus, *Juniperus*, which is found almost only in the northern hemisphere is divided into two subgenera, *Oxycedrus* and *Sabina*, with altogether some 50—60 species. It thus appears to be particularly suitable for systematic chemical investigation.

Only a few juniper woods have been investigated before and interest has been mainly directed towards the constituents of the berries, leaves and bark [1,2].

Bredenberg and Gripenberg [3–5] made the interesting discovery that the diterpene sugiol and related compounds are present in *Juniperus communis* and Nakatsuka and Hirose [6] have found tropolones (nootkatin and β-thujaplicin) in *J. chinensis*. Cedrol and "cedrene" have frequently been found in juniper woods. However, they appear to be absent from those species of the subgenus *Oxycedrus* that have been investigated and Bredenberg has suggested that cedrol and cedrene might be characteristic of the *Sabina* junipers.

Thirty years ago Ushida [7] published a note on some constituents of the wood of *J. chinensis (Sabina)* and recorded an interesting "cedrol" of abnormally high rotation $[\alpha]_D + 85.4°$. Three years ago the sesquiterpene alcohol widdrol [8] (m.p. 98°, $[\alpha]_D + 105°$) from *Widdringtonia* was isolated in this institute and one of us (C.P.), working with Professor H. Erdtman, made a preliminary study of the wood of *J. chinensis* with the intention of comparing Ushida's "cedrol" with widdrol. Cedrol of normal optical properties was

* Part XXIV. *Acta Chem. Scand.* **14** (1960) 81.

easily obtained but some fractions had a higher rotation (up to about + 60°) and may have been similar to the preparation obtained by Ushida.

Other constituents isolated during this study included thymohydroquinone, a constituent of *Tetraclinis articulata* [9] and *Libocedrus decurrens* [10] that had not previously been found among the junipers, and a crystalline acid. Ultraviolet spectra of the ligroin-soluble part of the acid fraction indicated the presence of tropolones. A more detailed study has now been made (J.R.) of the extract from a larger sample of *Juniperus chinensis* heartwood.

J. chinensis is a native of China and Japan but the wood used in these investigations came from a tree grown in the Glasnevin National Botanic Garden, Dublin. Our thanks are due to Mr. T. Walsh, keeper, for kindly putting the wood at our disposal. It should be noted that the wood came from a tree that was probably killed by a fungal infection. It is therefore possible that some of the substances found, *e.g.* the hydroxythymoquinones (see below), do not occur in sound wood. An interesting case of changed metabolism due to infection has been described by Hasegawa and Shirato [11].

The air-dried wood was extracted with acetone and the light petroleum-soluble part of the extract was separated into neutral and acid fractions with alkali.

The tropolones were concentrated by precipitation from the ligroin soluble part of the acid fraction with cupric acetate, decomposition of the crude copper salts with hydrochloric acid and steam distillation. The fraction most volatile in steam gave 3-hydroxy-thymoquinone. According to paper chromatographic analysis the next fraction contained a mixture of nootkatin and α- and β-thujaplicins but in such small amounts that a separation was not attempted (Nakatsuka and Hirose obtained 6 g nootkatin and 0.3 g β-thujaplicin from 147 kg of wood).

Fractional distillation of the tropolone-free acid portion of the oil yielded thymohydroquinone, 3,6-dihydroxy-thymoquinone and carvacrol. The high-boiling fractions gave two sesquiterpene acids. One was identified as hinokiic acid ("widdrenic acid" [12]), recently isolated from a number of *Widdringtonia* species and also prepared by oxidation of thujopsene ("widdrene"). The other was found to be identical with the "Acid II", m.p. 192—194°, $[\alpha]_D$ −94°, from the same source [8].

The neutral portion of the oil was fractionally distilled. It contained only traces of monoterpenes or compounds of similar boiling point. The lowest boiling fraction was yellow and it was therefore expected that thymoquinone would be present but this could not be confirmed.

To check the possibility that the 3- and 3,6-hydroxylated thymoquinones might have been formed from thymoquinone during isolation, a solution of thymoquinone in light petroleum was shaken with either aqueous or ethanolic alkali in the presence of air. The product was chromatographed on paper by the method developed for tropolones by Wachtmeister and Wickberg [13]; this indicated that both the hydroxylated thymoquinones were present. Even though attempts to isolate thymoquinone from the wood failed, it is thus possible that the two hydroxythymoquinones are artefacts formed during the alkali extraction of the oil or as a result of *post mortem* enzymatic oxidation in the wood.

Since the presence of carvacrol methyl ether in the neutral oil was to be expected, a sample of the lowest boiling fraction was demethylated and chromatographed on paper. No carvacrol was detected but spots corresponding to two unidentified phenols were found.

The infrared spectrum of the rather large sesquiterpene fraction that followed resembled those of corresponding fractions isolated from *Widdringtonia* [8]. According to gas chromatographic analysis, fraction 2 (Table 1, see experimental part) contained four components. The substances were present approximately in the ratio 300:90:10:1, assuming complete resolution. The principal constituent was identified as thujopsene by conversion into the corresponding aldehyde by oxidation with selenium dioxide. The next largest constituent, according to gas chromatographic evidence, was α-cedrene. Fraction 3 (Table 1) contained the two main components in a ratio of 1:4, but the minor constituents could not be detected in this fraction.

The next higher boiling fraction was redistilled and treated with ozone at low temperature. From the material unaffected by ozone cuparene [14] was isolated.

According to the infrared spectrum the highest boiling fraction of the neutral material appeared to contain alcohols and carbonyl compounds.

The compounds isolated and a very approximate estimate of the amounts present are given below. The figures are subject to the uncertainties of the estimation and to the wide variations possible in biological material. The amounts are given as a percentage of the air-dried wood. Total acetone extract 8.37, ether-soluble acetone extract 7.48, light petroleum-soluble acetone extract 5.92, sodium bicarbonate-soluble 0.058, sodium hydroxide-soluble 0.83, soluble in ethanolic potassium hydroxide 0.43, neutral 4.6. Tropolones (nootkatin, α- and β-thujaplicin) 0.007, thymohydroquinone 0.018, 3-hydroxythymoquinone 0.0009, 3,6-dihydroxy-thymoquinone 0.0003, carvacrol 0.11, hinokiic acid 0.001, "Widdringtonia acid II" 0.061, thujopsene 0.27, cuparene 0.10, cedrol 1.7, widdrol 0.14, high-boiling carbonyl compounds 0.043.

EXPERIMENTAL

Rotations were measured in chloroform. Melting points, taken on a hot stage, are uncorrected. Light petroleum refers to the fraction b. p. 40—60°.

Isolation of the oils. Ground, air-dried heartwood (6.0 kg) was continuously extracted with acetone for 48 h. The acetone was evaporated and the remaining oil was poured with stirring into ten volumes of ether. The ether solution was filtered (precipitate 54 g), evaporated, and the rest similarly poured into ten volumes of light petroleum. After filtration (precipitate 94 g) the solution was evaporated to about three l and extracted successively with a saturated solution of sodium bicarbonate, with 2 N sodium hydroxide and with 2 N ethanolic potassium hydroxide. On acidification and extraction with ether the sodium bicarbonate solution yielded a viscous oil (3.5 g) which was not further investigated. The sodium hydroxide-soluble material (50.6 g) (A) was isolated in the same way by acidification of the alkaline solution and extraction with ether. The ethanolic potassium hydroxide solution was shaken several times with light petroleum, acidified and extracted with ether. The ether extract was washed with water and gave on evaporation a reddish brown oil (39.4 g) (B). The remaining petroleum ether solution was washed with water and evaporated yielding neutral material (260.8 g) (C).

I. *Alkali-soluble fraction.* The viscous product A (19.8 g) was dissolved in acetone, poured onto cotton wool and the acetone was evaporated. This material was then

extracted with hot ligroin (b. p. 100—125°) and the extract was shaken with a saturated solution of cupric acetate; the sticky copper salts were filtered off, washed with ligroin and water and decomposed with 2 N hydrochloric acid. The product was extracted with ether and the ether solution was washed with water, dried, and evaporated affording a resin (6.8 g) (A_1) which was steam distilled.

The first 100 ml of distillate deposited a small amount (20 mg) of orange red needles which gave a strong violet colour with sodium hydroxide. This substance was recrystallised from ethanol-water and sublimed, m. p. 168—170°, undepressed when mixed with an authentic sample of *3-hydroxy-thymoquinone* prepared from 2,4-dinitrothymol *via* 2,4-diaminothymol [15]. The infrared spectra of the two samples were identical.

The next 200 ml of steam distillate was extracted with ether. The ether extract on evaporation gave a syrupy material (314 mg) which according to paper chromatographic [13] evidence contained nootkatin and *α*- and *β*-thujaplicins in amounts decreasing in this order.

The ligroin solution remaining after the removal of the copper salts was evaporated and the residue was separated by distillation into lower boiling (b. p. below 180°/2 mm, 5.7 g) (A_2) and higher boiling (b. p. 180—184°/2 mm, 4.8 g) (A_3) fractions.

The material soluble in ethanolic potassium hydroxide (B) was subjected to a quick preliminary distillation. The fraction boiling below 160°/1.5 mm (B_1) was added to fraction A_2 and the combined material (27 g) was distilled through a spinning band column. On standing the fraction boiling at 117—152°/20 mm (2.4 g) deposited a small amount (6 mg) of bright red needles, which gave a strong violet colour with sodium hydroxide. This compound was recrystallised from 95 % ethanol and sublimed, m. p. 223—224°, undepressed when mixed with synthetic *3,6-dihydroxy-thymoquinone* prepared from thymoquinone *via* 3,6-bismethylamino-thymoquinone [16].

The fraction boiling at 117—152°/20 mm was found to contain mainly *carvacrol*. After 3,6-dihydroxy-thymoquinone had been removed by filtration a sample was converted into carvacroxyacetic acid, m. p. 150.0—151.5°, undepressed by an authentic sample.

The fraction b. p. 152—165°/20 mm crystallised on standing. This was a mixture of cedrol and widdrol (see below) indicating that the separation of neutral material from weak phenols had been unsatisfactory. (It has later been found that extraction with ethanolic potassium hydroxide should be avoided.)

The fraction b. p. 166°/20 mm (3.0 g) was dissolved in ether and extracted with 2 N sodium hydroxide. Acidification of the alkaline solution furnished a product (330 mg), which was recrystallised from ether-light petroleum and sublimed, m. p. 145.0—145.5°, undepressed by an authentic sample of *thymohydroquinone*.

A part of product A (22.4 g) was fractionally distilled in a vacuum. The fraction boiling between 145—175°/0.8 mm (8.1 g) crystallised partly on standing. It was dissolved in ether and the solution was extracted with 2 N sodium carbonate. On acidification the alkaline solution afforded a substance (1.4 g) which was recrystallised from ether, m. p. 192—194°, $[\alpha]_D$ −94° (*c*, 1.3). It was identified (mixed m. p., I.R.) as *Acid II* from *Widdringtonia* [8].

Table 1. Distillation of fraction C_1. Total distillate 107 g or 79 %.

Fraction	Weight (g)	B.p./21 mm (°C)	Rotation $[\alpha]_D$	Refractive index (n_D^{21})
1	5.3	124—136	−48.7	1.4990
2	14.5	136—137	−70.5	1.5025
3	7.5	137—141	−70.8	1.5041
4	18.1	141—165	+ 8.8	1.5088
5	27.1	165—166	+13.9	—
6	28.1	166	+14.7	—
7	6.6	166	+66.7	—

In another experiment a similar fraction of the sodium hydroxide soluble oil on treatment with light petroleum partly crystallised. Recrystallisation from methanol-water afforded thymohydroquinone. The methanol-water mother liquor was evaporated and the residue combined with the material soluble in light petroleum. On standing for several months the combined oils deposited another compound (0.2 g), which was recrystallised from methanol-water, m. p. 169.5—170.5°, $[\alpha]_D$ −86° (*c*, 1.3). It was identified as *hinokiic acid* [12] (mixed m. p., I.R.).

II. *Neutral fraction:* A quick preliminary distillation of the neutral oil C afforded a product boiling below 160°/3 mm (C_1) and a higher boiling residue (C_2). C_1 on fractional distillation through a vacuum-jacketed, packed column, gave the fractions listed in Table 1.

Attempts to demonstrate the presence of thymoquinone in fraction 1 (Table 1): Fraction 1 (0.5 g) was suspended in water (20 ml) saturated with sulphur dioxide and allowed to stand for a week. The solution was extracted with ether and the ether extract was washed with water and evaporated. The residue, like the starting material, was yellow and afforded no acidic material on extraction of a solution in light petroleum with 2 N potassium hydroxide.

No phenolic material was obtained on reduction with zinc and acetic acid.

Demethylation of Fraction 1 (Table 1): Fraction 1 (1.5 g) in glacial acetic acid (6 ml) was refluxed with hydrobromic acid (48 %, 8 ml) for 1 h. The reaction mixture was extracted with light petroleum, the organic phase was extracted with 2 N ethanolic potassium hydroxide and the alkaline extract was acidified, extracted with light petroleum, washed with water dried and evaporated affording an oil (0.48 g). This was examined by paper chromatography [13]. No spot corresponding to carvacrol was found but two spots of higher R_F value were observed.

Gas chromatographic examination of the sesquiterpene fraction: A Perkin-Elmer Vapor Fractometer Model 154 was used together with a Speedomax Type G (Leeds & Northrup Co.) recorder. (Column length 2 m, internal column diameter 5 mm, stationary phase 60—80 mesh celite, impregnated with 2,4-dinitrophenyl-2-naphthyl ether (m. p. 95°C) in the proportion of 25 % by weight [17], charge 1 μl, temperature 145°, flow of helium 64 ml per minute.)

The following peaks were obtained (Recorder deflection (mV) given as a function of time (min)). Fraction 2 (Table 1): 1.1 (15.4), 4.2 (16.9). Fraction 3 (Table 1): 0.4 (11.9), 1.6 (15.4), 4.7 (16.9). Pure α-cedrene, prepared from cedrol [18] gave a peak at 15.4 min and pure thujopsene [12] gave a peak at 16.9 min.

Thujopsene: Fraction 2 (Table 1) (1.0 g) was dissolved in 95 % ethanol (20 ml) and selenium dioxide (0.6 g) was added. The solution was refluxed for 4 h, filtered and evaporated to dryness. The product on sublimation yielded a substance (160 mg) which was recrystallised from light petroleum, m. p. 74.5—75.5°. It was identified as widdrenal (mixed m. p., I.R.).

The infrared spectrum of fraction 4 (Table 1) showed medium height aromatic absorption at 1 527 cm^{-1}. This fraction (17.3 g) was redistilled through a spinning band column yielding the fractions listed in Table 2.

Table 2. Redistillation of fraction 4 (Table 1.) (17.3 g.) Total distillate 14.8 g, 86 %.

Fraction	Weight (g)	B.p./20 mm (°C)	Rotation $[\alpha]_D$	Refractive index (n_D^{21})
1	1.06	141—146	−59.8	1.5033
2	1.04	146	−60.8	1.5040
3	2.18	146—149	−26.7	1.5062
4	3.14	149—151	+18.7	1.5104
5	1.23	151	+67.5	1.5127

7	0.77	155	+27.1	1.5121
8	1.00	155—168	+13.6	1.5077
9	2.58	168	+11.4	—

Cuparene. Fractions 5 and 6 (Table 2) were combined and a sample (2.2 g) in methylene chloride (15 ml) was ozonised at −70°C until an excess of ozone was indicated by the appearance of a blue colour. The reaction mixture was then treated with hydrogen peroxide (30 %, 4 ml) in potassium hydroxide (10 %, 1.5 ml) added dropwise at room temperature. Water (30 ml) was added, the organic phase was separated and the water phase extracted with methylene chloride. The methylene chloride solution was evaporated and the residue was chromatographed on basic aluminium oxide (50 g). Light petroleum (100 ml) eluted a colourless oil (760 mg) which was fractionally distilled. The main fraction b.p. 117°/7 mm, $[\alpha]_D$ +65°, n_D^{21} 1.5230, was identified as cuparene [14] by comparison of the infrared spectrum with that of an authentic sample.

Cedrol: Fraction 6 (Table 1) was recrystallised four times from 95 % ethanol, m. p. 88.0−88.5°, $[\alpha]_D$ +10.4° (*c*, 3.2). The compound was identified as cedrol (mixed m. p., I.R.).

Widdrol: The mother liquor from the first recrystallisation of cedrol was concentrated and two further crops of crystalline material collected. The non-crystalline material (2.5 g) was chromatographed on basic aluminium oxide (200 g). Benzene eluted an oily material which was not investigated; benzene-ether (1:1) eluted mainly cedrol and ether eluted a substance, $[\alpha]_D$ +95° (*c*, 2.5), which was recrystallised from light petroleum and sublimed twice along a temperature gradient, m. p. 98.0−99.0°, $[\alpha]_D$ +105° (*c*, 1.0) identical with widdrol [8] (mixed m. p., I.R.).

The high-boiling neutral fraction: The residue from the distillation described in Table 1 was combined with the distillation residue C_2. A sample of the combined material (C_3) was fractionally distilled through a spinning band column. 65 % of the oil distilled between 143°/10 mm and 183°/5 mm. A main fraction (43 %) was obtained at 160−165°/10 mm ($[\alpha]_D$ +1.1°). According to infrared spectra all the fractions seemed to be rather complex mixtures showing strong hydroxyl and carbonyl bands.

On separation using Girard D reagent the oil C_3 gave 12 % of a mixture of carbonyl compounds. This material showed no hydroxyl absorption and on chromatography gave only liquid fractions.

The authors are indebted to Professor H. Erdtman for his interest in this work, to Miss G. Hammarberg for the infrared and ultraviolet spectra, and to *the Swedish Natural Science Research Council* for financial support.

ACTA CHEMICA SCANDINAVICA 14 (1960) 359–378

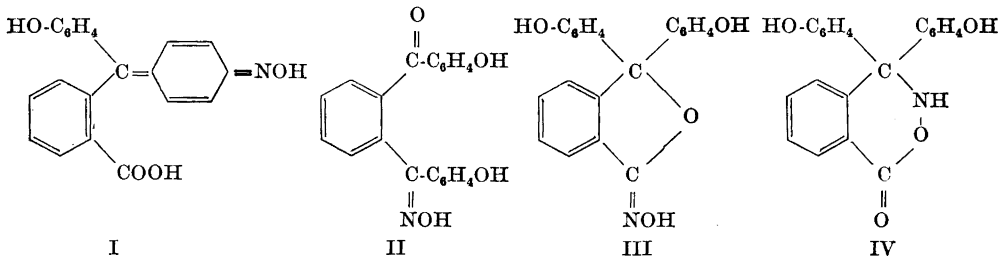
On the Constitution of Phenolphthalein Oxime and Related Compounds

HENNING LUND

Leo Pharmaceutical Products, Ballerup, Denmark

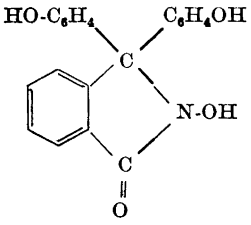
Phenolphthalein oxime is suggested to be a *p*-hydroxyanil of *o*-(*p*-hydroxybenzoyl)benzoic acid. Chemical evidence, infrared spectra, and polarographic data supporting the proposed constitution are presented. Structures for the "pseudoanilides" and "anilides" of *o*-benzoylbenzoic acids are suggested. According to the proposed constitution of phenolphthalein oxime a new rearrangement, which ressembles that of the Lossen degradation, occurs during the formation of the compound.

Phenolphthalein reacts in alkaline solution with hydroxylamine and a yellow, insoluble compound is obtained on acidifying with acetic acid [1]. Friedländer assumed that the compound was an oxime of the quinoid form of phenolphthalein and suggested formula I accordingly. The phenolphthalein oxime was found to be hydrolysed by mineral acid to *o*-(*p*-hydroxybenzoyl)-benzoic acid and *p*-aminophenol, and the latter was assumed to be obtained by a rearrangement of the supposed primarily formed phenylhydroxylamine. Shortly after, however, Friedländer [2] abandoned the structure I, as it did not explain the behaviour of the oxime of 3',5',3'',5''-tetrabromophenolphthalein, which on acid hydrolysis yielded 2,6-dibromo-4-aminophenol instead of 3,5-dibromo-4-aminophenol expected from I.

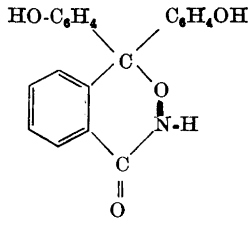


I II III IV

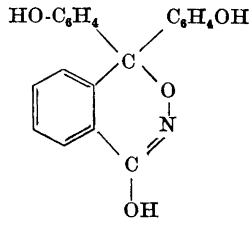
Later H. Meyer [3] proposed formula II and R. Meyer [4] discussed the structures III and IV without deciding between them. Orndorff and Murray [5] adopted the formula V, which H. Meyer [6] previously had considered, and this seemed to be common accepted constitution for many years. Some inconsistencies of this formulation with the experimental facts were pointed out by Lund [7] who instead proposed the structures VI, which take in consideration the tautomerism found in this series of compounds.



V



VI a



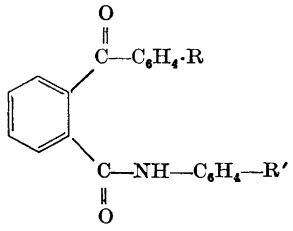
VI b

Although the proposed formulations are rather different, all but II assume that the *p*-hydroxyphenyl groups are bonded to the central carbon atom in the same manner as in phenolphthalein.

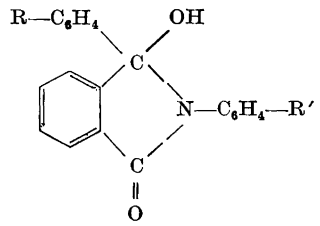
The purpose of the present investigation was to decide between the proposed structures of phenolphthalein oxime, and to this end a chemical, spectrophotometric, and polarographic investigation of the compound and derivatives thereof was undertaken.

CHEMICAL INVESTIGATION

It has long been known [8] that phenolphthalein oxime on reaction with dimethyl sulfate in alkaline solution yields a yellow trimethyl ether, which on boiling with alcoholic potassium hydroxide splits off one methyl group thus forming a dimethyl ether. This dimethyl ether can exist as a yellow and a colourless compound [7], which are readily interconvertible. On boiling with acetic anhydride it rearranges into 2-(4'-methoxybenzoyl)benz-*p*-anisidide (VIIa or VIIb, R = R' = OCH_3). On hydrolysis of the dimethyl ether with mineral acid *o*-(*p*-anisoyl) benzoic acid and *p*-anisidine are obtained.



VII a



VII b

As might have been expected the mixed anhydride made from *o*-(*p*-methoxybenzoyl) benzoic acid and ethyl chloroformate reacted with *p*-anisidine yielding *o*-(*p*-methoxybenzoyl)benz-*p*-anisidide. When *o*-(*p*-methoxybenzoyl)benzoic acid, however, was treated with excess of thionyl chloride and the resulting chloride, after removing the excess of thionyl chloride *in vacuo*, reacted with *p*-anisidine in dry benzene, a compound was obtained in high yield, which proved to be phenolphthalein oxime dimethyl ether.

If it is assumed that phenolphthalein oxime dimethyl ether has one of the structures previously proposed with the two *p*-methoxyphenyl groups bonded to the central carbon atom one of the anisyl groups must have come from the anisoylbenzoic acid and the other one by some rearrangement from the *p*-anisidine. It would, however, in the phenolphthalein oxime dimethyl ether be impossible to determine which group has come from the acid and which one from the amine. Only one compound would, therefore, be expected to be formed in the reaction between *o*-(*p*-anisoyl)benzoic acid chloride and aniline and in the reaction between *o*-benzoylbenzoic acid chloride and *p*-anisidine.

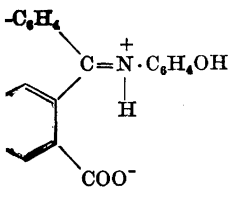
When *o*-(*p*-anisoyl)benzoic acid after treatment with thionyl chloride reacted with aniline an "*o*-(*p*-anisoyl)benz-pseudoanilide" was formed with properties similar to that of phenolphthalein oxime dimethyl ether. On hydrolysis with mineral acid only *o*-(*p*-anisoyl)benzoic acid and aniline were obtained. The compound rearranged on boiling with acetic anhydride to "*o*-(*p*-anisoyl)benzanilide" with a structure represented by VII a or b (R = OCH_3, R' = H).

o-Benzoylbenzoic acid, after treatment with thionyl chloride, reacted with *p*-anisidine yielding an "*o*-benzoylbenz-pseudo-*p*-anisidide", which, too, had properties very similar to those of phenolphthalein oxime dimethyl ether. This compound had previously been obtained by H. Meyer [9] by heating a mixture of *o*-benzoylbenzoic acid and *p*-anisidine. On boiling with mineral acid *o*-benzoylbenzoic acid and *p*-anisidine were obtained, and as found by Meyer it reacted with phenylhydrazine yielding "benzoylbenzoic acid phenylhydrazone", *i.e.* 2,4-diphenyl-phthalazin-1-one. On boiling with acetic anhydride the "*o*-benzoylbenz-pseudo-*p*-anisidide" rearranged into "*o*-benzoylbenz-*p*-anisidide" (VIIa or b, R = H, R' = OCH_3).

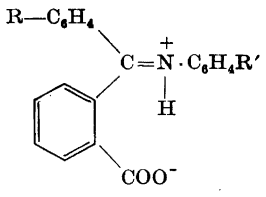
As the "*o*-(*p*-anisoyl)benz-pseudoanilide" is not identical with "*o*-benzoylbenz-pseudo-*p*-anisidide" it follows that the two *p*-anisyl groups in phenolphthalein oxime dimethyl ether are not bonded in the same manner to the central carbon atom. None of the previously suggested structures can account for this fact and must, therefore, be rejected.

Instead are proposed the following constitutions for phenolphthalein oxime (VIII), its dimethyl ether (IXa and b; R = R' = OCH_3), and trimethyl ether (XIV). Whether the compounds VIII and IXa exist in solution as zwitterions or with an undissociated carboxyl group is not known; in the solid state the oxime is assumed to possess the zwitterion structure.

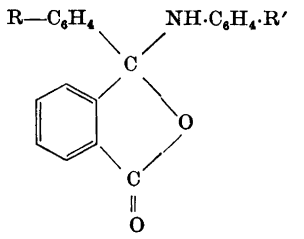
This formulation, where phenolphthalein oxime is a *p*-hydroxyanil of *o*-(*p*-hydroxybenzoyl)benzoic acid, requires that during the formation of the oxime a rearrangement, not previously described, of the type found in the Lossen degradation occurs.



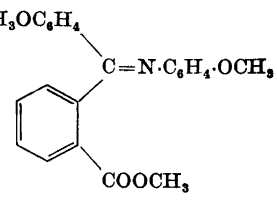
VIII



a



b



XIV

IX R = R′ = OCH_3
X R = OCH_3; R′ = H
XI R = H; R′ = OCH_3
XII R = R′ = H
XIII R = OCH_3; R′ = OH

The constitution of the oxime assumed here is in accordance with the hydrolysis of the oxime in mineral acid and alkaline solution to *o*-(*p*-hydroxybenzoyl)benzoic acid and *p*-aminophenol. The formation of 2,6-dibromo-4-aminophenol on hydrolysis of the oxime of 3',5',3'',5''-tetrabromophenolphthalein is expected from this formulation. The solubility of the phenolphthalein oxime and its dimethyl ether in alkali, the insolubility in alkali of the trimethyl ether, the alkaline hydrolysis of the trimethyl ether to the dimethyl ether, and the hydrolysis of "*o*-(*p*-anisoyl)benz-pseudoanilide" (X) to *o*-(*p*-anisoyl) benzoic acid and aniline and the hydrolysis of "*o*-benzoylbenz-pseudo-*p*-anisidide" (XI) to *o*-benzoylbenzoic acid and *p*-anisidine are readily understood from the structures VIII to XIV. The difference in colour of the phenolphthalein oxime at pH 10 and 13 [1] is explained by the successive dissociation of the three acidic groups, and the yellow and the colourless form of the phenolphthalein oxime dimethyl ether [7] correspond to IXa and b, respectively.

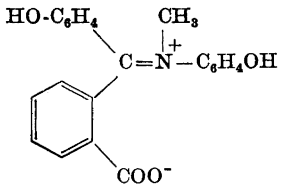
A titration curve of phenolphthalein oxime has not been obtained due to the insolubility of the compound at pH-values lower than 7, but on rapid titration of the hydrochloride of the dimethyl ether in 50 % alcohol with 0.1 N NaOH a pK-value of 5.8 was found for the supposed carboxyl group under conditions, where the pK-value of *o*-(*p*-anisoyl)-benzoic acid was found to be 5.0.

The solubility of phenolphthalein oxime and its ethers in mineral acid is assumed to be due to the presence of the azomethine group. Benzophenone anil and benzophenone *p*-hydroxyanil are soluble in mineral acid, and the latter is claimed by Reddelin [10] to require boiling with strong mineral acid for hydrolysis.

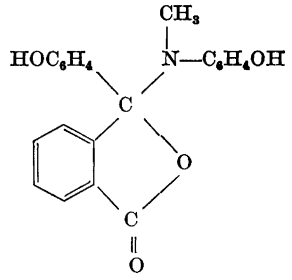
The phenolphthalein oxime contains one mole of water of crystallization which is not removed by drying in high vacuum at 100°C over phosphorus pentoxide for 18 h. On raising the temperature to 120°C for 18 h most of the water was removed, but still about 0.3 mole of water of crystallization was found by a Fischer-titration. This might explain the low values for carbon

and high values for hydrogen reported by Friedländer [1] for the analysis of the phenolphthalein oxime.

Phenolphthalein reacts with N-methyl hydroxylamine analogously with the reaction with hydroxylamine yielding a compound similar to phenolphthalein oxime; the compound is hydrolysed to *o*-(*p*-hydroxybenzoyl)benzoic acid and N-methylaminophenol [7]. This "phenolphthalein N-methyl-oxime" also contains one mole of water of crystallization which is difficult to remove. The yellow "phenolphthalein N-methyl-oxime" is soluble in alkali and acid yielding a yellow solution, but the solution in ether or dioxane is colourless. The yellow form is assumed to possess the structure XVa, whereas the colourless form would be represented by XVb. None of the previously suggested formulations allow the "phenolphthalein N-methyl-oxime" to exist in two forms.



XV a



XV b

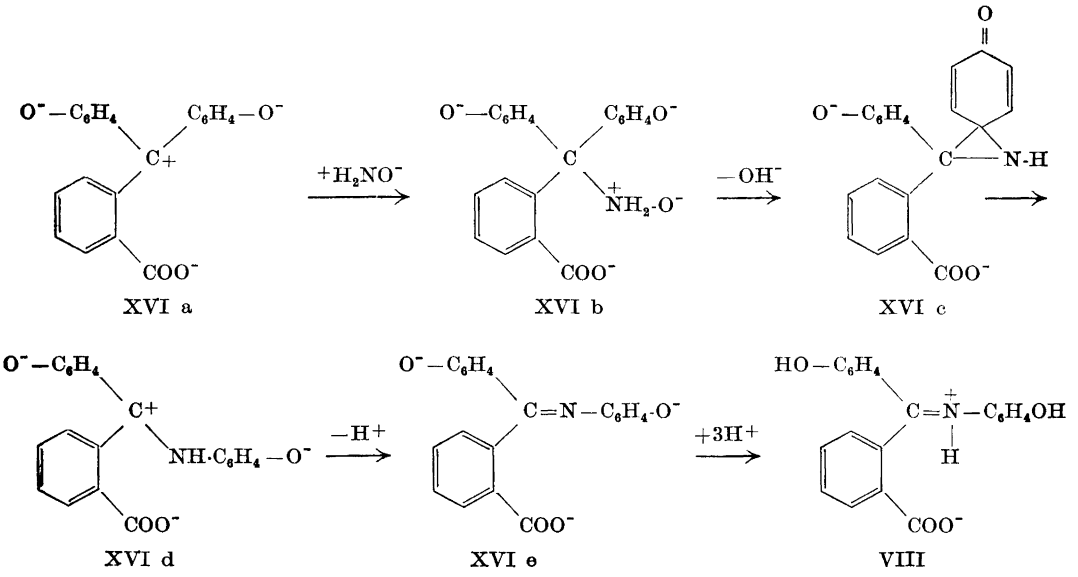
o-(*p*-Anisoyl)benzoic acid reacts after treatment with thionyl chloride with N-methylaniline yielding a white compound, which dissolves in acid with a yellow colour. The colourless form of "*o*-(*p*-anisoyl)benz-pseudo-N-methylanilide" is assumed to have a structure similar to XVb, whereas in acid solution a protonated form corresponding to XVa is likely.

From a similar reaction between the acid chloride of 2-benzoylbenzoic acid and N-methylaniline Wawzonek *et al.*[11] isolated a white compound which they assumed to be a non-cyclic normal N-methylanilide with the nitrogen bonded to the carboxyl carbon atom. In view of the similarities with the above mentioned "*o*-(*p*-anisoyl)benz-pseudo-N-methylanilide" it seems likely that the compound obtained by Wawzonek *et al.* is "*o*-benzoylbenz-pseudo-N-methylanilide" with a structure similar to XVb.

Phenolphthalein monomethylether reacts with hydroxylamine yielding a "phenolphthalein monomethylether oxime" (XIII), which is hydrolyzed on boiling with mineral acid to *o*-(*p*-anisoyl)benzoic acid and *p*-aminophenol. The same compound is formed by action of *p*-aminophenol on the chloride obtained from *o*-(*p*-anisoyl)benzoic acid on treatment with thionyl chloride.

On reaction with diazomethane in a mixture of ether and dioxane the phenolphthalein oxime yields a mixture of different methylated compounds from which phenolphthalein oxime trimethyl ether and a dimethyl ether were isolated. This dimethyl ether was different from IX as it was hydrolyzed by alcoholic potassium hydroxide to "phenolphthalein monomethylether oxime" (XIII).

A mechanism of the postulated rearrangement, which proceeds during the formation of phenolphthalein oxime, is presented below.



The structure XVIa is one of the resonance structures of phenolphthalein in alkaline solution. This carbonium ion is assumed to react with the anion of hydroxylamine forming a bond between carbon and nitrogen. The migration of the phenyl group requires the formation of a quinoid form of the phenyl group, and the plane of the migrating phenyl group is at a right angle to the plane of the three-membered ring. After completion of the migration the carbonium ion XVId loses a proton, and on addition of acid the phenolphthalein oxim (VIII) precipitates.

This mechanism is in agreement with many features found in the reaction between phenolphthalein and hydroxylamine. It has been found [12] that only phthaleines containing at least one *p*-hydroxyphenyl group are able to form oximes. The mechanism suggested above makes that requirement understandable. If, however, a nitro group is present *ortho* to the hydroxyl group it is found that the phthalein does not form an oxime; thus 3',3''-dinitrophenolphthalein forms no oxime, whereas 3',5'-dinitrophenolphthalein does [12]. This is explained by the formation of an *aci*-form of the nitro group in alkaline solution containing an *o*-quinoid structure, which excludes the possibility of a *p*-quinoid form of the phenyl group during the migration.

Furthermore, the formation of N-(*p*-hydroxyphenyl)phthalimide on reaction of phenolphthalein with excess of hydroxylamine can be explained by assuming that the carbonium ion XVId reacts with hydroxylamine analogously with the carbonium ion XVIa with the migration of the second *p*-hydroxyphenyl group. The compound formed would split off one mole of *p*-aminophenol and yield N-(*p*-hydroxyphenyl)phthalimide.

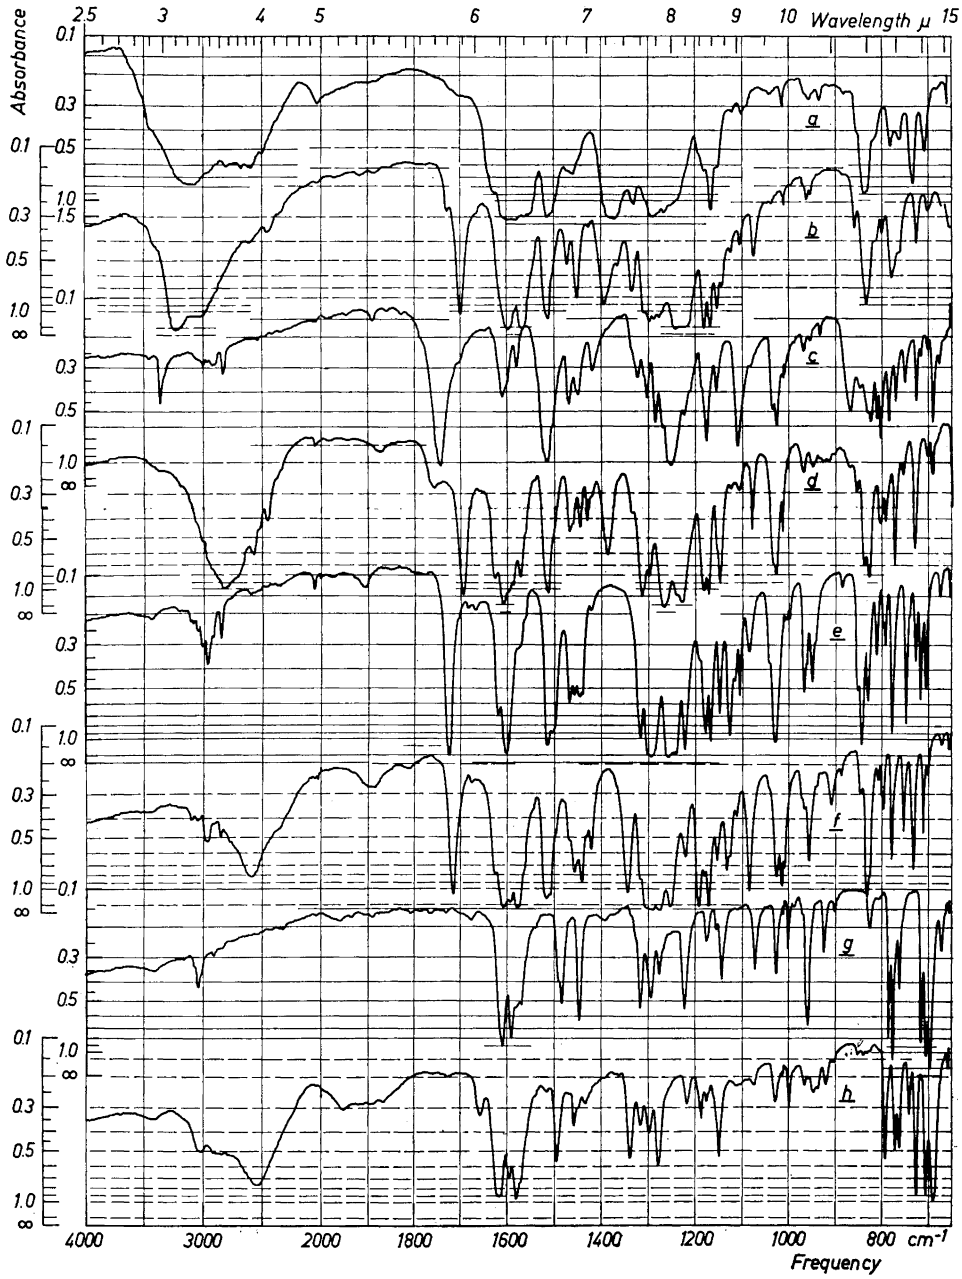


Fig. 1. Infrared spectra (potassium bromide) of phenolphthalein oxime (a), its hydrochloride (b), phenolphthalein oxime dimethyl ether (c), its hydrochloride (d), phenolphthalein oxime trimethyl ether (e), its hydrochloride (f), benzophenone anil (g), and its hydrochloride (h).

Fluorescein does not form an oxime on treatment with hydroxylamine which might be understood as a migration of one of the phenyl groups is hindered by the oxygen bridge between them. Hydroquinonephthalein [8] forms 3 "oximes" on reaction with hydroxylamine, but as they on hydrolysis with mineral acid yield hydroquinonephthalein [8] their constitution must be different from that of phenolphthalein oxime.

SPECTROPHOTOMETRIC INVESTIGATION

The infrared spectra were obtained using potassium bromide discs which had been kept at 100°C for 2—3 minutes before the spectra were recorded following the procedure of Buur Jensen [13].

The spectrum of phenolphthalein oxime (Fig. 1a) shows a strong absorption from 3 500 cm^{-1} to 2 300 cm^{-1}. The absorption between about 2 800 cm^{-1} and 2 300 cm^{-1} is believed to be an "ammonium band" [14] and the absorption about 2 040 cm^{-1} an "immonium band" [14], both of which would be expected from the structure VIII. The strong absorption from 1 615 cm^{-1} to 1 550 cm^{-1} is assumed to contain the phenyl bands and the bands of the carboxylate ion. In this respect the spectrum of the phenolphthalein oxime resembles those of many amino acids. A shoulder at 1 630 cm^{-1} may be due to the azomethine group. The absence of any absorption from 1 800 cm^{-1} to 1 640 cm^{-1} makes the structures I, II, IV, and V very unlikely, whereas III and VIb would not be expected to have absorption in this region; however, the presence of the "ammonium band" excludes III.

The hydrochloride of phenolphthalein oxime (Fig. 1b) has an absorption band at 1 700 cm^{-1} which is attributed to the presence of an unionized carboxyl group. It may be recalled [15] that the carboxyl group of the hydrochlorides of β- and γ-amino acids generally have a carbonyl absorption in the region 1 730 cm^{-1} to 1 700 cm^{-1} and aromatic carboxyl groups at 1 700 cm^{-1} to 1 680 cm^{-1}. This is in accordance with VIII, whereas it seems more difficult to accept that the hydrochloride of VIb would absorb about 1 700 cm^{-1}, when VIb as zwitterion does not do so.

The colourless form of phenolphthalein oxime dimethyl ether (Fig. 1c) has a sharp absorption peak at 3 390 cm^{-1} which is attributed to an N—H stretching frequency. A carbonyl absorption is found at 1 750 cm^{-1}, which also is present in phthalide and substituted phthalides as phenolphthalein and its dimethyl ether. Both the presence of the N—H stretching frequency and the phthalide ring is required by the suggested structure IXb and excludes the formulations I, II, III and V. The yellow form (IXa) has not been obtained free from the colourless dimethyl ether in the solid state, why no spectrum of this compound can be presented.

In the spectrum of the hydrochloride of phenolphthalein oxim dimethyl ether (Fig. 1d) a carbonyl absorption band is found at 1 700 cm^{-1} as in the hydrochloride of the oxime itself, which also would be expected from IXa.

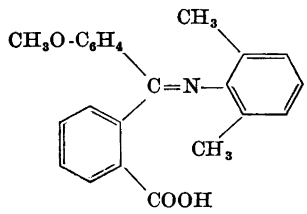
It might be mentioned that in all the compounds containing an aryl methyl ether a band of medium intensity is found between 1 040 cm^{-1} and 1 025 cm^{-1} besides the strong ether band about 1 250 cm^{-1}. A similar observation has been made by Colthup [16].

The carbonyl absorption of phenolphthalein oxime trimethyl ether (Fig. 1e) is at 1 726 cm^{-1}. This is in accordance with the structure XIV which contains an aryl ester group, and the normal frequency for aryl esters is in the region 1 730 cm^{-1} to 1 717 cm^{-1} [15]. A band of medium intensity at 1 620 cm^{-1} might be attributed to the presence of the azomethine group. In the hydrochloride (Fig. 1f) of the trimethyl ether a similar band is found at 1 625 cm^{-1}. The carbonyl frequency at 1 717 cm^{-1} is attributed to an ester group as in XIV. The "ammonium band" and "immonium band" required by the suggested structure is found about 2 600 cm^{-1} and 1 900 cm^{-1}, respectively.

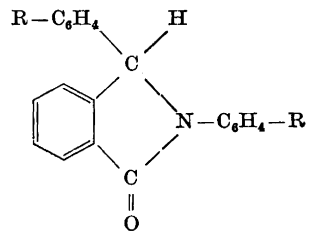
For comparison the spectra of benzophenone anil (Fig. 1g) and its hydrochloride (Fig. 1h) are presented, and the similarities in the spectra of the phenolphthalein oxime trimethyl ether and the benzophenone anil on the one hand and their hydrochlorides on the other support the proposed structures.

The spectra of "*o*-(*p*-anisoyl)benz-pseudoanilide" (X), "*o*-benzoylbenz-pseudo-*p*-anisidide" (XI) and "*o*-benzoylbenz-pseudoanilide" (XII) are similar to that of the colourless form of phenolphthalein oxime dimethyl ether in that they contain an N—H stretching frequency about 3 390 cm^{-1} and a carbonyl absorption about 1 750 cm^{-1}. They are, therefore, believed to possess structures similar to IXb in the solid state.

The yellow compound, *o*-(*p*-methoxybenzoyl)benz-pseudo-2,6-dimethyl-anilide, obtained from the action of 2,6-xylidine on the acid chloride from *o*-(*p*-anisoyl)benzoic acid and thionyl chloride, yields a spectrum without a N—H absorption about 3 400 cm^{-1} and with a carbonyl absorption at 1 711 cm^{-1}. This is attributed to an unionized carboxyl group, although the frequency is slightly higher than the usual one for aromatic carboxyl acids. The structure XVII is suggested for the compound in the solid state. The presence of the azomethine group is in accordance with the yellow colour. It is noteworthy that the two methyl groups in the xylidine nucleus prevent the formation of a phthalide structure or a zwitterion. However, the absorption from 2 800 cm^{-1} to 2 300 cm^{-1} attributed to the O—H stretching vibrations of the carboxyl group might contain an amount of "ammonium"-absorption.



XVII



XVIII

The spectrum of "phenolphthalein N-methyl-oxime" in potassium bromide is similar to that of the phenolphthalein oxime, but in a dioxane solution, which is colourless, the spectrum is quite different. In the dioxane solution the "phenolphthalein N-methyl-oxime" shows a strong carbonyl absorption at 1 760 cm^{-1} which suggests the presence of a phthalide ring. As some absorp-

tion about 1 750 cm^{-1} is found in the spectrum obtained in potassium bromide it is possible that a certain amount of the compound contains the lactone form in the solid state. The analysis seems to exclude that the presence of the absorption at 1750 cm^{-1} (in potassium bromide) is due to a small content of unreacted phenolphthalein. The spectra are thus in accordance with the structures XVa and b.

The white compounds, "*o*-(*p*-anisoyl)benz-pseudo-N-methylanilide" and "*o*-(*p*-anisoyl)benz-pseudo-N-methyl-*p*-anisidide" contain a carbonyl absorption about 1 760 cm^{-1} and no other carbonyl absorption. A structure as that suggested by Wawzonek *et al.*[11] for "*o*-benzoylbenz-pseudo-N-methylanilide" containing a keto and an amide group is thus unlikely for these compounds, and a structure similar to XVb is suggested. This structure is also in accordance with the fact that the compounds are hydrolyzed by cold, dilute alkali, which would not be expected for a normal anilide.

The "*o*-(*p*-anisoyl)benz-*p*-anisidide", obtained from phenolphthalein oxime dimethyl ether on treatment with acetic anhydride [7], yields a spectrum containing a broad absorption around 3 250 cm^{-1}, which is attributed to the presence of a hydroxyl group. A carbonyl absorption is found at 1 675 cm^{-1} and a small shoulder is visible at 1 660 cm^{-1}. This suggests that in the solid state most of the compound is found in the cyclic form VIIb and a minor part possesses the open chain structure VIIa.

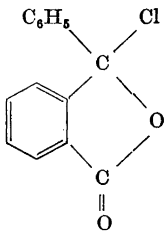
The compounds obtained on treatment of the "pseudoanilides" and "pseudoanisidides" with acetic anhydride yield similar spectra and are assumed to exist mainly in the cyclic form corresponding to VIIb with varying contents of the open chain structure. The presence of the methoxy groups seems to favour the cyclic form, and in *o*-benzoylbenzanilide the diaryl ketone group manifests itself as a band with medium intensity at 1 660 cm^{-1} indicating that an appreciable amount of this compound possesses the open chain structure.

Whereas the spectrum of *o*-(*p*-anisoyl)benz-N-*cyclo*hexylamide, obtained from the acid chloride and *cyclo*hexylamine, only suggests the presence of the cyclic structure of the amide, the *o*-benzoylbenz-N-ethylamide shows three carbonyl bands (1 689 cm^{-1}, 1 676 cm^{-1}, 1 660 cm^{-1}) indicating the presence of approximately equal amounts of both forms in the solid state.

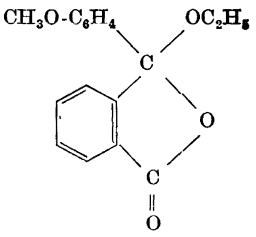
On controlled potential reductions of phenolphthalein oxime was obtained a compound with a carbonyl absorption at 1 645 cm^{-1} which is in accordance with the structure XVIII suggested by H. Meyer [17] for the reduction product obtained from the action of zinc on phenolphthalein oxime.

The spectrum in carbon tetrachloride of the acid chloride from thionyl chloride and *o*-benzoylbenzoic acid contains a carbonyl band at 1 790 cm^{-1} and no bands between 1 760 cm^{-1} and 1 620 cm^{-1}. As no diaryl ketone thus is present it is likely that the chloride exists in the cyclic form XIX, which supports the formulation of the reaction products of the chloride and aromatic amines.

The "*o*-(*p*-anisoyl)benz-pseudo-ethyl ester", formed on reaction between the acid chloride and ethanol, shows in potassium bromide and in chloroform solution a carbonyl band at 1 765 cm^{-1} indicating the presence of a phthalide ring and the spectrum contains no absorption corresponding to a diaryl ketone. The spectrum is thus in accordance with the structure XX.



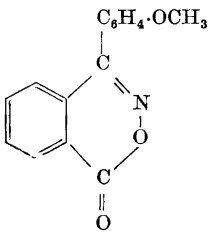
XIX



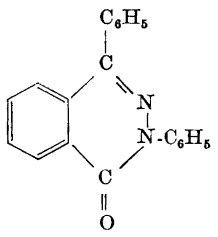
XX

The carbonyl absorption of the "α-oxime" of hydroquinonephthalein is found about 1 680 cm^{-1}. The formula proposed by Meyer [8] for this white compound contains a ring system similar to that (V) suggested by Orndorff and Murray [5] for the phenolphthalein oxime. The spectrum of the "α-oxime" seems not to exclude the structure proposed by Meyer.

The anhydride of the oxime of *o*-(*p*-anisoyl)benzoic acid, 4-(4'-methoxyphenyl)-2,3-benzoxazin-1-one, XXI has a spectrum containing a carbonyl absorption at 1 730 cm^{-1}, whereas the anhydride of the phenylhydrazone of 2-benzoylbenzoic acid, 2,4-diphenyl-phthalazin-1-one, XXII, absorbs at 1 660 cm^{-1}.



XXI



XXII

POLAROGRAPHIC INVESTIGATION

Phenolphthalein has been investigated polarographically by Kolthoff *et al.*[17,18] The compound was assumed to be reduced in a 2 electron reduction to phenolphthalin which in this investigation has been confirmed by controlled potential reduction. The wave showed in certain media a characteristic minimum, and at higher alcohol concentrations the height of the wave was dependent upon the alcohol concentration in such a way, that the wave height diminished at higher alcohol concentrations and became rate controlled [18]. It was assumed that the current below pH 7 was determined by the rate of the transformation of phenolphthalein through its anion into a quinoid form, which was reduced. Some experimental facts, however, seem to be incompatible with this assumption. It would be expected that the rate of the formation of the anion would be very much lower at pH 1 than at pH 7; furthermore,

phenolphthalein dimethyl ether is reduced at potentials similar to those of phenolphthalein, and the wave is best defined in solutions more acid than pH 1; at higher pH-values minima are found. In this case no possibility of a transformation through an anion into a quinoid form exists, and it seems more likely that the rate of a reaction which involve some kind of protonization is determining for the height of the wave. This might also be the case for phenolphthalein but the mechanism of the reduction is still not clear.

The polarographic behaviour of 2-benzoylbenzoic acid, 2-(4'-hydroxybenzoyl)benzoic acid, and 2-(4'-methoxybenzoyl)benzoic acid resembles that of pyruvic acid [19] in that the acids and their anions are reduced at different potentials. In a certain pH-region the height of the more positive wave is determined by the rate of the recombination of the anion and the proton.

By controlled potential reduction of 2-(4'-methoxybenzoyl)benzoic acid it was found that the reaction was a two-electron reduction to 3-(4'-methoxyphenyl)-phthalide.

In Table 1 are given the polarographic data of phenolphthalein oxime (VIII), its monomethyl- (XIII), dimethyl-(IX), and trimethyl ether (XIV), "*o*-(*p*-anisoyl)benz-pseudoanilide" (X), "*o*-benzoylbenz-pseudo-*p*-anisidide" (XI), "*o*-benzoylbenz-pseudoanilide" (XII), "*o*-(*p*-anisoyl)-benz-pseudo-2,6-dimethylanilide" (XVII), "phenolphthalein N-methyl-oxime", and "*o*-(*p*-anisoyl)benz-pseudo-N-methylanilide".

[a] 40 % dioxane. [b] Minimum. [c] The compound is hydrolyzed.

The phenolphthalein oxime yields below pH 11 a diffusion controlled, two-electron wave. The half-wave potentials are dependent upon pH with a slope of the $E_{\frac{1}{2}}$-pH curve of about 0.02 V/pH-unit below pH 5 and about 0.08 V/pH-unit between pH 5 and 10. The presence of the dissociable groups in the compound explains this behaviour. In strongly alkaline solution the height of the wave diminishes somewhat.

The half-wave potentials of phenolphthalein oxime are a little less negative than those of 2-(4'-hydroxybenzoyl)benzoic acid in accordance with the proposed structure VIII. This makes formula V very unlikely, as neither phenolphthalein imide nor benzoylhydroxamic acid are reducible in the medium used.

Controlled potential reduction in acid solution of phenolphthalein oxime showed that the reduction consumed 2 electrons per molecule, and the isolated product was 2-(4'-hydroxyphenyl)-3-(4''-hydroxyphenyl)-2,3-dihydro-2-*iso*-benzazol-1-one (XVIII, R = OH).

The compounds IX, X, XI, and XII behave below pH 10 similarly to the oxime. The "*o*-benzoylbenz-pseudoanilide" (XII) has previously been investigated by Wawzonek *et al.*[11] who from the polarographic data concluded, that the compound in acid solution contained the azomethine group in accordance with the assumption made here. In strongly alkaline solution the wave diminishes in height and another wave appears at more negative potentials. According to Wawzonek *et al.*[11] the second wave is due to the reduction of the compound with the form XIIb containing a phthalide ring. As the height of the first wave in strongly alkaline solution is almost independent of the height of the mercury reservoir it is assumed to be determined by the rate of some reaction. This might be the opening of the phthalide ring, but as IX, X, and XI are soluble in alkali yielding a yellowish solution, it is likely that the phthalide ring in these solutions is opened. It must thus be another reaction which determines the height of the first wave of these compounds.

Controlled potential reduction of phenolphthalein oxime dimethyl ether yielded both in acid and alkaline solution 2-(4'-methoxyphenyl)-3-(4''-methoxyphenyl)-2,3-dihydro-2-*iso*benzazol-1-one (XVIII, R = OCH_3). The reduction of the dimethyl ether is thus analogous with that of phenolphthalein oxime.

The reduction of the phenolphthalein oxime trimethyl ether is slightly different from that of the above mentioned compounds in that the slope of the $E_{\frac{1}{2}}$/pH-curve is about 0.08 V/pH-unit from pH 1 to 10. This is due to the methylation of the carboxyl group; no dissociable groups are thus present in the molecule. In strongly alkaline solution two waves are found, and in this case no phthalide ring, whose reduction can be due to the occurrence of the more negative wave, is present. In the reduction of oximes and other azomethine compounds [20] minima are often found in alkaline solution and in some cases a second wave is found. It is generally assumed that the height of the first wave of the oxime is dependent upon the rate of the protonization of the oxime, and the second wave is due to the reduction of the unprotonated compound. The pH at which the first wave diminishes is in the case of phenolphthalein oxime trimethyl ether considerably higher than in the case of the oximes, but possibly not high enough to exclude the occurrence of such a

protonization at the electrode surface, and at present no other explanation of the two waves in alkaline solution can be offered.

Controlled potential reduction at pH 3 and pH 5 of phenolphthalein oxime trimethyl ether yielded in a two-electron reduction the same compound (XVIII, R = OCH_3) as the reduction of the dimethyl ether. As anils generally are reduced to the aniline derivatives it is assumed that the primarily formed derivative of benzhydrylaniline reacts with the methyl ester yielding the lactam.

The *o*-(*p*-anisoyl)benz-pseudo-2,6-dimethylanilide (XVII) resembles phenolphthalein oxime dimethyl ether below pH 8. However, in the region pH 2 to 4 a second wave, probably catalytic, appeared; the nature of this wave was not investigated further. At higher pH-values the first wave diminishes in height and disappears completely in strongly alkaline solution without the appearence of a second wave. The reduction thus resembles that of many oximes, and the height of the wave is, too, in a certain pH-interval assumed to be governed by the rate of protonization of the azomethine compound at the electrode surface.

Controlled potential reduction of the "*o*-(*p*-anisoyl)benz-pseudo-2,6-dimethylanilide" at pH 0.5 showed the reduction to be a two-electron reduction. In the reaction medium was precipitated a compound, which was identified as 3-(4'-methoxyphenyl)-phthalide. Steric hindrance might be responsible for the failure to form a derivative of 2,3-dihydro-2-*iso*benzazol-1-one, analogously with the reduction product of phenolphthalein oxime dimethyl ether, and for the instability of the assumed, primarily formed, benzhydrylaniline derivative.

The "*o*-(*p*-anisoyl)benz-pseudo-N-methylanilide" (XXIII) is reduced from pH 1 to 10 in a single two-electron wave. The slope of the $E_{\frac{1}{2}}$/pH-curve is about 0.04 V/pH-unit. In strongly alkaline solution the compound is hydrolyzed and the wave of *o*-(*p*-anisoyl)benzoic acid appears.

From a controlled potential reduction in acid solution of the compound 3-(4'-methoxyphenyl)-phthalide was isolated. The reduction thus results in a cleavage of the carbon-nitrogen bond. This might be a direct reduction of the single bond or a reduction of the carbon-nitrogen double bond resulting from an opening of the phthalide ring by forming a zwitterion. As the solution in the neutral region is colourless the compound predominantly exists with the phthalide ring intact, and if the zwitterion is the reducible species the ring opening is a fast reaction. This is likely as the opening of the phthalide ring just requires a displacement of electrons without the participation of hydrogen ions.

The polarographic data of *o*-(*p*-anisoyl)benz-*p*-anisidide (VII), *o*-benzoylbenz-*p*-anisidide (XXVI), *o*-benzoylbenzanilide (XXVII), and *o*-(*p*-anisoyl)-benz-N-*cyclo*hexylamide (XXVIII) are given in Table 2. In acid solution the wave is hardly visible, but at higher pH-values the wave grows and reaches at pH 13 for some of the compounds a height to be expected of a diffusion controlled wave. At lower pH-values the height of the wave is governed by the rate of some reaction. The compounds can exist in a cyclic (VIIb) and a non-cyclic (VIIa) form. From the infrared spectra it can be concluded that the compounds in the solid state to a high degree are found in the cyclic form. As the potentials at which the compounds are reduced are not much different

Table 2. [a] 45 % dioxane. [b] Drawn out wave.

from those of *o*-benzoylbenz-N,N-diethylamide, which from the infrared spectrum (>C = O, $\nu = 1\ 665$ cm^{-1}; —CO—N<, $\nu = 1\ 620$ cm^{-1}) can be shown to possess the non-cyclic structure, it is assumed that the wave is due to the reduction of the form containing a free keto group (VIIa). The wave height would thus be determined by the rate of the transformation of the cyclic into the non-cyclic form.

Controlled potential reduction in strongly alkaline solution of *o*-(*p*-anisoyl)-benz-*p*-anisidide showed the reduction to be a two electron reduction and the isolated product was 3-(4'-methoxyphenyl)-phthalide. If it is the non-cyclic form which is reduced the expected compound would be a benzhydrol derivative. It seems a little unexpected that the carbon-nitrogen bond in the amide group is broken under the influence of the primarily formed secondary alcohol group.

o-Benzoylbenz-N,N-diethylamide (XXIX) yields from pH 1 to 13 a diffusion controlled, two-electron wave (Table 2). Controlled potential reduction in 0.5 N sodium hydroxide showed the reduction product to be 3-phenylphthalide. In this case, too, the carbon-nitrogen bond in the amide group is cleaved.

The polarographic reduction of *o*-(*p*-anisoyl)benz-2,6-dimethylanilide (XXX) showed that the compound to a higher degree than, e.g. *o*-benzoylbenzanilide, possessed the non-cyclic structure, and/or the rate of the ring opening is higher.

Whereas phenolphthalein imide, phenolphthalein hydrazide, and hydroquinonephthalein-*a*-oxime are not polarographically reducible 4-(4'-methoxyphenyl)-2,3-benzoxazin-1-one (XXI) and 2,4-diphenyl-phthalazin-1-one (XXII) are (Table 3). The polarographic data of the oxime of 2-(4'-methoxyphenyl)-benzoic acid (XXIV) are also shown in Table 3.

The behaviour of the oxime XXIV resembles that of benzophenone oxime. In a region around the neutral point the wave due to the reduction of the compound protonated at the electrode surface diminishes in height and disappears, whereas a more negative wave becomes visible, which represents the reduction of the unprotonated oxime. In strongly alkaline solution this wave

[a] Minimum.

disappears, probably due to a loss of a proton from the oxime group. In strongly acid solution the compound loses water and is transformed to the 2,3-benzoxazin-1-one (XXI).

This compound is in acid solution reduced in two two-electron steps, but due to the low solubility of the compound no preparative reduction has been made. From pH about 5 to 10 a single four-electron wave is found. In alkaline solution the 2,3-benzoxazin-1-one ring is opened and the oxime XXIV is formed

The 2,4-diphenyl-phthalazin-1-one is in acid solution reduced in a single wave. At higher pH-values the height of the wave diminishes and a minimum on the curve is found as in the case of many oximes and phenylhydrazones [20]. About pH 9 the first wave has disappeared and a more negative wave is found. This wave disappears, however, in strongly alkaline solution. The height of the wave corresponds to a two-electron reduction, but due to the low solubility of the compound this could not be tested in a controlled potential reduction.

Hydroquinonephthalein (XXV) is reduced (Table 4) from pH 0 to 10 in a single, two-electron wave, which at least in acid solution is diffusion controlled. At pH about 9 the oscillations due to the mercury drops are abnormal from −0.8 to −1.1 V *vs* S.C.E.; when the alcohol concentration was raised to 65 % the height of the wave about −0.7 V diminished and another wave about −1.2 V appeared. In strongly alkaline solution two waves are found both of which become smaller with time, probably due to the formation of a carbinol as in the case of phenolphthalein. It seems somewhat unexpected that hydroquinonephthalein is reducible at such positive potentials, when the phthalide ring is assumed to be reduced at about −1.9 V *vs* S.C.E. as in 3,3-(4'-hydroxydiphenyl)phthalide [21]. An explanation similar to that given by Kolthoff for the reduction of phenolphthalein is not likely as no quinoid structure can be formed after removal of a proton; the only possible quinoid structure seems to be an *ortho* quinoid form with the oxygen bridge between the phenyl groups carrying a positive charge. However, the mechanism of the reduction is not clear.

2-(4'-Methoxybenzoyl)benzoic acid pseudoethylester XX shows (Table 4) a single two-electron wave from pH 1 to 10. In more alkaline solutions the compound is hydrolyzed. From pH about 7 minima are found as in the case of phenolphthalein. On the evidence from the infrared investigation the com-

Table 4. Limiting currents in μA and half-wave potentials *vs* S.C.E. at different pH-values for 2-(4'-anisoyl)benzoic acid pseudo-ethylester (XX) and hydroquinonephthalein (XXV). Concentration 10^{-3} M. 0.01 % gelatin added as maximum suppressor.

[a] Minimum. [b] The compound is hydrolyzed. [c] Abnormal drop oscillations. [d] The wave height diminishes with time.

pound is assumed to possess the structure XX containing a phthalide ring. As a transformation to the normal, non-cyclic ester is unlikely under the conditions employed, and the presence of the phthalide ring also is suggested by the occurrence of the minima, which would not be expected for the non-cyclic ester, it seems likely that the compound in the solution has the assigned structure XX. It is, however, unexpected that this structure would be reducible below −1.0 V *vs* S.C.E. in view of the reduction of phthalide at −2.03 V *vs* S.C.E.[21]

Controlled potential reduction at −1.2 V *vs* S.C.E. in an acetate buffer showed that the wave was due to a two-electron reduction, and the isolated product was 3-(4'-methoxyphenyl)-phthalide.

o-Benzoylbenzoic acid pseudoethyl ester is reduced in the medium used (40 % ethyl alcohol containing buffer and 1 M potassium chloride) in the same manner as XX and different from the normal ester of *o*-benzoylbenzoic acid; in 50 % dioxane containing 0.1 M tetraethylammonium iodide Wawzonek *et al.*[21] found a pH-independent wave at a much more negative potential (about −1.9 V *vs* S.C.E.) for the pseudoester, and this was confirmed in the present investigation. However, in solutions containing less dioxane than about 40 % a wave is visible about −1.1 V *vs* S.C.E. which is the higher the lower the concentration of dioxane is. In 50 % dioxane containing potassium chloride the wave about −1.1 V is found, but on addition of tetraethylammonium iodide this wave disappears. This kind of influence of the supporting electrolyte where one wave is replaced by another one in the presence of capillary-active cations has apparently not been described before and will be discussed in a later communication.

EXPERIMENTAL

The polarograph was a recording polarograph Radiometer Type PO 3a. The capillary delivered 2.16 mg of mercury at a corrected mercury column height of 48.5 cm. The drop time 3.90 sec. (H_2O, open circuit). The capillary constant $m^{2/3}t^{1/6} = 2.13$ $mg^{2/3}$ $sec^{-\frac{1}{2}}$.

The apparatus used for the controlled potential reductions was an electromechanical potentiostat of the Lingane-Jones type. The buffer solutions employed were from pH 2.5 to 8 a sodium phosphate-citric acid buffer and from pH 8 to 11 a sodium borate buffer. The medium generally used was 40 % aqueous alcohol containing 1 M potassium chloride and 0.01 % gelatin. In a few cases the alcohol was replaced by peroxide-free dioxane.

For the infrared measurements a Perkin-Elmer Model 21 infrared spectrophotometer was employed. The potassium bromide discs were heated to 100°C for 2—3 min before use [13].

Phenolphthalein oxime was prepared and purified according to Friedländer [1] and Lund [7]. The compound contained one mole water of crystallization. (Found: C 68.32; H 4.72; N 3.86; H_2O 4.43. Calc. for $C_{20}H_{15}NO_4$, H_2O: C 68.37; H 4.88; N 3.98; H_2O 5.13. After drying for 20 h at 120°C *in vacuo* was found: H_2O 1.82.) Infrared spectrum, Fig. 1a.

In a similar manner was prepared *phenolphthalein monomethyl ether oxime* from phenolphthalein monomethyl ether and hydroxylamine, m. p. 228°. (Found: C 72.24; H 4.97; N 3.94. Calc. for $C_{21}H_{17}NO_4$: C 72.16; H 4.93; N 4.03.) The same compound was prepared analogously to the phenolphthalein oxime dimethyl ether (below) from the acid chloride of 2-(4′-methoxybenzoyl)benzoic acid and *p*-aminophenol. (Found: C 72.31; H 4.91; N 4.12; OCH_3 8.72. Calc. for $C_{21}H_{17}NO_4$: C 72.16; H 4.93; N 4.03; OCH_3 8.93.)

Phenolphthalein oxime dimethyl ether: 5.0 g of *o*-(*p*-anisoyl)benzoic acid were refluxed with 15 ml redestilled thionyl chloride for 30 min. The excess of thionyl chloride was removed *in vacuo* from a water bath, $t < 80$°C. 20 ml dry benzene were added to the residue and evaporated *in vacuo*. The residue was dissolved in 40 ml dry benzene, and 5 g of *p*-anisidine + 5 g of triethylamine in 50 ml dry benzene were added. The mixture was warmed for 15 min and after cooling poured into water. By addition of acetic acid pH was lowered to about 4, and the aqueous layer was discarded. The reaction product was extracted from the benzene layer with N sodium hydroxide, and on addition of acetic acid a precipitate, 5.8 g, was obtained. It was dissolved in ether, from which a white compound, 4.0 g, precipitated, m. p. 156°—158°. It was identified as phenolphthalein oxime dimethyl ether (here suggested to be 3-(4′-methoxyphenyl)-3-(N-4″-methoxyphenylamino)-phthalide, IXb) as the infrared spectrum, the polarographic data and m. p. were identical with those of authentic phenolphthalein oxime dimethyl ether [7]. (Found: C 72.85; H 5.20; N 3.91; OCH_3 16.99. Calc. for $C_{22}H_{19}NO_4$: C 73.09; H 5.30; N 3.89; OCH_3 17.18.) Infrared spectrum, Fig. 1c.

In a similar manner were prepared the following compounds: "o-(p-*anisoyl)benz-pseudoanilide*" (3-(4′-methoxyphenyl)-3-(N-phenylamino)-phthalide, Xb), m. p. 161°. (Found: C 76.05; H 5.26; N 4.37; OCH_3 9.30. Calc. for $C_{21}H_{17}NO_3$: C 76.12; H 5.18; N 4.23; OCH_3 9.37.) "o-*Benzoylbenz-pseudo*-p-*anisidide*" (3-phenyl-3-(N-4′-methoxyphenylamino)-phthalide, XIb), m. p. 195° (198°[9]). (Found: C 76.02; H 5.25; N 3.98. Calc. for $C_{21}H_{17}NO_3$: C 76.12; H 5.18; N 4.23.) "o-*Benzoylbenz-pseudoanilide*" (3-phenyl-3-(N-phenylamino)-phthalide), m. p. 220°—221° (220°—221°[22]). (Found: C 79.49; H 4.96; N 4.51; Calc. for $C_{20}H_{15}NO_2$: C 79.72; H 5.02; N 4.65.) "o-*(p-Anisoyl)benz-pseudo-2,6-dimethylanilide*" (2,6-dimethylanil of 2-(4′-methoxybenzoyl)benzoic acid), m. p. 187°—189°. (Found: C 76.41; H 5.82; N 3.98. Calc. for $C_{23}H_{21}NO_3$: C 76.86; H 5.89; N 3.90.)

"o-(p-*Anisoyl)benz-pseudo-N-methylanilide*" (3-(4′-methoxyphenyl)-3-(N-methyl-N-phenylamino)-phthalide): 5.0 g of 2-(4′-methoxybenzoyl)benzoic acid was transformed to the acid chloride as described above. 10 ml N-methylaniline in 50 ml dry benzene were added. After reaction the mixture was poured into water. The benzene layer was washed with dilute acid (too concentrated acid extracts the compound) and dilute alkali. After drying the benzene was removed, and the residue crystallized spontaneously after some days. It was recrystallized from benzene-ligroin. M. p. 103°. (Found: C 76.52; H 5.39; N 4.13. Calc. for $C_{22}H_{19}NO_3$: C 76.50; H 5.54; N 4.07.)

In the same manner was prepared "o-(p-*Anisoyl)benz-pseudo-N-methyl*-p-*anisidide*" (3-(4′-methoxyphenyl)-3-(N-methyl-N-4″-methoxyphenylamino)-phthalide), m. p. 145°—146°. (Found: C 73.52; H 5.72; N 3.74. Calc. for $C_{23}H_{21}NO_4$: C 73.60; H 5.63; N 3.72.)

Phenolphthalein oxime trimethyl ether (4-methoxyanil of 2-(4′-methoxybenzoyl)benzoic acid methyl ester, XIV) was prepared according to Meyer and Spengler [8]. (Found: C 73.43; H 5.52; N 3.95; OCH_3 24.58. Calc. for $C_{23}H_{21}NO_4$: C 73.60; H 5.63; N 3.72; OCH_3 24.80.) Infrared spectrum, Fig. 1e.

"*Phenolphthalein N-methyl-oxime*": 10 g of phenolphthalein and 8 g of potassium hydroxide were dissolved in 40 ml water and heated to 70°. 3.0 g of N-methyl hydroxylamine oxalate in 20 ml water were added. After 5—10 min the blood-red solution was cooled, 100 ml ether added and the mixture acidified with acetic acid. The yellow precipitate dissolved in ether giving a colourless solution. The ether layer was extracted with a mixture of carbonate and bicarbonate, which was acidified with acetic acid. The yellow precipitate was recrystallized from dioxane-water. It smelted unsharply between 160°

and 165°. (Found: C 68.87; H 5.24; N 3.80. Calc. for $C_{21}H_{17}NO_4$, H_2O: C 69.03; H 5.24; N 3.83.)

o-(p-*Anisoyl)benz*-p-*anisidide* was prepared according to Lund[7] by boiling the "pseudo"-compound with acetic anhydride for 2 min., m. p. 175°—177°. In the same manner were prepared o-(p-*anisoyl)benzanilide*, m. p. 190°—192°, o-*benzoylbenz*-p-*anisidide*, m. p. 202° (204°[9]), o-*benzoylbenzanilide* m. p. 195° (195°[22]), o-(p-*anisoyl)benz*-2,6-*dimethylanilide*, m. p. 238°. (Found: C 76.83; H 6.16; N 3.82. Calc. for $C_{23}H_{21}NO_3$: C 76.86; H 5.89; N 3.90.)

2-(4′-*Methoxybenzoyl)benzoic acid pseudo ethyl ester:* 7 g of the acid was transformed to the acid chloride as described before and treated with excess of ethyl alcohol. The excess alcohol was removed under reduced pressure and the residue dissolved in ether, which was washed with bicarbonate solution; the ether was dried and removed. The residue crystallized spontaneously after some time and was recrystallized from alcohol, 3.5 g. M. p. 76°—78°. (Found: C 71.67; H 5.89. Calc. for $C_{17}H_{16}O_4$: C 71.83; H 5.67.)

Reduction of phenolphthalein oxime: 1.0 g of the compound was reduced at —0.8 V *vs* S.C.E. in a mixture of 15 ml 4 N hydrochloric acid, 10 g potassium chloride, 80 ml water, and 50 ml alcohol. The reduction consumed two electrons per molecule; the yellow colour disappeared during the reduction and some of the reduction product precipitated. After completion the reaction mixture was diluted with water and extracted with ether, which was washed with dilute acid and bicarbonate and dried. After removal of the ether the residue was recrystallized from alcohol, m. p. 254°—256°. It was identified as 2,3-bis-(*p*-hydroxyphenyl)-phthalimidine[3] (2-(4′-hydroxyphenyl)-3-(4″-hydroxyphenyl)-2,3-dihydro-2-*iso*benzazol-1-one). (Found: C 75.69; H 4.94; N 4.38. Calc. for $C_{20}H_{15}NO_3$: C 75.70; H 4.77; N 4.42.)

In a similar manner was performed the *reduction of phenolphthalein oxime dimethyl ether.* The reaction product was identified as 2-(4″-methoxyphenyl)-3-(4′-methoxyphenyl)-2,3-dihydro-2-*iso*benzazol-1-one from m. p. 130° (130°—131°[23]) and analysis. (Found: C 76.49; H 5.53; N 3.88. Calc. for $C_{22}H_{19}NO_3$: C 76.50; H 5.55; N 4.06.) The same compound was isolated from an alkaline reduction.

Reduction of phenolphthalein oxime trimethyl ether: The compound (1 g) was reduced in a mixture of 40 ml water, 100 ml methanol, 30 ml ethyl acetate, 15 ml glacial acetic acid, and 10 g potassium hydroxide. After completion of the reduction (two electrons per molecule) the reduction product was isolated as described above for the phenolphthalein oxime. The product was identical with that obtained above from the dimethyl ether as shown from the m. p. 128°—130° and infrared spectrum.

Reduction of "o-(p-*anisoyl)benz-pseudo-N-methylanilide*": A suspension of 1 g of the compound in 40 % alcoholic acetate buffer was reduced at —0.85 V *vs* S.C.E. consuming 2 electrons per molecule. The compound dissolved during the reduction. The reaction mixture was diluted with water and made acid with mineral acid. The reaction product precipitated (0.5 g); it was identified as 3-(4′-methoxyphenyl)-phthalide from the m. p. 116°—117° (117,5°—118.5°[24]) and an infrared spectrum identical with that of actual 3-(4′-methoxyphenyl)-phthalide.

Reduction of "o-(p-*anisoyl)benz-pseudo-2,6-dimethylanilide*": This compound was reduced at —0.85 V *vs* S.C.E. in 50 % alcohol containing hydrochloric acid and potassium chloride. The reduction required two electrons per molecule, and the product precipitated during the reaction. After dilution of the reaction mixture the product was filtered off and identified as 3-(4′-methoxyphenyl)-phthalide from its m. p. 117° and infrared spectrum.

Reduction of o-(p-*anisoyl)benz*-p-*anisidide:* 1 g of the compound was reduced at —1.6 V *vs* S.C.E. in 40 % dioxane containing 0.5 N potassium hydroxide. After completion of the reduction (two electrons per molecule) the reaction mixture was diluted and acidified with mineral acid. The product precipitated and was identified as 3-(4′-methoxyphenyl)-phthalide from its m. p. 117° and infrared spectrum.

Reduction of o-(p-*anisoyl)benzoic acid pseudo ethyl ester:* The compound was reduced at —1.2 V *vs* S.C.E. in 50 % alcohol containing acetate buffer. The reduction required 2 electrons per molecule, and after removing some of the alcohol the mixture was acidified with mineral acid. The product precipitated and was identified as 3-(4′-methoxyphenyl)-phthalide from the m. p. 117° and the infrared spectrum.

In a similar manner the normal ester *ethyl* o-*benzoylbenzoate* was reduced in a two-electron reduction, and the isolated product was 3-phenyl-phthalide, m. p. 115°, identified from the infrared spectrum.

Reduction of o-*benzoylbenz*-N,N-*diethylamide:* The compound was reduced in 50 % alcohol containing 0.5 N sodium hydroxide and 5 g of potassium chloride at −1.6 V *vs* S.C.E. During the electrolysis a blue colour was observed which, on interruption of the current, faded in the course of half a minute, but reappeared when electrolysis was continued. The reduction required two electrons per molecule, and on acidifying the colourless solution the product precipitated. It was identified as 3-phenyl-phthalide from the m. p. 115° and the infrared spectrum.

Dipole Moments of Guaiacol Derivatives

J. JOHAN LINDBERG

Institute of Chemistry, University of Helsingfors, Finland

The molar polarizations and dipole moments of eugenol, dehydrodi-*iso*eugenol, 2,6-dimethoxyphenol, vanillin and *o*-vanillin have been determined in benzene and dioxan solution. It is found impossible to distinguish by means of dipole moment data between a stiff configuration containing an $OH...OCH_3$-chelate and a structure with "freely" rotating substituents. The rearrangements observed in the ultraviolet spectrum of guaiacol, when changing from an inert solvent (*cyclo*hexane) to dioxan, however, indicate a loss of planarity of the molecule when going from intramolecular to intermolecular hydrogen bond formation in accordance with previous infra-red spectroscopic investigations. A marked intermolecular interaction between *o*-vanillin and dioxan is noted.

It has been observed that the association between solute and solvent due to hydrogen bonds brings about an increase of the dipole moment of the associated molecules which is higher than the pure vectorial addition of the moments of the isolated molecules [1–3]. The observed dipole moment increment grows usually with the increase of the hydrogen bond strength. An exception is made by guaiacol, which shows the same moment in inert solvent (benzene) as in hydrogen acceptor solvent (dioxan). This effect was explained by Curran [4] as being caused by the $OH...OCH_3$ chelate, which should hinder the formation of the intermolecular hydrogen bond between the phenolic hydroxyl group and the oxygen atom of dioxan. This explanation, however, is contradicted by spectroscopic evidence, which indicates that guaiacol, like phenol, forms intermolecular hydrogen bonds with proton acceptor solvents [5–7]. Furthermore a series of investigations seems to indicate that the chelate in question is very weak in nature [7–9]. Actually, Fischer and Zengin [10] concluded from measurements of relaxation times that the hydroxyl group in eugenol is completely free to rotate also in such inert solvents as carbon tetrachloride. However, in the light of investigated infra-red spectra this assumption does not seem to be justified [7].

Full clarity regarding the interpretation of the dipole data of guaiacol appears to be obtainable only by determining the dipole moments of a series of guaiacylic and related compounds in inert and proton acceptor solvents. In order to achieve this end the measurements in benzene and dioxan solutions of the dipole moments of a series of compounds related to guaiacol are reported in the present paper.

EXPERIMENTAL

The dielectric constants required in the dipole moment determinations, were measured by the heterodyne-beat method at 500 kc using an apparatus described elsewhere [11]. The cylindrical measurement cell used in the investigation was made of Pyrex glass and was of the type described by le Fevre [12]. Its volume was 50 ml and its variable capacity about 25.5 pF.

The refractivities used in the calculations of the dipole moments were partially taken from the relevant literature and partially determined experimentally using an Abbe refractometer. The molar polarization at infinite dilution was calculated by the methods developed by Halverstadt and Kumler [13] and Smith and Cleverdon [14], from the dielectric increment and the variation of the specific volume with concentration.

The dipole moments were calculated employing the usual formula

$$\mu = 0.01281\sqrt{(P_{2\infty} - [R])\ T}\quad D \qquad (1)$$

Table 1. Weight fractions, dielectric constants and specific volumes of benzene solutions at 25°C. w_2 denotes weight fraction of solute, v_2 specific volume of solution, $\alpha = \frac{\partial \varepsilon}{\partial w_2}$ and $\beta = \frac{\partial v_2}{\partial w_2}$ at infinite dilution. ε is dielectric constant of solution.

* For the sake of conformity, the dipole data of methanol, phenol and anisol are taken from one and the same publication although also other data are available, cf. *e.g.* Ref.[1].

** On dilution with heptane 1.86 *D* [2].

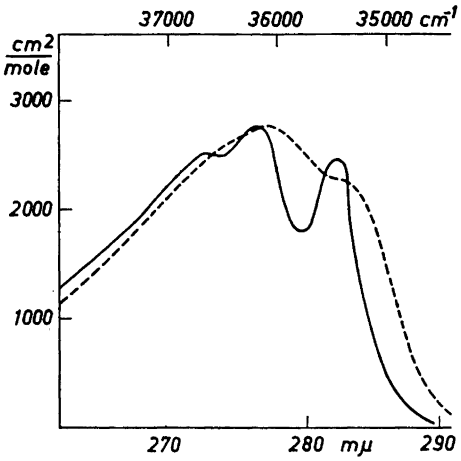

Fig. 1. Ultraviolet absorption spectrum of guaiacol at 20°C. Solvents: *Cyclo*hexane ———, dioxan -------.

No correction was made for the influence of the atomic refraction, *cf.* Ref.[15].

The ultraviolet spectra investigated were determined with a Beckmann spectrophotometer Model DU equipped with a thermostat, which was adjusted to 20.0°C.

Reagents. The investigated phenols were purified as previously described[7]. *Pro analysi* benzene (Merck AG) was distilled twice and stored over sodium. Dioxan was purified using the method given by Hess and Frahm[16] and stored over sodium. The *cyclo*hexane used was of "spectrograde" purity (Eastman Kodak).

DISCUSSION

The experimental data and the results of the investigation are found in Tables 1—3 and Fig. 1. An examination of Table 3, especially the column giving $\Delta\mu$-values, *i.e.* differences between dipole moments in dioxan and benzene solution, shows that the investigated substances, roughly taken, can be divided into three groups:

a) Substances with free hydroxyl groups (phenol, methanol), showing a moderate increase in dipole moment (about 0.3 *D*) when forming hydrogen bonds with dioxan.

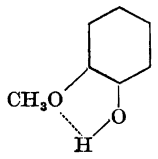
b) Substances forming chelates of the type OH...OCH_3 (guaiacol, eugenol, 2,6-dimethoxyphenol and dehydrodi*iso*eugenol), having almost identical moments in benzene and dioxan solution.

c) Vanillin and *o*-vanillin, having substantially higher dipole moments in dioxan than in benzene solution (about 0.5 *D*). A small increase in the dipole moment is also shown by salicylaldehyde (0.11 *D*), which forms a strong chelate of the same type as *o*-vanillin, *i.e.* CHO...HO[8].

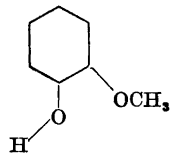
Below, some of the experimental results will be discussed in closer detail. Taking guaiacol as an example it is found, that in the same manner as in phenol[2], there is a marked rearrangement of the ultraviolet spectrum of guaiacol, when going from an inert solvent (*cyclo*hexane) to dioxan (*cf.* Fig. 1). Thus, counting from the band maxima there seems to be a "red shift" of the bands in the 280 mμ region of about 200—300 cm^{-1}. Furthermore a marked

deletion of spectral fine structure is observed. According to Merkel [18] such phenomena could be accounted for by an increase of the significance of polar valence structures and a decrease of the planarity of the whole molecule. In the case under review it would mean that the planar, stiff chelate structure is replaced by a less symmetric guaiacol-dioxan complex, where the positive and negative charge centers of the hydroxyl group are more separated. This interpretation is also in conformity with previous infra-red spectroscopic investigations on guaiacylic compounds and their deuterated derivatives [7,19].

According to the calculations made by Curran [4] a stiff *cis*-configuration of guaiacol (I) should cause a dipole moment of 2.45 *D*, while in the same



I



II

conditions a stiff *trans*configuration (II) should cause a moment of only 0.8 *D* in benzene and 0.9 *D* in dioxan solution. In the light of the previously discussed spectroscopic results it can be stated, that although in benzene solution a stiff *cis*-configuration can be taken for granted, it is not as likely, that a stiff structure would at all be present in dioxan solution. Using known dipole data for phenol and anisol (*cf.* Table 3) simple vector rules [20] give a moment of about 2.5 *D* for a guaiacol molecule with "freely" rotating substituents. Thus, in this case, a selection between the different possibilities must be made by other means than dipole data.

The ionization constants in water, pK (and thus also the hydrogen bond formation capacity of the hydroxyl group [7]), of phenol, guaiacol, 2,6-dimethoxyphenol and eugenol (and probably also of dehydrodi*iso*eugenol) are nearly equal and about 10, *cf.* Refs. [21, 22], whereas the pK-values of vanillin and *o*-vanillin are considerably lower, *i.e.* 7.4 and 7.9, respectively [23]. Bearing in mind the introductory discussion it would be expected that the difference between dipole moment in dioxan and benzene solution, $\Delta\mu$, should be much higher in the latter two substances than in the former ones. It is of interest to note that this is indeed the case (*cf.* Table 3).

On the other hand, the small $\Delta\mu$-value of salicylaldehyde, *i.e.* + 0.11 *D*, is worth noting. In *p*-hydroxybenzaldehyde the $\Delta\mu$-effect must be very high as indicated by the strong dipole moment in dioxan solution, *i.e.* 4.19 *D*. The great difference in behaviour between the two isomers must principally be attributed to the influence of the CHO...HO chelate in salicylaldehyde. This chelating effect seems to be of greater strength than the corresponding one in *o*-vanillin, *cf.* Refs. [21, 24], where a more marked intermolecular interaction is noted.

Summing up the results it can be concluded that it is impossible to distinguish between a stiff *cis*-structure and a structure with "freely" rotating substituents in guaiacylic compounds by means of dipole moment studies.

The absence of increase of dipole moment in guaiacylic compounds of very weak acidity (pK 10) when an intermolecular hydrogen bond is formed with a proton acceptor solvent must apparently, at least partly, be ascribed to charge rearrangements when the weak OH...OCH_3 chelate is broken.

Investigations on Xanthoperol and its Precursor

JOHAN B.-SON BREDENBERG

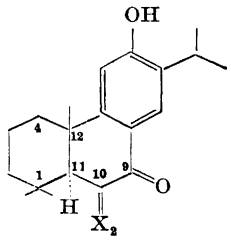
Department of Chemistry, Institute of Technology, Helsingfors, Finland

The 11-epimer of xanthoperol has been found as a precursor. The natural 11α-configuration (Ia) has been assigned to the precursor and the 11β-configuration (IIa) to xanthoperol. The epimerisation is effected by heating in alkaline solution. The stability of the *cis*- and *trans*-forms of the A/B ring junction is discussed.

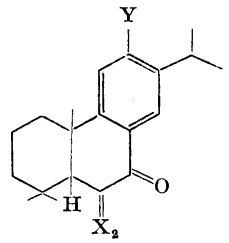
Xanthoperol has been acetylated to a diacetate, the alkaline hydrolysis of which has been studied.

Previous attempts to isolate the precursor of xanthoperol have been unfruitful. It has now been possible, by repeated chromatography, to obtain a small amount of a yellow compound, $C_{20}H_{26}O_3$, m.p. 207—210°, from the fractions containing the precursor. After boiling in sodium hydroxide solution, the yellow compound gives spectra in infrared and ultraviolet which are almost identical with the spectra of xanthoperol. The extinction values for the ultraviolet spectra are slightly lower owing to a small amount of 9-ketoferruginol which has nearly the same solubility as the compound. The compound is therefore the precursor sought. The precursor has ultraviolet spectra with the same shape as those of xanthoperol [1], with maxima at 249 and 341 mμ in neutral and 269 and 405 mμ in alkaline solution. The infrared spectrum has peaks at 3 160, 1 725 and 1 645 cm^{-1}, thus indicating the presence of a hydroxyl group and two keto groups, which latter nicely correspond to an α-diketo group conjugated with a benzene ring. The precursor has therefore the same functional groups in the same chromophore as xanthoperol and the change under the conditions employed can only be explained as an epimerisation.

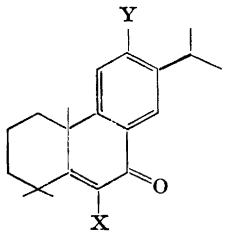
Nuclear magnetic resonance investigations [2] have shown that xanthoperol has the structure of 9,10-diketoferruginol, but it is assumed that the configuration at C-11 is inverted (IIa). The inference has been drawn from the closer relationship of the nmr spectra of xanthoperol to its mono-keto reduction product than to that of 9-ketoferruginol (Ic), from which the mono-keto product differs only in the configuration at C-11, since the centre at C-12 cannot have been influenced under the conditions employed during the rapid reduction of xanthoperol. Inversion at C-12 requires more powerful reagents



I a : $X_2 = O$
b : $X_2 = (OH)_2$
c : $X_2 = H_2$



II a : $X_2 = O$ $Y = OH$
b : $X_2 = O$ $Y = OAc$
c : $X_2 = H_2$ $Y = OH$
d : $X_2 = O$ $Y = O^-$



III a : $X = OAc$ $Y = OAc$
b : $X = OAc$ $Y = O^-$
c : $X = O^-$ $Y = O^-$

V

($AlCl_3$)[3,4]. This leaves structure IIc for the reduction product * and leads to the above assumption.

Apart from some recently investigated compounds [5,6], the natural diterpenes with an angular methyl group at C-12 have the same configuration at the rings A/B, which are *trans*-locked with the methyl group at C-12 in β-orientation [7,8]. All the diterpenes hitherto found in *Juniperus communis* L.[9,10] have this configuration and it seems therefore obvious that it should be assigned to the precursor isolated. From the foregoing it can be seen that the precursor is the less stable epimer. It has previously been found [11,12] that the A/B ring *cis* juncture is more stable than the *trans* juncture in octahydrophenanthrenes with an angular methyl group at C-12. It seems reasonable to assume that 9-keto-11 β-ferruginol (IIc) is more stable than the epimer (Ic) since it is formed under conditions that probably lead to the more stable epimer, and the *cis*-form would therefore be more stable in the 9-keto compounds also. The extension of the stability relationships to the 9,10-diketones cannot be presumed without fuller investigation but does not seem unreasonable in the light of the fact that the configuration for a *cis-syn-trans* perhydrophenanthrene with the keto group next to the *cis*-head is not inverted under the conditions normally employed for conversion [13]. The present evidence therefore strongly suggests that the precursor has the *trans*-form (Ia) and

* Wenkert and Chamberlin [11] have independently proposed this structure for the compound.

xanthoperol the *cis*-form (IIa). For it would seem very strange to assign the unnatural *cis*-form to the precursor and the natural *trans*-form to the artefact xanthoperol.

It has previously [14] been assumed that the precursor would have the same chromophore as 9-ketoferruginol. The ultraviolet spectra of the fractions containing the precursor still gave an appreciable reduction of the intensity at 280 mμ after hydrolysis but, in addition, it was found that a previously overlooked inflexion at 330 mμ had disappeared. The present evidence does not rule out the possibility of the existence of other precursors.

The ultraviolet and infrared spectra of the diketoferruginol epimers need some comment. The 10-keto group in the *trans*-form is evidently less conjugated with the 9-keto group owing to a larger angle between the keto groups [15]. The 9-keto group, on the other hand, is more strongly conjugated with the aromatic ring than the corresponding group in the *cis*-form. The cross-conjugation is therefore much stronger in the *cis*-form, as is clearly seen from the ultraviolet spectra. When the precursor is left to stand in alkaline solution at room temperature, the intensity of the maximum at 405 mμ slowly diminishes. This fall in intensity could be explained by the formation of a hydrate of the 10-keto group (I b). The same behaviour has been observed in several α-diketones [16–18]. (In methanol solution the compound IV [18] has about the same spectrum as acetophenone.) Unfortunately, the ultraviolet spectra in this connection were taken only between 355 and 500 mμ and lack of material prevented further investigation.

Several papers have recently been published in which α-diketo compounds with the general structure V are described. Wenkert and Jackson [4] have found that chromic acid oxidation of the corresponding hydrocarbons can be used as a method for determining the A/B ring junction, since only *cis*-compounds give α-diketones. Ghatak [19] has arrived at the same conclusion in a study of desoxypodocarpic acid isomers and the method has also been used by Saha *et al.*[12] The diketones readily give the enol acetate upon refluxing with acetic anhydride and sodium acetate [4,19]. This acetylation procedure was therefore applied to xanthoperol. In the crude product after 1 hour's boiling the infrared spectrum showed that the phenolic OH band had disappeared. In the region 1 800—1 630 cm^{-1} there were four bands at 1 765, 1 724, 1 685, and 1 667 cm^{-1}. When these bands were compared with the bands for xanthoperol monoacetate (IIb), the band at 1 685 could be assigned to the keto group at C-9 in the diketo compound and the band at 1 724 to the keto group at C-10. The band at 1 667 could be assigned only to the keto group at C-9 in a diacetate IIIa and the slightly broadened band at 1 765 therefore belonged to the unresolved phenol and enol acetate bands. Thus, it was found that the acetylation had only been partial and it was therefore continued for 20 h. The crude product now gave only two bands, at 1 765 and 1 665 cm^{-1}, in the afore-mentioned region and the expected diacetate was obtained as prisms, m.p. 158—159°, by crystallisation from aqueous ethanol.

On acidic hydrolysis, the diacetate afforded only mixtures but alkaline hydrolysis yielded interesting results. Short hydrolysis for 1 min with 0.5 N NaOH at room temperature gave a crude product with an infrared spectrum having bands at 3 330, 1 770 and 1 642 cm^{-1}, a side band at 1 747 and an

inflexion at 1 670 cm^{-1}. The spectrum can be nicely explained if it is assumed that the phenol acetate is rapidly hydrolysed, leaving behind the enol acetate with a small amount of diacetate. It has previously been observed that the phenol acetates of 9-ketoferruginol and xanthoperol are rapidly hydrolysed in alkaline solutions. One minute after the solution has been made alkaline, the ultraviolet spectrum of xanthoperol diacetate was of the same shape and intensity as the spectrum of 9-keto-Δ^{10}-dehydroferruginol in alkaline solution [10], thus supporting the conclusion above. The spectrum slowly changes, with isosbestic points at 400, 320 and 268 mμ, to the spectrum of xanthoperol in alkaline solution. The change in the spectra shows that only two absorbing substances are taking part in the alkaline hydrolysis and this can be explained by the reaction sequence IIIa—IIIb—IIIc—IId, where the absorbing substances are IIIb and IId. After the rapid hydrolysis of the phenol acetate group, the enol acetate group is slowly hydrolysed with the immediate formation of xanthoperol. The hydrolysed diacetate has been isolated and an infrared spectrum of the crude product gives the bands for xanthoperol. Pure xanthoperol has been crystallised from the crude product. The results obtained thus strongly support the structure IIa for xanthoperol.

The non-enolisation of the compound, which was partly responsible for erroneous conclusions [14]. has been commented on by Wenkert and Jackson [4]. They have explained it as due to steric compression. The steric conditions are, in our view, not the sole reason for the non-enolisation, but the phenol hydroxyl apparently also has an influence on it. This applies at least to alkaline solutions, in which the phenoxide ion is formed.

Kondo *et al.*[20] have recently obtained xanthoperol from the heartwood of *Cryptomeria japonica* D.Don. The bulk of the compound has been obtained after alkaline hydrolysis but a small amount has been isolated by extraction with sodium hydroxide without previous hydrolysis and the authors therefore conclude that xanthoperol is present as such in the tree. In the light of the present results it seems necessary to investigate whether the precursor is rearranged during the isolation procedure that has been used by Kondo *et al.*

EXPERIMENTAL

All m.p.s were determined with a Kofler microscope. The microanalyses were performed by Dr. A. Bernhardt, Mülheim. The infrared spectra were recorded with a Beckman IR-5 instrument, and the ultraviolet spectra with a Beckman DK-2 instrument.

9-Keto-11β-ferruginol (IIc). Clemmensen-reduced xanthoperol (0.24 g) was acetylated and the acetate oxidised with CrO_3 as before [14]. The oxidised product was hydrolysed and extracted in the usual way. Upon crystallisation from benzene, 15 mg of small prisms were obtained, m. p. 254—256°. UV spectrum: ethanol, λ_{max} 235 mμ (logε 4.20), 286 mμ (logε 4.12).

Isolation of the precursor. One hundred grams of the non-steam-volatile portion of the neutral extract from *Juniperus communis* L.[9] was chromatographed on alumina and small samples from each fraction were taken for investigation of the content of the precursor by taking the ultraviolet spectra before and after hydrolysis. The fractions containing the precursor were chromatographed anew and the spectra were taken as before. The fractions now containing the precursor were combined (0.54 g) and dissolved in 100 ml ether. The solution was extracted four times with 25 ml 2 % NaOH solution. The alkaline solutions were acidified and extracted with ether within 5 min after the extraction with alkaline solution. The ether extracts were combined and worked up as usual, leaving a crystalline

residue. This was crystallised from benzene and yielded 10 mg of small prisms, m. p. 207—210°, easily soluble in ethanol and difficultly soluble in benzene. (Found: C 77.0; H 8.2. Calc. for $C_{20}H_{26}O_3$: C 76.4; H 8.3.) UV spectrum: ethanol, λ_{max} 249 mμ (log ε 3.73), 341 mμ (log ε 3.94); 0.5 N NaOH in ethanol-water (1:1), 269 mμ (log ε 3.83) 405 mμ (log ε 4.08). IR spectrum: 1 mg/300 mg KBr, principal bands, cm^{-1}, 3 160 (s), 2 940 (s), 2 870 (m), 1 725 (m), 1 645 (s), 1 600 (s), 1 585 (s), 1 560 (s), 1 500 (s), 1 465 (m), 1 380 (m), 1 365 (m), 1 345 (m), 1 310 (s), 1 270 (s), 1 220 (m), 1 170 (m), 1 100 (m), 965 (w), 917 (w), 897 (w), 870 (m), 835 (w). The compound was contaminated with a small amount of 9-ketoferruginol.

Epimerisation of the precursor. The precursor was dissolved in 0.5 N NaOH in water (c 20 mg/l) and ultraviolet spectra were recorded in the range 500—355 mμ. The following extinction values were recorded at the maximum at 405 mμ at room temperature: a (time after solution, min), 38 (5), 36 (30), 33 (60), 27 (120), and 12 (300). The solution was thereafter heated on a water bath and the following values were recorded: λ_{max}, a (min), 410, 20 (15), 430, 19 (30), 440, 19.5 (45), and 445, 37 (120). UV spectrum of the epimerised product: ethanol, λ_{max} 251 mμ (log ε 3.74), 352 mμ (log ε 3.86); 0.5 N NaOH in ethanol-water (1:1), plateau at 260—270 mμ (log ε 3.9), max. 445 mμ (log ε 4.07) and an inflexion at 350 mμ due to the presence of a small amount of 9-ketoferruginol. IR spectrum: film on KBr, principal bands, cm^{-1}, 3 350 (broad), 2 950 (s), 2 870 (m), 1 718 (m), 1 660 (m), 1 595 (s), 1 565 (s), 1 505 (m), 1 460 (m), 1 370 (m), 1 330 (s), 1 295—1 265 (broad), 1 180 (m), 1 163 (m), 1 149 (m), 920 (w, broad), 865 (w, broad).

Xanthoperol diacetate (IIIa). Xanthoperol (140 mg) was acetylated with acetic anhydride and sodium acetate according to the procedure of Wenkert and Jackson [4]. The crude product after 1 hour's boiling had the maxima in the infrared: (film on KBr), 1 765 (s), 1 724 (m), 1 685 (s), 1 667 cm^{-1} (s), no hydroxyl band. The acetylation was completed by boiling for 20 h. The crude product was crystallised from aqueous ethanol, yielding 100 mg colourless prisms, m. p. 158—159°. By sublimation of the evaporated mother liquor a further amount (30 mg) of a colourless sublimate was obtained, m. p. 159—160°, identical with the previous crystals. (Found: C 72.0; H 7.5; O 20.3. Calc. for $C_{24}H_{30}O_5$: C 72.3; H 7.6; O 20.1.) UV spectrum: ethanol, λ_{max} 263 mμ (log ε 4.10), plateau 277 mμ (log ε 4.08). IR spectrum: 1 mg/300 mg KBr, principal bands, cm^{-1}, 2 960 (m), 2 870 (w), 1 765 (s), 1 665 (s), 1 612 (m), 1 565 (w), 1 495 (w), 1 460 (w), 1 420 (w), 1 385 (w), 1 370 (s), 1 320 (m), 1 205 (s), 1 170 (m), 1 155 (m), 1 110 (m), 1 095 (m), 1 035 (s), 932 (m), 903 (w), 885 (w), 865 (w), 795 (w).

Hydrolysis of xanthoperol diacetate. a. Acid hydrolysis. Hydrolysis with 2 N HCl gave ultraviolet and infrared spectra which showed that the hydrolysis was slow and gave a mixture of compounds.

b. Alkaline hydrolysis. 1. The diacetate (7 mg) was dissolved in ethanol (20 ml) and 1 N NaOH (20 ml) was added. The hydrolysis was stopped after 1 min at room temperature by acidification and extraction with ether. An infrared spectrum of the extracted product (film on KBr) showed bands at 3 330 (broad), 1 770 (s), 1 747 (m), 1 670 (inflexion), and 1 642 cm^{-1} (s). Attempts to obtain crystals from the crude product failed.

2. The diacetate (1.3 mg) was dissolved in ethanol (50 ml) and 1 N NaOH (50 ml) was added. A series of ultraviolet spectra were taken at 1, 5, 20, 60, 90, 120, 240, and 1 320 min at room temperature and warming for 10 min on a water bath. The spectra had isosbestic points at 268, 320 and 400 mμ, except the two last-mentioned which did not pass through the two lower points, probably owing to slow deterioration of the alkaline solutions. The first spectrum had λ_{max} 246 mμ (log ε 4.17, calc. for xanthoperol monoacetate) and 382 mμ (log ε 4.13). At the times given the high-end maximum had the following values: λ_{max} (a), 382 (38), 382 (37), 387 (35), 395 (33), 400 (33), 405 (34), 410 (34), 415 (35), and 420 (35). At the time when the experiment was interrupted the maxima were at 270 and 420 mμ in the alkaline solution and 250 and 345 mμ in the acidified solution.

3. The diacetate (4 mg) was hydrolysed for 2 h on a water bath with 1 N NaOH. After acidification and extraction the crude product gave the infrared spectrum of xanthoperol, and upon crystallisation from light petroleum-benzene, 1 mg of xanthoperol was isolated.

Xanthoperol monoacetate [14] *(IIb).* IR spectrum: 1 mg/300 mg KBr, principal bands, cm^{-1}, 2 960 (m), 2 870 (w), 1 780 (s), 1 724 (s), 1 685 (s), 1 610 (s), 1 555 (m), 1 490 (m),

1 460 (m), 1 385 (w), 1 370 (s), 1 320 (m), 1 265 (m), 1 250 (s), 1 190 (s), 1 180 (s), 1 150 (m), 1 120 (w), 1 110 (m), 1 098 (m), 1 050 (m), 1 022 (m), 1 010 (m), 970 (w), 952 (w), 928 (m), 915 (m), 882 (w), 868 (m), 846 (w), 778 (m).

The author is indebted to the late Prof. K. Alder for an ultraviolet spectrum of compound IV.

Crystal Structure of the 1:1 Addition Compound Trimethylamine — Iodo Monochloride

O. HASSEL and H. HOPE

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

As a part of a research programme dealing with the structures of charge transfer compounds having halogen molecules as electron acceptors the crystal structure of the 1:1 compound trimethylamine — iodo monochloride has been determined. The crystals are orthorhombic, the space group is *Pbca* and the lattice constants:

$a = 11.52$ Å $\quad b = 11.08$ Å $\quad c = 10.77$ Å

The number of molecules per unit cell is *eight*.

The nitrogen atom is tetrahedrally surrounded by the methyl groups and the I—Cl group, the N—I—Cl arrangement is at least nearly linear. The N—I distance (2.30 Å) corresponds closely to the distance previously observed in addition compounds formed by tertiary amines, the I—Cl distance of 2.52 Å is very nearly the same as that observed in the pyridine iodo monochloride compound (2.54 Å).

During the last few years crystal structure determinations of a series of charge transfer compounds have been carried out in this laboratory in which halogen molecules act as acceptors; ethers, amines and different other organic molecules as donors. The following report deals with the 1:1 compound formed by trimethylamine and iodo monochloride.

This compound (apparently first described as a simple addition compound by Pictet and Krafft [1]) is easily obtained by bringing together equimolecular quantities of the two components dissolved in a non-polar solvent like ligroin, carbon disulphide or carbon tetrachloride at temperatures below 10°C. We used the latter solvent and added the iodo monochloride solution drop by drop to the amine solution which was cooled by ice water. The yellow precipitate was dried *in vacuo* in the dark and stored at a low temperature. It was recrystallized from methylene chloride at temperatures below 10°C.

Analysis of the compound was carried out as follows: The substance was dissolved in glacial acetic acid and solid potassium iodide added, thereafter water in portions. Free iodine was titrated with a standard thiosulphate solution. The results obtained correspond within one per cent to theoretical values for $(CH_3)_3NICl$. Combustion analysis gave the following result: Found C 16.2; H 3.9. Calc. for C_3H_9NICl: C 16.3; H 4.1.

Single crystals were grown from methylene chloride solution by slowly evaporating the solvent in a refrigerator box. The most ideally developed crystals were obtained by

putting fine glass fibres into the vessel in which the crystals were grown. The crystals thus obtained were firmly fixed to the fibre and could be mounted on the goniometer head of the camera and set in the desired position. In cases where the linear extension of the crystal exceeded 0.1 mm its dimensions could be reduced by repeatedly bringing it for a short time into methylene chloride. Although the crystals are not very stable even at room temperature, the first Weissenberg pictures intended for a determination of lattice constants and space group could be obtained without cooling the crystals or putting them into sealed capillary tubes. Later exposures used for intensity measurements were performed at about −20°C in a Weissenberg camera equipped with cooling devices. The multiple film technique was employed and the intensities estimated visually. All diagrams were taken with CuK radiation.

The crystals are orthorhombic, bipyramidal in shape, the space group is *Pbca*. The lattice constants are as follows (−20°C):

$$a = 11.52 \text{ Å}; \qquad b = 11.08 \text{ Å}; \qquad c = 10.77 \text{ Å}$$

with a possible error of ± 0.5 %. Inserting the density measured at room temperature (2.10 g cm^{-3}) the calculated number of molecules in the unit cell is 7.84.

The number of observed reflexions in the *hk0* zone was 68 (theor. 82), in the *0kl* zone 69 (theor. 82) and in the *h0l* zone 61 (theor. 83).

The plane group of all three projections along the principal axes is the same, *pgm*. The first of these projections to be worked out was that along the z-axis (Fig. 1). The structure factor signs were computed on the basis of a Patterson synthesis and a Fourier synthesis subsequently worked out. The y parameter of chlorine, determined from the Fourier map, was not very accurate, however, because of overlapping, and the next step was the working out of a synthesis with projection along the x axis (Fig. 2). The coordinates of both iodine and

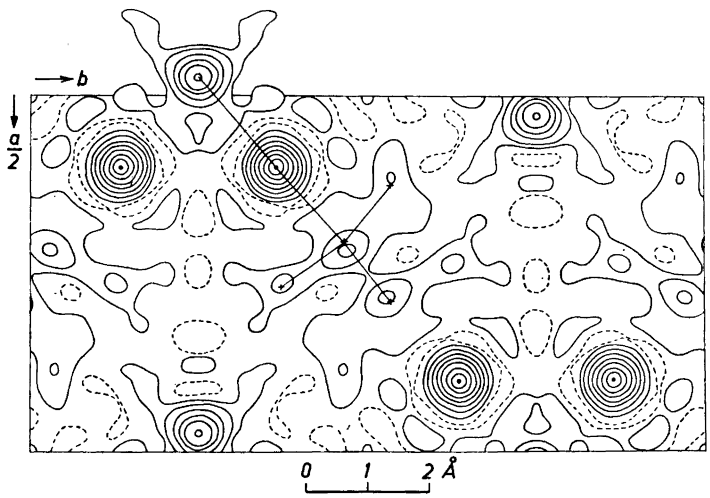

Fig. 1. Fourier projection along the z-axis. Contour lines for I at 0, 5, 20, 35, ... eÅ^{-2}, for Cl at 0, 5, 10, 20... eÅ^{-2}, for lighter atoms at 0, 5, 10, 15... eÅ^{-2}.

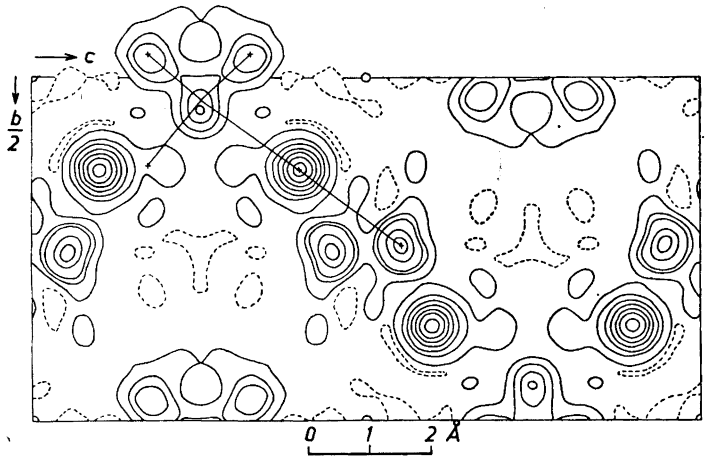

Fig. 2. Fourier projection along the x-axis. Contour lines for I at 0, 5, 20, 35... eÅ^{-2}, for all other atoms at 0, 5, 10, 15... eÅ^{-2}.

chlorine atoms were thus determined, but due to overlapping the x and z coordinates of the nitrogens were still rather uncertain and a Fourier projection along the y axis was therefore carried out inserting the structure factor signs obtained from the two first projections.

For all three projections difference Fourier projections were worked out with subtraction of the contribution from iodine.

The atomic coordinates arrived at by combining the information obtained from all the projections are listed in Table 1.

The agreement between observed and calculated structure factors may be judged by inspecting Table 2. When calculating the values listed in this table a temperature factor $B = 2.40$ was employed which was independently derived both from the xy and the yz projection. The "reliability factor" R including all observed reflexions is 0.09.

The agreement between observed and calculated intensities appears to be good enough to garantee that the iodine coordinates and even the chlorine coordinates have been determined with considerable accuracy. The coordinates

of the lighter atoms, however, are certainly less accurate. The small deviation from linearity observed for the N-I-Cl group with an angle at the I atom deviating by less than 4° from 180° may therefore not be significant. The atomic distances and bond angles derived from the coordinates listed in Table 1 are given in Table 3.

It is obvious that the type of structure found for the trimethylamine — iodo monochloride compound is closely analogous to structures previously derived for halogen addition compounds of aliphatic amines.[2] The linear arrangement nitrogen-halogen-halogen has been observed in all solid halogen addition compounds of aromatic amines so far investigated and also in the 1:1 iodine compounds of γ-picoline and quinoline which are now being investigated in this laboratory. It is interesting to note that the nitrogen-iodine bond length is very nearly the same in all these compounds, whether aliphatic or aromatic, and that the lengthening of the halogen-halogen bond as compared with the bond distance in the free iodine or iodo monochloride molecules is also practically the same (Table 4). The base property of the amine as judged from the dissociation constant in aqueous solution does not appear to be of any importance for the structure of the addition compound. The results of X-ray analyses do not substantiate Hantzsch's suggestion[3] that the solid halogen compounds of amines should be regarded as salt-like substances containing a halogen-substituted ammonium cation and a halogen anion.

Thus the evidence available from X-ray analysis of simple addition compounds formed by amines and halogens do not indicate a tendency towards the formation of ions like PyI^+. This does not mean, however, that salt-like structures cannot be formed. Some simple salts are known which must be expected to contain ions like Py_2I^+. In a recently started analysis of the crystal structure of the 1:2 compound formed by pyridine and iodine we have

actually observed the Py_2I^+ ion. According to space group requirements it has a center of symmetry. This means that the N-I-N arrangement is linear. The ion is probably at least very nearly planar. The remaining iodine atoms form an arrangement consisting of centrosymmetric I_3^- ions and iodine molecules very similar to that observed by Havinga [4] in tetra-ethylammonium heptaiodide. Additional examples of ionic compounds formed by amines and halogens will probably be found in the future.

Crystal Structure of the 1:1 Molecular Compound 1,4-Dioxan, Sulphuric Acid

O. HASSEL and CHR. RØMMING

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The 1:1 addition compound 1,4-dioxan, sulphuric acid crystallizes in the monoclinic system — space group $P2_1/c$ — with lattice parameters:

$$a = 13.22 \text{ Å}; \; b = 7.73 \text{ Å}; \; c = 7.71 \text{ Å}; \; \beta = 92°.$$

Hydrogen bonds link each sulphuric acid unit to two neighbouring dioxan molecules, thus producing endless chains of alternating dioxan and sulphuric acid molecules. Two sets of non-equivalent dioxan molecules are present in the structure, and two sets of hydrogen bonds are therefore also present. The lengths of these bonds are found equal to 2.51 and 2.59 Å, respectively.

In order to establish the crystal structure of one solid compound formed by an ether and a strong mineral acid, an X-ray analysis of the 1:1 compound 1,4-dioxan, sulphuric acid has been carried out. This compound has a melting point of 101°C (Faworski [1]). The possible structure of the isolated complex has been discussed on the basis of dipole moment measurements by Syrkin and Anisimova [2] who have concluded that both hydrogen atoms of the sulphuric acid molecule are linked to one particular ether oxygen atom. The angle between the two hydrogen bonds thus established would, however, appear to be rather small and we would therefore prefer a model in which both ether oxygen atoms are involved in hydrogen bond formation. In this case the dioxan molecule would of course be present in the »boat» form. Both models would lead to a rather high dipole moment. In the crystal the possibility of chains built up of alternating sulphuric acid and dioxan molecules would also have to be considered. In this case centrosymmetrical dioxan molecules might be expected.

EXPERIMENTAL

The compound was prepared as described by Faworski [1]. Sulphuric acid was added to a solution of dioxan in benzene and the reaction mixture cooled slowly. The needle-shaped crystals thus obtained turned out to be well fitted for X-ray examination. The

procedure of bringing a crystal into a capillary tube without admitting small traces of moisture which would eventually liquefy the crystal after the tube had been sealed, turned out to be difficult. By careful handling this could, however, be achieved. The cross section of the crystals used in the X-ray work was approximately 0.15 × 0.15 mm².

The experimental material on which the analysis was based consisted of integrated Weissenberg (Wiebenga) diagrams (CuK_α-radiation) with rotation about the *c*-axis (needle-axis) and precession diagrams (MoK_α-radiation, $\mu = 30°$) of the (*h*0*l*)- and (0*kl*)-zones. The number of reflexions recorded in the (*hk*0)-zone was 113 (theor. 135), in the (*h*0*l*)-zone 101 (theor. 129) and in the (0*kl*)-zone 49 (theor. 72). The intensities in the Wiebenga diagrams were recorded photometrically, whereas the precession diagram intensities were estimated visually. Most of the computation work was performed using a Ferranti Mercury machine.

The crystals are monoclinic, space group $P2_1/c$, and the parameters obtained are as follows:

$$a = 13.22 \text{ Å}; \; b = 7.73 \text{ Å}; \; c = 7.71 \text{ Å}; \; \beta = 92°.$$

These figures are believed to be accurate to within 0.03 Å and 0.5°. The calculated density, assuming the unit cell to contain four molecules of either kind, is 1.57.

STRUCTURE DETERMINATION

If the dioxan and sulphuric acid molecules take up fourfold general positions no symmetry requirements for the single molecules have to be fulfilled. On the other hand, the dioxan molecules may occupy two two-fold positions involving centers of symmetry, in this case two types of dioxan molecules are present in the structure.

Projection along the c*-axis.* From the Weissenberg data a two-dimensional Patterson synthesis was worked out. This synthesis made possible the localization of the sulphur atom and the determination of approximate coordinates of the sulphuric acid oxygen atoms. The atoms belonging to dioxan molecules could not be determined, but it became obvious that two non-equivalent sets of dioxan molecules are present in the structure having their centers of symmetry

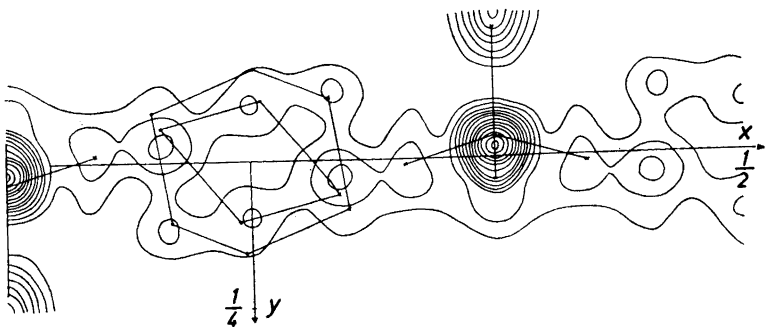

Fig. 1. Fourier map based on the (*hk*0)-reflexions using F_{hk0} with $h+k = 2n$ only.

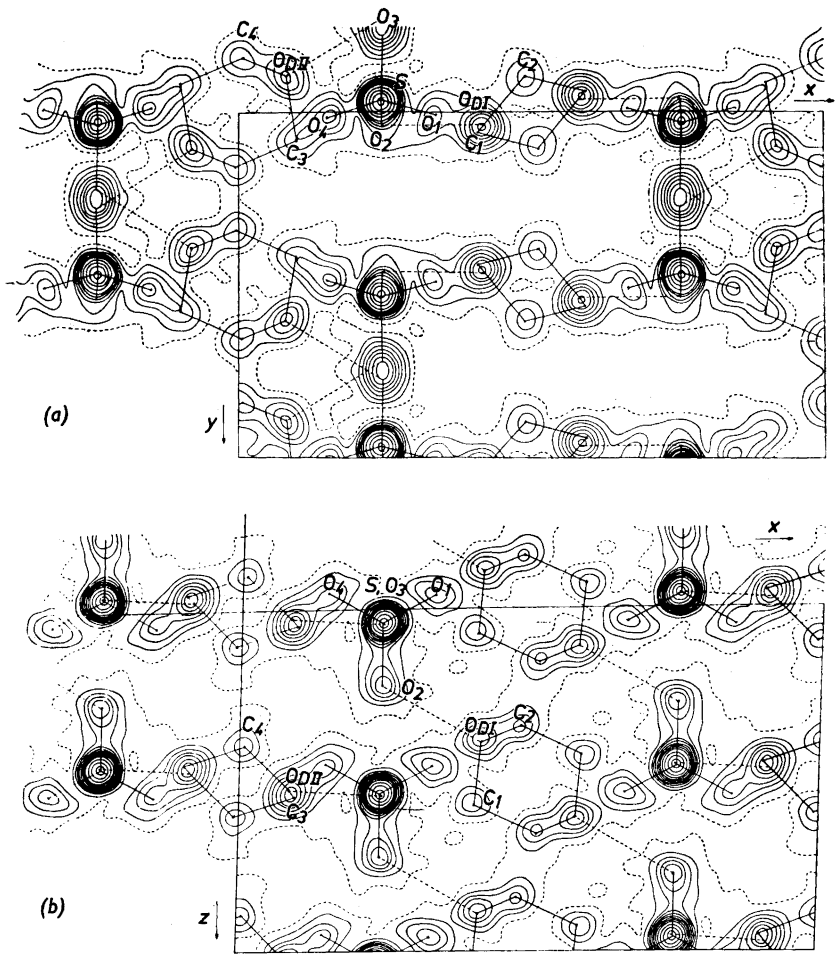

Fig. 2. Electron density projection along the *c*-axis (a) and *b*-axis (b). Contour lines at intervals of 2e. Å^{-2} from 2—16 e. Å^{-2} and 4 e. Å^{-2} from 16 e. Å^{-2} upwards.

in (0,0) and (1/2,0), respectively. The approximate coordinates of the sulphur and oxygen atoms of the sulphuric acid group were as follows: S: (0.250, —0.013) ; O_1: (0.345, 0) ; O_2: (0.250, 0) ; O_3: (0.250, —0.208) and O_4: (0.155, 0). On the basis of these coordinates only the structure factor signs of reflexions with $h + k = 2n$ could be determined. The neglection of other reflexions introduced an extra line of symmetry ($x = 1/4$) in the resulting Fourier synthesis (reproduced in Fig. 1). Here the sulphuric acid molecule therefore exhibits a symmetry line which is not real and the peaks around (0,0) indicate two overlapping dioxan molecules rather than one molecule. Using a reasonable

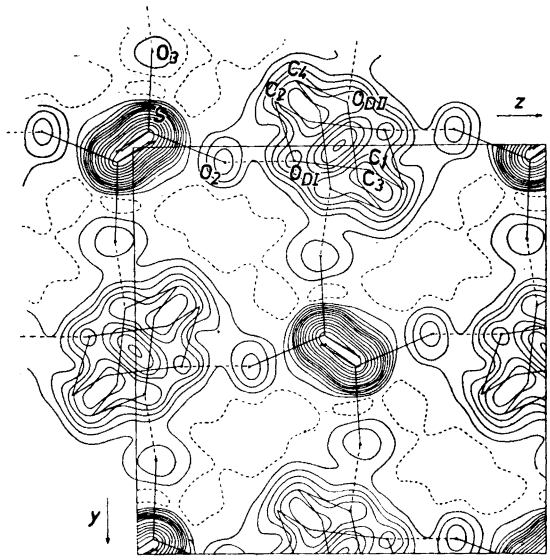

Fig. 3. Electron density projection along the *a*-axis. Contour lines as in Fig. 2.

model of the dioxan ring it was possible to split up the "double molecule" into two molecules, the centers of which were placed in (0,0) and (1/2, 0) thus bringing the symmetry in accordance with the true symmetry requirements of the plane group *pgm*. (The dioxan rings drawn in Fig. 1 are based on the ultimate, refined coordinates).

The *R* factor of the [001] projection at this preliminary stage of the analysis was 0.32. Successive refinements brought it down to 0.19 and after employing difference syntheses and least squares refinements it dropped to 0.13. At this stage further refinements of this projection were not attempted.

Projection along the b-*axis*. From a Patterson synthesis based on the (*h*0*l*) intensities and the coordinates obtained from the [001] projection a preliminary spatial model of the structure could be set up. It was assumed that hydrogen bonds are established between the hydroxy oxygens of the sulphuric acid molecules and the ether oxygen atoms of dioxan corresponding to "equatorial" directions in the dioxan molecules. After refinements the *R* factor was 0.14.

Projection along the a-*axis*. Using parameters derived from the two earlier projections the Fourier projection along the *a*-axis was refined until an *R* factor of 0.16 was obtained.

In all three projections overlapping of atoms occurred preventing further direct refinements. Nearly all coordinates could be determined, however, from at least one of the projections. Combining parameters obtained from different projections, and also (at this stage) introducing hydrogen parameters determined by projection of a model it was possible to perform least squares refinements on all three data sets alternatingly. The mean value of the atomic

Table 1. Atomic coordinates as fractions of the cell edges.

Atom	x	y	z
S	0.2446	−0.0355	0.0383
O_1	0.3354	0.0118	−0.0401
O_2	0.2450	0.0358	0.2212
O_3	0.2479	−0.2322	0.0494
O_4	0.1505	0.0133	−0.0481
O_{DI}	0.4182	0.0344	0.3894
O_{DII}	0.0830	−0.1069	0.5226
C_1	0.410	0.060	0.573
C_2	0.487	−0.106	0.343
C_3	0.098	0.072	0.559
C_4	0.008	−0.156	0.397

coordinates thus obtained are listed in Table 1. Estimates of the standard deviations [3] for the positions of resolved atoms were as follows:

Oxygen: $\sigma(x) = 0.014$ Å ; $\sigma(y) = 0.016$ Å ; $\sigma(z) = 0.018$ Å
Carbon: $\sigma(x) = 0.018$ Å ; $\sigma(y) = 0.020$ Å ; $\sigma(z) = 0.023$ Å

A comparison between observed and calculated structure factors is given in Table 3. In the calculations the analytical approximation to the atomic scattering factors computed by Forsyth and Wells [4] was employed.

The final R factors not including unobserved reflexions were as follows: $R_{hk0} = 0.09$; $R_{h0l} = 0.12$ and $R_{0kl} = 0.09$. The Fourier maps are reproduced in Figs. 2 and 3.

DISCUSSION OF THE STRUCTURE

The structure is built up of chains of alternating sulphuric acid and dioxan molecules. Two dioxan molecules are linked to a particular sulphuric acid

Table 2. Angles and interatomic distances.

$\angle$ S O_2O_{DI} = 115.8°
$\angle$ S O_3O_{DII}' = 117.1°
$\angle$ $O_{DI}'O_{DI}O_2$ = 166° } "equatorial" = 153°
$\angle$ $O_{D'II}O_{DII}O_3'$ = 172° }

unit by hydrogen bonds,the direction of which is roughly "equatorial" (Fig. 4). Both dioxan molecules are centrosymmetrical, but they are not crystallographically equivalent. The two O—H—O distances as computed from the coordinates listed in Table 1 are 2.51 Å and 2.59 Å, respectively, the standard deviation is 0.025 Å. It is obvious that two different types of S—O distances are present in the sulphuric acid group, one of which (involving the "keto" oxygen atom) is 1.42 Å, the other 1.51 Å. Some of the atomic distances computed have been listed in Table 2. (Compare also Fig. 5).

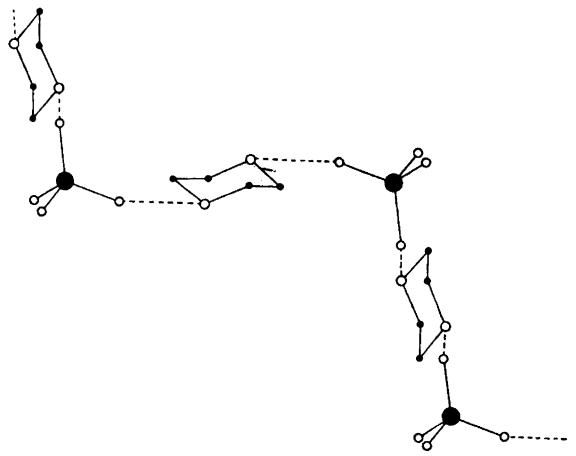

Fig. 4. Structure of the sulphuric acid-dioxan chains.

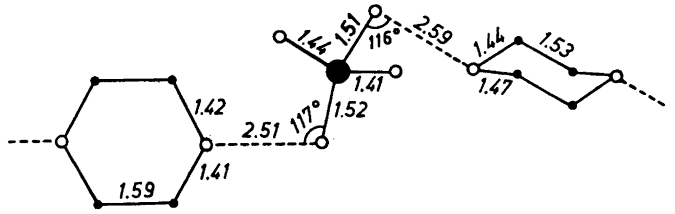

Fig. 5. Distances and angles. Open circles indicate oxygens, closed circles sulphur (large) and carbon (small) atoms.

This investigation has in part been sponsored by the *United States Air Force Development Command* under contract AF 61(052)-71.

Benzaurinstudien

III. Gleichgewichte und Reaktionskinetik des Benzaurins und des 4″-Chlor-benzaurins in wässrigen Lösungen

HANS GUSTAF HANSSON

Abteilung für anorganische und physikalische Chemie des Chemischen Instituts der Universität Lund, Schweden

In a previous paper [1] the equilibrium conditions of 3,3′,5,5′-tetrabromo-benzaurin and 3,3′-dibromo-5,5′-dimethyl-benzaurin in aqueous solutions were described. It was shown that these derivates of benzaurin constitute an equilibrium system, which consists of six different forms, three of which are coloured "anhydrous" forms in instantaneous pH-equilibrium with each other and three of which are colourless "carbinolic" forms, likewise in instantaneous pH-equilibrium. A coloured form is reversibly converted into the corresponding colourless form by taking up water, a time reaction that appears as a gradual fading of the colour of the solution. The equilibrium and velocity constants of the system were determined by light absorption measurements at different pH-values.

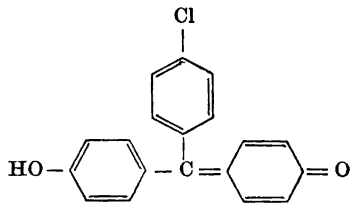
In the present paper the corresponding investigation of the unsubstituted benzaurin and the 4″-chloro-benzaurin is presented, and — as expected — the results can be described according to the scheme that proved valid for tetrabromo-benzaurin and dibromo-dimethyl-benzaurin [1].

The constants determined refer to the ionic strength 0.50 M and a solvent with the composition 98 % water + 2 % acetone. The temperature was 20°C.

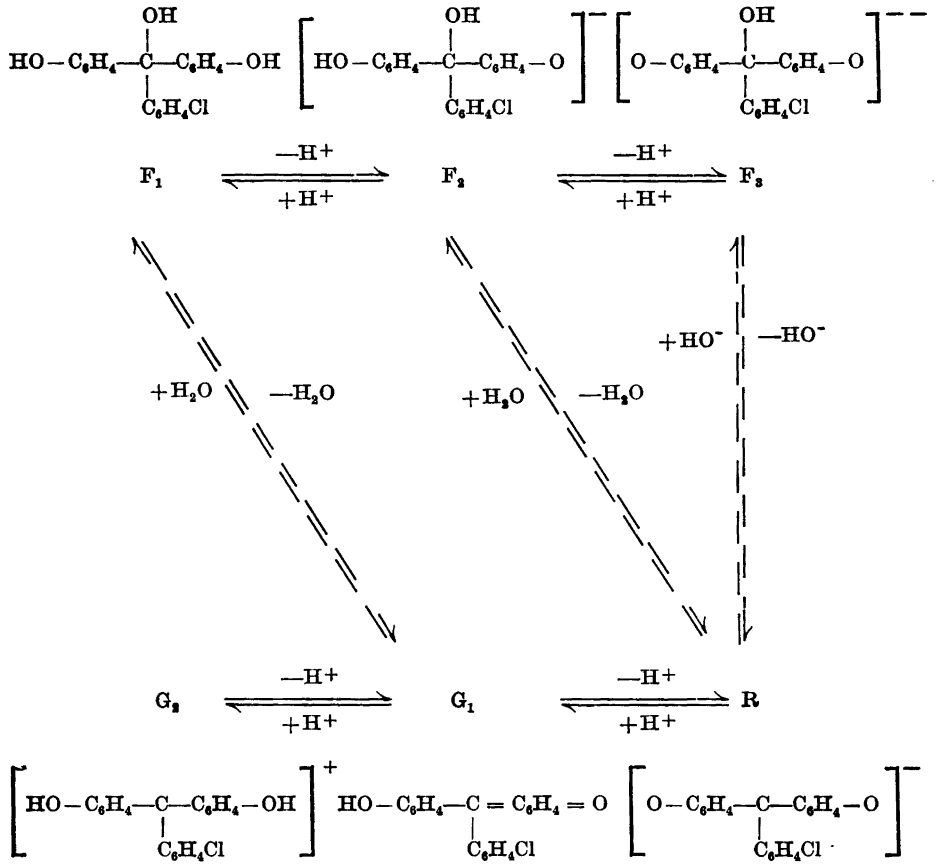
In einem früheren Aufsatz [1] wurde über eine Untersuchung über die Gleichgewichte und die Reaktionskinetik in wässriger Lösung bei zwei Derivaten von Benzaurin, nämlich 3,3′,5,5′-Tetrabrom-benzaurin und 3,3′-Dibrom-5,5′-dimethyl-benzaurin, berichtet. Das Resultat ergab, dass bei Farbstoffen dieses Typus in wässrigen Lösungen ein Reaktionsschema vorliegt, das gewisse Ähnlichkeiten mit dem der früher von Bodforss und Cigén untersuchten basischen Triphenylmethanfarbstoffe vom Malachitgrüntypus zeigt.[2–4] Die in das Schema eingehenden Konstanten wurden bestimmt.

In der vorliegenden Arbeit werden die Resultate entsprechender Untersuchungen, teils über die unsubstituierte Stammsubstanz Benzaurin, teils

4″-Chlor-benzaurin. (Anhydrid).



über 4″-Chlor-benzaurin, dargelegt. Wie erwartet können die Verhältnisse bei diesen mit demselben Reaktionsschema beschrieben werden. Es ist hier unten (für 4″-Chlor-benzaurin) wiedergegeben, wobei Bezeichnungen und Definitionen mit den vorher verwendeten [1,3] übereinstimmen.*



* Ausgezogene Pfeile bezeichnen momentane Reaktionen, gestrichelte Pfeile Zeitreaktionen. Sämtliche Reaktionen sind völlig reversibel.

Unter Verwendung der Bezeichnungen R, G_1 und G_2 für die gefärbten Formen und F_1, F_2 und F_3 für die farblosen (siehe das Schema oben) werden die Konstanten wie folgt definiert:

Die Protolysenkonstanten:

$$K_1 = \frac{[G_1]}{[H] \cdot [R]}\ ;\ K_7 = \frac{[H^+] \cdot [G_1]}{[G_2]}\ ;\ K_3 = \frac{[H^+] \cdot [F_2]}{[F_1]}\ ;\ K_4 = \frac{[H^+] \cdot [F_3]}{[F_2]}$$

Die Hydratationskonstanten (bei konstanter Wasseraktivität):

$$K_2 = \frac{[F_1]}{[G_1]} \quad ; \quad K_6 = \frac{[R]}{[F_2]}$$

Nach den Definitionen gilt $K_1K_2K_3K_6 = 1$. Ferner wird $K_5 = K_6/K_4$ gesetzt.

Die Geschwindigkeitskonstanten:

k_1 für die Reaktion $G_1 + H_2O \rightarrow F_1$
k_2 für die Reaktion $F_1 \rightarrow G_1 + H_2O$
k_3 für die Reaktion $R + H_2O \rightarrow F_2$ einschliesslich $R + OH^- \rightarrow F_3$
k_4 für die Reaktion $F_2 \rightarrow R + H_2O$ einschliesslich $F_3 \rightarrow R + OH^-$
k_1 und k_3 enthalten die Konzentration des Wassers. Ferner ist $k_2 = k_1/K_2$ und $k_4 = k_3 \cdot K_6$.

Aus dem Farbstoffperchlorat werden Stammlösungen in Aceton bereitet. Beim Mischen einiger ml einer solchen Stammlösung, welche die farblosen Karbinolformen F_1, F_2 und F_3 nicht enthält, mit einer geeigneten Wasserpufferlösung stellt sich das Gleichgewicht $G_1 \rightleftharpoons H^+ + R$ momentan ein *. Die Lösung hellt sich wegen der Zeitreaktionen $G_1 + H_2O \rightarrow F_1$ und $R + H_2O \rightarrow F_2$ (einschliesslich $R + OH^- \rightarrow F_3$) allmählich auf, ohne dabei ihren Farbton zu ändern, wobei ebenfalls die Gleichgewichte $F_1 \rightleftharpoons H^+ + F_2$ und $F_2 \rightleftharpoons H^+ + F_3$ sich momentan einstellen.

Durch Messen der Aufhellungsgeschwindigkeiten bei verschiedenen H^+-Konzentrationen — die Messungen werden spektrophotometrisch bei geeignet gewählter Wellenlänge ausgeführt — können teils die Geschwindigkeitskonstanten, teils durch Extrapolation auf die Zeit Null die Lichtextinktion E_0 im Augenblick des Mischens festgestellt werden. Aus der Variation von E_0 mit der $[H^+]$ kann K_1 berechnet werden. Nachdem die Aufhellung erfolgt und Gleichgewicht eingetreten ist, erhält man (mit gewissen Ausnahmen, siehe unten) einen stabilen und reproduzierbaren Wert (E_∞) der Lichtextinktion. Aus zusammengehörigen Werten von E_∞ und $[H^+]$ kann man in geeignet gewählten pH-Intervallen ** die Konstanten K_2, K_3, K_4 und K_6 und in stark sauren Lösungen (in denen die Aufhellung schnell verläuft) K_7 berechnen. Da die Formeln dieser Berechnungen schon abgeleitet worden sind[1] (abgesehen von der Berechnung von K_7), wird die Darstellung unten kurz gefasst.

Die Protolysenverläufe bei Benzaurin und 4″-Chlor-benzaurin sind im Vergleich zu denen bei Tetrabrom-benzaurin und Dibrom-dimethyl-benzaurin stark gegen niedrigere $[H^+]$ verschoben. So bildet sich die Form G_2 schon bei

* G_2 tritt erst in verhältnismässig stark sauren Lösungen auf.
** pH bedeutet $-\log[H^+]$.

mässiger Säurestärke (0,1 M HCl), weshalb K_7, im Gegensatz zum Falle beim Tetrabrom-benzaurin und beim Dibrom-dimethyl-benzaurin, bei der gewählten Ionenstärke, 0,50 M, für die Bestimmung zugänglich wird. Leider sind die Resultate bei Benzaurin und 4″-Chlor-benzaurin in einer anderen Hinsicht unvollständig. Bei Messungen in alkalischen Lösungen mit pH $>\sim$ 10 erwies es sich als unmöglich, einen stabilen und reproduzierbaren Wert von E_∞ zu erhalten. Dadurch wurde die genaue Bestimmung von K_4 unmöglich gemacht.

FORMELN

I. Berechnung von K_1 aus den Anfangsextinktionen

Für eine Reihe von Lösungen, erhalten durch Mischen einer Acetonstammlösung des Farbstoffes mit geeigneten Puffern, werden die Anfangsextinktionen E_0 bei gleicher Schichtdicke d und Gesamtkonzentration C des Farbstoffes durch Extrapolation auf die Zeit Null bestimmt. Falls die Messungen bei einer Wellenlänge stattfinden, wo nur R absorbiert, gilt [1]

$$\frac{1}{E_0} = \frac{1}{E_R} + \frac{K_1 \cdot [H^+]}{E_R} \tag{1}$$

wo E_R die Extinktion bei der betreffenden Schichtdicke für eine Lösung ist, in der $[R] = C$ ist. $1/E_0$ wird als Funktion von $[H^+]$ aufgetragen und gibt eine Gerade. Aus deren Schnittpunkt a_1 mit der Ordinate und dem Richtungskoeffizienten b_1 erhält man

$$E_R = 1/a_1 \quad ; \quad K_1 = b_1/a_1$$

II. Berechnungen aus den Gleichgewichtsextinktionen

Eine Lösung, die durch Mischung von einem Puffer mit einer Stammlösung des Farbstoffes in Aceton erhalten worden ist, enthält beim Gleichgewicht die Formen G_1, R, F_1, F_2 und F_3 (siehe Fussnote * S. 409).

A. Wenn $[H^+] \ll 1/K_1$ ist, kann $[G_1]$ vernachlässigt werden. Wenn E_∞ die Lichtextinktion beim Gleichgewicht ist und E_R wie oben (I.) definiert ist, gilt wie schon gezeigt wurde [1]:

$$E_\infty = E_R \cdot \frac{K_6}{1 + K_6 + [H^+]/K_3 + K_4/[H^+]} \tag{2}$$

und für $[H^+] = \sqrt{K_3 \times K_4}$

$$(E_\infty)_{max} = E_R \cdot \frac{K_6}{1 + K_6 + 2 \cdot \sqrt{K_4/K_3}} \tag{2a}$$

1. *Bestimmung von K_3K_6 und K_6.* In einem Gebiet, wo $[H^+] \gg K_4$ ($[F_3] \ll [F_1] + [F_2] + [R]$) ist, kann $K_4/[H^+]$ in Formel (2) vernachlässigt werden. Man bekommt dann:

$$\frac{1}{E_\infty} = \frac{1 + 1/K_6}{E_R} + \frac{1}{E_R \cdot K_3K_6} \cdot [H^+] \tag{3}$$

Die zusammengehörigen Werte von E_∞ und $[H^+]$ werden bestimmt. $1/E_\infty$ als Funktion von $[H^+]$ aufgetragen, gibt eine Gerade. Aus deren Schnittpunkt a_2 mit der Ordinate und dem Richtungskoeffizienten b_2 bekommt man:

$$K_6 = 1/(a_2 \cdot E_R - 1) \quad ; \quad K_3K_6 = 1/b_2 \cdot E_R$$

E_R erhält man entweder oben (I) und/oder/durch Extrapolation auf die Zeit Null für Lösungen mit genügend kleinen $[H^+]$-Werten. Wenn $[H^+] \ll 1/K_1$ ist, ist $E_0 = E_R$. Bei evtl. grösseren $[H^+]$-Werten muss $[G_1]$ berücksichtigt und eine entsprechende Korrektion in E_0 gemacht werden.

2. Bestimmung von $K_6/K_4 = K_5$ und K_6. Wenn $[H^+] \ll K_3$ ($[F_1] \ll [F_2] + [F_3] + [R]$) ist, kann $[H^+]/K_3$ in Formel (2) vernachlässigt werden. Man bekommt dann folgende lineare Funktion von $[H^+]$:

$$\frac{[H^+]}{E_\infty} = \frac{1}{E_R \cdot K_5} + \frac{1 + 1/K_6}{E_R} \cdot [H^+] \qquad (4)$$

Aus zusammengehörigen Werten von E_∞ und $[H^+]$ wird $[H^+]/E_\infty$ als Funktion von $[H^+]$ aufgetragen. Man erhält eine Gerade. Aus deren Schnittpunkt a_3 mit der Ordinate und dem Richtungskoeffizienten b_3 bekommt man (mit bekanntem E_R, siehe oben)

$$K_5 = 1/a_3 \cdot E_R \quad ; \quad K_6 = 1/(b_3 \cdot E_R - 1)$$

Wenn erforderlich wird bei den Berechnungen unter 1. und 2. oben E_∞ durch korrigierte Werte, und zwar durch E'_∞ oder E''_∞ unter 1. und E'''_∞ unter 2., ersetzt. Die Korrektionen, die nur einige Prozent von E_∞ betragen, und die in der bereits beschriebenen Weise[1] ausgeführt werden, berücksichtigen die geringen Konzentrationen, die nicht ganz zu vernachlässigen sind, von G_1 und F_3 bzw. F_1 in den Randgebieten bzw. im Randgebiet des betreffenden pH-Intervalls.

B. Bestimmung von K_2. Wenn $[H^+]$ grösser ist als in A und wenn es als sicher gilt, dass $[H^+] \gg K_4$ ist, hat man beim Gleichgewicht die Formen G_1, R, F_1 und F_2. ($[F_3]$ wird vernachlässigt). Aus zusammengehörigen Werten von E_∞ und $[H^+]$ und entsprechendem, bekanntem E_R kann dann K_2, wie schon gezeigt worden ist [1], aus der Formel

$$K_2 = \frac{E_R - E_\infty(1 + K_1 \cdot [H^+] + 1/K_6)}{E_\infty \cdot K_1 \cdot [H^+]} \qquad (5)$$

berechnet werden.

C. Bestimmung von K_7. Wenn HCl-Lösungen mit einer Säurestärke $> 0{,}1$ M mit einigen ml einer Stammlösung des Farbstoffes in Aceton versetzt werden, stellt sich zwischen den Formen F_1, G_1 und G_2 ein Gleichgewicht fast momentan ein. Wenn die Lichtabsorption der Lösung E und die Gesamtkonzentration des Farbstoffes C ist, gilt

$$\frac{[H^+] \cdot [G_1]}{[G_2]} = K_7 \quad ; \quad \frac{[F_1]}{[G_1]} = K_2$$

$$E = E_{G_1} \cdot [G_1]/C + E_{G_2} \cdot [G_2]/C$$

$$C = [F_1] + [G_1] + [G_2]$$

wo E_{G_1} (E_{G_2}) die Extinktion bei gleicher Schichtdicke für eine Lösung ist, in der $[G_1]$ ($[G_2]$) gleich C ist. Durch Vereinfachung erhält man

$$E = \frac{K_7 \cdot E_{G_1} + [H^+] \cdot E_{G_2}}{K_7(1 + K_2) + [H^+]} \tag{6}$$

Aus diesem Ausdruck kann man teils die Formel

$$\frac{[H^+]}{E - \frac{E_{G_1}}{1 + K_2}} = \frac{K_7(1 + K_2)}{E_{G_2} - \frac{E_{G_1}}{1 + K_2}} + \frac{[H^+]}{E_{G_2} - \frac{E_{G_1}}{1 + K_2}} \tag{7}$$

teils die Formel

$$\frac{E - \frac{E_{G_1}}{1 + K_2}}{E_{G_2} - E} = \frac{[H^+]}{K_7(1 + K_2)} \tag{8}$$

bekommen, in denen die linken Glieder lineare Funktionen von $[H^+]$ sind.

Bei der Anwendung von Formel (7) wird für zusammengehörige Werte von E und $[H^+]$ der Ausdruck $[H^+]/\left(E - \frac{E_{G_1}}{1 + K_2}\right)^*$ als Funktion von $[H^+]$ aufgetragen. Man erhält eine Gerade. Aus deren Schnittpunkt a_4 mit der Ordinate und dem Richtungskoeffizienten b_4 bekommt man

$$K_7 (1 + K_2) = a_4/b_4 \qquad (7a); \qquad E_{G_2} = 1/b_4 + \frac{E_{G_1}}{1 + K_2} \qquad (7b)$$

Die Formel (7) verlangt bei der Anwendung, dass die Messungen sich auf Wasserstoffionenkonzentrationen erstrecken, die nicht viel kleiner als $K_7 (1 + K_2)$ sind. Im vorliegenden Falle bedeutet dieses, dass die Ionenstärke 0,50 M überschritten werden muss. K_2 hat in diesem Falle einen Wert, der sich von dem früheren, bei der Ionenstärke 0,50 M bestimmten, unterscheidet. K_7 kann daher nicht aus der Formel (7a) oben berechnet werden und es wird folgendermassen verfahren. Eine Mess-serie wird bei einer höheren, konstanten Ionenstärke (1,00 M) durchgeführt und zusammengehörige Werte von E und $[H^+]$ werden graphisch nach Formel (7) dargestellt, wonach E_{G_2} nach Formel (7b) berechnet wird. Danach wird eine neue Messerie bei der Ionenstärke 0,50 M durchgeführt, wobei zusammengehörige Werte von E und $[H^+]$ nach Formel (8) graphisch dargestellt werden, unter Einsetzen des oben bestimmten Wertes von E_{G_2}. Das linke Glied der Formel wird als Funktion von $[H^+]$ aufgetragen. Man bekommt eine Gerade durch Origo mit dem Richtungskoeffizienten b_5, wo $K_7 = 1/b_5(1 + K_2)$ ist, wobei das Einestzen vom früher bestimmten K_2 die Konstante K_7 ergibt.

III. Berechnungen der Geschwindigkeitskonstanten

Beim Mischen einer Stammlösung des Farbstoffes in Aceton mit einer Pufferlösung hellt sich die Mischung wegen der Zeitreaktionen $G_1 + H_2O \rightarrow F_1$

---

* E_{G_1} ist bekannt, siehe "Messungen und Ergebnisse". Der Ausdruck $\frac{E_{G_1}}{1 + K_2}$ hat sowohl in (7) als auch in (8) den Charakter eines Korrektionsgliedes und beträgt nur einige Prozent von E. (K_2 ist gross).

und $R + H_2O \rightarrow F_2$ auf. Die Konstante k der Aufhellungsgeschwindigkeit wird durch Messung der Lichtextinktion E als Funktion der Zeit t ermittelt. Folgende Formeln [1,3,4] gelten:

$$k = \frac{1}{t} \cdot \ln \frac{E_0 - E_\infty}{E - E_\infty} \tag{9}$$

$$k = \frac{k_2 \cdot [H^+]^2 + k_4 K_3 \cdot [H^+]}{[H^+]^2 + K_3 \cdot [H^+] + K_3 K_4} + \frac{k_1 K_1 \cdot [H^+] + k_3}{1 + K_1 \cdot [H^+]} \tag{10}$$

k ist über das ganze in Frage kommende pH-Gebiet experimentell bestimmt worden, wobei E im Absorptionsmaximum von R gemessen wird, wo $[R] \geqq [G_1]$ ist, bei geringerem pH im Absorptionsmaximum von G_1. Log $(E - E_\infty)$ als Funktion von t aufgetragen ergibt eine Gerade, deren Richtungskoeffizient $= - k \cdot {}^{10}\log e$ ist.

A. Bestimmung von k_1 und k_2. In genügend sauren Lösungen, wo die Reaktion $G_1 + H_2O \rightleftharpoons F_1$ dominiert, und man von der Reaktion $R + H_2O \rightleftharpoons F_2$ absehen kann, gilt [1]

$$k = k_1 \cdot \frac{K_1 \cdot [H^+]}{1 + K_1 \cdot [H^+]} + k_2 \tag{11}$$

Da $k_2 = k_1/K_2$ ist, kann k_1, bei verschiedenen $[H^+]$-Werten, aus (11) mit zusammengehörigen Werten von k und $[H^+]$ eingesetzt, berechnet werden. Man findet wie früher [1], dass k_1 mit $[H^+]$ gemäss der Formel

$$k_1 = k_1^\circ + k_1' \cdot [H^+] \tag{12}$$

wächst, wo k_1° von Null verschieden ist. (Man bekommt k_2 aus der Relation $k_2 = k_1/K_2$.) Die Reaktion $G_1 + H_2O \rightleftharpoons F_1$ wird folglich durch die H^+-Ionen katalysiert. Die Katalyse mag einer eventuellen schnellen Reaktion $G_2 + H_2O \rightleftharpoons F_1 + H^+$ entsprechen.

B. Bestimmung von k_3 und k_4. Bei genügend hohen pH-Werten, wo von der Reaktion $G_1 + H_2O \rightleftharpoons F_1$ abgesehen werden kann, und wo ferner $[H^+] \ll K_3$ ist, gilt [1]

$$k = k_4 \frac{[H^+]}{[H^+] + K_4} + k_3 \tag{13}$$

Evtl. kann die Formel weiter vereinfacht werden, wenn bei geringen $[H^+]$-Werten der erste Ausdruck des rechten Gliedes vernachlässigt werden kann und daher $k = k_3$ wird. Die Bestimmung von k_3 $(= k)$ bei verschiedenen pH-Werten zeigt, dass k_3 wie früher [1] der Formel

$$k_3 = k_3^\circ + k_3' \cdot [OH^-] \ * \tag{14}$$

folgt. Man findet dass k_3° von Null verschieden ist. (k_4 erhält man aus der Relation $k_4 = k_3 \cdot K_6$.) Folglich wird die Reaktion $R + H_2O \rightleftharpoons F_2$ durch die OH^--Ionen katalysiert. Die Katalyse entspricht wahrscheinlich der Reaktion $R + OH^- \rightleftharpoons F_3$.

ALLGEMEINES ÜBER DEN EXPERIMENTELLEN TEIL

Die Stammlösungen des Farbstoffes in Aceton, welche durch Auflösung einer abgewogenen Menge des Perchlorats des Farbstoffes** zubereitet wurden, waren von der Stärke

* $[OH^-]$ erhält man aus $[H^+] \cdot [OH^-] = K_w$. ** G_1-Perchlorat.

4×10^{-4} M. Ohne Zusatz einer Base erwiesen sich die Stammlösungen als schlecht haltbar und sehr empfindlich gegen Spuren von Wasser, das durch Hydratation (Bildung der F-Formen) die Lösung aufhellt. Infolgedessen wurden die für die Messungen benutzten Stammlösungen bei der Zubereitung mit Triäthylamin bis zu einer Konzentration von 1×10^{-2} M versetzt. Solche Lösungen zeigten eine ausgezeichnete Haltbarkeit, was dadurch zu erklären ist, dass die Hydratation für das Gleichgewicht $R + H_2O \rightleftharpoons F_2$, das in basischen Lösungen dominiert, verhältnismässig gering ist und bedeutend geringer als beim Gleichgewicht $G_1 + H_2O \rightleftharpoons F_1$. (Vergleiche die Werte für $1/K_6$ und K_2).

Die Messlösungen wurden in Kolben aus Pyrex- oder Jenaer-Glas bereitet, dadurch dass zu 49,0 ml Puffer 1,050 ml Farbstoffstammlösung mittels einer Injektionsspritze aus Pyrex-Glas zugesetzt wurde. Das Volumen der Spritze war durch Auswägen mit Wasser ermittelt worden; die Reproduzierbarkeit betrug 0,1 %. Folglich beziehen sich die bestimmten Konstanten durchgehend auf ein Lösungsmittel von der Zusammensetzung 98 % Wasser + 2 % Aceton. Die Ionenstärke war durch Zusatz von NaCl konstant und gleich 0,50 M (siehe jedoch die Bestimmung von K_7 und die Aufnahme der E_{G_2}-Kurven). Die Temperatur betrug 20°C.

Die Messung von $[H^+]$ wurde wie früher [1] für $pH < 8$ mit Chinhydronelektroden und für $pH > 8$ mit Platin-Wasserstoffgaselektroden ausgeführt. Als Vergleichslösung diente eine HCl-NaCl-Lösung mit bekannter $[H^+]$. In den sauren Lösungen ($0 \leq pH \leq 1$), die bei der Bestimmung von K_7 zur Verwendung kamen, wurde die $[H^+]$ durch Zusatz von einer bekannten Menge HCl festgelegt. Für Messungen über die Reaktionskinetik bei $pH > 11{,}8$ wurde die $[OH^-]$ durch Zusatz von bekannter Menge NaOH festgelegt. $K_w = [H^+] \cdot [OH^-]$ ist in der früheren Arbeit [1] zu $1{,}22 \times 10^{-14}$ bestimmt worden.

Für die Messungen der Lichtextinktion wurde ein Beckman-Quarz-Spektrophotometer, Modell DU, benutzt. Die Glas- oder Quarzküvetten waren mit Schliffstopfen versehen. Von jedem Paar diente eine, mit dest. Wasser gefüllt, als Nullreferenz.

Bei den früheren Untersuchungen [1] über Tetrabrom-benzaurin und Dibrom-dimethyl-benzaurin musste die Konzentration des Farbstoffes in gewissen Mess-serien wegen der Schwerlöslichkeit der Substanzen (der Formen G_1) sehr niedrig ($3{,}5 \times 10^{-7}$ M) gehalten werden. Benzaurin und 4'-Chlor-benzaurin scheinen bedeutend leichter löslich zu sein; die Konzentration des Farbstoffes in den Messlösungen konnte durchgehend $\sim 9 \times 10^{-6}$ M betragen.

Wie schon erwähnt erwies es sich als unmöglich, reproduzierbare Werte der Lichtextinktion (E_∞) beim Gleichgewicht für $pH > \sim 10$ zu erhalten. Der Grund ist wahrscheinlich ein irreversibler Abbau des Farbstoffes in alkalischem Milieu. Messlösungen, bereitet aus Stickstoff-gesättigten, von gelöstem Saurstoff befreiten Puffern, zeigten keine Verbesserung der Reproduzierbarkeit bei E_∞. Auch nicht der Zusatz von geringen Mengen KCN führte zu einer Verbesserung. Demzufolge ist es nicht möglich gewesen, die für eine sorgfältige Bestimmung von K_4 nach Formel (4) erforderlichen Messungen auszuführen. Ebenfalls konnte nicht $(E_\infty)_{max}$ (vgl. Formel (2a)) aus den Messungen ermittelt werden. Da E_∞ verglichen mit E_0 klein ist, spielt jedoch die Unsicherheit in E_∞ keine grössere Rolle bei der Bestimmung der Geschwindigkeitskonstante k. Die Kurven über die Variation dieser Konstante mit dem pH-Wert weisen im Gegensatz zum Verhalten beim Tetrabrom-benzaurin und Dibrom-dimethyl-benzaurin [1] kein Maximum auf (Fig. 8 und 18, Formel (10)).

Die Geschwindigkeitskonstanten sind mit Brigg'schen Logarithmen berechnet worden und enthalten also die Grösse $^{10}\log e$.

Die bestimmten Konstanten sind so angegeben worden, dass die Unsicherheit normalerweise 2 – 5 Einheiten in der letzten Ziffer beträgt. Bei evtl. grösserer Unsicherheit wurde die Ziffer in Klammern gesetzt.

Die verwendeten Chemikalien waren pro-analysi-Produkte von Baker oder Merck.

MESSUNGEN UND ERGEBNISSE

I. Benzaurin

Präparat: Das Benzaurin wurde nach Döbner [5] synthetisiert. Nach Reinigung mit Bisulfit wurde der Farbstoff in reiner Form als Perchlorat hergestellt (Pfeiffer [6], Meyer und Gerloff [7]). Das Endprodukt bestand aus roten Kristallen

mit ausgeprägtem, grünem Oberflächenglanz. Die Elementaranalyse ergab folgendes Resultat: C 60,61; H 3,89; O 25,40; Cl 9,32; 9,64. Berechnet für $C_{19}H_{15}O_6Cl$: C 60,89; H 4,03; O 25,62; Cl 9,46.

Puffersubstanzen waren Dinatriumhydrogenphosphat-Natriumhydroxyd, Borsäure-Natriumhydroxyd, Natriumdihydrogenphosphat-Dinatriumhydrogenphospat, Essigsäure-Natriumacetat in folgenden ungefähren pH-Intervallen: 10,5—11,5; 8,7—9,6; 7,4—8,5; 5,1—6,7.

Die Lichtabsorptionskurven * für das rote Ion R, das gelbe Molekül G_1 und das rotgelbe Ion G_2 finden sich in Fig. 1 wieder, wo der molekulare Lichtextinktionskoeffizient ε der betreffenden Formen als Funktion der Wellenlänge λ in mμ aufgetragen ist. Die Kurve für R wurde durch Messung von E_∞ in einem Puffer mit pH = 9,58 und $C = 8{,}0 \times 10^{-6}$ M aufgenommen; d betrug 5 cm. Durch Extrapolation auf $t = 0$ wurde bei $\lambda = 550$ mμ entsprechendes E_R zu 1,90 (0,758 bei $d = 2$ cm) bestimmt. Da E_∞ bei 550 mμ zu 0,692 gemessen wurde, galt für die Lösung, dass $E_R/E_\infty = 2{,}74$ war. ε_R wurde aus

$$2{,}74\, E_\infty = \varepsilon_R \times 5 \times 8{,}0 \times 10^{-6}$$

berechnet.

Die G_1-Kurve wurde bei pH = 5,85 aufgenommen. Da der Gleichgewichtswert E_∞ klein ist (K_2 ist gross), wurden sämtliche Punkte auf der Kurve durch Extrapolationsverfahren erhalten. C war $8{,}0 \times 10^{-6}$ M und $d = 5$ cm. E_0 wurde durch Extrapolation auf $t = 0$ erhalten. Aus diesem E_0 wurde E_{G_1} gemäss der Formel

$$E_0 = \frac{[H^+]}{1/K_1 + [H^+]} \cdot E_{G_1} + \frac{1/K_1}{1/K_1 + [H^+]} \cdot E_R$$

berechnet, und ε_{G_1} nach $E_{G_1} = \varepsilon_{G_1} \times 5 \times 8{,}0 \times 10^{-6}$.

Die Kurve für G_2 wurde in einer Lösung mit $[H^+] = 0{,}825$ (Ionenstärke 1.00 M) M aufgenommen. E wurde mit $C = 8{,}1 \times 10^{-6}$ M und $d = 5$ cm gemessen. Bei der Bestimmung von K_7 unten wurde E_{G_1} bei $\lambda = 490$ mμ (und

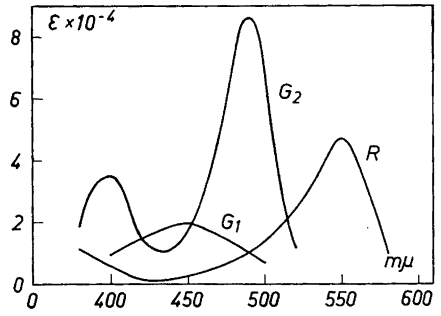


Fig. 1. Benzaurin. Lichtabsorptionskurven. R ist das rote Ion, $[(OC_6H_4)_2\ C(C_6H_5)]^+$; G_1 ist das gelbe Molekül $(HOC_6H_4)C(C_6H_5)(C_6H_4O)$; G_2 das rotgelbe Ion $[(HOC_6H_4)_2\ C(C_6H_5)]^+$.

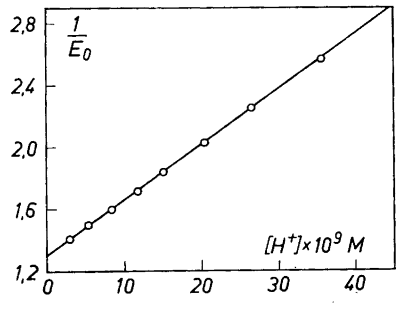

Fig. 2. Benzaurin. $1/E_0$ als Funktion von $[H^+]$ für die Bestimmung von K_1 (und E_R). $\lambda = 550$ mμ, $d = 2$ cm und $C = 8{,}0 \times 10^{-6}$ M.

* E_R, E_{G_1} und E_{G_2} sind im Kap. Formeln (I. und II.C) definiert.

$d = 2$ cm) erhalten. Aus E_{G_2} und dem bei 490 mμ gemessenen Wert von E wurde der Quotient E_{G_2}/E für die Lösung zu 2,50 berechnet. ε_{G_2} wurde also aus der Relation $2{,}50\ E = \varepsilon_{G_2} \times 5 \times 8{,}1 \times 10^{-6}$ erhalten.

Die Daten für die Maxima betrugen:

$$\begin{aligned}(\varepsilon_R)_{max} &= 4{,}7 \times 10^4 \text{ bei } \lambda \approx 550 \text{ m}\mu\\ (\varepsilon_{G_1})_{max} &= 1{,}8(8) \times 10^4 \text{ bei } \lambda \approx 450 \text{ m}\mu\\ (\varepsilon_{G_2})_{max} &= 8{,}6 \times 10^4 \text{ bei } \lambda \approx 490 \text{ m}\mu\\ (\varepsilon_{G_3})_{max} &= 3{,}5 \times 10^4 \text{ bei } \lambda \approx 400 \text{ m}\mu\end{aligned}$$

Bestimmung von K_1 aus Formel (1). Im Gebiet $7{,}4 < \text{pH} \leq 8{,}5$ wurden Messlösungen durch Mischen von 49 ml Puffer mit 1 ml Acetonstammlösung des Farbstoffes bereitet. Die Aufhellung wurde extinktiometrisch bei $\lambda = 550$ mμ verfolgt und E_0 durch Extrapolation erhalten. Die Messungen wurden bei einer Schichtdicke d von 2 cm ausgeführt; die Gesamtkonzentration C des Farbstoffes betrug $8{,}0 \times 10^{-6}$ M. In Fig. 2 ist $1/E_0$ als Funktion von $[H^+]$ dargestellt.

Resultat: $E_R = 0{,}76(6)$; $K_1 = 2{,}7(2) \times 10^7$; $1/K_1 = 3{,}7 \times 10^{-8}$

Bestimmung von K_3K_6 und K_6 aus Formel (3). Die Messlösungen wurden im Gebiet $8{,}7 < \text{pH} < 9{,}6$ bereitet. C war $9{,}3 \times 10^{-6}$ M. E_∞ wurde bei 5 cm Schichtdicke und bei der Wellenlänge 550 mμ gemessen. Entsprechendes E_R wurde bei $d = 2$ cm durch Extrapolation auf $t = 0$ für sieben Lösungen im selben pH-Gebiet bestimmt. Aus den E_0-Werten wurde, nach Korrektion für $[G_1]$, $(E_R)_{2\text{ cm}} = 0{,}876 \pm 0{,}005$ erhalten, folglich ist $(E_R)_{5\text{ cm}} = 2{,}19 \pm 0{,}01$. Fig. 3 gibt $1/E''_\infty$ als Funktion von $[H^+]$ wieder.

Resultat: $K_6 = 0{,}93$; $K_3K_6 = 3{,}4(2) \times 10^{-10}$; $K_3 = 3{,}7 \times 10^{-10}$

Die Reproduzierung der Messungen ergab das gleiche Resultat.

Bestimmung von $K_5' = K_6/K_4$ und K_6 aus Formel (4) konnte nicht durchgeführt werden, weil es, wie schon erwähnt wurde, bei einem $\text{pH} > \sim 10$ unmöglich ist, reproduzierbare Werte von E_∞ zu erhalten. Aus den Messungen wurde ein ungefährer Wert von K_4 geschätzt. $K_4 \approx 7 \times 10^{-11}$.

Bestimmung von K_2 aus Formel (5) erfolgte im Gebiet $7{,}6 \leq \text{pH} \leq 8{,}3$. Die Messlösungen waren identisch mit einigen von den Lösungen, die bei der Bestimmung von K_1 oben zur Verwendung kamen. Nachdem Gleichgewicht eingetreten war, wurde E_∞ bei $\lambda = 550$ mμ und $d = 2$ cm gemessen. Durch

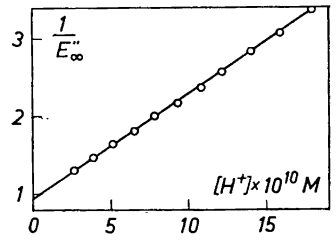

Fig. 3. Benzaurin. $1/E''_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_3K_6 und K_6. $\lambda = 550$ mμ, $d = 5$ cm und $C = 9{,}3 \times 10^{-6}$ M.

Tabelle 1. Benzaurin. Messungen bei 550 mμ zur Bestimmung von K_2; $d = 2$ cm, $C = 8{,}0 \times 10^{-6}$ M.

$[H^+] \times 10^9$ M	26,4	20,4	15,0(8)	11,7(5)	8,3(3)	5,2(6)
E_∞	0,010(0)	0,012(5)	0,017(5)	0,022(5)	0,030(5)	0,046(0)
K_2	101	103	101	99	99	100

Extrapolation bei pH = 9,58 wurde $E_R = 0{,}758$ erhalten. Für K_1 und K_6 wurden die oben bestimmten Werte verwendet. Die Resultate sind in Tabelle 1 aufgeführt. Im Mittel wurde $K_2 = 100$ erhalten.

Die oben erhaltenen Konstanten ergeben das Produkt $K_1K_2K_3K_6 = 0{,}93$.

Bestimmung von K_7. Zuerst wurde eine Mess-serie bei der Ionenstärke 1,00 M ausgeführt. $[H^+]$ variierte in den Messlösungen zwischen 0,17 und 1,00 M. C war $8{,}2 \times 10^{-6}$ M und E wurde bei der Wellenlänge 490 mμ (im Absorptionsmaximum von G_2) mit $d = 2$ cm gemessen. In Fig. 4 ist $[H^+]/(E - \frac{E_{G_1}}{1 + K_2})$ als Funktion von $[H^+]$ aufgetragen. Man bekommt (mit $E_{G_1}/(1 + K_2) = 0{,}002$)

$$E_{G_2} = 1{,}39(2); \qquad (K_7 (1 + K_2) = 1{,}21)$$

Danach wurde eine Mess-serie bei der Ionenstärke 0,50 M und mit gleichem C wie oben ausgeführt. $[H^+]$ variierte zwischen 0,085 und 0,49 M, und E wurde bei gleichem λ und d wie oben gemessen. Mit obenstehendem E_{G_2} wird in Fig. 5 $(E - \frac{E_{G_1}}{1 + K_2})/(E_{G_2} - E)$ als Funktion von $[H^+]$ wiedergegeben. Resultat *

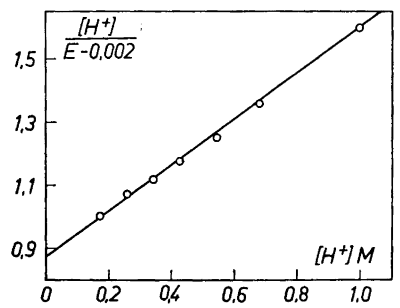

Fig. 4. Benzaurin. $[H^+]/\left(E - \frac{E_{G_1}}{1 + K_2}\right)$ als Funktion von $[H^+]$ für die Bestimmung von $E_{G_2} \cdot \lambda = 490$ mμ, $d = 2$ cm und $C = 8{,}2 \times 10^{-6}$ M.

* Eine graphische Berechnung aus der weniger genauen Formel (7) ergibt das Resultat $K_7 (1 + K_2) = 1{,}7(7)$ und $E_{G_2} = 1{,}46$.

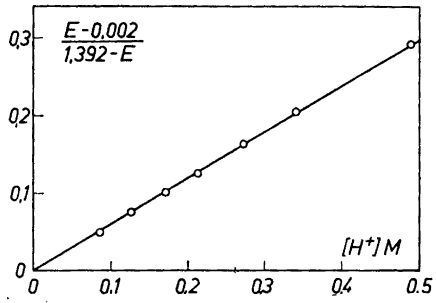

Fig. 5. Benzaurin. $\left(E - \frac{E_{G_1}}{1 + K_2}\right) / (E_{G_2} - E)$ als Funktion von [H+] für die Bestimmung von K_7. $\lambda = 490$ mμ, $d = 2$ cm und $C = 8{,}2 \times 10^{-6}$ M.

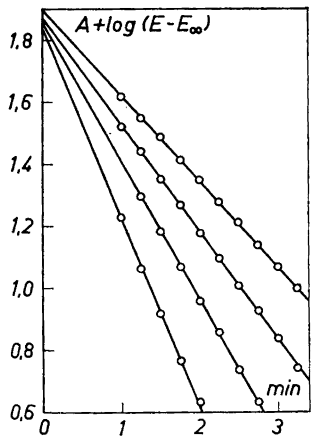
$K_7(1 + K_2) = 1{,}6(8)$. Einsetzen von $K_2 = 100$ ergibt $K_7 = 1{,}6(6) \times 10^{-2}$.

Messungen der Reaktions- (Aufhellungs-) geschwindigkeiten. Die Geschwindigkeitskonstante k wurde im Gebiet $5{,}1 < \text{pH} < 12{,}7$ bestimmt. In den Gebieten $8{,}7 < \text{pH} < 9{,}6$ und $6{,}0 < \text{pH} < 6{,}7$ war (mit einer Ausnahme) $C = 9{,}3 \times 10^{-6}$ M, für die übrigen Lösungen $8{,}0 \times 10^{-6}$ M. E wurde bei $\lambda = 450$ mμ



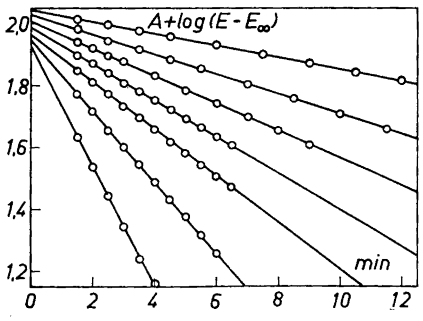


Fig. 6. Benzaurin. Reaktionskinetik bei $\lambda = 450$ mμ, $d = 5$ cm und $C = 8{,}0 \times 10^{-6}$ M. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

A:	2,03	2,00	2,00	1,95
pH:	5,460	5,350	5,227	5,114

Fig. 6a. Benzaurin. Reaktionskinetik bei $\lambda = 450$ mμ und $d = 5$ cm. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

A:	2,17	2,13	2,10	2,13	2,04	2,08	2,05
pH:	6,659	6,433	6,284	6,157	6,038	5,850	5,610
$C \times 10^6$ M:	9,3	9,3	9,3	8,0	9,3	8,0	8,0

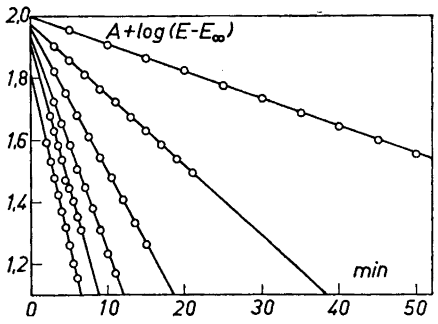

Fig. 7. Benzaurin. Reaktionskinetik bei $\lambda = 550$ mμ, $d = 2$ cm und $C = 8{,}0 \times 10^{-6}$ M. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

A:	2,13	2,10	2,08	2,05	2,03	1,94
pH:	11,50(5)	11,95(5)	12,25(5)	12,43	12,55(5)	12,65

(Absorptionsmaximum von G_1)| mit $d = 5$ cm für pH < 7 gemessen, und bei $\lambda = 550$ mμ (Absorptionsmaximum von R) mit $d = 2$ cm für pH > 7 gemessen. In den Figuren 6, 6a und 7 sind die kinetischen Verläufe in den sauren und alkalischen Lösungen wiedergegeben, in welchen die Messungen der graphischen Berechnung von k_1 und k_2 bzw. k_3 und k_4 zu Grunde lagen. Fig. 8 zeigt k als Funktion des pH-Wertes. (Vergleiche Formel (10)).

Bestimmung von k_1 und k_2. Im Gebiet $5{,}1 <$ pH $< 6{,}7$ ist k_1 aus Formel (11) durch Einsetzen der Beziehung $k_2 = k_1/K_2$ und zusammengehörigen Werten von k und $[H^+]$ berechnet worden. Die Figuren 9 und 9a zeigen, dass k_1 als Funktion von $[H^+]$ eine Gerade ist. Graphische Bestimmung ergab das Resultat: $k_1^\circ = 5{,}2 \times 10^{-3}$, $k_1' = 8{,}0 \times 10^4$. Man erhält also:

$k_1 = 5(,2) \times 10^{-3} + 8{,}0 \times 10^4\ [H^+]$; $k_2 = 5(,2) \times 10^{-5} + 8{,}0 \times 10^2\ [H^+]$ (Min^{-1}); $[H^+]$ in Mol/l.

Bestimmung von k_3 und k_4. Im Gebiet pH $> 11{,}9$ gilt, dass $k = k_3$ ist. Fig. 10 zeigt, dass k_3 in diesem Gebiet eine lineare Funktion von $[OH^-]$ ist. Da k_3° klein ist, konnte es nicht graphisch ermittelt werden; k_3' wurde zu 2,0(4) bestimmt.

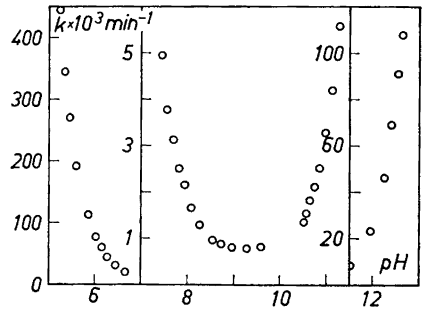

Fig. 8. Benzaurin. Die Geschwindigkeitskonstante k als Funktion von pH. O sind experimentell gefundene Werte.

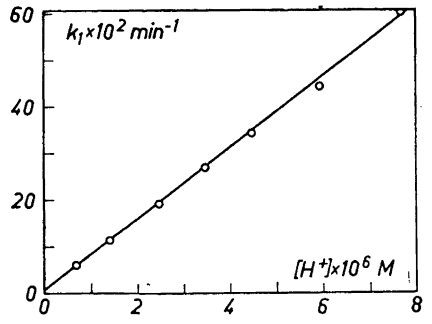
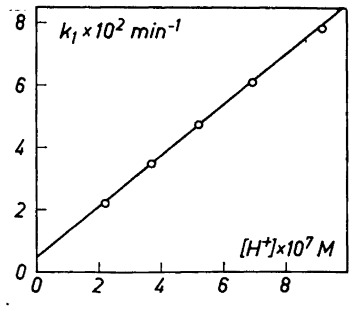


9.



9a.

Fig. 9 und 9a. Benzaurin. Die Geschwindigkeitskonstante k_1 als Funktion von [H+].

Für die Bestimmung von $k_3°$ wurden zusammengehörige Werte von k und [H$^+$] in Formel (10) eingesetzt. k_3 wird mit den bekannten Werten von k_1, k_2, K_1, K_3, K_4 und K_6 und der Beziehung $k_4 = k_3 \cdot K_6$ berechnet. [H$^+$] wird so gewählt, dass der Ausdruck K_3K_4 in Formel (10) nur den Charakter eines Korrektionsgliedes hat, in welchem Falle der geschätzte Wert von K_4 ausreichend ist. Aus dem erhaltenen k_3 wird $k_3° = k_3 - k_3' \cdot [OH^-]$ berechnet. Folgende vier Berechnungen wurden ausgeführt:

[H+] $\times 10^9$ M	0,452	0,78(2)	1.59(2)	2,96
$k \times 10^4$ Min^{-1}	7,9(1)	7,7(5)	8.5(9)	9,6(9)
$k_3° \times 10^4$ Min^{-1}	4,5(4)	4,6(4)	5.1(2)	4,9(7)

Mittelwert: $k_3° = 4{,}8 \times 10^{-4}$ Min^{-1}.
Man erhält also
$k_3 = 4{,}8 \times 10^{-4} + 2{,}0(4)\,[OH^-]$; $k_4 = 4{,}5 \times 10^{-4} + 1{,}8(9)\,[OH^-]$ (Min^{-1}); [OH$^-$] in Mol/l.

II. 4″-Chlor-benzaurin

Als *Präparat* wurde das in einer früheren Arbeit beschriebene Perchlorat des Farbstoffes verwendet (Benzaurinstudien I.[8]).

Puffersubstanzen waren Dinatriumhydrogenphosphat-Natriumhydroxyd, Borsäure-Natriumhydroxyd, Natriumdihydrogenphosphat-Dinatriumhydrogenphosphat in den pH-Intervallen 9,8—11,5, 8,0—9,7, 5,6—7,9.

In sämtlichen unten dargelegten Messungen war die Gesamtkonzentration C des Farbstoffes in den Messlösungen $9{,}0 \times 10^{-6}$ M.

Die *Lichtabsorptionskurven* für R (rot), G_1 (gelb) und G_2 (rotgelb) finden sich in Fig. 11 wieder. Sämtliche Kurven wurden bei $d = 5$ cm aufgenommen; die R-Kurve bei pH = 9,45 mit $E_R/E_\infty = 3{,}80$, die G_1-Kurve durch Extrapolationsverfahren bei pH = 6,15 und die G_2-Kurve bei [H$^+$] = 1,015 M mit $E_{G_1}/E = 5{,}25$. Die Berechnungen von ε wurden wie beim Benzaurin ausgeführt.

Es wurden folgende Daten für die Maxima erhalten:

$(\varepsilon_R)_{max} = 4{,}0 \times 10^4$ bei $\lambda \approx 555$ mμ; $(\varepsilon_{G_1})_{max} = 1{,}6(5) \times 10^4$ bei $\lambda \approx 450$ mμ;
$(\varepsilon_{G_2})_{max} = 13(,0) \times 10^4$ bei $\lambda \approx 495$ mμ; $(\varepsilon_{G_2})_{max} = 6{,}0 \times 10^4$ bei $\lambda \approx 410$ mμ.

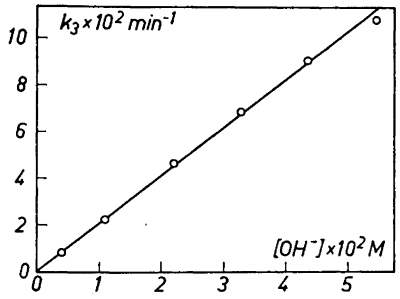


Fig. 10. Benzaurin. Die Geschwindigkeitskonstante k_3 als Funktion von $[OH^-]$.

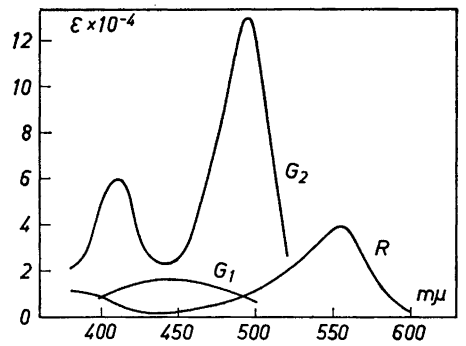

Fig. 11. 4″-Chlor-benzaurin. Lichtabsorptionskurven. R ist das rote Ion $[(OC_6H_4)_2 C(C_6H_4Cl)]^+$, G_1 das gelbe Molekül $(HOC_6H_4) C(C_6H_4Cl)(C_6H_4O)$ und G_2 das rotgelbe Ion $[(HOC_6H_4)_2 C(C_6H_4Cl)]^+$.

Bestimmung von K_1 aus Formel (1) erfolgte im Gebiet $7{,}2 < \text{pH} < 8{,}3$. Die Extinktionsmessungen wurden bei $\lambda = 550$ mμ und $d = 2$ cm ausgeführt; E_0 wurde durch Extrapolation erhalten. Fig. 12 zeigt $1/E_0$ als Funktion von $[H^+]$.

Resultat: $E_R = 0{,}69(5)$; $K_1 = 2{,}2(2) \times 10^7$; $1/K_1 = 4{,}5 \times 10^{-8}$

Bestimmung von K_3K_6 *und* K_6 aus Formel (3) im Gebiet $8{,}4 < \text{pH} < 9{,}5$. E_∞ wurde bei $d = 5$ cm und $\lambda = 550$ mμ gemessen. E_R wurde bei $d = 2$ cm durch Extrapolation für sechs Lösungen zu $0{,}692 \pm 0{,}004$ bestimmt (in guter Übereinstimmung mit dem Wert oben bei der Bestimmung von K_1). Folglich war $(E_R)_{5\text{ cm}} = 1{,}73(0)$. Fig. 13 zeigt $1/E''_\infty$ als Funktion von $[H^+]$.

Resultat: $K_6 = 0{,}90$; $K_3K_6 = 3{,}0(7) \times 10^{-10}$; $K_3 = 3{,}4 \times 10^{-10}$

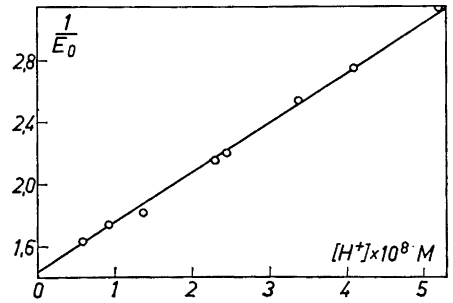

Fig. 12. 4″-Chlor-benzaurin. $1/E_0$ als Funktion von $[H^+]$ für die Bestimmung von K_1 (und E_R). $\lambda = 550$ mμ und $d = 2$ cm.

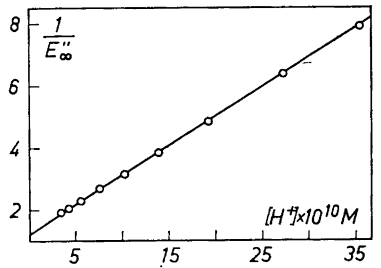

Fig. 13. 4″-Chlor-benzaurin. $1/E''_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_3K_6 und K_6. $\lambda = 550$ mμ und $d = 5$ cm.

Tabelle 2. 4″-Chlor-benzaurin. Messungen bei 550 mμ zur Bestimmung von K_2; $d = 5$ cm, $C = 9{,}0 \times 10^{-6}$ M.

$[H^+] \times 10^6$ M	41,0	33,7	24,5	23,1	13,7(3)	9,2(1)	5,9(5)
E_∞	0,014(0)	0,016(0)	0,022(5)	0,023(5)	0,042(0)	0,055(5)	0,083(5)
K_2	133	140	136	139	127	141	140

Bestimmung von $K_5 = K_6/K_4$ *und* K_6 aus Formel (4) konnte aus bereits erwähntem Grund nicht ausgeführt werden. Aus den Messungen wurde ein ungefährer Wert von K_4 geschätzt. $K_4 \approx 14 \times 10^{-11}$.

Bestimmung von K_2 aus Formel (5) im Gebiet $7{,}2 < \text{pH} < 8{,}3$. Die Messlösungen waren identisch mit denen, die bei der Bestimmung von K_1 oben verwendet wurden. E_∞ wurde bei $\lambda = 550$ mμ und $d = 5$ cm gemessen; das entsprechende E_R ist dann 1,73(0). Für K_1 und K_6 wurden die oben bestimmten Werte eingesetzt. Die Resultate sind in Tabelle 2 aufgeführt. Als Mittelwert wurde $K_2 = 137$ erhalten.

Die oben bestimmten Konstanten ergeben das Produkt $K_1K_2K_3K_6 = 0{,}93$.

Bestimmung von K_7. In der ersten Mess-serie bei der Ionenstärke 1,00 M variierte $[H^+]$ zwischen 0,25 und 1,00 M. E wurde bei $d = 5$ cm und bei $\lambda = 490$ mμ gemessen. Fig. 14 zeigt $[H^+]/\left(E - \frac{E_{G_1}}{1 + K_2}\right)$ als Funktion von $[H^+]$. Man erhält (mit $E_{G_1}/(1 + K_2) = 0{,}004$)

$$E_{G_2} = 5{,}5(9) \quad ; \quad (K_7(1 + K_2) = 4{,}3)$$

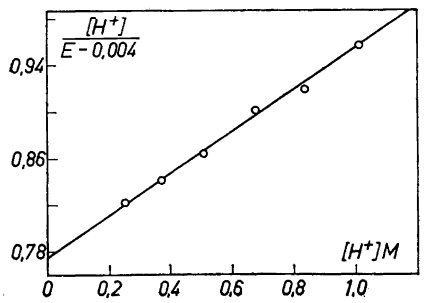

Fig. 14. 4″-Chlor-benzaurin. $[H^+]/\left(E - \frac{E_{G_1}}{1 + K_2}\right)$ als Funktion von $[H^+]$ für die Bestimmung von E_{G_2}. $\lambda = 490$ mμ und $d = 5$ cm.

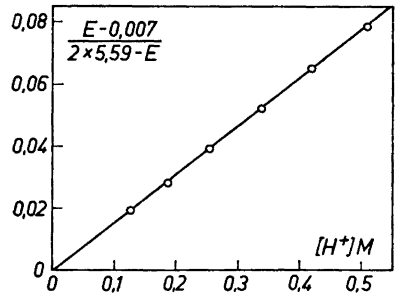

Fig. 15. 4″-Chlor-benzaurin. $\left(E - \frac{E_{G_1}}{1 + K_2}\right) / (E_{G_2} - E)$ als Funktion von [H+] für die Bestimmung von K_7. $\lambda = 490$ mμ und $d = 10$ cm.

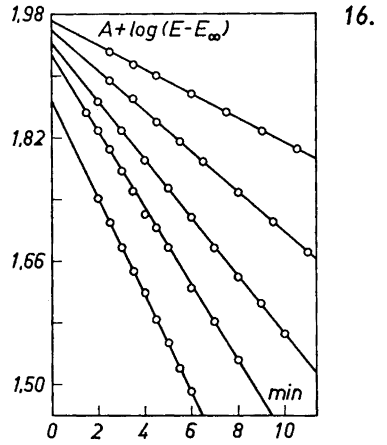
In der zweiten Mess-serie bei der Ionenstärke 0,50 M, wo $[H^+]$ zwischen 0,12 und 0,50 M variierte, wurde E bei $d = 10$ cm gemessen. Mit $E_{G_2} = 2 \times 5{,}59$ und $E_{G_1}/(1 + K_2) = 0{,}007$ wird in Fig. 15 $(E - \frac{E_{G_1}}{1 + K_2})/(E_{G_2} - E)$ als Funktion von $[H^+]$ wiedergegeben. Man erhält $K_7(1 + K_2) = 6{,}4(4)$. Das Einsetzen von $K_2 = 137$ ergibt $K_7 = 4{,}7 \times 10^{-2}$.



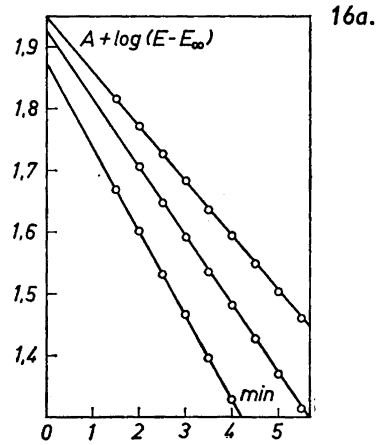


Fig. 16. 4″-Chlor-benzaurin. Reaktionskinetik bei $\lambda = 450$ mμ und $d = 5$ cm. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

pH:	6,555	6,313	6,151	6,003	5,915

Fig. 16a. 4″-Chlor-benzaurin. Reaktionskinetik bei $\lambda = 450$ mμ und $d = 5$ cm. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

A:	2,10	2,08	2,02
pH:	5,752	5,648	5,590

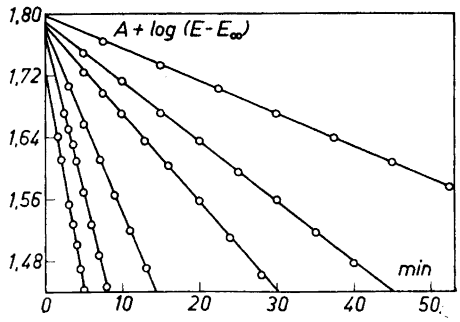

Fig. 17. 4″-Chlor-benzaurin. Reaktionskinetik bei $\lambda = 550$ mμ und $d = 2$ cm. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

A:	1,98	1,96	1,95	1,94	1,93	1,88
pH:	11,03(5)	11,33	11,51(5)	11,82	12,06	12,21(5)

Messungen der Aufhellungsgeschwindigkeit. k wurde im Gebiet $5{,}5 < \text{pH} < 12{,}3$ bestimmt. Für $\text{pH} < 7$ wurde E bei $\lambda = 450$ mμ mit $d = 5$ cm gemessen; für $\text{pH} > 7$ wurde E bei $\lambda = 550$ mμ mit $d = 2$ cm gemessen. Die Figuren 16, 16a und 17 zeigen die kinetischen Verläufe in den sauren und alkalischen Lösungen, in welchen die Messungen der graphischen Berechnung von k_1 und k_2 bzw. k_3 und k_4 zu Grunde lagen. Fig. 18 zeigt k als Funktion von pH.

Bestimmung von k_1 und k_2 erfolgte im Gebiet $5{,}6 < \text{pH} < 6{,}5$, analog den Berechnungen für Benzaurin. Fig. 19 zeigt k_1 als Funktion von $[H^+]$ (eine Gerade). Man erhält $k_1^\circ = 5{,}0 \times 10^{-3}$ und $k_1' = 4{,}8 \times 10^4$. Es gilt also (mit $[H^+]$ in Mol/l):

$$k_1 = 5{,}(0) \times 10^{-3} + 4{,}8 \times 10^4\,[H^+];\; k_2 = 3{,}(65) \times 10^{-5} + 3{,}5 \times 10^2\,[H^+]\,(\text{Min}^{-1})$$

Bestimmung von k_3 und k_4. Für $\text{pH} > 11$ wächst k stark mit dem pH-Wert. Aus zusammengehörigen Werten von k und $[H^+]$ wird k_3 aus Formel (13)

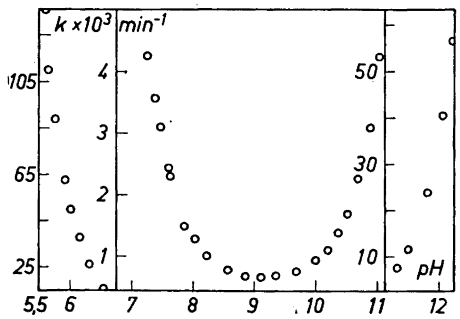

Fig. 18: 4″-Chlor-benzaurin. Die Geschwindigkeitskonstante k als Funktion von pH. O sind experimentell gefnndene Werte.

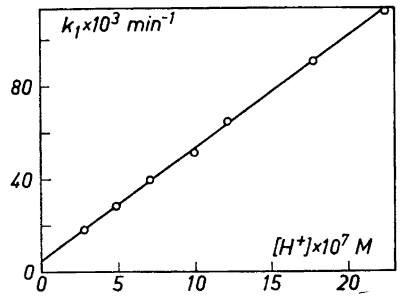

Fig. 19. 4″-Chlor-benzaurin. Die Geschwindigkeitskonstante k_1 als Funktion von $[H^+]$.

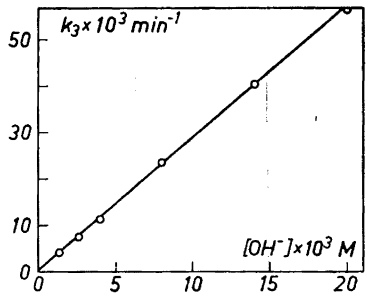

Fig. 20. 4″-Chlor-benzaurin. Die Geschwindigkeitskonstante k_3 als Funktion von [OH$^-$].

berechnet. Der Ausdruck $k_4 \cdot [H^+]/([H^+] + K_4)$ ist hier ein Korrektionsglied, weniger als 5 % von k betragend, und kann daher mit dem oben geschätzten Wert von K_4 zufriedenstellend berechnet werden (bei den höheren pH-Werten wird es vernachlässigt). Aus Fig. 20 geht hervor, dass k_3 eine lineare Funktion von [OH$^-$] ist. Wie beim Benzaurin ist $k_3°$ so klein, dass es nicht graphisch ermittelt werden kann. Man erhält $k'_3 = 2{,}8(7)$. $k_3°$ wurde wie beim Benzaurin nach untenstehenden Berechnungen bestimmt.

$[H^+] \times 10^9$ M	0.397	0,76(7)	1,39(0)	2,72
$k \times 10^4$ Min^{-1}	6.9(8)	6,6(8)	6,8(2)	7,8(1)
$k_3° \times 10^4$ Min^{-1}	3.8(5)	4,0(4)	4,1(3)	4,2(3)

Mittelwert: $k_3° = 4{,}1 \times 10^{-4}$ Min^{-1}.
Man erhält also mit [OH$^-$] in Mol/l:

$$k_3 = 4{,}1 \times 10^{-4} + 2{,}8(7)[OH^-]; \; k_4 = 3{,}7 \times 10^{-4} + 2{,}5(9)[OH^-] \; (Min^{-1})$$

DISKUSSION

Tabelle 3 enthält eine Zusammenstellung der bestimmten Konstanten für Benzaurin und 4″-Chlor-benzaurin. Es geht aus der Zusammenstellung hervor, dass eine Substitution von Wasserstoff gegen Chlor in der freien Parastellung die Konstanten des Systems wenig ändert. Nur bei drei Gleichgewichtskonstanten ist eine mit Sicherheit verifizierte Änderung vorzufinden. Die Protolysenkonstanten K_7 und $1/K_1$ sind mit den ungefähren Faktoren 2,8 bzw. 1,2 und die Hydratationskonstante K_2 mit dem ungefähren Faktor 1,4 gewachsen. Sonstige Abweichungen in den Gleichgewichtskonstanten dürfen als innerhalb der Fehlergrenzen liegend betrachtet werden. Bezüglich der Geschwindigkeitskonstanten ist es auffallend, dass $k_1°$ (ganz besonders) und $k_3°$ fast die gleichen sind. Dagegen wächst k_1 mit der [H$^+$] bedeutend schneller bei Benzaurin ($k_1' = 8{,}0 \times 10^4$) als bei 4″-Chlor-benzaurin ($k_1' = 4{,}8 \times 10^4$). (Vergleiche die Änderung in K_7.) In alkalischen Lösungen wächst k_3 mit der [OH$^-$] schneller bei 4″-Chlor-benzaurin als bei Benzaurin (k_3' ist 2,9 im Vergleich zu 2,0).

The Measurement of Self-diffusion with a New Continuous Monitoring Method

I. Evaluation of the "Δl-Effect" in the Open-ended Capillary Method

E. BERNE and J. BERGGREN

Department of Inorganic Chemistry, Chalmers Institute of Technology, and Swedish Institute of Silicate Research Gothenburg, Sweden

A new continuous monitoring capillary method is introduced. A mathematical treatment involving only the experimental values of the activity remaining in the capillary at various times gave evidence for the existence of a constant "Δl-effect" which could be calculated.

I. INTRODUCTION

Many authors have pointed out the fact that a possible source of error with the open-ended capillary method is due to convection disturbances at the top of the capillary.

Two effects can be distinguished, both of them tending to sweep out part of the active solution of the capillary, and leading therefore to effective diffusion paths shorter than the geometric length of the capillary. Such convection disturbances may occur:

— Firstly, when the boundary between the active and the inactive solutions is broken, *i.e.* when the capillary is immersed in the inactive bath. This effect, termed "immersion error", has been tested by Mills and Kennedy [1], Krauss and Spinks [2] and Mills and Adamson [3], who found activity losses in the capillary equal to 1.3 %, 0.5 % and 1.7 %, respectively.

— Secondly, when the outer inactive solution is stirred, in order to maintain the boundary condition $c = 0$ at the mouth of the capillary (c being the concentration of the labelled particles). If the stirring is too rapid or turbulent, part of the active solution may be swept more or less continually out of the capillary during the diffusion run. Wang, who termed this latter effect the "Δl-effect", has proposed a method for measuring it by using capillaries of different lengths [4]. But this method appears to be quite unsatisfactory, since it only gives an accuracy of the same magnitude as the "Δl-effect" itself, *i.e.* $\pm$ 2 % [1,3,4].

The only way to check whether a diffusion process out of an open-ended capillary is ideal should consist in a continuous registering of the activity inside the capillary during a whole diffusion run. In this case, the diffusion process should correspond to the solution of Fick's general diffusion equation for the actual boundary conditions:

$$\frac{I}{I_0} = \frac{8}{\pi^2} \sum_0^\infty \frac{1}{(2n+1)^2} \exp[-(2n+1)^2\pi^2 Dt/4l^2] \quad (1)$$

where I = activity remaining in the capillary after a diffusion time t,
I_0 = initial activity in the capillary before diffusion
l = length of the capillary.

Mills and Godbole have recently made a first attempt in this direction by building an apparatus allowing them to make several measurements during a single diffusion run. [5] However ,the frequency of their observations (13 to 20 for a run) was not high enough for a complete and accurate survey of the whole diffusion run.

The following work was undertaken in order to observe, by continuous registering of the activity inside the capillary, how the diffusion really proceeds, when experimental techniques such as Wang's modification [6] of the initial Anderson and Saddington method [7] are used, *i.e.* with mechanical stirring of the outer inactive solution.

II. EXPERIMENTAL

1) Description of apparatus

The apparatus is shown in Fig. 1. The container for the inactive solution was a 3-liter glass beaker (A), with a lateral cylindrical connection (B) (diameter = 3.5 cm) terminated at right angles by another narrow cylindrical tube (C) (diameter = 0.8 cm) which contained the capillary. An opening (diameter = 0.8 cm) was made in tube (B), immediately above tube (C), to allow the lowering of the capillary into the cell. It could be closed with a rubber stopper (E). The solution was stirred mechanically by means of a propeller (F) placed vertically in the 3-liter beaker, and a plexiglas top (G) was laid over the beaker to prevent any evaporation. The capillaries used had internal and external diameters of 0.08 and 0.6 cm, respectively, and a length of (3.89 ± 0.01) cm.

A special G.M. tube for γ-ray counting (H), enclosed in a steel envelope, was tightly pressed to, and fixed along the wall of, the capillary. (For more details about the relative positions of capillary and G.M. tube, see further below.)

The whole diffusion cell and the G.M. tuber were immersed in a 30-liter water thermostat, kept at a temperature of (25.00 ± 0.01)°C.

The G.M. tube was connected to a counter, working on Preset Count. A special additive electronic device gave the apparatus the ability to choose, by itself, between two different preset number of counts to be registered, according to the radioactivity of the measured samples (UL and LL for high and low radioactivities, respectively). During a counting operation, the counter first worked on UL (*i.e.* it started as if it would count the higher preset number of impulses), but if the time for counting a certain number of impulses appeared to be too long, it turned over automatically to LL after 30 sec, (*i. e.* it would only count the lower preset number of impulses). Both for UL and for LL, the manipulator could select in advance one of two different preset number of counts, 10 000 and 5 000 counts for UL and 600 and 400 counts for LL, respectively.

The times corresponding to each measurement were printed on a paper roll by a registering device, connected to the counter (a number 1 or a number 2, printed before

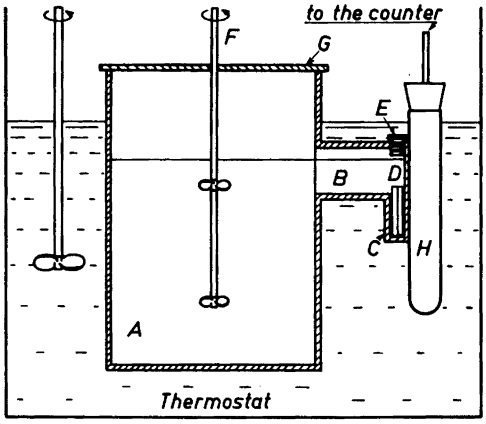

Fig. 1. Apparatus for continuous monitoring open-ended capillary method.

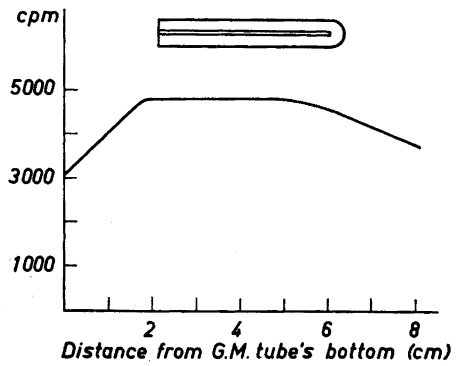

Fig. 2. Efficiency curve of the G.M.tube. The representation of the capillary, at the same scale, shows the relative positions of the G.M.tube and the capillary.

the time data in different characters, indicated whether the counter had worked on UL or on LL). After each measurement, the counter stopped for one minute, and then restarted automatically.

2) Preparation of solutions

All experiments were performed with 0.001 M sodium iodide solutions.

The radioactive solutions were prepared by adding 5 to 15 μl of a carrier-free Iodine-131 solution (specific activity = 12 mC/ml) to 25 ml of the inactive sodium iodide solution. The corresponding activities were 9 000 to 15 000 cpm for the contents of a capillary. The isotope was provided by the Isotope Division AERE, Harwell, England.

3) Experimental procedure

The capillary was filled with the radioactive solution by means of a thin micropipette, operated with a medical syringe. A small drop of active solution was left on top in order to prevent evaporation during the time necessary to reach thermal equilibrium, and also to avoid as far as possible convection disturbances when the capillary was immersed in the inactive bath. Then the capillary was put in place in the holder (C), and the inactive solution, already at 25°C, was gently poured into the cell, along the walls of the beaker (A), until its level reached to 4/5th of the height of the capillary. After 10 min, the thermal equilibrium could be considered as established, and more inactive solution was slowly poured into the cell, until its total volume was about 1 600 ml. This last operation was done just before the counter started a new measurement. After 9 000 minutes, only about 15 % of the initial activity was left in the capillary, and the experiment was stopped.

4) Preliminary experiments

a. Relative positions of capillary and G.M.tube. The counting efficiency of the G.M. tubes we used has been measured by displacing a radioactive point source along the tube, and measuring its activity at all positions. It was found in this way that the counting

efficiency for each G.M. tube was constant along a region extending on both sides of its middle point. The length of this region was comparable to that of the capillary, but somewhat shorter. Fig. 2 represents the efficiency curve of one of our G. M. tubes as well as the position which was given to the capillary.

Since the greatest concentration changes occur in the upper end of the capillary, its top was placed in the constant efficiency zone. By taking into account the efficiency gradient of the G.M. tube and the activity gradient in the capillary, it could be demonstrated mathematically that the center of gravity of the total measured radioactivity in the capillary no longer moved after a diffusion time t = 2 000 to 3 000 min. It may be noteworthy that Mills and Godbole came to the same conclusions for their own semi-continuous monitoring apparatus, with a 2 cm long capillary placed inside the hole (2 cm high) of a well-crystal of a scintillation counter [8].

b. Background. Before each diffusion run, the background was measured over a period of 15 min. It was of course impossible to check it during a run. We assumed that it kept approximately constant, and the measurement made at the beginning of each run (250 to 300 cpm) was used in the calculation.

c. Control of convection in the cell. A capillary was very accurately filled with the radioactive solution, and its contents (obtained by withdrawing them and rinsing five times with water) transferred using a micropipette into the inactive bath, right above the top of a sealed capillary in holder (C). Stirring was then started, and the radioactivity continually measured. It was found that with a stirring rate of 80 to 150 rpm, the radioactivity was evenly dispersed in the bath after 3 to 4 min. With a stirring rate of 320 rpm, uniform repartition was established in less than a minute. For our diffusion experiments, a stirring rate of 80 rpm was used.

d. Influence of the radioactive species which have diffused out from the capillary. The last experiment may be used for the determination of the constant ratio a between the number of counts per minute I'' corresponding to a certain amount of radioactivity evenly dispersed in the main body of the cell, and the number of counts I' corresponding to the same amount contained in the capillary. Five experiments yielded a mean value a = 3.8 %.

III. RESULTS AND DISCUSSION

1) The activities I_i' corresponding to the registered time data τ_i were calculated as follows:

$$I_i' = \frac{A}{\tau_i} - B \tag{2}$$

A being the number of registered counts (5 000 or 400)
B being the background.

As there was so much data, and as each individual value was known with a poor accuracy (the statistical counting accuracy), the individual values were not used for calculation, but mean values, I_i', of sets of 10 single values. It was assumed that in the case of Iodine-131, the half-life of the isotope was long enough for the radioactive decay between the measurements i and $(i + 10)$ to be neglected.

A mean diffusion time t_i, corresponding to each I_i' value was then calculated as follows:

$$t_i = \sum_{1}^{10(i-1)} (\tau_i + 1) + \frac{1}{2} \sum_{10_i-g}^{10_i} \tau_i \tag{3}$$

(it was assumed that the error arising from taking a linear mean time instead of a logarithmic one was negligible).

I_i' values were then corrected for radioactive decay over the period $t = 0$, $t = t_i$.

$$I_i'^0 = I_i'/e^{-\lambda t_i} \tag{4}$$

λ being the decay constant of the isotope.

Then $I_i'^0/I_0$ was calculated, and corrected for the contribution of the activity, I'' which had diffused out, according to eqn. (5):

$$\frac{I_i^0}{I_0} = \frac{\frac{I_i'^0}{I_0} - \alpha}{1 - \alpha} \tag{5}$$

Finally, D could be calculated from eqn. (1).

All these long calculations have been done with an electronic computer Alwac III E.

We reproduce in Fig. 3 two characteristic shapes of the curves $D = f(t)$.

It is seen that the experiments did not yield a constant value of D. It may consequently be deduced that the diffusion did not follow an ideal process.

The difference between curves (1) and (2) seems to be due to a difference in the size of the radioactive drop left on top of the capillary before immersion. Curves of type (2) were obtained when rather large drops were left (covering the whole top of the capillary tube), while curves of type (1) were obtained with smaller drops (4 to 6 % of the capillary volume).

The influence of the size of the drop may be roughly explained in the following way. When a large drop is left on top of the capillary, there may be no "immersion error". On the contrary, part of the active solution of the drop may remain for a while in the neighbourhood of the capillary, and the apparent D is then too low. After a certain time, a "Δl-effect" gradually takes place, and D increases slowly. When a smaller drop is left on top, there may be an "immersion error". The values for D found at the beginning of the run are consequently too high, but tend to decrease as the diffusion current again

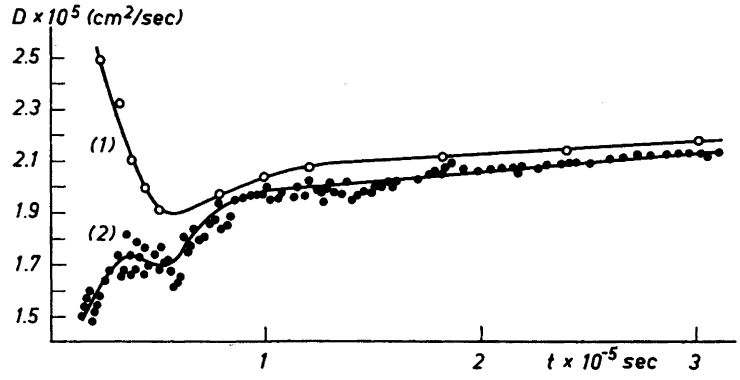

Fig. 3. Plot of D *vs.* t. O: experimental points for curve (1). ●: experimental points for curve (2).

fills the top of the capillary with radioactive solution. After a certain time, a "Δl-effect" is established, and D tends to increase again.

2) Plots similar to those of Mills and Godbole [5], *i.e.* plots of $\log (I^0/I_0)$ *vs.* t. gave approximately straight lines, as may be seen from Fig. 4. The slopes of these lines were calculated from the general equation:

$$s = \frac{\sum_{i=1}^{i=n} \log (I_i^0/I) - \sum_{i=n+1}^{i=2n} \log (I_i^0/I_0)}{\sum_{1=i}^{i=n} t_i - \sum_{i=n+1}^{i=2n} t_i} \qquad (6)$$

An example is given in Table 1, related to the curve in Fig. 4:

Table 1.

Number of points	Time interval	$D \times 10^{-5}$ (cm²/sec)
90	$2.18 \times 10^5 - 5.46 \times 10^5$	2.30
30	$2.18 \times 10^5 - 2.95 \times 10^5$	2.21
30	$2.95 \times 10^5 - 4.10 \times 10^5$	2.26
30	$4.01 \times 10^5 - 5.46 \times 10^5$	2.39

Two conclusions may be drawn from these results:

a) Obviously, the self-diffusion coefficients calculated are too high. For the very dilute solutions investigated here, they ought to be equal to the

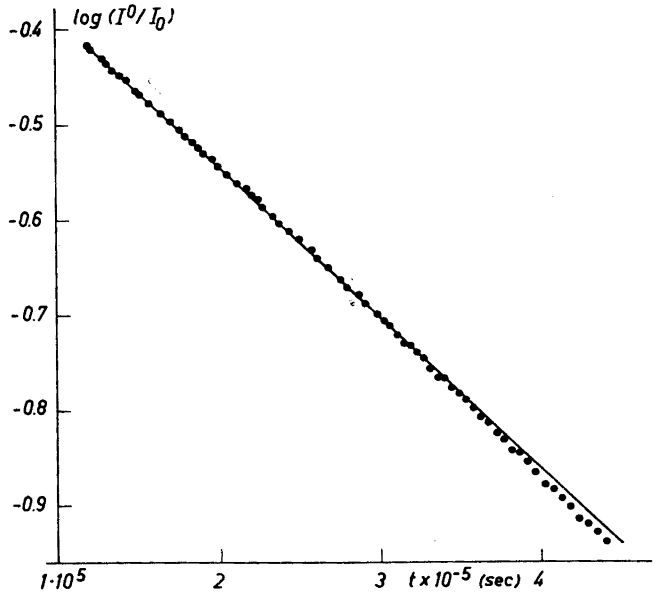

Fig. 4. Plot of $\log(I^0/I_0)$ *vs.* t. (Same experiment as Fig. 3, Curve 1.)

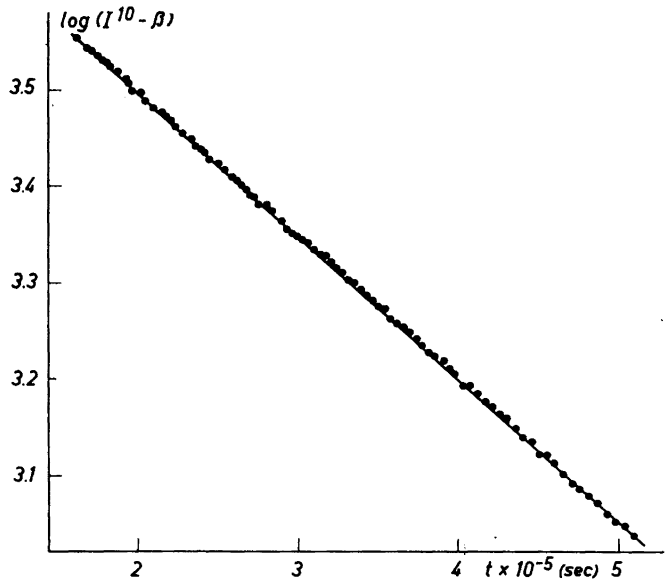

Fig. 5. Plot of $\log(I'^0-\beta)$ *vs. t.* (Same experiment as Fig. 4.)

Nernst limitimg value: $D^0 = 2.045 \times 10^{-5}$ cm²/sec. This discrepancy may be due to two factors: the poor accuracy of α and I_0, and probably the relatively high convection disturbances at the top of the capillary. This last factor is not to be regarded here as serious, since our purpose was in fact the investigation of these disturbances and their influence on the diffusion process.

b) As may be seen on Fig. 4, it is possible to draw a straight line through the experimental points of the plot $\log(I^0/I_0)$ *vs. t*, even if the diffusion process is far from being theoretical. Only calculations enable conclusions to be drawn about the diffusion process. So that it is regrettable that Mills and Godbole [5] did not report the data corresponding to their measurements during a single diffusion run. Although it is very probable that their own apparatus did not give rise to such important convection disturbances as ours, these authors have not yet given evidence that the convection disturbances were negligible.

3) We have already pointed out the fact that a source of error in the calculation of D was the poor accuracy of α and I_0.

It will be proved in the following part that if the convection disturbances at the top of the capillary have the same influence on the diffusion process as a constant "Δl-effect" *i.e.* if the experimental $I_i'^0$ values fit the case of an ideal process out of a capillary of effective length l_{eff}, shorter than its geometrical length, then it is possible to calculate the value of the product $\alpha I_0 = \beta$, by making use of only the experimental $I_i'^0$ values; this value, now exact, may then be used for the calculation of D/l^2_{eff}.

The abreviated diffusion equation

$$\frac{I_i'^0 - a\ I_0}{I_0\ (1-a)} = \frac{8}{\pi^2} \exp\ [-\pi^2 D t_i / 4 l^2_{eff}] \tag{7}$$

(which is valid with in an accuracy of 0.2 % for $Dt/l^2 > 0.2$) may also be written

$$\ln(I_i'^0 - \beta) = \frac{\pi^2 D t_i}{4\ l^2_{eff}} + C \tag{8}$$

C and β being constants.

If there exists a constant diffusion path l_{eff}, and if the apparent D does not vary with time, eqn. (8) will be satisfied by any experimental point $(I_i^{0\prime}, t_i)$. A set of 4 experimental points: $(I'_1{}^0, t_1)$, $(I'_2{}^0, t_2)$, $(I'_3{}^0, t_3)$, $(I'_4{}^0, t_4)$ will then satisfy the following equation:

$$\frac{\ln \dfrac{I'_1{}^0 - \beta}{I'_2{}^0 - \beta}}{\ln \dfrac{I'_3{}^0 - \beta}{I'_4{}^0 - \beta}} = \frac{t_2 - t_1}{t_4 - t_3} \tag{9}$$

β has been determined by a method of "trial and error" for 50 different sets of 4 points. The 50 values of β thus obtained differed from each other, as each $I_i'^0$ value is only known with the statistical counting error, but it has been verified that they followed a gaussian statistical distribution, and that they also were statistically distributed along the time axis. * An example is given in Table 2.

Table 2. $\bar{\beta} = (357 \pm 28)$ cpm. Relative dispersion $\sigma = 140$ cpm.

Interval	Frequency of β values
$\bar{\beta}-2\sigma;\ \bar{\beta}$	24
$\bar{\beta}-\sigma;\ \bar{\beta}$	10
$\bar{\beta};\ \sigma + \bar{\beta}$	10
$\bar{\beta}\ ;\ \bar{\beta} + 2\sigma$	24
$\bar{\beta}-2\sigma;\ \bar{\beta} + 2\sigma$	48 = 96 % of total amount

The good statistical repartition of the β values proves that our initial hypothesis concerning an ideal diffusion process out of a fictive capillary of length l_{eff} was correct.

The plot of log $(I'^0 - \beta)$ *vs.* t. appears to be rigorously linear, as may be seen in Fig. 5. The slope of this line, K, has been calculated for 50 sets of 2 points, and the statistical distribution of the various K values analyzed, in order to detect possible deviations from a theoretical diffusion process. An example is given in Table 3:

* This was only the case for experiments performed with relatively small drops left on top of the capillary before immersion. When larger drops were left, it was found that the positive deviations from the β mean value occurred at the beginning of the diffusion run, and the negative ones at the end.

Table 3. $\overline{K} = (1.481 \pm 0.003) \times 10^{-6}$ sec^{-1}. Relative dispersion $\sigma = 0.02 \times 10^{-6}$ sec^{-1}.

Interval	Frequency of K values
$\overline{K}-2\sigma$; $\overline{K}$	19
$\overline{K}-\sigma$; $\overline{K}$	9
$\overline{K}$; $\overline{K}+\sigma$	8
$\overline{K}$ $\overline{K}+2\sigma$	13
$\overline{K}-2\sigma$; $\overline{K}+2\sigma$	49 = 98 % of total amount

The constant ratio D/l^2_{eff} may be now calculated from the value of $\overline{K}$.

If one assumes l_{eff} to be equal to l, the diffusion coefficient obtained is somewhat too high. If, on the other hand, one assumes l_{eff} to be different from l, and D equal to the Nernst limiting value, the magnitude of the "Δl-effect" can be determined. The following results were obtained:

if $l_{\text{eff}} = l = 3.89$ cm	then $D = 2.091 \times 10^{-5}$ cm^2/sec.
if $D = 2.045 \times 10^{-5}$ cm^2/sec	then $l_{\text{eff}} = 3.84_7 = 3.85$ cm.

Thus, the present method has enabled a precise determination of the magnitude of the "Δl-effect", which was evaluated to 0.4 mm, *i.e.* 1 % of the capillary's length.

Work is proceeding in this laboratory to investigate whether the "Δl-effect" is constant for various solutions, and to what extent it depends on the viscosity of the solutions. If it were found that reasonable changes in the viscosity have no influence on its magnitude, then a capillary could be calibrated with known solutions, *i.e.* dilute solutions for which $D = D^{\circ}_{\text{Nernst}}$, and used for the study of unknown solutions.

Acknowledgments. The authors are grateful to Professor C. Brosset for his constant interest in the present work.

Ribose in Meat

H. FREDHOLM

Research laboratory of the Sveriges Slakteriförbund, Stockholm 20, Sweden

Careful chromatographic methods for detection, estimation and quantitative determination of ribose in meat are described in detail. Samples of meat from the gracilis-muscle of hogs and cattle were collected and examined immediately after slaughter as well as after different kinds of storage up to 6 months.

Immediately after slaughter all samples of meat from cattle contained less than 5, probably less than 1 μg of ribose per g meat, that is, no ribose could be detected by the technique used which does not account for the ribose bound, *e. g.*, in ribonucleic acids in the samples. In a few samples of meat from hogs immediately after slaughter traces of ribose could be detected, but in most samples none.

During storage under refrigeration the ribose content of the meat, as determined by the methods described increases up to 120 μg per g meat in 16 days (meat from cattle). The increase is practically proportional to storage-time. Cold storage of meat (−20°C) shows the same result, so that a ribose content, defined as above, of 60 μg per g meat can be obtained after 1 month. If meat is frozen immediately after slaughter and then kept in cold storage, it will last much longer until ribose can be detected by the methods described.

For several reasons it seems likely that the ribose detected and determined by using the methods described is free or loosely bound.

Even very small amounts of ribose may be of importance in meat influencing its properties as a chemical system as well as a microbiological medium. Therefore it seemed to be of interest to know if "free" ribose is formed in meat from, *e.g.*, ribonucleic acids during ordinary handling and storage of meat, and if so, what quantities of ribose would be formed by different kinds of handling and storage. Possibly a method of determining "free" ribose would furnish a tool for the judging of meat in regard to certain qualities.

The term free ribose is used here for the quantity of ribose which can be detected by the mild methods developed, even if some part of this quantity might be formed, *e.g.*, from more complex products of hydrolysis of ribonucleic acids, such as mononucleotides, during analysis.

A similar investigation on deoxyribose in meat is beeing carried out, the results of which will be published later.

EXPERIMENTAL

Meat from cattle and hogs were used in this work. In order to get defined meat the raw material was obtained from the gracilis-muscle only.

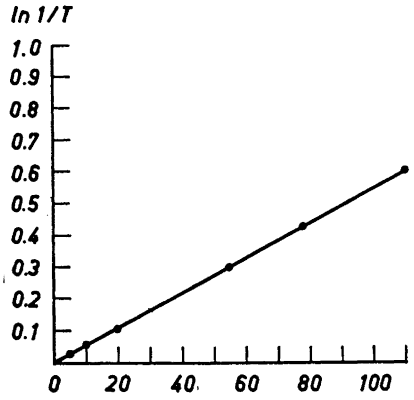

Fig. 1. Evaluation curve for ribose from light absorbance at 5 100 Å. Extinction in 10 mm cells.

First a method for detection and estimation of ribose was developed, then a method for the quantitative determination of ribose in meat was worked out. It is essential in both methods that free ribose can be extracted with no or the slightest possible hydrolysis of ribonucleid acids or other compounds containing ribose.

Detection and estimation of ribose in meat. To 30 g of finely but carefully ground sample of meat 110 ml of distilled water and 30 ml of 20 % phosphotungstic acid were added. The mixture was well stirred, then heated on a waterbath for 10 min and centrifuged. The waterphase was filtered into a glassvessel, desalted using Dowex 50, evaporated and made up to 5 ml.

Paper chromatograms were taken using the technique of Partridge [1] with modifications published later by several authors as described by Block *et al.*[2] On every chromatogram known quantities of ribose were run. As usual parallel chromatograms were carried out using other carbohydrates and related compounds which occur in meat.

Quantitative determination of ribose in meat. To 50 g of finely but carefully ground sample of meat 100 ml of distilled water and 50 ml of 20 % phosphotungstic acid were added. The mixture was then treated as described above under Detection and estimation, except that the desalted, evaporated filtrate was made up to 10 ml.

The chromatographic method, which was used by Pridham [3] for determination of aldohexoses, some aldopentoses though not ribose, hexuronic acids and 6-deoxy-aldohexoses was found to give excellent results with ribose too and therefore was used.

After the colour of the spots had been eluted from the paper with aqueous methanol containing stannous chloride (1.0 g of stannous chloride in 5 ml of water + 90 ml of absolute methanol, then filtered) the absorbances were measured in a Zeiss spectrophotometer PMQ II at 5 100 Å. At this wavelength there is an absorption maximum for the coloured compounds formed by the interaction of ribose with the *p*-anisidine-hydrochloride reagent.

The same precautions to avoid confusion were observed, as were described above under Detection and estimation. The evaluation curves obtained with known quantities of ribose on the same paper chromatograms, using the same procedure, application, development, drying, spraying with *p*-anisidine, eluting and spectrophotometric measuring show straight lines with varying amounts of ribose from 5 to 110 μg as will be seen from Fig. 1.

RESULTS

Detection of ribose in meat. Samples of meat from cattle were collected:

1. Immediately after slaughter, that is within 15 min.
2. After storage under refrigeration (+ 1 to + 4°C) for 2, 6, 8, 10, 13 and 15 days.

3. After 2 and 6 months cold storage at −20°C. Carcasses handled commercially before cold storage, including refrigeration.
4. Samples collected within 15 min after slaughter, then immediately frozen (within 1 h after slaughter), then kept 1, 3, 7, 14 and 30 days at −20°C.
5. Samples collected and ground within 1 h after slaughter, then 110 ml dist. water added to 30 g ground meat. The mixture kept under refrigeration (+ 1 to + 4°C) during 2, 6, 8, 10, 13 and 15 days.
6. The same series as sub 5 but 110 ml dist. water + 30 ml 20 % phosphotungstic acid added instead of water only.

Samples of meat from hogs were collected as follows.
1. Immediately after slaughter.
2. After storage under refrigeration (+ 1 to + 4°C) for 2 and 8 days.
3. After cold storage for 4 months at −20°C.

Tables 1 and 2 contain the results of qualitative chromotogrophy.

Quantitative determination of ribose in meat. Table 3 gives the results of the quantitative measurements of ribose in meat from cattle determined as described above. Samples were collected, 1) Immediately after slaughter 2) After storage under refrigeration (+ 1 to + 4°C) for 2, 4, 6 and 16 days, 3). After cold storage at −20°C during 1 month. 0.02 ml of resulting solution applied.

Refrigerated for:		
2 days	3	1
4 days	1	8
6 days	4	5−7
16 days	1	12
Cold storage for:		
1 month	3	6

CONCLUSIONS AND DISCUSSION

Whilst ribose cannot be detected in fresh meat from cattle immediately after slaughter, and only in traces and in some cases of such meat from hogs if the careful chromatographic methods described are used which allow detection of about 1 μg of ribose, there will appear an increasing amount of ribose *e.g.* during storage even if this storage is carried out under refrigeration or as cold storage. Immediate freezing of the meat after slaughter delays the appearence of ribose for at least 1 month.

Though it is not possible at present to decide if the quantity of ribose detected and determined by the methods described exists as free ribose or as partly bound, there are reasons to believe that this quantity of ribose is in a free or loosely bound state. The most important reason to think so seems to be the fact that all samples examined have been very finely ground in order to allow all chemical compounds therein to be uniformly distributed in the samples and free to be attacked by chemical action during analytical procedure.

The Crystal Structure of Potassium Perchromate

ROLF STOMBERG and CYRILL BROSSET

Department of Inorganic Chemistry, Chalmers University of Technology, Göteborg, Sweden

The crystal structure of potassium perchromate has been determined by two- and three-dimensional X-ray methods. The perchromate crystallizes in the space group $I\,\bar{4}2m$, with $a = 6.703 \pm 0.003$ Å and $c = 7.632 \pm 0.003$ Å The length of the bond between the two oxygen atoms in a peroxide group is 1.489 ± 0.022 Å. The oxidation number of +5 for the chromium has been confirmed.

The crystal structure of potassium perchromate, K_3CrO_8, has previously been determined by Wilson [1], who, by means of powder diffraction data, found the oxygen-oxygen single bond in the peroxide group to be 1.34 ± 0.06 Å, a rather uncertain and somewhat low value in comparison with those obtained by other authors [6,7]. This would justify a refinement of the structure. It would also be of interest to establish definitely if chromium is surrounded by four equidistant O_2^{2-}-ions and consequently has the oxidation number +5, or if it might be enclosed both by O_2^{2-} and O_2^--ions.

EXPERIMENTAL

Preparation and analysis. K_3CrO_8 was prepared according to Riesenfeld [2] by adding hydrogen peroxide to a cooled, alkaline solution of potassium chromate. The temperature did not exceed −5°C. The crystals were filtered, and dried with alcohol and ether. The chromium content was determined by converting the sample into chromate, adding KI and titrating the liberated iodine with a thiosulfate solution. The potassium content was determined as potassium perchlorate. (Found: K 39.6; Cr 17.5. Calc. for K_3CrO_8: K 39.5; Cr 17.5.)

Magnetometric measurement. K_3CrO_8 has been found to be paramagnetic and the moment was determined by the Gouy method which gave the approximate value $\chi_M = 1\,240 \pm 30$ units, clearly indicating the existence of a single unpaired electron found also by Tjabbes [4] and Klemm and Werth [5].

X-Ray methods. In order to determine the cell dimensions accurately powder photographs of Guinier type were taken using Cu $K\alpha$ radiation and with NaCl as reference substance. Due regard was taken to film shrinkage according to Hägg by copying a scale on the films before development.

The structural investigation was based on single crystal methods. Multiple-film equi-inclination Weissenberg photographs were taken with rotation about [1$\bar{1}$0] (layer lines 0, 1, 2 and 4), [100] (layer lines 0, 1, 2, and 3) and [001] (layer lines 0, 1, 2, 4 and 6) using molybdenum radiation. Thin tinfoils were placed between the films in order to increase

the absorption. The reflexion intensities were estimated by visual comparison with standard scales. A subjective correction was made for variation in spot shape. As molybdenum radiation was used and the crystals were only 0.1 mm thick no correction was made for absorption. The reflexion intensities were corrected using Lorentz and polarization factors.

As the perchromate was decomposed in a few days under the influence of the X-rays it was necessary to use new crystals after about 20 h exposure.

DETERMINATION OF THE STRUCTURE

The cell dimensions were obtained from powder diffraction data by the method of least squares. K_3CrO_8 is tetragonal with

$$a = 6.703 \pm 0.003 \text{ Å.}$$
$$c = 7.632 \pm 0.003 \text{ Å.}$$

Calculated and observed $\sin^2\Theta$-values are given in Table 1.

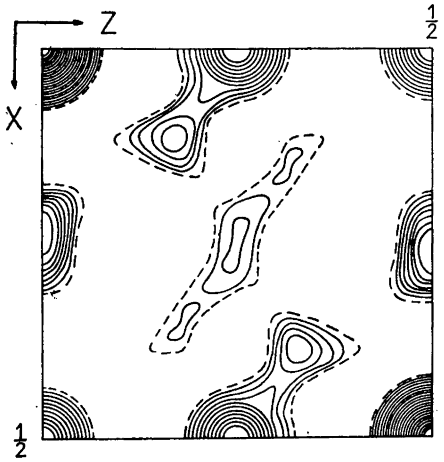

Fig. 1. Patterson projection on (010).

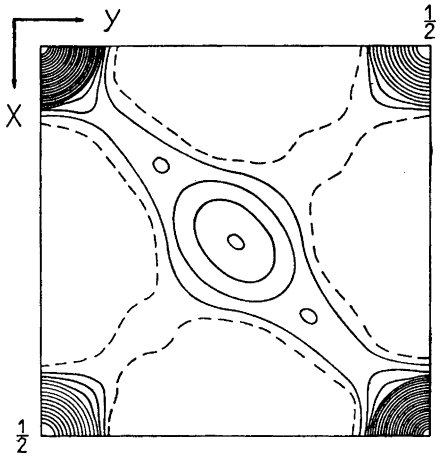

Fig. 2. Patterson projection on (001).

In all photographs only reflexions from planes of the following types were observed:

hkl	with	$h + k + l = 2n$
$hk0$	with	$h + k = 2n$
hhl	with	$l = 2n$
$0kl$	with	$k + l = 2n$
$00l$	with	$l = 2n$

The following space groups are thus possible:
$I4/mmm$ (No. 139), $I4mm$ (No. 107), $I\bar{4}m2$ (No. 119), $I\bar{4}2m$ (No. 121) and $I422$ (No. 97).

The experimentally determined density [1] is 2.79, from which the number of molecules per unit cell appears to be 2 (1.94).

From a Patterson projection on (010) (Fig. 1) it was concluded that the heavy atoms (Cr and K) are situated at (0;0), (0;$\frac{1}{4}$), (0;$\frac{1}{2}$), (0;$\frac{3}{4}$), ($\frac{1}{2}$;0), ($\frac{1}{2}$;$\frac{1}{4}$), ($\frac{1}{2}$;$\frac{1}{2}$) and ($\frac{1}{2}$;$\frac{3}{4}$), whereas the oxygen co-ordinates are of the general type.

Further information could be obtained from a Patterson projection on (001) (Fig. 2), which shows that the Cr and K atoms occupy the positions (0;0), (0;$\frac{1}{2}$), ($\frac{1}{2}$;0) and ($\frac{1}{2}$;$\frac{1}{2}$) and that the oxygen parameters seem to be of the type (x;x).

Of the possible space groups only $I\bar{4}2m$ is consistent with all these observations. According to this space group the positions of the heavy atoms will be the following

2 *a* 000
2 *b* 00 1/2
4 *d* 0 1/2 1/4, 1/2 0 1/4

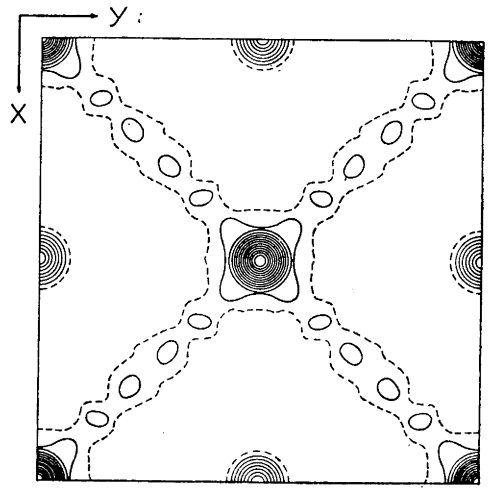

Fig. 3. Projection of the electron density in K_3CrO_8 on (001) (arbitrary units).

As no heavy peaks have appeared in the Patterson projection, except the one at origo it seemed very probable that the Cr atoms occupy the position 2 *a* and the K atoms 2 *b* and 4 *d*.

That this assumption is correct is indicated by the close agreement between observed and calculated structure factors arrived at in the final stage of the investigation.

The signs of the structure factors were calculated on the assumption that the chromium and potassium positions alone determined these. Two Fourier projections were synthesised, one (see Table 2, column 1) on (001) (Fig. 3) and one (Table 2, column 2) on (010) (Fig. 4).

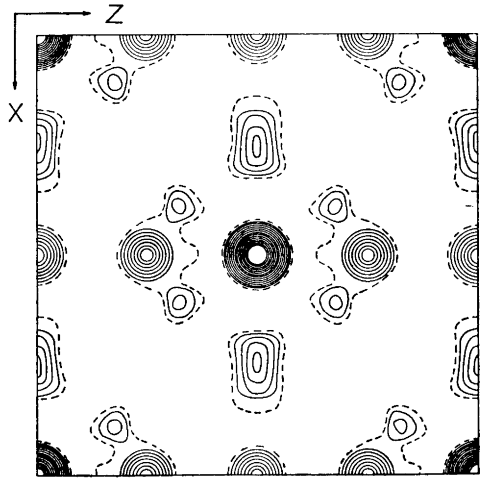

Fig. 4. Projection of the electron density in K_3CrO_8 on (010) (arbitrary units).

Table 2. Atomic parameters obtained from the various Fourier syntheses.

Atom		1	2	3	4	5	6
O_1	x	0.138	0.117	0.134	0.125	0.132	0.1355
	y	0.138	—	0.135	—	0.132	0.1355
	z	—	0.175	—	0.183	0.183	0.1825
O_2	x	0.207	0.200	0.203	0.208	0.206	0.2050
	y	0.207	—	0.204	—	0.206	0.2050
	z	—	0.000	—	0.011	0.011	0.0075

The heavy peaks all occurred at the above-mentioned positions for potassium and chromium. The oxygen parameters thus obtained are subject to great errors, however, because of the considerable differences in the electron densities between the chromium and potassium atoms on the one hand and the oxygen atoms on the other hand.

In order to attain greater accuracy two difference syntheses were produced (Table 2, columns 3 and 4) by subtracting the contributions of the chromium and potassium atoms from the structure factors with due regard to the temperature factor. The parameters obtained from these two projections were in better agreement with each other, but there was still great uncertainty in the $O_{(2)}$-position because of the overlapping. A $(F_o - F_c)$-synthesis was tried but with the aid of this it was not possible to get sufficiently exact parameter displacements. It was therefore necessary to make a three-dimensional Fourier analysis in order to resolve the peaks.

Three-dimensional refinement

The final atomic co-ordinates from the (010)- and (001)-projections, which are shown in column 5 of Table 2, were used to calculate $\sum_r f_r A_r$ and $\sum_r f_r B_r$ in the expression

$$|F(hkl)| = \{[\sum_r f_r A_r]^2 + [\sum_r f_r B_r]^2\}^{\frac{1}{2}} \quad ,$$

where the notation is that adopted in the International Tables for X-ray Crystallography [10]. The phase angle $\alpha(hkl)$ could thereafter be deduced by means of the equation

$$\alpha(hkl) = \tan^{-1}\left\{\frac{[\sum_r f_r B_r]}{[\sum_r f_r A_r]}\right\}$$

This quantity was used in the expression for the electron density

$$\varrho_{xyz} = \frac{8}{V_c} \sum_h \sum_k \sum_l |F(hkl)| \{\cos 2\pi hx \cos 2\pi ky \cos 2\pi lz \cos\alpha(hkl) -$$

$$\sin 2\pi hx \sin 2\pi ky \sin 2\pi lz \sin\alpha(hkl)\}.$$

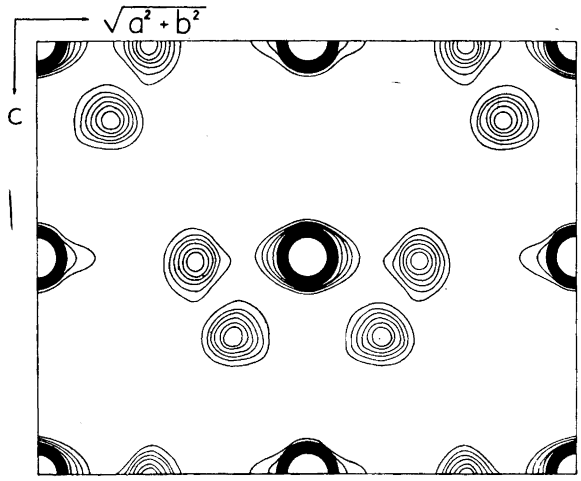

Fig. 5. The electron density of K_3CrO_8 in the plane $(1\bar{1}0)$. Contours at 2 e/Å^3. The curves are not drawn in the centers of the heavy atoms.

In the first stage of the calculation the quantities $\sum_h\sum_k |F(hkl)| \cos 2\pi hx \cos 2\pi ky \cos\alpha(hkl)$ and $\sum_h\sum_k |F(hkl)| \sin 2\pi hx \sin 2\pi ky \sin\alpha(hkl)$ were determined with $h = 0-8$, 10 and $k = 0-8$, 10, and with x taken at intervals of 1/200 of the cell side, and with y at intervals of 1/60 of the cell side. With the aid of these two-dimensional data one-dimensional Fourier syntheses were computed in the z-direction, with z taken at intervals of 1/200 of the cell side. Because $x_1 = y_1$ and $x_2 = y_2$ it was sufficient to calculate the electron density in the plane $(1\bar{1}0)$ (Fig. 5).

Final parameter values of the oxygen atoms are given in column 6 of Table 2. The arrangement of the atoms is given in Table 3. In Table 4 are

Table 3. Arrangement of the atoms in K_3CrO_8.

given observed structure factors and those calculated using the values of the atomic parameters given in Table 3. In Table 4 are also included the phase angles $\alpha(hkl)$ used in computing the electron density in the plane $(1\bar{1}0)$.

The structure factor disagreements,

$$R = \frac{\Sigma(|F_{calc}| - |F_{obs}|)}{\Sigma|F_{obs}|}$$

of the final coordinates are $R_{hkl} = 13.2$ %, $R_{hk0} = 8.4$ % and $R_{h0l} = R_{0kl} = 17.4$ %, excluding those terms too weak to be observed.

Observed structure factors have been corrected for thermal vibrations by the factor $\exp[B(\sin\Theta/\lambda)^2]$ with $B = 2.0 \times 10^{-16}$ cm^2, determined by the method of least squares from the final structure factors. An isotropic temperature factor has been applied in spite of the fact that the $(F_o - F_c)$-synthesis showed the existence of somewhat different magnitudes in the thermal vibrations in the x- and z-directions.

Accuracy of the determination

The standard deviations $\sigma(x)$ and $\sigma(z)$ of atomic coordinates were estimated from the differences ΔF between the magnitudes of observed and calculated values of the structure factors according to Cruickshank's method [3], where

$$\sigma(x) = \frac{2\pi[\Sigma h^2(F_o - F_c)^2]^{\frac{1}{2}}}{a \cdot V \cdot \frac{\partial^2\varrho}{\partial x^2}}$$

and

$$\sigma(z) = \frac{2\pi[\Sigma l^2(F_o - F_c)^2]^{\frac{1}{2}}}{c \cdot V \cdot \frac{\partial^2\varrho}{\partial z^2}};$$

here a and c are the cell edges and V the cell volume.

As proposed by Shoemaker, Donohue, Schomaker and Corey [8] these values have been increased by the factor of 1.3 as the structure has no centre of symmetry but the projections are centro-symmetric.

The values of $\frac{\partial^2\varrho}{\partial x^2}$ and $\frac{\partial^2\varrho}{\partial z^2}$ were obtained from the values of the electron density in the neighbourhood of the final Fourier peaks. Mean values for the oxygen atoms are

$$\frac{\partial^2\varrho}{\partial x^2} = 610 \text{ and } \frac{\partial^2\varrho}{\partial z^2} = 625 \text{ e/Å}^5$$

The standard deviations of the oxygen atomic positions are thus $\sigma(x) = 0.0084$ and $\sigma(z) = 0.0096$ Å. The standard deviations in the bond lengths are 0.022 Å for O_1-O_2 and 0.015 Å for K—O and Cr—O. The probable error in the bond angles is 1°.

Table 5. Interatomic distances.

Cr_1-O_1	1.895 Å
Cr_1-O_2	1.944
K_1-O_1	2.743
K_1-O_4	2.797
K_2-O_1	2.661
O_1-O_2	1.489
O_1-O_4	2.905
O_2-O_5	2.569
O_4-O_{10}	2.744
O_4-O_{12}	2.751

Description of the structure

Bond lengths and other interatomic distances are given in Table 5 and bond angles in Table 6. Fig. 6 shows the arrangement of the oxygen atoms about the chromium atom. From this figure, and from the data obtained, it follows that the chromium atom in K_3CrO_8 is surrounded by eight oxygen atoms, four being at a distance of 1.895 Å and four at 1.944 Å. The discrepancy between these two values is not significant. Thus the close agreement between the bond lengths indicates that the chromium atom is bonded to eight oxygen atoms. This 8-coordination with the symmetry $\bar{4}\ 2\ m$ has a dodecahedral configuration.

The length of the bond between the two oxygen atoms, as a peroxide ion is 1.489 Å, close to values found in other peroxy compounds [6,7]. The shortest distances between oxygen atoms not belonging to the same peroxide ion are 2.91 Å, 2.57 Å, 2.75 Å, and 2.74 Å.

The potassium atoms are also 8-coordinate, the shortest potassium-oxygen distances being 2.74 Å, 2.80 Å, and 2.66 Å.

DISCUSSION

The likely configurations for a complex ion or a molecule of formula AB_8 are four in number, [9,11] namely the cube, the Archimedean antiprism with symmetry $\bar{8}2m$, the dodecahedron with symmetry $\bar{4}2m$ and the face-centered trigonal prism. The need to use *f*-orbitals of the central atom in forming cubic bonds has been quoted as unfavourable [11], although it is believed that diketone complexes of Ce(IV), Th(IV) *etc.* have cubic arrangements [15].

Table 6. Bond angles.

$O_1-Cr_1-O_2$	45.6°
$Cr_1-O_1-O_2$	68.9
$Cr_1-O_2-O_1$	65.5
$O_4-Cr_2-O_{16}$	89.8
$O_4-Cr_2-O_{10}$	91.2
$O_3-Cr_2-O_5$	95.4
$O_3-O_{12}-O_5$	55.8
$O_1-K_1-O_4$	63.9

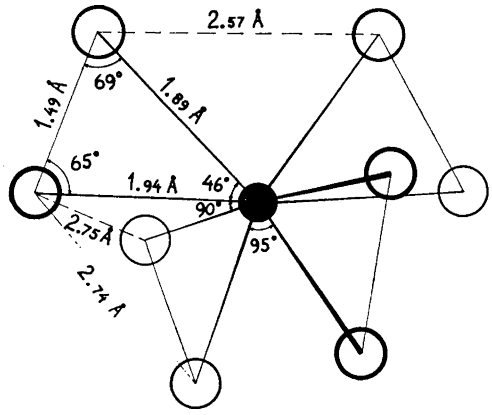

Fig. 6. Bond lengths and bond angles in K_3CrO_8.

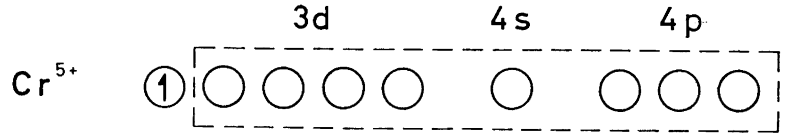
According to the literature [14] other molecules and ions with co-ordination number 8 are 8-quinolinol chelates of tetrapositive metals; cyano- and fluoro-complexes such as $Mo(CN)_8^{4-}$, $W(CN)_8^{4-}$, and TaF_8^{3-}; and oxalato complexes such as $U(C_2O_4)_4^{4-}$. So far only the antiprismatic and the dodecahedral arrangements have been established for a discrete group AB_8.

Hoard and Nordsieck [9] have found that $Mo(CN)_8^{4-}$ has the dodecahedral arrangement with the carbon atoms at the vertices, and that the symmetry of the complex ion can be approximated to $\bar{4}2m$. The present investigation has shown that CrO_8^{3-} has the symmetry $\bar{4}2m$ and that the geometrical arrangement of the oxygen atoms surrounding the central chromium atom is dodecahedral. One would have expected the same configuration for $Mo(CN)_8^{4-}$, CrO_8^{3-} and TaF_8^{3-}, but Hoard *et al.* [12] have shown by X-ray analysis that TaF_8^{3-} has the arrangement of an Archimedean antiprism.

According to Kimball [11] the dodecahedral, antiprismatic and face-centered trigonal prismatic configurations are given by appropriate linear combinations of *spd*-orbitals, but Higman [13] has concluded that one *f*-orbital is required for the $Mo(CN)_8^{4-}$-arrangement. This conclusion does not seem adequate as there are no available *f*-orbitals in CrO_8^{3-}. It is highly probable that the bonds are d^4sp^3-hybrids because the paramagnetism of the substance is in accordance with the orbital configuration



The stability of this arrangement has also been found to occur with Mo^{5+} in $Mo(CN)_8^{3-}$ which is not oxidized to $Mo(CN)_8^{2-}$. This is in contrast to other Mo(V) compounds which are readily oxidized to Mo(VI).

It is rather remarkable that the two non-isoelectronic ions $Mo(CN)_8^{4-}$ and CrO_8^{3-} have the same configuration. It should also be pointed out that the structure of the $Mo(CN)_8^{3-}$-ion, which is isoelectronic with CrO_8^{3-}, has not yet been determined.

Finally it should be mentioned that $Cr(O_2)_4^{4-}$ does not seem to exist. This may be explained by assuming that the configuration with a single electron in the 3*d* orbital has a stabilizing effect.

On Relative Donor Strengths: A Thermochemical Study

INGVAR LINDQVIST and MARGARETA ZACKRISSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

A simple method for qualitative studies of relative orders of enthalpy changes has been developed. The relative orders of donor strength of some oxide chlorides and organometalloid oxides have been established. A brief discussion of the effects of substitution has been given.

In a previous paper [1] it has been pointed out that in the study of addition compounds, the determination of the relative acceptor and donor strengths of the reacting molecules is a very important problem. In the work described there, a spectroscopic method was used for this purpose. A more direct method is to measure the heat of reaction of the adduct formation. The discussion in the earlier paper [1] about such reactions in a solvent is valid in this case too.

This paper deals with an attempt to determine the relative donor strengths of a number of molecules in reactions with $SbCl_5$ and $SnCl_4$ as acceptors by a simple thermochemical method. In most of the reactions studied here the formation of adduct molecules is probably complete but some dissociation will not influence the measured order of donor strengths because only reactions of the same type have been compared.

EXPERIMENTAL

Chemicals. 1,2-$C_2H_4Cl_2$, $(CH_3)_2SO$, $(C_6H_5)_2S$, $(CH_3)_2CO$, $CH_3COOC_2H_5$, $(C_2H_5)_2CO$, $(C_2H_5)_2O$, $POCl_3$ and $SOCl_2$ were purified by distillation. (B.p. 84°, 95°/30 mm, 92°, 57°, 77°, 103°, 35°, 105° and 80°C.) $SeOCl_2$ was repeatedly distilled until it had a final melting point of + 10.5°C. In order to obtain $(C_6H_5)_2SeO$, $(C_6H_5)_2Se$ was prepared [2] and oxidized according to a method described by Bergson [3] (for preparing selenanthren-5,10-dioxide). This method gave a hydrate which was dried at 70°/10 mm for 12 h (M.p.113°C). $(CH_3)_3PO$ and $(C_6H_5)_3PO$ were prepared as described earlier [4] (M.p. 137–139° and 152–154°C). $(CH_3)_2SO_2$ was prepared by oxidation of $(CH_3)_2SO$ according to McAllan *et al.*[5] (M.p. 108–109°C). $(C_6H_5)_2SO_2$ was prepared by Dr. B. Sjöberg whose help is gratefully acknowledged (M.p. 125°C). $(C_6H_5)_3AsO$ was friendly sent to us by Prof. S. Y. Tyree, Chapel Hill, North Carolina. $SbCl_5$ and $SnCl_4$ were purified according to Dodd and Robinson [6].

THERMOCHEMICAL MEASUREMENTS

The apparatus used for this purpose is very simple. In each of two reaction vessels of Dewar type, thermistors are placed, functioning as resistances in a Wheatstone bridge. Equal volumes of a solution of the acceptor molecule are placed in the reaction vessels. The bridge is balanced with a variable resistance, using a galvanometer as null indicator. Solutions of two different donor molecules are poured into each of the vessels simultaneously. If the heat of reaction is not the same in both of the reactions the galvanometer needle deflects, thus indicating which of the reactions has the larger change of enthalpy.

1,2-Dichlorethane has been used as a solvent and the solutions of the donor molecules have been 0.4 M. Because $SbCl_5$ in most of the cases we know gives addition compounds with one donor molecule, but $SnCl_4$ with two molecules, 0.4 M solutions of $SbCl_5$ and 0.2 M solutions of $SnCl_4$ and equal volumes of donor and acceptor solutions have been used for the reactions. We have assumed that if there is any difference in the heat capacity of the solutions at such dilutions, it must be so small that it cannot influence the results. (This has also been checked by experiments which will not be presented in this paper, because only crude qualitative experiments are described here, which cannot be influenced by such minor sources of error.)

RESULTS

The results are summarized in Table 1.

Table 1.

Acceptor: $SbCl_5$

1. $(C_6H_5)_2SeO = (C_6H_5)_3AsO > (CH_3)_3PO > (CH_3)_2SO$
2. $(C_2H_5)_2S > (CH_3)_2CO = CH_3COOC_2H_5 = (C_2H_5)_2CO = (C_2H_5)_2O$
3. $(CH_3)_2SO_2 > (C_6H_5)_2SO_2 = POCl_3 = SeOCl_2 > SOCl_2$

Acceptor: $SnCl_4$

1. $(C_6H_5)_2SeO = (C_6H_5)_3AsO > (CH_3)_3PO > (C_6H_5)_3PO$
2. $(C_2H_5)_2S > (CH_3)_2CO = CH_3COOC_2H_5 > (C_2H_5)_2CO = (C_2H_5)_2O$

The donor molecules studied fall naturally into three classes of decreasing strength. Each of the compounds of a class are of the same order of strength compared to the difference between the classes, which is especially large between class 1 and class 2. The sequence within each class is not definitely proved to be correct but the experiments strongly indicate the given order. Such a small amount of substance of $(C_6H_5)_3AsO$ was available that solutions which were only 0.04 M had to be used. The effect at this dilution is very small and the position of this donor in the sequence is thus doubtful, but its placement in class 1 is certainly correct.

$(C_6H_5)_3PO$ gives HCl-evolution and dark color with $SbCl_5$[4] even at this dilution and could not be studied with that acceptor. $(CH_3)_2SO$ could not

be studied with $SnCl_4$ as acceptor because of the formation of a precipitate. The nature of this precipitate was not further explored. The compounds of class 3 gave no measurable effect with $SnCl_4$ as acceptor. The reason is probably that the addition compounds are completely dissociated in their components at this dilution.

DISCUSSION

It is often assumed that the order of relative donor strengths of the molecules will also give information about the bond strength between the donor and the acceptor atoms of the compound formed. There are some objections against this assumption, however. In adduct formation the acceptor molecule has changed its structure completely and there might be subsequent energy changes which have been ignored in the assumption. For the determination of *relative* interaction strengths with the same acceptor molecule this complication is of importance only if the structure of the donor molecule also has changed appreciably.

Another complication is the fact that in some cases a secondary acceptor-donor interaction takes place, *e.g.* with $SeOCl_2$[7] and with sulfoxides [8]. In the detailed discussion of the order of relative donor strengths this secondary interaction might be important.

Finally it can be remarked that any attempt to subdivide the energy of a molecule into different bond energies is a rather arbitrary procedure.

The donor function of the oxygen atoms in $POCl_3$[9], $(C_6H_5)_2SO$[8], $(CH_3)_3PO$[10], and $(C_6H_5)_2SO_2$[11] with $SbCl_5$ as acceptor and in $POCl_3$[10] and $SeOCl_2$[7] with $SnCl_4$ as acceptor has recently been definitely established by X-ray work and there is no reason to suspect that the other molecules studied here, in which oxygen is bonded to the central atom of the molecule, will react differently. Concerning the ether and the sulfide it can safely be assumed that the oxygen and the sulfur atoms, respectively, are the donor atoms. In ethyl acetate it is not established which of the oxygen atoms functions as the donor atom and it should be of great interest to know.

The results show that not only the donor atom, but also the other atoms in the donor molecule are of great importance for the donor strength. All oxychlorides are much weaker as donors than the corresponding compounds with organic substituents. The larger electronegativity of chlorine compared with the organic groups causes a drift of electrons from oxygen and thus a lower tendency to donate an electron pair. In most cases we can even see the difference between molecules with the same central atom but with different organic substituents.

Other facts also seem to influence the donor strength. Sulfur in $(CH_3)_2SO$ and carbon in $(CH_3)_2CO$ have the same electronegativity (2.5). Nevertheless, $(CH_3)_2SO$ has much stronger donor properties than $(CH_3)CO$. One difference between those molecules is that the sulfur atom of the sulfoxide has a free electron pair lacking at the carbon atom in acetone.

In class 2 we can note that ethyl sulfide seems to be a stronger donor than ethyl ether. Ahrland *et al.*[12] have divided acceptor atoms into two classes and placed antimony and tin in the class which should form more stable

complexes with oxygen than with sulfur, but these experiments indicate that they are probably border-line elements.

It has been established that only one of the oxygen atoms in the sulfones is functioning as a donor atom [11] and the other oxygen atom seems to decrease the donor strength to an appreciable extent compared with methyl-sulfoxide.

Steric hindrances might also affect the strength of the acceptor-donor bond, but there is no obvious example of this among the molecules studied.

These experiments give good hope of further exploring relative donor and acceptor strengths in a simple way. We also intend to improve the apparatus and perhaps be able to give an approximative value of the magnitude of the enthalpy changes at the reactions.

A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged. Finally we wish to thank Prof. G. Hägg for all facilities put at our disposal.

Die Biosynthese der Orsellinsäure und Penicillinsäure (1)

KLAUS MOSBACH

Biochemisches Institut der Universität Lund, Lund, Schweden

Die in Gegenwart von $CH_3{}^{14}COONa$ aus *Chaetomium cochliodes* gebildete Orsellinsäure wurde isoliert und ihre ^{14}C-Verteilung bestimmt. Es wurde gezeigt, dass das Orsellinsäuremolekül entsprechend der Acetattheorie aufgebaut wird. Das Vorkommen von Orsellinsäure in *Penicillium barnense* wurde festgestellt. Spezifisch markierte Orsellinsäure wurde als Substrat zu *Penicillium barnense* gegeben und die gebildete Penicillinsäure isoliert. Das radioaktive Markierungsmuster der Penicillinsäure entsprach dem der zugesetzten Orsellinsäure, womit gezeigt wurde, dass Orsellinsäure Precursor der Penicillinsäure ist.

Der klassische Metabolit in Schimmelpilzen, Penicillinsäure, wurde unter anderem auch in *Penicillium barnense* gefunden.[1] Es lagen auch Beweise für das Vorkommen einer aromatischen Substanz von phenolischem Charakter im Kulturmedium desselben Pilzes vor. Es wurde nun gezeigt, mit den schon einmal beschriebenen Analysenmethoden [2], dass es sich bei dieser Verbindung um Orsellinsäure handelt. Nach etwa 10 Tagen wurde der Anteil der Orsellinsäure im Kulturmedium immer geringer, wobei sich gleichzeitig der Anteil der Penicillinsäure erhöhte.

Das gemeinsame Vorkommen dieser beiden Metaboliten in derselben Spezies, ihre wechselweisen quantitativen Beziehungen zueinander sowie die strukturelle Ähnlichkeit der Orsellinsäure und Penicillinsäure lassen auf einen metabolischen Zusammenhang schliessen. Man könnte sich dabei die Penicillinsäure durch eine Ringspaltung der Orsellinsäure entstanden denken. Dieser Gedanke war schon vor einigen Jahren von Ehrensvärd [3] ausgesprochen worden und unabhängig von ihm von Birch [3].

Eine Parallele zu dieser Ringspaltung wäre der Übergang biosynthetischer ^{14}C-markierter 6-Methylsalicylsäure zu Patulin.[4,5].

Um diese Hypothese zu untersuchen, wurde spezifisch markierte Orsellinsäure, (2-^{14}C- und karboxyl-^{14}C-markiert), zum Medium von *Penicillium barnense* gegeben und die Penicillinsäure isoliert. Jedoch musste zunächst einmal festgestellt werden, inwieweit die von Birch [6] gezeigte head-to-tail-Kupplung von Acetateinheiten bei 6-Methylsalicylsäure auch für Orsellinsäure Gültigkeit hat. Dabei hat sich gezeigt, dass auch für Orsellinsäure

die Acetattheorie in vollem Umfang gilt, und dies ist somit neben der von Gatenbeck [7] gezeigten Acetatkupplung bei der 3-Hydroxyphthalsäure ein weiterer Beweis für deren Richtigkeit.

Auch der von Gatenbeck und dem Verfasser [8] gezeigte Einbau des Sauerstoffisotopen ^{18}O aus $CH_3{}^{14}CO^{18}ONa$ in die Karboxyl- und die beiden Hydroxylgruppen der Orsellinsäure kann als ein weiterer Beweis für die Acetattheorie gelten.

EXPERIMENTELLER TEIL

1). Degradation der Orsellinsäure

Kulturbedingungen: Vier Fernbachkolben mit je 500 ml Czapek-Dox-Lösung (5 % Dextrose) wurde mit Perithecien von *Chaetomium cochliodes Pall.* okuliert. Nach 12 Tagen wurde in die Kolben eine Lösung von $CH_3{}^{14}COONa$ (insgesamt 0.5 mC) pipettiert. Nach weiteren 7 Tagen wurde das Myzelium durch Filtrieren vom Medium getrennt und die Orsellinsäure in der schon beschriebenen Weise isoliert [2]. Ein kleiner Teil des Mediums wurde mit Äthyläther extrahiert und der Extrakt chromatographiert. (System: Wasser-Äthyl-Methylketon-Diäthylamin.)[9] Das Messen der Radioaktivität entlang des Papierchromatogrammes ergab nur zwei Aktivitätsspitzen, deren R_F-Werte jeweils denen der Orsellinsäure bzw. des Orcinols entsprachen. (Orsellinsäure $R_F = 30$; Orcinol $R_F = 90$.)

Oxydation der Orsellinsäure nach van Slyke-Folch: 270 mg nicht radioaktiver Orsellinsäure wurde zu 72 mg der isolierten radioaktiven Säure gegeben. Durch wiederholtes Lösen und Eindunsten in Äthyläther wurde eine homogene Mischung erhalten.

5 mg der Substanz wurden nun nach der Methode von van Slyke-Folch [10] oxydiert und das dabei gebildete Kohlendioxyd in karbonatfreiem Bariumhydroxyd aufgefangen. Das Bariumkarbonat wurde isoliert und dessen Radioaktivität gemessen. Bei allen radioaktiven Messungen wurden jeweils 15 mg/cm^2 Bariumkarbonat verwendet.

Dekarboxylierung der Orsellinsäure: 131 mg Orsellinsäure wurden in 12 ml Glyzerin durch Erwärmen im Ölbad gelöst. Das dabei gebildete Kohlendioxyd wurde durch einen durch das System geleiteten Strom von kohlendioxydfreiem Stickstoff in eine Bariumhydroxydlösung gebracht und als Bariumkarbonat isoliert.

Kuhn-Roth-Oxydation der Orsellinsäure: Die Kuhn-Roth-Oxydation von 100 mg Orsellinsäure ergab Essigsäure, die durch Wasserdampfdestillation isoliert wurde. Das während der Reaktion gebildete Kohlendioxyd wurde in Bariumhydroxid aufgefangen. Die Essigsäure wurde durch eine Schmidt-Reaktion dekarboxyliert und das Kohlendioxyd als Bariumkarbonat isoliert. Das dabei gebildete Methylamin wurde dann durch eine alkalische Permanganatlösung zu Kohlendioxyd oxydiert. Nach Ansäuern derselben wurde das dadurch freigemachte Kohlendioxyd in Baryt aufgefangen.

2,4,6-Trinitroorcinol: 75 mg Orsellinsäure wurden in 0,350 ml konz. Schwefelsäure gelöst und bei 0°C eine kalte Mischung von 0,135 ml konz. Salpetersäure und 0,27 ml konz. Schwefelsäure zugegeben. Nach einem weiteren Zusatz von 0,220 ml konz. Salpetersäure und einer halben Stunde Stehen bei Zimmertemperatur wurde die Mischung in Eiswasser gebracht. Das dabei ausgefällte 2,4,6-Trinitroorcinol wurde abfiltriert und aus Wasser umkristallisiert. (Schmelzp. 171°C.)[11]

Hypobromit-Oxydation von 2,4,6-Trinitroorcinol: Zu 33 mg Trinitroorcinol in 5 ml heissem Wasser wurden 7 ml einer gesättigten Bariumhydroxydlösung gegeben. Die auf 0°C gekühlte Suspension wurde mit einer eiskalten Bariumhypobromitlösung (0,2 ml Br_2, 1,6 g $Ba(OH)_2$, 30 ml H_2O) versetzt. Nach 5 Stunden Umrühren in einem verschlossenen Erlenmeyerkolben bei Zimmertemperatur wurde das gebildete Brompikrin mit Wasserdampf überdestilliert. Das Destillat wurde in einem vorgekühlten Zntrifugenrohr aufgefangen und abzentrifugiert. Nach Waschen mit angesäuertem destillierten Wasser wurde das Brompikrin erneut zentrifugiert und nach van Slyke-Folch zu Kohlendioxyd oxydiert. Das während der Hypobromitreaktion gebildete Bariumkarbonat wurde filtriert und mit kochendem destilliertem Wasser gewaschen. Durch Ansäuern mit Perchlorsäure wurde das Kohlendioxyd freigemacht und noch einmal als Bariumkarbonat isoliert.

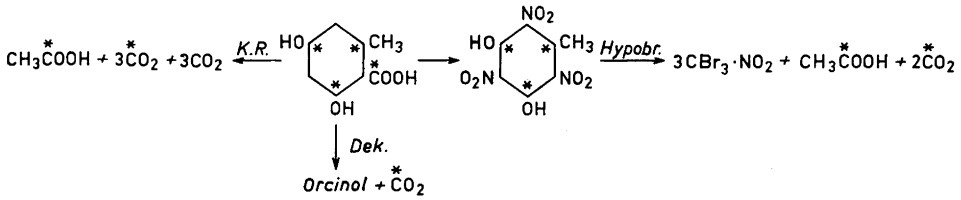

Abb. 1. Degradationsschema der Orsellinsäure.

2). Synthese von 2-^{14}C- und karboxyl-^{14}C-markierter Orsellinsäure

Äthylacetoacetat: ($CH_3{}^{14}COCH_2{}^{14}COOH$): 250 mg ^{14}C-markiertes Bariumkarbonat wurde mit Perchlorsäure versetzt und das dabei gebildete radioaktive Kohlendioxyd in eine Ätherlösung von Magnesiumjodmethyl eingeleitet und die durch Hydrolyse mit

* Die Radicaktivität der Karboxylgruppe der durch Kuhn-Roth-Oxydation erhaltenen Essigsäure ist als Basis für die Ausrechnung der theoretischen Aktivität der einzelnen Proben verwendet worden, da sie durch direktes Messen erhalten worden ist.

Wasser gebildete karboxylmarkierte Essigsäure isoliert. Das Natriumsalz der gebildeten Essigsäure wurde dann mit nicht radioaktivem Natriumacetat vermischt und durch Erwärmen mit Diäthylsulfat bei 180°C verestert. Das sich bildende Äthylacetat wurde sukzessiv abdestilliert. 25 g des gebildeten Äthylacetates wurde dann mit Natrium versetzt, um eine Kondensation zu Äthylacetoacetat zu ermöglichen [12]. Das Äthylacetoacetat wurde vom Reaktionsgemisch getrennt und schliesslich durch Destillation im Vakuum gereinigt. (Ausbeute: 6 g Äthylacetoacetat.) Dass gerade dieser Weg für die Synthese gewählt wurde, lag daran, dass die sich gleichzeitig bildende Dehydracetsäure für andere Versuche gebraucht wurde.

Dihydroorsellinsäureester: 0,69 g Natrium wurden in 10 ml abs. Äthylalkohol gelöst und 4,2 g des markierten Acetessigesters sowie 3,4 g Krotonsäureäthylester hinzugegeben [13]. Nach Erhitzen auf dem Wasserbad wurde das sich gebildete Natriumsalz des Dihydroorsellinsäureesters mit verdünnter Schwefelsäure zersetzt und der freie Ester isoliert.

Dibromorsellinsäureäthylester: 3,3 g Dihydroorsellinsäureester ergab nach Bromieren mit 8 g Br_2 Dibromorsellinsäureäthylester [14], der sich als kristalliner Brei abscheidete.

Orsellinsäureäthylester: 1,5 g markierter Dibromorsellinsäureäthylester wurde in 25 ml 2 N Natronlauge gelöst und nach Zusatz von 2 g nach Busch und Stöve bereitetem Katalysator (Palladium auf Calciumkarbonat) hydriert. Der gebildete Orsellinsäureäthylester wurde dann nach Filtrieren des Katalysators durch Ansäuern der Lösung ausgefällt und isoliert.

Orsellinsäure: Ein Teil des Esters der Osellinsäure wurde in 10 %-iger NaOH-Lösung bei Zimmertemperatur verseift und zwar während 10 Tagen. (Ausbeute: 250 mg markierte Orsellinsäure.)

Lokalisieren der Markierung in der synthetisierten Orsellinsäure: Bei der Kondensation des Krotonsäureäthylesters mit dem markierten Acetessigester zu Dihydroorsellinsäureäthylester is ausser dem in der Literatur beschriebenen Weg der Kondensation theoretisch ein weiterer möglich. Um diese Möglichkeiten zu untersuchen, wurde ein Teil der synthetischen Orsellinsäure nach van Slyke-Folch oxydiert und ein anderer zu Orcinol dekarboxyliert.

Tabelle 2. ^{14}C-Verteilung in der synthetisierten Orsellinsäure.

Material (1)	Anzahl der Kohlenatome von der (2) Orsellinsäure	Totale Radioaktivität des Materiales in Imp./Min. (3)
Orsellinsäure Oxydation nach van Slyke-Folch	8	138 480
Dekarboxylierung	1	66 900

Aus den erhaltenen Werten geht hervor, dass sich genau die Hälfte der Radioaktivität in der Karboxylgruppe befindet, welches somit die Alternative (1) der Kondensation zu Dihydroorsellinsäureäthylester bestätigt.

3). Zugabe der Orsellinsäure

Zu zwei Fernbachkolben mit 14 Tagen alten Kulturen von *Penicillium barnense* (in jedem Kolben 500 ml Czapek-Dox-Lösung) wurden je 100 mg markierte Orsellinsäure gegeben. Von einem Kolben wurde zuerst das alte Medium aufgesaugt und dann die Orsellinsäure, in 500 ml frischer Czapek-Dox-Lösung gelöst, vorsichtig unter den Myzelienteppich hineinpippetiert. Der pH-Wert der SCD-Lösung war vorher mit Natronlauge auf den Wert des alten Mediums (pH = 7,5) gebracht worden. Ausserdem wurde 1 ml abs.

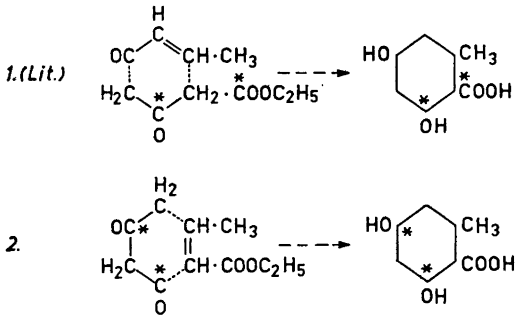

Abb. 2. Die zwei theoretisch möglichen Wege der Kondensation von Krotonsäureäthylester mit Acetessigester.

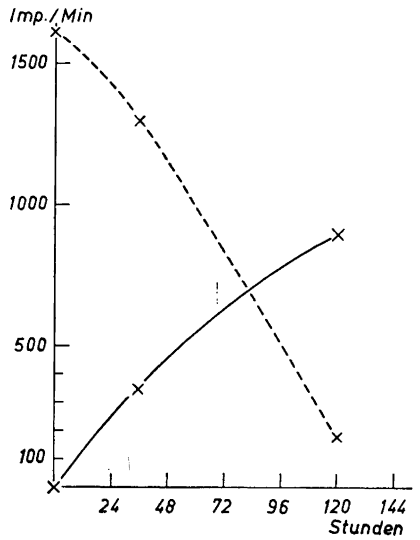

Abb. 3. Veränderung der Menge radioaktiver Orsellinsäure im Verhältnis zur Menge radioaktiver Penicillinsäure mit der Zeit. Da die zugesetzte Orsellinsäure im Gegensatz zur isolierten Penicillinsäure eine doppelte Markierung hat, sind die erhaltenen radioaktiven Werte der Orsellinsäure um die Hälfte reduziert worden, um eine direkte Vergleichsmöglichkeit zu haben.

Alkohol hinzugegeben, um die Orsellinsäure in Lösung zu bringen. In dem anderen Kolben wurde die auch hier in 1 ml abs. Alkohol gelöste Säure direkt in das alte Medium pippetiert. Es zeigte sich allerdings später im wesentlichen kein Unterschied im Produktionsbild der beiden Kulturen, weshalb in der Fortsetzung hierauf nicht mehr eingegangen wird. In einem Vorversuch war zunächst einmal gezeigt worden, dass die zugesetzte Orsellinsäure vom Organismus metabolisiert wurde. Weiterhin hatte sich ergeben, dass 6 Tage nach dem Zusatz in der Fettfraktion des Myzeliums fast keine Radioaktivität zu finden war, also keine schnelle Degradierung der Säure zu C_2-Einheiten. Um nun das eventuelle Auftreten radioaktiver Penicillinsäure zu verfolgen, wurden in gewissen Zeitabständen 25 ml-Fraktionen aus dem Medium genommen, angesäuert, mit Äther extrahiert und chromatographiert. (Lösungsmittelsystem: Benzol-Ameisensäure [9]. R_F: Orsellinsäure 0,02. R_F: Penicillinsäure 0,40.) Die Radioaktivität wurde direkt auf dem chromatographierten Papierstreifen (Whatman 3 MM) gemessen.

4). Isolierung und Degradation der Penicillinsäure.

6 Tage nach Zusatz der Orsellinsäure wurde aus dem Medium durch Ansäuern mit Salzsäure die Penicillinsäure mit Äthyläther extrahiert. Nach Zugabe von nicht radioaktiver Penicillinsäure konnte aus dem braunen Extrakt nach mehrfachem Umkristallisieren aus Benzol 550 mg chromatographisch reine Penicillinsäure von konstanter Aktivität isoliert werden.

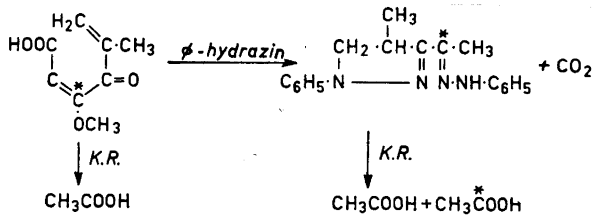

Abb. 4. Vereinfachtes Degradationsschema der isolierten Penicillinsäure.

Van Slyke-Folch-Oxydation der Penicillinsäure: 5 mg der reinen Penicillinsäure wurde nach der Methode von van Slyke-Folch oxydiert und das dabei gebildete Kohlendioxyd in eine karbonatfreie Bariumhydroxydlösung gebracht.

Kuhn-Roth-Oxydation der Penicillinsäure: 33 mg Penicillinsäure wurden oxydiert und das dabei gleichzeitig gebildete Kohlendioxyd als Bariumkarbonat isoliert. Die erhaltene Essigsäure wurde nach van Slyke-Folch totalverbrannt.

Darstellung und Degradation von 3-Acetyl-4:5-dihydro-4-methyl-1-phenylpyrazol Phenylhydrazon: 500 mg Penicillinsäure wurden zusammen mit 500 mg wasserfreiem

Tabelle 3. ^{14}C-Verteilung in der Penicillinsäure.

Material (1)	Anzahl C-Atome (2)	Radioaktivität in Imp/Min (3)	Totale Radioaktivität des Materiales in Imp/Min (4)
van Slyke-Folch-Oxydation der Penicillinsäure	8	221	1 768
van Slyke-Folch-Oxydation der durch Kuhn-Roth-Oxydation von Penicillinsäure erhaltenen Essigsäure	2	42	84
van Slyke-Folch Oxydation des Phenylhydrazones	18	95	1 710
Das bei der Phenylhyd. behandlung freigemachte CO_2	1	72	72
Kuhn-Roth-Oxydation des Phenylhydrazones, Karboxylgruppe der Essigsäure *	2	857	1 714
Kuhn-Roth-Oxydation des Phenylhydrazones, Methylgruppe der Essigsäure	2	0	0

* Da die durch Kuhn-Roth-Oxydation des Phenylhydrazones erhaltene Essigsäure zur Hälfte aus nicht radioaktiver Essigsäure (siehe Kuhn-Roth-Oxidation der Penicillinsäure) besteht, muss der erhaltene Wert von 857 Imp/Min für die totale Radioaktivität verdoppelt werden = 1 714 Imp/Min.

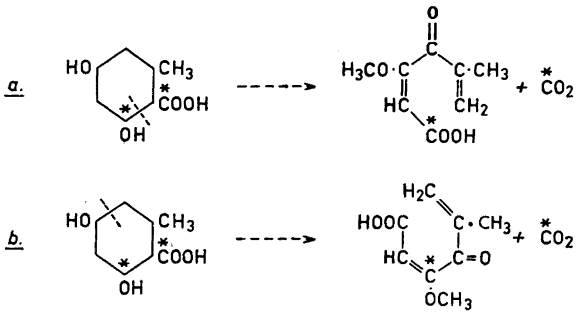

Abb. 5. Die zwei theoretisch möglichen Wege einer Ringspaltung der Orsellinsäure zu Penicillinsäure.

Natriumacetat in 3 ml Wasser durch Erwärmen gelöst. 0,41 ml Eisessig und 0,69 ml Phenylhydrazin wurden zugesetzt und das sich dabei bildende Kohlendioxyd in Baryt aufgefangen. Nach etwa einer Stunde wurde die wässrige Lösung abdekantiert und die zurückbleibende gelbe Masse aus abs. Äthylalkohol umkristallisiert. (Ausbeute: 100 mg Phenylhydrazon. Schmelzp. 176°C.)

5 mg des gebildeten Phenylhydrazones wurden nach van Slyke-Folch oxydiert und als Bariumkarbonat isoliert.

85 mg des Phenylhydrazones wurden oxydiert (Kuhn-Roth) und die Essigsäure isoliert.

Die erhaltene Essigsäure wurde dann nach Schmidt dekarboxyliert und die Karboxylgruppe als Bariumkarbonat isoliert. Das sich dabei gleichzeitig gebildete Methylamin wurde mit Stickstoff in eine 0,1 N Salzsäurelösung gebracht, eingedunstet und nach van Slyke-Folch oxidiert.

RESULTATE UND DISKUSSION

Tabelle 1 zeigt, dass die Biosynthese der Orsellinsäure *via* einer head-to-tail-Kupplung von Acetat vorsichgeht. Dies war schon vor Beginn der Versuche mit $CH_3{}^{14}CO^{18}ONa$ gezeigt worden.[8] Aus den erhaltenen Werten in Tabelle 3 geht hervor, dass die aromatische Verbindung Orsellinsäure Precursor der heterocyklischen Verbindung Penicillinsäure ist. Ausserdem ist gezeigt worden, dass von den beiden theoretisch möglichen Wegen einer Ringspaltung, der letztere Gültigkeit hat. [b.]

Die Ringspaltung der Orsellinsäure scheint durch einen hydrolytischen Vorgang vorsichzugehen. Ähnliches lässt sich auch für den Übergang 6-Methylsalicylsäure-Patulin vermuten. Versuche in Gegenwart von $H_2{}^{18}O$ könnten hierüber Auskunft geben. Auch die Präparation zellfreier Enzymextrakte kann Aufschluss über die einzelnen Schritte bei der Umwandlung der Orsellinsäure zu Penicillinsäure geben. Versuche in dieser Richtung sind im Gang.

Aus Tabelle 3 ist auch ersichtlich, dass sich in zwei weiteren Kohlenatomen der Penicillinsäure eine, allerdings schwache (knapp 5 % der totalen), Radioaktivität befindet. Diese Kohlenatome entsprechen genau dennen, die bei der Biosynthese der Penicillinsäure in Gegenwart von $CH_3{}^{14}COONa$ markiert werden.[3] Der Gedanke liegt somit nahe, dass hier ein geringer Teil der zuge-

setzten spezifisch markierten Orsellinsäure zu C_2-Einheiten degradiert worden ist, die dann als markierte Essigsäure auf dem normalen Wege zur Bildung der Penicillinsäure beigetragen hat.

Aus Abbildung 4 geht hervor, wir in einem Zeitraum von 120 Stunden die Menge der radioaktiven Orsellinsäure allmählich zugunsten der Menge der radioaktiven Penicillinsäure abnimmt.

Ich möchte Herrn Prof. Gösta Ehrensvärd, der diese Arbeit angeregt hat, für sein gezeigtes Interesse herzlich danken. Auch Herrn Dr. Sten Gatenbeck danke ich vielmals für wertvolle Diskussionen, sowie Herrn Dr. Martin Tveit.

Phase Analysis Studies on the Vanadium — Oxygen System within the $VO_{0.25}$—$VO_{1.5}$ Region at 800° C

SVEN WESTMAN and CLAES NORDMARK

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The lower vanadium oxides existing at 800° have been investigated by X-ray methods. Powder diffraction data are given for the two phases $VO_{0.53}$ and $VO_{1.27}$. The homogeneity range and lattice occupancy of the VO phase have been established.

The phase relations of the vanadium-oxygen system have been studied by several investigators, using various methods. The results may be summarized as follows. The solubility limit for oxygen in b.c.c. vanadium (α phase) was found, by Tucker, Seybolt and Sumsion [1], to be 3.2 at. % ($VO_{0.033}$). Rostoker and Yamamoto [2] found this to be valid only above 900°C, the solubility decreasing at lower temperatures.

The tetragonal β phase, "V_4O", obtained by Seybolt and Sumsion [3] was shown to be homogeneous between 15 and 21.8 at. % O (*i.e.* $VO_{0.17}$—$VO_{0.28}$). This was confirmed by Schönberg [4] and by Rostoker and Yamamoto [2].

Klemm and Grimm [5] found X-ray diffractograms of $VO_{0.3}$ to contain weak reflexions in addition to those given by the tetragonal phase. They ascribed this to a continuous deformation of the tetragonal lattice. From metallographic evidence, Rostoker and Yamamoto [2] postulated the existence of a δ phase which they thought to be V_2O. The phase was, however, never obtained in a pure state. The authors gave a tentative indexing of the X-ray pattern of the δ oxide, assuming a hexagonal unit cell.

The homogeneity range of the "VO" phase, which has a structure of the sodium chloride type [6], was found, by Schönberg [4] and Andersson [7], to extend from $VO_{0.80}$ to $VO_{1.20}$ at 900°C. Schönberg [4] assumed the vanadium lattice to be only partly occupied by atoms above the composition $VO_{1.0}$.

The existence of an "X phase" ($VO_{\sim 1.3}$) proposed by Klemm and Grimm [5] has not been confirmed by subsequent work.

The corundum structure of the sesquioxide was established by Goldschmidt *et al.*[8]

Phase analyses by Andersson [7] and Aebi [9] cover the higher vanadium oxides.

In connection with a wider research programme covering the oxide chemistry of several transition metals, a reinvestigation of the lower vanadium oxides was thought desirable, considering the rather incomplete evidence reviewed above.

EXPERIMENTAL

The starting materials for the preparations were vanadium metal (Fairmount Chemical Co. 99.7 % pure) and vanadium pentoxide (LKB-produkter, reagent grade). Vanadium sesquioxide was obtained by reduction of vanadium pentoxide with hydrogen [10].

Preparations of vanadium oxides with compositions between $VO_{0.25}$ – $VO_{1.5}$ were obtained by melting pressed pellets consisting of weighed amounts of vanadium metal and vanadium sesquioxide in an argon atmosphere by means of an electric arc furnace [11]. The samples were subsequently heat-treated in sealed, evacuated silica tubes at 800°C for two weeks and then quenched in water.

The preparations were analyzed for oxygen content by dissolution in cerium(IV) sulphate solution followed by back-titration with iron(II) sulphate solution. The procedure is similar to the one described by Reuter and Siewert [12]. A weighed sample (~0.1 g) of finely divided oxide was dispersed in 10 ml of 50 % sulphuric acid and dissolved by addition of $Ce(SO_4)_2$ solution in excess, so that all the vanadium was oxidized to the vanadyl state. During the dissolution process the mixture was kept hot and the sample was ground with a glass rod. After cooling and dilution, 5 ml of concentrated phosphoric acid was added, and the small amount of vanadate formed back-titrated to the vanadyl state using ferrous ammonium sulphate solution, with diphenylamine sulphonic acid as indicator.

The phase analysis was performed by means of X-ray powder photographs taken in a Guinier focusing camera of 80 mm diameter with strictly monochromatized $CuK\alpha_1$ radiation. An aluminium foil (35 μ) covering the film served to reduce the background fogging caused by fluorescent radiation from the samples. Potassium chloride (a = 6.2919 Å at 20°C [13]) was added to the specimens as an internal standard. Details of the techniques employed in the X-ray work have been given in a previous article [14].

RESULTS

The present phase analysis has established the existence of two phases with the approximate compositions $VO_{0.53}$ and $VO_{1.27}$. The results are summarized in Fig. 1. The homogeneity range of the "VO" phase and the occupancy of its vanadium and oxygen lattices have been determined.

The "V_4O" phase appears to be homogeneous up to the composition $VO_{\sim 0.3}$. No accurate determination of the phase boundary has been made however, since the result seemed to be in fairly good agreement with previously published work.

The $VO_{0.53}$ phase (possibly V_2O) seems to have an extremely narrow range of composition. X-Ray powder data are given in Table 1. It is evident from Fig. 1 that the structure of "V_2O" represents a transition between the V_4O and the VO structures. It has not been possible so far to obtain single crystals of this phase.

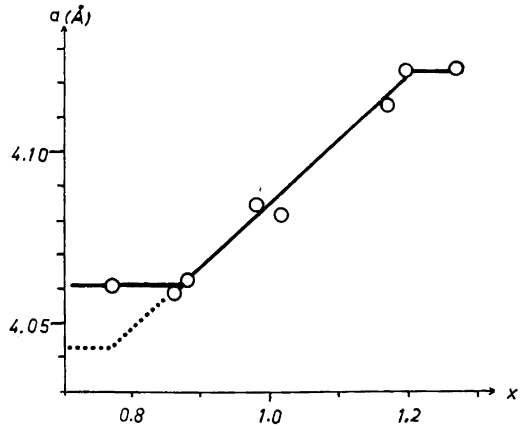

Fig. 2. Lattice parameter of VO_x (800°C).

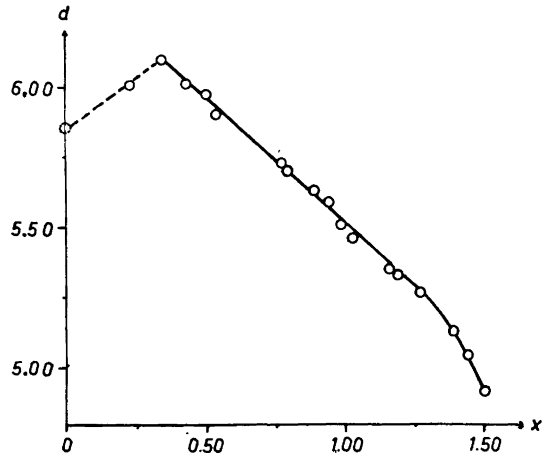

Fig. 3. Density of VO_x samples (g cm^{-3})

The cubic "VO" phase is homogeneous between the limits $VO_{0.89}$ and $VO_{1.20}$. The lattice parameter varies between $a = 4.062$ Å and $a = 4.125$ Å (Fig. 2).

Schönberg [4] found a somewhat extended homogeneity range towards lower oxygen content at 900°C (indicated by the dotted line in Fig. 2). The lattice parameter *vs.* composition curve obtained in the present investigation is, within its limits, in excellent agreement with the results of Schönberg [4] and Andersson [7].

The densities of the oxide preparations have been determined (Fig. 3) and the occupancy of the vanadium and oxygen lattices of the NaCl-type structure calculated for various compositions of the "VO" phase. The result is shown in Fig. 4.

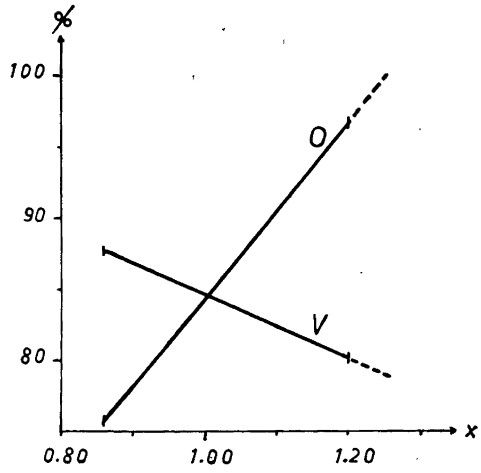

Fig. 4. Percent occupancy of atomic sites in cubic VO_x.

The upper composition limit, $VO_{1.20}$, represents an almost completely occupied oxygen lattice (96 %), whereas no similar relation defines the lower phase boundary. It is noteworthy that the boundaries of the high-temperature "TiO" phase with the same type of structure ($TiO_{0.64}$—$TiO_{1.26}$) are defined by 96 % and 98 % occupancy of the Ti and O lattices, respectively [15].

The $VO_{1.27}$ phase forms below ~ 900°C and appears to have a very narrow range of homogeneity. The X-ray powder diffractogram given in Table 2 has been indexed on the basis of single crystal data. The symmetry of the phase is body-centered tetragonal with

$$a = b = 16.623 \text{ Å} = 4 \times 4.156 \text{ Å}$$
$$c = 16.515 \text{ Å} = 4 \times 4.129 \text{ Å}$$
$$V = 4\,563 \text{ Å}^3$$

The diffraction symmetry is pseudo-cubic with reflexions $h00$, $h \neq 4n$, missing. It is shown, by single crystal as well as powder data, that the crystal structure is a superstructure of a slightly deformed VO (NaCl-type) structure.

The observed density of the phase indicates that the vanadium lattice is only partly occupied. The vacancies should, on the above evidence, be

ordered; and the number per unit cell, a multiple of four. If the cell content is assumed to be $V_{204}O_{256}$, observed and calculated values of density and composition agree rather well:

obs.	*calc*
$d = 5.269$	$d = 5.272$
$VO_{1.269}$	$VO_{1.255}$

$VO_{1.27}$ ought to be the "X phase" reported by Klemm and Grimm [5]. Crystal structure studies are in progress.

Acknowledgements. The authors wish to express their gratitude to Dr. A. Magnéli for having suggested this work and for his continuing interest in the investigation. Further, we want to thank Mr. G. Kruuse and Mr. T. Karlsson for their assistance in the preparative and analytical work.

The investigation has been sponsored by the *Office, Chief of Research and Development, U.S. Department of Army* through its European Research Office.

The Copper(II) Complexity of O-Phosphorylethanolamine

RAGNAR ÖSTERBERG

Department of Medical Biochemistry, University of Göteborg, Göteborg, Sweden

The complex formation between copper(II) and O-phosphorylethanolamine (H_2A) ions has been studied in 0.15 M KCl medium at 25° by pH titration.

By an adaption of Hedström's method [39] the concentration of free O-phosphorylethanolamine was calculated. The experimental data could be explained by formation of the complexes: $CuHA^+$, CuA, $Cu(HA)A^-$ and CuA_2^{2-}. The corresponding equilibrium constants were computed (Table 2).

Probable coordination sites involved in the complexes are suggested, and are discussed in relation to copper(II) binding of phosphoproteins and phosphatides.

As pointed out by several authors [1–5] phosphoproteins and phosphopeptides may under physiological conditions act as strong metal binders. The great metal affinity of these compounds has been partly ascribed to the presence of phosphorus [2,4,6–9], which in view of recent investigations [2,10–18] occurs mainly as monophosphate esters linked through the hydroxyl groups of serine and threonine residues *. Informations of the metal binding power of phosphoproteins and their break-down products may, thus, be obtained from studies on O-phosphorylated model compounds. Apparent stability constants of some metal complexes of O-phosphorylserine have previously been reported [20,21]. The present paper describes the copper(II) complexity of another model compound, O-phosphorylethanolamine; this ligand itself being an important metabolite existing in living tissues both in free [22–29] and combined state [28–35].

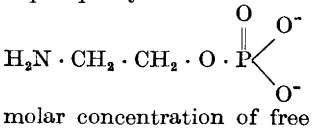
The complex formation was measured by pH titration [36–38] at 25° in 0.15 M KCl. In this case several titrations for different ligand concentrations were carried out to allow calculation of the free ligand concentration more directly from the experimental data by graphical integration (*cf.* Ref.[39]), assuming the possible presence of any set of mononuclear equilibria including hydrogen and hydroxo copper(II) complexes of the ligand. An equation required for this calculation was derived by applying the equations formulated by Hedström [39].

* Apart from the phosphomonoester bond, the occurrence of other linkages of phosphorus has been suggested for some phosphoproteins [19].

The existing complexes and corresponding overall equilibrium constants were evaluated graphically. The pK values of the ligand, determined under the same experimental conditions [40], were used in the computations.

SYMBOLS

A O-phosphorylethanolamine with all dissociable hydrogen removed,



a molar concentration of free A

b_q apparent stability constant of the complex $CuA_q^{(2-2q)+}$ defined by $b_q = [CuA_q^{(2-2q)+}]\ [CuA_{q-1}^{(4-2q)+}]^{-1}\ [Cu^{2+}]^{-1}$

b_{CuHA} apparent stability constant of the complex CuHA+, defined by $b_{CuHA} = [CuHA^+]\ [HA^-]^{-1}\ [Cu^{2+}]^{-1}$

$b_{Cu(HA)A}$ apparent stability constant of the complex $Cu(HA)A^-$, defined by $b_{Cu(HA)A} = [Cu(HA)A^-]\ [CuHA^+]^{-1}\ [A^{2-}]^{-1}$

b_{CuCl} apparent stability constant of the complex CuCl+, defined analogical to b_q

C_A total molar concentration of O-phosphorylethanolamine, defined by eqn. 5

C_{Cu} total molar concentration of copper(II) ions, defined by eqn. 4

C_H total molar concentration of hydrogen ions, defined by eqn. 6

C_{Cl} total molar concentration of chloride ions

h molar concentration of free hydrogen ions

I defined by eqn. 21

j number of protons bound in the proton complex H_jA

K_{CuHA} apparent acid ionization constant of the complex CuHA+, defined by $K_{CuHA} = h\ [CuA]\ [CuHA^+]^{-1}$

$K_{Cu(HA)A}$ apparent acid ionization constant of the complex $Cu(HA)A^-$, defined by $K_{Cu(HA)A} = h[CuA_2^{3-}]\ [Cu(HA)A^-]^{-1}$

L defined by eqn. 22

M g moles/litre

p,q,r number of HA^-, A^{2-}, OH^- groups bound in the complex $Cu(HA)_pA_q(OH)_r^{(2-p-2q-r)+}$, respectively

R defined by eqn. 9

S defined by eqn. 10

Z ligand number, defined by eqn. 8

β_2 apparent complexity constant, $= b_1 b_2$

$\beta_{Cu(HA)A}$ apparent complexity constant, $= b_{CuHA} b_{Cu(HA)A}$

$\varkappa_{1,1p,0q,r}$ apparent overall equilibrium constant defined by eqn. 2

$\varkappa_{j1}$ apparent complexity constant defined by eqn. 3

φ defined on page 478

[ ] molar concentration of the species indicated

MATERIALS

O-Phosphorylethanolamine, prepared according to Baer and Stancer [41], was a generous gift from Ing. G. Fölsch of this institute. The data of analysis for the present preparation are to be found in Ref.[40] Aqueous stock solutions of this compound were standardized by potentiometric titrations. When not used, these solutions had to be kept frozen in order to obtain satisfactory reproducibility.

Aqueous stock solutions of copper(II) chloride were prepared from the British Drug Houses Ltd. (A.R.) product and was standardized by an ion exchange method [42].

Carbonate-free 0.2557 M KOH, containing 0.15 M KCl was prepared and standardized as before [17].

The other reagents used in this work were of analytical grade and were not purified further. Tripple distilled water and weighed-in pipettes were used throughout.

METHOD

The quantities, h and C_H, were varied at each pH titration, while C_{Cu} and C_A were held practically constant. This was carried out by successive delivering KOH to the titration solution, recording pH after each addition. As recording instrument a Radiometer PHM 3j valve potentiometer, equipped with a Radiometer glass electrode G 102 B, and a calomel electrode K 100 was used. The activity coefficients were assumed to be constant in the presence of 0.15 M KCl. All measurements were carried out at 25.00 ± 0.03°.

The pH meter was standardized with 0.05 M potassium biphthalate and 0.05 M borax as recommended by Hitchock *et al* [43]. The pH meter readings were transformed to values of $-\log h$ by a calculated activity coefficient [40] being 0.79 ± 0.02. It was thought to apply in the pH range, 4—7, involved in the computations below. For routine calibration of the entire measuring system, acetic acid titrations were used, *cf.* Ref.[40], the deviations never exceeding 0.01 pH units.

Assuming O-phosphorylethanolamine only to interact with copper(II) ions, when both protons are removed from the phosphoryl group, *i.e.* as HA^- and A^{2-}, the complex equilibria can be written

$$Cu^{2+} + pH^+ + (p+q)A^{2-} + rH_2O \rightleftharpoons Cu(HA)_pA_q(OH)_r^{(2-p-2q-r)+} + rH^+ \quad (1)$$

$$(p = 0,1,2,...;\ q = 0,1,2,...;\ r = 0,1,2,...;\ p+q+r = 1,2,3,...;)$$

Since H_2O is approximately constant, the system is defined by the overall equilibrium constants * (all charges omitted in the following for the sake of clarity):

$$\varkappa_{1,1p,0q,r} = \frac{[Cu(HA)_pA_q(OH)_r]}{[Cu]\ h^{p-r}\ a^{p+q}} \quad (2)$$

The quantities p,q, and r may attain any integer values given above, restricted by $(p+q+r)_{max}$, which is equal to the maximum coordination number of copper(II). Occurrence of polynuclear complexes was assumed to be negligible with the use of low values for C_A and C_{Cu}, with C_A in excess of C_{Cu}.

Analogously to eqn. 2, constants for the formation of proton complexes are defined

$$\varkappa_{j1} = \frac{[H_jA]}{h^j\ a} \qquad (j = 1,2,3) \quad (3)$$

The values of these constants, used in this work, have been re-calculated from the pK values reported earlier [40].

Due to presence of bulk electrolyte (0.15 M KCl), the species $CuCl^+$ has also to be considered. The total content of copper(II), ligand and dissociable hydrogen will thus be given by (*cf.* Ref.[38])

* The notation of these constants is simplified, when only one or two complex forming groups are bound to the central metal ion. Thus will, *e.g.*, the constants corresponding to $CuOH^+$ and CuA be written $\varkappa_{1,1}$ and $\varkappa_{1,01}$, respectively.

$$C_{Cu} = [Cu](1 + \sum \varkappa_{1,1p,0q,r} h^{p-r} a^{p+q} + b_{CuCl}[Cl]) \quad (4)$$

$$C_A = a + \sum (p+q)\varkappa_{1,1p,0q,r}[Cu]h^{p-r}a^{p+q} + \sum \varkappa_{j1} h^j a \quad (5)$$

$$C_H = h - [OH] + \sum (p-r)\varkappa_{1,1p,0q,r}[Cu]h^{p-r}a^{p+q} + \sum j\varkappa_{j1} h^j a \quad (6)$$

The summations have been carried out in respect of all stated values of p,q and r. The value of C_H for each point of titration may be calculated from

$$C_H = 2C_A - [KOH] \quad (7)$$

The figure $b_{CuCl}[Cl]$ in eqn. 4 will be constant as $[Cl] \approx C_{Cl} = 0.15$, and $[OH]$ in eqn. 6 negligible in the $-\log h$ range involved.

From eqns. 4 and 5 we obtain the ligand number defined thus (*cf.* Ref.[38])

$$Z = \frac{C_A - a - \sum \varkappa_{j1} h^j a}{C_{Cu}} = \frac{\sum (p+q)\varkappa_{1,1p,0q,r} h^{p-r} a^{p+q}}{1 + \sum \varkappa_{1,1p,0q,r} h^{p-r} a^{p+q} + b_{CuCl}[Cl]} \quad (8)$$

It follows from eqn. 8 that the constants $\varkappa_{1,1p,0q,r}$ can be determined, if Z is known as a function of h and a. As Z is given by eqn. 8, if h and a are known, we have, thus, first to compute a. This computation as well as the evaluation of p,q,r and $\varkappa_{1,1p,0q,r}$ will be described after the following section.

MEASUREMENTS

Solutions for titration of metal complexes were prepared by pipetting stock solutions of O-phosphorylethanolamine, copper(II) chloride, potassium chloride and aq. dest. in order to obtain the initial concentrations C_A, C_{Cu} and 0.15 M KCl. The titrations were continued to pH 10.5. All titration equipment was the same as that described [17]. The content (initially 10 ml) of the titration vessel was stirred and freed from carbon dioxide by bubbling nitrogen, pretreated as previously [17].

Five titrations with different C_A were carried out in this manner covering the concentration ranges $C_A = (0.8-3) \times 10^{-3}$, $C_H = (0.8-6) \times 10^{-3}$ and $C_{Cu} = 7.8 \times 10^{-4}$. Each titration could be reproduced within 0.01 in pH. The data used for the calculations below constituted a mean of at least two titrations.

At $-\log \approx 6.3$ the measuring solutions grew slightly opalescent, developing into a greenish-blue precipitate at $-\log h \approx 7$. Semi-quantitative analysis of the washed and dried precipitate, isolated from a solution of pH 7.8, showed the presence of about 4 % N and 16 % P. This apparently indicates the precipitate to be a copper(II)-O-phosphorylethanolamine compound. Due to this sparing solubility of the present system above $-\log h \approx 6.3$, the computations were not extended further than up to $-\log h = 6.10$.

The results of the measurements are shown in Fig. 1, where the titrations are represented as $-\log h(C_H)c_A$ curves.

DETERMINATION OF THE FREE O-PHOSPHORYLETHANOLAMINE CONCENTRATION

No true indications about the kind of complexes formed could be obtained from usual titration curves (as for example in the Cu(II)-O-phosphorylserine

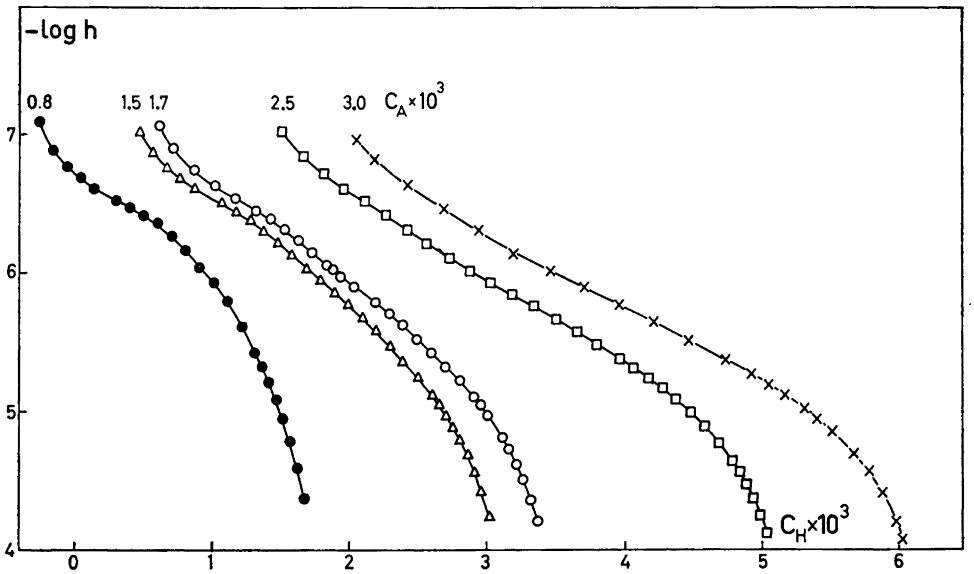


Fig. 1. The potentiometric measurements. $-\log h$ as a function of the total concentration of hydrogen ions, C_H (obtained from eqn. 7), for different total O-phosphorylethanolamine concentration, C_A.

system [21]). The free ligand concentration was therefore computed without any special assumptions about the complexes formed. For this purpose Hedström's method [39] was made applicable to measurements and equilibria of the present type.

We define the functions R and S

$$R = \sum \varkappa_{j1} h^j a = \sum [H_jA] \tag{9}$$

$$S = \sum \varkappa_{1,1p,0q,r} h^{p-r} a^{p+q} \tag{10}$$

Partial differentiation of R with respect to $\ln h$, followed by partial differentiation with respect to $\ln a$, results in

$$\left(\frac{\partial R}{\partial \ln h}\right)_a = \sum j \varkappa_{j1} h^j a \tag{11}$$

$$\left(\frac{\partial^2 R}{\partial \ln h \, \partial \ln a}\right) = \sum j \varkappa_{j1} h^j a = \left(\frac{\partial R}{\partial \ln h}\right)_a \tag{12}$$

Partial differentiation of S with respect to $\ln h$ and $\ln a$, followed by partial differentiation with respect to $\ln a$ and $\ln h$, gives

$$\left(\frac{\partial S}{\partial \ln h}\right)_a = \sum (p-r) \varkappa_{1,1p,0q,r} h^{p-r} a^{p+q} \tag{13}$$

$$\left(\frac{\partial S}{\partial \ln a}\right)_h = \sum (p+q)\varkappa_{1,1p,0q,r} h^{p-r} a^{p+q} \tag{14}$$

$$\left(\frac{\partial^2 S}{\partial \ln h\ \partial \ln a}\right) = \left(\frac{\partial^2 S}{\partial \ln a\ \partial \ln h}\right) = \sum (p-r)(p+q)\varkappa_{1,1p,0q,r} h^{p-r} a^{p+q} \tag{15}$$

We may eliminate [Cu] from eqns. 5 and 6 by extension of the expression in those equations, containing [Cu] with C_{Cu}. By substituting eqns. 9—11 and 13—14 into the resulting equations, followed by partial differentiation with respect to ln$h$ and ln$a$, respectively, we obtain

$$\left(\frac{\partial C_A}{\partial \ln h}\right)_a = C_{Cu}\left[\frac{(1 + S + b_{CuCl}[Cl])\left(\frac{\partial^2 S}{\partial \ln a\ \partial \ln h}\right) - \left(\frac{\partial S}{\partial \ln a}\right)_h\left(\frac{\partial S}{\partial \ln h}\right)_a}{(1 + S + b_{CuCl}[Cl])^2}\right] + \left(\frac{\partial R}{\partial \ln h}\right)_a \tag{16}$$

$$\left(\frac{\partial C_H}{\partial \ln a}\right)_h = C_{Cu}\left[\frac{(1 + S + b_{CuCl}[Cl])\left(\frac{\partial^2 S}{\partial \ln h\ \partial \ln h}\right) - \left(\frac{\partial S}{\partial \ln h}\right)_a\left(\frac{\partial S}{\partial \ln a}\right)_h}{(1 + S + b_{CuCl}[Cl])^2}\right] + \left(\frac{\partial^2 R}{\partial \ln h\ \partial \ln a}\right) \tag{17}$$

From eqns. 12 and 15 follows that the right hand sides of eqns. 16 and 17 are identical. Consequently

$$\left(\frac{\partial C_A}{\partial \ln h}\right)_a = \left(\frac{\partial C_H}{\partial \ln a}\right)_h \tag{18}$$

This equation may be transformed [39] to

$$\left(\frac{\partial \ln a}{\partial \ln h}\right)_{C_A} = -\left(\frac{\partial C_H}{\partial C_A}\right)_h \tag{19}$$

Solving for $-\log a$ within the range $-\log h_0$ to $-\log h$ results in

$$-\log a = -\left[\int_{-\log h_0}^{-\log h} \left(\frac{\partial C_H}{\partial C_A}\right)_h \mathrm{d}(-\log h)\right]_{C_A} + (-\log a_0) \tag{20}$$

From eqn. 20 values of $-\log a_0/a$ were determined by graphical integration [39]. The $-\log h(C_H)_{C_A}$ curves of Fig. 1 were thus cut for constant $-\log h$, and C_H drawn against C_A (Fig. 2a). The quantity $\left(\frac{\partial C_H}{\partial C_A}\right)_h$ was determined, and plotted against $-\log h$ (Fig. 2b). The area under the resulting curve from $-\log h = -\log h_0$ to $-\log h$ gave then $-\log a_0/a$. After the calculation of a_0 from

$$a_0 = C_A/(1 + \varkappa_{11} h + \varkappa_{21} h^2) \tag{5a}$$

at a $-\log h$ value ($= -\log h_0$), where no complex formation could be detected, the corresponding a values were obtained. The a values, determined in this manner, are listed in Table 1. For each a value determined the corresponding Z value was calculated; the result has been compiled in the same table.

In spite the graphical integration method [39] by Hedström usually requires many values for the known variables, the rather few C_A values of this study, seem sufficient, due to the constancy of $\left(\frac{\partial C_H}{\partial C_A}\right)_h$ in the C_A range involved (Fig. 2a).

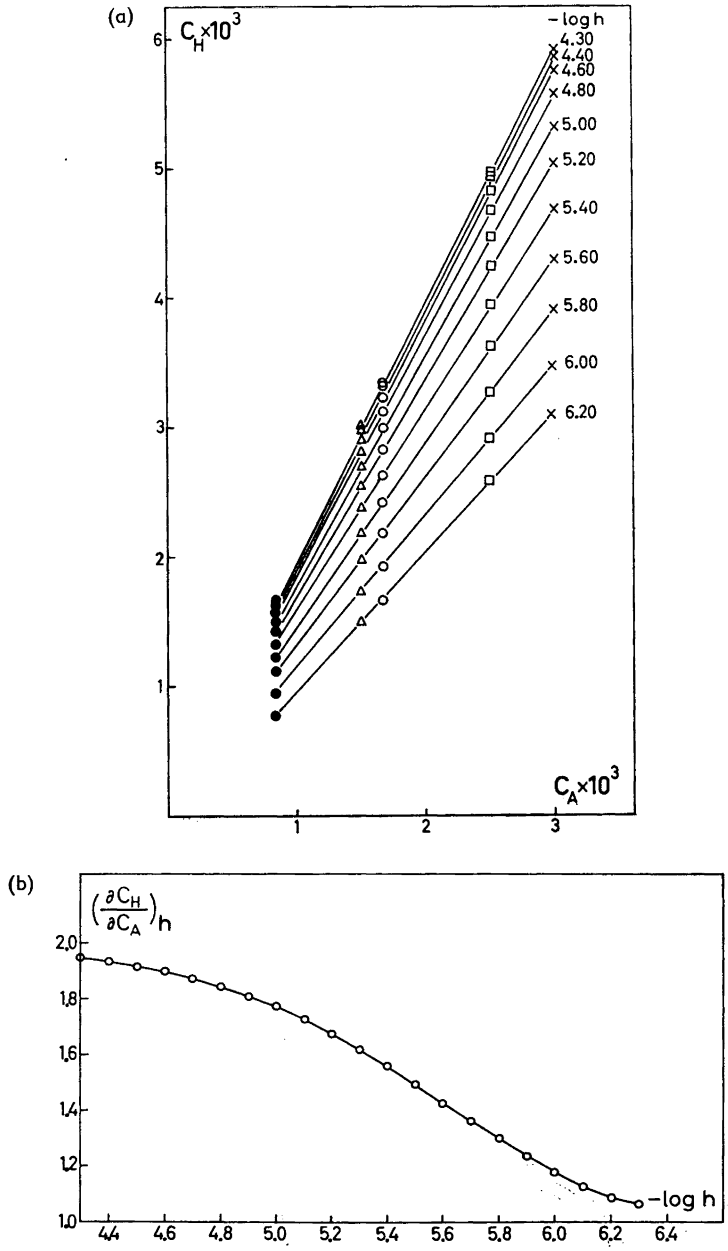

Fig. 2. Evaluation of the free O-phosphorylethanolamine concentration. (a). C_H *vs.* C_A for different $-\log h$. (b). $\left(\frac{\partial C_H}{\partial C_A}\right)_h$ *vs.* $-\log h$ for $C_A = (0.8-3) \times 10^{-3}$.

EVALUATION OF THE EQUILIBRIUM CONSTANTS

As can be seen from Table 1 all values of Z are below 1. To include all possibly existing complexes, $(p+q)_{max}$ was therefore in the first place assumed to equal 2. For $p = q = 0$, r was assigned to 1, but otherwise r was set equal to zero. Eqn. 8 will thus be reduced to

$$\frac{Z}{(1-Z)a}\varphi = \varkappa_{1,11}h + \varkappa_{1,01} + \frac{(2-Z)a}{(1-Z)}(\varkappa_{1,12}h^2 + \varkappa_{1,11,01}h + \varkappa_{1,02}) \qquad (8a)$$

where $\varphi = 1 + \varkappa_{1,1}h^{-1} + b_{CuCl}[Cl]$

Since the term $b_{CuCl}[Cl]$ is approximately constant in this study (*cf.* p. 474), the expression φ in eqn. 8a will be constant for constant h. Varying values of $\varkappa_{1,1}$ in this expression are reported in the literature [44]. In the present study use will therefore be made of a range of values from $10^{-7.5}$ to $10^{-8.25}$ M. From these values follow that the amount of $CuOH^+$ will be rather negligible in the present $-\log h$ range.

To identify complexes formed, $Z(1-Z)^{-1}a^{-1}$ was first plotted against h (Fig. 3). In this plot of eqn. 8a the presence of $CuHA^+$ and CuA only should give a straight line independant of C_A; existing $CuHA^+$ species making the ordinata values to decrease with h. At the occurrence of higher complexes, *i.e.* $(p+q)>1$, the plotted data should vary with C_A. As the latter case applies to Fig. 3, we may identify the higher complexes apparently present.

In Fig. 4 the quantity $Z(1-Z)^{-1}a^{-1}$ has therefore been plotted against $(2-Z)a(1-Z)^{-1}$ for constant h. As shown in the figure data are best represented by a serie of straight lines, indicating the true value of $(p+q)_{max}$ to be 2. Conse-

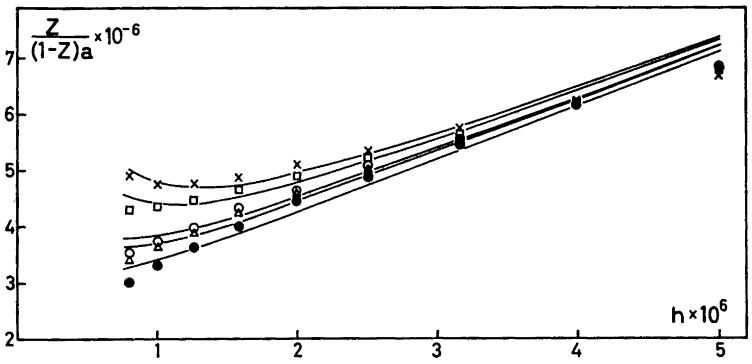

Fig. 3. $Z(1\text{-}Z)^{-1}a^{-1}$ *vs.* h for different C_A (eqn. 8 a). The curves are calculated for $\varkappa_{1,11} = 1.1 \times 10^{12}$ M^{-2}, $\varkappa_{1,01} = 2.45 \times 10^{6}$ M^{-1}, $\varkappa_{1,11,01} = 2.3 \times 10^{18}$ M^{-3}, $\varkappa_{1,02} = 2.45 \times 10^{12}$ M^{-2}; $\varkappa_{1,1} = 10^{-7.73}$M, $b_{CuCl} = 1.0$ M^{-1}. The symbols of the plotted points are those indicated in Table 1.

quently we may consider the probable existence of $Cu(HA)_2$, $Cu(HA)A^-$ and CuA_2^{2-} apart from $CuHA^+$ and CuA. In Fig. 4 there is, however, a slight upward trend for increasing C_A at high $-\log h$. For this reason the plotted points corresponding to $C_A > 2.52 \times 10^{-3}$ and $-\log h > 6.0$ were excluded at the calculation of slopes and intercepts of the straight lines.

From these intercepts (I) and slopes (L) the following functions were formed:

$$I\varphi = \varkappa_{1,11}h + \varkappa_{1,01} \tag{21}$$

$$L\varphi = \varkappa_{1,12}h^2 + \varkappa_{1,11,01}h + \varkappa_{1,02} \tag{22}$$

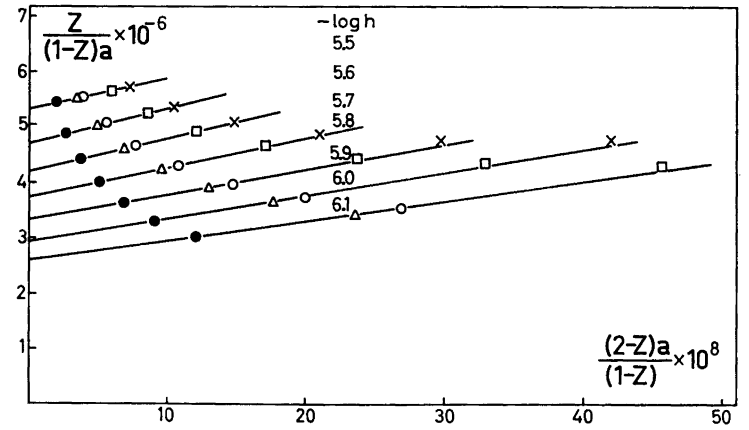

Fig. 4. $Z(1\text{-}Z)^{-1}a^{-1}$ as a function of $(2\text{-}Z)a(1\text{-}Z)^{-1}$ with h as parameter (eqn. 8a). The symbols are the same as indicated in Table 1.

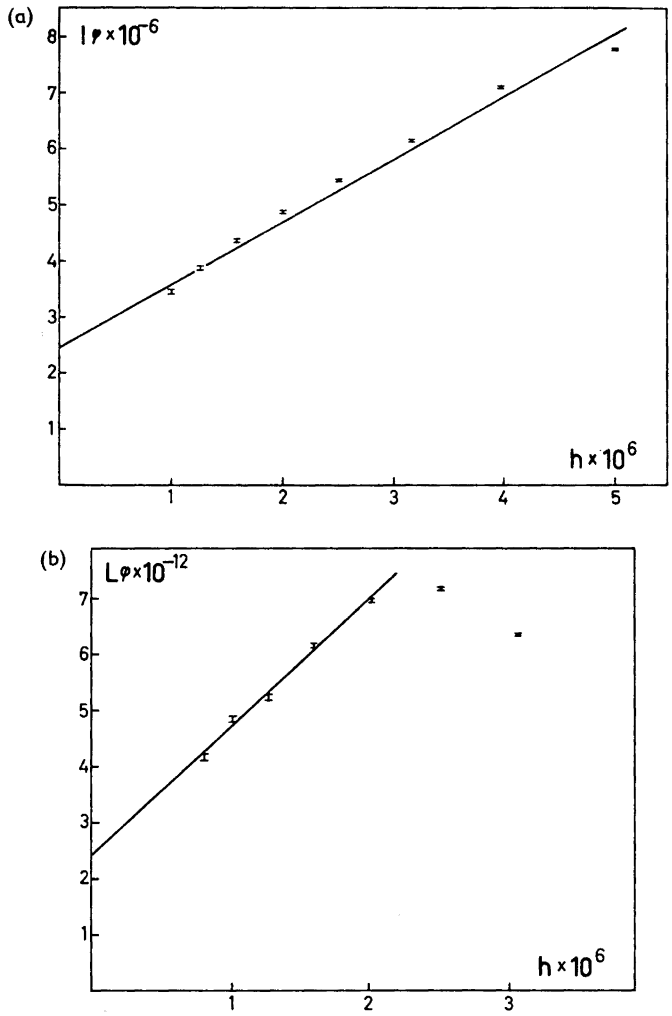

Fig. 5. Graphical evaluation of the overall equilibrium constants, assuming $\varkappa_{1,1} = 10^{-7.73}$M (indicated range $10^{-7.5}$ — $10^{-8.25}$ M) and $b_{CuCl} = 1.0$ M^{-1}.
(a) Eqn. 21 plotted as $I\varphi$ *vs.* h.
(b) Eqn. 22 plotted as $L\varphi$ *vs.* h.

In Fig. 5a, eqn. 21 is plotted as the curve $I\varphi(h)$. For each h-value the above-mentioned range of $\varkappa_{1,1}$ is indicated (mean value $10^{-7.73}$ M). The constant b_{CuCl} was set equal to 1.0 M^{-1} (Ref.[44]). As shown in the figure, data can be fitted to a straight line with finite slope and intercept. The species $CuHA^+$ and CuA are thus obviously existing. The intercept ($\varkappa_{1,01}$) and the slope ($\varkappa_{1,11}$) of the best straight line furnished the equilibrium constants:

$$\varkappa_{1,01} = (2.45 \pm 0.2) \times 10^6\ \mathrm{M}^{-1}$$
$$\varkappa_{1,11} = (1.1 \pm 0.2) \times 10^{12}\ \mathrm{M}^{-2}$$

In a similar manner $L\varphi$ has been plotted against h in Fig. 5b. Even in this case, data can be fitted to a straight line, which may provide evidence of existence of the species $Cu(HA)A^-$ and CuA_2^{2-}. Formation of $Cu(HA)_2$, in measurable quantities can reasonable be ruled out. In the present plot data should then have been represented as a parabola with its vertex downwards. The values of equilibrium constants related to $Cu(HA)A^-$ and CuA_2^{2-} were computed from the best straight line to be:

$$\varkappa_{1,02} = (2.45 \pm 0.2) \times 10^{12}\ \mathrm{M}^{-2}$$
$$\varkappa_{1,11,01} = (2.3 \pm 0.2) \times 10^{18}\ \mathrm{M}^{-3}$$

The logarithms of the computed overall equilibrium constants, $\varkappa_{1,1p,0q,r}$, were converted into logarithms of apparent stability constants and apparent complexity constants of the complexes, as well as into pK values of the hydrogen copper(II) complexes. This is evident from Table 2, where all these constants are given in logarithmic form.

DISCUSSION

As can be seen in Fig. 3, the curves calculated from the computed constants reasonably agree with the plotted data. As expected the deviations are most apparent at high h, as the pH decrements due to complex formation are least pronounced there.

The complexes evaluated as formed in this study, *i. e.* $CuHA^+$, CuA, $Cu(HA)A^-$ and CuA_2^{2-}, may not exclude the existence of other complexes for true, and at least some other possibilities may therefore be discussed.

An indication of the existence of complexes with more than two O-phosphorylethanolamine groups per central ion, thus, seems to be the upward trend of the curves of Fig. 4 at high $-\log h$. This trend is, however, too slight to allow any accurate proof of the existence of such species.

In the present computations, only a hydroxo complex $CuOH^+$ was considered, which apparently is the only inorganic hydroxo species formed in the present concentration ranges [44]. Other monohydroxo complexes, *i. e.* in the first place Cu(HA)OH and $CuA(OH)^-$, would at $-\log h = 6.1$ (the upper limit of $-\log h$ used in this work) apparently constitute less than 5 % of the corresponding species $CuHA^+$ and CuA, *cf.* Ref.[45]. These hydroxo complexes, consequently, cannot appreciably change the proposed reaction scheme. This is also evident from the curves of Figs. 3 and 5a, as the occurrence of a large amount of $CuA(OH)^-$ would have been indicated as an upward trend for decreasing h. The right hand side of eqn. 8a should then include the figure $\varkappa_{1,01,1}h^{-1}$. The presence of Cu(HA)OH on the other hand, cannot be excluded, as these measurements do not distinguish this complex from CuA.

The apparent negligible amount of these mononuclear hydroxo species may exclude the existence of *ol* complexes [7,46-50]. Polynuclear complexes, where one copper(II) ion is coordinated through either the phosphoryl and amino group of the ligand, can reasonably also be excluded. In the $-\log h$ range involved the pK value of the ligand amino group ($=10.10$) does not allow for such complex formation due to the relatively low copper(II)-ammine affinity (see, *e. g.*, $\log b_1$ for the Cu(II)-ammine system [44]), *cf.* Ref.[51]

Table 2. Logarithms of $\varkappa_{1,1p,0q,r}$ constants, apparent stability constants, and apparent complexity constants of the complexes, and apparent pK values of the acid complexes in 0.15 M KCl medium at 25°.

$C_A = (0.8-3) \times 10^{-3}$, $C_{Cu} = 7.84 \times 10^{-4}$, $-\log h = 5.30-6.10$.
$\log\varkappa_{11} = 10.10$, $\log\varkappa_{21} = 15.67$, $\varkappa_{1,1} = 10^{-7.73}$M, $b_{CuCl} = 1.0$ M^{-1}

Reaction				Log. equilibrium constant	
$Cu^{2+} + H^+ + A^{2-}$	$\rightleftharpoons$	$CuHA^+$		$\log\varkappa_{1,11}$	= 12.04
$Cu^{2+} + HA^-$	$\rightleftharpoons$	$CuHA^+$	$\log \frac{\varkappa_{1,11}}{\varkappa_{11}}$	$= \log b_{CuHA}$	= 1.94
$Cu^{2+} + A^{2-}$	$\rightleftharpoons$	CuA	$\log\varkappa_{1,01}$	$= \log b_1$	= 6.39
$Cu^{2+} + H^+ + 2A^{2-}$	$\rightleftharpoons$	$Cu(HA)A^-$		$\log\varkappa_{1,11,01}$	= 18.36
$Cu^{2+} + HA^- + A^{2-}$	$\rightleftharpoons$	$Cu(HA)A^-$	$\log \frac{\varkappa_{1,11,01}}{\varkappa_{11}}$	$= \log\beta_{Cu(HA)A}$	= 8.26
$CuHA^- + A^{2-}$	$\rightleftharpoons$	$Cu(HA)A^-$	$\log \frac{\varkappa_{1,11,01}}{\varkappa_{1,11}}$	$= \log b_{Cu(HA)A}$	= 6.32
$Cu^{2+} + 2A^{2-}$	$\rightleftharpoons$	CuA_2^{2-}	$\log\varkappa_{1,02}$	$= \log\beta_2$	= 12.39
$CuA + A^{2-}$	$\rightleftharpoons$	CuA_2^{2-}	$\log \frac{\varkappa_{1,02}}{\varkappa_{1,01}}$	$= \log b_2$	= 6.00
$CuHA^+$	$\rightleftharpoons$	$CuA + H^+$	$\log \frac{\varkappa_{1,11}}{\varkappa_{1,01}}$	$= pK_{CuHA}$	= 5.65
$Cu(HA)A^-$	$\rightleftharpoons$	$CuA_2^{2-} + H^+$	$\log \frac{\varkappa_{1,11,01}}{\varkappa_{1,02}}$	$= pK_{Cu(HA)A}$	= 5.97

The existence of $CuHA^+$ and $Cu(HA)A^-$ provides evidence for the ligand phosphoryl group to act complexing. This is in contrast to the Ag(I) — O-phosphorylethanolamine system [52], where the species AgA^- and AgA_2^{3-} only could be detected in a similar concentration range as the present. The amino group of the ligand was suggested as single coordination site for the latter species [52], which may be attributed to Ag(I) preferably forming linear complexes with this type of ligand, *cf.* Ref.[53]. The great difference between b_{CuHA} and b_1 in this work (*cf.* Table 2) indicates the ligand amino group to be introduced as dentate site, when $CuHA^+$ is converted to CuA. The species CuA and CuA_2^{2-} may, thus, be coordinated through the ligand phosphoryl and amino group or the amino group only. The former alternative is more probable, at least for CuA, as $\log b_1$ of the Cu(II)-ammine system [44] is reported to be about 2 log. units lower than that of the present. The effect of the increased net negative charge, caused by the presence of the phosphoryl group, cannot reasonable alone explain this great difference in b_1. — Due to the same fact

copper(II) reasonably interacts with the phosphoryl group also in the corresponding O-phosphorylserine 1:1 complex [21]. The central copper(II) ion is, however, in this complex apparently mainly coordinated through a five-membered chelate ring formed by the amino and carboxyl donor groups. The value of $\log b_1$ (= 9.64) in this system is about 1.5 — 2 log. units greater than $\log b_1$, in copper(II) systems of similar unphosphorylated amino acids [38,54,55].

Klotz *et al.*[6,56] studied the copper(II) binding properties of α- and β-casein. The α-casein was found to have the greater copper(II) binding capacity, being greater than that of any other protein investigated [6]. The difference in copper (II) affinity of α- and β-casein paralleled the phosphorus content of those proteins, suggested to be due to difference in net negative charge [6]. The apparent complexing action of the phosphoryl group in the present complexes, and in the O-phosphorylserine complexes [21] may indicate that the greater copper(II) binding power of these phosphoproteins is partly due to complex formation through phosphoryl groups.

In the phospholipids, phosphatidylethanolamine and phosphatidylserine, where the phosphoryl group is diesterified, the same groups are free to react as those proposed as main dentate sites in O-phosphorylethanolamine and O-phosphorylserine. Since the pK values of the amino group in these phosphatides are of the same size [57] as those of the corresponding low molecular weight phosphates [21,40], both types of compounds may at a physiological pH form copper(II) complexes of nearly the same strength. The complexes formed by those ligands will then be those, where the dissociable proton is removed from the amino nitrogen group due to the pK value of the hydrogen copper(II) complexes (*cf.* Table 2 and Ref.[21]). This gives evidence for a considerable copper(II) complexity of these phosphatides, which may have biological significance. At inhibition of tromboplastinase action by copper(II) ions [58], for instance, complexes will obviously be formed between Cu(II) ions and the tromboplastical active lipid substrate, mainly constituting phosphatidylethanolamine and phosphatidylserine [59].

Acknowledgements. The author wishes to express his gratitude to Docent Ido Leden for valuable discussions. The skilful technical assistance of Mr. Åke Lundquist is greatly acknowledged. The investigation was aided by grants from the *Medical Faculty, University of Göteborg.*

Studies on Local Anesthetics XX *

Synthesis of Some α-Monoalkylamino-2-methylpropionanilides. A New Useful Local Anesthetic

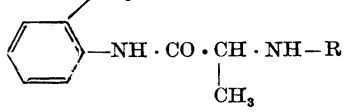
NILS LÖFGREN and CLAËS TEGNÉR

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, and Research Laboratories, AB Astra, Södertälje, Sweden

Five new α-monoalkylamino-2-methylpropionanilides in which the alkyl group is an ethyl, *n*-propyl, *iso*propyl, *n*-butyl or *iso*butyl group have been synthesised. All five compounds possess local anesthetic activity and one of them, the *n*-propylamino compound ("L 67"), had such valuable properties that it was subjected to clinical tests. These showed the new compound to be an effective injection anesthetic.

A review of the chemistry of local anesthetics has recently been published by Killian [2] in which the aminoacylanilides are discussed as well as other groups of anesthetics. A number of papers on the synthesis of local anesthetics of this type have been published from this institute, one of which describes the preparation of α-diethylamino-2,6-dimethylacetanilide [3] (Xylocaine®). Since its introduction into clinical use it has become the most important injection anesthetic. This paper presents a new local anesthetic, α-n-*propylamino-2-methylpropionanilide*, which in its pharmacological properties is similar to Xylocaine.

A series of compounds of the general formula



in which R is an ethyl (I), *n*-propyl (II), *iso*propyl (III), *n*-butyl (IV), or *iso*butyl (V) group were synthesised and tested pharmacologically. The inter-

* For paper XIX of this series, see Lüning [1].

mediate α-bromo-2-methylpropionanilide was prepared by reacting α-bromopropionyl bromide with *o*-toluidine in an aqueous acetate buffer [4]. One mole of the α-bromo-2-methylpropionanilide was then heated with an excess of the appropriate monoalkylamine in benzene solution.

Compounds I—V were tested for local anesthetic activity on rabbit cornea, using the technique of Wiedling [5] and the lethal doses (LD50) of each compound was determined by subcutaneous injection in white mice. The activity and toxicity values presented here are relative values referring to Xylocaine as a standard, *i.e.* the activity and toxicity of Xylocaine are both, by definition, taken as unity. Thus, a compound is characterised by its *relative anesthetic activity*, RA (for Xylocaine: RA = 1) and its *relative toxicity*, RT (for Xylocaine: RT = 1)*. For the quotient RA/RT the term *anesthetic index*, Q, is used (for Xylocaine: Q = 1). The results of the pharmacological measurements are compiled in Table 1. As can be seen from the table, compound I has the lowest activity (RA $\sim$ 0.3) being approximately 70 % lower than that of Xylocaine. Compound I has also, compared with Xylocaine, a low toxicity (RT = 0.41) and therefore its anesthetic index (Q $\sim$ 0.7) is only about 30 % lower than that of Xylocaine. Compound IV possesses the highest activity (RA = 2.2). It also has the highest toxicity (RT = 0.91), equal to or slightly less than that of Xylocaine. Since however RA is considerably higher than RT, the Q value is high (2.4). The RA values of II, III and V are 0.9, 0.7 and 0.8 respectively and since their relative toxicities are all < 0.7, they have Q values higher than that of Xylocaine. When tested for irritant properties by injection in the rabbit ear ** (aqueous solutions of the hydrochlorides), IV gave a moderate and V a strong irritant action but the other three compounds (I, II and III) did not appreciably irritate the skin. Among the three nonirritant compounds, II and III have rather good RA values (especially II) and very favourable Q values and they were therefore subjected to clinical tests.

Table 1. Local anesthetic activity (rabbit cornea) and toxicity (white mouse) of compounds I—V. For the terms relative anesthetic activity and relative toxicity, see above.

Compound	Relative anesthetic activity (RA)	Toxicity, LD50		Relative toxicity (RT)	$Q\left(=\frac{RA}{RT}\right)$
		g base/kg	moles/kg × 10^3		
Xylocaine	1.0	0.34	1.45	1.0	1.0
I	0.30	0.72	3.5	0.41	0.7
II	0.86	0.71	3.2	0.45	1.9
III	0.68	0.73	3.3	0.44	1.5
IV	2.2	0.38	1.6	0.91	2.4
V	0.82	0.55	2.3	0.63	1.3

* For further information on the meaning of the terms RA and RT, see Löfgren, Tegnér and Takman [6].

** For this technique, see Wiedling [7].

At present we are able to present briefly the clinical results for compound II, in clinical tests known as *L 67* or *Astra 1512* *. This compound, *i.e.* α-n-*-propylamino-2-methylpropionanilide*, did not produce any sign of irritation when tested for infiltration anesthesia in man **. No side effects were observed. The efficiency of the compound was studied in practically all forms of injection anesthesia (subcutaneous anesthesia of the skin, terminal anesthesia of the teeth, various forms of block anesthesia, *e.g.* sacral and mandibular anesthesia, *etc.*). From these tests it is evident that compound II has a similar action to that of Xylocaine. The two compounds produce approximately the same incidence, onset, extent and duration of anesthesia. In dental use, compound II gives a shorter anesthesia of the soft tissues than Xylocaine, *i.e.* in this respect compound II is more favourable than Xylocaine. Furthermore, as shown in Table 1, the toxicity of compound II is about 50 % lower than that of Xylocaine ***. It is thus a very promising injection anesthetic for clinical use.

EXPERIMENTAL †

α-Bromo-2-methylpropionanilide was prepared from α-bromopropionyl bromide and *o*-toluidine by the aqueous acetate buffer method given by Löfgren [4]. Colourless needles were obtained from benzene, m. p. 132—133°, yield 81 %. The melting point agrees with that observed by Tigerstedt [10] who synthesised the compound from α-bromopropionyl bromide and *o*-toluidine in a dry organic solvent.

α-Ethylamino-2-methylpropionanilide (I). A mixture of α-bromo-2-methylpropionanilide (24 g, 0.10 mole), ethylamine (12 g, 0.27 mole) and benzene (50 ml) was heated in a steel autoclave at 80° for 8 h. The reaction mixture was then diluted with absolute ether and filtered to remove the amine hydrobromide formed. After evaporation of the solvent the residue was distilled under reduced pressure and the fraction b. p. 145—147°/0.9 mm was collected as a colourless oil (16.5 g, 80 %). The oil soon solidified and was recrystallised from petroleum ether (b. p. 40—60°). Colourless crystals, solidifying point 36—37°. (Found: C 69.7; H 8.92. Calc. for $C_{12}H_{18}N_2O$ (206.3): C 69.9; H 8.79.)

α-n-*Propylamino-2-methylpropionanilide* (II). A solution of α-bromo-2-methylpropionanilide (24 g, 0.10 mole) and *n*-propylamine (16 g, 0.27 mole) in benzene (100 ml) was refluxed for 8 h. The reaction mixture was treated as described under compound I and the base was isolated as colourless needles, m. p. 37—38°, b. p. 159—162°/1 mm, n_D^{20} 1.5298†† (19 g, 87 %). (Found: C 71.0; H 8.95. Calc. for $C_{13}H_{20}N_2O$ (220.3): C 70.9; H 9.15.)

Salts of this compound were prepared by dissolving the base in dry ether and adding an ether solution or an ether-ethanol solution of the acid. The precipitated salts were recrystallised from ethanol — *iso*propyl ether. To prepare the sulphamate a different technique had to be used (see below). The following salts were prepared:

Hydrochloride. M. p. 167—168°. (Found: C 60.8; H 8.21; N 10.73. Calc. for $C_{13}H_{21}ClN_2O$ (256.8): C 60.8; H 8.24; N 10.91.)

---

* A paper on clinical results with the compound has already appeared [8]. Further results of the pharmacological and the clinical investigations will be published shortly.

** Aqueous solutions of the hydrochloride, with or without the addition of epinephrine, were used for the clinical tests.

*** In experiments carried out by Wiedling [9] both the intravenous and the intraperitoneal toxicities (white mouse) were 60—65 % of those of Xylocaine.

† All melting points are corrected.

†† supercooled liquid.

Hydrogen sulphate. M. p. 175—176°. (Found: C 49.7; H 6.95; N 8.66. Calc. for $C_{13}H_{22}N_2O_5S$ (318.4): C 49.0; H 6.97; N 8.80.)

Monohydrogen citrate. On treating 1 mole of the base with 1 mole of citric acid the dibasic citrate separated, m. p. 140—142° decomp. (Found: C 60.7; H 7.55; N 9.10. Calc. for $C_{32}H_{48}N_4O_9$ (632.8): C 60.7; H 7.65; N 8.85.)

Lactate. M. p. 133—134°. (Found: C 61.7; H 8.45; N 9.18. Calc. for $C_{16}H_{26}N_2O_4$ (310.4): C 61.9; H 8.44; N 9.03.)

Methanesulphonate. M. p. 169—171°. (Found: C 53.2; H 7.63; N 8.50. Calc. for $C_{14}H_{24}N_2O_4S$ (316.4): C 53.1; H 7.65; N 8.86.)

Sulphamate. The sulphamate of compound II was prepared in the following way:

A mixture of the base (22 g, 0.10 mole) and sulphamic acid (9.7 g, 0.10 mole) in absolute ethanol (40 ml) was boiled under reflux (condenser with calcium chloride tube) until dissolved. Dry acetone (30 ml) and then absolute ether (30 ml) were added to this clear solution through the condenser. After cooling the crystals that separated were sucked off and washed with a mixture of equal volumes of dry acetone and dry ether. Yield 24 g, 75 %. The salt thus obtained is of high purity but, if desired, it can be recrystallised from absolute ethanol-*iso*propyl ether. M. p. 130—131°. (Found: C 49.1; H 7.42; N 12.9. Calc. for $C_{13}H_{23}N_3O_4S$ (317.4): C 49.2; H 7.30; N 13.2.)

If in the procedure described above aqueous alcohol is used instead of absolute alcohol the sulphamate may be obtained in a hydrated form. However, a closer characterisation has not yet been carried out.

All the salts, described here, are readily soluble in water.

*α-Iso**propylamino-2-methylpropionanilide hydrochloride* (III). A mixture of α-bromo-2-methylpropionanilide (24 g, 0.10 mole), *iso*propylamine (16 g, 0.27 mole) and benzene (100 ml) was heated in a steel autoclave at 80° for 8 h. The reaction mixture was then diluted with dry ether and filtered to remove precipitated *iso*propylammonium bromide. The addition of a dry ethereal solution of hydrogen chloride precipitated the hydrochlorides of III and the remaining *iso*propylamine. The salts were filtered off, washed with ether and then dissolved in hot water to which had been added some activated carbon. From the filtered solution the hydrochloride of III separated as colourless crystals, m. p. 236—237° decomp. (16.5 g, 64 %). (Found: C 61.3; H 8.30; Cl (Mohr) 13.8. Calc. for $C_{13}H_{21}ClN_2O$ (256.8): C 60.8; H 8.24; Cl 13.8.)

α-n-Butylamino-2-methylpropionanilide hydrochloride (IV). α-Bromo-2-methylpropionanilide (24 g, 0.10 mole), *n*-butylamine (20 g, 0.27 mole) and benzene (100 ml) were boiled under reflux for 8 h. After dilution with dry ether the *n*-butylammonium bromide was filtered off and the filtrate evaporated to dryness. The residue was dissolved in ether and ethereal hydrogen chloride was added until no more precipitate was formed. This was filtered off and then recrystallised from absolute ethanol giving colourless crystals, m. p. 175—177° (19 g, 71 %). (Found: C 61.9; H 8.39; Cl (Mohr) 13.1. Calc. for $C_{14}H_{23}ClN_2O$ (270.8): C 62.1; H 8.56; Cl 13.1.)

*α-Iso**butylamino-2-methylpropionanilide hydrochloride* (V). The compound was obtained from α-bromo-2-methylpropionanilide and *iso*butylamine. The procedure described under compound III was followed, but instead of heating the reaction mixture in an autoclave it was boiled under reflux for 8 h. The hydrochloride was obtained from water as colourless crystals (*cf.* under compound III) and was recrystallised from the same solvent, m. p. 221—223° decomp., yield 63 %. (Found: C 61.9; H 8.29; Cl (Mohr) 13.1. Calc. for $C_{14}H_{23}ClN_2O$ (270.8): C 62.1; H 8.56; Cl 13.1.)

Thanks are due to Dr. B. Sjögren, director of research of AB Astra, for facilitating this work and to Dr. S. Wiedling for performing the pharmacological tests.

Short Communications

Reactivity of Polyvinyl Chloride

SVEN SONNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

It was shown in a previous paper [1] that the thermal instability of polyvinyl chloride, prepared in emulsion systems, is related to the presence of polymeric (hydro)peroxides, formed by the occurrence of an induction period during the initiating step, by random copolymerization with oxygen as comonomer, or by deactivation of trapped polymer radicals at grinding and drying operations. As a consequence inhibition or retardation of color formation and decomposition on heating can be achieved by the formation of a redox system, where the polymer takes part as an active component. The same principle may be used in the preparation of graft copolymers by the interaction of polymeric peroxide radicals and acrylonitrile in an aqueous suspension at 32°C.

Complementary studies have been carried out from other points of view. A summary is given below. As earlier [1], the rate of color formation and gelation in pyridine at 100°C is used to indicate the inhibitory action of coreactants or the change of thermal stability, caused by earlier operations in other media. Any discoloration arising from side reactions between solvent and additives is identified in a blank. The concentration of stabilizers in test solutions was kept high (1–10 % by wt of polymer) to make sure that an excess is at hand, compared to the amount of radical intermediates in the degradation cycle.

New types of inhibitors. a. *Carbon black.* Addition of *High Abrasion Furnace* or *Easy Processing Channel* blacks to a solution of polyvinyl chloride in pyridine gives a satisfactory inhibition of thermal degradation according to the standard schedule. This statement merely implies the nonappearance of the later steps — strong discoloration and gelation — in the degradation cycle, as a weak color formation is visually undetectable for obvious reasons. The removal of suspended inhibitor by filtration is unfeasible, because the average end to end distance of the polymer molecules far exceeds the diameter of a carbon particle.

The inhibitory properties of carbon black are known from rubber chemistry. It has been recently shown that reinforcing carbon black fillers act as radical acceptors [2]. Analogous effects have also been reported on milling of polyethylene [3].

b. *Thiophenol.* This compound gives a complete protection against thermal decomposition in pyridine. A prolonged heating beyond the standard schedule (more than 330 min) gives no other visible change but a light yellow color formation. This is expected from the type reactions of an aromatic modifier and a polymeric hydroperoxide (= POOH):

$$\begin{aligned}
&\mathrm{POOH} && \rightarrow \mathrm{PO\cdot} + \mathrm{HO\cdot}\\
&\mathrm{PO\cdot} + \mathrm{C_6H_5SH} && \rightarrow \mathrm{POH} + \mathrm{C_6H_5S\cdot}\\
&\mathrm{HO\cdot} + \mathrm{C_6H_5SH} && \rightarrow \mathrm{H_2O} + \mathrm{C_6H_5S\cdot}\\
&2\ \mathrm{C_6H_5S\cdot} && \rightarrow \mathrm{C_6H_5-S-S-C_6H_5}
\end{aligned}$$

Arylmercaptans are known to react with alkenes [4]. When peroxides are present, addition occurs contrary to the Markownikoff rule. As technical grades of polyvinyl chloride always show a low, significant degree of unsaturation, this side reaction cannot be ignored. No distinction, however, between the separate contributions is made here, as they necessarily work in the same direction of improved stability. Moreover the quantitative relations would be obscured by a conceivable combination reaction between PO· and RS· radicals.

c. *Oxalic acid.* Oxidation of oxalic acid by free radicals is a case of hydrogen abstraction, where the transfer agent acquires radical character but loses its activity in a secondary step by thermal decomposition:

$$\mathrm{POOH} + \mathrm{HOOC-COOH} \rightarrow \mathrm{POH} + \mathrm{H_2O} + 2\ \mathrm{CO_2}$$

The inhibiting action of oxalic acid is comparable to that of thiophenol. An analy-

tical grade of highest purity (oxalic acid dihydrate) was used in order to exclude catalytic effects from metallic impurities, especially ferrous compounds.

Deactivation of the polymer in an aqueous medium. Hydroperoxides may decompose by thermal dissociation, by reduction activation and by acid or base catalysis. The influence of neutral, alkaline and acid water on the polymer properties was therefore considered, preferably in the vicinity of 100°C, because such treatments are believed to occur as routine methods of purification of technically produced material. An improvement of heat stability was observed in all three cases (pH range 1—12), but the most acid medium was distinctly superior, yet insufficient to impart a complete stability to the polymer when heated in pyridine. This statement is valid for aqueous media, containing hydrochloric, sulfuric or phosphoric acid. The necessary time of reaction seems to be short. The main improvement of heat stability is obtained within 15 min, followed by a moderate change of purity and whiteness of the sample when heating is continued for arbitrary periods.

Analogous effects are obtained by adding cobaltous chloride to the water. This reduction activator operates at a satisfactory rate in a neutral medium at a moderate temperature (35°C). Its action is enhanced by the presence of sulphur dioxide. Samples of polyvinyl chloride, soaked in this way for 8 h, or more, are stable in pyridine according to the actual testing schedule.

A variety of coreactants might be mentioned here, working in the same manner. *Vinyl acetate* is active in the presence of nonionic detergents, allowing solubilization of monomer in the polymer particles. This is particularly interesting, as no indication of graft copolymerization has been found. On the contrary a strict emulsion homopolymerization of vinyl acetate takes place by use of the activator system polyvinyl chloride-ferrous chloride-sodium pyrosulphite. Separation of the two polymers is preferably carried out by filtration in standard glass equipment. The opposite case-grafting — seems to be restricted to *acrylic* monomers (acrylonitrile, acrylic esters and related derivatives, such as N,N′-methylene-*bis*(acrylamide)).

Graft copolymerization and interpolymerization in solution. a. *N-vinyl-2-pyrrolidone* is a solvent for polyvinyl chloride at elevated temperature. When such a solution is stored at 100°C for several hours in the absence of air, viscosity is gradually increased. At increasing time of reaction the water soluble fraction of the system gradually disappears, even when the weight ratio polymer/solvent is low. Practical working conditions are found in the concentration range of 2—5 %.

As no reduction activator is present, an attempt of interpretation is obscured by a number of conceivable overlapping cases. A thermally dissociating polymeric hydroperoxide would be able to initiate a graft copolymerization as well as a homopolymerization of the comonomer. The latter reaction might even be superposed by a pure thermal initiation of the monomer, resulting in an appreciable formation of water soluble homopolymer. No experimental evidence for the existence of such a fraction has been found at high extents of reaction. It is probable that growing macromolecules of this kind are deactivated by combination reaction with radical species of hydrophobic origin. The ultimate composition would then be undistinguishable from a graft copolymer, formed directly by a chain reaction between the primary components.

b. *Polyvinyl chloride-polyvinyl alcohol* interpolymers. Accumulated experience makes probable that a second vinyl polymer, added to a fresh solution of polyvinyl chloride in pyridine, would give a block copolymer on heating, provided the added compound is accessible to reactivation by hydrogen abstraction. Polyvinyl alcohol of low acetyl content was selected for this purpose. An equimolar mixture of the two components was heated at 100°C in pyridine, until turbidity had decreased to a low, constant value. At this interchange level the polyvinyl alcohol is no more extractable with water. The formation of an interpolymer is expected from previous studies [5] on reactivation of polyvinyl alcohol by free radicals.

Studies on Fibrinopeptides from Different Species

BIRGER BLOMBÄCK

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden, and

JOHN SJÖQUIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Starting with the work of Bailey, Bettelheim, Lorand and Middlebrook [1] in 1951, it has now been fairly well established by these authors and by others that when bovine thrombin acts on bovine fibrinogen at least two different peptides (A and B) are released from the fibrinogen molecule revealing N-terminal glycyl residues in the fibrin (*cf.* Refs.[2-4]). Both peptides isolated from the supernatant contain arginine as the C-terminal amino acid residue [5,6]. The release of at least peptide A is followed stoichiometrically by the appearance of N-terminal glycine in the fibrin [3]. Thus peptide bonds involving arginylglycyl residues in fibrinogen are apparently hydrolyzed by thrombin.

With respect to synthetic substrates such as tosylarginine methyl ester the thrombin specificity seems to resemble that of trypsin [7]. Thrombin action differs, however, in many respects from that of trypsin [8,9] and in any case when acting on fibrinogen the proteolysis brought about by thrombin is much more limited than that by trypsin. Probably, the structure of the amino acid sequence in the vicinity of the peptide bonds hydrolyzed by thrombin or the secondary and tertiary structure of the fibrinogen molecule determines the narrow specificity of this enzyme.

Bovine thrombin also acts on fibrinogen from other species and species specific peptides seem to be released [10-13]. The characterization of these peptides may give information on the specific requirements for thrombin action. This paper gives preliminary data concerning the amino acid composition and amino acid sequences of some peptides released from human, pig and rabbit fibrinogen. The experiments which have been performed to establish the amino acid sequence of bovine peptides A and B have recently been reported elsewhere [3,6,14,15].

The different fibrinogens were mainly prepared according to a method previously described [16]. The coagulability of the fibrinogen preparations was 94—99 %. The peptides split off by bovine thrombin were isolated from the clot supernatant by column chromatography [17] on Dowex 50—X2.

From human fibrinogen two main peptides could be isolated and one of them was studied in detail. Also from each of pig and rabbit fibrinogen two main peptides could be isolated. The origin of other, smaller peptides observed on the chromatograms will not be discussed in this paper. All peptides containing tyrosine-O-sulphate have in this work been denoted as B-peptides in view of their similarity in this respect to bovine peptide B. The other peptides have tentatively been denoted as A-peptides.

The fact that the isolated peptides contain the N-terminal amino acids disappearing from the corresponding fibrinogen during the transformation to fibrin [10-12] establishes their relation to the proteolytic activity of thrombin.

The amino acid composition of the peptides (Table 1) was determined using the method recently reported [18,19]. As only small amounts of human, pig and rabbit peptides were accessible their content of cystine (or cysteine) was not determined. Peptides designated HP4-4 and KP10-A in Table 1 have not yet been analyzed for tryptophan. The other peptides do not contain tryptophan as judged from spectrophotometric readings in the ultra-violet. For comparison the amino acid residues of the bovine fibrinopeptides [6,15] are included in Table 1.

Although the amino acid compositions show remarkable differences some common features should be pointed out. Thus, all peptides in Table 1 have a high content of dicarboxylic amino acids. Furthermore, the peptides contain one or two arginine residues. In the bovine fibrinopeptides A and B the C-terminal position is occupied by arginine. The C-terminal amino acids in the other peptides have not yet been determined. It is also of interest that only one peptide, the pig peptide SP1-1, contains histidine.

Tyrosine has hitherto been found in fibrinopeptides from ox [20,17,21,4] and from rabbit fibrinogen [12]. It is also present in a fibrinopeptide from the pig. In all cases the hydroxyl group of tyrosine is esterified with sulphuric acid. The occurrence of tyrosine-O-sulphate in fibrinopeptides from

several species might indicate that this unique structural unit is of importance for the biological function of the protein. However, tyrosine-O-sulphate has been reported to be absent in peptide material from human fibrinogen [21]. In the peptide designated A from man tyrosine is absent (Table 1). The other main peptide present in the clot supernatant of human fibrinogen has, however, not been analyzed since it has not yet been obtained in homogeneous form.

Table 2 shows the amino acid sequences of the different peptides as determined with a modification of the phenylthiohydantoin method of Edman [15,22]. Except for bovine peptide A only partial sequences from the N-terminal end are known. All peptides with the possible exception of the bovine B-peptide seem to be made up of a single peptide chain. The partial sequences as well as the amino acid composition show clearly that these peptides are species specific.

The amino acid sequences of bovine peptides A and B have shown that the C-terminal part consists, in addition to arginine, mainly of neutral amino acid residues, whereas the dicarboxylic amino acids are displaced towards the N-terminal end of the molecule. Further elucidation of the amino acid sequences of the different peptides will show if this arrangement is a common feature.

It has been suggested that the pro · pro sequence in bovine A-peptide should be of importance in directing thrombin action [14]. This sequence, however, seems not to be a constant finding among fibrinopeptides as the peptide from man and one of the pig peptides does not contain proline.

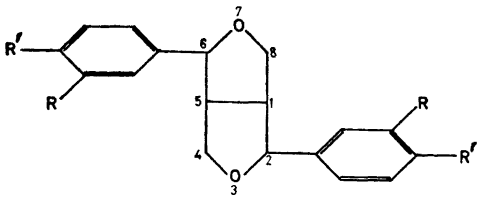
Crystallographic Data of Two Pinoresinol Derivatives

EINAR WANG LUND

Kjemisk Institutt, Universitetet i Oslo, Blindern, Norway

Pinoresinol belongs to that class of naturally occurring lignans which contains the 2,6-diaryl-3,7-dioxabi*cyclo*[3.3.0]octane nucleus:



In pinoresinol R = OCH_3, R' = OH. In the same class of lignans is found a number of compounds, some of which are optical isomers or diastereoisomers.

Conclusive evidence for a *cis*-configuration of the central bi*cyclo*-octane nucleus is given by the presence of optical activity in the dilactone formed by oxydative degradation [1] and in the diol formed by opening of the tetrahydrofuran rings by mild hydrogenolysis[2]. Another argument against a *trans* configuration is that this would be a sterically highly strained structure. It has further been shown by Erdtman [3] and by Gripenberg [4] that pinoresinol is symmetrical in the respect that the substituted phenyl groups are either both in *cis* or both in *trans* position to the bridge hydrogen atoms at 1 and 5.

In order to decide which of the two possibilities is present in pinoresinol, an X-ray crystallographic investigation has been started. Compounds chosen for this study are dibromo- and diiodopinoresinol-dimethylether (R = R' = OCH_3, halogen in *para* position to R). Crystals of these two compounds have been prepared by Professor H. Erdtman and placed at the author's disposal for an X-ray study.

Both halogen derivatives crystallize in very fine needles. The crystals of the bromo-compound show monoclinic symmetry with unit cell dimensions: a = 8.25 Å, b = 26.7 Å, c = 4.83 Å, β = 103.3°. With two molecules in the unit cell the calculated density is 1.75 gcm^{-3}. Very fine thread-like crystals have been observed to float in an aqueous solution of zinc iodide of density 1.70 gcm^{-3}.

Extinctions of the reflexions $0k0$ with $k = 2n + 1$ indicate one of the space groups $P2_1/m$ or $P2_1$. With two molecules in the unit cell only the latter is possible, because a point or plane of symmetry is not compatible with what is known about the molecule.

The crystals of the iodo-compound are tetragonal with unit cell dimensions a = 21.3 Å, c = 4.86 Å. Calculated density on the basis of four molecules in the unit cell is 1.93 gcm^{-3}. The observed density of very fine, thread-like needles, determined in the same way as for the bromo-compound, is 1.96 gcm^{-3}.

Extinctions of the reflexions 001 and 003 indicate one of the space groups $P4_2/m$ or $P4_2$. The former of these requires the molecule to possess a plane of symmetry. Therefore the space group $P4_2$ is considered to be the most probable.

An important detail of the unit cell of both halogen derivatives is the short c-axis of about 4.8 Å. This fact in itself may decide between the two possibilities for the geometry of the pinoresinol molecule, because it has to be confined to a rather low-ceilinged unit cell.

From what is known about the structure of furanose compounds certain details of the five-membered rings in the nucleus can be inferred. Each ring may be characterized by a plane of reference containing the bridge C—C bond and the oxygen atom. It is highly probable that the two remaining carbon atoms of one ring are situated on each side of such a plane. With a *cis* configuration of the central nucleus the planes of the two condensed five-membered rings make an angle of about 120° with one another.

As a plane of reference of the whole molecule may be chosen one going through the two oxygen atoms and being parallel to the bridge C—C bond. Taking reasonable bond angles and interatomic distances into account, the following features of the molecular structure may be inferred with a high degree of probability. Of the two bonds at each of the carbon atoms 2 and 6, not engaged in the ring, one must be pointing nearly perpendicular to the plane of reference, being in *trans* position to the bridge hydrogen atoms at 1 and 5. The other bond at 2 and 6 is closer to being

parallel to the plane mentioned, making probably an angle near the tetrahedral with the first bond mentioned. For the molecule to be accommodated in the unit cell, the last mentioned bond must be the one occupied by the substituted phenyl group. A conclusion of these considerations is thus that the phenyl groups must be in *cis* position to the hydrogen atoms at the bridge carbons. The same conclusion is reached by Beroza [5], taking stability and intramolecular steric factors into consideration.

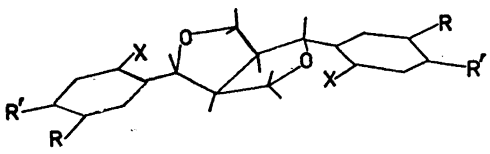


Fig. 1. A probable model of halogen derivatives of pinoresinoldimethylether. X = Br or I.

Fig. 1 shows a drawing in perspective of a probable model based on the arguments given.

A detailed structure determination of diiodopinoresinoldimethylether is in progress.

The author wishes to thank Professor H. Erdtman for placing crystals of the halogen derivatives of pinoresinoldimethylether at his disposal.

The Structure and Conformation of 1,2,3-Tribromo*cyclohexane* (m.p. 51° C) in the Gas Phase

V. A. ATKINSON and K. THURMANN-MOE

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Bornubert, Rio and Senechal [1] synthesized a 1,2,3-tribromo*cyclo*hexane (m. p. 51°C) to which they assigned the *eee* conformation on grounds of the compounds reaction used. A sample of their compound was investigated by gas phase electron diffraction in Oslo in order to test the validity of the asigned conformation. The diagrams were taken using distances of 48 cm and 19 cm between the diffraction point and the photographic plate. The data was treated in our usual manner [2], using a damping factor of 0.0036. The $\sigma(r)/r$ radial distribution curve obtained is shown in Fig. 1 (a).

The peak at r = 5.72 Å can only be due to a Br (1*e*)—Br (3*e*) distance. Of the six conformations of 1,2,3-tribromo*cyclo*hexane that can be distinguished with electron diffraction, only those corresponding to *eee* and *eae* contain this distance. Theoretical radial distribution curves were therefore calculated for each of these conformations. It was found that the theoretical *eee* curve gave better agreement with the experimental curve than did the theoretical *eae* curve. However, the agreement was still not particularly good. The peaks at r = 5.72 Å and 4.27 Å in the theoretical *eee* curve were too high, and that at r = 4.63 Å too low. Since the substance is a well defined isomer, these anomalies could only be explained by assuming that in the gas phase it contains either a mixture of the *eee* and *aaa* forms, or else a mixture of the *eae* and *aea* forms. Only the *aaa* conformation would give rise to a substantial peak in the neighbourhood of r = 4.63 Å (due to the Br (1*a*)—Br (2*a*) and Br (2*a*)—Br (3*a*) distances), so it was concluded that the substance must be a mixture of the *eee* and *aaa* forms in the gas phase.

Further theoretical calculations were made using structural models based on the latest parameters for the *cyclo*-hexane ring obtained in our department: C—H=1.103 Å,

parallel to the plane mentioned, making probably an angle near the tetrahedral with the first bond mentioned. For the molecule to be accommodated in the unit cell, the last mentioned bond must be the one occupied by the substituted phenyl group. A conclusion of these considerations is thus that the phenyl groups must be in *cis* position to the hydrogen atoms at the bridge carbons. The same conclusion is reached by Beroza [5], taking stability and intramolecular steric factors into consideration.

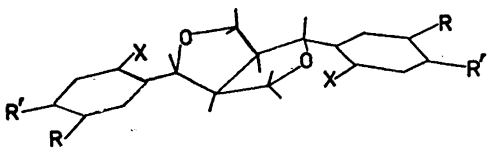

Fig. 1. A probable model of halogen derivatives of pinoresinoldimethylether. X = Br or I.

Fig. 1 shows a drawing in perspective of a probable model based on the arguments given.

A detailed structure determination of diiodopinoresinoldimethylether is in progress.

The author wishes to thank Professor H. Erdtman for placing crystals of the halogen derivatives of pinoresinoldimethylether at his disposal.

The Structure and Conformation of 1,2,3-Tribromo*cyclohexane* (m.p. 51° C) in the Gas Phase

V. A. ATKINSON and K. THURMANN-MOE

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Bornubert, Rio and Senechal [1] synthesized a 1,2,3-tribromo*cyclo*hexane (m. p. 51°C) to which they assigned the *eee* conformation on grounds of the compounds reaction used. A sample of their compound was investigated by gas phase electron diffraction in Oslo in order to test the validity of the asigned conformation. The diagrams were taken using distances of 48 cm and 19 cm between the diffraction point and the photographic plate. The data was treated in our usual manner [2], using a damping factor of 0.0036. The $\sigma(r)/r$ radial distribution curve obtained is shown in Fig. 1 (a).

The peak at r = 5.72 Å can only be due to a Br (1*e*)—Br (3*e*) distance. Of the six conformations of 1,2,3-tribromo*cyclo*hexane that can be distinguished with electron diffraction, only those corresponding to *eee* and *eae* contain this distance. Theoretical radial distribution curves were therefore calculated for each of these conformations. It was found that the theoretical *eee* curve gave better agreement with the experimental curve than did the theoretical *eae* curve. However, the agreement was still not particularly good. The peaks at r = 5.72 Å and 4.27 Å in the theoretical *eee* curve were too high, and that at r = 4.63 Å too low. Since the substance is a well defined isomer, these anomalies could only be explained by assuming that in the gas phase it contains either a mixture of the *eee* and *aaa* forms, or else a mixture of the *eae* and *aea* forms. Only the *aaa* conformation would give rise to a substantial peak in the neighbourhood of r = 4.63 Å (due to the Br (1*a*)—Br (2*a*) and Br (2*a*)—Br (3*a*) distances), so it was concluded that the substance must be a mixture of the *eee* and *aaa* forms in the gas phase.

Further theoretical calculations were made using structural models based on the latest parameters for the *cyclo*-hexane ring obtained in our department: C—H=1.103 Å,

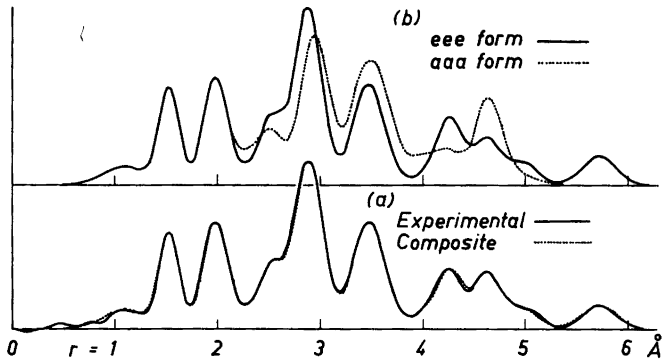

Fig. 1. Theoretical and experimental $\sigma(r)/r$ curves for the 1,2,3-tribromo*cyclo*hexane.

C–C = 1.529 Å, <CCC = 111.5°, <CCH = 110.0°, <HCH = 108.7°.

The C–Br bond distance used was 1.974 Å obtained from the experimental radial distribution curve. In order to get reasonable agreement between the experimental and theoretical curves, some distortion of the models was necessary. The well-defined peak at r = 3.48 Å suggested that this distance represented the closest approach of two non-bonded bromine atoms. This corresponds to a van der Waals radius of 1.74 Å for bromine (*cf.* Pauling's value [3] of 1.95 ± 0.1 Å). Using this value for the Br(1*e*)–Br(2*e*) and Br(1*a*)–Br(3*a*) distances, we calculated the parameters of models with the C–Br bonds distorted from the usual *cyclo*hexane positions. In the case of the *eee* model the distortion was slight; the C(1)–Br and C(3)–Br bonds were out of position by 2°, moved away from the Br(2) atom. As might be expected, the distortion of the *aaa* model was greater; the C(1)–Br and C(3)–Br bonds deviated 20° from the axial position, while the C(2)–Br bond was 9° from the axial position.

Fig. 1(b) shows the theoretical radial distribution curves for these *eee* and *aaa* conformations. Least squares procedure showed that the composite theoretical radial distribution curve giving best agreement with the experimental curve should be constructed on a basis of 19 % of the *aaa* form and 81 % of the *eee* form. In Fig. 1(a) this composite radial distribution curve is compared with the experimental curve. The dispersion of the standard deviation is 4 %.

The accuracy of the ratio between the two forms that we have derived clearly depends on the models we have used for the calculation of the theoretical radial distribution curves. It seems quite probable that small changes in the models would have given slightly different theoretical curves, which might have combined in slightly different proportions to give a composite curve agreeing as well or better with the experimental curve. For this reason we assess our possible error in the distribution ratio as high as ±5 %. The presence of 19 ± 5 % of the *aaa* form corresponds to an energy difference of 1.2 ± 0.3 kcal/mole between the two conformations.

Preliminary X-ray studies of the 1,2,3-tribromo*cyclo*hexane crystals have established a monoclinic structure, with space group $P2_1$, containing two molecules in a unit cell of dimensions: a = 6.44 Å, b = 9.22 Å, c = 7.52 Å and β = 106°.

We wish to thank Cand.real. A. Almenningen for taking the electron diffraction pictures and Prof. O. Hassel for his advice and encouragement. Thanks are also due to *Norges Teknisk-Naturvitenskapelige Forskningsråd* for financial support (V.A.A.).

Precursors of Benzoxazolinone in Rye Plants

I. Precursor II, the Aglucone

ARTTURI I. VIRTANEN and
PENTTI K. HIETALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

When benzoxazolinone (BOA) was isolated from crushed rye seedlings, it was at first regarded as a primary substance in these plants [1]. It was, however, difficult to understand why this ether-soluble compound could not be extracted from crushed plants with ether. Before long it was found that it is formed from a precursor (precursor II) which in turn is a product of an enzymatic splitting of a compound (precursor I) found in intact rye plants [2].

Glucosides proved to be primary precursors, the enzymatic hydrolysis of which led to the formation of the corresponding aglucones after the plants were crushed, or the plant sap was pressed[3]. BOA was formed from the aglucone in rye plants and MBOA (methoxybenzoxazolinone) from the aglucone in wheat and maize plants by chemical transformation. If the enzymes are destroyed by placing intact plants in boiling water or boiling ethanol solution, or by keeping them in 70 % ethanol at −20°C for a longer time, the aglucone is no longer formed when plants are crushed. Only the glucoside (precursor I) is to be found in plants treated in this way.

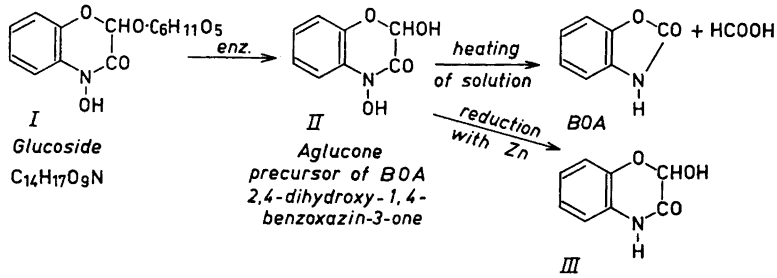
When experimental results accumulated, Virtanen and Hietala [3,4] found that only the splitting off of glucose takes place in the enzymatic decomposition of the glucoside. Soon thereafter they were able to propose the probable structure for the glucoside (I) in rye and the aglucone (II) formed from it. At the same time evidence was obtained that BOA is formed from the aglucone by the liberation of formic acid.

A proof for structure II for the aglucone was obtained by reducing the oxime group to the imido group (III) [4]. This compound was synthesized by Honkanen and Virtanen [5] from *ortho*(dichloroacetamido)-phenol by heating in a dilute sodium bicarbonate solution. Recently Honkanen and Virtanen [6] also succeeded in synthesizing the aglucone, and thus proved its structure.

Wahlroos and Virtanen [7] have described the isolation of the glucoside and aglucone from maize plants and demonstrated that these precursors of MBOA have anologous structures to those of the precursors of BOA in rye plants.

The spectroscopic identification of precursor II (the aglucone) of BOA in the press juice of rye plants. 5 ml of juice were pressed from 13 g of 8-day-old rye seedlings. The juice was heated in a water bath for 2 min (the temperature rose to about 70°C) to coagulate proteins. No noticeable amount of BOA was formed by this treatment. The juice was filtered through a hard filter paper. The clear solution was pipetted into two test tubes, 2 ml into each. The one was heated in a water bath for 1 h. Both water solutions were extracted four times with 2 ml of ether. Five different samples were then obtained: 1. The original juice. 2. The ether extract obtained from the juice heated for 1 h. 3. The water solution of the above. 4. The ether extract obtained from the unheated juice. 5. The water solution of the above.

All the solutions were diluted with water to 1:100 (the ether had been evaporated before this at room temperature). The curves in Fig. 1 show the UV-absorption curves of the solutions. Water was used as control solution in all measurements.



The examination of the spectra: The ether extract spectra of the heated and the unheated juice differ completely from each other. Spectrum 2 is that of BOA (max. 270 mμ and min. 245 mμ). If spectra 4 (ether extract) and 5 (water solution after ether extraction), obtained from the unheated juice, are summed, a spectrum nearly identical with spectrum 1 is obtained. This is not the case if spectra 2 and 3 are summed. Spectrum 4 is thus derived from the substance from which BOA is formed on heating the water solution.

In agreement with the spectroscopic investigation reported above, a paper chromatographic analysis (*iso*propanol:ammonia:

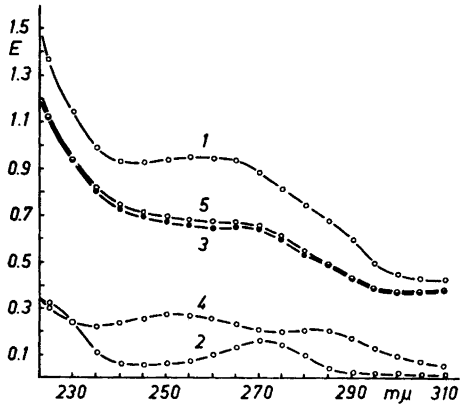


Fig. 1. UV spectra of solutions 1—5 mentioned in the text.

water 8:1:1, Whatman No. 4 paper) of solutions 1—5 showed that a substance (R_F 0.23) is found in ether extract 4. This substance had disappeared in ether extract 2, which on the other hand contained the BOA spot moving near the solvent front. When again it was found that the ether-soluble precursor II is not present in intact rye seedlings if these are placed in boiling water or ethanol, it was obvious that the substance was formed enzymatically from the primary precursor on crushing. This substance was found to be a glucoside and precursor II the aglucone formed from it.

The isolation of the aglucone. 1 190 g of rye seedlings (Pekka), grown for 7 days in the light, were ground. The mass was allowed to stand for 1 h at room temperature to ensure the enzymatic decomposition of the glucoside (in fact the hydrolysis took place very rapidly). The mass was vigorously pressed, and 850 ml of juice was obtained. The juice was kept in two bottles in a water bath for 4 min during which the temperature rose to about 70°C. The filtered, clear solution was shaken twice with ether, twice with *n*-butanol, and finally twice with ether. The combined ether and butanol solutions were evaporated to dryness *in vacuo* (the temperature did not rise above 20°C). The residue was dissolved in 100 ml of water, the solution was shaken 3 times with 100 ml of ether. The ether solutions were evaporated, and 75 ml of ether was added to the residue. The unsoluble, reddish substance was filtered off, 250 mg of active charcoal was added, the mass was shaken, and the charcoal was filtered off after standing. 40 ml of *cyclo*hexane was added to the solution, and it was evaporated *in vacuo* until crystallization began. The crystals were separated, washed with *cyclo*hexane, and dried at low temperature. They were recrystallized in the same way from a mixture of ether and *cyclo*hexane, washed with *cyclo*hexane, and finally dried at 100°C. Yield 428 mg; m. p. 152°.

Properties of the aglucone

1. *Analysis.* Found: C 53.40; H 3.98; N 7.40; O 33.15. Calc. for $C_8H_7O_4N$: C 53.04; H 3.90; N 7.73; O 35.33.

2. It gives a strong blue-violet colour with $FeCl_3$.

3. Its R_F value with *iso*propanol-ammonia-water 8:1:1 is 0.23.

4. Formic acid and BOA are rapidly formed when a dilute water solution of the aglucone is heated in a sealed tube in a water bath. A strong formic acid reaction was obtained with chromotropic acid. Formic acid was determined quantitatively by a fractionated steam distillation.

5. It does not react with 2,4-dinitrophenylhydrazine at room temperature. Upon heating a dark precipitate is formed. This has not been further investigated.

6. A potentiometric titration with 0.0200 N NaOH gave 190 as the equivalent weight and a $pK = 7.02$ (calculated from the curve). On titration with acid no clear equivalent point could be noticed and hence the aglucone does not consume acid in the pH range of the titration. This indicates that it has not a betaine structure.

7. By paper chromatography *ortho*-aminophenol was found to be formed as the main

product on strong hydrolysis with hydrochloric acid. This compound was extracted with ether from the hydrolysate neutralized with $NaHCO_3$ and identified by the UV-spectrum. *Ortho*-aminophenol was formed also on alkali fusion.

8. Hydroxylamine is a product of strong acid hydrolysis.

9. On reduction with hydrogen iodide and red phosphorus (62 mg of substance, 30 mg of red phosphorus, and 0.5 ml of hydrogen iodide, heating for 4 h at 170°C) *ortho*-aminophenol and a smaller amount of glycine (about 3 to 4 mg) were formed. Amino compounds were separated in an Amberlite IR-120 column. *Ortho*-aminophenol was separated by ether extraction from the ammonia eluate, from which ammonia was evaporated *in vacuo*, and identified by the UV-spectrum. Glycine was identified in the remaining water solution on a two-dimensional paper chromatogram. Other amino acid spots were not observed.

10. Methylation with dimethylsulphate (73 mg of substance and a five-fold excess of dimethylsulphate) led to a reaction product which after ether extraction was recrystallized from water, m. p. 84–85°. Its UV-spectrum greatly resembled that of BOA. (Found: N 9.82. Calc. for $C_8H_7O_2N$: N 9.40.) The substance obtained is probably N-methylbenzoxazolinone, the m. p. of which has been reported to be 86°.

11. Reduction with zinc and hydrochloric acid (123 mg of aglucone, 2 g of zinc dust, and 0.1 ml of 1 % ferric chloride solution; dropwise addition of concentrated hydrochloric acid until the ferric chloride reaction disappeared) led to a reduction product with m. p. 198° without recrystallization, and 201–203° (corr.)[5] after recrystallization. Mol. wt. (Rast) 167; calc. for $C_8H_7O_3N$: 165. Since the substance no longer gives any colour reaction with ferric chloride, the NOH group has apparently been reduced to NH. The UV-spectrum of the reduction product is shown in Fig. 2.

12. The aglucone did not consume hydrogen on catalytic hydrogenation with platinum in ethanol solution.

Conclusions: The results mentioned in paragraphs 7 and 9 can be understood only if nitrogen and carbon atoms outside the benzene ring are in the order —N—C—C—, and the nitrogen atom is attached to a carbon atom in the benzene ring. The formation of glycine in paragraph 9 is possible only if two oxygen atoms are bound to the terminal carbon atom.

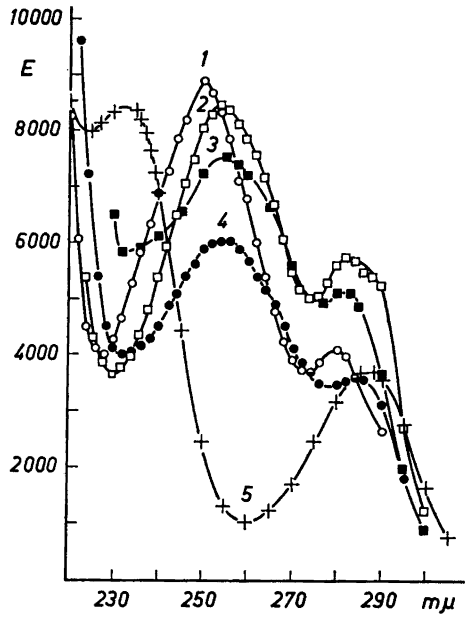

Fig. 2. UV spectra in ethanol solutions of

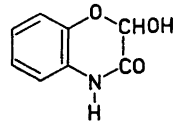
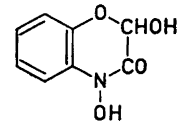
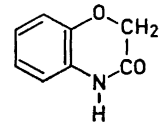


1. reduced aglucone,

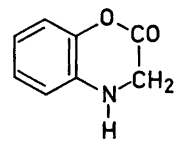


2. aglucone,

3. glucoside $C_{14}H_{17}O_9N$,



4. 2H-1,4-benzoxazin-3-(4H) one (synth.),



5. 3H-1,4-benzoxazin-2-(4H) one (synth.).

The formation of hydroxylamine mentioned in paragraph 8 and the positive Feigl-Amaral test [8] for an N—O bond suggests that the hydroxyl group is combined with the nitrogen atom and that the aglucone is a hydroxylamine derivative.

Taking into account these conclusions and the elementary composition of the aglucone, the possibility of an aliphatic side chain in the aglucone is ruled out, and a ring formed of nitrogen, carbon, and oxygen atoms is indicated. Structure II was suggested for the aglucone. This structure was supported by the similarity of the UV-spectra of the aglucone and its reduction product with 2H-1,4-benzoxazin-3-(4H) one synthesized by us (Fig. 2).

The structure of the aglucone could later be confirmed by synthesis by Honkanen and Virtanen [5,6], as already mentioned in this paper.

The support given by the *Rockefeller Foundation* is gratefully acknowledged.

Precursors of Benzoxazolinone in Rye Plants

II. Precursor I, the Glucoside

PENTTI K. HIETALA and
ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The identification and isolation of precursor I (the glucoside). As reported in previous communications [1], the glucoside $C_{14}H_{17}O_9N$ was isolated from rye seedlings. It is a primary compound present in intact rye plants. The aglucone $C_8H_7O_4N$ which is the immediate precursor of benzoxazolinone (BOA) is formed from the glucoside enzymatically.

225 g of 10-day-old seedlings of Pekka rye were put into 1.5 l of boiling water, the solution was decanted, filtered, and evaporated to 250 ml *in vacuo*. Ether-soluble substances were removed by extraction, and a chromatogram was made from the water solution with water-saturated butanol. 150 μl were pipetted on the starting spot. The dark spot, R_F 0.57, visible in UV light, represented the glucoside sought, from which precursor II is formed enzymatically. The spectrum of the substance is very similar to that of the aglucone.

The isolation of larger amounts of the substance was performed by counter-current extraction, using the butanol-water solvent system. In another connection, one of us (H) will give a detailed account of the isolation. The m. p. of the glucoside was 186.5—187°C (uncorr.). R_F 0.57 in water-saturated *n*-butanol. (Found: C 49.04; H 4.98; N 3.81; O 41.04. Calc. for $C_{14}H_{17}O_9N$: C 48.98; H 4.99; N 4.08; O 41.95.) UV spectrum (in ethanol). Glucoside: max. 255 mμ, ε = 7 570, max. 281 mμ, ε = 5 160. Aglucone: max. 254 mμ, ε = 8 500, max. 282 mμ, ε = 5 800. The curves of the UV spectra are presented in the paper of Virtanen and Hietala [1].

The UV spectra of the glucoside and the aglucone are very similar. Already from this it was probable that the structure of the free aglucone was the same as that bound to the sugar glucosidically. This concept was supported by all other observations. Some of these which elucidate the

The formation of hydroxylamine mentioned in paragraph 8 and the positive Feigl-Amaral test [8] for an N—O bond suggests that the hydroxyl group is combined with the nitrogen atom and that the aglucone is a hydroxylamine derivative.

Taking into account these conclusions and the elementary composition of the aglucone, the possibility of an aliphatic side chain in the aglucone is ruled out, and a ring formed of nitrogen, carbon, and oxygen atoms is indicated. Structure II was suggested for the aglucone. This structure was supported by the similarity of the UV-spectra of the aglucone and its reduction product with 2H-1,4-benzoxazin-3-(4H) one synthesized by us (Fig. 2).

The structure of the aglucone could later be confirmed by synthesis by Honkanen and Virtanen [5,6], as already mentioned in this paper.

Precursors of Benzoxazolinone in Rye Plants

II. Precursor I, the Glucoside

PENTTI K. HIETALA and
ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The identification and isolation of precursor I (the glucoside). As reported in previous communications [1], the glucoside $C_{14}H_{17}O_9N$ was isolated from rye seedlings. It is a primary compound present in intact rye plants. The aglucone $C_8H_7O_4N$ which is the immediate precursor of benzoxazolinone (BOA) is formed from the glucoside enzymatically.

225 g of 10-day-old seedlings of Pekka rye were put into 1.5 l of boiling water, the solution was decanted, filtered, and evaporated to 250 ml *in vacuo*. Ether-soluble substances were removed by extraction, and a chromatogram was made from the water solution with water-saturated butanol. 150 μl were pipetted on the starting spot. The dark spot, R_F 0.57, visible in UV light, represented the glucoside sought, from which precursor II is formed enzymatically. The spectrum of the substance is very similar to that of the aglucone.

The isolation of larger amounts of the substance was performed by counter-current extraction, using the butanol-water solvent system. In another connection, one of us (H) will give a detailed account of the isolation. The m. p. of the glucoside was 186.5—187°C (uncorr.). R_F 0.57 in water-saturated *n*-butanol. (Found: C 49.04; H 4.98; N 3.81; O 41.04. Calc. for $C_{14}H_{17}O_9N$: C 48.98; H 4.99; N 4.08; O 41.95.) UV spectrum (in ethanol). Glucoside: max. 255 mμ, ε = 7 570, max. 281 mμ, ε = 5 160. Aglucone: max. 254 mμ, ε = 8 500, max. 282 mμ, ε = 5 800. The curves of the UV spectra are presented in the paper of Virtanen and Hietala [1].

The UV spectra of the glucoside and the aglucone are very similar. Already from this it was probable that the structure of the free aglucone was the same as that bound to the sugar glucosidically. This concept was supported by all other observations. Some of these which elucidate the

chemical nature of the glucoside are reported in the following (*cf.* the corresponding observations made on the aglucone [1]).

A potentiometric titration with 0.0200 N NaOH gave equiw.wt. 338 (calc. 343). The p*K* calculated from the curve was 6.67. Titration with acid showed that the structure of the glucoside cannot be betainic. The result was thus the same as with the aglucone.

With $FeCl_3$ the glucoside gave an intensely violet colour, as did the aglucone.

On hydrolysis with 1 N HCl (100°C, 3 h) the largest part of the glucoside remained unchanged. The glucoside is accordingly rather stable on acid hydrolysis. A sugar which gave a weak reaction with aniline phthalate on paper chromatograms was found in the solution. Using three different solvent systems (water-saturated *n*-butanol, *iso*-propanolwater 16:4, phenol-water-NH_3), this sugar travelled as glucose.

Ortho-aminophenol was formed on strong acid hydrolysis (89 mg of glucoside and 1 ml of conc. HCl in a sealed tube for 40 h at 100°C). It was extracted with ether from a solution neutralized with $NaHCO_3$. Hydroxylamine could be found in the hydrolysate, and the qualitative Feigl-Amaral reaction for the N—O bond was positive. The result was thus the same as with the aglucone.

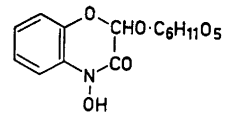
Ortho-aminophenol was formed as the main product on alkali fusion (4.1 mg of glucoside, 371 mg of KOH, and 0.1 ml of water, the temperature was raised to 200°C in 30 min). It was isolated in crystalline form and identified by paper chromatography, mixed m. p., and UV spectrum.

The same products as with the aglucone were also obtained on reduction with HI (*d* 1.96) and red phosphorus at 170—180°C, using reaction times of 2, 4, and 10 h. *Ortho*-aminophenol was identified by the UV spectrum. Glycine was found by amino acid chromatography.

The number of acetylating hydroxyl groups was determined in a pyridine solution by titrating the acetic acid formed from the excess acetanhydride. About five OH groups per mole were found.

The hydrolysis of the glucoside by a homogenate of rye seedlings leads to the formation of the aglucone and glucose. The aglucone can be extracted from the water solution by ether.

The above observations on the glucoside indicate that no rearrangement takes place in the molecule during hydrolysis. Since on the basis of the $FeCl_3$ reaction there is still a free NOH group in the glucoside, the glucose has to be bound to the OH group which is attached to carbon atom 2 in the heterocyclic ring. The structure of the glucoside is accordingly the following.



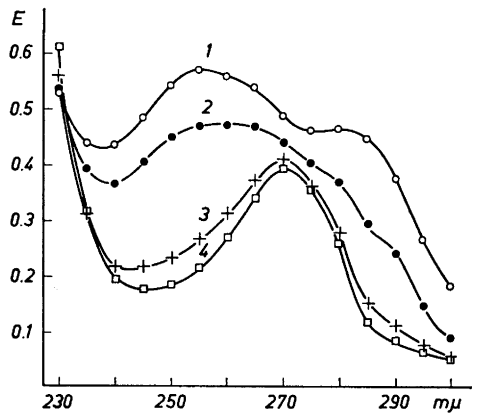


Fig. 1. UV spectra of the raw aglucone preparation from rye seedlings. A dilute solution was heated in a water bath for 2 min (2), 6 min (3), and 60 min (4). 1 was not heated.

The quantitative determination of the glucoside in rye seedlings. Since the glucoside is rapidly hydrolysed to the aglucone in crushed rye seedlings, it can be determined by the UV spectrum of the aglucone extracted by ether. A quantitative method has not, however, been developed yet for the estimation of the aglucone. On the other hand, a method has been developed by the present authors [2] for the determination of BOA formed rapidly from the aglucone at 100°C. The transfer of the aglucone into BOA in very dilute solutions is an extremely rapid reaction as shown in Fig. 1. Already at 50°C a slow formation of BOA can be observed. The kinetics of this complicated reaction has not been investigated closely, but it seems that the relative amount of BOA formed from the aglucone

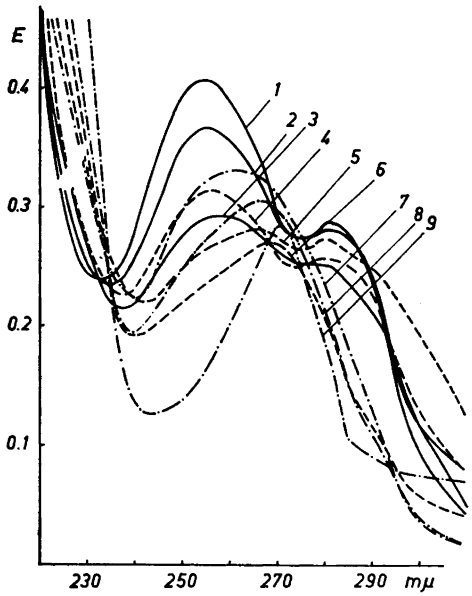

Fig. 2. UV spectra of water solutions of the aglucone of different concentrations heated at 100°C. Aglucone, max. 254 mμ, 282 mμ; BOA max. 270 mμ.

1. 10 mg/ml 5 min, *2.* 15 min, *3.* 60 min, *4.* 300μg/ml 5 min, *5.* 15 min, *6.* 60 min, *7.* 10 μg/ml 5 min, *8.* 15 min, *9.* 60 min.

decreases when the aglucone concentration rises. This is shown by the following test.

The aglucone was heated in a test tube in a boiling water bath at concentrations of 10 mg/ml, 300 μg/ml, and 10 μg/ml for 5 min, 15 min, and 1 h. For the measurement of spectra the first solution was diluted 1:1 000 and the second 1:30, and the most dilute solution was measured as such. Fig. 2 shows the changes occurring in the spectra of the different solutions.

When a relatively short reaction time is used, the formation of BOA can therefore be followed by spectrophotometry only in very dilute solutions of the aglucone.

The highest values found in this laboratory for BOA in rye seedlings have been about 1.1 mg of BOA per g fresh weight[3], corresponding to 2.8 mg of the glucoside if the yield is quantitative. The quantitativeness of the yield depends decisively on how thoroughly the plant material is crushed. A 90 % yield of BOA is more probable when plant material (0.5—1 g) is crushed in a mortar. The hydrolysis of the glucoside in a homogenate of rye seedlings is rapid. For the sake of safety it is best to allow the homogenate to stand at room temperature for 30 min before heating.

The Synthesis of Precursor II of Benzoxazolinone Formed in Rye Plants, and the Enzymic Hydrolysis of Precursor I, the Glucoside

ERKKI HONKANEN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In earlier papers Virtanen *et al.*[1,2] have presented the structure 2,4-dihydroxy-1,4-benzoxazin-3-one (I) for the aglucone enzymatically formed in crushed rye seedlings. The structure is now confirmed by the synthesis of the aglucone itself and its reduction product (II), which is obtained by reduction with zinc dust in boiling acetic acid[3].

The starting material for the synthesis of the aglucone was *o*-(methoxymethoxy)-nitrobenzene (III), from which the corresponding phenylhydroxylamine derivative (IV) is prepared in the usual way by reduction with zinc dust in a neutral medium. By allowing this compound to react with dichloroacetylchloride, N-(*o*-methoxymethoxyphenyl)-dichloroacethydroxamic acid (V) is obtained. The methoxymethoxy group is then hydrolysed by heating in a dilute methanolic hydrochloric acid solution. Finally the compound formed (VI) is

The Synthesis of Precursor II of Benzoxazolinone Formed in Rye Plants, and the Enzymic Hydrolysis of Precursor I, the Glucoside

ERKKI HONKANEN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In earlier papers Virtanen *et al.*[1,2] have presented the structure 2,4-dihydroxy-1,4-benzoxazin-3-one (I) for the aglucone enzymatically formed in crushed rye seedlings. The structure is now confirmed by the synthesis of the aglucone itself and its reduction product (II), which is obtained by reduction with zinc dust in boiling acetic acid[3].

The starting material for the synthesis of the aglucone was *o*-(methoxymethoxy)-nitrobenzene (III), from which the corresponding phenylhydroxylamine derivative (IV) is prepared in the usual way by reduction with zinc dust in a neutral medium. By allowing this compound to react with dichloroacetylchloride, N-(*o*-methoxymethoxyphenyl)-dichloroacethydroxamic acid (V) is obtained. The methoxymethoxy group is then hydrolysed by heating in a dilute methanolic hydrochloric acid solution. Finally the compound formed (VI) is

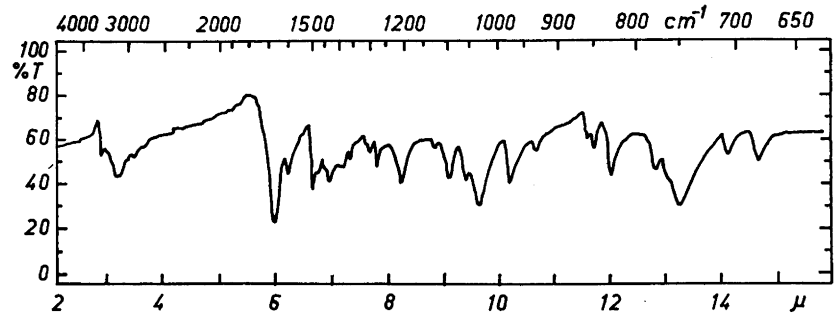

Fig. 1. The IR spectrum of the synthetic and the natural aglucone.

dissolved in a sodium hydroxide solution and allowed to stand for some time at room temperature, whereby hydrolysis and cyclisation to 2,4-dihydroxy-1,4-benzoxazin-3-one(I) occurs.

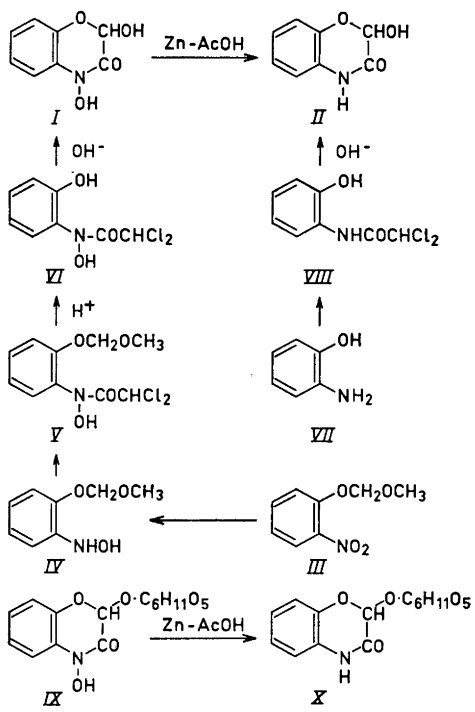
The synthesis of the reduction product [3] is carried out by an analogous procedure. The starting material was now *o*-aminophenol (VII), from which the N-dichloroacetyl derivative (VIII) is prepared. When this compound is dissolved in a dilute sodium hydrogencarbonate solution and boiled for a short time, the 2-hydroxy-1,4-benzoxazin-3-one (II) is formed.

The identity of these compounds with the aglucone and its reduction product were confirmed by the mixed melting points, the UV and the IR spectra. Fig. 1 shows the IR spectrum of the synthetic aglucone. The IR spectrum of the natural aglucone is identical with the spectrum in the figure. The spectrum is in accord with the structure proposed by Virtanen and Hietala for the aglucone.

When the glucoside, also isolated from rye seedlings, was reduced by an analogous procedure as the aglucone, a substance (X) is obtained, which also did not give any colour reaction with ferric chloride. On the basis of the similarity of its UV spectra with that of the reduction product of the aglucone, the structure (X) can be suggested for this compound and the structure (IX) for the glucoside. The attempts to synthesize the compound (X) from the reduction product (II) and acetobromoglucose failed.

All melting points are corrected.

o-(Methoxymethoxy)-nitrobenzene. A mixture of 5.31 g of dry potassium salt of *o*-nitrophenol and 2.5 g of chloromethyl-



methylether [4] in 15 ml of dry benzene was refluxed for one hour. The benzene solution was then washed several times with dilute sodium hydroxide solution and dried over sodium sulphate. The solvent was evaporated and the residue distilled in a vacuum. The yield was 3.9 g (71 %). B. p. 134—135°/7 mm. (Found: N 7.74. Calc. for $C_8H_9NO_4$: N 7.65.)

o-(Methoxymethoxy)-phenylhydroxylamine. A solution of 3.66 g of *o*-(methoxymethoxy)-nitrobenzene and 2.0 g of ammonium chloride in 50 ml of 60 % alcohol was cooled below 10°C. To this solution 2.0 g of zinc dust were added in the course of half an hour with stirring. The solution was filtered and 50 ml of water were added, and then extracted with ether. The ether solution was dried and the solvent evaporated. The residue (3.3 g) was a yellow oil which did not crystallize. It was used without further purification for the following reaction.

2,4-Dihydroxy-1,4-benzoxazin-3-one. To a solution of 3.3 g of the crude *o*-(methoxymethoxy)-phenylhydroxylamine in 50 ml of dry ether 1.45 g of dichloroacetylchloride in 20 ml of ether were gradually added under cooling (0°C). The ether solution was decanted from the dark brown oil and evaporated to dryness. The residue was dissolved in 20 ml of methanol and 2 ml of 2 N hydrochloric acid and refluxed for half an hour. The solvent was evaporated under reduced pressure, and the residue was dissolved in 20 ml of 1 N sodium hydroxide solution, and allowed to stand for 2 h at room temperature. After addition of dilute hydrochloric acid to the acid reaction, the solution was filtered and extracted first several times with benzene (to remove the coloured impurities) and then with ether. The ether solution was dried and the solvent evaporated. The residue was dissolved in a few ml of 0.5 N hydrochloric acid and extracted several times with benzene. The water solution was filtered and then extracted with ether. After drying, the solvent was evaporated and the residue crystallized from a mixture of ether-benzene. The overall yield was 61 mg (3.5 %). M. p. 153–154° C, mixed m. p. 151–152°C with the aglucone (m. p. 151–152°C).

UV spectrum (in ethanol).

Synthetic product: max. 255 mμ, ε = 8 850; max. 282 mμ, ε = 5 880.

Aglucone: max. 254 mμ, ε = 8 500; max. 282 mμ, ε = 5 800.

Reduction of the aglucone: 48 mg of the aglucone were dissolved in 20 ml of glacial acetic acid, and 100 mg of zinc dust were added. The mixture was boiled for 15 min and excess zinc was filtered off. The acetic acid was evaporated under reduced pressure, and the residue was crystallized from an ether-benzene mixture. Yield 25 mg (57 %). M. p. 201–203°C. UV spectrum (in ethanol): Max. 250 mμ, ε = 8 900, max. 282 mμ, ε = 4 350. (Found: C 58.23 H 4.45; O 28.82. Calc. for $C_8H_7NO_3$: C 58.18; H 4.27; O 29.06.)

o-(Dichloroacetamido)-phenol. To a solution of 2.18 g of pure *o*-aminophenol in dry ether 1.5 g of dichloroacetylchloride in ether were added gradually. After standing for one hour at room temperature, the precipitated *o*-aminophenol hydrochloride was filtered off, and the filtrate evaporated to dryness, whereat the product crystallizes. After recrystallization from a mixture of benzene-petroleum ether the m. p. was 134–135°C and the yield 1.7 g (77 %). (Found: N 6.20. Calc. for $C_8H_7Cl_2NO_2$: N 6.37.)

The synthesis of the reduction product. 220 mg of *o*-(dichloroacetamido)-phenol and 10 ml of 0.2 M $NaHCO_3$ solution were boiled for 10 min. The solution was cooled and made slightly acid with hydrochloric acid and extracted with ether. The ether solution was dried, a few ml of benzene were added, and most of the ether was evaporated, upon which the product crystallizes. M. p. 201–203°C. Yield 124 mg (75 %). Mixed m. p. 201–203°C with the reduction product of the aglucone. UV spectrum (in ethanol): Max. 250 mμ, ε = 8 850, max. 282 mμ, ε = 4 400.

Reduction of the glucoside. To a boiling solution of 10 mg of the glucoside in 5 ml of acetic acid 25 mg of zinc dust were added. After boiling for 15 min, the excess zinc was filtered off. The acetic acid was evaporated under reduced pressure, and the residue was dissolved in a few ml of water. The zinc was then precipitated as sulphide. After filtration the solution was evaporated to dryness and the residue was dissolved in absolute alcohol. Benzene was added, and the alcohol was distilled off, upon which the product crystallized. M. p. 158–160°C. (Found: N 4.12. Calc. for $C_{14}H_{17}NO_8$: N 4.28.) UV spectrum (in ethanol): Max. 250 mμ, ε = 7 500, max. 278 mμ, ε = 3 800.

The hydrolysis of the glucoside occurs rapidly through an enzyme present in rye seedlings, as previously shown in this laboratory. The enzyme has not been purified or further investigated yet. The glucoside was not hydrolysed by yeast in our experiments. On the other hand, hydrolysis of the glucoside was observed in a homogenate of the small intestine of the rabbit, although a much weaker one than in rye seedlings. A homogenate of rat intestine had much the same effect as that

of the rabbit. From these observations we may conclude that the glucoside can be decomposed in the animal organism without the enzyme present in plants.

The Enzymic Formation of Thiocyanate (SCN^-) from a Precursor(s) in *Brassica* Species

ROLF GMELIN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The chemical nature of the goitrogenic "*Brassica* factors" is still unclear to a great extent. This is partly due to the fact that several active factors may be involved, which are moreover formed only through enzymic reactions when plants are crushed. This has long been known in regard to the formation of the strongly goitrogenic thiooxazolidones occurring in the crushed and moistened seeds of many crucifers [1]. Recently Virtanen *et al.*[2], and Kreula and Kiesvaara [3] found the formation of vinyl-thiooxazolidone also in cabbage, kale, rape, and other fodder plants belonging to the *Cruciferae* family.

The same authors [4] have also demonstrated the transfer of this substance to milk in very small amounts (about 0.05 % of the amount fed). These quantities are so small that they cannot be expected to have any goitrogenic effect in the milk. Kreula and Kiesvaara [4] have given a detailed report on the methods used in these investigations. Somewhat later Altamura *et al.*[5] independently also demonstrated the formation of vinyl-thiooxazolidone in cabbage.

The goitrogenic effect of thiooxazolidones is due to the fact that they inhibit the synthesis of thyroid hormones. This effect cannot be overcome by high doses of iodide.

Another type of goitrogenic substances belonging to the *Brassica* factors has a primary influence on the uptake of iodide by the thyroid gland. This influence can be prevented by increasing the amount of the iodide dose. Many pieces of information given in the literature [6,7] indicate that salts of thiocyanic acid (SCN^-) represent this type in crucifers. Jirousek [8], who has investigated and reviewed the thiocyanate metabolism, found that in the animal organism SCN^- is formed endogenously from cyanides, nitriles, and sulphur-containing compounds, and that both the SCN^- brought exogenously into the organism and that formed endogenously in it have to be taken into consideration as goitrogenic factors. Michajlovskij and Langer [9,10] have performed systematic determinations on the SCN^- content in different vegetables. They found a particularly high SCN^- content in the press juice of different cabbage species (up to 50 mg %). They used the term "präformiertes Rhodanid" for the SCN^- present in food stuffs, obviously in contrast to the SCN^- formed endogenously.

Our investigations concerning the problem whether it is possible to make milk goitrogenic by feeding cows with plants, especially those belonging to the *Cruciferae*, have led to some new findings regarding the *Brassica* factors. These findings are briefly reported in the present paper.

An account was recently given about the formation of organic thiocyanates in some crucifers [11]. Benzyl thiocyanate was found to be formed enzymatically from glucotropaeolin in *Lepidium ruderale* and allyl thiocyanate from sinigrin in *Thlaspi arvense*. It was found in this laboratory that after the injection of benzyl thiocyanate into rats, the SCN^- content has risen considerably in blood serum and in different organs. This finding led us to look for thiocyanate esters also in *Brassica oleracea* species. For the present we have, however, no indications for the formation of such esters in fresh cabbage species. On the other hand, the result of these investigations was the finding that free SCN^- is formed from glucosidic precursors, present in cabbage. The thiocyanate found by Michajlovskij and Langer in the press juice of cabbage is thus not "preformed SCN^-"

of the rabbit. From these observations we may conclude that the glucoside can be decomposed in the animal organism without the enzyme present in plants.

The Enzymic Formation of Thiocyanate (SCN^-) from a Precursor(s) in *Brassica* Species

ROLF GMELIN and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The chemical nature of the goitrogenic "*Brassica* factors" is still unclear to a great extent. This is partly due to the fact that several active factors may be involved, which are moreover formed only through enzymic reactions when plants are crushed. This has long been known in regard to the formation of the strongly goitrogenic thiooxazolidones occurring in the crushed and moistened seeds of many crucifers [1]. Recently Virtanen *et al.*[2], and Kreula and Kiesvaara [3] found the formation of vinyl-thiooxazolidone also in cabbage, kale, rape, and other fodder plants belonging to the *Cruciferae* family.

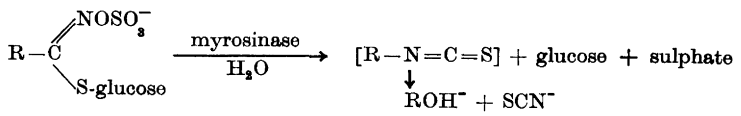
The same authors [4] have also demonstrated the transfer of this substance to milk in very small amounts (about 0.05 % of the amount fed). These quantities are so small that they cannot be expected to have any goitrogenic effect in the milk. Kreula and Kiesvaara [4] have given a detailed report on the methods used in these investigations. Somewhat later Altamura *et al.*[5] independently also demonstrated the formation of vinyl-thiooxazolidone in cabbage.

The goitrogenic effect of thiooxazolidones is due to the fact that they inhibit the synthesis of thyroid hormones. This effect cannot be overcome by high doses of iodide.

Another type of goitrogenic substances belonging to the *Brassica* factors has a primary influence on the uptake of iodide by the thyroid gland. This influence can be prevented by increasing the amount of the iodide dose. Many pieces of information given in the literature [6,7] indicate that salts of thiocyanic acid (SCN^-) represent this type in crucifers. Jirousek [8], who has investigated and reviewed the thiocyanate metabolism, found that in the animal organism SCN^- is formed endogenously from cyanides, nitriles, and sulphur-containing compounds, and that both the SCN^- brought exogenously into the organism and that formed endogenously in it have to be taken into consideration as goitrogenic factors. Michajlovskij and Langer [9,10] have performed systematic determinations on the SCN^- content in different vegetables. They found a particularly high SCN^- content in the press juice of different cabbage species (up to 50 mg %). They used the term "präformiertes Rhodanid" for the SCN^- present in food stuffs, obviously in contrast to the SCN^- formed endogenously.

Our investigations concerning the problem whether it is possible to make milk goitrogenic by feeding cows with plants, especially those belonging to the *Cruciferae*, have led to some new findings regarding the *Brassica* factors. These findings are briefly reported in the present paper.

An account was recently given about the formation of organic thiocyanates in some crucifers [11]. Benzyl thiocyanate was found to be formed enzymatically from glucotropaeolin in *Lepidium ruderale* and allyl thiocyanate from sinigrin in *Thlaspi arvense*. It was found in this laboratory that after the injection of benzyl thiocyanate into rats, the SCN^- content has risen considerably in blood serum and in different organs. This finding led us to look for thiocyanate esters also in *Brassica oleracea* species. For the present we have, however, no indications for the formation of such esters in fresh cabbage species. On the other hand, the result of these investigations was the finding that free SCN^- is formed from glucosidic precursors, present in cabbage. The thiocyanate found by Michajlovskij and Langer in the press juice of cabbage is thus not "preformed SCN^-"



but is formed enzymatically from a glucosidic precursor(s) in cabbage. This fact was established when enzymes were destroyed in cabbage leaves by placing them intact in boiling methanol. The solution obtained was free from SCN^-. After addition of myrosinase solution to the purified extract SCN^- was formed, as determined by colour reactions for SCN^- and by paper chromatography.

The determination of SCN^- formed enzymatically in fresh plants was performed in the following way. 10 g of whole leaves of *Brassica oleracea* species were twice extracted by boiling for 15 min in 50 ml portions of methanol. The methanolic solutions were decanted. The plant material was thoroughly ground in a mortar, and was once more extracted by boiling in 50 ml of 70 % methanol. The combined extracts were evaporated *in vacuo*. The residue was taken up in water, and the solution was treated with about 0.6 ml of 20 % lead acetate solution. Filtration and washing of the filter residue with water. Excess lead ions in the filtrate were precipitated by H_2S. The filtrate was concentrated *in vacuo* to about 20 ml and brought to 25 ml (volumetric flask). 10 ml of this solution, 1 ml of myrosinase solution *, and 1 ml of phosphate buffer at pH 7 were incubated for 2 h at 37°. The solution was then brought to 100 ml. A control without addition of myrosinase solution was treated in the same way, and was used as a blank. 5 ml samples were mixed with 1 ml of Fe-reagent, measured at 500 mμ with a Klett-Summerson colorimeter, and the values compared with a standard SCN^- curve, essentially as in the method of Barker [13].

Table 1 shows the amounts of SCN^- formed in different cabbage species.

As is apparent from the list, varying amounts of SCN^- are formed in different cabbage species. The thiocyanate content of the press juices found by Langer and Michajlovskij corresponds to the amounts found by us.

* prepared according to Neuberg and Wagner [12]. SCN^- originally present in the myrosinase solution, was removed by shaking the solution for 30 min with Dowex 2 × 4 in chloride form.

Table 1. SCN^- content in cabbage species after myrosinase treatment.

Brassica species	SCN^- formation per 100 g fresh plants

• root

No formation of SCN^- was found in the crushed and moistened seeds of different cabbage species.

Attempts to isolate the glucosidic precursor from cabbage have been unsuccessful so far. The following findings can, however, be presented.

1. The precursor(s) of SCN^- decomposes with myrosinase so that SCN^- is liberated.
2. On spraying with $AgNO_3$ solution and heating, the precursor of SCN^- gives the same reaction on the paper chromatogram as mustard oil glucosides (gray-brown spot[14]).
3. On spraying with $FeCl_3$ solution, the precursor of SCN^- gives a brownish red spot after a short heating to 100°.
4. The position of the precursor on the paper chromatogram could be established furthermore either by spraying the paper first with myrosinase solution, and after standing for 1 h with $FeCl_3$ solution or by eluting the zones by the usual colour reactions for SCN^- after treatments of the eluates by myrosinase.

5. In a butanol-acetic acid-water system, the R_F value [15] of the SCN^- precursor was 0.76, in a pyridine-amylalcohol-water system it was 1.0.

Although the information about the chemical nature of the precursor is still scanty, we think it reasonable to publish a preliminary communication about our results at this stage. In our opinion the finding of the enzymatic formation of SCN^- is rather important, since it may help to shed light on many discrepancies about the *Brassica* factors.

If the SCN^- precursor is a mustard oil glucoside, as we suppose on the basis of the present indications, the formation of SCN^- according to the following reaction scheme seems probable, (see p. 508).

This secondary decomposition of an *iso*thiocyanate is no unknown reaction. Already in 1879 Will and Laubenheimer [16] have observed that *p*-hydroxybenzyl mustard oil (the *iso*thiocyanate formed from the glucoside sinalbin, present in white mustard) is split almost quantitatively into SCN^- by the action of alkali.

We have, however, found that considerable amounts of SCN^- are formed from glucosinalbin during the enzymatic cleavage even at pH 7. The initially present, pungent tasting *p*-hydroxybenzyl isothiocyanate decomposes gradually, loosing its irritating properties, into SCN^- and probably *p*-hydroxybenzyl alcohol. This secondary reaction seems to proceed at pH 7 at a slower rate than is the case with the SCN^- precursor of cabbage. Treatment of glucosinalbin with alkali, however, affords complete and fast fission, and permits a simple assay for the glucosinalbin content in the seeds of *Sinapis alba* by colorimetric SCN^- determination.

As long as the SCN^- precursor has not yet been isolated from *Brassica oleracea* species, the plants containing glucosinalbin (*Sinapis* species, *Bunias* species, *Lepidium campestre etc.*) may be used as suitable models for studies on the goitrogenic effect of the SCN^- precursor. Wagner-Jauregg and Koch [17] have for example observed a slight goitrogenic effect by application of myrosinase treated sinalbin solution to rabbits (sinalbin itself was without effect) but have not recognized or regarded SCN^- as the evidently responsible goitrogenic factor in this experiment.

Several thioglucosides were found in the limited number of cabbage species used so far for the attempted isolation of the SCN^- precursor: glucoraphanin, sinigrin, and glu-

Acta Chem. Scand. 14 (1960) No. 2

conapin in the fresh parts of *Brassica oleracea* var. *gemmifera;* glucoiberin and sinigrin in the fresh parts of marrow stem kale ("Chou Moellier"); glucoiberin and glucoraphanin in *Brassica oleracea* var. *cretica.* They were detected [14] directly by paper chromatography and comparison with authentic thioglucosides, or indirectly as thioureas derived from the enzymatically formed *iso*thiocyanates by the method of Kjær and Rubinstein [18] in different solvent systems.

From 500 g fresh parts of *Brassica oleracea* var. *gemmifera* 15 mg of analytically pure sulphoraphan-phenylthiourea were isolated (m. p. 145°C) *.

The presence of glucoiberin and glucoraphanin and their *iso*thiocyanates, respectively, in cabbage species becomes of special interest since Bachelard and Trikojus [20] have recently found that cheirolin (3-methylsulphonylpropyl *iso*thiocyanate) has a significant thyreostatic effect in animals. Iberin (3-methylsulphinylpropyl *iso*thiocyanate) and sulphoraphan (4-methylsulphinylbutyl *iso*thiocyanate) belong to the same isothiocyanate type as cheirolin, and may thus be considered as potential members in the group of "Brassica factors".

This investigation is a part of a research project under U.S. Public Law No. 480, 83rd Congress.

Isolation of an Iron-Containing Red Protein from Human Milk

BENGT JOHANSON

Department of Medical Biochemistry, University of Göteborg, Göteborg, Sweden

The presence of a red protein in bovine milk has been observed by several authors [1-4]. Sörensen and Sörensen [1] as well as Polis and Shmukler [3] performed a partial purification of this protein and recently a procedure for its isolation was described by Grooves [4]. The protein isolated by Grooves contained iron and was in certain respects similar to the iron-binding protein in blood plasma (transferrin [5] or β_1-metal-combining protein [6]). According to Schäfer [7] *human* milk assumes a red color after addition of small amounts of iron, probably due to the formation of an iron-protein complex. It has also been observed in this laboratory that crude preparations of human milk whey proteins are often salmon coloured[8]. This colour becomes more pronounced after addition of iron to the milk. A partial purification of the red component has been achieved by chromatography on calcium phosphate [9]. A method for isolation of the red protein has now been worked out and will be presented below.

Four litres of fresh human milk were defatted by centrifugation. After addition of 10 mg of Fe^{2+} (in the form of ferrous ammonium sulphate) to the milk, giving it a distinct reddish tint, solid ammonium sulphate was added to 45 % saturation and pH adjusted to 8.0 by careful addition of concentrated ammonia. When the milk was warmed to 37° for 30 min a flocculent precipitate was formed, which was removed by filtration through a fluted paper (Whatman No. 12). The rate of filtration was most often slow and the filtration had to proceed overnight at +4°C. The precipitate was discarded and the red-brown filtrate was acidified to pH 4.0 with 1 M sulfuric acid. The precipitate formed was quickly removed by gravity filtration or better by centrifugation and the pH of the filtrate (supernatant) immediately readjusted to 8.0. Ammonium sulphate was added to 80 % saturation and the red precipitate collected by filtration and dissolved in a minimal amount of distilled water. The dark red solution was dialyzed against distilled water followed by dialysis against 0.02 M sodium phosphate buffer, pH 8.0. The solution was then chromatographed on DEAE-cellulose [10] previously equilibrated with the same buffer. Under the conditions described the red protein was not sorbed on the ion-exchanger but appeared in the effluent without significant retardation. The red fraction was further chromatographed on calcium phosphate as described earlier [9], using phosphate buffers of pH 8.0 instead of 6.9. The red fraction eluted with 0.5 M phosphate buffer was dialyzed against distilled water and finally

Isolation of an Iron-Containing Red Protein from Human Milk

BENGT JOHANSON

Department of Medical Biochemistry, University of Göteborg, Göteborg, Sweden

The presence of a red protein in bovine milk has been observed by several authors [1-4]. Sörensen and Sörensen [1] as well as Polis and Shmukler [3] performed a partial purification of this protein and recently a procedure for its isolation was described by Grooves [4]. The protein isolated by Grooves contained iron and was in certain respects similar to the iron-binding protein in blood plasma (transferrin [5] or β_1-metal-combining protein [6]). According to Schäfer [7] *human* milk assumes a red color after addition of small amounts of iron, probably due to the formation of an iron-protein complex. It has also been observed in this laboratory that crude preparations of human milk whey proteins are often salmon coloured[8]. This colour becomes more pronounced after addition of iron to the milk. A partial purification of the red component has been achieved by chromatography on calcium phosphate [9]. A method for isolation of the red protein has now been worked out and will be presented below.

Four litres of fresh human milk were defatted by centrifugation. After addition of 10 mg of Fe^{2+} (in the form of ferrous ammonium sulphate) to the milk, giving it a distinct reddish tint, solid ammonium sulphate was added to 45 % saturation and pH adjusted to 8.0 by careful addition of concentrated ammonia. When the milk was warmed to 37° for 30 min a flocculent precipitate was formed, which was removed by filtration through a fluted paper (Whatman No. 12). The rate of filtration was most often slow and the filtration had to proceed overnight at +4°C. The precipitate was discarded and the red-brown filtrate was acidified to pH 4.0 with 1 M sulfuric acid. The precipitate formed was quickly removed by gravity filtration or better by centrifugation and the pH of the filtrate (supernatant) immediately readjusted to 8.0. Ammonium sulphate was added to 80 % saturation and the red precipitate collected by filtration and dissolved in a minimal amount of distilled water. The dark red solution was dialyzed against distilled water followed by dialysis against 0.02 M sodium phosphate buffer, pH 8.0. The solution was then chromatographed on DEAE-cellulose [10] previously equilibrated with the same buffer. Under the conditions described the red protein was not sorbed on the ion-exchanger but appeared in the effluent without significant retardation. The red fraction was further chromatographed on calcium phosphate as described earlier [9], using phosphate buffers of pH 8.0 instead of 6.9. The red fraction eluted with 0.5 M phosphate buffer was dialyzed against distilled water and finally

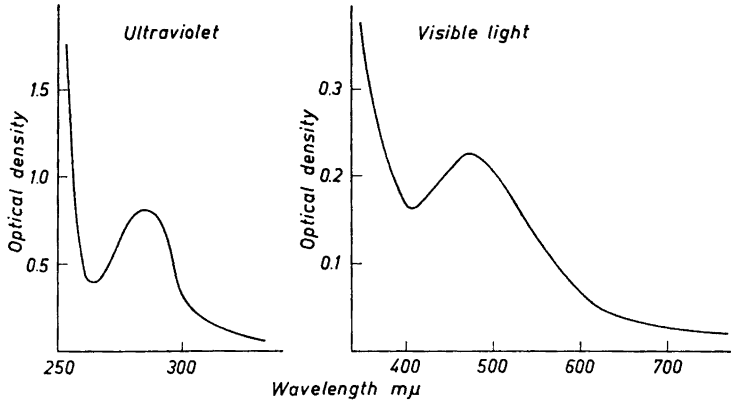

Fig. 2. Absorption spectrum of the red protein at pH 9.0.

precipitated with ammonium sulphate between 60 and 75 % saturation at pH 8.0.

The product obtained was run in moving boundary electrophoresis and found to be homogeneous in glycine-NaOH buffer of pH 9.4 and ionic strength 0.1 (Fig. 1) and also in sodium veronal-HCl buffer of pH 8.6 and ionic strength 0.1. Electrophoresis at pH 8.0, however, showed an asymmetric peak on the ascending limb that might be due to a heterogeneity of the preparation.

Analysis of the iron content according to Lorber [11] after combustion with sulfuric acid and 30 % hydrogen peroxide [12] showed the presence of 0.13—0.15 % iron in different preparations. After passage of the protein through a column with cation exchange resin (Dowex 50, X-12) at pH 8.5 the iron content was diminished to 0.10—0.11 %. The main part of the iron could thus not be removed by the resin. The light absorption was examined in the wavelength range of 225—700 mμ (Fig. 2) in a Zeiss spectrophotometer, PMQ II, using 1 cm cuvettes. In the ultraviolet region only the expected maximum around 280 mμ was found. In the region of visible light a broad maximum at 460—470 mμ and a minimum around 410 mμ were found. At a protein concentration of 1.0 % (pH 9.0) the optical density at 460 mμ varied between 0.40 and 0.45 for different preparations (1 cm light pathway). The ratio of the optical densities at 460 to 408 mμ varied between 1.30 and 1.38. The type of light absorption curves and the presence of

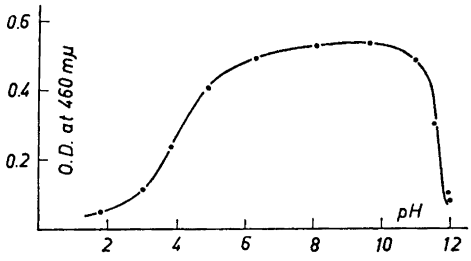

Fig. 3. The pH-dependance of the light absorption of the red protein at 460 mμ.

strongly bound iron suggests a certain similarity to blood serum transferrin. The milk protein is, however, not identical to transferrin, as there is no immunological relationship between the two proteins as determined by diffusion-in-gel analysis [13]. Furthermore the iron complex formed by the milk protein seems to be more stable in acid media than the iron-transferrin complex. The milk protein is thus not completely decolorized until pH 2 (Fig. 3) and at this pH 90—95 % of the iron is removable by passing the protein through a column of Dowex 50, X-12.

These and further studies will be reported in detail shortly.

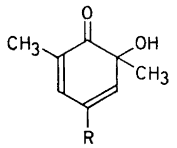
Perjodatoxydation von Phenolen VI*. Dimere *o*-Chinole aus Mesitol und 2,6-Dimethylphenol

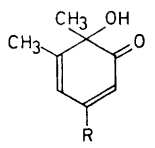
ERICH ADLER, JOSEF DAHLÉN und GERTRUD WESTIN

Organisch-chemisches Institut, Chalmers Technische Hochschule, Göteborg, Schweden

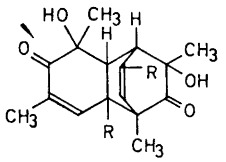
Die Einwirkung von Natriumperjodat auf wässrige Lösungen von Mesitol bzw. 2,6-Dimethylphenol führt in rascher Reaktion zu Substanzen vom Schmp. 183° bzw. 196°, für welche die Strukturen der Dimeren V[1] bzw. VI angenommen wurden. Ihre Entstehung war verständlich mit der Annahme, dass die Phenole zunächst zu den *o*-Chinolen I bzw. II oxydiert werden, und dass die letzteren sich durch Diels-Alder-Reaktion dimerisieren. Wessely und Mitarb. hatten das Dimere vom Schmp. 183° auch bei der alkalischen Verseifung von 2,4,6-Trimethyl-*o*-chinolacetat (I, OAc statt OH) erhalten und für das Produkt ebenfalls Struktur V vermutet [2]. Direkter Vergleich der beiden Präparate bestätigte deren Identität.



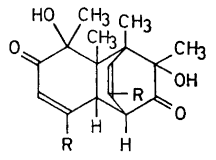
I. R = CH_3
II. R = H



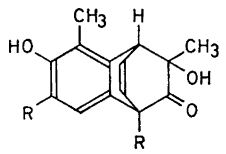
III. R = CH_3
IV. R = H



V. R = CH_3
VI. R = H



VII. R = CH_3
VIII. R = H



IX. R = CH_3
X. R = H

Kürzlich berichteten jedoch Wessely und Mitarb.[3] über Versuche, welche die genannten Autoren zu einer Revision der Formel V veranlasste. Man fand, dass die alkalische Verseifung von 2,4,6-Trimethyl-*o*-chinolacetat (I, OAc statt OH) neben dem Dimeren vom Schmp. 183° überraschenderweise monomeres 2,3,5-Trimethyl-*o*-chinol (III) lieferte. Perjodatoxydation von Phenolen VI*. Dimere *o*-Chinole aus Mesitol und 2,6-Dimethylphenol

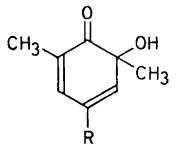
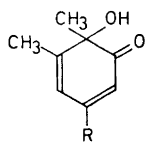
ERICH ADLER, JOSEF DAHLÉN und GERTRUD WESTIN

Organisch-chemisches Institut, Chalmers Technische Hochschule, Göteborg, Schweden

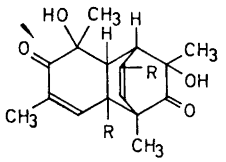
Die Einwirkung von Natriumperjodat auf wässrige Lösungen von Mesitol bzw. 2,6-Dimethylphenol führt in rascher Reaktion zu Substanzen vom Schmp. 183° bzw. 196°, für welche die Strukturen der Dimeren V[1] bzw. VI angenommen wurden. Ihre Entstehung war verständlich mit der Annahme, dass die Phenole zunächst zu den *o*-Chinolen I bzw. II oxydiert werden, und dass die letzteren sich durch Diels-Alder-Reaktion dimerisieren. Wessely und Mitarb. hatten das Dimere vom Schmp. 183° auch bei der alkalischen Verseifung von 2,4,6-Trimethyl-*o*-chinolacetat (I, OAc statt OH) erhalten und für das Produkt ebenfalls Struktur V vermutet [2]. Direkter Vergleich der beiden Präparate bestätigte deren Identität.



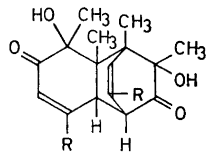
I. R = CH_3
II. R = H



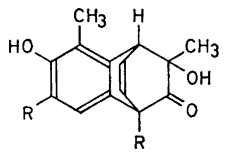
III. R = CH_3
IV. R = H



V. R = CH_3
VI. R = H



VII. R = CH_3
VIII. R = H



IX. R = CH_3
X. R = H

Kürzlich berichteten jedoch Wessely und Mitarb.[3] über Versuche, welche die genannten Autoren zu einer Revision der Formel V veranlasste. Man fand, dass die alkalische Verseifung von 2,4,6-Trimethyl-*o*-chinolacetat (I, OAc statt OH) neben dem Dimeren vom Schmp. 183° überraschenderweise monomeres 2,3,5-Trimethyl-*o*-chinol (III) lieferte. Im alkalischen Medium war demnach eine Acyloinumlagerung einge-

* V. Mitt.: Adler, E., Junghahn, L., Lindberg, U., Berggren, B. und Westin, G. *Acta Chem. Scand.* **14** (1960). *Im Druck.*

treten. Da ferner das Dimere vom Schmp. 183° beim Erhitzen auf 200° zum Teil unter Bildung von III zerfiel und anderseits III bei 130° wieder das genannte Dimere lieferte, nahmen Wessely und Mitarb.[3] für die Substanz vom Schmp. 183° die Formel VII eines dimeren 2,3,5-Trimethyl-*o*-chinols an. Aus ähnlichen Gründen schrieben sie einem bei Verseifung von 2,6-Dimethyl-*o*-chinolacetat (II, OAc statt OH) erhaltenen Produkt vom Schmp. 196° die Struktur eines dimeren 2,3-Dimethyl-*o*-chinols (VIII) zu. Direkter Vergleich der letztgenannten Substanz mit dem von uns aus 2,6-Dimethylphenol und Perjodat erhaltenen Produkt gleichen Schmelzpunkts ergab wiederum Identität.

Wären die von Wessely c.s.[3] für die beiden Dimeren vorgeschlagenen Strukturen VII und VIII richtig, so müsste also angenommen werden, dass auch unter den von uns angewandten Bedingungen der Perjodatoxydation die primär entstehenden *o*-Chinole I bzw. II sich in III bzw. IV umlagerten, bevor Dimerisierung eintrat. Da wir bei pH 4—5 (Zimmertemp.) arbeiteten und die Reaktion innerhalb 5 Min. abgeschlossen ist, erschien uns diese Annahme unwahrscheinlich. Aus den nachstehenden Ergebnissen folgern wir, dass den Dimeren die "normalen" Strukturen V bzw. VI zukommen.

Perjodatoxydation von 2,3,5-Trimethylphenol gab kein Dimeres, sondern (neben 2,3,5-Trimethyl-*p*-chinon) das monomere 2,3,5-Trimethyl-*o*-chinol III, das bei gewöhnlicher Temperatur stabil war. Die rasche Bildung des Dimeren vom Schmp. 183° bei der Perjodatoxydation von Mesitol kann demnach nicht über das 2,3,5-Trimethyl-*o*-chinol verlaufen.

Das Diacetylderivat (Schmp. 158°) des aus 2,6-Dimethylphenol gewonnenen Dimeren vom Schmp. 196° zerfiel beim Erhitzen auf 180° unter Bildung von 2,6-Dimethyl-*o*-chinolacetat [3,4] (II, OAc statt OH). Letzteres konnte bei 120° wieder zum Dimeracetat vom Schmp. 158° dimerisiert werden; dagegen blieb 2,3-Dimethyl-*o*-chinolacetat [5] (IV, OAc statt OH) bei 120° unverändert. Milde alkalische Verseifung des Dimerdiacetats gab neben dem Ausgangsdimeren ein Anhydrodimeres, Schmp. 176°, von phenolischem Charakter. Ganz ähnlich erhielten wir bei Verseifung des dimeren 2-Methyl-*o*-chinolacetats von Metlesics und Wessely [6] das Phenol X, dessen Struktur eindeutig festgelegt ist [6]. Das Anhydroprodukt vom Schmp. 176° ist spektral und im chemischen Verhalten mit X völlig analog; es kann ihm daher Struktur IX zugeschrieben werden. Die bei der Bildung von IX erfolgte Aromatisierung ist nur mit Struktur VI (dimeres 2,6-Dimethyl-*o*-chinol) und nicht mit Struktur VIII (dimeres 2,3-Dimethyl-*o*-chinol) für das Dimere vom Schmp. 196° in Einklang zu bringen.

Es scheint, dass die Versuchsergebnisse von Wessely c.s.[3] damit zu erklären sind, dass sowohl in Alkali wie beim trockenen Erhitzen die *o*-Chinolpaare I, III bzw. II, IV sich in Acyloinumlagerungs-Gleichgewichten befinden, und da wohl I und II, nicht aber III und IV zur Dimerisierung neigen, so werden unter den genannten Bedingungen I und II immer in dimerer Form (V und VI), III und IV immer in monomerer Form gefunden.

Ausführliche Publikation obiger und weiterer Versuche erfolgt demnächst.

Der eine von uns (E.A.) dankt Herrn Prof. Wessely, Wien, bestens für die Freundlichkeit uns von seinen Ergebnissen durch Übersendung eines Korrekturabzugs der Arbeit [3] vorzeitig zu unterrichten, sowie für sein Entgegenkommen beim Austausch der Dimerpräparate.

Periodate Oxidation of Phenols

II *. Oxidation of 2,6-Dimethoxyphenol and 3-Methoxycatechol. Formation of a 1,2-Naphthoquinone **

ERICH ADLER, RUNE MAGNUSSON, BRITT BERGGREN and HANS THOMELIUS

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The action of sodium periodate on an aqueous solution of 2,6-dimethoxyphenol (I) rapidly produces coerulignone (II), 2,6-dimethoxy-*p*-quinone (III), 3-methoxy-*o*-quinone (IV), 3,8-dimethoxy-1,2-naphthoquinone (V), m. p. 198–199°, and a violet substance (VI), m. p. 205–206°, of unknown structure. Compounds IV, V, and VI were also obtained by periodate oxidation of 3-methoxycatechol (VII). A similar treatment of IV yielded V and VI.

A dimeric 3-methoxy-*o*-quinone (VIII), m. p. 139–140°, is formed in solutions of the monomer (IV) in certain organic solvents; in aqueous solutions of IV, or of VIII, a monohydrate of dimer VIII (XIII, m. p. 114–115°) is formed. Both dimer VIII and its monohydrate XIII, when treated with periodate, are degraded to the β-naphthoquinone V. Thus, V arises from phenols I or VII in aqueous periodate solution by dimerisation of the 3-methoxy-*o*-quinone (IV) first formed and degradation of the dimer.

A second dimeric 3-methoxy-*o*-quinone (m. p. 110°) was obtained from benzene solutions of the monomer. On periodate oxidation it is converted to the violet compound VI.

In Part I [1] of this series it was shown that the action of sodium periodate on monoethers of catechol results in rapid oxidative cleavage of the ether group. Guaiacol, for instance, yielded about 90 % of the calculated amount of methanol, in addition to *o*-benzoquinone. Sodium bismuthate was found [2] to act in a similar way.

Lead tetraacetate however, although largely equivalent to periodate and bismuthate as a glycol-splitting agent, differs from them in its action on guaiacol. As reported by Wessely and Kotlan [3], lead tetraacetate attacks mainly the free 4-position, yielding methoxy-*p*-benzoquinone as the major reaction product. Similarly, the pyrogallol derivative 2,6-dimethoxyphenol

* Part I, see Ref. [1].

** Preliminary report: Adler, E. *Angew. Chem.* **71** (1959) 580.

(I) is oxidised by lead tetraacetate at the position *para* to the phenolic hydroxyl group, with the formation of 2,6-dimethoxy-*p*-quinone (II) (78 %) and coerulignone (III) (10 %) [3]. The action of Fremy's salt (potassium nitrosodisulphonate, $ON(SO_3K)_2$) on guaiacol and 2,6-dimethoxyphenol resembles that of lead tetraacetate and gives methoxy-*p*-quinone and 2,6-dimethoxy-*p*-quinone, respectively, in high yields [4].

PERIODATE OXIDATION OF 2,6-DIMETHOXYPHENOL (I)

As in the case of guaiacol, periodate treatment of 2,6-dimethoxyphenol (I) in dilute aqueous solution resulted in rapid consumption of the oxidant and the liberation of nearly 1 mole of methanol per mole of phenol after a reaction time of only 1—2 min. In addition to this *ortho* oxidative demethylation, some *para* oxidation also occurred, the ratio between *ortho* and *para* oxidation being dependent on the experimental conditions used and especially on the initial concentration of the phenol.

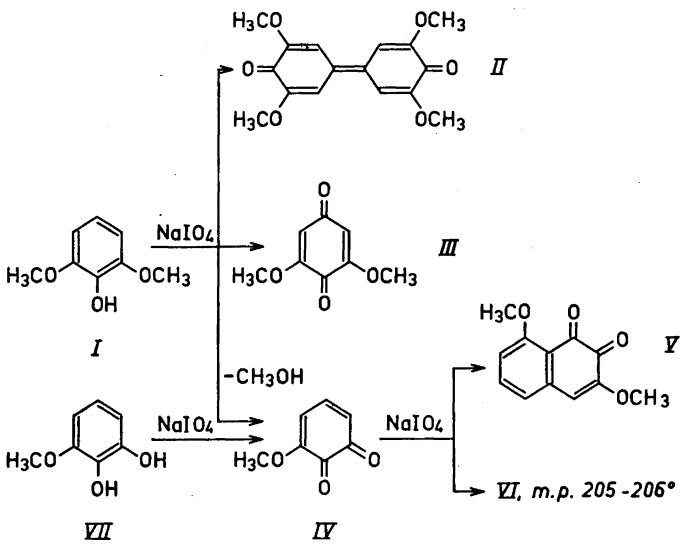
When a reaction mixture containing 8 mmole of I and 24 mmole of $NaIO_4$ per litre was used, and the oxidation was allowed to proceed at 4° for only 2 min, the expected product of the *o*-oxidative demethylation, *i.e.*, 3-methoxy-*o*-quinone (IV), was formed in 58 % yield (Table 1, Expt. 1). In addition to this compound there were also obtained small amounts of a brilliant red compound, $C_{10}H_4O_2(OCH_3)_2$, m.p. 198—199°, and traces of a dark-violet substance (VI), m.p. 205—206°, with the same composition. As will be described in a following communication [5], the red substance has been shown to be the hitherto unknown β-naphthoquinone V (3,8-dimethoxy-1,2-naphtoquinone). The dark-violet product (VI), which, on treatment with *o*-phenylenediamine, yielded an orange phenazine, m.p. 229—230°, is believed to be the isomeric 3,5-dimethoxy-1,2-naphthoquinone. Further investigation of the structure of substance VI is in progress. As shown below, both products, V and VI, originate from the 3-methoxy-1,2-benzoquinone (IV) that is formed first.

The *para* oxidation of I also gave small amounts of coerulignone (II) and 2,6-dimethoxy-1,4-benzoquinone (III) (Scheme 1).

Increasing the reaction temperature to 20° and the time of oxidation to 10 min (Table 1, Expt. 2) reduced the yield of the *o*-benzoquinone IV, but increased the yields of the β-naphthoquinone V and of coerulignone (II). This change in the ratio of the yields of products II, IV, and V was still more pronounced when the initial concentration of the starting phenol was increased ten-fold (Expt. 3). *Para* oxidation, mainly with the formation of coerulignone (II), then occurred to a greater extent and the yield of the β-naphtoquinone V was also further increased, but the yield of the *o*-benzoquinone IV was insignificant.

The separation of the various reaction products was based on the following procedure (for details, see Experimental). Coerulignone (II), which is practically insoluble, was recovered from the reaction mixture by filtration, and the products III, IV, V, and VI were extracted from the filtrate with chloroform and separated by chromatography on alumina. Fractional elution yielded the pure products III, V, and VI, but the *o*-benzoquinone IV was irreversibly adsorbed (and destroyed) on the alumina column. The difference between

Scheme 1.



the weight of the crude residue, obtained on evaporation of the chloroform extract and the combined weights of compounds III, V, and VI, eluted from the alumina column, was taken as a measure of the amount of 3-methoxy-1,2-benzoquinone (IV) present.

The yields given for IV may thus be slightly too high, as they could include minor amounts of polymeric transformation products of IV (and their periodate oxidation products) formed in the aqueous reaction mixture. However, polymeric products of this

Table 1. Periodate oxidation of 2,6-dimethoxyphenol (I), 3-methoxycatechol (VII), and 3-methoxy-1,2-benzoquinone (IV) in water [a].

[b] Unreacted starting material and polymers.

sort are sparingly soluble in chloroform and the error due to this source should be limited. As expected, the yield of water-soluble material not extractable with chloroform (= 100 minus total yield of products II—VI, as given in Table 1, last column) increases with increasing temperature, reaction time, and phenol concentration (*cf.* Expts. 1, 2, and 3).

On recrystallisation from ether, the crude solids remaining on evaporation of the chloroform extracts from reaction mixtures similar to those given in Expts. 1 and 2 (Table 1), gave 3-methoxy-1,2-benzoquinone (IV), m.p. 110° [6], in yields of 30—40 % based on the amount of phenol I used.

OXIDATION OF 3-METHOXYCATECHOL (VII)

As reported in Part I [1], periodate oxidation of 3-methoxy catechol (VII) yielded 3-methoxy-1,2-benzoquinone (IV) (nearly 60 %), *i.e.*, the oxidation occurred preferentially at the "catechol grouping" of VII rather than at the "guaiacol grouping" which was also present in VII. The experimental conditions were comparable to those used in Expt. 1, Table 1, for the oxidation of 2,6-dimethoxyphenol (low phenol concentration, low temperature, short reaction time).

Increasing the phenol concentration, temperature or time (Table 1, Expt. 4) resulted in a remarkably high yield of 3,8-dimethoxy-1,2-naphthoquinone (V) (48 %) and a simultaneous decrease of the amount of 3-methoxy-1,2-benzoquinone (IV). This is in accordance with the results of the oxidation of 2,6-dimethoxyphenol reported above. In the case of 3-methoxycatechol no defined *para* oxidation products were detected, and the yield of the β-naphthoquinone derivative V was considerably higher than in the oxidation of 2,6-dimethoxyphenol (*cf.* Expts. 3 and 4).

THE FORMATION OF 3,8-DIMETHOXY-1,2-NAPHTHOQUINONE (V). DIMERIC 3-METHOXY-1,2-BENZOQUINONE (VIII) AND ITS MONOHYDRATE (XIII)

While the formation of the *para* oxidation products, coerulignone (II) and 2,6-dimethoxy-*p*-quinone (III), from 2,6-dimethoxyphenol (I), and the formation of 3-methoxy-1,2-benzoquinone (IV) from I or from 3-methoxycatechol (VII) are easily understood, the formation of 3,8-dimethoxy-1,2-naphthoquinone (V) from the phenols I or VII was rather surprising. It obviously involved the fusion of two molecules of the starting phenol with the loss of two carbon atoms per two molecules of the phenol, and, in the case of 2,6-dimethoxyphenol (I), the oxidative removal of one methoxyl group per molecule of the starting phenol.

Such a fusion of two C_6-entities could be assumed to arise by spontaneous dimerisation of the 3-methoxy-1,2-benzoquinone (IV) first formed by periodate oxidation of both phenols, I and VII. In fact, comparatively concentrated aqueous solutions of the *o*-benzoquinone IV when treated with periodate (Table 1, Expt. 5) were found to give the dimethoxy-1,2-naphthoquinone V in yields (about 50 %) similar to those obtained from 3-methoxycatechol (*cf.* Expt. 4). As in the case of the phenols I and VII, respectively, the formation of the β-naphtoquinone V from the *o*-benzoquinone IV was practically complete within a reaction time of 10 min.

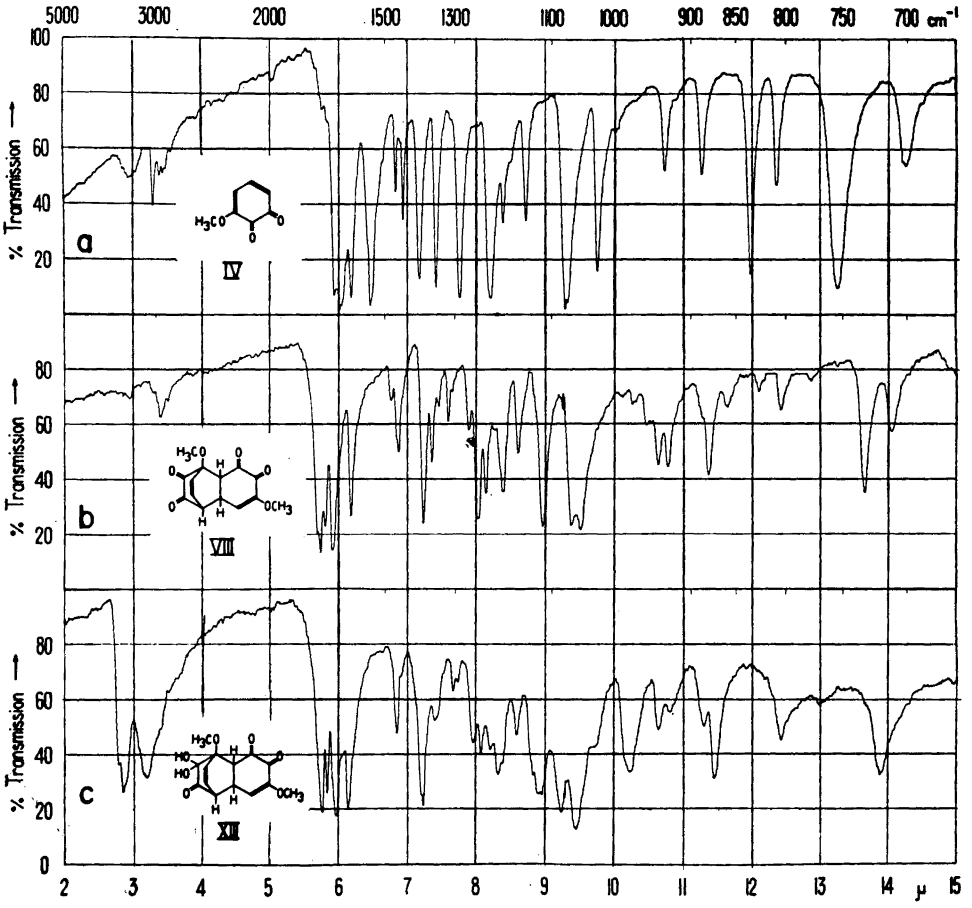

Fig. 1. Infra-red absorption spectra. a. 3-Methoxy-1,2-benzoquinone (IV). b. Dimeric 3-methoxy-1,2-benzoquinone (VIII). c. Monohydrate (XIII) of dimer VIII.

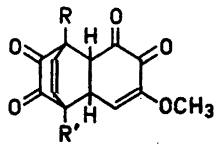
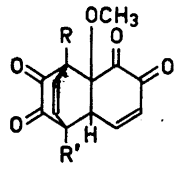
The assumption that the oxidative conversion of 3-methoxy-1,2-benzoquinone (IV) into 3,8-dimethoxy-1,2-naphthoquinone (V) involved an initial dimerisation of IV, could be examined experimentally when it was found that a dimeric 3-methoxy-1,2-benzoquinone could be easily obtained. When solutions of the monomer IV in certain solvents, such as acetone, methylene chloride, chloroform, dioxane, or ethyl acetate, were allowed to stand for a day at room temperature, a yellow product, m.p. 139—140°, was formed which had the same elemental composition as IV.

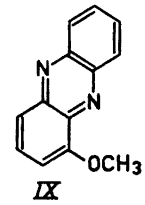
The infra-red spectrum of 3-methoxy-1,2-benzoquinone (IV) (Fig. 1a), shows very similar carbonyl absorption to that reported for the 5-ethyl homologue [7,8], but the infra-red spectrum of the yellow product (Fig. 1b) shows absorption bands at comparatively short wave-lengths, 5.69, 5.74, and

5.82 μ, indicating the presence of three isolated CO groups, and also a band at 5.93 μ, indicating an α,β-unsaturated carbonyl group. These bands, and a further band at 6.19 μ (ethylenic bond of C=C—C=O system), are practically identical with those reported by Harley-Mason and Laird [9] (*cf.* also Ref.[10]) for the yellow dimer of unsubstituted *o*-benzoquinone described by Willstätter and Müller [6], the structure of which was recently elucidated (VIII, H instead of CH_3O) [10,9,11]. Its formation by diene addition of two molecules of *o*-benzoquinone is analogous to the dimerisation of alkylated *o*-quinones clarified a few years ago [12,7,13].

Similar diene addition of 2 molecules of 3-methoxy-1,2-benzoquinone can give rise to four isomeric adducts, VIII—VIIIc:







IX

VIII: R = CH_3O; R′ = H VIIIb: R = CH_3O; R′ = H

VIIIa: R = H; R′ = CH_3O VIIIc: R = H; R′ = CH_3O

The light absorption of the dimeric 3-methoxy-*o*-quinone, m.p. 139—140°, (Fig. 2, curve 1) seems to be in harmony with structures VIII or VIIIa rather than VIIIb or VIIIc. The main maximum at 300 mμ can be acsribed to the methoxyl-substituted conjugated ene-dione chromophore of VIII or VIIIa, and the broad maximum at higher wave-length will be due to the 1,2-diketo groupings present.

Treatment of dimeric 3-methoxy-*o*-quinone with *o*-phenylenediamine, in pyridine solution, gave a yellow phenazine derivative, m.p. 172—173°, which was identical with 1-methoxypenazine (IX) obtained from monomeric 3-methoxy-*o*-quinone. The yield was 90 %, indicating that both the monomer units in VIII had reacted, "retrodiene cleavage" giving rise to the phenazine derivative of the free monomer. A similar reversed diene reaction has been observed in the reaction between dimeric 4,5-dimethyl-*o*-quinone and *o*-phenylenediamine [12].

It appeared not quite impossible that 3-methoxy-*o*-quinone (IV), when treated with *o*-phenylenediamine in an organic solvent, might dimerise before condensation with the amine, and that consequently the phenazine derivative obtained from IV might be that of the dimeric rather than the monomeric *o*-quinone. However a determination of the molecular weight of the phenazine (Rast, found 224, calc. 210) confirmed that the derivative actually was that derived from the monomer.

Structures VIII—VIIIc, proposed for the dimeric 3-methoxy-*o*-quinone, clearly suggest that it should be possible to convert the substance, by periodate oxidation, into a β-naphthoquinone. In fact, treatment of the dimer with periodate gave 3,8-dimethoxy-1,2-naphthoquinone (V)[5], m.p. 198—199°, in

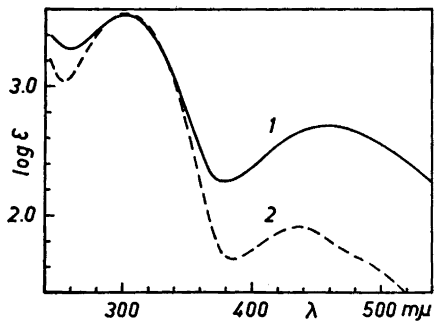


Fig. 2. Absorption spectra of dimeric 3-methoxy-1,2-benzoquinone (VIII) (curve 1), and the monohydrate XIII of dimer VIII (curve 2). Solvent: Chloroform.

87 % yield *. Together with the data reported above (analysis, IR and UV absorption), this proves structure VIII for the yellow dimer, and excludes the alternative structures VIIIa—c. The conversion VIII → V by treatment with periodate obviously involved oxidative removal of the diketo group of the bi*cyclo*octene system as well as of the two angular hydrogen atoms. The mechanism of this reaction will be discussed further in a subsequent communication [14].

The results just described strongly supported the view that the formation of β-naphthoquinone V from 3-methoxy-1,2-benzoquinone (IV) or its precursors, *i.e.* the phenols I or VII, in aqueous periodate solution, is due to dimerisation of IV followed by periodate degradation of the dimer. As mentioned above, this conversion of the *o*-benzoquinone IV into the β-naphthoquinone V proceeds very rapidly; under the conditions used (see, for instance, Table 1, Expt. 5) V could be detected already after a reaction time of 2 min, and the reaction was practically complete in 10 min.

Thus, it had to be assumed that the first step of the reaction, the dimerisation of the *o*-benzoquinone IV, proceeds in water at a comparatively high rate. This assumption, however, was not self-evident, since the dimerisation

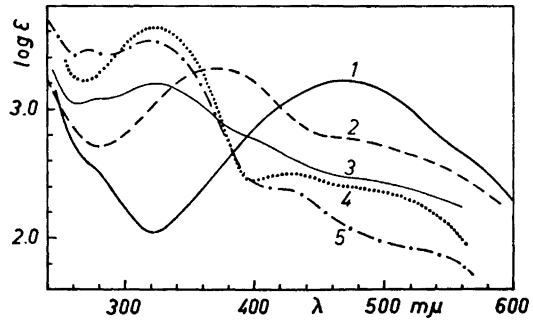

Fig. 3. Absorption spectra of 3-methoxy-1,2-benzoquinone (IV) in chloroform (curve 1), of IV dissolved in water to give a concentration of 0.6 mmole/l (curve 2), of IV dissolved in water to give a saturated solution (40 mmole/l), and then diluted to 0.6 mmole/l (curve 3) and of dimeric 3-methoxy-1,2-benzoquinone (VIII) dissolved in 25 % aqueous acetic acid (curve 4) and in water (curve 5).

* Briefly reported in Part I[1].

of IV in the organic solvents mentioned above appeared to be a comparatively slow reaction. The behaviour of 3-methoxy-1,2-benzoquinone in water — in the absence of periodate — was therefore examined in some detail.

While dilute solutions (about 1 mmole/l) of 3-methoxy-1,2-benzoquinone (IV) in chloroform show the absorption spectrum presented in Fig. 3 (curve 1, λ_{max} 468 mμ, log ε 3.23, which is very similar to the curve reported [7] for the 5-ethyl homologue of IV), a freshly prepared aqueous solution of similar concentration showed an absorption maximum at a considerably lower wavelength (Fig. 3, curve 2; λ_{max} 370 mμ, log ε 3.31). Since the absorption curve for a chloroform extract of a freshly prepared dilute aqueous solution of IV was practically identical with curve 1, the lower wavelength of the maximum in the aqueous solution could not be caused by any irreversible reaction between the methoxy-*o*-quinone and water. It might however be caused by the reversible addition of one molecule of water, forming one of the monohydrates Xa and Xb. The assumption of an equilibrium between the *o*-quinone IV and its hydrate X seems also to find support in the appearance of the long-wave branch of absorption curve 2, which has a shoulder at 460—470 mμ, *i.e.*, at the maximum position of the absorption curve of the quinone in chloroform solution (curve 1). Hydration in this way would imply the conversion of the *o*-quinonoid system of IV into an *o*-quinol-like

	IV	*Xa*	*Xb*	*XI*	*XII*
λ_{max}:	468	370		375	310
log ε_{max}:	3.23	3.31		3.23	3.6
Solvent:	$CHCl_3$	H_2O		$CHCl_3$	C_2H_5OH

(2,4-dienone) system (Xa or Xb), which would appear compatible with the hypsochromic shift of the absorption maximum by 98 mμ.

For comparison, absorption data for *o*-benzoquinone (XI) [7] and 2-acetoxy-*o*-quinol acetate (XII) [3] are given above; the 2,4-dienone XII has a maximum at a wavelength 65 mμ shorter than that of the *o*-quinone XI. A comparison of the pair IV and X with the pair XI and XII also shows the strongly bathochromic effect of the methoxyl substituent in the chromophoric systems involved.

Of the two isomeric hydrates Xa and b, the first seems more probable. Due to the mesomeric effect of the methoxyl group, carbon atom 1 in IV (see formula above) will be less positive than 2, and therefore less accessible to nucleophilic attack by water; furthermore, the inductive effect of the methoxyl group will strengthen the positive character of carbon atom 2. Thus, both effects will act together, and the formation of Xa will be favoured. The comparatively strong bathochromic effect of the methoxyl group, indicated by a comparison of the maxima of XII and X, would also be in harmony with formula Xa, in which the methoxyl group is at the end of the conjugated system (δ-methoxydienone).

If a freshly prepared dilute aqueous solution of 3-methoxy-1,2-benzoquinone (IV), showing absorption curve 2 (Fig. 3), is kept at room temperature, the maximum at 370 mμ gradually decreases, and new maxima at 265 and 300 mμ form during the course of a few hours. Simultaneously, the initial deep-red colour of the solution turns to brown, the material extracted by chloroform gradually decreases in amount and develops maxima at 262 and 296 mμ rather than the broad maximum at 468 mμ characteristic of the intact *o*-quinone IV. These comparatively slow transformations of the monomer in dilute aqueous solutions have not yet been further examined.

An absorption curve quite different from curve 2 in Fig. 3 (freshly prepared 0.6 mmolar aqueous solution of *o*-quinone IV) was obtained by preparation of a saturated, *i.e.*, about 40 mmolar, solution of the quinone in water and then as soon as the substance had dissolved (after about 5 min), diluting the solution with water to a concentration suitable for absorption measurement (0.6 mmolar) (Fig. 3, curve 3). The long-wave branch with a shoulder at about 470 mμ (unchanged 3-methoxy-*o*-quinone (IV)?) was markedly lower than in curve 2, and the absorption maximum of curve 2 at 370 mμ (monohydrate X?) was now only a weak inflection. A new maximum had, however, appeared at 315 mμ.

A similar maximum was also shown by aqueous and aqueous acetic acid solutions of the dimeric 3-methoxy-*o*-quinone VIII (Fig. 3, curves 5 and 4, respectively), which suggested that dimerisation of the *o*-quinone IV had taken place in the saturated aqueous solution. When the latter solution was concentrated *in vacuo*, a pale-yellow crystalline solid, m.p. 114—115° (decomp.), deposited. On treatment with periodate in aqueous acetic acid, this compound was converted, in high yield, into 3,8-dimethoxy-1,2-naphthoquinone (V). It thus behaved in the same way as dimer VIII.

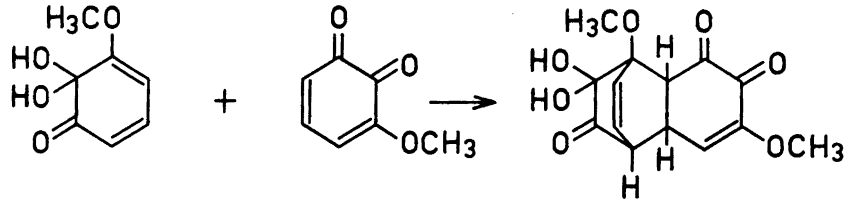
The new, pale-yellow product, in an air-dry condition analysed for a dimeric methoxy-*o*-quinone containing 3 molecules of water. Two molecules of water were removed on drying at 0.04 mm Hg over phosphorus pentoxide at room temperature and can therefore be regarded as water of crystallisation, but the third molecule could not be removed. The ultra-violet absorption of the substance in chloroform solution (Fig. 2, curve 2) exhibited a maximum at 302 mμ close to that of the anhydrous dimer VIII (Fig. 2, curve 1), which indicates that the main chromophores of both compounds are similar. However, the long-wave absorption band of the new compound was markedly weaker than that of dimer VIII, indicating the presence of only one 1,2-diketo grouping.

In contrast to dimer VIII (Fig. 1b), the new product (Fig. 1c) showed a distinct hydroxyl band (2.84 μ) in the infra-red spectrum, and only three CO stretching vibration bands (5.74, 5.81, 5.95 μ) instead of the four CO bands characteristic of dimer VIII. The presence of a strong absorption band at 6.12 μ, in addition to the CO band at 5.95 μ, indicates the presence of a C=C—C=O grouping.

These data indicate that the compound, m.p. 114—115°, is a monohydrate of dimer VIII, the molecule of water being linked to VIII by covalent bonds. Since the conjugated ene-dione chromophore appears to be unaffected, the molecule of water present must have been added to one of the keto groups of the bi*cyclo*octene system. Structure XIII is therefore proposed for the substance.

Like the anhydrous dimer VIII, the hydrate XIII, when treated with *o*-phenylenediamine in pyridine, gave 1-methoxyphenazine (IX) in excellent

Scheme 2.



Xa *IV* *XIII*

yield (93 %), indicating that both monomer halves reacted and that a "retro-diene cleavage" had occurred. This result also supports structure XIII.

As expected, a solution of the isolated dimer hydrate XIII in water or aqueous acetic acid showed the absorption maximum at 315 mμ which had been observed in a saturated solution of 3-methoxy-*o*-benzoquinone (IV) a few minutes after it had been dissolved (*cf.* p. 523). There is therefore no doubt that XIII is formed very rapidly in aqueous solutions of IV, provided that the concentration is comparatively high, and this explains the rapid conversion of phenols I and VII and of *o*-quinone IV into β-naphthoquinone V by aqueous periodate, as described above.

The remarkably high rate of the dimerisation of 3-methoxy-*o*-quinone in water could possibly be explained as follows.It has been found earlier (preliminary report, see Ref.[15]) that *o*-quinols undergo dimerisation by Diels-Alder addition, and also that an *o*-quinol and an *o*-quinone molecule may add in a similar way, with the *o*-quinol molecule acting as a diene and the *o*-quinone molecule as a philodiene. Both types of reactions have been found to proceed very rapidly in an aqueous medium, and, in the special case studied, the *o*-quinol-*o*-quinone addition proceeded considerably faster than the self-dimerisation of the *o*-quinone involved. Monohydrate X, assumed to be formed from 3-methoxy-*o*-quinone in water (see p. 522), would be of an *o*-quinol type, and, hence, would probably possess a strong tendency to undergo a Diels-Alder reaction. The rapid formation of XIII in saturated aqueous solutions of 3-methoxy-*o*-quinone IV might then be regarded as a dimerisation of monohydrate X with subsequent loss of one molecule of water, or, alternatively, as an addition of a molecule of the *o*-quinol-like monohydrate X (diene) to a molecule of unchanged *o*-quinone IV (philodiene), as shown in Scheme 2*.

---

* *Note added in proof.* It has been found that an aqueous solution of 3-methoxy-5-methyl-1,2-benzoquinone [7] has its main absorption maximum at 370 mμ, an additional, weak band with maximum at 480 mμ also being present, whereas a single, strong band with maximum at 480 mμ is observed in chloroform solution. Although this behaviour of the compound is similar to that shown by 3-methoxy-1,2-benzoquinone (IV), the 5-methyl homologue differs from IV in being comparatively stable in aqueous solutions and showing no marked tendency to dimerisation. Therefore the view presented above (p. 524) that hydration of IV, which is believed to be the reason for the short-wave absorption in aqueous solution, might be responsible for the rapid dimerisation of this *o*-quinone in concentrated aqueous solution, seems to be contradicted by the results obtained with the 5-methyl homologue.

Alcoholic solutions of IV and its 5-methyl homologue show short-wave absorption maxima similar to those observed in water (hemiketal formation?). This behaviour is specific for 3-

There is also of course the third possibility of a diene-addition between two molecules of the *o*-quinone, followed by hydration of the dimer, which cannot be excluded.

The absorption spectrum of the dimer hydrate XIII in 25 % acetic acid was identical with that of the anhydrous dimer VIII in the same solvent (Fig. 3, curve 4), indicating that the dimer VIII, when dissolved in aqueous solvents, is converted into XIII. In fact, crystalline XIII deposited from aqueous or aqueous acetic acid solutions of VIII on concentration under reduced pressure.

The anhydrous dimer VIII dissolves rather slowly in water at room temperature, the rate of hydration probably being the limiting factor. During the time necessary for dissolution (1—2 h), the solution acquires a slightly red colour, and the absorption spectrum (Fig. 3, curve 5) differs somewhat from that of a freshly prepared, pale yellow solution in 25 % acetic acid (Fig. 3, curve 4), in which dimer VIII dissolves much more rapidly than in water; an "aged" solution in aqueous acetic acid, however, shows similar changes to those in the aqueous solution.

Neither freshly prepared nor "aged" solutions of VIII or XIII in water or in alcohols gave distinct colour reactions with ferric chloride. Heating the solutions gave dark brown-red products which were not further investigated. These also gave negative ferric chloride reactions. The dimeric 3-methoxy-*o*-quinone VIII and its monohydrate XIII thus differ from the similar dimer of unsubstituted *o*-quinone [9-11], which, on heating for a short time in water, enolises to yield the corresponding phenolic isomer. The latter gives coloured ferric complexes typical of a catechol structure.

Only one case of oxidative conversion of a phenol into a β-naphthoquinone seems to have been reported in the literature. Zincke and Francke [16] ** found that treatment of 6-bromoprotocatechuic acid with conc. nitric acid yields 3,6-dibromo-1,2-naphthoquinone-7-carboxylic acid. It can be assumed that the course of this reaction is similar to that described in the present paper.

Note: A second dimer of 3-methoxy-1,2-benzoquinone. After solutions of 3-methoxy-1,2-benzoquinone (IV) in benzene had been kept at room temperature for several hours, there could be isolated a yellow crystalline substance, m. p. 110° (decomp.). It is obviously a dimeric *o*-quinone different from the dimer VIII (m. p. 139—140°) which is formed in the (polar) organic solvents mentioned on p. 519. On treatment with *o*-phenylenediamine the new product behaved like dimer VIII (see p. 520), yielding the phenazine derivative IX of monomeric 3-methoxy-*o*-quinone (1-methoxyphenazine, m. p. 172—173°). This supports the view that the new product is formed by diene addition of 3-methoxy-*o*-quinone, in an analogous way to the formation of VIII, and reverts to the monomer when the phenazine is formed.

The dimer of m. p. 110° is still less stable than dimer VIII, and, although it was apparently obtained in a state of purity, elemental analysis has not yet given any clear results.

When treated with periodate, the new dimer is converted in high yield into the dark-violet compound (VI), m. p. 205—206°, which was obtained as a by-product in the periodate oxidation of phenols I and VII and the *o*-quinone IV in aqueous solutions (see p. 516). Thus, the dimer of m. p. 110°, or possibly a hydrate of it, appears to be formed,

---

methoxy-1,2-quinones; aqueous or alcoholic solutions of 4-methoxy-1,2-quinone and of 3-methyl- and 3-bromo-1,2-quinones, for instance, have absorption curves very similar to those found in chloroform solutions (Adler, E., Thomelius, H. and Granerus, G. *To be published*).

One of the ketonic oxygen atoms is very rapidly exchanged for ^{18}O, if 3-methoxy-5-methyl-1,2-quinone is dissolved in water enriched of $H_2{}^{18}O$, and reextracted with methylene chloride. This supports the view (see above) that rapid reversible hydration of one of the keto groups takes place (Adler, E. and Falkehag, I. *To be published*).

** Prof. H. Erdtman, Stockholm, has kindly drawn the authors' attention to this paper.

in small amounts, in aqueous solutions of *o*-quinone IV, in addition to the hydrate XIII of dimer VIII. If the assumed structure for substance VI, *i. e.*, 3,5-dimethoxy-1,2-naphthoquinone (*cf.* p. 516), is correct, the structure of the new dimer, which is the precursor of VI, will probably be represented by formula VIIIa (p. 520).

Mixtures of both dimers, VIII and VIIIa (?), were repeatedly obtained when 3-methoxy-*o*-quinone (IV) was allowed to dimerise in various organic solvents. The mixtures showed melting points between those of the pure dimers. Attempts to separate the two components by fractional crystallisation were unsuccessful and, furthermore, both dimers are adsorbed and destroyed on alumina. The presence of both dimers in these mixtures is easily demonstrated, however, by periodate oxidation and chromatographic separation of the crude oxidation product; this gives both β-naphthoquinone V and the violet substance VI in a pure state.

The dimerisation of IV in nitromethane, yielding a product with m.p. 130° (mixture of VIII and VIIIa ?), was recently reported by Horner and Dürckheimer [20].

EXPERIMENTAL

Ultra-violet spectra were measured with a Beckman DU instrument; infra-red spectra with a Perkin-Elmer instrument, model 21. Microanalyses were done by A. Bernhardt, Mülheim (Ruhr), Germany.

Periodate consumption and methanol formation were determined as described previously [17,1].

Periodate oxidation of 2,6-dimethoxyphenol (I). An ice-cooled, stirred solution of I (1.004 g = 6.52 mmole) in water (400 ml), was treated with sodium metaperiodate (4.164 g = 19.45 mmole) in ice-cold water (400 ml), added all in one lot, and the temperature of the mixture was kept at about 4°. After 2 min, excess periodate was reduced by addition of ethylene glycol (1.2 g). The dark-blue needles which had settled out during the oxidation period, were filtered off and were identified with *coerulignone (II)* by comparison with an authentic sample and by reduction with warm 50 % aqueous sodium bisulphite to dihydrocoerulignone, m. p. 190° [18]. The yield of coerulignone was 70 mg (7 %).

The dark brown-red filtrate was extracted with five 100 ml portions of chloroform. The combined dark-red chloroform solutions were dried briefly over anhydrous sodium sulphate, filtered, and divided into two equal parts, which were evaporated to dryness under reduced pressure. (Both the chloroform extraction and the evaporation were carried out as rapidly as possible in order to avoid any appreciable dimerisation of the *o*-quinone.)

a) Isolation of 3-methoxy-1,2-benzoquinone (IV). One of the crude, partially-crystalline chloroform residues (328 mg, *i.e.* 65 % yield by weight, based on I) was treated with three 150 ml portions of boiling, dry ethyl ether. The ether extracts after filtration and cooling to −80° deposited dark brown-red crystals (166 mg), m. p. 98−105°; no depression with 3-methoxy-*o*-quinone, m. p. 107−110°, prepared according to Willstätter and Müller [6]. The infra-red spectra of the two samples were essentially identical. The lower m. p. of the sample obtained by periodate oxidation was due to the presence of traces of oxidation products III and V, detected by chromatography on alumina (see below), and probably also of dimer VIII, which could not be completely removed even by repeated recrystallisation from ether.

b) *Isolation of 2,6-dimethoxy-1,4-benzoquinone (III), 3,8-dimethoxy-1,2-naphthoquinone (V) and substance VI.* The second of the two chloroform residues (325 mg) obtained above was treated with three 100 ml portions of boiling benzene. A small amount of undissolved material (2 mg) was removed by filtration, and the solution was chromatographed on a column of neutral alumina (1 × 20 cm). Elution with benzene gave the yellow 2,6-dimethoxy-*p*-quinone (III), m. p. and mixed m. p. 255−256° (31 mg, 5 % based on I), followed by the dark-violet *compound VI*, m. p. 205−206°, (12 mg, 2 %), needles from benzene-hexane. Analysis of VI indicated the composition $C_{10}H_4O_2(OCH_3)_2$. (Found: C 66.05; H 4.61; OCH_3 27.99. Calc. for $C_{12}H_{10}O_4$: C 66.05; H 4.62; OCH_3 28.44.)

Further elution of the alumina column with benzene containing 3 % ethanol eluted the red 3,8-dimethoxy-1,2-naphthoquinone (V), flat prisms or plates from benzene or acetone,

m. p. 198—199° (20 mg, 7 %). (Found: C 66.25; H 4.54; OCH_3 28.36. Calc. for $C_{12}H_{10}O_4$: C 66.05; H 4.62; OCH_3 28.44.) For derivatives of V and proof of its structure see Ref.[5].

After elution of compounds III, VI, and V, a broad black zone remained in the upper part of the column. It could not be washed out with common solvents. 3-Methoxy-1,2-benzoquinone (IV) and its dimer (VIII) both gave similar, very strongly adsorbed degradation products on alumina. The difference between the total weight of solids chromatographed (323 mg) and the combined weights of the eluted substances III, V, and VI (63 mg), *i. e.* 260 mg, was taken as a measure of the amount of *3-methoxy-1,2-benzoquinone (IV)* formed in the periodate oxidation (yield 58 %).

The experiment described above is listed as Expt. 1 in Table 1. The same procedure was used in the other experiments presented in Table 1, although neither coerulignone nor 2,6-dimethoxy-*p*-quinone were formed from 3-methoxycatechol (VII) and 3-methoxy-*o*-quinone (IV) on treatment with periodate.

Phenazine derivative obtained from VI. When the dark-violet solution of substance VI (80 mg) in pyridine (8 ml) was mixed with a solution of *o*-phenylenediamine (200 mg) in the same solvent (2 ml), the colour of the mixture immediately turned to orange. After 1 h at room temperature part of the solvent was removed under reduced pressure. Addition of water gave a crystalline precipitate which was recrystallised from methanol and methanol-water. Orange needles or prisms, m. p. 229—230°. (Found: C 74.31; H 4.84; N 9.89; OCH_3 21.09; Mol. wt. (Rast) 299. Calc. for $C_{18}H_{14}O_2N_2$: C 74.47; H 4.86; N 9.63; OCH_3 21.38; Mol. wt. 290.)

Dimeric 3-methoxy-1,2-benzoquinone, m. p. 139—140° (VIII). A solution of 3-methoxy-1,2-benzoquinone (IV) (1.6 g) in acetone (200 ml) was kept at room temperature for about 16 h. The solvent was evaporated under reduced pressure and the partially crystalline residue was washed with cold chloroform which removed unchanged monomer and brown, amorphous material. The yellow crystals remaining (yield 30—40 %), m. p. 136—138°, were dissolved in acetone with brief heating (prolonged heating in any solvent causes discoloration). Cooling to —20° yielded the dimer VIII as deep-yellow prisms, m. p. 139—140°. (Found: C 60.74; H 4.50; OCH_3 22.55. Calc. for $C_{14}H_{12}O_6$: C 60.87; H 4.31; OCH_3 22.47.)

Dimer VIII was also obtained in the same way from solutions of IV in methylene chloride, chloroform, ethyl acetate, and dioxane. Dimerisation of IV could also be carried out in the solid state. For instance, a solution of IV in methylene chloride was taken to dryness under reduced pressure in a rotating film evaporator, giving a layer of solid IV spread over the wall of the round-bottomed flask. A few millilitres of acetone or methylene chloride were then added without dissolving the major part of the solid, and the flask was stoppered. After about 16 h the initially dark-brown layer of IV had turned yellow. The crude product was purified as described above.

The product has to be stored at —20°. At room temperature and in day-light, it gradually darkens.

IR spectrum, see Fig. 1. UV spectrum, see Figs. 2 and 3.

1-Methoxyphenazine (IX) from dimer VIII. The yellow solution of dimer VIII (100 mg) in pyridine (5 ml) was mixed with a solution of *o*-phenylenediamine (130 mg) in 1 ml of the same solvent. The mixture turned orange. After 1 h at room temperature, the solvent was removed under reduced pressure and the solid residue was dissolved in chloroform. The chloroform solution was washed with 0.5 N sulphuric acid and water, and then was dried and evaporated. The yellow crystalline residue (140 mg) had m. p. 170—171°. Yield 90 %. Recrystallisation from methanol-water raised the m. p. to 172—173°, undepressed by a sample of 1-methoxyphenazine, m. p. 172—173°, (Literature [19]: 169°) obtained from 3-methoxy-*o*-quinone. The IR spectra of both samples also proved their identity.

Periodate oxidation of dimer VIII. A solution of dimer VIII (77 mg) in 50 % aqueous acetic acid (10 ml) was mixed with an aqueous solution (20 ml) of sodium metaperiodate (245 mg). After 2.5 h at room temperature, the red solution was extracted with methylene chloride. The methylene chloride solution was washed with water, dried over anhydrous calcium sulphate, and evaporated. Dark-red crystals of nearly pure 3,8-methoxy-1,2-naphthoquinone (V), m. p. 194—195°, remained. Yield 87 %. Recrystallisation from benzene raised the m. p. to 198—199°, undepressed on admixture of V, prepared as above.

Monohydrate of dimeric 3-methoxy-o-quinone (XIII). a) From 3-methoxy-o-quinone (IV). A freshly-prepared, almost saturated solution of IV (100 mg) in water (20 ml)

(36 mmole/l) was concentrated under reduced pressure to a volume of about 5 ml. On cooling in the refrigerator, a greyish yellow crystalline product deposited. Recrystallisation from acetone-hexane, ethyl acetate-hexane, or acetone-water (without heating) gave pale-yellow plates or prisms, m. p. 114—115° (decomp.). Yield 25 %.

b) *From dimer VIII.* Dimer VIII (439 mg) was dissolved in 25 % aqueous acetic acid (50 ml); the time required for it to dissolve completely (with shaking) was about 20 min. The solution was concentrated under reduced pressure to a volume of a few millilitres; water was added gradually in the final stages of the evaporation in order to reduce the amount of acetic acid in the concentrate. After cooling in the refrigerator the crystalline product which deposited, was collected. Yield 40 %. The product was identified by m. p., mixed m. p., and IR spectrum with the dimer monohydrate obtained from 3-methoxy-*o*-benzoquinone.

The methoxyl content of the air-dry product indicated that the dimer contained 3 mols. of water. (Found: OCH_3 18.52. Calc. for $C_{14}H_{12}O_6$, $3H_2O$: 18.79.) On drying over P_2O_5 for 6 h at room temperature and 0.04 mm Hg the substance lost 2 mols. of water (loss of weight found, 10.5 %, calc., 10.9 %). The dried product analysed for a monohydrate of a dimeric methoxyquinone. (Found: C 56.80; H 5.04; OCH_3 20.65. Calc. for $C_{14}H_{14}O_7$: C 57.14; H 4.80; OCH_3 21.09.) An aqueous solution of the substance was neutral. Ferric chloride colour tests for phenolic or catechol groupings were negative. The substance darkened gradually, even at low temperature. IR spectrum, Fig. 1. UV spectrum, Figs. 2 and 3.

When allowed to react with *o*-phenylenediamine in pyridine, the hydrated dimer VIII gave *1-methoxyphenazine (IX)*, m. p. 171—172°, in 93 % yield.

Treatment of an aqueous acetic acid solution of the monohydrate XIII with periodate gave *3,8-dimethoxy-1,2-naphthoquinone* (V) in about 80 % yield.

Periodate Oxidation of Phenols

III. The Conversion of Dimeric *o*-Benzoquinones into β-Naphthoquinones *

ERICH ADLER and BRITT BERGGREN

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

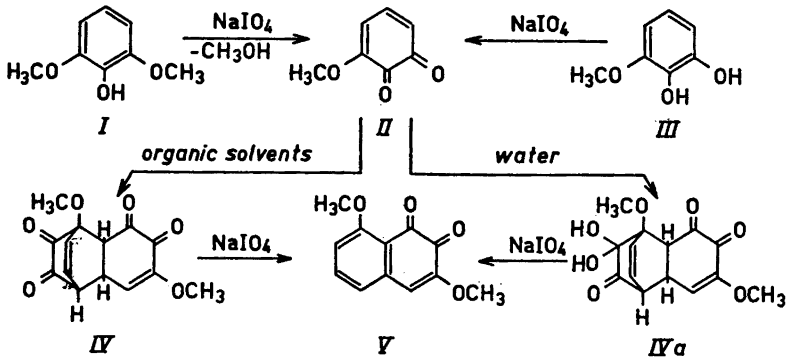
Dimeric *o*-benzoquinone (VI) and its phenolic isomer (VIII) both react with 3 moles of periodate to give β-naphthoquinone in 70 % yield. In the same way both dimeric 3-methoxy-*o*-benzoquinone (IV) and its monohydrate (IVa) are degraded by periodate to 3,8-dimethoxy-1,2-naphthoquinone (V). The course of these reactions was investigated. Dehydrogenation of the catechol grouping present in VIII with silver oxide gave the *o*-quinone IX, which was converted, by treatment with 2 moles of periodate, into β-naphthoquinone. Periodate cleavage of the α-diketo grouping in the diacetyl derivative of VIII, followed by alkaline hydrolysis of the product (XI), yielded 1,2-dihydroxy-5,8-dihydronaphthalene-5,8-dicarboxylic acid (XII). The latter was converted into β-naphthoquinone by treatment with periodate (2 moles) or with silver oxide. IX and XII are probable intermediates in the conversions of VI and VIII, respectively, into β-naphthoquinone.

A reaction scheme is given showing the probable course of these conversions (Scheme 3).

As reported in Part II [1] of this series, the action of excess sodium periodate on pyrogallol-1,3-dimethyl ether (I) in aqueous solution results mainly in oxidative removal of one of the methoxyl groups with the liberation of methanol and the formation of 3-methoxy-1,2-benzoquinone (II). The *o*-quinone undergoes further reactions, which are rapid when relatively high initial concentrations of phenol I are used. For instance, periodate oxidation of phenol I in 80 mM solution gave 3,8-dimethoxy-1,2-naphthoquinone (V) in 25 % yield, with a reaction time of 10 min. Under similar conditions, the β-naphthoquinone V was obtained in yields of about 50 % when pyrogallol-1-methyl ether (III) or 3-methoxy-1,2-benzoquinone (II) were treated with periodate.

* Preliminary report: Adler, E. *Angew. Chem.* **71** (1959) 580.

Scheme 1.



It was also found [1] that 3-methoxy-1,2-benzoquinone (II) in various organic solvents undergoes dimerisation by diene-philodiene addition, yielding the yellow dimer IV, m.p. 139—140°; in aqueous solution a monohydrate of IV, (IVa) m.p. 114—115°, is produced. Both forms of the dimeric 3-methoxy-*o*-quinone, when treated with aqueous periodate solution, were smoothly converted into the *β*-naphthoquinone V.

The formation of the 1,2-naphthoquinone V from the 1,2-benzoquinone II, in aqueous solution in the presence of periodate, is thus the result of dimerisation of II followed by periodate oxidation (*cf.* Scheme 1).

As briefly reported previously [8], the dimer of unsubstituted *o*-benzoquinone (VI) [2-5], when treated with periodate, undergoes a similar degradation, with the formation of *β*-naphthoquinone (VII). (Scheme 2).

The present communication deals with the mechanism of this oxidative conversion of dimeric 1,2-benzoquinones into 1,2-naphthoquinones. For reasons presented below, detailed studies have, as yet, only been made on the conversion of dimeric *o*-benzoquinone into *β*-naphthoquinone but probably the results obtained in these studies are also valid for the analogous reaction of the dimeric 3-methoxy-*o*-benzoquinone.

CONVERSION OF DIMERIC *o*-BENZOQUINONE (VI, VIII) INTO *β*-NAPHTHOQUINONE (VII)

Dimeric *o*-quinone (VI), dissolved in 50 % acetic acid, was found to consume nearly 3 moles of sodium periodate in about 20 min (Fig. 1, curve 1); the resulting orange solution gave *β*-naphthoquinone (VII), m.p. 145—146°, in 70 % yield.

The phenolic isomer (VIII) of dimeric *o*-quinone (VI), which is obtained by heating the quinone with ethanolic hydrochloric acid [3] or simply with water [4,5], also consumes 3 moles of periodate. In aqueous solution, the main reaction is complete after 3 min, giving *β*-naphthoquinone in 70 % yield. In 50 % acetic acid the reaction is slightly slower (Fig. 1, curves 2 and 3).

The rapid main reaction is followed by further slow periodate consumption. The similar slow oxidation of *β*-naphthoquinone itself (Fig. 1, curve 4) indicates

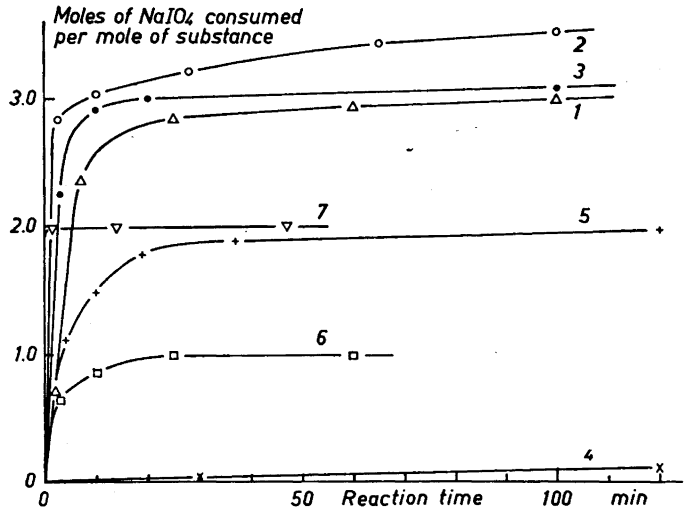


Fig. 1. Periodate consumption by dimeric *o*-quinone (VI) in 50 % aqueous acetic acid (curve 1), by the phenolic isomer VIII of dimeric *o*-quinone in water (curve 2) and in 50 % aqueous acetic acid (curve 3) and by β-naphthoquinone (VII) (curve 4), the *o*-quinone IX (curve 5), the diacetyl derivative of VIII (X) (curve 6), and 1,2-dihydroxy-5,8-dihydronaphthalene-5,8-dicarboxylic acid (XII) (curve 7), in 50 % aqueous acetic acid. The molar ratio substance/$NaIO_4$ was 1/4.

that this is due to cleavage of the 1,2-diketo grouping of the β-naphthoquinone formed in the main reaction.

When β-naphthoquinone was treated with periodate at pH 6.5 instead of the slightly acidic conditions used above (the pH value of an unbuffered aqueous solution of sodium metaperiodate is about 3.5) the oxidation proceeded at a satisfactory rate, and *o*-carboxycinnamic acid was obtained in good yield [6].

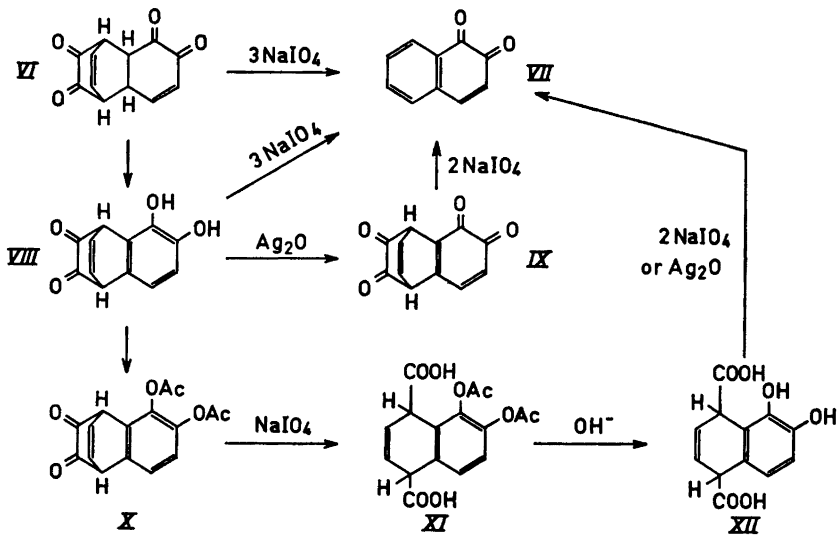
The next step in the investigation of the conversions VI → VII and VIII → VII, was the preparation of substances IX and XII, which obviously were possible intermediates.

The red *o*-quinone IX was obtained by dehydrogenating the phenolic dimer VIII with silver oxide. It has also been prepared recently by Horner and Dürckheimer [5], who used tetrachloro-*o*-quinone as dehydrogenating agent.

The dicarboxylic acid XII, m.p. 182—183°, was made by cleaving the diketo bridge of the diacetate (X) [4] of the phenolic dimer (VIII) with periodate (Fig. 1, curve 6), to give the dicarboxylic acid XI, m.p. 189—190°, and then removing the protecting acetyl groups by alkaline hydrolysis under nitrogen.

The ultra-violet and visible light absorption spectra of the ketonic dimer VI, its phenolic isomer VIII, the *o*-quinonoid substance IX, and the diacetate X are shown in Fig. 2; the spectra of the dicarboxylic acids XI and XII are shown in Fig. 3. Substances VI, VIII, IX, and X show the characteristic absorption band between 400 and 500 mμ of α-diketones. As expected, this long-wave absorption is absent from the spectra of the dicarboxylic acids XI

Scheme 2.



and XII. The infra-red absorption data for the acids XI and XII (see Experimental) are also in harmony with the proposed structures.

An examination was then made of the behaviour of compounds IX and XII on treatment with periodate. The *o*-quinone IX consumed 2 moles of the oxidant (Fig. 1, curve 5), and was converted into β-naphthoquinone. The dicarboxylic acid XII also consumed 2 moles of periodate very rapidly (Fig. 1, curve 7), and gave β-naphthoquinone. Surprisingly enough, the same transformation, (XII → VII), could be brought about merely by shaking a solution of XII in acetone with silver oxide.

The results described so far are summarised in Scheme 2. They suggest that the periodate oxidation of the two forms of dimeric *o*-benzoquinone (VI, VIII) giving β-naphthoquinone (VII) follows the reaction sequences shown in Scheme 3.

As indicated in Scheme 3, the primary step in the oxidation of the ketonic dimer (VI) with excess periodate can be assumed to be the cleavage of the diketo grouping of the bi*cyclo*octene system. However, attempts to isolate the expected cleavage product, *i.e.*, the diketodicarboxylic acid XIII, after treating VI (in aqueous acetic acid solution) with an equimolar amount of periodate, were without success. β-Naphthoquinone (VII) was formed, but the yield was only about a third of that obtained in experiments with excess periodate. Three moles of the oxidant were required for maximum conversion of the dimer VI into the end product, VII. This seems to indicate that the diketodicarboxylic acid (XIII) first formed, rapidly enolises to give the dihydroxydicarboxylic acid (XII), which is then converted into β-naphthoquinone (VII) with further consumption of periodate.

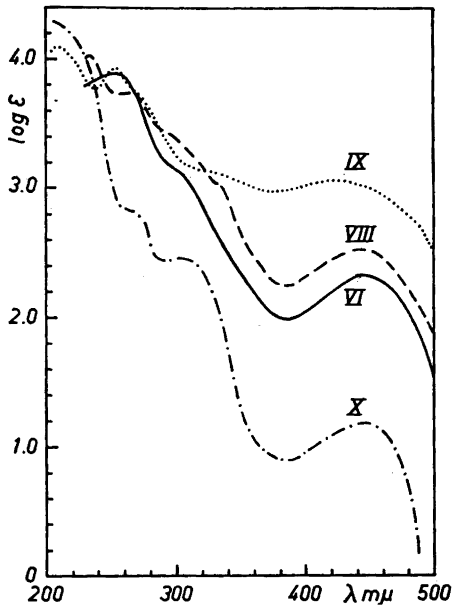


Fig. 2. Absorption spectra of dimeric *o*-quinone (VI), the phenolic isomer of dimeric *o*-quinone (VIII), the diacetyl derivative of VIII (X), and the *o*-quinone IX. Solvents: For VI and VIII, methylene chloride, for X and IX, 95 % ethanol.

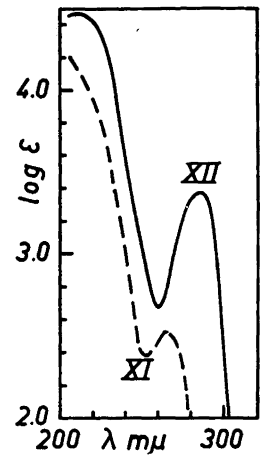

Fig. 3. Ultraviolet absorption of 1,2-dihydroxy-5,8-dihydronaphthalene-5,8-dicarboxylic acid (XII) and its diacetyl derivative (XI), in 95 % ethanol.

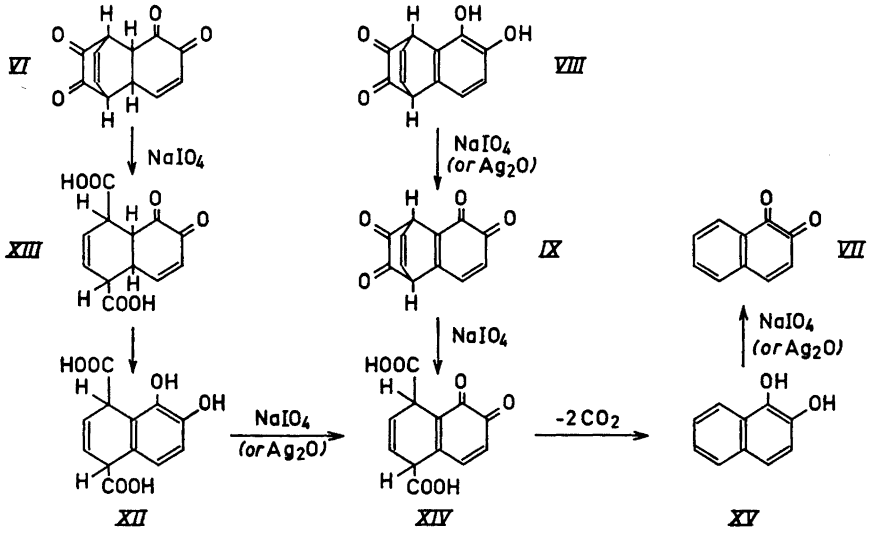
As described above, the dihydroxydicarboxylic acid XII is almost instantly converted into VII not only by periodate (2 moles) but also by silver oxide. This suggests that the conversion XII → VII involves dehydrogenation of the catechol grouping of XII to form an intermediate *o*-quinonoid dicarboxylic acid XIV, which immediately undergoes spontaneous decarboxylation to yield 1,2-dihydroxynaphthalene (XV), which is then dehydrogenated to give the end-product, VII. As expected, the suggested final step, XV → VII, could be shown to proceed with great ease when XV was treated either with periodate in aqueous acetic acid, in which case an equimolar amount of $NaIO_4$ was consumed almost instantly, or with silver oxide in acetone.

Starting from the phenolic form of dimeric *o*-benzoquinone (VIII), the primary step is assumed to be the dehydrogenation of the catechol grouping rather than the oxidative opening of the diketo bridge. The diketo grouping of the *o*-quinone IX thus formed would then be opened by a further mole of periodate to give the hypothetical intermediate XIV; the rapid concluding steps XIV → XV → VII are identical with those postulated above for the oxidation of the ketonic dimer VI.

The assumption of two different paths, VI → XIII → XII → XIV and VIII → IX → XIV, for the initial steps of the oxidation of the ketonic dimer

Scheme 3.



(VI) and of its phenolic isomer (VIII) might appear unnecessary. It could be supposed instead that in polar solvents the ketonic dimer VI was in equilibrium with the phenolic form VIII and that in both cases it was the phenolic form that was attacked by the periodate. However, freshly prepared solutions of the ketonic dimer VI in aqueous acetic acid or aqueous ethanol do not give the catechol colour reaction with ferric chloride, given by solutions of the phenolic dimer VIII. In these solvents the isomerisation VI → VIII proceeds so slowly at room temperature that it cannot be involved in the rapid conversion of the ketonic dimer VI into β-naphthoquinone by periodate.

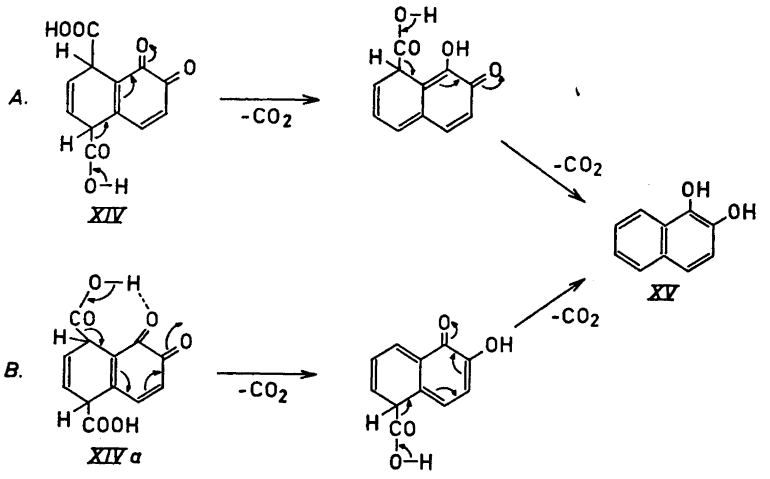
It was assumed above that the hypothetical primary intermediate XIII enolises rapidly to give the partially aromatic compound XII which readily undergoes further oxidation. This assumption may seem to be in contrast to the remarkably low tendency of VI to enolise. However, an inspection of Stuart-Briegleb models indicates that the stability of VI might be explained by the greater strain shown by the bridged ring system in the enol form (VIII) than in the keto form (VI). This would cause some resistance to enolisation in the latter compound. The dihydronaphthalene derivative XII on the other hand is not more strained than XIII and enolisation of the latter would therefore be expected to proceed easily.

In dioxane or aqueous dioxane solution the enolisation VI → VIII was found to take place comparatively rapidly even at room temperature; this was indicated by the appearance of a distinct ferric chloride colour reaction immediately after dissolving the ketonic dimer (VI). The intensity of the colour increased and after about one hour approached that given by a solution of the phenolic isomer (VIII).

According to the view presented above (cf. also Scheme 3), the keto bridge carbon atoms of dimers VI and VIII are removed as carbon dioxide from the intermediate XIV, which is assumed to be formed by oxidation of both the dihydroxydicarboxylic acid (XII) and the *o*-quinone IX. Compound XIV is thus common to both pathways, VI → VII, and VIII → VII. The finding that both VI and VIII require 3 moles of periodate for conversion into β-naphthoquinone, supports this view. If, for instance, β-naphthoquinone were formed directly from the diketodicarboxylic acid XIII, by the loss of two molecules of formic acid, then one mole of periodate would have been sufficient to convert dimer VI into β-naphthoquinone.

The spontaneous rapid decarboxylation of the postulated *o*-quinonoid intermediate XIV can be attributed to the special position of the carboxylic groups, both of which are part of vinylogous β-keto acid structures (Scheme 4 A). Furthermore, a Stuart-Briegleb model of XIV suggests the possibility

Scheme 4.



of chelation between the carboxyl group in position 8 and the keto group in position 1, as indicated in formula XIVa. This points to a mechanism for the decarboxylation of the 8-carboxyl group that is closely related to the generally accepted mechanism [7] for the decarboxylation of β-keto acids (Scheme 4 B).

CONVERSION OF DIMERIC 3-METHOXY-1,2-BENZOQUINONE (IV) AND ITS MONOHYDRATE (IVA) INTO 3,8-DIMETHOXY-1,2-NAPHTHOQUINONE(V)

As reported previously [1], treatment of dimeric 3-methoxy-1,2-benzoquinone (IV) with periodate in aqueous solution produces 3,8-dimethoxy-1,2-naphthoquinone (V) in about 85 % yield. Fig. 4, curve 1, shows the consumption of the oxidant as a function of reaction time. The comparatively rapid initial phase of the reaction seems to be completed after about 1 h. In 25 % aqueous

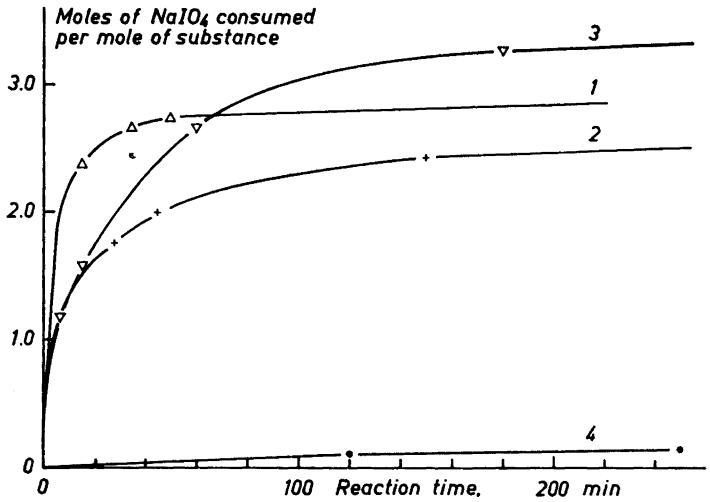


Fig. 4. Periodate consumption by dimeric 3-methoxy-1,2-benzoquinone (IV) in water (curve 1) and in 25 % aqueous acetic acid (curve 2), by the monohydrate of IV (IVa), (curve 3), and by 3,8-dimethoxy-1,2-naphthoquinone (V) in 25 % aqueous acetic acid (curve 4). Molar ratio, substance/$NaIO_4$ = 1/4.

acetic acid the reaction proceeded at a somewhat decreased rate (Fig. 4, curve 2).

The periodate consumption of the hydrated dimer IVa, in 25 % aqueous acetic acid, is shown in curve 3.

As in the degradation of dimeric *o*-quinone, further oxidation of the *β*-naphthoquinone formed was very slow; the rate of periodate consumption by isolated 3,8-dimethoxy-1,2-naphthoquinone (V) in 25 % aqueous acetic acid is shown in curve 4.

In a buffered aqueous medium (pH 6.5) the naphthoquinone V was oxidised fairly rapidly and gave 2-carboxy-3-methoxy-α-methoxycinnamic acid. This reaction was used in the elucidation of the structure of V, which will be reported in a following paper[6].

Extrapolation of curves 1 and 2 back to time zero indicates that 2,7 and 2,4 mole $NaIO_4$ per mole of dimer IV were required for the production of the naphthoquinone V, in water and dilute acetic acid, respectively. The hydrated dimer IVa however consumed about 3 mole $NaIO_4$/mole (curve 3), thus behaving in the same way as the dimeric *o*-quinone (VI, VIII, Fig. 1). The reason for the somewhat lower consumption of periodate in the case of the anhydrous dimer IV is still unknown. In spite of the differences in periodate consumption the yields of naphthoquinone V were equally high (80—85 %)[1] in the three experiments represented by curves 1, 2 and 3. Since, as reported in Part II[1], the anhydrous dimer IV, when dissolved in water, or 25 % acetic acid, is converted into the hydrate IVa, it would be expected that IV and IVa would also show the same periodate consumption. Possibly, the anhydrous

dimer to some extent undergoes some periodate-saving reaction (autoxidative cleavage of the diketo bridge?) before the hydration is complete.

Apart from the minor discrepancies just mentioned, the periodate uptake by dimeric 3-methoxy-*o*-quinone (IV, IVa) was similar to that found for dimeric *o*-quinone (VI). It therefore seems probable that the mechanism discussed above for the conversion VI → VII, will also be valid for the similar conversion IV (IVa) → V but it has not yet been possible to carry out a more detailed investigation of this reaction. The phenolic isomer of IV has not so far been obtained. Attempts to prepare its diacetate by treating IV with acetic anhydride in pyridine gave a product, which, although showing some of the properties expected, has not yet been obtained in a state of purity. For these reasons, possible intermediates corresponding to compounds IX and XII in the *o*-quinone series, have not been available for an examination of their role in the degradation of the 3-methoxy-*o*-quinone dimers (IV, IVa).

EXPERIMENTAL

Ultra-violet and visible absorption spectra were measured with a Beckman DU spectrophotometer, infra-red spectra with a Perkin-Elmer model 21 instrument (KBr). Analyses were carried out by A. Bernhardt, Mülheim (Ruhr), Germany.

Periodate consumption. In the experiments of Fig. 1 the substance (1 mmole) was dissolved (or suspended) in glacial acetic acid (50 ml) (except for curve 2, where water was used instead of HOAc), and a solution of $NaIO_4$ (4 mmole) in water (50 ml) was added. Substances VI and IX only dissolved completely about 10 min after the addition of the periodate. In the experiment of Fig. 4, curve 1, the dimeric 3-methoxy-*o*-quinone (IV) was allowed to dissolve in water, which required about 1.5 h at room temperature (hydration, *cf.* Ref.[1]), before the periodate solution was added. In the remaining experiments of Fig. 4 the samples were readily soluble in the solvents used. The concentrations were the same as given above.

Unconsumed periodate was determined on 5 ml samples of the reaction mixture as described previously [8]. The β-naphthoquinones formed were extracted before the addition of the thiosulphate-iodide mixture.

Periodate oxidation of dimeric o-*benzoquinone (VI).* A suspension of the substance (108 mg = 0.5 mmole) in glacial acetic acid (25 ml) was mixed with an aqueous solution of sodium metaperiodate (25 ml containing 440 mg = 2.0 mmole). After 30 min the clear orange-red solution was extracted with methylene chloride. The methylene chloride solution was washed with water, dried over anhydrous sodium sulphate, and taken to dryness under reduced pressure. The red crystalline residue had m.p. 144°, after recrystallisation from ether 146°, undepressed on admixture of *1,2-naphthoquinone*, m.p. 145—147° [9]. The infra-red spectra of both samples were identical. Yield of crude product, 70 %.

In the same way, *1,2-naphthoquinone* was obtained (70 %) from the *phenolic isomer VIII* by periodate oxidation in aqueous or aqueous acetic acid solution.

o-*Quinone IX.* A solution of the phenolic isomer of the dimeric *o*-quinone (VIII) [4] (300 mg) in acetone (20 ml) was shaken, in the presence of anhydrous sodium sulphate, with silver oxide (1.0 g) for 10 min. The solution was filtered and evaporated under reduced pressure. The crystalline residue was washed with cold ethyl acetate and recrystallised, without heating, from acetone-hexane. Dark-red prisms, decomposing above 220°. (Found: C 67.23; H 3.08. Calc. for $C_{12}H_6O_4$: C 67.29; H 2.83.)

The same substance has been obtained by Horner and Dürckheimer [5], who used tetrachloro-*o*-quinone as dehydrogenating agent. UV absorption see Fig. 2; the infra-red spectrum shows CO stretching vibration bands at 5.76, 5.89 and 6.02 μ. Oxidation with periodate yielded *β-naphthoquinone.*

The diacetate (X) of the phenolic form of dimeric o-*quinone*, which was previously obtained from VIII with boiling acetic anhydride [4], was prepared by treatment with acetic anhydride-pyridine at room temperature; m.p. 144°.

1,2-Diacetoxy-5,8-dihydronaphthalene-cis-*5,8-dicarboxylic acid (XI).* A solution of the diacetate X (150 mg = 0.5 mmole) in glacial acetic acid (25 ml) was mixed with an aqueous solution of $NaIO_4$ (3 mmole). After 60 min the colourless solution was extracted with methylene chloride and the extract was washed with water, dried over anhydrous Na_2SO_4 and evaporated to dryness. Colourless prisms, m.p. 189—190° after recrystallisation from ethyl acetate. Yield 70 %. (Found: C 57.47; H 4.35. Calc. for $C_{16}H_{14}O_8$: C 57.49; H 4.22.) Potentiometric titration in ethanolic solution gave two equivalence points, corresponding to equivalent weights of 342 and 170, respectively (calc.: 334 and 167).

UV-absorption spectrum see Fig. 3. IR-absorption bands: 3.2 and 3.75—4.0 μ (COOH); 5.72—5.82 μ (CO of vinyl ester and carboxyl groups); 6.17, 6.30 (both weak) and 6.72 μ (aromatic nucleus).

1,2-Dihydroxy-5,8-dihydronaphthalene-cis-*5,8-dicarboxylic acid (XII).* Diacetate XI (500 mg) was dissolved, with careful exclusion of air, in a mixture of ethanol (25 ml) and 10 % aqueous sodium hydroxide (6 ml). After 6 h, the solution was acidified with aqueous sulphuric acid. Extraction with methylene chloride removed only traces of an oily material; the solution was then extracted with ethyl acetate and the extract was washed with water, dried over anhydrous calcium sulphate and evaporated to dryness. The crystalline residue (yield 67 %) was recrystallised from ethyl acetate-hexane; colourless prisms, m.p. 182—183° (decomp.). The product contained 1/3 mole of water of crystallisation, which was not removed on drying over P_2O_5 in a high vacuum at room temperature. (Found: C 56.46; H 4.16. Calc. for $C_{12}H_{10}O_6$,1/3 H_2O: C 56.25; H 4.20). When heated for 2 h at 90° (0.1 mm Hg), the substance lost 2.30 % of its weight (calc. for 1/3 mole H_2O: 2.48 %) and then analysed for the anhydrous product. (Found: C 57.66; H 4.20. Calc. for $C_{12}H_{10}O_6$: C 57.60; H 4.03). Neutralisation equivalent of the substance before dehydration: found 128, calc. 125.

Addition of ferric chloride to an ethanolic solution of the substance produced a rather unstable dark-green colour, which turned to blue-violet on addition of aqueous sodium bicarbonate. UV absorption of the substance see Fig. 3. IR absorption bands: 2.91 μ (phenolic OH); 3.25 and 3.65—3.90 μ (COOH); 5.79 μ (COOH) and 5.91 μ (8-COOH chelated with 1-OH?); 6.14, 6.26 and 6.67 μ (aromatic nucleus).

Oxidation of XII. a) A solution of XII in 50 % aqueous acetic acid was treated with sodium periodate (3 mole/mole of XII); 2 moles $NaIO_4$ were consumed in 1—2 min (*cf.* Fig. 1). Extraction with methylene chloride gave *β-naphthoquinone* in high yield.

b) A solution of XII in acetone was shaken for 5 min with silver oxide and anhydrous Na_2SO_4. Filtration and evaporation yielded red crystals, identified as *β-naphthoquinone* by m.p. (145—146° after sublimation *in vacuo*), mixed m.p. and infra-red absorption.

Oxidation of 1,2-dihydroxynaphthalene (XV) with periodate or with silver oxide, as in the preceding experiments, also yielded *β-naphthoquinone.*

Periodate Oxidation of Phenols

IV. Structure of the Periodate Oxidation Product of a Dimeric 3-Methoxy-*o*-quinone

ERICH ADLER, RUNE MAGNUSSON and BRITT BERGGREN

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The red product, m. p. 198 – 199°, formed by the action of periodate on pyrogallol-1,3-dimethyl ether, pyrogallol-1-methyl ether, 3-methoxy-*o*-quinone, and dimeric 3-methoxy-*o*-quinone (m. p. 139 – 140°), was shown to be 3,8-dimethoxy-1,2-naphthoquinone (IIIa).

In the initial step of a series of degradation reactions, IIIa was treated with periodate at pH 6.5. Although unbuffered solutions of $NaIO_4$ (pH about 4) attack the β-naphthoquinone IIIa extremely slowly, oxidative cleavage proceeded at a satisfactory rate in the buffered medium and gave 2-carboxy-3-methoxy-α-methoxycinnamic acid (VIII) in good yield. A similar periodate cleavage was carried out with 3-methoxy-1,2-naphthoquinone (XVII) and with unsubstituted β-naphthoquinone.

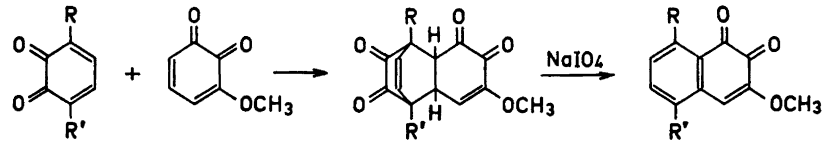
The cinnamic acid VIII was converted, via 7-methoxyphthalide-3-methoxyacetic acid (IX), into 8-methoxy-*iso*coumarin-3-carboxylic acid (X), which was demethylated to give the corresponding 8-hydroxy compound (XI). X was degraded by alkali to 2-methyl-6-methoxybenzoic acid (XII), which gave *m*-cresol on boiling with aqueous hydriodic acid.

2-Carboxy-α-methoxycinnamic acid (XVIII), obtained by periodate oxidation of XVII, was converted to *iso*coumarin-3-carboxylic acid (XIX) on heating.

As reported in preceding papers [1,2], the action of sodium periodate on pyrogallol-1,3-dimethyl ether, pyrogallol-1-methyl ether, and 3-methoxy-1,2-benzoquinone (I) in aqueous solutions gives, among other products, a red compound, $C_{10}H_4O_2(OCH_3)_2$, m.p. 198—199°. Its formation has been shown to be due to a dimerisation of I (which is either used as starting material or formed as an intermediate in the periodate oxidation of the pyrogallol ethers) followed by degradation of the dimer by the periodate present. A dimeric 3-methoxy-*o*-quinone, m.p. 139—140°, could be obtained from solutions of I in organic solvents, and a monohydrate of the dimer, m.p. 114—115°, was obtained from aqueous solutions of I. Both products were readily converted into the red substance, m.p. 198—199°, when treated with periodate. The present paper deals with the structure of the red oxidation product.

The isolation of a further dimer of 3-methoxy-*o*-quinone, m. p. 110°, which is formed in benzene solutions of the monomer, and the periodate degradation of this lower-melting dimer to a violet compound, m. p. 205—206°, isomeric with the red product, m. p. 198—199°, have been mentioned in a previous paper [1]. The structures of this second dimer and its oxidation product are still under investigation.

The properties of the first-mentioned dimer, m.p. 139—140°, indicated [1] that it was formed by Diels-Alder reaction between two molecules of monomer I, and probably had structure II, analogous to the structure of the dimeric *o*-quinone [3]. Due to the unsymmetrical substitution of I, its dimerisation could give rise to two isomers, IIa and IIb. The analytical composition of the red periodate oxidation product of II showed that it might be a dimethoxy-naphthoquinone, and structures IIIa or IIIb therefore seemed very probable. This paper describes experimental evidence showing that this was correct and enabling a decision to be made between IIIa and IIIb.



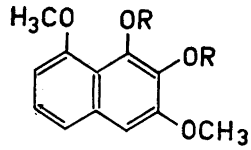
Ia, Ib *I* *IIa, IIb* *IIIa, IIIb*

Ia, IIa, IIIa: R = OCH_3, R′ = H
Ib, IIb, IIIb: R = H, R′ = OCH_3

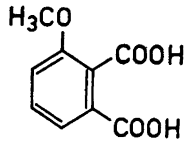
The absorption spectra of the red compound were in harmony with the view that it was a naphthoquinone derivative. Its infra-red absorption spectrum exhibited the double carbonyl band (maxima at 5.98 and 6.03 μ) characteristic of quinones. Comparison of the absorption spectrum in the ultraviolet and visible region (Fig. 1) with the absorption spectra of known naphthoquinones [4,5] revealed a close resemblance with that reported for 3-methyl-6,8-dimethoxy-1,2-naphthoquinone [5]. Furthermore, reduction with zinc dust in acetic acid gave a leuco compound, m.p. 141—143°, which was converted into a diacetate, m.p. 152—153°, with an ultra-violet absorption (Fig. 1) typical for a naphthalene derivative. Oxidation of the red compound with permanganate gave 3-methoxyphthalic acid (VI), and treatment with *o*-phenylenediamine gave a yellow phenazine, m.p. 164—165°, the absorption spectrum of which (Fig. 1) was similar to those reported for benzo[*a*]phenazines [4]. These data clearly indicate that the red substance is a dimethoxy-1,2-naphthoquinone carrying one methoxyl group in each ring (IIIa or IIIb). The structures of the derivatives mentioned above can then be represented by formulae IV, V and VII, with the methoxyl groups arranged as in IIIa, or by corresponding formulae, in which the positions of the methoxyl groups would be those shown in IIIb.

A decision between the two possibilities IIIa and IIIb could be made by the following experiments.

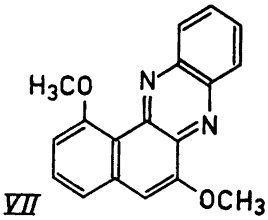
Although the degradation of dimer II to β-naphthoquinone III by periodate was fast [1,2], the latter compound, although containing a 1,2-diketo grouping,



IV R=H
V R=Ac



VI



VII

was attacked only very slowly by excess of the oxidant under the conditions used, *i.e.* in aqueous or aqueous acetic acid solution. However, on treatment with an aqueous periodate solution, buffered to pH 6.5, naphthoquinone III was comparatively rapidly oxidised to a colourless acid, m.p. 142°. Its analytical composition and equivalent weight were in harmony with structure VIII, 2-carboxy-3-methoxy-α-methoxycinnamic acid, or the corresponding 6-methoxy isomer. The similarity of the ultra-violet absorption spectrum of the substance with those of 2-carboxycinnamic acid (XXII) [6,7] and 2-carboxy-α-methoxycinnamic acid (XVIII) (see below) (Fig. 2) supported this structure.

It was intended to convert the 2-carboxy-3-(or 6-) methoxy-α-methoxy cinnamic acid VIII, by heating with hydriodic acid, into either 2-carboxy-3-hydroxy-hydrocinnamic acid (XV) or its 6-hydroxy isomer. Identification of either of the latter products would have been easy, since the methyl ethers of both isomers and, as well, the lactone of the 6-hydroxy isomer had been made available by recent work of Eastham and Larkin [8]. In a preparatory attempt to demethylate 2-carboxy-3-methoxy-hydrocinnamic acid (XIV) * with hydriodic acid, the expected acid XV was decarboxylated and 3-hydroxy-hydrocinnamic acid (XVI) was formed.

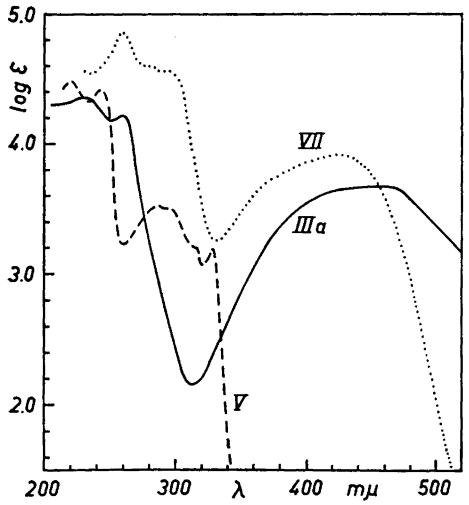


Fig. 1. Absorption spectra of 3,8-dimethoxy-1,2-naphthoquinone (IIIa), 1,2-diacetoxy-3,8-dimethoxy-naphthalene (V), and 1,6-dimethoxybenzo[*a*]phenazine (VII). Solvent: 95 % ethanol.

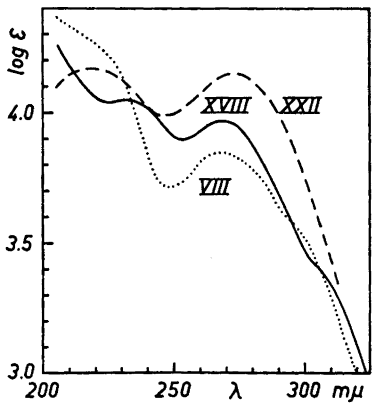

Fig. 2. Ultraviolet absorption spectra of 2-carboxycinnamic acid (XXII), 2-carboxy-α-methoxycinnamic acid (XVIII), and 2-carboxy-3-methoxy-α-methoxycinnamic acid (VIII). Solvent: 95 % ethanol.

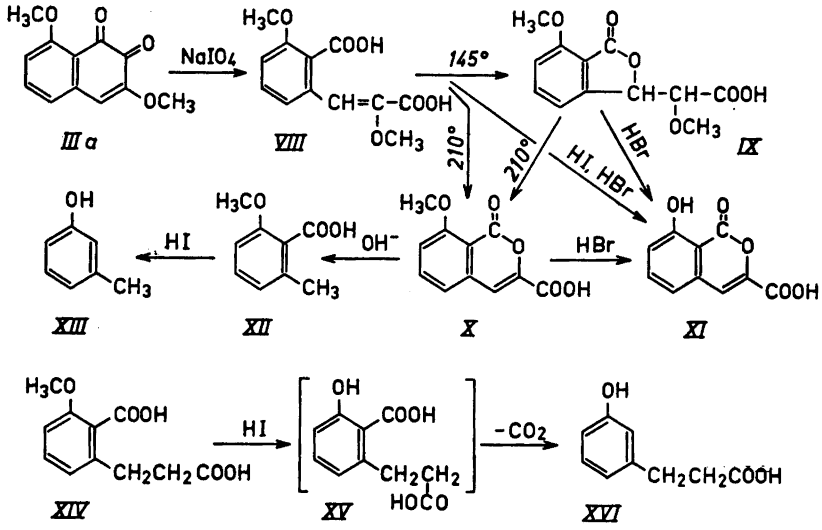
Treatment of VIII with boiling aqueous hydriodic acid (d = 1.70) produced neither of the possible hydrocinnamic acids, but instead, gave 8-hydroxy-*iso*coumarin-3-carboxylic acid (XI) (*cf.* below).



Like 2-carboxycinnamic acid (XXII)[6,7], the dimethoxy derivative VIII (or the corresponding 6-methoxy isomer?) underwent cyclisation when heated to the melting point, giving a lactone acid, m.p. 205°, which must be either 7-methoxyphthalide-3-methoxyacetic acid IX or the corresponding isomer with a methoxyl group in position 4 rather than 7. These structures are supported by infra-red data (see Experimental) as well as by the general appearance of the ultra-violet absorption curve of the substance, which is similar to that of XXIII which was obtained by cyclisation of XXII, although the long-wave maximum of IX is shifted towards higher absorbance and wave-length, which can be explained by the presence of the nuclear methoxyl substituent (Fig. 3).

The lactone acid IX melted (at 205°) with vigorous evolution of gas, and the melt solidified to yield a new compound (X), m.p. 258°. Analysis showed that the decomposition occurring at the melting point of IX was not due to decarboxylation but to the loss of one mol. of methanol. As expected, X was also obtained directly from the cinnamic acid VIII, by heating to 205—210°, the transformations VIII → IX and IX → X taking place consecutively at 145° and 205—210°, respectively.

The structure of compound X was elucidated in the following way.

3-Methoxy-1,2-naphthoquinone (XVII)[4], when treated with periodate at pH 6.5, gave 2-carboxy-α-methoxycinnamic acid (XVIII), m.p. 137° (U.V. absorption curve see Fig. 2). On melting, this substance reacted in the same way as its 3- (or 6-)methoxy derivative (VIII). The primary cyclisation pro-

* The authors are indebted to Prof. J. F. Eastham, University of Tennessee, Knoxville, U.S.A., for a gift of samples of the 3-methoxy and 6-methoxy derivatives of 2-carboxy-hydrocinnamic acid.

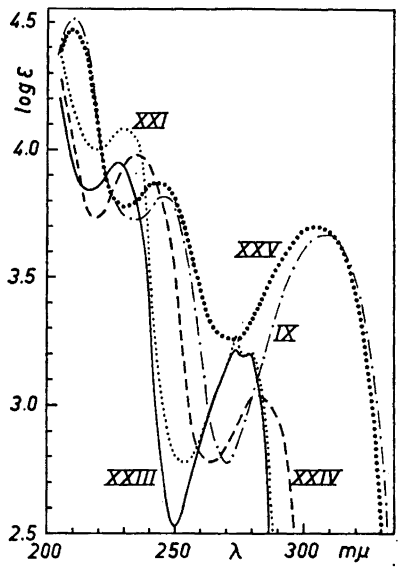


Fig. 3. Ultraviolet absorption spectra of 3-phthalide acetic acid (XXIII, ————); 7-methoxyphthalide-3-methoxyacetic acid (IX, —.—.—); γ-lactone of 2-carboxyphenylglyceric acid (XXI b, ...); 3,4-dihydro*iso*coumarin-3-carboxylic acid (XXIV, — — —); 8-methoxy-3,4-dihydro-*iso*coumarin-3-carboxylic acid (XXV, °°°°°). Solvent: 95 % ethanol.

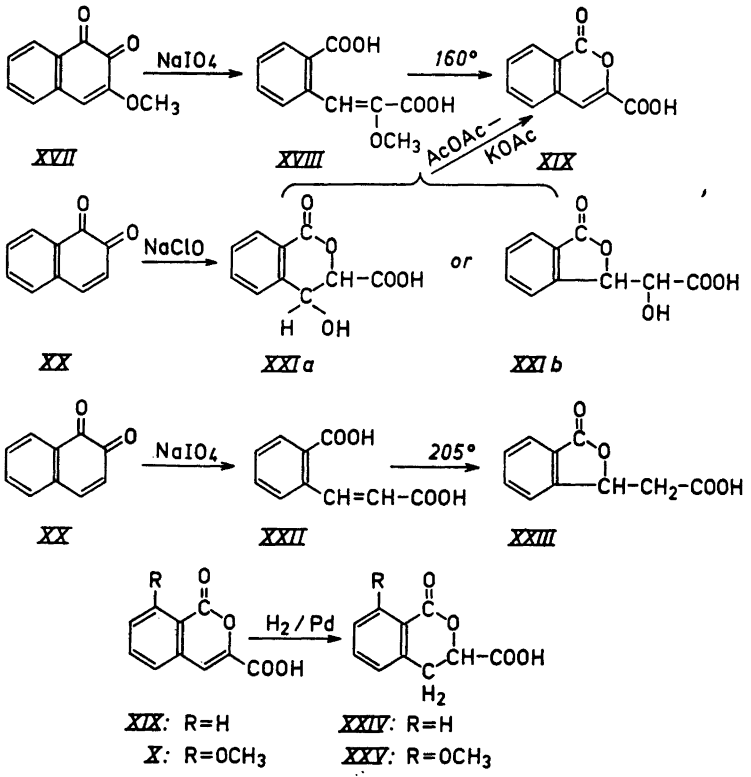
duct, which would correspond to structure IX (H instead of the nuclear methoxyl substituent), was not isolated in this case, as the second reaction step, *i.e.*, the loss of one mole of methanol, obviously began at a temperature only slightly above the melting point of XVIII. Thus, on heating at 142—160°, a methoxyl-free lactone acid, m.p. 244—245°, was formed. As expected, it was identical with *iso*coumarin-3-carboxylic acid (XIX) obtained by Bamberger [9] and Zincke [10] from β-naphthoquinone (XX) *via* the hydroxylactone acid XXI. The ultra-violet absorption spectrum of XIX is of the same type as that of product X, although the long-wave maximum of the latter is shifted to higher absorbance and wave-length due to the presence of the methoxyl group (Fig. 4). The infra-red absorption spectra of X and XIX are very similar, both exhibiting bands typical of carboxylic OH, a lactone-CO, a carboxylic CO, and a C=C bond conjugated with carboxyl, the corresponding bands for the two compounds being situated at almost the same wave-lengths (see Experimental). On the basis of these results, the analytical composition, $C_{11}H_8O_5$, and the neutralisation equivalent (found: 205, calc.: 220), substance X can be assigned the structure 8- (or 5-)methoxy-*iso*coumarin-3-carboxylic acid.

On treatment with boiling aqueous hydrobromic acid (d = 1.49), X was converted into a phenol, m.p. 290°, which was also obtained from both VIII and IX by similar treatment, or by heating with aqueous hydriodic acid. The ultra-violet absorption curve of the phenolic substance (Fig. 4) was very similar to that of the ether X, and titration indicated that the carboxyl group had been retained. Ethanolic ferric chloride gave a stable, intense violet-blue colour, the absorption spectrum of which was comparable to that of the ferric complexes of salicylic acid and — at least in the position of the maximum — of methyl salicylate (Fig. 5). The phenolic product must therefore be 8-hydroxy-*iso*coumarin-3-carboxylic acid (XI). This implies that the methoxyl



groups of β-naphthoquinone III are in the 3,8-positions (IIIa) rather than in the 3,5-positions (IIIb). Correspondingly, the positions of the nuclear methoxyl substituent in the derivatives IV, V and VII, as well as in the degradation intermediates VIII, IX and X are those given in the formulae above.

This conclusion was confirmed by further degradation of 8-methoxy-*iso*-coumarin-3-carboxylic acid (X). Bamberger [12] has shown that *iso*coumarin-3-carboxylic acid (XIX), when heated with strong alkali, is broken down to *o*-toluic acid. Compound X in this way yielded 2-methyl-6-methoxybenzoic acid (XII). On heating with hydriodic acid, acid XII was demethylated, and the expected 2-methyl-6-hydroxybenzoic acid was simultaneously decarboxylated giving *m*-cresol (XIII) as the only reaction product.

These results definitely establish structure IIIa for the starting material, and, therefore, structure IIa for the dimeric 3-methoxy-*o*-quinone.

A few remarks may be added regarding the structures of some of the compounds involved in the present work, especially the structure of the hydroxylactone acid XXI mentioned above.

The five-ring lactone (phthalide) structure of the cyclisation products IX and XXIII seems to be well established, as it is highly probable that the addition of the aryl carboxylic group to the ethylenic bond of the acrylic acid substituent in VIII and XXII will follow the general mechanism of such reactions. The six-ring enol lactone (*iso*coumarin) structure of substances X, XI and XIX is also undoubtedly correct, satisfactory evidence for the structure of XIX having been provided by the work of Bamberger [9] and Zincke [10,11].

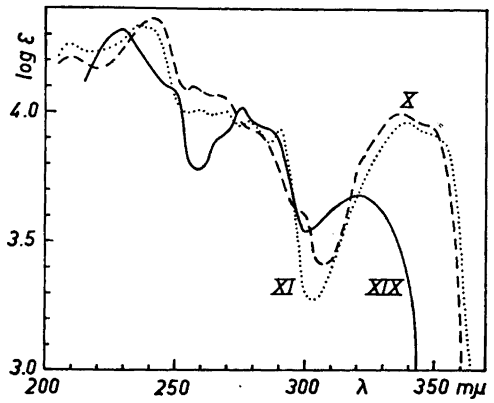


Fig. 4. Ultraviolet absorption spectra of *iso*coumarin-3-carboxylic acid (XIX, ————); 8-methoxy*iso*coumarin-3-carboxylic acid (X, — — —); 8-hydroxy*iso*coumarin-3-carboxylic acid (XI . . . . .). Solvent: 95 % ethanol.

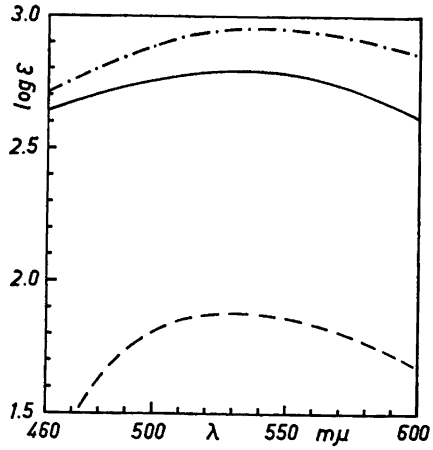

Fig. 5. Light absorption of the Fe^{3+} chelates of 8-hydroxy*iso*coumarin-3-carboxylic acid (XIX, ————); salicylic acid, —.—.—.—, methyl salicylate — — — —. The ferric chelate solutions were prepared by adding 0.2 ml of a 1 % solution of $FeCl_3$ in 96 % ethanol to 4 ml of a solution of the substance in the same solvent. The concentration of substance XIX and of salicylic acid was 1.5×10^{-3} M, that of methyl salicylate was 8.5×10^{-3} M.

However, there did not appear to be unambiguous evidence for the δ-lactone structure XXIa proposed by the latter authors for the hydroxylactone acid obtained by hypochlorite oxidation of β-naphthoquinone. The δ-lactone structure XXIa rather than a γ-lactone structure (XXIb) had been accepted [9,10] as it seemed to explain the ease with which the substance was dehydrated to give the *iso*coumarincarboxylic acid XIX when it was heated above the m. p.[10], or on heating with mineral acid [9], or with acetic anhydride [11]. As shown above, the *iso*coumarin system is, however, also readily formed from a γ-lactone (*cf.* IX → X or IX → XI) with a methoxyacetic acid substituent at position 3 of the phthalide system. By analogy, the assumption of a γ-lactone structure (XXIb) for the hydroxylactone acid of Bamberger and Zincke would also seem to be in harmony with its convertibility into the *iso*coumarin XIX.

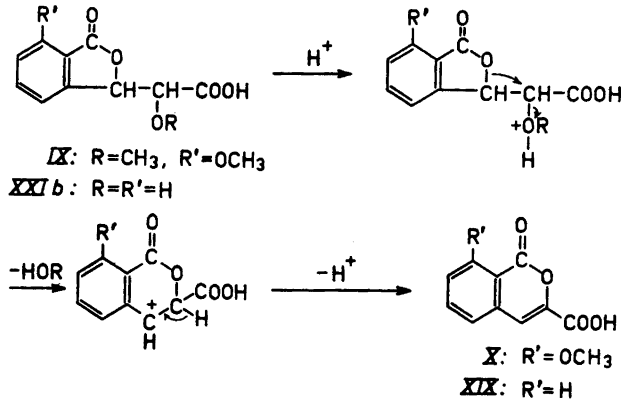
In fact, the ultra-violet spectrum of the hydroxylactone acid XXI is very similar to that of the γ-lactone XXIII (see Fig. 3), and differs markedly from that of 3,4-dihydro-*iso*coumarin-3-carboxylic acid (XXIV) [12], a δ-lactone isomeric with the γ-lactone XXIII.

The 8-methoxyl analogue of XXIV, *i. e.*, the δ-lactone XXV, m. p. 238°, cannot be used in this comparison, as the methoxyl group present causes a hyperchromic and bathochromic shift similar to that encountered in the case of the isomeric γ-lactone IX; *cf.* Fig. 3. XXV was obtained by catalytic hydrogenation of X.

The infra-red spectrum of the hydroxylactone acid XXI shows a lactone carbonyl band at 5.67 μ, *i. e.*, at the same position as the γ-lactones IX (5.67 μ) and XXIII (5.65—5.70 μ). However, the corresponding bands of the δ-lactones XXIV (5.63—5.69 μ) and XXV (5.68—5.73 μ) are very close to these positions, and, therefore, no conclusion on the size of the lactone ring of XXI can be drawn from the position of its lactone carbonyl band.

Consideration of the ultra-violet absorption data given above, strongly suggests however that Bamberger and Zincke's hydroxylactone acid has the γ-lactone structure XXIb rather than the previously accepted δ-lactone structure XXIa.

The conversion of the γ-lactones IX and XXIb into the *iso*coumarin derivatives X and XIX, respectively, by loss of a molecule of methanol (or water) and simultaneous ring enlargement, could proceed by the following mechanism:



EXPERIMENTAL

Ultra-violet spectra were measured with a Beckman DU spectrophotometer. Infra-red spectra were recorded on a Perkin-Elmer model 21 instrument, using KBr discs. Microanalyses were made by Alfred Bernhardt, Mülheim.

3,8-Dimethoxy-1,2-naphthoquinone (IIIa). The isolation of this substance from reaction mixtures obtained on periodate oxidation of pyrogallol-1,3-dimethyl ether, pyrogallol-1-methyl ether, 3-methoxy-*o*-quinone (I), dimeric 3-methoxy-*o*-quinone (IIa) and the monohydrate of IIa has been described previously [1,2]. As a starting material in the present investigation the compound was prepared as follows.

An aqueous solution of sodium metaperiodate (20.6 g in 200 ml) was added to a stirred solution of pyrogallol-1-methyl ether (4.5 g) in water (200 ml), the temperature of the reaction mixture being kept below 20° by the addition of ice. After 10 min, ethylene glycol (6.0 g) was added. The reaction mixture was stirred a few minutes longer, diluted with water and extracted exhaustively with chloroform. The dark-red chloroform solution was dried over anhydrous calcium sulphate, and evaporated to dryness. The solid residue (2.3 g), after one recrystallisation from benzene, yielded 1.74 g (49.5 %) of nearly pure IIIa, brilliant red plates, m. p. 194–195°. Further recrystallisation increased the m. p. to 198–199°. Analyses see Ref.[1]. Absorption spectrum, Fig. 1.

Chromatography of the benzene mother liquors on alumina gave further amounts of IIIa and small amounts of a violet substance, m. p. 205–206° (*cf.* Ref.[1]).

1,2-Dihydroxy-3,8-dimethoxynaphthalene (IV). 3,8-Dimethoxy-1,2-naphthoquinone (IIIa) (200 mg), dissolved in glacial acetic acid (5 ml), was reduced with zinc dust giving a nearly colourless solution. After dilution with water, the mixture was filtered, and the filtrate was extracted with ether. The ethereal solution was dried over anhydrous sodium sulphate and evaporated. The crystalline residue (120 mg) was found to undergo rapid autoxidation; sublimation (120° bath temperature, 0.5 mm Hg) yielded light-red crystals. This material was recrystallised from benzene, to which ascorbic acid was added, which brought about decolorisation of the boiling solution. On cooling, slightly reddish flat prisms (97 mg) were obtained, which after a further recrystallisation from benzene had m. p. 141–143°. (Found: C 66.53; H 5.75; OCH_3 27.39. Calc. for $C_{12}H_{12}O_4$: C 65.44; H 5.49; OCH_3 28.18.) Brief treatment of IV with aqueous sodium periodate regenerated the naphthoquinone.

The *diacetate* (V) was obtained by treating freshly prepared IV with a boiling mixture of acetic anhydride and pyridine for a few minutes. Colourless prisms from ethanol, m. p. 152–153°. (Found: C 63.15; H 5.27; OCH_3 20.40. Calc. for $C_{16}H_{16}O_6$: C 63.03; H 5.26; OCH_3 20.07.)

Permanganate oxidation of 3,8-dimethoxy-1,2-naphthoquinone (IIIa). A 4 % aqueous solution of potassium permanganate (25 ml) was added slowly to a stirred suspension of IIIa (226 mg) in N sulphuric acid (25 ml). After 24 h sulphur dioxide was passed into the reaction mixture. The resulting solution, which was practically colourless, was continuously extracted with ether for 18 h. The ethereal solution was dried and evaporated, and the residue was recrystallised from ether, giving *3-methoxyphthalic acid (VI)*, (yield 23 %), m. p. 173—175°, undepressed on admixture of an authentic sample of VI (m. p. 174—176°), obtained by acid permanganate oxidation of 1,2-dimethyl-3-methoxybenzene [13]. Heating of either sample of the acid to 180°, followed by sublimation at a bath temperature of 170° (0.01 mm Hg), yielded *3-methoxyphthalic anhydride*, m. p. and mixed m. p. 164—165°. The identity of the two samples of the anhydride was confirmed by comparison of their IR absorption spectra.

1,6-Dimethoxybenzo[a]phenazine (VII). A solution of 3,8-dimethoxy-1,2-naphthoquinone (IIIa) (0.5 mmoles) in glacial acetic acid (40 ml) was mixed with a solution of *o*-phenylenediamine (1 mmole) in the same solvent (10 ml). After 30 min heating on a steam-bath the solvent was removed under reduced pressure and the residue was dissolved in methanol. Addition of water produced a voluminous precipitate of fine brownish-yellow needles, which softened at 80—100°, solidified again on further heating, and melted at 160°. Analysis of the substance after drying at room temperature, indicated the presence of 2 moles of water. (Found: C 66.75; H 5.47; N 8.45; OCH_3 18.83. Calc. for $C_{18}H_{14}O_2N_2$, $2H_2O$: C 66.25; H 5.56; N 8.58; OCH_3 19.02.)

When dried at 60° (0.01 mm Hg), the substance lost 12.65 % of its weight (calc. for 2 H_2O: 11.04 %). Recrystallisation from benzene-hexane gave golden-yellow prisms, m. p. 164—165°. (Found: C 73.94; H 4.95; N 10.07; OCH_3 21.05. Calc. for $C_{18}H_{14}O_2N_2$: C 74.47; H 4.86; N 9.63; OCH_3 21.38.) UV spectrum, Fig. 1.

2-Carboxy-3-methoxy-α-methoxycinnamic acid (VIII). 3,8-Dimethoxy-1,2-naphthoquinone (IIIa) (600 mg) was suspended in 0.5 M phosphate buffer solution (180 ml) of pH 6.5, sodium metaperiodate (3 g) in water (60 ml) was added and the mixture was shaken for 2.5 h. Some inorganic material ($NaIO_3$) was removed by filtration and the pale yellow filtrate was then acidified with 2 N HCl and thoroughly extracted with ethyl acetate. After drying over anhydrous calcium sulphate the solvent was evaporated under reduced pressure. The crystalline residue (644 mg) was recrystallised from acetone-chloroform. Colourless rods (437 mg; yield 63 %), m. p. 142—143°; the melt solidified (cyclisation product IX). On slow heating substance VIII is gradually converted to IX and may not show any sharp melting point. (Found: C 57.06; H 4.86; OCH_3 24.30. Calc. for $C_{12}H_{12}O_6$: C 57.14; H 4.79; OCH_3 24.61.) Neutralisation equivalent, found, 132, calc., 126. UV spectrum, Fig. 2. IR maxima (μ): 3.5 and 3.75—3.95 (carboxylic OH); 5.84—5.92 (CO of α,β-unsaturated carboxylic and arylcarboxylic acid); 6.12 (C=C conjugated with COOH).

7-Methoxyphthalide-3-methoxyacetic acid (IX). A sample of substance VIII (100 mg) was heated to the melting point. The melt resolidified at the melting temperature or after some cooling. Recrystallisation from ethyl acetate-hexane gave thin colourless plates (86 mg), m. p. 204—205° (gas evolution; the melt resolidified with formation of X). (Found: C 57.08; H 4.85; OCH_3 24.71. Calc. for $C_{12}H_{12}O_6$: C 57.14; H 4.79; OCH_3 24.61.) UV spectrum, Fig. 3. IR maxima (μ): 3.3 and 3.9 (broad carboxylic OH bands); 5.67 (carbonyl of α,β-unsaturated lactone); 5.87 (CO of carboxyl group); the band at 6.12 which is present in the IR spectrum of VIII was absent.

*8-Methoxy-*isocoumarin-3-carboxylic acid (X). A sample of VIII (289 mg) was heated to 205—210°. When the evolution of gas (CH_3OH) had ceased and the melt had become solid again, the product was allowed to cool. It was then treated with warm ethyl acetate; the undissolved, almost white, crystalline material (198 mg) was collected and recrystallised from methanol (charcoal) giving needles, m. p. 257—258°. Yield 75 %. The same product was obtained by heating substance IX to its melting point. The product contained about 1 mole of methanol of crystallisation, which was not completely removed unless drying was done at 100—120° (0.1 mm Hg). (Found: loss of weight, 11.75 %. Calc. for $C_{11}H_8O_5$, CH_3OH: 12.73 %. Analysis of a dried sample gave: C 60.14; H 3.65; OCH_3 14.09. Calc. for $C_{11}H_8O_5$: C 60.00; H 3.66; OCH_3 14.03.) Neutralisation equivalent, found, 205, calc., 220. UV spectrum, Fig. 4. IR maxima (μ): 3.25—3.5 and 3.8—4.0 (carboxylic OH); 5.73 (CO of unsaturated lactone); 5.85 (CO of unsaturated carboxylic acid); 6.06 (C=C conjugated with carboxyl).

8-Hydroxy-isocoumarin-3-carboxylic acid (XI). This substance was obtained by heating VIII, IX, or X with either aqueous hydriodic or hydrobromic acid. In a typical example, substance VIII (100 mg) was treated for 4 1/2 h with boiling aqueous hydriodic acid (15 ml, d = 1.70) in the presence of red phosphorus. On cooling, the reaction product deposited as a crystalline solid; it was filtered off, together with the phosphorus, and separated from the latter by elution with ethyl acetate. The ethyl acetate solution was evaporated to dryness. The residue was washed with methylene chloride, which removed some iodine, and recrystallised from ethyl acetate-hexane; colourless prisms, m. p. 290°; yield, 36 %.

In another example, substance IX (19.5 mg) was treated for 1 h with boiling aqueous hydrobromic acid (2 ml, d = 1.49). Crystals of XI were deposited, m. p. 287°, undepressed on admixture of a sample obtained as above. Yield, 68 %. (Found: C 58.40; H 3.10. Calc. for $C_{10}H_6O_5$: C 58.26; H 2.93.) Neutralisation equivalent, found, 224, calc., 206. UV spectrum, Fig. 4. Absorption spectrum of the ferric complex, Fig. 5. IR maxima (μ): 3.1—3.5 and 3.75—4.0 (phenolic and carboxylic OH); 5.74 (CO of unsaturated lactone); 5.90—6.02 (CO of unsaturated carboxylic acid, probably also some lactone carbonyl, chelated with phenolic OH); 6.09 (C=C conjugated with carboxyl)*.

Alkaline degradation of X. A solution of substance X (190 mg) in 40 % aqueous NaOH (2 ml) was refluxed for 1 h. The mixture was diluted with water and filtered, and the filtrate was acidified with dilute sulphuric acid. On cooling, the filtrate deposited colourless needles (92 mg), m. p. 141—142°, unchanged after recrystallisation from water. For *2-methyl-6-methoxybenzoic acid* (XII) Chuit and Bolsing [14] reported m. p. 139°.

m-Cresol from 2-methyl-6-methoxybenzoic acid (XII). A sample of XII (59 mg) was treated with boiling aqueous hydriodic acid (d = 1.70) and some red phosphorus for 35 min. After cooling, the phosphorus was filtered off and washed with water. The filtrate was extracted with ether and the ethereal solution was shaken with aqueous sodium bisulphite, which removed iodine, and then with aqueous sodium bicarbonate. The ether phase was dried and evaporated; the IR spectrum of the oily residue was indistinguishible from the spectrum of *m*-cresol.

The bicarbonate solution contained no organic material.

2-Carboxy-α-methoxycinnamic acid (XVIII) (G.B.) **. 3-Methoxy-1,2-naphthoquinone (XVII) [4] was oxidised with periodate at pH 6.5, as described above for similar oxidation of IIIa. The quinone colour had disappeared after about 2 h. Extraction of the filtered solution with ethyl acetate gave thin plates, m. p. 137° after recrystallisation from ethyl acetate-hexane. Yield 70 %. (Found: C 59.53; H 4.58; OCH_3 14.02. Calc. for $C_{11}H_{10}O_5$: C 59.46; H 4.54; OCH_3 13.97.) UV spectrum, Fig. 2. IR maxima (μ): 3.3—3.5 and 3.75—3.95 (carboxylic OH); 5.85 and 5.90 (CO of aryl and α,β-unsaturated carboxyl); 6.12 (C=C conjugated with carboxyl).

Isocoumarin-3-carboxylic acid (XIX) (G.B.). Substance XVIII, when heated, melted at 137° and began to decompose at a temperature only slightly above the m. p. After heating to 160° the melt solidified. Recrystallisation from water gave plates, m. p. 237°

---

* *Note added in proof.* In a recent paper, Gerd Bendz [*Arkiv Kemi* **14** (1959) 511] reports the isolation of 8-hydroxy-3-methyl*iso*coumarin from the culture medium of *Marasmius ramealis*. The compound differs from substance XI only in carrying a methyl rather than a carboxyl group in the 3-position. As expected, the UV maxima of both substances are rather similar. There is, however, a striking difference in the positions of the lactone CO peaks of the two compounds. Whereas Bendz' 3-methyl compound has a CO band at 5.95 μ, the corresponding band of the 3-carboxy compound (XI) is found at 5.73 μ. As was pointed out by Bendz, the wave-length value of 5.95 μ is within the region expected for an unsaturated six-membered ring lactone carbonyl, a similar value (5.98 mμ) being found for the 3,4-dihydro derivative of Bendz' compound. Then the value found for substance XI is unexpectedly low. Similar relationships are found for the methyl ether of Bendz' compound and its 3,4-dihydro derivative on the one hand (*cf.* also Ref.[18]) and the carboxylic compounds X, XXIV and XXV on the other hand. This seems to indicate that the 3-carboxyl substituent of the unsaturated six-membered ring lactone causes the lactone CO stretching band to be shifted to the low wave-length values observed. It may be of interest ta note that a similarly low value, 5.70 μ, has been reported [15] for 5,6,7-trimethoxy-*iso*coumarin-3-aldehyde.

** Experiments marked "G.B." were carried out by Mr. Gunnar Bergström.

(yield 70 %), identical by mixed m. p. and IR absorption spectrum with XIX, prepared from XXI according to Zincke and Schmidt[11]. The UV absorption (Fig. 4) is rather similar to that reported for *iso*coumarin [15].

Periodate oxidation of β-naphthoquinone (XX) (G.B.). On oxidation, in the same way as for the β-naphthoquinones IIIa and XVII, XX yielded *2-carboxycinnamic acid (XXII)*, m. p. 205° (lit. [6,7], 203–205°). Yield 70 %. UV absorption, Fig. 2 (see also Ref. [16]).

*3,4-Dihydro-*iso*coumarin-3-carboxylic acid (XXIV) (G.B.).* A $PdCl_2$-$BaSO_4$ catalyst (0.5 g, with 5 % $PdCl_2$) was hydrogenated in 93 % acetic acid (10 ml), a solution of substance XIX (95 mg) in the same solvent (5 ml) was added, and the mixture was stirred in a hydrogen atmosphere. The hydrogen uptake ceased when 1 mole of H_2/mole of XIX had been consumed. Evaporation of the filtered solution, and recrystallisation of the residue from benzene gave XXIV, m. p. 154–155°. For the same substance obtained by sodium amalgam reduction of XIX, Bamberger [12] reported m. p. 153.5°. UV spectrum, Fig. 3. IR maxima (μ): 3.15 and 3.85–4.05 (carboxylic OH); 5.63–5.69 (lactone CO); 5.83 (carboxylic CO).

3-Hydroxyhydrocinnamic acid (XVI). A mixture of 2-carboxy-3-methoxyhydrocinnamic acid (XIV) [8] (see Note, p. 542) (100 mg), aqueous hydriodic acid (d = 1.70) (7 ml) and a little red phosphorus was boiled under reflux for 45 min. After filtration, the solution was diluted with water, and extracted six times with ether. The ethereal solution was washed with aqueous sodium bisulphite and water, dried and evaporated. Recrystallisation of the residue from ethyl acetate-hexane gave colourless needles (34 mg), m. p. 110°. (Lit.[17], 111°.) Neutralisation equivalent, found, 170; calc. for XVI, 166.

*3,4-Dihydro-8-methoxy*iso*coumarin-3-carboxylic acid (XXV).* This substance was prepared by catalytic hydrogenation of X, as described for the preparation of XXIV from XIX. It was recrystallised from ethyl acetate-hexane, prisms, m. p. 238°. (Found: C 59.47; H 4.43; OCH_3 14.26. Calc. for $C_{11}H_{10}O_5$: C 59.46; H 4.54; OCH_3 14.97.) The UV maxima (Fig. 3) are similar to those reported for (–)-3,4-dihydro-8-hydroxy-3-methyl*iso*coumarin (= mellein) [18]. IR maxima (μ): 3.24 and 3.7–4.0 (COOH); 5.68–5.73 (lactone carbonyl; 5.84 (COOH).

Effect of Temperature and Concentration of Sulphuric Acid on the Rate of Formation of the Boron 1,1′-Dianthrimide Complex

O. B. SKAAR and F. J. LANGMYHR

University of Oslo, Chemical Institute A, Blindern, Norway

The effect of temperature and concentration of sulphuric acid on the rate of formation of the boron-1,1′-dianthrimide complex has been investigated spectrophotometrically. Series of solutions containing boron, 1,1′-dianthrimide and varying amounts of water were prepared and heated at four different temperatures. At intervals solutions were removed and measured photometrically. On the basis of the extinction data velocity constants were calculated. An empirical equation was derived for the influence of temperature and concentration of sulphuric acid on the velocity constant. The velocity constant is redoubled either by an 8°C increase of temperature, or by a decrease of concentration of sulphuric acid corresponding to the difference between 100.6 % sulphuric acid and the strength of the initial acid.

In the literature qualitative indications are given on the effect of temperature and concentration of sulphuric acid on the development of the colour of the boron 1,1'-dianthrimide complex. Ellis, Zook and Baudisch [1] state that 3 h heating at 90°C or 5 h heating at 80°C is necessary to develop the colour. According to Otting [2] the rate of colour formation increases with increasing water content. In a previous paper the authors [3] have described the determinations of formula, rate of reaction and stability constant of the boron 1,1'-dianthrimide complex. The solvent applied in these investigations was 93.8 % sulphuric acid, and the rate of reaction and the stability constant were determined for solutions heated at 71° and 70°C, respectively.

The present paper describes the effect of temperature and concentration of sulphuric acid upon the rate of reaction of the complex.

EXPERIMENTAL

Instruments. Extinction measurements were made with a Klett-Summerson spectrophotometer equipped with a B 650 filter. (In the authors previous publication [3] the absorption maximum of the boron 1,1′-dianthrimide complex was found at 630 mμ.)

Reagents. The 1,1'-dianthrimide (E. Merck) was recrystallized twice from nitrobenzene before use. Boric acid, sulphuric acid (95—97 %), and other chemicals were of reagent grade quality. The strength of sulphuric acid was found to be 96.8 %. The acid was protected against absorption of water vapour and contamination with dust.

Glassware. Reagent solutions were prepared in 50 ml bottles (Jena *Geräteglas*) with ground-in glass stoppers. The solutions were heated in specially made photometric cells, prepared from ordinary soda glass tube (14 mm outer, 12 mm inner diameter). The length of these cells was about 20 cm. The cells were marked to keep them in the same position during photometric measurement.

Heat treatment. This was given in a thermostatically controlled water bath. The temperature of the bath varied regularly about the prefixed temperature, the maximum deviations being ± 2°C.

Standard solutions. 0.5715 g of boric acid were weighed out, dissolved in concentrated sulphuric acid and diluted to 1 000 ml with the same acid. From this standard solution (containing 100 μg B per ml) 50 ml were pipetted into another 1 000 ml volumetric flask and diluted to volume with concentrated sulphuric acid. From this latter solution (containing 5 μg B per ml) known amounts of boron were taken. 0.0794 g of 1,1'-dianthrimide were dissolved in concentrated sulphuric acid and diluted to 1 000 ml with the same acid.

Preparation of reacting solutions. Reaction mixtures of boron and 1,1'-dianthrimide were prepared according to the formula: X ml of distilled water + (14—X) ml of concentrated sulphuric acid + 1 ml of boron standard solution + 5 ml of 1,1'-dianthrimide standard solution. The following values of X were chosen: 0.5—1.0—1.5—2.0—2.5 and 3.0. In a series of corresponding blank solutions the volume of boron standard solution was replaced by concentrated sulphuric acid. The solutions were pipetted into 50 ml bottles and were thoroughly mixed. Suitable amounts were then transferred to the photometric cells. To prevent uptake of water vapour during the heating period the cells were fitted with rubber stoppers. Four different series of solutions were prepared according to the formula given above, each series being heated at one of the following mean temperatures: 49.5—67.0—71.0 and 79.8° C.

PHOTOMETRIC MEASUREMENTS

The six reacting solutions and their corresponding blanks (all belonging to one temperature series) were placed in the water bath. At 1 to 1.5 h intervals a solution and its corresponding blank were removed and the extinction of both was measured against distilled water. A constant time of 10 min was employed for photometric measurement. The reacting solutions were finally brought near equilibrium by heating them for an extended period of time varying with the temperature applied. (Excessive heating resulted in destruction of considerable amounts of 1,1'-dianthrimide). The extinction data obtained were corrected for the absorption of the cells (filled with distilled water) and for the absorption of the blanks. The final, corrected extinction values are given in Figs. 1a, b, c and d. The data are given in per cent of the final extinction value obtained after the heating time specified in the figures. The values in Fig. 1 given in parenthesis for zero time indicate time of preheating period.

DISCUSSION

Figs. 1a, b, c and d show that the rate of complex formation increases with the temperature and the content of water. In order to develop an approximate expression for the influence of these factors on the rate of reaction the

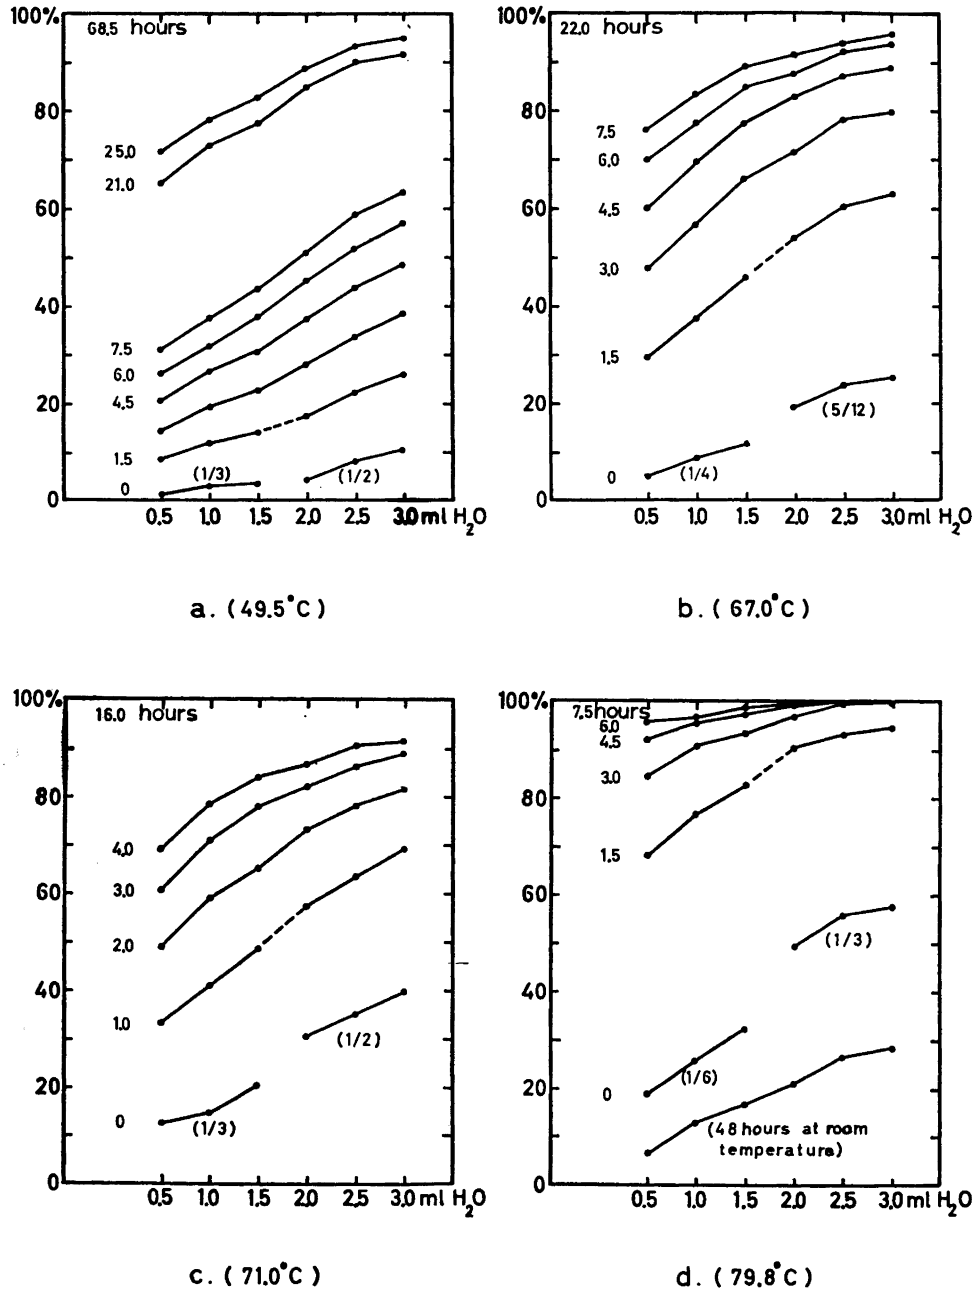

Fig. 1a, b, c and d. The effect at different temperatures and heating times of concentration of sulphuric acid on the formation of the boron 1,1′-dianthrimide complex.

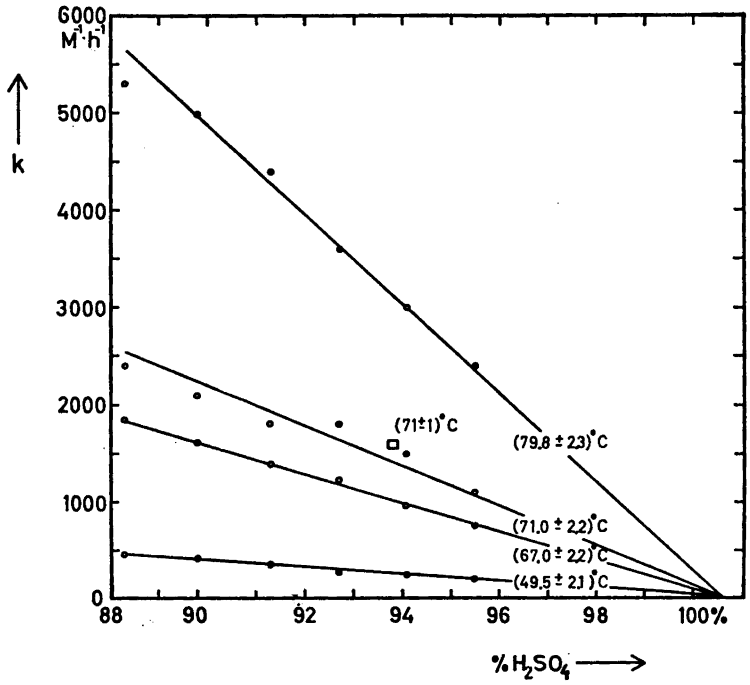

Fig. 2. The effect at different temperatures of concentration of sulphuric acid on the velocity constant of the boron 1,1'-dianthrimide complex.

following assumptions were made. The time of heating t employed in the calculations is the observed time of standing in the water bath. It was assumed that the reduced rate of reaction during photometric measurement corresponds approximately to the lowered rate of complex formation during reheating in the water bath. The assumptions were further made that equilibrium is attained at the final extinction measurements, and that the contamination of boron originating from the reagents is compensated for by subtracting the extinction of the blanks. The stability constant [3] $K = 1.4 \times 10^5$ M^{-1} was applied, and this value was considered constant within the temperature range 50°—80°C and concentration range 88.3—95.5 % sulphuric acid. All concentrations were calculated on the basis of a volume of 19.6 ml (19 ml of concentrated sulphuric acid plus 1 ml of water). In cases where the starting volume differed from 19.6 ml, corrections were made by multiplication with $19.6/V$, where V (in ml) was the volume in question. The original concentrations of boron and 1,1'-dianthrimide were 2.36×10^{-5} M and 29.7×10^{-5} M, respectively. The amount of boron not complexed at equilibrium was $2.3 \times 10^{-5} / (1.4 \times 10^5 \times 27.4 \times 10^{-5}) = 0.06 \times 10^{-5}$ M. The molar concentration of the boron 1,1'-dianthrimide complex (X) determined spectrophotometrically was $X = p\ (2.36 - 0.06) \times 10^{-5}/100$ where p is the percentage of maximum extinc-

tion. In the authors earlier publication [3] an expression for the velocity constant k was developed. Taking into consideration the assumptions made above, the original equation is transformed to:

$$k = \frac{2.303 \times V}{(t_2 - t_1) \times 19.6 \times 28.16 \times 10^{-5}\ \mathrm{M}} \log \frac{13.1 - p_2/100}{13.1 - p_1/100} \cdot \frac{100 - p_1}{100 - p_2}$$

This equation was then applied to calculate the velocity constants given in Table 1.

Due to the simplifications made, the values based on first and second extinction measurement are considered to be more reliable than those based on second and third. The values for k based on first and second measurement are also shown in Fig. 2 (the room temperature values are not included in this figure).

Table 1. Velocity constants at different temperatures and concentrations of sulphuric acid.

Temperature °C	Time interval in hours	Velocity constants in $M^{-1} \cdot h^{-1}$ at the following concentrations of sulphuric acid (%):					
		95.5	94.1	92.7	91.3	89.8	88.3
Room temperature	0 −48.0	5	10	13	16	21	23
49.5	0 − 1.5	190	240	270	360	410	460
49.5	1.5− 3.0	170	220	250	330	400	440
67.0	0 − 1.5	750	950	1 220	1 400	1 620	1 740
67.0	1.5− 3.0	760	960	1 210	1 240	1 510	1 550
71.0	0 − 1.0	1 100	1 500	1 800	1 800	2 100	2 400
71.0	1.0− 2.0	1 000	1 400	1 500	1 800	2 000	2 000
79.8	0 − 1.5	2 400	3 000	3 600	4 400	5 000	5 300
79.8	1.5− 3.0	2 000	2 500	2 600	3 100	(7 900)	(6 100)

It is seen from Fig. 2 that the k values at a constant temperature lie approximately on straight lines converging at at point corresponding to 100.6 % sulphuric acid. (The square seen in Fig. 2 indicates the value of k (1 600 M^{-1} h^{-1}) determined previously by the authors [3].)

The following empirical equation was finally derived for the influence of temperature and concentration of sulphuric acid on the velocity constant:

$$k_{t,c} = 235(100.6 - c)10^{0.038(t-71)}$$

The indexes t and c indicate the temperature and the concentration of sulphuric acid, respectively, for which the velocity constant is calculated. The formula was developed on the basis of the previously determined value for k, *viz.* $k_{71;\,93.8} = 1\,600\ M^{-1}\ h^{-1}$. In view of the approximations made, the expression for the velocity constant is assumed to be valid within the ranges $50° < t < 80°C$ and $88.3\ \% < c < 95.5\ \%$ sulphuric acid. It is seen, that the velocity con-

stant is redoubled by an 8°C increase of temperature, or by a decrease of concentration of sulphuric acid corresponding to the difference between 100.6 % sulphuric acid and the strength of the initial acid.

Acknowledgement. The authors are indebted to Professor Haakon Haraldsen for his interest in the investigation and for the facilities placed at their disposal.

Nuclear Magnetic Resonance Investigations of Xanthoperol

JOHAN B-SON BREDENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland

and

JAMES N. SHOOLERY

Varian Associates, Palo Alto, California, U.S.A.

It has by nuclear magnetic resonance investigations been found that xanthoperol has the structure of 9,10-diketoferruginol, but with the configuration at C-11 probably inverted.

The structure I, without configurational implications, has been previously proposed for xanthoperol [1]. The evidence for this structure were indirect and it was therefore necessary to study it further, especially as the biogenetic relationship between the proposed structure and the structures of the other diterpene compounds in *Juniperus communis* L. [2,3] was obscure.

The nuclear magnetic resonance spectrum of xanthoperol in $CDCl_3$ at 60 Mc has been taken and is presented in Fig. 1. The reference is pure benzene in an external space. The peak at −51 cps arises from residual $CHCl_3$ in the solvent while the small peak immediately adjacent to the $CHCl_3$ peak is almost certainly due to residual benzene which has been used in the crystallisation of the compound. The assignments of the two benzene ring protons, H—8 at −95 cps and H—5 at −30 cps, are based on comparison of this spectrum with the spectra of a number of alkaloids [4] in which it has been found that a keto group conjugated with the ring shifts the resonance of the adjacent benzene ring proton down to the vicinity of −100 cps relative to the zero of reference. The resonance from the phenolic hydrogen, −11 cps, has been identified by its temperature dependence. The signal-to-noise ratio obtainable in this solution makes it rather difficult to see the seven lines from the C—H proton in the *iso*propyl group, but there is little doubt that they lie at about +200 cps, since a reproducible series of peaks with about the right spacing has been observed in this vicinity in several spectra. The spacing of the two peaks

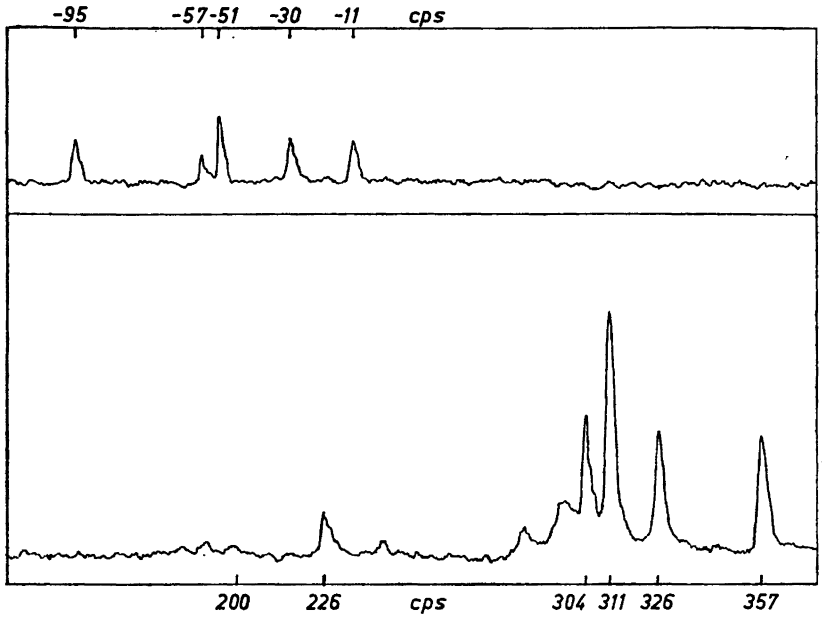

Fig. 1. Nmr-spectrum of xanthoperol in $CDCl_3$, external reference benzene. 60 Mc.

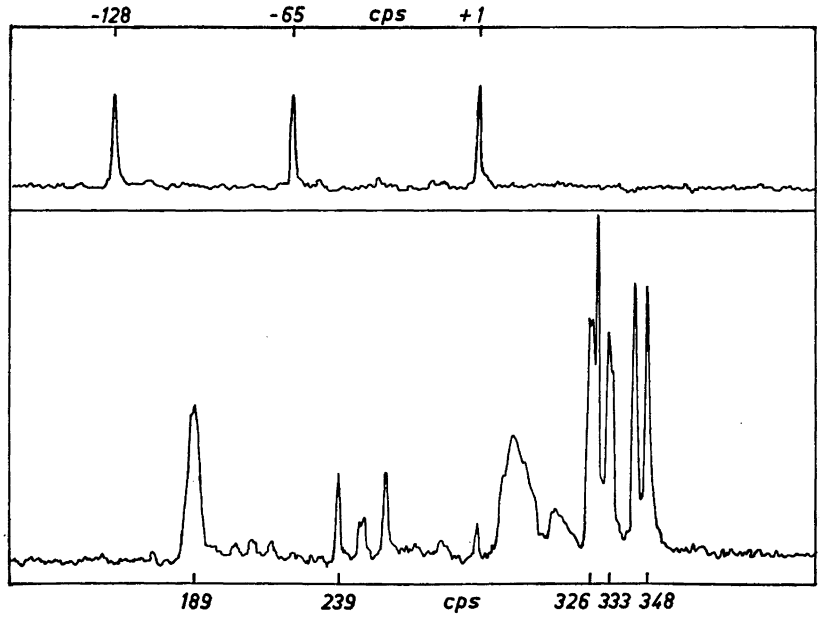

Fig. 2. Nmr-spectrum of 9-ketoferruginol in deuterated tetrahydrofuran, external reference benzene. 60 Mc.

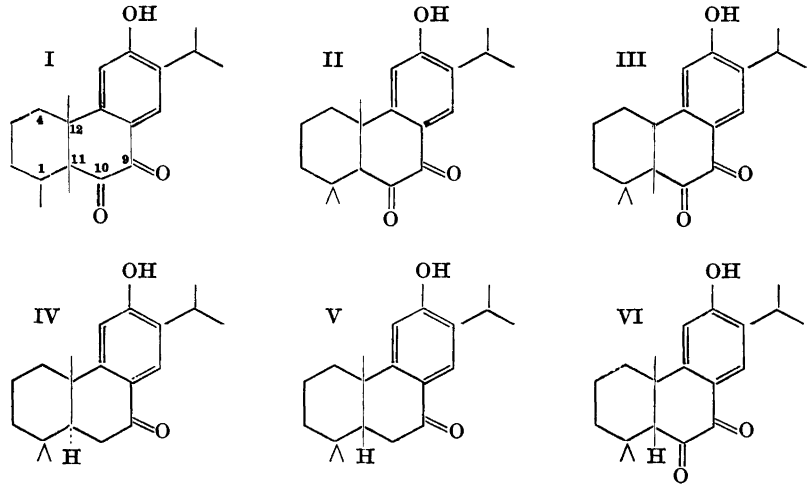
at 304 cps and 311 cps, 7 cps apart, is on the other hand completely characteristic of the spin coupling for the *iso*propyl group methyl doublet. The fact that the line at 311 cps is twice as large as the one at 304 cps can only be explained on the basis of an accidental overlap by one other methyl group in the molecule. In addition, there are two methyl group lines at 326 and 357 cps, both of which are equally as sharp as the line at 311 cps. This fact shows that none of the methyl groups in the A-ring is attached to a carbon atom which also possesses a hydrogen, in which case the methyl group resonance would be split into a doublet. Therefore, structure I is not acceptable. These leaves two structures, II and III, with a geminal dimethyl group. The line at 357 cps is assigned to the angular methyl since angular methyl groups in steroids generally fall at higher positions than side chain methyls [5]. The lines at 311 and 326 cps therefore correspond to the *gem.*-dimethyl group.

The assignments given above have been confirmed from the spectrum of 9-ketoferruginol in fully deuterated tetrahydrofuran (Fig. 2). The spectrum shows clearly three sharp methyl group peaks and two slightly broader peaks



belonging to the doublet from the *iso*propyl methyl groups, all lying between 326 and 348 cps from external benzene. These numbers must all be diminished by about 25 cps to correct for the difference in the diamagnetic bulk susceptibilities of deuterated tetrahydrofuran and chloroform. One can then compare the numbers with those obtained for xanthoperol and it is found that the two peaks previously assigned to the *iso*propyl methyls in xanthoperol correspond within a few cycles to those which are assigned to the same groups in 9-ketoferruginol. The two benzene ring protons give resonances at −65 and + 1 cps and when we correct for the bulk susceptibility effect, we find that these two peaks correspond fairly well, both in position and spacing, to the two peaks in xanthoperol which were assigned to the benzene ring protons. The phenolic proton must give a resonance at −128 cps which indicates an enormous shift to low field compared with the position found in xanthoperol.

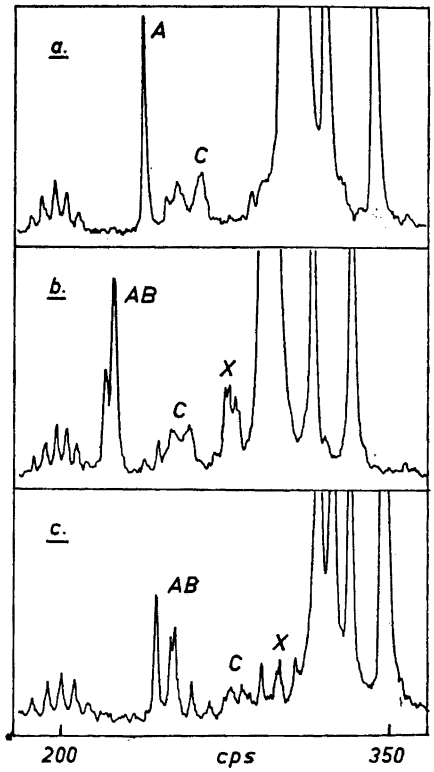


Fig. 3. The high-field end of the nmr-spectra of *a.* xanthoperol, *b.* its monoketonic reduction product, and *c.* 9-ketoferruginol. All spectra are taken in pyridine at 60 Mc with external benzene as reference.

This is probably due to formation of a strong hydrogen bond between this proton and the solvent since a shift towards lower field would be expected in that case.

The decision between structures II and III for xanthoperol must be based on a study of the peak at 226 cps (Fig. 1) which is assigned to the angular hydrogen. The position of this peak could be accounted for in a satisfactory way by either of these structures. However, only structure II places this hydrogen far enough from other hydrogen nuclei so that no spin coupling would be expected, and therefore only structure II accounts for the sharpness of this line. It is very unlikely that if the angular hydrogen were located at C-12 it would not couple its spin fairly strongly to one or the other of the two protons on C-4. For a closer study of this coupling the high-field end of the spectra of xanthoperol, its monoketonic reduction product [1] and 9-ketoferruginol have been taken in pyridine solution (Fig. 3). Unfortunately, the three spectra were not run at exactly the same scale factor and no internal reference compound was added with the result that the spectra cannot be perfectly lined up and compared directly.

The central five lines of the seven-line multiplet due to the C—H proton in the *iso*propyl side chain are now clearly seen at 200 cps. Xanthoperol

has a single sharp line labelled A which is assigned to the proton on C-11, the methyl group on C-12 accounting for its lack of spin coupling. The resonance from this proton moves toward higher fields when the adjacent keto group is reduced and becomes the pattern of four lines marked X in the mono-keto product. The four lines almost certainly arise from spin coupling to the two protons on C-10 to give an ABX pattern [6] similar to the one for 9-ketoferruginol. The AB pattern in the mono-keto reduction product is not so well defined as in 9-ketoferruginol, however, because the couplings are smaller, as can be seen in the X pattern. The shape of the AB pattern in the monoketo reduction product is predicted with $J_{AB} = 16$ cps, $J_{AX} = 5$ cps, $J_{BX} = 2.5$ cps, and $\delta_{AB} = 14$ cps at 60 Mc. The AB pattern in 9-ketoferruginol is satisfactorily described by $J_{AB} = 16$ cps, $J_{AX} = 7.2$ cps, $J_{BX} = 8.5$ cps, and $\delta_{AB} = 7$ cps at 60 Mc. The nmr spectra are, therefore, most compatible with structure II for xanthoperol, since III would not be expected to yield an ABX pattern in its mono-keto reduction product. The structure for the monoketonic reduction product accordingly has to be changed and since it differs, for reasons discussed more closely elsewhere [7], from 9-ketoferruginol (IV) only in its configuration at C-11 it must be assigned the configuration in structure V. The change from *trans* to *cis* ring fusion has therefore changed one of the spin couplings quite a lot, but left the other relatively unchanged. The configuration of xanthoperol cannot be conclusively determined from its nmr spectra but a closer examination of the region C (Fig. 3) which is tentatively assigned to the C-4 protons, and the spacing of the methyl groups seems to indicate a much closer relationship between xanthoperol and the *cis*-form characteristic of the mono-keto reduction product rather than the *trans*-form characterized by 9-ketoferruginol. This result points to the *cis*-form for xanthoperol as given by the configuration in VI.

EXPERIMENTAL

The nmr spectra were taken at Varian Associates, Palo Alto, California, with a 60 Mc High Resolution NMR Spectrometer in a field of 14 100 gauss.

The authors wish to express their thanks to Mr. L. F. Johnson for taking the nmr spectra.

Heats of Hydrolysis of Phenyl Acetate and Phenyl Thiolacetate

INGEMAR WADSÖ

*Thermochemistry Laboratory *, University of Lund, Sweden*

The heats of hydrolysis of phenyl acetate and phenyl thiolacetate have been determined calorimetrically at 25°C. For the idealized, isothermal hydrolysis reactions

$$PhOAc(l) + H_2O(l) \rightarrow PhOH(s) + HOAc(l)$$

and

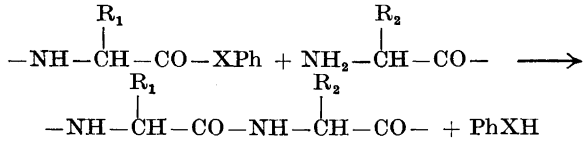
$$PhSAc(l) + H_2O(l) \rightarrow PhSH(l) + HOAc(l)$$

the enthalpy changes were found to be -6.86 ± 0.06 and -2.97 ± 0.08 kcal/mole, respectively.

Heat and free energy changes in transacylation from phenyl thiolacetate to thiols have been briefly discussed.

The simple phenyl thiolacetate as well as aminoacyl derivatives of thiophenol have been used extensively during recent years, as acylating agents towards thiols and amines in peptide chemistry. Also O-phenylesters, preferably nitro-substituted, have been proved to be useful in this connection [1].

Phenol and thiophenol derivatives of aminoacids and peptides can be looked upon as "active forms" of the corresponding acids. They can be condensed, under conditions that are possible in the cell, with another aminoacid or peptide, by which reaction a peptide bond is formed:



X = O, S.

The acylated phenols have been described as "energy-rich" *i.e.* their hydrolysis reactions have been supposed to proceed under release of a large amount

* Sponsored by *The Swedish Natural Science Research Council* and by *The Swedish Technical Research Council.*

Table 1. Heats of hydrolysis of phenyl acetate and phenylthiol acetate.

of free energy. As in a simple hydrolysis reaction the entropy term is small, the enthalpy change is of the same order as the free energy change. Therefore, it seemed to be of interest to determine the heats of hydrolysis of the acetic acid esters of the simple phenol and thiophenol, thereby also supplementing the recently performed measurements on alkyl acetates [2] and alkyl thiolacetates [3].

EXPERIMENTAL

Materials. Phenyl acetate was prepared from phenol and acetic anhydride [4]. The crude product was purified by distillation at different pressures in a 10-plate column, followed by fractional freezing out. The product reacted neutral. The equivalent weight, as determined by potentiometric titration of the acetic acid formed by hydrolysis, coincided with the theoretical value within the limits of experimental error. $d_4^{25} = 1.0740$, $n_D^{25} = 1.5010$.

Phenyl thiolacetate was prepared from benzene thiol and acetyl chloride [5]. The ester was purified by distillation, until the equivalent weight, as determined by iodometric titration of thethiol formed by alkaline hydrolysis [3], indicated 100.0 % purity. The product reacted neutral and did not consume any iodine. $d_4^{25} = 1.1164$, $n_D^{25} = 1.5690$.

Phenol of purum grade was purified by fractional freezing out until a colourless substance with a melting point at 41.0°C was obtained.

Benzene thiol was distilled until iodometric titration in water-ethanol gave an equivalent weight indicating 100.0 % purity.

Acetic acid was purified by fractional freezing out 4 times. Titration values proved the substance to be pure within the limits of experimental error.

Apparatus. The reactions were carried out in a metal "isothermal" calorimeter which has been described in detail elsewhere (Type D in Ref.[6]).

Calibration. The heat equivalent of the calorimeter, including its content, was determined electrically by passing a known current for a given time (240 sec) through the heating element. The calibrations were performed on the system after hydrolysis had taken place. The result of each calibration experiment was adjusted to give the heat equivalent of a "standard system", ε°, in which the calorimetric liquid contained the hydrolysis products from a certain amount of ester (450 mg). The actual heat equivalent values, ε, were obtained from ε° by applying small corrections for the variations in the amount of substance used.

Calorimetric procedure. In order to obtain a rapid reaction, the hydrolyses were performed in strong (0.8 N) sodium hydroxide, water-ethanol (2:3) solution. The calorimeter was charged with 100 ml of this solution. After equilibration, the reaction was started by breaking the sealed glass ampoule containing the ester. The thiol formed from phenyl thiolacetate was to a certain extent oxidised in the alkaline medium, as was the case with

Table 2. Heat of solution measurements.

aliphatic thiols [3]. However, it was found that the autoxidation of benzene thiol was much slower than that observed for aliphatic thiols. In order to cancel the heat effect of autoxidation, the same technique as given in Ref.[3] had to be used. Thus the experiments on phenyl thiolacetate and benzene thiol were performed in a solution in which a small amount (0.5 ml) of benzene thiol has been substituted for the calorimetric liquid. As seen from the results given in Table 2, presence of thiol did not significantly change the heat of solution value of acetic acid.

In every case the reaction period was 8 minutes or less. The initial and final thermistor resistances (R_i and R_f, respectively) were obtained graphically.

Corrections to standard states. The ideal isothermal hydrolysis reaction V is obtained from eqns. I and IV, which correspond to the reactions taking place under actual experimental conditions.

I	$PhXAc(l) + H_2O(soln) \longrightarrow PhXH(soln) + HOAc(soln)$	ΔH_1
II	$PhXH(s/l) \longrightarrow PhXH(soln)$	ΔH_2
III	$HOAc(l) \longrightarrow HOAc(soln)$	ΔH_3
IV	$H_2O(l) \longrightarrow H_2O(soln)$	ΔH_4
V	$RXAc(l) + H_2O(l) \longrightarrow RXH(s/l) + HOAc(l)$	ΔH^0

$$\Delta H^0 = \Delta H_1 - \Delta H_2 - \Delta H_3 + \Delta H_4$$

Units of measurement. The results of the calorimetric experiments are expressed in terms of the defined calorie, equal to 4.1840 abs. joules, and refer to the isothermal process at 25°, and to the true mass. The molecular weights were computed from the 1951 table of international atomic weights [7].

* PhSH present. 99.79 ml of calorimetric liquid.

RESULTS

From four calibration experiments on the system (containing 99.79 ml of calorimetric liquid) where no benzene thiol was added, the standard heat equivalent, ε°, was found to be 7 750 $\pm$ 8 * cal/unit of log R_i/R_f. From four calibration experiments on the system (99.40 ml of calorimetric liquid) where benzene thiol was present, the ε^0-value was found to be 7 721 $\pm$ 7 cal/unit of log R_i/R_f.

In the tables the following symbols have been used:

log R_i/R_f the expression proportional to the temperature change; R_i and R_f are the corrected thermistor resistance values at the start and the end, respectively, of the main period;

ε the heat equivalent of the actual system in calories per unit of log R_i/R_f.

Table 3.

Substance	$-\Delta H_1$	$-\Delta H_2$	$-\Delta H_3$	$-\Delta H_4$	$-\Delta H^0$
PhOAc	20.92	2.64	11.62	0.20	6.86 $\pm$ 0.04
PhSAc	21.49	7.10	11.62	0.20	2.97 $\pm$ 0.06

Table 3 contains a summary of the obtained data and the heat of hydrolysis of the idealized reaction V. The uncertainties given in the table do not include possible systematic errors. As the accuracy of the titrations, by which the purity of the esters and actic acid was tested, cannot be considered to be better than $\pm$ 0.2 %, the true uncertainties are somewhat greater. Taking this into consideration, the standard heats of hydrolysis for phenyl acetate and phenyl thiolacetate will be -6.86 ± 0.06 and -2.97 ± 0.08 kcal/mole, respectively.

DISCUSSION

In a forthcoming paper, heats of hydrolysis data for some O, S and N-acetyl compounds will be discussed more generally. Here, the derived heat of hydrolysis of phenyl thiolacetate will be compared with the corresponding data for some alkyl thiolacetates (Table 4).

Table 4. ΔH^0 for the hydrolysis of some alkyl thiolacetates [2] and phenyl thiolacetate.

Substance	EtSAc	*n*-PrSAc	*n*-BuSAc	*i*-PrSAc	*t*-BuSAc	PhSAc
ΔH^0, kcal/mole	−0.95	−0.93	−1.09	−1.39	−3.00	−2.97

The enthalpy change for a transacylation reaction $R_1SAc + R_2SH \rightarrow R_1SH + R_2SAc$ is equal to the difference of the heat of hydrolysis of the two thiolesters. If all reaction participants are liquids, the entropy change must be very small, considering the symmetric nature of the reaction. The same applies to the substances in solution, provided the interactions between the

* All uncertainties given are the average deviation of the mean.

medium and the reactants, and the reaction products, respectively, are of the same magnitude. Therefore, the standard free energy change for the reaction, should in this case be very nearly the same as the standard enthalpy change. Thus, when acetylating alkyl thiols by phenyl thiolacetate, the reaction seems to be accompanied by a standard free energy change of *ca* 2 kcal/mole or less. Therefore, from an energetic point of view, phenyl thiolacetate cannot be considered as an effective acetylating agent towards alkyl thiols. This conclusion is confirmed, *e.g.*, by the experiments carried out by Wieland and Bokelmann [8], who had to use phenyl thiolacetate in a tenfold excess in order to get glutathione "completely" S-acetylated in an acid water methanol solution.

An Adiabatic Calorimeter for Measuring Heats of Vaporisation at 25° C

INGEMAR WADSÖ

*Thermochemistry Laboratory *, University of Lund, Sweden*

An adiabatic calorimeter for measuring heats of vaporisation at 25°C has been constructed. It has been designed preferably for compounds having vapour pressures between 1 and 100 mm Hg at 25°C. An adequate amount of substance for each run is 150 mg. The accuracy has been checked by remeasuring some well-known heats of vaporisation. The results indicate an accuracy of 0.5 % or better.

By combustion and reaction calorimetry it is possible to obtain very accurate heat of formation data for most kinds of substances. Unfortunately, there are many thermochemical precision data which at present cannot be used to their full extent, because of a lack of heat of vaporisation data. Calorimetric data have been obtained for many hydrocarbons, but are lacking for other substances, with very few exceptions. As a rule, heats of vaporisation data must be obtained indirectly from vapour pressure measurements by use of Clausius-Clapeyron's equation, or simply from empirical rules [1].

Several types of calorimeters for measuring heats of vaporisation have been described in the literature (see, *e.g.*, Ref.[2]). However, most of them were designed for work at a temperature higher than 25°C, and values obtained have therefore to be recalculated to the standard reference temperature. Also, in all of the methods, it is necessary to use a considerable amount of substance. It was therefore undertaken to design and build a simple but accurate calorimeter for the determination of heats of vaporisation at 25°C, using small amounts of substance.

The apparatus described in the present paper is of a very simple design and requires only *ca* 150 mg of substance per determination. The accuracy is 0.5 % or better, which for most purposes is quite satisfactory. However, the method in its present form is limited to substances having vapour pressures at 25°C in the range 1—100 mm Hg.

* Sponsored by *The Swedish Natural Science Research Council* and by *The Swedish Technical Research Council.*

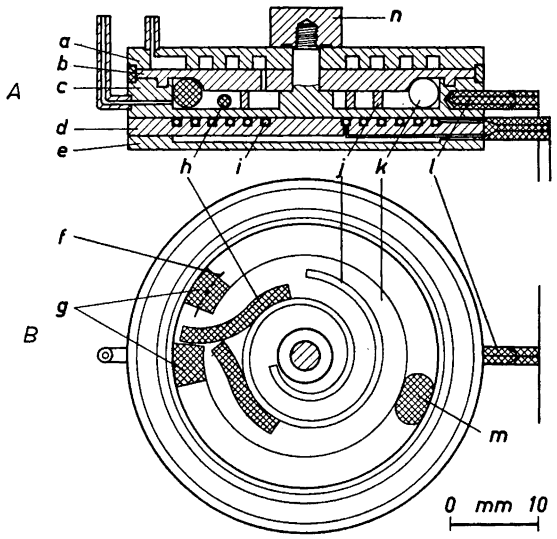

Fig. 1. A. Section through the calorimeter.
B. Disc *c* seen from above. For explanations see the text.

Principle. The evaporation of the substance is caused by a flow of nitrogen kept under reduced pressure *. The heat taken from the calorimeter is compensated electrically in such a way as to keep the temperature of the calorimeter constant and equal to that of the surrounding thermostat. From the amount of substance evaporated, as determined by weighing, and from the amount of supplied electrical energy, the molar heat of vaporisation can be calculated.

Construction. The construction of the calorimeter is shown in Fig. 1. The calorimeter body consists of five gold plated brass discs, *a*—*e*. The liquid substance to be vaporised is introduced into an ampoule placed in the cavity between discs *b* and *c*. The ampoule, *k*, consists of a bent thin-walled teflon tube, inner diameter 4 mm, closed in both ends by silicone rubber stoppers, *g*. One of these stoppers holds a capillary teflon tube, *f*, length 10 mm, inner diameter *ca* 0.3 mm. The ampoule is divided into two parts by means of a silver wool pellet, *m*. At the start of an experiment the liquid is kept between the pellet and the capillary tube, but when the pressure inside the calorimeter is lowered, the liquid will be pressed out from the ampoule and absorbed on glass fibre wicks, *h*.

The carrier gas passes from the gas inlet tube through the evaporation chamber into a spiral groove between discs *a* and *b*. The heat loss accompanying the vaporisation is compensated by electrical energy generated in the heating element *i*, which is a spiralized manganin wire lacquered and nylon spun (resistance 40 Ω), lying in a spiral groove in disc *d*. An air gap between disc

* This "carrier gas technique" has been used previously, *e. g.* by Coon and Daniels [3].

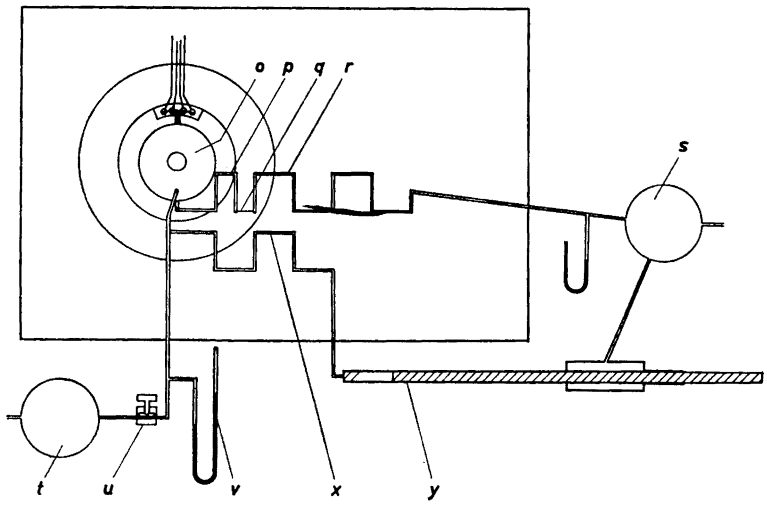

Fig. 2. Schematic view of the calorimetric equipment.

d and the bottom disc *e* prevents the bottom surface from being overheated. The saturated carrier gas is allowed to reach thermal equilibrium in the spiral duct in disc *a* before passing through the outlet tube. To ensure a good thermal contact between the gas mixture and the calorimeter, *ca* 50 mm of the spiral duct is filled by loosely packed silver wool. To improve the thermal conductivity between the discs *b* and *c*, a gold spiral, *j*, is introduced in the evaporation chamber.

A thermistor, *l*, is inserted in a drilled hole in disc *c*. The thermistor was a Stanthel, type F 2311, 2000 Ω, sealed off with a microflame *ca* 5 mm from the top, with subsequent cooling of the thermistor bead. Electrical connections from the thermistor and the heater consist of 0.4 mm platinum wires dipping into mercury cups.

In order to obtain a vacuum tight system silicone rubber gaskets had to be used between discs *a* and *c*, and between the nut *n* and disc *a*.

The calorimeter is placed on three polystyrene pegs inside a chromium plated brass can, fitted with a thin-walled lid. The can is placed in a bigger brass vessel and the space between the two cans is filled by copper chips. The outer can is immersed in a water thermostat kept at 25°C by means of a standard mercury contact thermometer fitted with an electronic relay.

The carrier gas is brought to 25°C by passing it through a copper tube (*r* in Fig. 2) inside the thermostat. In order to keep the gas flow at a suitable rate, the gas is passed through a capillary tube, *q*.

Heat effects due to the expansion of the carrier gas, after having passed the capillary tube, are avoided by allowing the gas to pass through a small silver tube, *p*, in contact with the copper chips between the two cans, before it reaches the calorimeter, *o*.

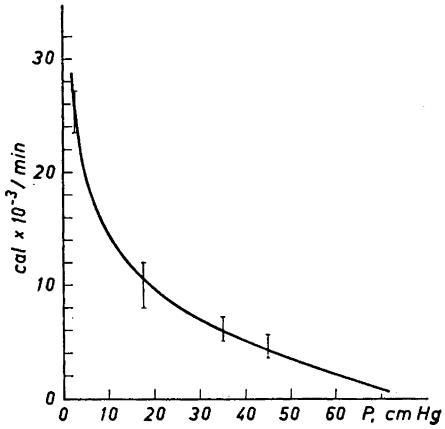

Fig. 3. The "zero" effect *versus* the pressure as shown by the manometer *v*.

By altering the pressure inside the calorimeter the flow of the carrier gas through the capillary tube, and thereby the evaporation rate, is changed. The pressure can be regulated by means of a screw clamp, *u*, and a "leakage valve", *y*. The valve consists of a metal tube and polystyrene rod as shown in Fig. 2. The rod is close fitting but movable to allow variation in the leakage from the nitrogen tank *s* to the vacuum tank *t*. By moving the rod of this valve it is possible to regulate the pressure inside the calorimeter within very small limits. The pressure in the nitrogen tank is kept slightly higher than atmospheric so that no air can reach the calorimeter by leakage through the end of the metal tube.

The temperature of the calorimeter is observed by means of the thermistor which forms one of the arms in a conventional D.C. bridge circuit. A Sullivan Spot Galvanometer (T 2001/D) with sensitivity 0.005 μA/mm, was used as a zero point instrument. The sensitivity corresponded to a temperature change of 0.0002°C, equivalent to a change in energy content of 0.002 cal.

Procedure. The ampoule was charged with *ca* 150 mg of substance and placed in the evaporation chamber. Discs *a* and *b* were fastened to discs *c*, *d* and *e*, by means of the central screw and the nut *n*. A slow stream of nitrogen was forced through the calorimeter in order to remove adsorbed water. The gas inlet and outlet tubes were closed by stoppers and the calorimeter was weighed to the nearest 0.01 mg. After being cooled to a temperature slightly below 25°C, the calorimeter was placed in the thermostat and the two gas tubes were connected to the metal tubes *p* and *x* by means of PVC tubes. The temperature of the calorimeter was raised to that of the thermostat, after which the system was allowed to equilibrate for 15 min. The vaporisation was started by opening the screw clamp *u*. A suitable voltage was applied to the heater, and by regulating the vaporisation with the leakage valve, the temperature of the calorimeter was kept equal to that of the surroundings.

By using a storage battery of high capacity (144 Ah), and by passing the current through a dummy heater circuit for *ca* half an hour before the experiment started, the variation in the current during a run was insignificant.

The current through the heater was determined by measuring the potential drop over a 10 Ω standard resistance in series with the heater, by use of a Rubicon High Precision Type B Potentiometer.

An appropriate time for the evaporation varied between *ca* 10 min for substances having vapour pressures of 100 mm Hg, to *ca* 60 min for substances having vapour pressures of 1 mm Hg. During this time *ca* 100 mg of the substance evaporated.

The experiment was finished by switching off the electrical current and closing the clamp *u*. The calorimeter was then filled with nitrogen to atmospheric pressure and the temperature was adjusted to that of the thermostat by addition of a small amount of electrical energy. The calorimeter was closed by the stoppers and the amount of substance evaporated was determined by reweighing the calorimeter. From the known resistance of the heater, and from the measured current and time, the supplied electrical energy could be calculated.

Zero effect.. When a stream of nitrogen was passed through the calorimeter, furnished with an empty ampoule, a small evolution of heat was observed, which included heat of friction and heat of expansion of the carrier gas. This heat effect could be determined by measuring the speed of the galvanometer spot when passing the zero position. As could be expected, the effect varied with the pressure (as shown by manometer *v*), that is, with the ve-

locity of the nitrogen stream through the calorimeter. In Fig. 3 the mean of this "zero" effect is plotted against the pressure. Each value in the figure is a mean of five to ten separate experiments. The uncertainties, expressed as the standard deviation of the mean, are indicated by the lengths of the vertical lines. The correction due to "zero" effect amounts only to *ca* 0.1 % for compounds having a vapour pressure of 100 mm Hg, but is as much as 2 % for compounds having vapour pressures of 2 mm Hg. Heat effects due to adsorption and wetting of the interior part of the calorimeter are negligible as judged from available data in the literature [4].

The vapour of the substance leaves the calorimeter with a directed velocity and thus has acquired some kinetic energy, which corresponds to a small amount of energy withdrawn from the system. The carrier gas has almost exactly the same kinetic energy when entering the calorimeter as when leaving it, and can thus be left out of consideration. The kinetic energy of the vapour can easily be estimated. The vapour velocity is calculated to be less than 5 m per sec, and thus the correction must be in the order of 10^{-4} cal, which is insignificant.

The accuracy of the method seems mainly to be limited by the uncertainty in the weight determinations and in the "zero" effect experiments. The ampoule technique worked satisfactorily; before the experiment the weight of the calorimeter was found to be constant. After a run, however, a small vapour leakage was observed for compounds having high vapour pressures. By graphical extrapolation over the short time between the finish of the experiment and the weighing, this error could be corrected for. Corrections applied were always less than 0.2 %.

The weight difference has to be corrected in order to obtain a value of the true mass evaporated. Therefore, it is necessary to consider the amount of nitrogen replaced by the ampoule content before the experiment, and by the remaining liquid and its vapour after the experiment. As the total cavity of the calorimeter is as small as 1.5 ml, these corrections are quite small, being 0.4 % for compounds having vapour pressures in the order of 100 mm Hg.

The "carrier gas technique" makes it possible to control the speed of the vaporisation accurately and in a very simple manner. Attempts to work without carrier gas were not successful as no constant rate of vaporisation could be obtained.

The apparatus, in the simple design described here, seems to be unsuitable for compounds having vapour pressures lower than 1 mm Hg. These demand either a long time of evaporation, in which case errors from the lack of adiabatic conditions will be very significant, or a high gas velocity, in which case the results will be strongly influenced by a high uncertainty in the "zero" effect.

The calorimeter has been tested on four hydrocarbons. Each compound was purified by fractional distillation through a 25-plate column until the purity, as judged by gas chromatographic analysis (Pye Argon Chromatograph), was better than 99.5 %. The results * of the measurements are given in Table 1.

* Uncertainties are given as the standard deviation of the mean. Uncertainties due to the "zero" effect are included.

The following symbols have been used:

Q electrical energy supplied
q amount of energy due to the "zero" effect
ΔH_v heat of vaporisation at 25°C

As seen in Table 2, the results obtained in this work, are in very good agreement with accurate values found in the literature [5]. The method seems therefore, not to be impaired by any significant systematic errors.

Raman and Infrared Spectra of 1,4-Dichloro-2-butyne

BØRGE BAK, J. J. CHRISTIANSEN and E. MADSEN

Chemical Laboratory of the University of Copenhagen, Copenhagen, Denmark

In order to investigate whether a barrier to internal rotation in compounds C(LMN)—C≡C—C(XYZ) is detectable by means of conventional Raman and infrared techniques, 1,4-dichloro-2-butyne was examined. The spectra show no signs of the presence of a barrier, but the existence of a *small* barrier (<100 cm^{-1}) cannot be excluded. For all 'practical' purposes the rotation may be considered as unhindered.

In the Vålådalmeeting (Sweden 1958) Pauling suggested that there might be a hindrance to the internal rotation about the bonds in compounds of the general formular C(LMN)—C≡C—C(XYZ) and that the barrier might be as high as 0.5 kcal per mole ($\sim$ 175 cm^{-1}). In an earlier investigation by Thompson *et al.*[1] the barrier in CH_3—C≡C—CH_3 has been shown to be zero. The slight chance existed, however, that a larger barrier might be present in polar compounds like CH_2Cl—C≡C—CH_2Cl (I). Electron-diffraction investigation of this compound has shown that the barrier is close to zero but admittedly this experimental procedure has no high sensitivity to fixation of the magnitude of small barriers. Of course, the experimental method *par excellence* to apply is a microwave investigation, either of (I) or, preferably, of a compound like CH_3—C≡C—CH_2Cl (II) in which no rotational isomers would exist. This investigation has already been started by Laurie and Lide [3] who found that an upper limit to the height of a small barrier actually present in (II) is 0.1 kcal per mole ($\sim$ 35 cm^{-1}). — This result is in harmony with our recent studies of the infrared and Raman spectra of (I). If the barrier were *high* (1—3 kcal per mole), the usual signs of rotational isomerism such as "extra" lines would be expected. A *lower* barrier would have a chance to make itself noticed by its low-lying "pseudo"-torsional level(s). Nothing of this happens. In fact, the number of observed fundamentals is so small that the idea of a force-field of higher symmetry than the nuclear skeleton is hard to avoid. The observed spectra are interpretable in a straightforward manner — at least within the area of the usual medium-resolved infrared and Raman spectra — if one assumes unhindered rotation.

EXPERIMENTAL

$CH_2Cl-C\equiv C-CH_2Cl$ (I) was prepared [4] from 31 g of commercial $CH_2OH-C\equiv C-CH_2OH$. Yield 30 g (b. p. 49°–51°C at 75 mm Hg). By redistillation, 3 fractions were obtained which were identical with respect to their infrared absorption curves in the 600–4 000 cm^{-1} region. The Raman and the infrared spectra to be discussed refer to spectra of the middle fraction (20 g).

The *Raman spectrum* has earlier been photographed by Valette [5]. Our Raman spectrum, given in Table 1, is more complete than Valette's. Exposure periods of 2–6 h were applied. The quality of the high-dispersion spectrograph of high light-gathering power has been described elsewhere [6]. Line positions were measured against an iron-arc spectrum on photographic enlargements (1:15). They are thought to be reliable to 1–2 cm^{-1}.

Infrared spectra were recorded on a commercial Perkin-Elmer 21 instrument using KBr, NaCl, and CaF_2 optics in the appropriate regions. A cell thickness of 0.025 mm was applied except in regions where no or only very weak lines were found. Here, cells of 0.1 and even 1.0 mm thickness were used, except for the 400–650 cm^{-1} region where only one cell thickness was available (0.025 mm). The 'Optical D' given in Table 1 for reason of comparison, is the density that would have been found if the cell thickness 0.025 mm had been applied throughout. The frequencies measured in the infrared are thought to be good to 2–3 cm^{-1}.

INTERPRETATION OF SPECTRA

A glance at Table 1 shows that we are very far from observing the 24 fundamental vibrations to be expected for a molecule with 10 atoms. Most of the observed bands are obviously combination — and overtones. In view of the fact that a thorough Raman-infrared investigation usually brings out all or nearly all of the fundamentals [7], something exceptional is at work. We believe that this is the unhindered rotation, which causes a higher symmetry for the potential function than for the nuclear skeleton. Hence, a number of normal vibrations that would usually be observed separately, degenerate.

$CH_3-C\equiv C-CH_3$, with no barrier to the internal rotation, has the instantaneous symmetry D_3, but the symmetry of the potential field, and hence of the normal vibrations, is greater than this [8]. Actually the pseudo-symmetry of dimethylacetylene is D_{3d} (*not* D_{3h}). If this description can be extended to involve (I) the vibrations would be classified in four classes: A_{1g} (4 vibrations), A_{1u} (3), E_g (4 double-degenerate), and E_u (4 double-degenerate), *i.e.* 15 distinct normal frequencies. One might, however, suspect *a priori*, that the introduction of chlorine might cause changes analogous to what happens if, *e.g.*, one or more hydrogen atoms in a highly symmetrical hydrocarbon are substituted by deuterium. If all the symmetry elements are hereby removed, all 3N-6 normal vibrations are observed (thorough work provided). According to this latter description we should be able to find 24 fundamentals in the combined Raman and infrared spectra.

Before we counted the observed normal vibrations it seemed wise to investigate whether we were reasonably sure to have all of them recorded. For this purpose approximately correct modes of vibrations were constructed for (I) in the two extreme positions, *i.e.* the *trans* and the *cis* configuration where the symmetry is high enough (C_{2h} and C_{2v}) to make such sketching possible. It appeared that probably only one low-lying frequency might have escaped

* Broad band.

observation in harmony with the findings of Crawford[9] for $CH_3-C\equiv C-CH_3$, in the spectrum of which a low-lying level at 213 cm^{-1} was found. If we assume that we did not observe a band at 215 cm^{-1} (*outside* the region accessible to us in the infrared and *in* a region where our Raman spectrum has some background) our scheme of combination bands fits well.

Table 1, then, indicates that we have observed fundamentals at 330, 425, 435, 490, 700, 778, 785, 903, 1 160, 1 165, 1 260, 1 266, 1 425, 1 430, 2 245, 2 947, 2 954, 2 990 and 2 995 cm^{-1}, *i.e.* 19 fundamentals. However, some of the observed bands may be grouped in close pairs, *viz.* 425—435, 778—785, 1 160—1 165, 1 260—1 266, 1 425—1 430. Counting "pairs + singles" we get 14 (+ 1 unobserved = 15). Thus, a description of the molecule as freely rotating but very slightly perturbed due to the chlorines, seems rather adequate.

For the present purpose we shall refrain from giving the forms of the normal vibrations although they are rather obvious in some of the cases (C—Cl valence vibrations at 700 and 778, C—C at 903 and 1 160, CH_2 scissoring at 1 425, C≡C vibration at 2 245 and C—H vibrations at 2 947, 2 954, 2 990 and 2 995). The numbering of the frequencies in Table 1 is completely arbitrary.

Acknowledgement. The authors thank professor Langseth for permission to use the Raman spectrograph.

The Kinetics of the Acid-Catalysed Hydrolysis of Alkyl Formates

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

The acid-catalysed hydrolysis of ethyl, *sec.*-propyl and *tert.*-butyl ormates has been studied kinetically in aqueous solutions over a wide range of temperature (15°C–86°C). The rate coefficients for ethyl and *sec.*-propyl formates are in reasonable accord with the Arrhenius equation over the whole temperature range, but the plot of log k against reciprocal absolute temperature for *tert.*-butyl formate is linear only in the low temperature range. The results suggest that all three esters are hydrolysed by essentially the same mechanism, a bimolecular acyl-oxygen fission, at the low temperatures. In the case of *tert.*-butyl formate, however, another mechanism which has a higher activation energy and which presumably involves unimolecular alkyl-oxygen fission, significantly augments the rate at the higher temperatures.

The hydrolysis reactions of the same esters have also been studied at 25°C in the presence of hydrogen chloride concentrations up to 3 M. The influence of the catalyst concentration on the rate was found to be similar for all the esters, and furthermore closely resembled its influence on the rate of hydrolysis of ethyl acetate. This is also in accord with the view that the hydrolysis of the three esters takes place by an essentially similar mechanism under these conditions.

It is well known that the acid-catalysed hydrolysis reactions of formic esters proceed at appreciably higher rates than the acid-catalysed hydrolysis reactions of the corresponding acetic esters in which a bimolecular acyl-oxygen fission is assumed to take place [1]. For this reason a change to a unimolecular alkyl-oxygen fission mechanism, which becomes apparent in different ways with the acetic esters [1,2] when the alkyl groups of the esters are varied in the sequence ethyl, *sec.*-propyl and *tert.*-butyl, may be expected to be less pronounced with the formic esters. Stimson [3], for example, concluded from the values of the Arrhenius parameters for the hydrolysis of *tert.*-butyl formate in acetone-water solution (60 % acetone by volume) that the mechanism of the reaction represents a bimolecular acyl-oxygen fission. So far as the hydrolysis in aqueous acid solutions is concerned, where the proton availability is much greater than in acetone-water mixtures [4] and which may therefore

be expected to favour the unimolecular mechanism, data for *tert.*-butyl formate have not been reported. The results of a kinetic study of the hydrolysis of alkyl formates in aqueous hydrogen chloride solutions, which is an extension of an earlier study of the acid hydrolysis of aliphatic esters [2,5], are presented and discussed in the following.

EXPERIMENTAL

Materials. Ethyl and *sec.*-propyl formates were prepared by customary methods [6] and purified by efficient fractional distillation. *tert.*-Butyl formate was synthesized by a method described recently by Young and Paré [7], in which *iso*butylene is passed into anhydrous formic acid to which cation exchange resin (Dowex X 50) has been added. The *iso*butylene was prepared by adding *tert.*-butyl alcohol dropwise to a large excess of anhydrous oxalic acid at a temperature of 80—90°C. The physical constants of the *tert.*-butyl formate after it had been fractionally distilled (*b. p.* 82.8°C at 755 mm Hg, d_4^{25} 0.8694, n_D^{25} 1.3787) were in accord with those reported by Young and Paré. The purities of the esters were checked by hydrolysing known weights in dilute acid solution and determining the formic acid produced by alkalimetric titration. The consumption of base did not deviate by more than 2 % from the calculated amount.

Kinetic measurements. Depending on the conditions, three different methods were employed in following the progress of the reactions. The first method, which was used to follow the reactions at 25°C when the catalyst acid concentration was high compared to that of the ester, has previously been described by the writer [5,2] and is based on the determination of the concentration of unreacted ester in samples removed from the reaction mixture after suitable intervals. The second method, which was used when the catalyst concentration and reaction temperature were relatively low (see below), was based on the alkalimetric titration of the formic acid present in samples pipetted from the reaction mixture. In the third method, employed at temperatures where volatility was appreciable, aliquots of the reaction mixture were transferred to ampoules which were sealed by fusion to avoid volatilization and which were opened after suitable intervals for the titrimetric determination of the liberated formic acid. For temperatures of 45°C and higher, electrically heated oil thermostats regulated by mercury contact thermometers were employed, whereas at the lower temperatures similarly heated and regulated water thermostats were used. The temperatures of the thermostats remained constant within ± 0.03°C.

The time periods used when the first method was employed to analyse the unreacted ester by alkaline hydrolysis were much shorter for the formic esters than for acetic esters [2] because of the higher rates of alkaline hydrolysis of the former esters. Periods of only a few minutes were considered sufficient in the case of ethyl and *sec.*-propyl formates. With *tert.*-butyl formate, the rate of alkaline hydrolysis of which was unknown, a time of one hour was chosen and was found by separate experiments to be sufficiently long. In the above experiments, as well as in those described below, the initial ester concentration was between 0.1 and 0.16 M.

In the second method, 5 ml samples taken with a semiautomatic pipette from the reaction mixtures were run into ice-water mixtures to arrest the reaction and titrated immediately in a nitrogen atmosphere (to exclude carbon dioxide) with 0.07—0.11 N standard sodium hydroxide to the phenolphthalein endpoint. Because each sample was cooled and diluted and the titration performed rapidly, no appreciable hydrolysis of the ester took place. Zero time was chosen as the time of taking the first sample. From 8 to 10 samples were withdrawn during the reaction in addition to those taken to determine the final value.

In the third method, the reaction mixture was prepared by mixing the components at 25°C, after which twelve 5 ml aliquots were pipetted into 6—7 ml glass ampoules. After the ampoules had been sealed by fusion, they were transferred simultaneously to a thermostat, the temperature of which was usually much above 25°C. After the ampoules had warmed to the temperature in the thermostat (in separate experiments a period of 5—10 min was found sufficient for the temperatures to become uniform in the solutions when

the group of ampoules was vigorously shaken), two ampoules were removed and cooled rapidly by shaking them in ice-water. After the ampoules had been opened, the acid in the solutions was titrated as in the second method. The time when the two ampoules were immersed in the ice-water mixture was taken as zero time and the mean base consumption as the initial value in the calculation of rate coefficients. Seven further samples were taken at intervals during the course of the reaction and titrated. The total amount of acid present at the end of the reaction was determined by titrating the samples in the three remaining ampoules after a sufficiently long period of time; the mean base consumption for these samples was employed as the final value. The procedure in which initial samples are analysed under the same conditions as the other samples taken during the course of the reaction reduces the time error to a minimum and is easily applied in practice. In principle it is of no importance how far the reaction has progressed before the first sample is taken.

Since in the experiments described the concentrations were measured at 25°C, usually a much lower temperature than that at which the reaction took place, the actual concentrations were calculated using the values of the density of water at different temperatures given in the International Critical Tables [8].

The change from the second to the third method of following the reaction took place with *sec.*-propyl and *tert.*-butyl formates at 45°C and 55°C, respectively, but with ethyl formate, owing to its greater volatility, at 25 – 35°C. The second and third methods were compared using ethyl formate at 25°C; the value of the second-order rate coefficient was 0.00337 l mole^{-1} s^{-1} when the second method was employed and 0.00335 l mole^{-1} s^{-1} when the third method was employed.

Kinetic equations for low catalyst concentrations. When relatively high catalyst acid concentrations were employed, the hydrogen ion concentration in the reaction mixture remained practically constant as the reaction progressed and the first-order rate law was satisfactorily obeyed. However, as it was necessary to employ relatively low catalyst acid concentrations at the highest temperatures because of the high reaction rates, the formic acid produced catalysed the reaction and this had to be taken into account in the calculations. In extreme cases, the increase in the hydrogen ion concentration during the reaction represented the greater part of the total catalyst concentration at the end of the reaction.

The time law for the reaction is

$$\frac{dx}{dt} = k_c \, C_{H^+} \, (a-x) \tag{1}$$

where a denotes the ester concentration at zero time, x the decrease in this concentration during time t, k_c the second-order rate coefficient and C_{H^+} the hydrion concentration, which was also a function of time in the experiments. Since $x = 0$ when $t = 0$, eqn. (1) yields on integration

$$k_c = \frac{\ln [a/(a-x)]}{\int_0^t C_{H^+} \, dt} = \frac{(1/t) \ln [a/(a-x)]}{(1/t) \int_0^t C_{H^+} dt} = \frac{k_t}{(C_{H^+})_t} \tag{2}$$

where k_t is the value of the rate coefficient computed from the usual first-order rate equation. This first-order coefficient has different values at different times during the course of the reaction and the corresponding hydrion concentration

$$(C_{H^+})_t = \frac{1}{t} \int_0^t C_{H^+} dt \tag{3}$$

is the time average of the hydrion concentration over the interval (0, t). The value of the integral in eqn. (3) can be determined when the variation of the hydrion concentration with time is known. The integral was calculated as a sum of trapezoids by a method described by the writer in connection with a study of the alcoholysis of α-halogenoethers [9]. The hydrion concentration at each time of sampling was determined as follows. The initial concentration of hydrogen chloride in the reaction mixture in moles per litre

Table 1. The hydrolysis of *sec.*-propyl formate at 86.22°C. ml NaOH = ml of 0.1102 N sodium hydroxide solution consumed in the titration of the sample. Sample volume (measured at 25°C) 5.01 ml. The coefficient for the thermal expansion from 25°C to 86.22°C is 1.0301. $10^3K = 0.1206$ mole l^{-1}, $10^3c = 0.816$ mole l^{-1} (at 86.22°C).

Average $k_c = 0.211$ l mole^{-1} s^{-1}

(denoted by c) was determined when the reaction medium was prepared. The total acid concentration in the sample is given by $(c + f)$, where f is the concentration of the formic acid formed. The hydrion concentration in the reaction mixture at the time of sampling can be computed from

$$C_{H+} = \tfrac{1}{2}(c-K) + \sqrt{\tfrac{1}{4}(c-K)^2 + (c + f)K} \qquad (4)$$

where K is the acid dissociation constant of formic acid at the temperature in question. For the temperature dependence of this dissociation constant, Harned and Embree [10] have given the following equation

$$\log K = -(173.624/T) + 17.88348 \log T - 0.0280397\ T - 39.06123 \qquad (5)$$

Although this equation is based on experimental data for the temperature range from 0° to 60°C, the general thermodynamic form of the equation and the fact that the value of K varies only slightly with temperature justified the use of the equation for extrapolation to obtain the values of the constant at temperatures above 60°C. Furthermore, any error resulting from the use of the equation was the same for all the esters studied and hence the values of the rate coefficients for the latter are comparable at each temperature. In addition, the fact that the data for ethyl and *sec.*-propyl formates obeyed the Arrhenius equation with satisfactory accuracy over the temperature range where eqn. (5) was employed showed that no serious errors resulted. As far as the effect of electrolyte concentration on the values of K is concerned, this could be disregarded because the ionic strength was very low in the experiments in which eqns. (2), (3), (4) and (5) were applied.

The data in Table 1 refer to a case where the initial concentration of hydrogen chloride was lower than the hydrion concentration due to the dissociation of formic acid produced in the reaction. The large increase in the values of k_t as the reaction progressed shows that the reaction was autocatalytic. On the other hand, the calculated values of k_c at different stages of the reaction are essentially constant, which shows that the equations employed correctly represent the course of the reaction. It may be mentioned, however, that constant values would have been obtained for k_c even if values of K deviating slightly from those derived from eqn. (5) had been employed. This is due to the fact that in this extreme case the second term under the root sign in eqn. (4) primarily determines the value of the hydrion concentration. Therefore the value of k_c includes, in addition to the usual experimental errors in kinetic measurements, the error in the value of K.

Table 2. The rate coefficients of the acid-catalysed hydrolysis of alkyl formates at different temperatures and the values of the parameters of the Arrhenius equation computed from the data for the lower temperatures (15—45.5°C).

RESULTS AND DISCUSSION

The acid-catalysed hydrolysis of alkyl formates could be followed kinetically by the methods described above over the temperature range from 15 to 86°C. The results of the experiments are collected in Table 2. Rate coefficients of the acid-catalysed hydrolysis of ethyl and *sec.*-propyl formates at relatively low temperatures have been reported previously. For comparison, the following values in 1 mole^{-1}s^{-1} units referring to 25°C may be mentioned: ethyl formate, 0.00312 (Palomaa [11]), 0.00325 (Salmi [12]), 0.00307 (Tommila and Hella [13]); *sec.*-propyl formate, 0.00280 (Palomaa [11]), 0.00293 (Palomaa *et al.*[14]).

The plots of the logarithm of the rate coefficient against reciprocal absolute temperature in Fig. 1 show that the Arrhenius equation is obeyed well by the data for the three formic esters at relatively low temperatures. The values of the activation energy and frequency factor computed by the method of least squares from the data referring to the temperature range from 15 to 45.5°C are given in Table 2; in this temperature range the plots are satisfactorily linear for all three esters. Since the values of the activation energy and the frequency factor for *tert.*-butyl formate are of the same magnitude as the values for ethyl and *sec.*-propyl formate in this temperature range, there is no reason to believe that the mechanism of hydrolysis of the first-mentioned ester differs essentially from that of the last two esters, *i.e.* all three esters presumably hydrolyse under the conditions by the normal mechanism of acid-catalysed ester hydrolysis designated as $A_{AC}2$ by Ingold [1].

It will be seen from Fig. 1 that the behaviour of *tert.*-butyl formate deviates from that of the other two esters at higher temperatures in that its rate coefficient increases more rapidly with temperature than the Arrhenius parameters

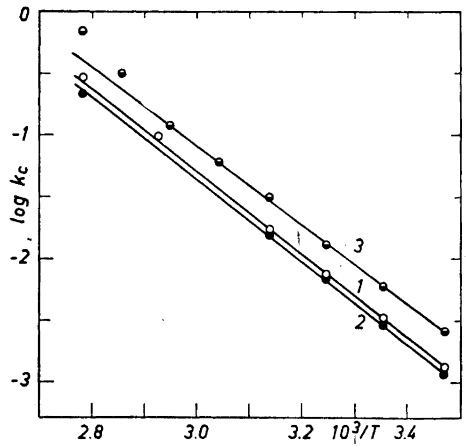

Fig. 1. Plots of log k_c against $1/T$ for the hydrolysis reactions of alkyl formates in dilute acid solution. 1. Ethyl formate. 2. *sec.*-Propyl formate. 3. *tert.*-Butyl formate. The straight lines are Arrhenius plots based on data obtained in the temperature range 15—45.5°C.

computed from the data for lower temperatures would imply. This different behaviour cannot be attributed to systematic errors in the method of following the reaction at the higher temperatures because the data obtained for ethyl and *sec.*-propyl formates by the same experimental procedure exhibit only slight deviations from the linear dependence of log k_c on reciprocal temperature.

The different behaviour of *tert.*-butyl formate at the higher temperatures suggests that under these conditions, in addition to the $A_{AC}2$ mechanism, another hydrolysis mechanism with a higher activation energy begins to contribute to the rate. This assumption is supported by the following rough estimates. If we assume that the Arrhenius equation based on the data obtained at the lower temperatures relates to the $A_{AC}2$ mechanism and also applies as far as this mechanism is concerned at the higher temperatures, as it approximately does in the case of ethyl and *sec.*-propyl formates, it is possible to determine the contribution of the $A_{AC}2$ mechanism to the rate of hydrolysis of *tert.*-butyl formate at the higher temperatures. When the rate coefficients of hydrolysis by the $A_{AC}2$ mechanism calculated for the higher temperatures are subtracted from the over-all observed rate coefficients, the resulting rate coefficients should represent the contribution of the assumed concurrent mechanism. The latter rate coefficients calculated from the data for *tert.*-butyl formate given in Table 2 are 0.261 l mole^{-1}s^{-1} at 86.22°C and 0.082 l mole^{-1}s^{-1} at 76.15°C. The values of the parameters of the Arrhenius equation derived from these rate coefficients are $E = 29$ kcal per mole and log $A = 17$ and are of such magnitudes that they can be taken to refer to the unimolecular alkyl-oxygen fission mechanism of acid-catalysed ester hydrolysis ($A_{AL}1$). For the acid-catalysed hydrolysis of *tert.*-butyl acetate, for example, which hydrolyses primarily by the unimolecular $A_{AL}1$ mechanism [1,2], the values of the parameters computed from the data reported by Palomaa *et al.*[14] are $E = 27.6$ kcal per mole and log $A = 16.34$. From the values derived for the Arrhenius parameters one can estimate the rate coefficient of the hydrolysis of *tert.*-butyl

formate by the $A_{AL}1$ mechanism to be about 10^{-4} l mole^{-1}s^{-1} at 25°C and hence this mechanism contributes very little to the over-all rate of hydrolysis, 59.8 $\times$ 10^{-4} l mole^{-1}s^{-1}, at this temperature.

It will be noted that the rates of hydrolysis by the $A_{AL}1$ mechanism of acetic esters do not differ greatly from the rates of hydrolysis of the corresponding formic esters, whereas in the case of the $A_{AC}2$ mechanism a corresponding change in structure leads to a marked change in reactivity. In water and water-alcohol mixtures, alkoxymethyl formates react by the $A_{AL}1$ mechanism only from 1.5 to 3 times as fast as the corresponding acetates [15]. If the rate coefficient for the hydrolysis of *tert.*-butyl acetate [2] in dilute acid at 25°C, 1.34 $\times$ 10^{-4} l mole^{-1}s^{-1}, can be taken to represent hydrolysis by the unimolecular $A_{AL}1$ mechanism, the magnitude of the estimated rate coefficient of the hydrolysis of *tert.*-butyl formate by the same mechanism at 25°C, 10^{-4} l mole^{-1}s^{-1}, is plausible.

One particular point of interest concerning the effect of structure on hydrolysis by the bimolecular $A_{AC}2$ mechanism is that when the alkyl group changes from ethyl to *tert.*-butyl the rate becomes smaller in the case of acetates in such a degree that the unimolecular $A_{AL}1$ mechanism begins to predominate, whereas in the case of formates the rate increases (*e.g.*, about twofold at 15°C). This latter increase in rate is not, at least not at the lower temperatures, due to a change in mechanism from $A_{AC}2$ to $A_{AL}1$, as other experimental evidence would lead one to conclude. This different effect of alkyl group structure in the hydrolysis of formates and acetates by the $A_{AC}2$ mechanism is probably due to the combined effect of several factors. One possible explanation is that the retardation of the rate of hydrolysis when a tertiary alkyl group replaces a primary alkyl group in acetic esters is primarily due to steric hindrance, and the $A_{AL}1$ mechanism, which is insensitive to steric effects, begins to predominate. In the case of the formic esters, steric hindrance is of lesser significance because in these compounds the carbonyl group is more exposed to the attack of a water molecule, and therefore the polar factors become more apparent. These assumptions are supported by the observation that at the lower temperatures where the different formic esters may be expected to react by the same mechanism the effect of structure on the rate becomes apparent primarily as a change in the activation energy

Table 3. The first-order rate coefficients k (in s^{-1}) for the hydrolysis of ethyl, *sec.*-propyl and *tert.*-butyl formates in aqueous hydrochloric acid solutions of various concentrations. Hydrochloric acid concentrations in moles per litre. 25°C.

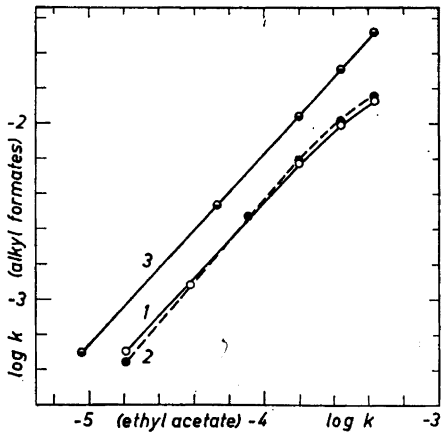

Fig. 2. Plots of the values of log k for alkyl formates against the values of log k for ethyl acetate at identical acid concentrations in aqueous hydrochloric acid solutions at 25°C. 1. Ethyl formate. 2. *sec.*-Propyl formate. 3. *tert.*-Butyl formate.

(see Table 2). The frequency factor, and hence the entropy of activation, does not vary significantly in value from one ester to the other, which suggests only slight changes in steric hindrance. A more detailed study of the effects of polar and steric factors on the acid-catalysed hydrolysis reactions of formic and acetic esters would be desirable.

Since the formic esters studied may be assumed to hydrolyse in acid solution at low temperatures by the bimolecular mechanism in which the critical complex includes a water molecule in addition to the ester molecule and a proton, these esters offered a possibility of studying the validity of the Zucker-Hammett hypothesis [16,17] by carrying out kinetic measurements of the rates of hydrolysis in moderately acid solutions by the method previously described by the author [5,2]. Measured values of the first-order rate coefficients, k, of the hydrolysis of the three formic esters in aqueous hydrochloric acid solutions of varying concentration are shown in Table 3. The data reveal that the rates fo all three esters react similarly to a change in the medium and the values of k increase slightly more rapidly than they would if they were proportional to the molar concentration of the catalyst hydrochloric acid. The curves in Fig. 2, in which the values of log k for the formic esters are plotted against the values of log k for ethyl acetate for the same hydrogen chloride concentrations (the latter values interpolated from previously reported data [5,2]), show that the effect of the acid medium on the rate is approximately the same for the formic esters as for ethyl acetate. The increase in the rate at the higher acid concentrations is, however, possibly slightly less rapid with the formic esters than with ethyl acetate. Since the rate of hydrolysis of ethyl acetate, in contrast to *tert.*-butyl acetate [2], follows more closely the acid concentration than the acidity function H_0, in qualitative agreement with the expectations based on the Zucker-Hammett hypothesis, it follows from the plots in Fig. 2 and the discussion above that this hypothesis is approximately valid also for the formic esters in the investigated media.

The Acid-Catalysed Solvolysis of Alkoxymethyl Esters

Part V. Hydrolysis of β-Chloroethoxymethyl Esters

PENTTI SALOMAA and RAILI LINNANTIE

Department of Chemistry, University of Turku, Turku, Finland

The acid-catalysed hydrolysis reactions of the β-chloroethoxymethyl esters of formic and acetic acids have been studied kinetically. Evidence has been collected which shows that the formic ester hydrolyses in dilute acid solution at low temperatures predominantly by the bimolecular $A_{AC}2$ mechanism with a minor contribution by the unimolecular $A_{AL}1$ mechanism. The existence of the two reaction paths is indicated, firstly, by the actual magnitudes of the rate coefficients in comparison to the values estimated from the linear free energy relations, secondly, by the deviation from linearity of the plot of the logarithm of the rate coefficient against reciprocal temperature, and, thirdly, by the variation of the rate coefficient in moderately acid solutions. The relative contributions of the two mechanisms to the over-all rates have been estimated.

The kinetic data for β-chloroethoxymethyl acetate, on the other hand, are consistent with the assumption that this ester hydrolyses predominantly by the unimolecular $A_{AL}1$ mechanism, although there is definite indication of a simultaneous, minor contribution by the $A_{AC}2$ mechanism.

In a recent study of the hydrolysis of alkoxymethyl esters of acetic and formic acids [1], evidence based on kinetic data obtained by different experimental methods was presented which suggested that methoxymethyl and ethoxymethyl esters of acetic acid hydrolyse in aqueous acid solutions by the unimolecular $A_{AL}1$ mechanism whereas a contribution of the bimolecular $A_{AC}2$ mechanism to the over-all rate was established in the hydrolysis of methoxymethyl formate. The magnitudes of the rate coefficients of the hydrolysis of β-chloroethoxymethyl formate * at different temperatures and the computed value of the activation energy indicated as highly probable that the electron-attracting substituent chlorine retards the unimolecular mecha-

* An error was made when the rate constants for this compound reported by Palomaa and Herna [2] were cited in *Ref.*[1]. The correct value at 25°C is 0.00368 l mole^{-1}s^{-1} and the correct value of the activation energy 15 300 cal/mole. These values are, however, close to those obtained for alkyl formates and do not therefore alter the conclusions drawn.

nism to such an extent that the bimolecular mechanism dominates this reaction. The present study was undertaken to obtain a more detailed picture of the nature of this reaction and also to determine the effect of the halogen on the reaction of the corresponding ester of acetic acid. The acid components of the esters were selected in order to effect a real change in the rate by the bimolecular mechanism (*cf.*, *e.g.*, *Ref.*[3]).

HYDROLYSIS OF β-CHLOROETHOXYMETHYL FORMATE

In dilute hydrochloric acid solutions, the rate of hydrolysis of β-chloroethoxymethyl formate was found to be proportional to the molar concentration of the acid and hence the values of the second-order rate coefficients k_c, obtained by dividing the directly computed first-order rate coefficients by the acid concentration, were essentially independent of the latter. Table 1 contains the values determined for k_c in these solutions at different temperatures. The values referring to the temperatures 15°, 25° and 35°C are from 4 to 9 % lower than the values obtained earlier by Palomaa and Herna [2] who used a slightly different method of following the reaction.

Table 1. Hydrolysis of β-chloroethoxymethyl formate in dilute (0.05—0.1 M) hydrochloric acid solutions. Values of k_c (in 1 mole^{-1}s^{-1}) at different temperatures.

°C	0.88	9.00	15.00	25.00	35.00	46.00	55.83	67.60
$10^3 k_c$	0.318	0.775	1.40	3.33	7.72	22.6	[51.2	134

Although the rate coefficients at low temperatures are of the magnitude generally observed for formic esters that react by the normal type of acid-catalysed ester hydrolysis involving a bimolecular acyl-oxygen fission, certain observations suggest that the over-all rate coefficients include a minor contribution of another mechanism, the unimolecular alkyl-oxygen fission. In a recent study [4] it was shown that the solvolytic reactions of alkoxymethyl compounds that can be assumed to involve a unimolecular formation of an unstable alkoxymethyl cation in the rate-determining stage exhibit approximately linear free energy correlations when the structure of the alkoxyl group is varied. On the basis of the values of the rate coefficients, polar substituent constants and reaction constants given, it is possible to obtain an estimate, $k_c = 9 \times 10^{-4}$ l mole^{-1}s^{-1}, for the rate coefficient of the hydrolysis of β-chloroethoxymethyl formate at 25°C by the unimolecular mechanism; this amounts to one-fourth of the measured over-all rate coefficient. Although the estimated value cannot be very accurate, its magnitude shows that a concurrent reaction mechanism is highly probable.

The existence of two independent reaction paths is indicated also by the observed temperature dependence of the rate coefficients. The plot of log k_c for β-chloroethoxymethyl formate against reciprocal temperature shown in Fig. 1 reveals a satisfactory linearity in the low temperature range but increases in slope at the higher temperatures. Such a behaviour is in accord with the occurrence of two concurrent reactions with different activation energies;

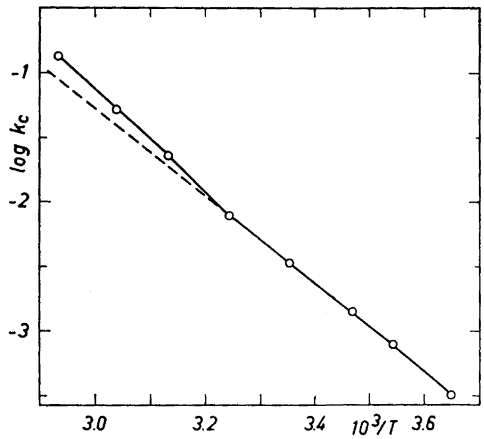

Fig. 1. Hydrolysis of β-chloroethoxymethyl formate at different temperatures. Plot of log k_c against $1/T$.

the reaction with the lower activation energy dominates in the low temperature range but the contribution of the second reaction with the higher activation energy gradually becomes more significant as the temperature rises. The situation is in principle similar to that observed with methoxymethyl formate [1].

Calculations made by the iteration method [1] assuming that the over-all rate coefficient is the sum of two rate coefficients which both vary with temperature in accordance with the Arrhenius equation, $k_c = k_1 + k_2 = A_1 \exp(-E_1/RT) + A_2 \exp(-E_2/RT)$, revealed that the following values of the four Arrhenius parameters, $E_1 = 22$ kcal/mole, $\log A_1 = 13$, $E_2 = 14.4$ kcal/mole and $\log A_2 = 8.0$, yield a plot which reasonably closely approximates the experimental plot. Although the above values of the constants include in addition to experimental errors any errors due to genuine deviations from the Arrhenius equation (the values for the reaction indicated by subscript 2 can be more reliably calculated than those for reaction 1 because the former reaction which has the lower activation energy dominates over the greater part of the temperature range), they are of the magnitudes expected for the postulated mechanisms (*cf. Ref.*[1]). From the values of the parameters it can be estimated that the contribution of the unimolecular mechanism is about one-fourth of the over-all rate at 25°C. This estimate is in good agreement with the estimate obtained above on the basis of polar substituent effects.

The third item of evidence for the simultaneous operation of two mechanisms is obtained from the kinetic data for the reaction in moderately acid solutions when the data are considered in relation to the acidity function H_0 of Hammett [5]. Although the general applicability of the Zucker-Hammett hypothesis [5,6] for a basis of criterion of reaction mechanism has recently been questioned [7-10], the hypothesis seems to be in satisfactory accord with the kinetic data for the hydrolysis reactions of aliphatic esters of different types in hydrochloric acid solutions [1,11-13]. In this connection it may be pointed out that there hardly exists any single, unequivocal experimental criterion for the determination of the molecularity of a solvolytic reaction.

In a preliminary communication [14] the authors drew attention to the fact that if the Zucker-Hammett hypothesis is valid for the types of reaction under study and these reactions involve concurrent unimolecular and bimolecular

mechanisms, the latter mechanism will not become clearly evident when the reactions take place in hydrochloric acid solutions of moderate concentration unless its contribution happens to be the dominating one. This is because the unimolecular mechanism becomes more significant with increasing acidity and finally overweighs the bimolecular mechanism so that the latter can no longer be experimentally detected. If, however, the contribution of the bimolecular mechanism is large enough in dilute acid solution, the plot of log k against $-H_0$ will have a special form characterized by a point of inflexion. This follows from the fact that the rate increases less rapidly at low acidities where the contribution of the bimolecular mechanism is significant than at high acidities where the unimolecular mechanism assumes control.

The above behaviour expected in the case of two concurrent mechanisms was actually observed in the hydrolysis of β-chloroethoxymethyl formate[14]. The data relating to 25°C on the basis of which the plot of *Ref.*[14] was made are given in Table 2. As the bimolecular mechanism could be assumed to become even more significant at lower temperatures because of its lower activation energy, the variation of the over-all rate with increasing acidity was investigated also at 0.88°C. These results are given in Table 2 in addition to those referring to 25°C. The curve plotting the logarithm of the observed first-order rate coefficient at 0.88°C against the value of the acidity function at 25°C (Fig. 2) is similar in form to that referring to the rate measurements at 25°C, but the unusual form of the curve is more clearly evident.

The contributions of the unimolecular mechanism to the over-all rate of hydrolysis of β-chloroethoxymethyl formate in dilute hydrochloric acid at 25°C as estimated by the three different methods are given below:

Method	*Fraction of over-all rate*
Effect of structure	0.3
» » temperature	0.3
» » acidity	0.2—0.5

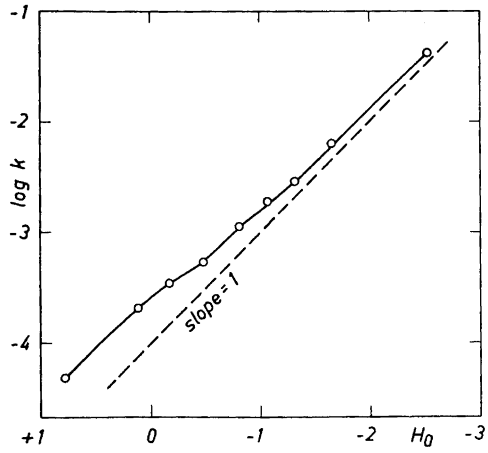

Fig. 2. Hydrolysis of β-chloroethoxymethyl formate at 0.88°C. Plot of log k against the values of the H_0 acidity function [15] at 25°C.

The estimate based on the last method [14] is the most uncertain because a more accurate result would require that the Zucker-Hammett hypothesis in its ultimate form [5] would be accurately true and not a satisfactory approximation. In view of this limitation, the above estimates are consistent.

HYDROLYSIS OF β-CHLORETHOXYMETHYL ACETATE

The second-order rate coefficients k_c of the hydrolysis of β-chloroethoxymethyl acetate at the temperatures 15°, 25° and 35°C were reported in a recent paper in connection with a study of polar effects on the reactions of alkoxymethyl compounds (*Ref.*[4], Table 3). Although the estimated substituent effect of the β-chloroethyl group conformed well with the effect of this group in other reactions of alkoxymethyl compounds which are assumed to involve the unimolecular formation of an alkoxymethyl cation, and although the values of the activation energy and frequency factor of β-chloroethoxymethyl acetate were of approximately the same magnitude as the values of other alkoxymethyl acetates studied, there is reason to suspect that the hydrolysis of β-chloroethoxymethyl acetate is a composite reation with a minor contribution due to the normal type of acid-catalysed ester hydrolysis. In other reactions of alkoxymethyl compounds the retarding effect of the β-chloroethyl group on the rate was associated with an elevated activation energy, whereas the opposite situation prevailed in the case of β-chloroethoxymethyl acetate. This exceptional observation can be explained by assuming that the over-all reaction includes a contribution of the bimolecular acyl-oxygen fission reaction with a lower activation energy that is not large enough to cause the Arrhe-

nius plot to deviate from linearity when the temperature range is narrow. The participation of the normal type of acid-catalysed ester hydrolysis is also plausible in view of the actual magnitudes of the rate coefficients. The value (0.000241 l $mole^{-1}s^{-1}$) of the rate coefficient k_c at 25°C is only 2.2 times the value reported by Tommila and Hella [16] for methyl acetate and 6.8 times the value obtained by Euranto [17] for chloromethyl acetate under the same conditions.

The simultaneous operation o :the two mechanisms is indicated by the kinetic data relating to a wide range of temperature that are shown in Table 3. The plot of log k_c against reciprocal temperature drawn in Fig. 3

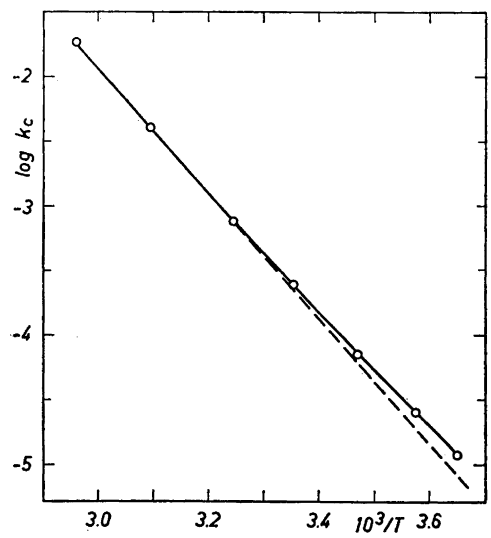

Fig. 3. Hydrolysis of β-chloroethoxymethyl acetate at different temperatures. Plot of log k_c against $1/T$.

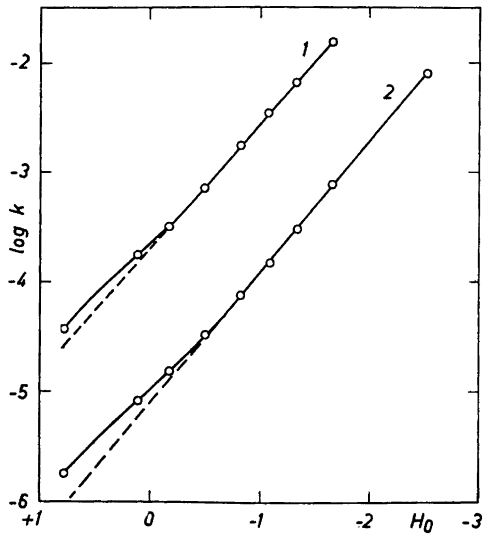

Fig. 4. Plot of log k against the values of the H_0 acidity function [15] at 25°C for the hydrolysis of β-chloroethoxymethyl acetate in hydrochloric acid solutions. 1. 25°C. 2. 0.88°C.

shows that the Arrhenius equation is not satisfactorily obeyed. Although the departure from linearity is less than in the case of methoxymethyl formate [1] and β-chloroethoxymethyl formate (see above), it is larger than could be ascribed to experimental errors or genuine deviations from the Arrhenius equation that could occur in the present type of reaction. In order to obtain a satisfactory estimate of the contribution of the bimolecular mechanism to the rate, it would be necessary to study the reaction at much lower temperatures where, owing to its lower activation energy, the mechanism would contribute more to the over-all rate.

To permit a better comparison with other alkoxymethyl esters, the hydrolysis of β-chloroethoxymethyl acetate was also studied over a wider range of hydrogen chloride concentration. The first-order rate coefficients at different acid concentrations are given in Table 4 and their logarithms are plotted as a function of the value of the acidity function H_0 in Fig. 4. The plot of the data referring to 25°C is approximately linear with a slope close to unity, the deviation from linearity being hardly greater than can be ascribed to experimental error, whereas the data referring to 0.88°C yield a plot that clearly has a smaller slope at low acidities than at high acidities. This is the expected result [14] if the Zucker-Hammett hypothesis can be assumed to be at least approximately valid for the reaction in question and if there are two concurrent reaction mechanisms which differ in their dependence on the acidity of the solution. Here the bimolecular acyl-oxygen fission with its lower activation energy can be expected to contribute more to the over-all rate at the lower temperatures.

EXPERIMENTAL

The preparation and purification of the compounds studied except β-chloroethoxymethyl formate have been described earlier [1,4]. β-Chloroethoxymethyl formate was synthesized from α-chloromethyl-β-chloroethyl ether and lead formate. It was found advantageous to use a large excess of lead formate (about 140 % of the calculated amount) to effect complete conversion of the chloroether. After the components were mixed, the mixture was heated on a water bath. The crude product was extracted with ether, the lead chloride and unreacted lead formate removed by centrifugation and the residue remaining after the ether was distilled off distilled under reduced pressure. The main ester fraction boiled at 82.5°C under a pressure of 17 mm Hg. When the purity was checked by titration of the formaldehyde formed from the ester (*cf.* Ref.[1]), 191.7 mg of the ester was equivalent to 41.16 ml of 0.0676 N iodine solution (calc. 40.93 ml).

The method of following the reactions was that used in earlier studies of alkoxymethyl esters [1]. In all cases the first-order rate equation was satisfactorily obeyed.

The authors wish to express their gratitude to the *Valtion Luonnontieteellinen Toimikunta (The Finnish State Council for Natural Sciences)* for financial aid.

ACTA CHEMICA SCANDINAVICA 14 (1960) 594–608

On the Equilibrium $In^{3+} + 2In(s) \rightleftharpoons 3In^{+}$

GEORGE BIEDERMANN and TOM WALLIN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The equilibrium between In^{3+}, indium metal and indium ions in the lower oxidation state has been studied at 25°C by bringing indium(III) perchlorate solutions into intimate contact with finely divided indium metal. After a steady state was attained in the solution a) the number of equivalents of the reducing agent formed, b) the emf of the couple and c) the emf of the In^{3+}-In(s) couple were measured. The indium(III) concentration varied between 0.01 and 0.2 M, the hydrogen ion concentration was kept ≤ 0.01 M and all solutions were made to contain 3 M ClO_4^- by the addition of $NaClO_4$.

The data can be well explained by assuming that only the In^+ ion is formed and that for $In^{3+} + 2In(s) \rightleftharpoons 3In^+$, $\log K = -8.4 \pm 0.1$. No evidence has been found for the species In^{2+}.

In the ionic medium 3 M ClO_4^- the following standard potentials have been determined at 25°C

$In^{3+} + 2e^- \rightleftharpoons In^+$	$e^\circ_{1,3} = -425.5 \pm 1$ mV
$In^{3+} + 3e^- \rightleftharpoons In(s)$	$e^\circ_{0,3} = -343 \pm 1$ mV
$In^+ + e^- \rightleftharpoons In(s)$	$e^\circ_{0,1} = -178 \pm 5$ mV

Experimental conditions influencing the rate of the reaction $In^+ + 2H^+ \rightarrow In^{3+} + H_2$ have been discussed.

The experiments of Thiel [1] in 1904 gave the first indication of the existence of the In^+ ion in water solution. Thiel found that InCl and InBr are readily dissolved in water, but that metallic indium is formed rapidly in the solution because of the reaction $3In^+ \rightarrow In^{3+} + 2In(s)$. Materials of the stoichiometric composition InX_2 (X = halogen) could not be dissolved; when these came into contact with water, decomposition to In^{3+} and InX(s) occurred immediately.

Hepler, Hugus and Latimer [2] published in 1953 the results of their investigation on the equilibrium between In^{3+}, indium metal and indium ions of the lower oxidation states. These authors attempted to equilibrate at 25°C indium(III) perchlorate solutions of $\log[H^+] = -1$ with finely divided indium, and measured the number of equivalents of the reducing agents present, after attainment of a steady state, by titrating with Ce(IV) solution. Assuming the simultaneous equilibria

$$In^{3+} + 2\,In(s) \rightleftharpoons 3\,In^{+} \qquad K_1 = [In^{+}]^3[In^{3+}]^{-1}$$
$$\text{and } 2In^{3+} + In(s) \rightleftharpoons 3\,In^{2+} \qquad K_2 = [In^{2+}]^3[In^{3+}]^{-2}$$

we have calculated from their data the constants $\log K_1 = -7.5$ and $\log K_2 = -6.4$.* These values are valid at the ionic strength 0.83; the inert salt added was $Ce(ClO_4)_3$.

Kangro and Weingärtner [3] in 1954 studied the reduction of In^{3+} by indium metal with emf measurements. These investigators measured at different temperatures the redox potential with a Pt electrode and the potential of indium metal in indium(III)sulfate solutions of $\log[H^+]$ about -2.5 which were in contact with indium metal. The equivalent concentration of the reduced ions was determined by titrating with $KMnO_4$ solution. Equilibrium could not be established under these experimental conditions because of the rapid oxidation of the indium ions in the lower oxidation state by hydrogen ions. This reaction was observed especially on the surface of the Pt foil used to measure the redox potential. By assuming that In^+ is formed exclusively and that the hydrolysis can be neglected, Kangro and Weingärtner obtained at 26.5°C with extrapolation to infinite dilution $\log K_1 = -6.917$.

EXPERIMENTAL DIFFICULTIES

The study of a redox equilibrium of this type involves a number of difficulties.

The standard potential of the indium redox couple lies at about -400 mV, the ions in the lower oxidation state are therefore unstable in respect to oxidation by hydrogen ions at $\log [H^+] > -7$. Solutions containing indium(III) in appreciable amount cannot be prepared, however, unless $\log [H^+] > -3$, because of the precipitation of indium hydroxide. The rate of oxidation by hydrogen ions may be much suppressed under suitable experimental conditions but it cannot be eliminated completely in acid solutions. The law of mass action consequently cannot be applied to a set of analytical data to ascertain the formulas of the ions formed by reduction, nor can the corresponding equilibrium constants be obtained, unless independent evidence is obtained that real equilibrium is established in the solution.

When a reversible redox electrode can be found, the correct value of the equilibrium constant can be computed by combination of the emf and the analytical data without the necessity of the attainment of a real equilibrium. The noble metals most often used to measure redox potentials are unfortunately good catalysts for oxidation reactions with hydrogen ions. If this reaction occurs with an appreciable speed on the electrode surface, the reliability of the emf measurements is impaired.

With a number of redox systems — Sn(II)—Sn(IV)[4], Cr(II)—Cr(III)[5], Ti(II)—Ti(III)[6] and V(II)—V(III)[7] — reproducible emfs have been obtained with mercury redox electrodes which were introduced by Forbes [4] in 1914. Evolution of hydrogen on the mercury surface is slow because of the high

* We have not been able to derive the constants $\log K_1 = -10.5$ and $\log K_2 = -7.7$ given in the original publication.

overvoltage but it cannot be avoided completely. Also there is always the possibility of amalgam formation when mercury electrodes are employed.

Since the In^{3+} ion is an acid of considerable strength [8] the hydrogen ion concentration of the solution should be known accurately. It is essential to choose an appropriate acidity. The concentration of the ions in the lower oxidation state is diminished if the hydrogen ion concentration is so low that hydrolyzed species of In(III) are formed in appreciable amounts, while if the acidity is high, then oxidation by hydrogen ions becomes rapid. In either case the analysis and emf measurements become more difficult.

In our experiments the concentration of the ions in the lower oxidation state varied between 0.1 and 1 mM. The accurate determination of a reducing agent at such low concentrations presents some difficulties. Visual end point indication proved to be quite unsatisfactory. The slowness of the electrode reaction in the neighborhood of the equivalence point made potentiometric methods impractical. Good results were obtained on the other hand with amperometric end point determination.

METHOD

To study the redox equilibrium, oxygen-free solutions of In^{3+} were brought into intimate contact with finely divided indium metal. The reduction started immediately and proceeded rapidly at the range of indium(III) concentrations studied in this work. The progress of the reduction was followed by a redox and an In electrode. When both these electrodes attained a steady value, which usually required 3 to 4 hours, the indium metal was removed from the solution and a known amount of an iodine solution was added. This immediately oxidized the indium ions of the lower oxidation state to In^{3+}; the excess iodine was measured with an 1 mM $Na_2S_2O_3$ solution.

The indium(III) concentration of the test solutions was varied between 0.0100 and 0.200 M. The hydrogen ion concentration was kept in the majority of the experiments at 0.0100 M; at this acidity the hydrolysis of In(III) is negligible for the indium concentrations studied [8] and the rate of oxidation of the ions in the lower oxidation state by hydrogen ions is slow. A few data were obtained also at $\log [H^+] < -2$ where hydrolyzed species of In(III) are formed in appreciable amounts.

In order to minimize the variation of the activity factors all solutions were made to contain 3 M ClO_4^- by adding $NaClO_4$. The test solutions thus had the general composition

B M In^{3+}, H M H^+, $(3.000-3B-[H^+])$ M Na^+, 3 M ClO_4^- = solution S

In each experiment three quantities were measured: 1) the number of moles of iodine reduced by one liter of the test solution in the steady state; this number will be denoted by R; 2) The emf of the redox half-cell against a standard half-cell SE; 3) The emf of the In^{3+}-In half-cell against SE. These are related to the concentrations of the ionic species present in the solution by the equations that follow.

The reaction between In^{3+} and In(s) may be generally written

$$q\ In^{3+} + (3\ p-q)\ In(s) \rightleftharpoons 3\ In_p^{q+},\ K_{p,q} = \{In_p^{q+}\}^3\ \{In^{3+}\}^{-q} \qquad (1)$$

where the symbol {} denotes activity. The standard state is defined so that the activity factors tend to unity if the solutes are present in negligible amounts in the solvent 3 M $NaClO_4$. Iodine oxidizes In_p^{q+} according to the equation

$$In_p^{q+} + \frac{3p-q}{2} I_2 \rightarrow p\ In^{3+} + (3p-q)\ I^- \quad (2)$$

thus R will be equal to

$$R = \sum \frac{3p-q}{2} [In_p^{q+}] \quad (3)$$

The electrode reaction at the indium metal may be written

$$In^{3+} + 3e^- \rightleftharpoons In(s) \quad (4)$$

and that at the redox electrode

$$p\ In^{3+} + (3p-q)e^- \rightleftharpoons In_p^{q+} \quad (5)$$

At equilibrium the emf of the cell

In/solution S/redox electrode

should be zero, hence at 25°C

$$e_r^\circ + \frac{59.15}{3p-q} \log \frac{\{In^{3+}\}^p}{\{In_p^{q+}\}} = e_{0,3}^\circ + \frac{59.15}{3} \log \{In^{3+}\} \quad (6)$$

where e_r° and $e_{0,3}^\circ$ denote the standard potentials referred to the hydrogen scale. If there are several species In_p^{q+} e_r° is of course different for each of them. From (1) and (6) we obtain

$$\log K_{p,q} = \frac{3p-q}{19.72} (e_r^\circ - e_{0,3}^\circ) \quad (7)$$

To determine the potentials of the redox and of the In^{3+}— In couples the cells

— redox electrode/solution S/SE + (A)

and — In/solution S/SE + (B)

have been employed. SE denotes the half-cell

Ag, AgCl/0.0100 M NaCl, 2.990 M $NaClO_4$/3 M $NaClO_4$/

The emf of these cells can be written at 25°C

$$E_A = e_{SE} - e_r^\circ - \frac{59.15}{3p-q} \log \frac{[In^{3+}]^p}{[In_p^{q+}]} - \frac{59.15}{3p-q} \log \frac{f^p(In^{3+})}{f(In_p^{q+})} + E_j \quad (8)$$

$$E_B = e_{SE} - e_{0,3}^\circ - 19.72 \log [In^{3+}] - 19.72 \log f\ (In^{3+}) + E_j \quad (9)$$

where $f(In^{3+})$ and $f(In_p^{q+})$ denote the activity factors, e_{SE} is a constant and E_j is the liquid junction potential between solution S and 3 M $NaClO_4$. In a previous paper [9] it has been shown that at low metal ion concentration E_j for

all practical purposes is a function of the $[H^+]$ only, namely $E_j = 16.7\,[H^+]$ mV in 3 M $NaClO_4$. The estimation of the activity factors has been treated in a separate study, and the results pertaining to our problem are discussed in a later section.

In order to eliminate the effect of the small variation of e_{SE} with time, before each E_A and E_B measurement the emf, E_C, of the cell

$$-\ \text{SE}/0.0100\ \text{M}\ H^+,\ 2.990\ \text{M}\ Na^+,\ 3\ \text{M}\ ClO_4^-,\ \text{quinhydrone (s)/Pt}\ + \qquad \text{(C)}$$

was determined. The relevant value of e_{SE} (which might vary slightly between different days) was calculated by the equation

$$E_C = e_Q^\circ + 59.15 \log [H^+] - E_j - e_{SE} \qquad (10)$$

The standard potential $e_Q^\circ = 677.7 \pm 0.1$ mV of the quinhydrone half-cell was determined using the cell

$$H_2\ (1\ \text{atm})/S_1/S_1,\ \text{quinhydrone(s)/Pt}$$

where S_1 denotes the solution: 0.0500 M H^+, 2.950 M Na^+, 3.000 M ClO_4^-.

By measuring E_A, E_B and R at a series of B values the functions $E_A\,(B, R)$ and $E_B\,(B)$ have been determined; the study of these functions is the subject of the following discussion.

MATERIALS AND ANALYSIS

Indium (III) perchlorate solutions were made from indium metal of 99.99 % purity generously provided and spectrographically examined by the Consolidated Mining and Smelting Company of Canada Ltd. The solutions were prepared and analyzed for indium and hydrogen ions as described previously [8]. A few experiments were made to determine the [In(III)] by electroanalysis but no satisfactory results were obtained. The deposition was not complete at log $[H^+]$ values greater than -2, whereas at lower log $[H^+]$ values the deposited metal contained some indium hydroxide.

Potassium iodate solutions were made from double recrystallized KIO_3, Merck p.a. This preparation was compared with recrystallized and water-free $K_2Cr_2O_7$ by titrating the same $Na_2S_2O_3$ solution with both solutions using a weight burette; the results agreed within 0.02 %.

Sodium thiosulfate solutions were prepared from $Na_2S_2O_3\,(H_2O)_5$ Merck p.a. To prevent bacterial decomposition *iso*butyl alcohol was added according to Winkler [10], and the solution was made 1 mM in Na_2CO_3 as recommended by Kolthoff [11].

Distilled water used to prepare ½ mM KIO_3 and 1 mM $Na_2S_2O_3$ solutions was first filtered through a G5 Jena glass filter, then boiled and finally made oxygen-free by bubbling nitrogen through it for 2 h. Without these precautions the dilute solutions deteriorated rapidly. *Hydrochloric acid* solutions were made from 38 % HCl Merck p.a. which was purified by distillation. *Sodium iodide* Malinckrodt p.a. was used without further purification; no traces of iodate could be detected in this preparation. *Sodium perchlorate, sodium hydrogen carbonate* and *sodium chloride* solutions were prepared and analyzed as usual in this laboratory [8]. *Carbon dioxide* and *nitrogen* were taken from cylinders and freed from oxygen by passage over hot activated copper. The gases were passed through water and 3 M $NaClO_4$ to obtain the right vapor pressure.

The *amperometric titrations* were carried out with a platinum wire as the indicator electrode and SE as the reference electrode, the solutions being stirred vigorously with a rotating magnet. The galvanometer had a sensitivity of 4×10^{-9} A/mm. The accuracy of the amperometric determination of iodine in our solutions was tested by adding a known amount of iodine to an indium perchlorate solution and titrating with thiosulfate which has been standardized against KIO_3. An accuracy of 0.2 % was obtained in the iodine concentration range 0.1 to 1 mM.

Experimental details of the emf measurements

All emf measurements were made at 25.0 ± 0.3°C in a thermostated room. The arrangement of the reference half-cell and the salt bridge is described elsewhere [12]. The emfs were measured with a valve potentiometer, Radiometer PHM 3, Copenhagen, which was calibrated against a Leeds and Northrup potentiometer of type K3. The reading accuracy was 0.1 mV.

Indium metal electrodes were prepared by electrolysis from an acid In(III) solution using a Pt gauze cathode. The deposited metal consisted of fine crystals and thus it had a large surface. This was of importance since the metal served also as the reducing agent in the test solution. Quite a thick layer of indium must be deposited because indium forms an alloy with platinum and this, in contrast to pure indium metal, is easily dissolved in $[HClO_4] \geq 10$ mM. In oxygen-free solutions and at $\log [H^+] \leq -2$ these electrodes came to equilibrium within 2–3 h and gave potentials which were constant and reproducible to within 1 mV for many hours. *Ag,AgCl electrodes* were prepared as usual in this laboratory [8].

On the measurement of the redox potential

We had considerable difficulty in finding an appropriate redox electrode. Platinum foils never attained a quite constant potential in our solutions, and the difference $E_A - E_B$ was in no case less than 20 mV. Gold, silver and mercury pool electrodes proved also to be unsatisfactory. The failure of these types of electrodes may be ascribed partly to their catalytic activities for the oxidation of In_p^{q+} by H^+ and partly to the slowness of the electrode reaction at the low R values studied in this work.

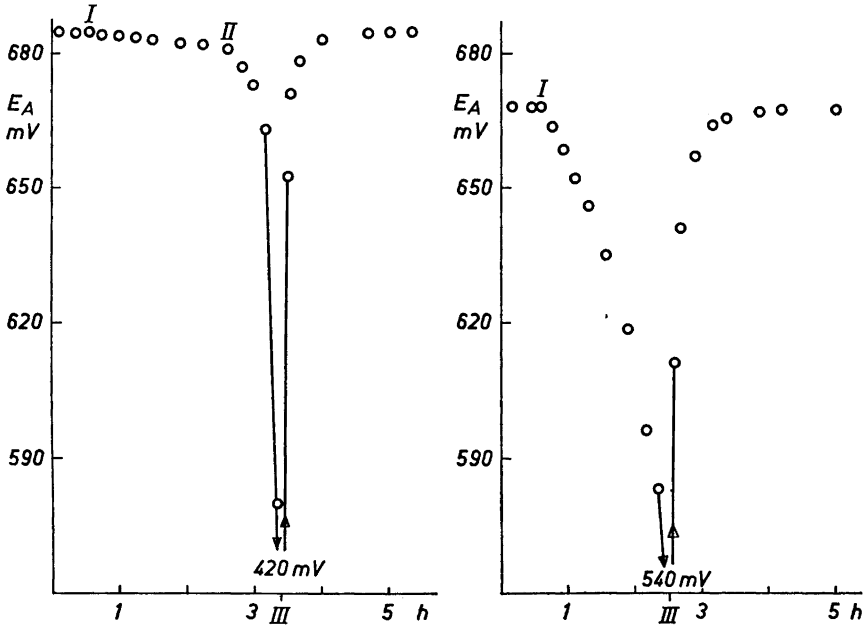

Fig. 1. Reproducibility of the redox electrodes. E_A (eqn (8)) as a function of time at $\log [H^+] = -2$ (Fig. 1a) and at $\log [H^+] = -1$ (Fig. 1b). The indium electrode was removed at point I, air was admitted at point II. At point III the indium metal electrode was reinserted and the CO_2 stream restarted.

Good results were obtained on the other hand with mercury coated platinum foils; these electrodes were found to give potentials reproducible within at least 0.5 mV and to reach a constant potential rapidly in solutions of log $[H^+] \leq -2$. The redox electrodes were made by precipitating mercury electrolytically on a platinum foil with a current density of about 5 mA cm^{-2} for about 10 min from a slightly acid $Hg(ClO_4)_2$ solution.

Several experiments were made to test these electrodes; a typical one concerning their reproducibility will now be described, *cf.* Fig. 1a. Four mercury-platinum electrodes were put into an oxygen-free solution of $B = 100$ mM and $R = 0.5$ mM which had been in contact with indium metal for several hours. The electrodes reached a constant potential within 20 min and they agreed within 0.2 mV. Now the indium metal was removed (point I in Fig. 1a), this caused a slow decrease of E_A due to the oxidation of In_p^{q+} by H^+. After 2 h the solution was brought into contact with air (point II); now of course E_A decreased rapidly. When the In metal was reinserted (point III) and the O_2 was expelled from the solution with CO_2 all the four redox electrodes had in an hour re-attained, within 0.1 mV, the constant starting potential.

In all experiments at least two but usually four electrodes were used; the potential difference between them never exceeded 0.5 mV.

Several experimental facts seem to indicate that the satisfactory function of this type of redox electrodes is to be ascribed to the formation of an alloy on the platinum surface. When a platinum foil was kept in mercury for about nine months at 25°C it was found by X-ray analysis that a substantial part of the foil had become transformed to $PtHg_4$. The crystal structure of this alloy was determined by Bauer, Nowotny and Stempfl [13], who found it to be the phase richest in mercury which can be prepared at 450 and 200°C. Our experiments give evidence that $PtHg_4$ is stable at room temperature and is the phase which is in equilibrium with liquid mercury.

No alloy formation could be detected by X-ray analysis on the redox electrodes prepared as described above. This failure is to be explained by the fact that the amount of alloy formed was too small to be detected by X-ray diffraction, it must have been less than one weight percent.

In the course of our work it was observed that the redox electrode became much less satisfactory when the electrolysis was prolonged and small drops of mercury were visible on the electrode surface. Electrodes prepared in the same way differed considerably and the potential difference between the indium and these redox electrodes was higher by several mV than that between the indium and the redox electrodes prepared by short electrolysis. A rapid alloy formation can occur on the platinum surface; when the surface is completely covered with the alloy further amounts of mercury cannot react except by diffusion through the alloy. Deposition of large amounts of mercury thus has the effect of decreasing the active surface of the electrode; perhaps some In of lower valency is also removed by amalgam formation.

In order to prepare properly functioning electrodes it was essential to boil the platinum foil in *aqua regia* before electrolysis. This treatment creates a large and active surface which can react rapidly with mercury, whereas on bright, polished platinum surfaces mercury is deposited in droplets.

Evidence for alloy formation between platinum and mercury has been found by several investigators who studied the electroanalysis of mercury [14]. When the deposited mercury is dissolved in hot concentrated nitric acid, appreciable amount of platinum(IV) can be detected in the solution and the surface of the gauze turns dark indicating the dissolution of some platinum.

Procedure

After the test solution was placed in a six-necked flask a vigorous stream of CO_2 or N_2 was passed through it for about an hour to expel oxygen. Then the indium electrode was immersed and the reference half-cell was connected. To hasten the attainment of the steady state the solution was stirred with a rotating magnet. When the indium electrode attained a constant value, which usually occurred after 2 to 3 h, two or more redox electrodes were put into the solution. These required a period of between 15 min and 2 h, depending on B, to reach a constant value. Before the final values of E_A and E_B were taken the magnetic stirring was stopped.

To determine R the indium electrode was taken out, the gas stream was stopped and a known amount of iodine was added to the solution. In a number of experiments the redox electrodes were removed before the titration. The presence of the redox electrodes was found not to influence appreciably the R value obtained. In separate experiments evidence was found that during the interval — about 1 to 2 min — which elapsed between the removal of the indium metal and the introduction of iodine no appreciable amount of the ions in the reduced form was oxidized by hydrogen ions, *cf.* Fig. 1a.

As dilute solutions of iodine are unstable the iodine was prepared just before the addition. To a 0.5 mM KIO_3 solution placed in a small separating funnel of about 50 ml capacity 10 ml of 0.2 M HCl was added and the solution was made oxygen-free by passing through CO_2 for 15 min. Now 0.2 g solid NaI was added and after 20 min the iodine solution was introduced into the flask. The titration was started immediately.

The 1 mM $Na_2S_2O_3$ solution used to measure the small excess of iodine was standardized each time immediately after the determination of R. In connection with the standardization an important point was to avoid any excess of thiosulfate when titrating the iodine which remained after the reduction with In_p^{q+}. Thiosulfate was found to decompose appreciably in our acid solutions. The excess could be avoided by plotting the current as a function of added ml thiosulfate during the titration and extrapolating the resulting line to zero current. The last increment of thiosulfate required to attain the equivalence point was calculated from this extrapolation. No appreciable error could be made in this way since the residual current was always less than 10^{-8} A, and the current as a function of ml thiosulfate proved to be strictly a straight line in the neighborhood of the equivalence point.

On the steady state and the rate of oxidation of In_p^{q+} by hydrogen ions

The data obtained in the final series of measurements are presented in Table 1. This final series was preceded by a preliminary one covering the same B range with 15 measurements. The results of this preliminary series are somewhat less trustworthy because insufficient attention was paid to a few experimental details of minor importance. These data are nevertheless in acceptable agreement with those of the final series.

Table 1. Survey of experimental data.

1) $\log [H^+] = -3.11$; $[In^{3+}] = 1.29 \times 10^{-2}$ M
2) $\log [H^+] = -2.90$; $[In^{3+}] = 4.52 \times 10^{-2}$ M

The $[In^{3+}]$ of the hydrolyzed solutions with log $[H^+] < -2$ was measured with an indium electrode, the equilibrium concentration of hydrogen ions was calculated from B, $[In^{3+}]$ and the analytical hydrogen ion concentration employing the hydrolysis constants determined previously [8].

The E_A and E_B values given in Table 1 indicate that true equilibrium could not be established in the bulk of our solutions. The difference $E_B - E_A$, which is a measure of the distance from the equilibrium, is 6 mV at the lowest B = 10 mM, and decreases to about 1 mV at the maximum B = 200 mM. The relatively small differences $E_B - E_A$ show that oxidation by hydrogen ions could be restrained to a great extent under the experimental conditions employed.

We may describe schematically the system consisting of the indium net, the test solution and the redox electrode as

$$In/R_e\colon\ R_s\colon\ R_A/Hg-Pt$$

where R_e is the equilibrium value of R which prevails in the layer surrounding the indium net, R_s is the value of R in the bulk of the solution and R_A is that in the vicinity of the redox electrode. These are related by the inequality

$$R_e \geq R_s \geq R_A$$

The symbol ":" denotes a concentration gradient. The steady state to which the data in Table 1 are referred is attained when the rate of diffusion of In_p^{q+} from the solution layer around the indium gauze becomes equal to the rate of the reaction

$$\overline{In}_p^{q+} + 3\,(p-q)\,H^+ \rightarrow p\,In^{3+} + \frac{3\,p-q}{2}\,H_2 \qquad (11)$$

occuring in the solution, on the wall of the flask or on the redox electrode. A similar condition holds for the layer surrounding the redox electrode and the solution if $R_s > R_A$.

The limited accuracy of the emf data does not permit a detailed study of the reaction mechanism of (11); a few interesting conclusions, however, can be drawn. The data in Table 1 give evidence that (11) is kinetically of less than first order in $[In_p^{q+}]$ at constant acidity. In the case of a first order reaction $E_B - E_A$ would be independent of $[In_p^{q+}]$, whereas if it were of a higher order, $E_B - E_A$ would increase with $[In_p^{q+}]$. An analysis of the $E_B - E_A = f(B, R)$ function indicates that (11) is retarded by In^{3+} ions. This may be explained by assuming that (11) is a heterogeneous reaction which may occur, *e.g.*, on the surface of the glass flask. As the $[In^{3+}]$ is increased a larger fraction of the surface becomes covered with adsorbed In^{3+} ions and thus the number of active centers available for (11) is decreased.

We have some evidence that (11) occurs chiefly on solid surfaces. In several experiments a solution containing In_p^{q+} was passed through a thin layer of glass wool and a fine glass capillary. A substantial decrease of R was always observed and gas bubbles could be seen on the glass wall. No difference was found between the catalytic activities of glass and polyethylene surfaces

of identical size. Metals which show a low overvoltage for hydrogen are very effective catalysts, as was discussed previously in connection with the redox electrodes.

In order to evaluate the redox potential measurements we had to assume that

$$R_s = R_A$$

i.e. reaction (11) does not occur to an appreciable extent on the Hg—Pt surface. The good reproducibility of the redox potential measurements seems to indicate that this assumption is a good approximation. When the redox potentials were measured with platinum or gold electrodes, several electrodes immersed in the same solutions differed by about 20 mV, whereas with the mercury-plated platinum electrodes the difference never exceeded 0.5 mV and usually was within 0.2 mV.

Another experimental fact seems to be in agreement with this hypothesis. Several redox potential measurements were made in the following way: after the first redox electrode attained a constant value two or three freshly prepared electrodes were put into the solution at the same time. This had no detectable effect on the potential of the first electrode. If the electrode surfaces were effective catalysts, R_s would be decreased (at least temporarily) by increase of the surface. This decrease of R_s would diminish the diffusion velocity of In_p^{q+} to the first electrode. Thus R_A would decrease, which should have been detected when measuring the redox potential.

The dependence of the reaction rate on the hydrogen ion concentration is illustrated in Fig. 2, which shows the potential difference between an indium and a redox electrode in the steady state as a function of log $[H^+]$ in a solution of $B = 100$ mM. The measurements were made with the technique described previously. The potential difference is seen to decrease rapidly with the $[H^+]$ and it attains a minimum value of about 2 mV at log $[H^+] = -2$. Substantially lower log $[H^+]$ values could not be studied because of the precipitation of indium hydroxide.

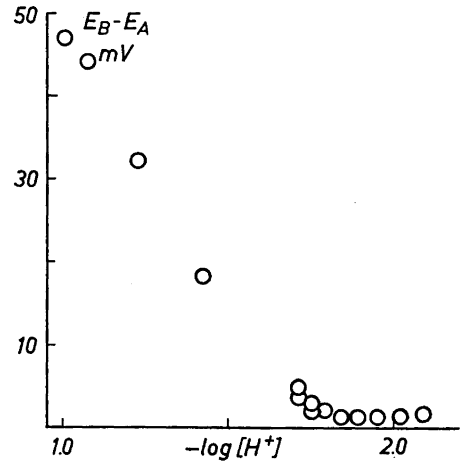

Fig. 2. Dependence of the rate of reaction (11) on log $[H^+]$. $E_B - E_A$ as a function of log $[H^+]$. The $[In(III)]_{total}$ was kept at 0.100 M.

The rapid increase of the reaction rate with increasing $[H^+]$ is also clearly demonstrated by the experiments whose results are shown in Figs. 1a and 1b. In the absence of metallic indium In_p^{q+} is seen to be oxidized rather slowly at log $[H^+] = -2$ (Fig. 1a) but very rapidly at log $[H^+] = -1$ (Fig. 1b). At log $[H^+] = -2$ the redox potential is decreased in one hour by 4 mV whereas at log $[H^+] = -1$ six minutes are sufficient for the same decrease.

RESULTS

In order to explain the data given in Table 1 we will assume in the first instance that only *one* species In_p^{q+} is formed by reduction and that the activity factors are constant. Then according to (1) and (3) the $[In_p^{q+}]$ and $[In^{3+}]$ are related to R and B by the equations

$$[In_p^{q+}] = \frac{2\,R}{3\,p-q} \tag{12}$$

and

$$B > [In^{3+}] \geq B - \frac{q}{3}\,\frac{2\,R}{3p-q} \tag{13}$$

We shall use in the following calculations the approximation

$$\log [In^{3+}] = \log B \tag{14}$$

the error made using this approximation has no appreciable influence on the results since R never exceeds 0.03 B.

The charge of the reduced species q and the number of indium atoms it contains p as well as the equilibrium constant $K_{p,q}$ can be found by using (7). When we eliminate e_r° and $e_{0,3}^\circ$ using (8) and (9), and employ (12) and (14) for $[In_p^{q+}]$ and log $[In^{3+}]$, eqn (7) will take the form

$$\log K_{p,q} = 3 \log \frac{2}{3\,p-q} + 3 \log R + \frac{3\,p-q}{19.72}\,\Delta E - q \log B \tag{15}$$

This can be rearranged to

$$3 \log R + 3\,p\,\frac{\Delta E}{19.72} = \log K_{p,q} - 3 \log \frac{2}{3\,p-q} + q\,(\log B + \frac{\Delta E}{19.72}) \tag{16}$$

where for convenience ΔE is written for $E_B - E_A$.

In (16) R, ΔE and B are determined experimentally, whereas p, q and $K_{p,q}$ are unknown. To find p and q and thus also $K_{p,q}$ we have calculated the left-hand side of (16) by assuming $p = 1$, 2, 3, and 4 and plotted the resulting values against $\log B + \frac{\Delta E}{19.72}$. For the correct value of p a straight line should result with the slope q.

The plot for $p = 1$ is given in Fig. 3a which shows that the points may be satisfactorily represented by a straight line of unit slope. In the plots for

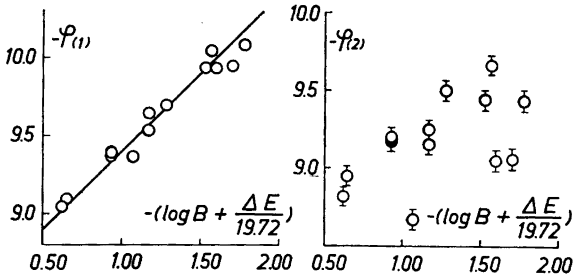

Fig. 3. Ascertainment of the species formed by reduction. $\varphi\,(p) = 3 \log R + \frac{3p\Delta E}{19.72}$ as a function of $\log B + \frac{\Delta E}{19.72}$. The line in Fig. 3a) represents the equation $3 \log R + \frac{3\Delta E}{19.72} = -8.40 + \log B + \frac{\Delta E}{19.72}$.

$p = 2$, 3, and 4, points belonging to practically the same $\log B + \frac{\Delta E}{19.72}$ but of different ΔE deviated from each other by an amount exceeding the experimental uncertainty. This indicates that the hypothesis $p > 1$ is inconsistent with (16) and cannot yield a constant value for $K_{p,q}$. The plot for $p = 2$ is shown in Fig. 3b. It was of no interest to consider higher values of p than 4 because the deviations increased rapidly as p exceeds one. We can thus conclude that our data can be explained only by assuming the formation of the species with $p = 1$ and $q = 1$, *i.e.* In^+. $\log K_{11}$ was calculated for each experimental point with (15); these are collected in Table 2. We can write as the most probable value

$$\log K_{11} = -8.4 \pm 0.1$$

The maximum uncertainty of the $\log K_{11}$ value corresponds to that of $\pm$ 1 mV in the ΔE measurements, which was sometimes found for $B < 0.05$ M. With the data of the preliminary series $\log K_{11}$ was calculated as -8.5 ± 0.2.

It should be pointed out that if true equilibrium had been attained when ΔE would equal zero, only the charge q could have been determined by emf and analytical data but not p, *cf.* (15). In such case one would have to measure the variation of the redox potential when increasing amounts of a solution containing only the oxidized form are added to the equilibrated solution.

The standard redox potential, $e^\circ_{1,3}$, may be obtained by substituting (12) and (14) into (8). The $e^\circ_{1,3}$ values calculated are summarized in Table 2. We find as the most probable value

$$e^\circ_{1,3} = -424 \pm 1.5 \text{ mV}$$

ON THE INFLUENCE OF THE ACTIVITY FACTORS

If one wishes to study ionic equilibria where the composition of the reaction products and their activity factors are not known with certainty beforehand,

one cannot hope to find reliable results unless large changes in the activity factors of the reacting species are eliminated by using a constant ionic medium. If the concentration of the reacting ions is kept low compared with that of the inert salt *e.g.* the indium(III) concentration is less than 10 mM in 3 M ClO_4^-, the error introduced by neglecting the variation of the activity factors is inappreciable even when the experimental accuracy is high. For many investigations, however, it is inevitable that the concentrations of the reacting species are increased to high values. This is the case with our present problem since at B values lower than 10 mM almost unsurmountable experimental difficulties arise.

In work now being carried out in this laboratory by one of us the variation of the activity factors in a constant ionic medium forms the subject of an extensive experimental study. The results pertaining to our problem are taken from this work.

In order to estimate the changes of $f^3(In^+)/f(In^{3+})$ caused by the replacement of Na^+ by In^{3+} we will introduce the assumption that $f(In^+)$ varies in the same way as $f(Ag^+)$ when the two ions are present in equal concentrations in solutions otherwise identical. It is believed that this is a reasonable assumption since a considerable number of experimental results indicate that the activity factors of ions of the same charge are influenced approximately to the same extent by changes in the ionic medium.

The determination of $f^3(Ag^+)/f(In^{3+})$ was made by measuring the emf's of the cells

— In (2 % in Hg)/B M In^{3+}, 0.0100 M H^+, (3.000—3 B — [H^+]) M Na^+, 3 M ClO_4^-/SE + (D)

and

—SE/0.00100 M Ag^+, B M In^{3+}, 0.0100 M H^+, (3.000—3 B—[Ag^+]—[H^+])M Na^+, 3 M ClO_4^-/AgCl, Ag + (E)

B was varied between 0.0100 and 0.200 M. The emf's of these cells can be written at 25°C

$$E_D = E_D^\circ - 19.72 \log [In^{3+}] - 19.72 \log f(In^{3+}) + E_j \quad (17)$$

$$E_E = E_E^\circ + 59.15 \log [Ag^+] + 59.15 \log f(Ag^+) - E_j \quad (18)$$

Plotting

$$E_D + E_E - 19.72 \log \frac{[Ag^+]^3}{[In^{3+}]} \left(= E_D^\circ + E_E^\circ + 19.72 \log \frac{f^3(Ag^+)}{f(In^{3+})}\right) \quad (19)$$

against the [In^{3+}] a straight line was obtained; thus by extrapolation to [In^{3+}] = 0 the constant $E_D^\circ + E_E^\circ$ could be read. With this constant we calculated $f^3(Ag^+)f^{-1}(In^{3+})$ up to B = 200 mM. The $f^3(Ag^+)f^{-1}(In^{3+})$ values are seen, *cf.* Table 2, to be rather close to unity; at B = 200 mM $f^3(Ag^+)f^{-1}(In^{3+})$ attains the maximum value 1.09. We have not been able to determine K_{11} with so high an accuracy that a correction for the variation of the activity factors would be warranted.

It is clear that $f(In^{3+})$ and $f(In^+)$ individually cannot be evaluated from these measurements because changes in the composition of the solution involve a change in E_j also, and the activity and liquid junction terms cannot be calculated separately. Conductance measurements recently made in this laboratory in solutions of 3 M ClO_4^- indicate that changes in E_j due to the replacement of Na^+ by In^{3+} cannot make up more than a small part of the variation of E_D + 19.72 log [In^{3+}] or E_E — 59.15 log[Ag^+]. E_j is determined primarily by the hydrogen ion concentration because the mobility of H^+ exceeds by far that of all other cations; the [H^+] was kept strictly constant in all measurements.

Assuming that changes in E_j are quite negligible we calculated from the E_D and E_E measurements log $f(In^{3+})f^{-1}(In^+)$, see Table 2. If these are introduced we can estimate as the most probable value $e_{1,3}^\circ = -425 \pm 1.5$ mV.

The $e_{0,3}^\circ$ values calculated from E_B measurements with the activity factors determined with E_D give evidence, see Table 2, that our indium electrodes functioned satisfactorily, thus indium is not dissolved to an appreciable extent by H^+ under the experimental conditions used in this work. We shall accept $e_{0,3}^\circ = -343 \pm 1$ mV. At higher log [H^+] values than —2 no constant and reproducible potentials could be obtained because the rate of dissolution becomes appreciable.

Acknowledgements. This work was financially supported by *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)*.

We are indebted to Professor Lars Gunnar Sillén for his great interest and for his valuable criticism. We should like to thank Dr. Clara Berecki-Biedermann for many valuable discussions especially concerning analytical problems, and Civilingenjör Rune Söderquist for his help in connection with the X-ray work. Professor Robert E. Connick has been kind enough to read the manuscript and to give valuable comments on it. Mr. Frans Ericson has been of great help by making many parts of our equipment.

Thanks are due to the Consolidated Mining and Smelting Company of Canada Ltd. for generously granting a large amount of indium metal of the highest purity.

Crystalline Leghemoglobin

1. Purification Procedure

NILS ELLFOLK*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

A procedure is described for the purification of leghemoglobin to give the two main components in a crystalline state. The different components were isolated by chromatography using diethylaminoethyl cellulose as adsorbent. The main components were crystallised from slightly acid ammonium sulphate solution. Both of the crystalline components were found to be electrophoretically homogeneous in long-time electrophoresis runs at two different pH values. The electrophoretically faster component contained 0.32 % iron, and the slower one 0.29 % iron.

In 1938 Pietz [1] reported the observation of a red pigment in the root nodules of *Vicia Faba*. He assumed this substance to be 5,6-quinone-2,3-dihydroindole-2-carboxylic acid, the red oxidation product of tyrosin or dihydroxyphenylalanin. In 1939 Kubo [2] extracted the pigment from soya bean root nodules, and fractionated it with ammonium sulphate. On the basis of his studies, Kubo concluded that the red pigment was a hemoprotein similar to hemoglobin. Burris and Haas [3] definitely showed that the pigment was a hemin compound, but disagreed with its classification as a hemoglobin-like compound. Keilin and Wang [4], as well as Virtanen [5], idependently confirmed the results of Kubo concerning the hemoglobin nature of the pigment. The same conclusion was later reached by Little and Burris [6]. Virtanen *et al.*[7] proposed that the name leghemoglobin be used for the hemoglobin-like pigments in the root nodules of leguminous plants. This name will be used in this paper.

Ellfolk and Virtanen [8] found that leghemoglobin could be fractionated by electrophoresis to give two components of equal concentration but of different hemin content. This was later confirmed by Thorogood [9], who also was able to find a third component, and probably a fourth one.

* Permanent address: Research Laboratories of the State Alcohol Monopoly, Helsinki, Finland.

The experiments to be reported here have been carried out in order to develop a technique to purify the different components. All the present studies on leghemoglobin have been done on the oxidized form, *i.e.* leghem*i*globin. A preliminary report of these results has recently been published [10].

MATERIAL

Soya bean root nodules. The soya beans were inoculated with root nodule bacteria *(Rizobium leguminosarum)*, and grown in a green-house with a relative humiditiy of 70—80 %, and a temperature of 25°C. The culture medium was sea sand. The watering solution (pH 6.5, and free from chemically bound nitrogen) had the following composition: 3.6 g $MgSO_4 \cdot 7\ H_2O$, 4.5 g KCl, 4.2 g KH_2PO_4, 4.0 g $CaSO_4$, 25 mg ferric citrate, 0.55 mg LiCl, 1.1 mg $CuSO_4 \cdot 5\ H_2O$, 1.1 mg $ZnSO_4 \cdot 7\ H_2O$, 12.3 mg H_3BO_3, 1.1 mg $Al_2(SO_4)_3$, 0.55 mg $SnCl_2$, 0.55 mg KI, 7.7 mg $MnCl_2 \cdot 4\ H_2O$, 1.1 mg $NiCl_2 \cdot 6\ H_2O$, 1.1 mg $CoCl_2 \cdot 6\ H_2O$, 0.55 mg KBr, and 60 liters of tap water. The plants were usually harvested after the first blossoms appeared (after about six weeks). The nodules were used immediately, or stored at −20°C.

Ion exchange material. An adsorbent (CM—W) [11] with carboxyl groups was prepared from Whatman cellulose powder, and an absorbent with diethylaminoethyl (DEAE) groups was prepared from Solka Flok as well as from Whatman cellulose powder [11]. The product prepared from Solka Flok was preferred for column chromatography because it resulted in a faster-flowing column.

METHODS

Iron determination. Iron was determined spectrophotometrically by the sulphosalicylic acid method [12]. Combustion of the material was performed with sulphuric acid and hydrogen peroxide. The intensity of the color that was formed in ammoniacal solution with sulphosalicylic acid was measured at 424 mμ in the spectrophotometer.

Pyridine hemochromogen was determined according to Paul, Theorell and Åkeson [13].

Column chromatography. Dry ion exchange cellulose was dispersed with rapid stirring in the buffer that was used for the first elution, and was allowed to settle. The buffer solution was changed several times until no pH change occurred. 10 cm high columns were prepared by allowing the slurry to settle under gravity in glass tubes. Tubes with an internal diameter of 1 cm were used for preliminary studies, whereas for preparative runs, tubes with an internal diameter of 2.5 cm were used. The chromatography was always performed at +3°C.

Electrophoresis. This was carried out at 0.6°C in a Tiselius electrophoresis apparatus (Beckman/Spinco Model H Electrophoresis-Diffusion Instrument). For most of the runs the 11 ml cell was used, though in some experiments the 2 ml cell was used. As the source of illumination, the 644 mμ spectral line from a Cd-Hg vapor lamp was isolated by means of a red filter. Before electrophoresis the protein was dialyzed for 48 h against 2 liters of buffer at +3°C.

The mobility was calculated by a simple equation $u = S/F$, where S is the apparent speed of the boundary, and F is the potential gradient. The latter quantity is calculated from the equation $F = i/q\varkappa$ where i is the current in amperes, q is the cross-section of the electrophoresis cell in cm^2 and $\varkappa$ is the specific conductance of the solutions.

RESULTS

Different methods were tried in an effort to separate the different components of leghemoglobin. Repeated fractionations with ammonium sulphate at small increments gave no separation of the different components as determined by paper electrophoresis. Fractionation with acetone also was unsuc-

cessful. In addition, preparative electrophoresis on a cellulose column [14], high voltage electrophoresis on paper, ion exchange chromatography on both carboxymethyl cellulose and diethylaminoethyl-cellulose were tested for their ability to separate the different components of leghemoglobin. Of these methods, only ion exchange chromatography on DEAE-cellulose could be successfully used on a preparative scale. The column was prepared at pH 5.2, which is slightly higher than the isoelectric points of the components. A lower pH was not used because of the danger of denaturation of the protein on the column. The following procedure was used for preparing crystalline fractions of the two main components:

Extraction. Frozen nodules were ground in a mortar with a small amount of distilled water, and centrifuged at + 3°C. The supernatant solution contained most of the leghemoglobin of the nodules. In order or remove all the leghemoglobin, the precipitate was extracted a second and third time with distilled water. The extracts were pooled, and fractionated at room temperature with ammonium sulphate.

Ammonium sulphate fractionation. Solid ammonium sulphate was added until the solution was 55 % saturated with respect to ammonium sulphate. The pH of the solution was kept just above pH 5 by the addition of ammonia. After 1 h, the solution was centrifuged, and the precipitate was discarded. To the clear red supernatant solution, solid ammonium sulphate was added to a saturation of 80 %. After 1 h, the crude leghemoglobin was centrifuged down, and the clear, yellow supernatant solution was discarded. The precipitate was dissolved in a small amount of 0.1 M phosphate buffer at pH 8. Further fractionation with ammonium sulphate was avoided because it was evident that the micro air bubbles formed by addition of solid ammonium sulphate had a denaturating effect on the heminprotein.

Dialysis. Before the resulting preparation was fractionated on the ion exchange column, the remaining ammonium sulphate had to be removed by dialysis. The dissolved precipitate was dialyzed for 6 h against 10^{-4} M phosphate buffer (pH 8) and for 24 h against distilled water.

Column chromatography. For preparative work, the column (2.5 cm in diameter) was loaded with 100 to 150 mg of protein in 10 to 15 ml of salt-free solution. All of the protein remained on top of the column as a sharp brown band (Fig. 1, column I). The eluation was started with acetate buffer pH 5.2, $\mu = 0.01$. With this ionic strength one band moved down the column and could easily be separated (Fig. 1, *a*). A very faint, broad band (Fig. 1, *b*) followed the first band. When fraction *b* had left the column, the ionic strength of the eluation buffer was increased to 0.02—0.03 by the addition of sodium chloride. At this ionic strength a very sharp band, followed by a small sharp band, moved down the column (Fig. 1, *c* and *d*). On the top of the column there remained a brown band (Fig. 1, *e*) which could not be quantitatively eluted even with buffers of high ionic strength (sodium chloride concentration increased to 3 M). The color of the bands was not uniform during the eluation procedure, but showed a change from red-brown to green. This was found not to depend upon the presence of any oxidized product of leghemiglobin (cholеglobin) but on the formation of a green complex between leghemiglobin and the acetic acid of the eluant.

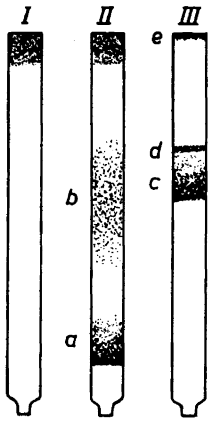

Fig. 1. Column chromatograms of leghemoglobin. Leghemoglobin adsorbed on the top of the DEAE-cellulose column (I). The chromatogram was developed with acetate buffer of pH 5.2, $\mu = 0.01$ (II), and $\mu = 0.03$ (III).

To concentrate the rather dilute fractions, the solutions were dialyzed against distilled water, and the proteins were adsorbed on the top of a short column (1.5—2 cm high). The proteins were eluted from the column by a small volume of 0.1 M phosphate buffer.

Crystallisation. The two main fractions of leghemoglobin were crystallised at + 3°C by dialysing a salt-free solution of each protein against an increasing concentration of ammonium sulphate. The dialysis was started against 55 % saturated ammonium sulphate at pH 6. The degree of saturation was increased by increments of 2.5 % every 12 h, while the pH was maintained at 6. At 60 % saturation, the pH was lowered to about 5 by the addition of sulphuric acid. The first crystals were usually obtained about 24 h later, after which the ammonium sulphate saturation was increased step-wise to 65 %.

Crystallisation of component *a* was also achieved by adding saturated ammonium sulphate solution of pH 5 to a concentrated solution of the protein until a clear "silkiness" was obtained. After keeping the solution at + 3°C for several days, crystals were formed. For some reason, crystals were not obtained from component *c* by this technique, although a silkiness could easily be produced. Fig 2A shows a photomicrograph (phase-contrast microscope) of separate needles of compound *a* and demonstrates the homogeneity of the preparation, whereas Fig. 2B shows a photomicrograph (phase-contrast microscope) of an association of these crystals to form a cluster of needles. Fig. 2C shows a photomicrograph of cyrstals of component *c* taken with an ultraviolet light microscope illuminated with light of 2 750 Å. The crystals are in the form of needles associated to form rosettes.

The photomicrographs show that the crystals of the two components have very similar forms, but that they differ in the way they associate. Both crystalline components were clearly double refracting in plane polarized light, except for the crystals in Fig. 2A which evidently were too thin to produce a double refraction.

Electrophoresis. The fractions that were crystallised (*a* and *c*), as well as fractions *b* and *d*, were examined in the Tiselius apparatus at two different pH

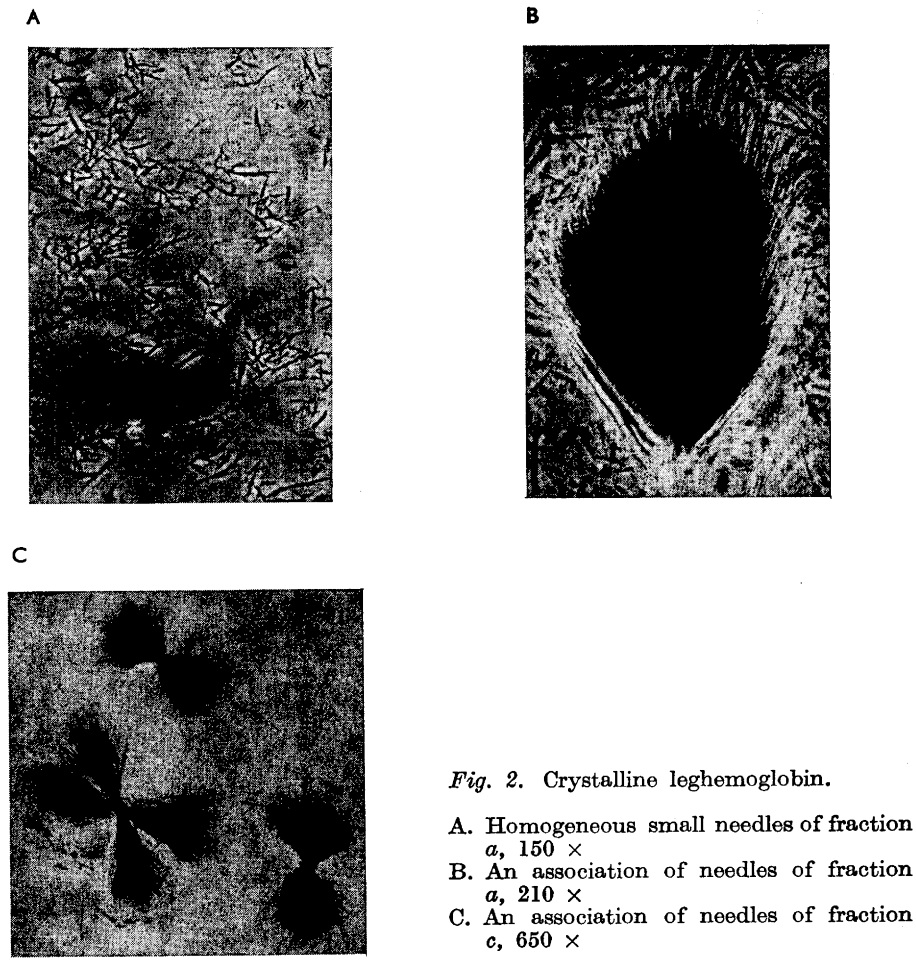

Fig. 2. Crystalline leghemoglobin.

A. Homogeneous small needles of fraction *a*, 150 ×
B. An association of needles of fraction *a*, 210 ×
C. An association of needles of fraction *c*, 650 ×

values. At pH 6.05, $\mu = 0.1$ (phosphate buffer), and at pH 9.0, $\mu = 0.1$ (veronal buffer), the two main crystallised fractions appeared to be homogeneous as determined by long run electrophoresis. Fig. 3 shows the electrophoretic patterns at pH 6.05. Similar patterns were obtained at pH 9.0 after 470 min. At both pH values the direction of migration was anodic. It can be seen that fraction *a* represents the electrophoretically slower component and fraction *c* the faster one.

During electrophoresis of fraction *b* at pH 6.05, only a very broad boundary with no distinct separate peaks was found, thereby indicating the presence of several different components. Electrophoresis of fraction *d* at pH 6.05 showed the presence of two components, one of which had the same mobility as fraction *c*, while the other had a slightly higher mobility.

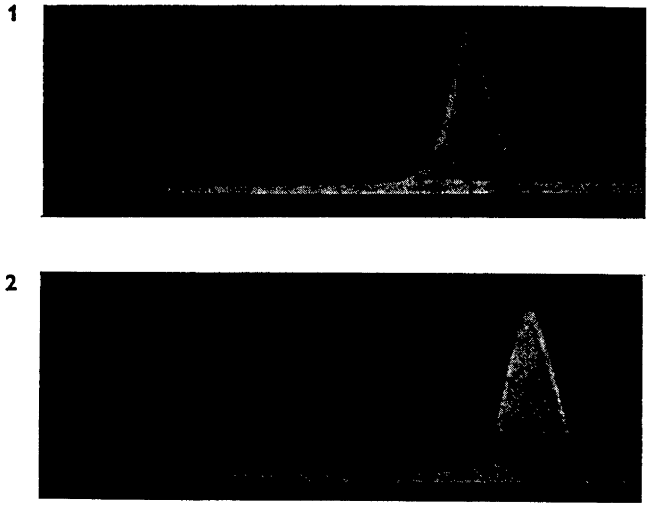

Fig. 3. Electrophoretic patterns of leghemoglobin; pH 6.05, $\mu = 0.1$ $F = 6.75$ V/cm, descending boundaries.
1) *a*, $t = 620$ min.
2) *c*, $t = 490$ min.

Iron content. Simultaneous iron and dry matter determinations were carried out on aliquots of the two main components. An average iron content of 0.32 % was found for the electrophoretically faster component (component *c*), while a value of 0.29 % was found for the slower component (component *a*).

Absorption spectra. The spectra of the components of leghemoglobin dissolved in acetate buffer were different from the spectra when the leghemoglobin was dissolved in phosphate buffer. The difference in the spectra was found to be caused by the formation of a green-colored reversible complex between leghemoglobin and acetate. Compared with the typical acid methemoglobin spectrum found for all of the different components (*a*—*d*), the spectrum of the acetate complex showed a typcial increase in absorption of the 625 mμ band accompanied by a slight shift in the absorption maximum toward the violet part of the spectrum. No quantitative differences were found in the methemoglobin spectra of the two main components (*a* and *c*). For fractions *b* and *d*, the maximum absorption in the region of 625 mμ was somewhat flattened, probably because of the presence of bile pigments. The sodium chloride extract of fraction *e* showed no maximum or minimum in the visible part of the spectrum, but showed a maximum corresponding to the Soret band in the ultraviolet region of the spectrum. The pyridine hemochromogens of the different components showed a typical peak at 557 mμ. In the case of fraction *e*, however, the ratio of absorbance at 630 mμ/557 mμ was 0.46, thereby indicating the presence of a high percentage of bile pigments or other pigments such as polyphenols.

DISCUSSION

It has been shown that leghemoglobin can be resolved into four components on a DEAE-cellulose column. The different fractions were eluted from the column in the order of increasing electrophoretic mobility so that the electrophoretically slower component was first eluted from the column. After the four bands were eluted, one band still remained on the top of the column. This evidently consisted of degradation products of leghemoglobin of different degrees of denaturation. This band was not totally eluted even if the ionic strength of the eluant was increased to $\mu = 3.0$. The band was not caused by a surface denaturation of the protein on top of the column. Rechromatographed material left no band on the top of the column after eluation of the other components.

The two electrophoretically homogeneous main components have been crystallised for the first time. The electrophoretically faster component was found to have an iron content of 0.32 %. This value compares favorably with the value of 0.34 % that was obtained previously when this component was isolated by free electrophoresis [15]. This component was earlier [15] assumed to represent pure leghemoglobin. The electrophoretically slower component, on the basis of its low iron content, was assumed to be an artefact consisting of pure leghemoglobin and an ironless protein. The present study does not support this assumption, but on the contrary shows that the electrophoretically slower component is a homogeneous individual protein.

Of the two smaller components that represent only a small percentage of the total chromoprotein, at least one represents a homogeneous individual protein (compound *d*). It is difficult to decide if component *b* contains an individual component or if it is a mixture of different oxidation products of fraction *a*. These two smaller components, however, are regularly found in different preparations of leghemoglobin. This might indicate that they represent real individual fractions, even though they contain some oxidized material (choleglobin). The existence of subfractions of proteins is known with other proteins. Crystalline myoglobin has been found to contain a main fraction and at least two subfractions in lower concentration [16]. The differences between these subfractions are very small, probably being caused by the substitution of one or more amino acids by others [17]. In a similar way it is possible that the smaller fractions of leghemoglobin might represent subfractions of the two main components.

Acknowledgments. The author wishes to express his thanks to Professor Hugo Theorell and coworkers at the Department of Biochemistry, Nobel Medical Institute, for valuable discussions and advice during the course of this work. The investigation has been supported by a grant from the *State Commission of Natural Sciences (Statens Naturvetenskapliga Kommission)* which is gratefully acknowledged.

Reduction to Standard Heat of Combustion of Bomb Calorimetric Data for Organic Bromine Compounds

LARS BJELLERUP

Department of Organic Chemistry, University of Lund, Lund, Sweden

The rigorous Washburn reduction of combustion calorimetric data for organic bromine compounds is discussed and applied to a recent high-precision moving-bomb method.

The general scheme for the reduction is treated in two respects: (i) The accuracy of the reduction is improved by presentation of experimental data for the auxiliary numerical quantities entering some of the more important corrections. For $As_2O_3-As_2O_5-HBr$ solutions of various composition, data are thus given for, (a) the density at 20 and 25°C, (b) the heat capacity at 25°C, and (c) the solubility of carbon dioxide at 20 and 25°C. (ii) The general scheme is modified to apply specifically to the above-mentioned bomb calorimetric method.

A combustion-bomb calorimetric method for organic bromine compounds has recently been described [1] by which results of an immediate precision [2] slightly better than 0.01 % can be obtained. To take full advantage of this high precision in order to obtain high-accuracy standard heats of combustion for organic bromine compounds, the application of rigorous Washburn corrections [3] to the calorimetric data obtained is required. The original Washburn reduction [3] treated data obtained on compounds containing only carbon, hydrogen and oxygen. Later, the Washburn reduction was extended to apply to nitrogen compounds of the formula $C_aH_bO_cN_d$ [4,5] and to sulfur compounds of the formula $C_aH_bO_cS_d$ [7–9]. In Ref. [9] a complete and rigorous treatment was given not only of those corrections usually described as the "Washburn corrections", but of all other corrections that must be applied to the original calorimetric data from combustion experiments with organic sulfur compounds in order to obtain the energy of the idealized combustion reaction, *i.e.* the standard heat of combustion of the compound investigated. The corrections were treated separately and presented in a systematic computation form in which the various terms were kept separate. This mode of presentation had several advantages. One was that many of the terms, either unchanged or modified, enter into reductions to standard heat of combustion of calorimetric data obtained on organic compounds containing other elements instead of sulfur. This was illustrated by discussion of the modifications to the general computation form for sulfur compounds that had to be made to apply it to

organic nitrogen, chlorine, bromine and iodine compounds, respectively. For chlorine and bromine compounds, however, no critical selection could be made of the numerical quantities that enter into some of the more important corrections, because reliable experimental data were not available for these quantities *cf.* Refs.[9] (p. 126—127), [10] (p. 217—218) Through recent work in this laboratory, data have been obtained for the more important of these auxiliary quantities. Part of this work has been reported elsewhere [11] and the remainder is given here.

More specifically, the aim of this paper is to describe the modifications and additions that have to be made to the treatment, given in Ref.[9] (p. 114—119), of the reduction to standard heat of combustion of bomb calorimetric data for bromine compounds, to make the reduction applicable to and commensurate in accuracy with the experimental method described in Ref.[1]

MODE OF PRESENTATION. NOTATION

For convenience the same presentation and notation as in Ref.[9] is used in this paper. On only a few points, which are clearly indicated in the text, is the treatment and the notation of this paper different from those of Ref.[9]

ACTUAL BOMB PROCESS AND IDEALIZED COMBUSTION REACTION

The actual process occurring in the bomb in combustion experiments with organic bromine compounds, using the method given in Ref.[1], was discussed in detail in the cited paper.

The idealized combustion reaction, to which the standard heat of combustion of the compound is referred, is defined by eqn. 1, where reactants and products are in their thermodynamic standard states [12].

$$C_aH_bO_cBr_d(\text{c or liq}) + (a + b/4 - c/2)\ O_2(g) \longrightarrow$$
$$\longrightarrow a\ CO_2(g) + b/2\ H_2O(\text{liq}) + d/2\ Br_2(\text{liq}) \qquad (1)$$

It should be noted that this idealized combustion reaction is the same as that given in Refs. [9] (p. 118), [10] (p. 211, eqn. 3)

CALCULATION OF THE CORRECTIONS

The calculation of the standard heat of combustion from the original calorimetric data was described in Ref.[1] * Some of the corrections were treated in detail and the rest, mainly those usually described as the Washburn corrections, are discussed here. These are presented as modifications to the various items of the computation form for bromine compounds given in Ref. [9] (p. 114—119) and make the reduction applicable to data obtained with the experimental method described in Ref.[1]

* There are two obvious misprints in eqn. 29 of Ref. [1]. The equation should read:

$$-\Delta Ec^\circ/M(\text{Compound}) = \frac{1}{m'}\left\{-\Delta E_{\text{I.B.P.}} - \left[-\Delta E(\text{As}) - \Delta E(\text{Oil}) - \Delta E(\text{Fuse}) - \Delta E(CO_2) - \right.\right.$$
$$\left.\left. - \Delta E(HNO_3) - \Delta E(\text{Au}) - \Delta E(\text{Pt})\right] - \Delta E(\text{HBr}) - \Delta E_\Sigma\right\}$$

Initial and final states

(1) $C_{a'}H_{b'}O_{c'}Br_{d'}$; (2)—(6) unchanged; (7) $C_{a''}H_{b''}O_{c''}Br_{d''}$; (8)—(12) unchanged; (13) $C_{a'''}H_{b'''}O_{c'''}Br_{d'''}$; (14)—(23) unchanged; (24)—(25) these two items are entirely formal. They can be deleted and the following treatment accordingly modified; (26)—(29b) unchanged;

(29c) g^i, the ratio of the vapor pressure of H_2O over the initial solution to that over pure water. Experimental data are not available for the lowering of the vapor pressure by arsenious oxide. From data [13 (p. 294)] on comparable compounds (boric acid) however, g^i for the 0.0625 M As_2O_3 solution, used in Ref.[1], can be estimated at 0.998;

(29d) $K^{*i}(O_2)$ the solubility of O_2 in the initial bomb solution in moles per liter of solution per atm O_2 pressure. Since no data on the solubility of O_2 in aqueous As_2O_3 solutions are available the values of the solubility in pure water, given in the table on p. 84 in Ref.[9], will be used as an approximation;

(30)—(34) unchanged;

(35) $n^i(O_2 \text{ diss.}) = K^{*i}(O_2)V^i(\text{soln.})[P^i(\text{gas.}) - P^i(H_2O \text{ vap.})]$. Since, in combustion experiments with bromine compounds, N_2 is present only as a small impurity in the O_2 and since it can be treated as though it were O_2, except for the formation of HNO_3, the notation $(O_2 + N_2)$ used in Ref.[9] has been changed to (O_2) in this paper;

(36) $n^i(O_2 \text{ tot.}) = n^i(\text{gas.}) - n^i(H_2O \text{ vap.}) + n^i(O_2 \text{ diss.})$.

The stoichiometry of the isothermal bomb process can be described by the following set of equations [1]:

$$C_aH_bO_cBr_d + [a + (b-d)/4 - c/2]\ O_2 \rightarrow \\ \rightarrow a\ CO_2 + (b-d)/2\ H_2O + d\ HBr \quad (2)$$

$$As_2O_3 + O_2 \rightarrow As_2O_5 \quad (3)$$

$$1/2\ N_2 + 5/4\ O_2 + 1/2\ H_2O \rightarrow HNO_3 \quad (4)$$

$$Au + 1/4\ O_2 + 2\ HBr \rightarrow HAuBr_2 + 1/2\ H_2O \quad (5)$$

$$Pt + 1/2\ O_2 + 4\ HBr \rightarrow H_2PtBr_4 + H_2O \quad (6)$$

The amounts of HNO_3, $HAuBr_2$ and H_2PtBr_4 present in the final bomb solution are listed in the items:

(37) $n^f(HNO_3)$; (37a) $n^f(HAuBr_2)$; (37b) $n^f(H_2PtBr_4)$. Under the conditions of the experimental technique described in Ref.[1] these quantities are small enough to permit decomposition, as outlined in Ref.[9 (p. 122–123)], of the corresponding substances under actual bomb conditions immediately after Step 12 without significant loss in accuracy. This means that all terms involving $n^f(HNO_3)$, $n^f(HAuBr_2)$ and $n^f(H_2PtBr_4)$, except in items 86a, 86b and 86c, can be left out from the subsequent discussion.

(38)—(38a) unchanged; (39) $n^f(HBr) = d$; (40) $n^f(H_2O \text{ liq.}) = n^i(H_2O \text{ tot.}) + (b-d)/2 - n^i(H_2O \text{ vap.})$; (41) $m^f(\text{soln.}) = 18.016n^f(H_2O \text{ liq.}) +$

$+ 197.82n^f(As_2O_3) + 229.82n^f(As_2O_5) + 80.924n^f(HBr)$; (42) wt.%$(As_2O_3)$ = $= 19\,782n^f(As_2O_3)/m^f(soln.)$; (42a) wt.%$(As_2O_5) = 22\,982n^f(As_2O_5)/m^f(soln.)$; (42b) wt.%$(HBr) = 8092n^f(HBr)/m^f(soln.)$; (43) delete;

(44) $\varrho^f(soln.) = \varrho(H_2O) + 0.00785$ wt.%$(As_2O_3) + 0.00808$ wt.%$(As_2O_5) +$ $+ 0.00710$wt.%(HBr) g/ml. This equation has been found to represent, within an uncertainty of $\pm$ 0.0001 g/ml, experimental data [14] on the densities at 20 and 25°C of seven aqueous As_2O_3—As_2O_5—HBr solutions of various compositions within the concentration ranges 0—1.23 wt.% of As_2O_3, 0—1.28 wt.% of As_2O_5 and 0—1.79 wt.% of HBr, which are the ranges of interest in the given method [1].

(45) unchanged; (46)—(47) delete; (48)—(49) unchanged;

(50) $n^f(CO_2$ tot.$) = a$;

(51) $K(CO_2) = 0.0383_5$ and 0.0336 mole/liter atm at 20 and 25°C, respectively. The solubility of CO_2 in aqueous As_2O_3—As_2O_5—HBr solutions, similar in composition to those obtained in combustion experiments, has been measured * by use of the method given in Ref.[7] (p. 85) It was found that the solubility of CO_2 was the same in each of three investigated solutions, which had the following compositions:
(A) 0.0633 M As_2O_3; (B) 0.0475 M As_2O_3—0.0158 M As_2O_5—0.0671 M HBr; (C) 0.0317 M As_2O_3—0.0316 M As_2O_5—0.122 M HBr. Therefore the solubility values given above can be used in all combustion experiments irrespective of the HBr concentration in the final bomb solution.

(52)—(55) unchanged;

(56) $n^f(O_2$ tot.$) = n^i(O_2$ tot.$) - [a + (b-d)/4-c/2] - n^f(As_2O_5)$;

(57) $K^f(O_2)$, the solubility of O_2 in the final bomb solution in moles per liter of solution at unit fugacity (in atm) of O_2 gas. Since no data on the solubility of O_2 in As_2O_3—As_2O_5—HBr solutions are available the values of the solubility in pure water, given in Ref.[9] (p. 88), will be used as an approximation;

(58) unchanged; (59) $K^{*f}(O_2) = D(O_2)K^f(O_2)$;

(60) $$n^f(O_2 \text{ diss.}) = \frac{0.082054(t_h + 273.2)K^{*f}(O_2)V^f(soln.)/V^f(gas.)}{1 + 0.082054(t_h + 273.2)K^{*f}(O_2)V^f(soln.)/V^f(gas.)} n^f(O_2 \text{ tot.});$$

(61) $n^f(O_2$ gas.$) = n^f(O_2$ tot.$) - n^f(O_2$ diss.$)$; (62) $n^f(gas.) = n^f(O_2$ gas.$) +$ $+ n^f(CO_2$ gas.$) + n^i(H_2O$ vap.$)$; (63)—(65) unchanged;

(66) g^f, the ratio of the vapor pressure of H_2O over the final solution to that over pure H_2O. Experimental data are not available for the vapor pressure lowering of water by the mixture of As_2O_3, As_2O_5 and HBr present in the final bomb solution. As in item 29c, however, g^f for an average final bomb solution, having the composition 0.02 M As_2O_3—0.04 M As_2O_5—0.16 M HBr, was estimated at 0.993 from data [13] (p. 293—294) on comparable compounds;

(67) $n^f(H_2O$ vap.$) =$
$g^f[C_0 + \{a(O_2) + [a(CO_2) - a(O_2)]x(CO_2)\}P^f(gas.)]\ V^f(gas.)/18.016.$

* The author's thanks are due to Dr. S. Sunner, Thermochemistry Laboratory, University of Lund, for making these measurements in connection with the work reported in Ref.[7]

Energy factors and calorimetric data

(68)—(69) unchanged. For the 0.0625 M As_2O_3 solution, used as initial bomb solution in Ref.[1], a value for $(\delta V/\delta T)_P$ of 2.57×10^{-7} liter/g deg was obtained from experimental density data. In the same way $(\delta V/\delta T)_P$ values were obtained for various As_2O_3—As_2O_5—HBr solutions having compositions corresponding to combustion experiments with samples containing from 4 to 7 mgatoms of bromine. In all cases the value of $(\delta V/\delta T)_P$ was found to be virtually the same and equal to 2.35×10^{-7} liter/g deg. Therefore the following values can be used at 25°C for all combustion experiments with the method of Ref.[1]: $(\delta E/\delta P)_T^i$(soln.) = −0.00186 cal/g atm and $(\delta E/\delta P)_T^f$(soln.) = −0.00170 cal/g atm;

(70) delete;

(71) $\Delta E'_{soln.}(O_2)$ and (71a) $\Delta E''_{soln.}(O_2)$, the change of internal energy in cal/mole at t_h for the solution of O_2 in the initial and final bomb solution, respectively. Since no data are available for the heat of solution of O_2 in aqueous As_2O_3 and As_2O_3—As_2O_5—HBr solutions, the corresponding values for pure water, given in Ref.[9] (p. 100), will be used as an approximation;

(71b) $\Delta E''_{soln.}(CO_2)$, the change of internal energy in cal/mole at t_h for the solution of CO_2 in the final bomb solution. From the solubility data given above in item 51 a value for $\Delta E_{soln.}(CO_2)$ of −4 000 cal/mole at 22.5°C was obtained for the pertinent final bomb solutions. By the use of a temperature coefficient of + 44 cal/mole deg [9] (p. 99),[15] the following values were obtained for $\Delta E''_{soln.}(CO_2)$: − 4 110 and −3 890 cal/mole at 20 and 25°C;

(71c) $\Delta E_{oxid.}$(HBr), the change of internal energy in cal/mole at t_h for the oxidation of HBr in Soln. I (under a pressure of 1 atm) with O_2 (in its standard state) to water and bromine (both in their standard states) according to the equation d(HBr·nH_2O)(in Soln. I) + d/4 O_2(g) → d(n + 1/2) H_2O(liq) + + d/2 Br_2(liq). No experimental values have been obtained for the energy of this reaction and since no data are available for the energy of formation of HBr in aqueous As_2O_3—As_2O_5 solutions, it is not possible to calculate values for $\Delta E_{oxid.}$(HBr). However, the values of $\Delta E^\circ_{oxid.}$(HBr), given in Ref.[9] (p. 119) can be used as a satisfactory approximation since the error introduced thereby is almost entirely cancelled by the introduction of the same error, but with opposite sign, in the $\Delta E_{decomp.}(As_2O_5)$ value given in the following item;

(71d) unchanged. From experimental data reported [11] for the heat of the reaction [As_2O_3 + 2 H_2O](aq) + 2 Br_2(liq) → [As_2O_5 + 4 HBr](aq) a value of $-(77.4 \pm 0.1) \times 10^3$ cal/mole was calculated for the change of internal energy, $\Delta E_{oxid.}$[As_2O_3(aq)], for the reaction As_2O_3(aq) + O_2(g) → As_2O_5(aq). In this calculation, it was assumed that the energy of formation of HBr in aqueous As_2O_3—As_2O_5 solution is the same as that in pure water [12]. Thus, by using $\Delta E_{oxid.}$[As_2O_3(aq)] for $-\Delta E_{decomp.}(As_2O_5)$, the error introduced by the approximation is almost entirely cancelled by an analogous error introduced in item 71c. The value 77.4×10^3 cal/mole will therefore be used for $\Delta E_{decomp.}(As_2O_5)$ at 25°C;

(71e) unchanged. No heat of dilution data for $As_2O_3 \cdot nH_2O$ are available and therefore the corresponding correction in item 92b has to be neglected.

Since C^i(Soln.) is rather small and since the difference in concentration of As_2O_3 in Soln. III and in the initial bomb solution is also small, the error introduced by neglecting the correction in item 92b certainly will be barely significant;

(72)—(73) unchanged;

(74) ε^o(Calor.), the energy equivalent of "the standard calorimetric system". As described in Ref.[1] the energy equivalent of the calorimetric system is divided in three parts: (i) ε^o(Calor.), the energy equivalent of the whole system as assembled for a fictive experiment with no contents in the bomb ("the standard calorimetric system"), (ii) $C_P(H_2O)m^i$(Cont.), the energy equivalent of an amount of water equal in mass to the contents of the bomb (*cf.* item 74a and 74b), and (iii) ε(Cont.), the energy equivalent of the contents of the bomb, by which is understood all removable matter in the interior of the bomb, including the platinum combustion crucible and its suspension ring (*cf.* item 75 and 76);

(74a) m^i(Cont.), the mass of the contents of the bomb, is obtained from the relation $m^i(\text{Cont.}) = 32.00n^i(O_2 \text{ tot.}) + V^i(\text{soln.})\varrho^i(\text{soln.}) + m(\text{Sub.}) + m(\text{Pt}) + m(\text{glass})$;

(74b) $\varepsilon(\text{Calor.}) = \varepsilon^o(\text{Calor.}) - C_P(H_2O)m^i(\text{Cont.})$;

(75) $\varepsilon^i(\text{Cont.}) = C_V(O_2)n^i(O_2 \text{ tot.}) + A^iV^i(\text{soln.})\varrho^i(\text{soln.}) + Bn^i(H_2O \text{ vap.}) + C'_Pm' + C''_Pm'' + C'''_Pm''' + 0.0317m(\text{Pt}) + 0.17m(\text{glass})$. For 0.0624 M As_2O_3 solution under a pressure of 1 atm the heat capacity, C_P, has been found [11] to be 0.988 cal/g deg at 25°C. This value will be used as an approximation for A^i. For C_P(Pt) the value 0.0317 cal/g deg at 25°C is given in Ref.[16]

(76) $\varepsilon^f(\text{Cont.}) = C_V(O_2)n^f(O_2 \text{ tot.}) + C_V(CO_2)n^f(CO_2 \text{ tot.}) + A^f[m^f(\text{soln.}) + 18n^f(H_2O \text{ vap.})] + Bn^f(H_2O \text{ vap.}) + 0.0317m(\text{Pt}) + 0.17\ m(\text{glass})$. As in the preceding item, C_P values for final bomb solutions under a pressure of 1 atm will be used as approximations for A^f. For As_2O_3—As_2O_5—HBr solutions having compositions corresponding to combustion experiments with samples containing 5 and 6 mgatoms of bromine the heat capacities, C_P, at 1 atm and 25°C have been found * to be 0.969 and 0.964 cal/g deg, respectively;

(77) unchanged. With the method of Ref.[1] $\Delta E_{ign.}$ is incorporated into the value of ε^o(Calor.). Therefore it is formally put equal to zero in the calculations;

(78)—(79) unchanged;

(80) $\Delta t_{ex.}$. This symbol was used in Ref.[1] for "the heat exchange correction" and it will be retained here. It represents the same quantity as does the symbol $\Delta t_{corr.}$ in Ref.[9]

Changes in internal energy

(81)—(83) unchanged; (84) $\Delta E^i_{soln.}(O_2) = \Delta E'_{soln.}(O_2)n^i(O_2 \text{ diss.})$; (85) unchanged; (86) $\Delta E_{I.B.P.} = \varepsilon(\text{Calor.})(t_i - t_f + \Delta t_{ex.}) + \varepsilon^i(\text{Cont.})(t_i - t_h) + \varepsilon^f(\text{Cont.})(t_h - t_f + \Delta t_{ex.}) + \Delta E_{ign.}$;

---

* The author's thanks are due to Dr. I. Wadsö, Thermochemistry Laboratory, University of Lund, for making the heat capacity measurements.

Step 12a. The HNO_3, $HAuBr_2$ and H_2PtBr_4 are decomposed under final bomb conditions according to the reactions $HNO_3(aq) \rightarrow 1/2\ N_2(g) + 5/4\ O_2(g) + 1/2\ H_2O(liq)$, $HAuBr_2(aq) + 1/2\ H_2O(liq.) \rightarrow Au(c) + 1/4\ O_2(g) + 2HBr(aq)$ and $H_2PtBr_4(aq) + H_2O(liq) \rightarrow Pt(c) + 1/2\ O_2(g) + 4\ HBr(aq)$. As discussed in Ref.[1] the following values of ΔE, at 25°C, can be used for these reactions: $\Delta E_{\text{decomp.}}(HNO_3) = 14.18 \times 10^3$, $\Delta E_{\text{decomp.}}(HAuBr_2) = 8 \times 10^3$ and $\Delta E_{\text{decomp.}}(H_2PtBr_4) = 43.4 \times 10^3$ cal/mole. The change of energy associated with this step is the sum of the following three items:

(86a) $\Delta E^{\text{f}}_{\text{decomp.}}(HNO_3) = \Delta E_{\text{decomp.}}(HNO_3) n^{\text{f}}(HNO_3)$;

(86b) $\Delta E^{\text{f}}_{\text{decomp.}}(HAuBr_2) = \Delta E_{\text{decomp.}}(HAuBr_2) n^{\text{f}}(HAuBr_2)$;

(86c) $\Delta E^{\text{f}}_{\text{decomp.}}(H_2PtBr_4) = \Delta E_{\text{decomp.}}(H_2PtBr_4) n^{\text{f}}(H_2PtBr_4)$;

(87) unchanged; (88) $\Delta E^{\text{f}}_{\text{soln.}}(O_2) = -\Delta E''_{\text{soln.}}(O_2) n^{\text{f}}(O_2\ \text{diss.})$; (89) unchanged; (90)—(91b) delete;

Step 19. The HBr is oxidized with O_2 (in its standard state) according to the reaction d $(HBr \cdot nH_2O)$(in Soln. I) + d/4 $O_2(g) \rightarrow$ d(n + 1/2) $H_2O(liq)$ + + d/2 $Br_2(liq)$. The water and the bromine are brought to their standard states.

(92) $\Delta E^{\text{f}}_{\text{oxid.}}(HBr) = \Delta E_{\text{oxid.}}(HBr) n^{\text{f}}(HBr)$;

Step 19a. The As_2O_5 in Soln. II is decomposed to As_2O_3 in Soln. III and O_2 gas in its standard state.

(92a) $\Delta E^{\text{f}}_{\text{decomp.}}(As_2O_5) = \Delta E_{\text{decomp.}}(As_2O_5) n^{\text{f}}(As_2O_5)$;

Step 19b. Water (in its standard state) is removed from Soln. III to bring the concentration of As_2O_3 to C^{i}(soln.).

(92b) $\Delta E^{\text{f}}_{\text{diln.}}(As_2O_3) = \Delta E_{\text{diln.}}(As_2O_3) n^{\text{i}}(As_2O_3)$;

(93) $\Delta E^{\text{f}}(\text{gas.})]^{\text{o f}}_{P^{\text{f}}(\text{gas.})} = -(\delta E/\delta P)_T(O_2\ \text{gas.})\{1 + 1.69x(CO_2)[1 + x(CO_2)]\} P^{\text{f}}(\text{gas.}) n^{\text{f}}(\text{gas.})$;

(94)—(98) unchanged;

(99) $\Delta Ec^{\circ}/M(\text{Compound}) = n'\Delta Ec^{\circ}(\text{Compound})/m'$;

(100) $\Delta Ec^{\circ}(\text{Compound}) = M'\Delta Ec^{\circ}/M(\text{Compound})/1\ 000$;

By definition of the quantities $\Delta E_{\text{B}}/M(\text{Compound})$ and ΔE_{Σ} as follows: $\Delta E_{\text{B}}/M(\text{Compound}) =$ [items 86+86a+86b+86c+87+92+92a—96—97]$/m'$ $\Delta E_{\Sigma} =$ items 81 + 82 + 83 + 84 + 85 + 88 + 89 + 92b + 93 + 94, item 99 becomes

(99) $\Delta Ec^{\circ}/M(\text{Compound}) = \Delta E_{\text{B}}/M(\text{Compound}) + \Delta E_{\Sigma}/m'$. The reason for this operation is given in Ref.[9] (p. 102–103)

It is seen that the symbols $\Delta Ec^{\circ}/M(\text{Compound})$, $\Delta E_{\text{I.B.P.}}$ and ΔE_{Σ} denote the same quantities in this paper as in Ref.[1], and the symbols $\Delta E^{\text{f}}_{\text{decomp.}}(HNO_3)$, $\Delta E^{\text{f}}_{\text{decomp.}}(HAuBr_2)$, $\Delta E^{\text{f}}_{\text{decomp.}}(H_2PtBr_4)$, $\Delta E^{\text{f}}_{\text{soln.}}(CO_2)$, $\Delta E^{\text{f}}_{\text{oxid.}}(HBr)$, $\Delta E^{\text{f}}_{\text{decomp.}}(As_2O_5)$, $n''\Delta Ec^{\circ}$(Auxiliary material) and $n'''\Delta Ec^{\circ}$(Fuse) of this paper correspond with the symbols $-\Delta E(HNO_3)$, $-\Delta E(Au)$, $-\Delta E(Pt)$, $-\Delta E(CO_2)$, $+\Delta E(HBr)$, $-\Delta E(As)$, $+\Delta E(Oil)$ and $+\Delta E(Fuse)$, respectively, in Ref.[1]

The numerical ΔE_{Σ} values reported in Ref.[1] were calculated according to the scheme given in this paper.

Hydrolysis of Phosphopeptides

I. Acid Hydrolysis of O-Phosphoryl-DL-serylglycine and Glycyl-(O-phosphoryl)-DL-serine. Sequence Inversion in Dilute Hydrochloric Acid

GEORG FÖLSCH, OLOF MELLANDER and LARS STRID

Department of Medical Biochemistry, University of Göteborg, Sweden

The hydrolysis of SerP-Gly * and Gly-SerP in 2 N hydrochloric acid at 100° and in conc. hydrochloric acid at 37° was studied by column chromatographic separation of the hydrolysis products on an anion exchange resin. In 2 N hydrochloric acid sequence inversion occurs with both phosphopeptides. Gly-SerP is hydrolysed faster than SerP-Gly in both conc. and 2 N acid and hydrolysis takes place almost entirely at the peptide bond. SerP-Gly is largely dephosphorylated to serylglycine.

Partial acid hydrolysis is the general method used for breaking down peptide chains to di- and tripeptide fragments. In the large amount of work done during the last deecade on the determination of amino acid sequences in polypeptides and proteins, the conditions of hydrolysis, *e.g.* temperature, time and acid strength, have been varied widely. It is known, however, that these variations can have a marked effect on the results of hydrolysis [1–4]. In the partial hydrolysis of phosphoproteins and phosphorylated polypeptides, different conditions of hydrolysis may cause still greater differences in results, since in these materials both peptide and phosphate ester bonds may be hydrolysed.

Several investigations have been reported on amino acid sequences near O-phosphorylserine residues in phosphoproteins such as casein, phosvitin, ovalbumin and pepsin [5–8]. A large amount of work has also been done on the determination of the structure around the "*active centers*" of enzymes such as trypsin, chymotrypsin, horse-liver ali esterase and phosphoglucomutase, using the technique of deactivation of the enzyme by a phosphorylating reagent, partial acid hydrolysis of the product and separation and determina-

* The following abbreviations are used here: SerP, O-phosphorylserine; SerP-Gly, O-phosphorylserylglycine; Gly-SerP, glycyl-(O-phosphoryl)-serine.

tion of the structure of the resulting peptides containing O-phosphorylserine [4,9–14].

In these investigations different concentrations of hydrochloric acid have been used for the partial hydrolysis, and it therefore appeared essential to know more about the hydrolysis of phosphorylated peptides, especially in view of the observations of Sanger and Thompson [2] and Schaffer *et al* [4], that sequence inversion may take place under certain conditions. Furthermore, a knowledge of the hydrolytic behaviour of phosphorylated peptides might assist an understanding of the action of proteolytic enzymes and phosphatases [15] on them. In the present investigation a study was therefore made of the hydrolysis of the two model peptides SerP-Gly and Gly-SerP in conc. hydrochloric acid at 37° and in 2 N hydrochloric acid at 100°.

EXPERIMENTAL

Materials

The *O-phosphoryl-*DL*-serylglycine* (SerP-Gly) and *glycyl-(O-phosphoryl)-*DL*-serine* (Gly-SerP) were samples of materials, of which the syntheses and analytical data have been described previously [16,17]. Their purity was further demonstrated by the column chromatographic results described below (Fig. 1, zero time hydrolysis).

Hydrolysis

A. In 2 N HCl: About 10 mg of phosphopeptide was dissolved in 1 ml of 2.02 N HCl (3 × glass-distilled azeotropic acid, diluted with distilled water), and 0.1 ml portions of the solution were hydrolysed in sealed tubes of 4 × 0.6 cm. Hydrolyses for 0.5 h and 1.0 h were done in boiling water, those for longer times in an oven at 100° ± 1°. After hydrolysis the tubes were immediately placed in an ice-box at −20° and kept at this temperature until just before the chromatographic analysis, when they were opened and diluted with 2 ml of water.

B. In conc. HCl: The hydrolyses in conc. HCl (Merck p.a.) were done essentially in the same way, but in an air thermostat at 37 ± 0.5°C. The sealed tubes containing the hydrolysates were kept at −20° until just before chromatography. The tube was then opened and the hydrochloric acid was removed *in vacuo* over NaOH. The dry residue was dissolved in 2 ml of water.

Chromatography

The method for the separation of phosphorylated peptides that has been described in a previous paper [18] from this laboratory was used. As only three phosphorus-containing compounds, SerP, SerP-Gly and Gly-SerP had to be separated, it was possible to decrease the height of the column and increase the solvent gradient. A column of 1.2 cm diameter was packed to a height of 20 cm with Dowex 1-X2 resin in formate form. The hydrolysate was applied and the column was eluted with 0.1 M formic acid. After 24 ml, gradient elution was started using 1.0 M pyridinium formate, pH 4.5, in the reservoir. The mixing chamber volume was 550 ml.

Fractions of 2 ml were collected in 180 × 18 mm calibrated test tubes. The flow rate was 24 ml/h, and a complete separation took 10 h. The fractions were analysed according to Moore and Stein [19] by addition of 1 ml of ninhydrin solution, dilution with 10 ml of ethanol-water (1:1) and measurement of the optical density at 575 mμ using a Bausch & Lomb monochromatic colorimeter. The peaks found were identified by their chromatographic behaviour (*cf.* Fig. 1) and by N-terminal analysis (see below). The results are shown in Tables 1 and 2.

Ninhydrin colour values. A value of 1.03 has been reported [7] for O-phosphorylserine. The colour values for SerP-Gly and Gly-SerP were determined as follows. Samples of

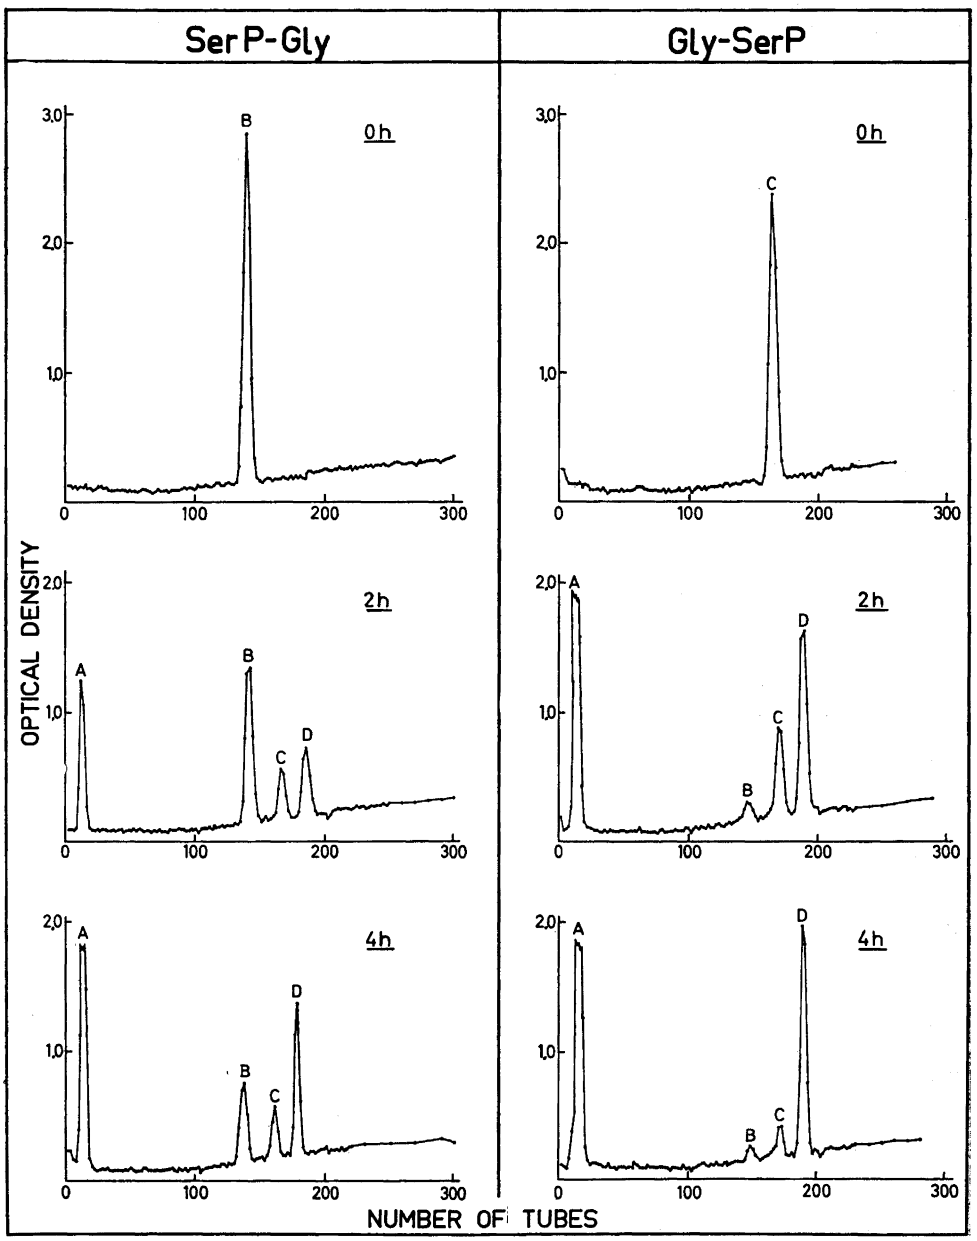

Fig. 1. Column chromatographic separation of the products of hydrolysis of SerP-Gly and Gly-SerP in 2 N HCl, 100°. Peak A contains the unphosphorylated amino acids and peptides; B is SerP-Gly; C is Gly-SerP and D is SerP.

these two compounds and of leucine were dried for 3 h at 70° *in vacuo* over P_2O_5 and 3—5 mg of each compound was dissolved in 50 ml of 0.2 M sodium citrate buffer, pH 5.0. One ml of these solutions was used for the ninhydrin reaction, and the optical density was measured with a Beckman B spectrophotometer at 570 mμ. The colour values obtained were: SerP-Gly 1.00 ± 0.02; Gly-SerP 0.98 ± 0.03.

Identification of peak B obtained from Gly-SerP as SerP-Gly by N-terminal analysis *. Fifty mg of Gly-SerP was hydrolysed for 2 h at 100° in 5 ml of 2 N HCl. After evaporation over NaOH *in vacuo* the hydrolysate was chromatographed as described above. Fractions of 2 ml were collected and 0.2 ml of each was used for ninhydrin reaction. The fractions containing peaks A and B (Fig. 1) were evaporated to dryness *in vacuo* (peak A was used for the complete hydrolysis experiment described below).

Peak B, from its position in the chromatogram was suspected to be SerP-Gly. Its N-terminal amino acid was identified by the DNP-method of Sanger as described by Janz *et al.*[13] The sample, weighing about 3 mg, was shaken for 3 h at 40° with 2 ml of 66 % ethanol containing 1 % $NaHCO_3$ and 1 % 1-fluoro-2,4-dinitrobenzene. After evaporation to dryness, the mixture was dissolved in 4 ml of water, acidified and extracted with 3 × 2 ml of ether to remove fluorodinitrobenzene and dinitrophenol. The DNP derivative of B was extracted from the water phase with 3 × 2 ml of methyl acetate and the combined extract was evporated to dryness and hydrolysed for 2 h at 100° with 2 ml of 2 N HCl. The hydrolysate was diluted with 1 ml of water and the DNP-amino acid was taken up in 3 × 2 ml of methyl acetate and identified as N-dinitrophenyl-(O-phosphoryl)-DL-serine (DNP-SerP) by paper chromatography in the solvent systems *tert*-amyl alcohol — diphthalate buffer and 1.5 M phosphate buffer, pH 6.0. Synthetic DNP-SerP prepared ** from SerP and fluorodinitrobenzene was used as reference, it had an R_F value of about 0.7 in the phosphate buffer. In the *tert*-amyl alcohol — diphthalate system, this compound had moved only 2 cm after 100 h running.

Authentic SerP-Gly, treated as peak B, gave exactly the same results.

Complete hydrolysis of peak A obtained from SerP-Gly and Gly-SerP. To determine the amount of peptide in the dephosphorylated fraction obtained from Gly-SerP, peak A from the above chromatogram was dissolved in 3 ml of water. Two samples of 1 ml were evaporated to dryness, and one of them was hydrolysed for 20 h at 110° in 0.1 ml of 6 N HCl and again evaporated to dryness. The two samples were then dissolved separately in 0.35 M sodium citrate buffer (5 ml), pH 5.28, and 2 ml of each solution was used for reaction with ninhydrin solution. The ninhydrin colour yields were:

Unhydrolysed peak A from Gly-SerP	1.88
Hydrolysed » » » »	1.96

This increase of 4 % in the ninhydrin colour is equal to about 7 % by weight of peptide in peak A.

From a 2 h hydrolysate of SerP-Gly, peak A when isolated and treated as above, gave the following ninhydrin colour yields:

Unhydrolysed peak A from SerP-Gly	0.913
Hydrolysed » » » »	1.177

Complete hydrolysis of this fraction from SerP-Gly gave an increase of 30 % in ninhydrin colour, indicating that the fraction contained about 45 % by weight of dephosphorylated peptide.

RESULTS

The rates of hydrolysis of SerP-Gly and Gly-SerP in 2 N HCl at 100° and in conc. HCl at 37° are shown in Fig. 2 as measured by the ninhydrin colour

* Schaffer *et al.*[4], by a similar procedure have demonstrated the formation of Gly-SerP from SerP-Gly in 2N HCl.

** The preparation of DNP-SerP was made by Bo Öberg in this laboratory.

Table 2. Hydrolysis of 1 mg of phosphopeptide in 0.1 ml of conc. HCl at 37°

Days	Ninhydrin colour							
	1.0 mg SerPGly				1.1 mg GlySerP			
	Unphospho-rylated	SerPGly	GlySerP	SerP	Unphospho-rylated	SerPGly	GlySerP	SerP
0	0	7.19	0	0	0	0	7.01	0
1	0.67	6.32	0	0.51	2.72	0	4.92	2.46
3	1.62	5.12	0	1.13	5.10	0	2.13	4.64
7	2.85	3.68	0	1.89	7.92	0	0.55	6.45

yield from chromatographic fractions of hydrolysates. Fig. 2 also shows the formation of a mixture of unphosphorylated amino acids and peptides (peak A), SerP (peak D) and the formation of phosphopeptide with an *inversed* amino acid sequence during hydrolysis in 2 N HCl.

The hydrolysis of Gly-SerP in 2 N HCl is appreciably faster than that of SerP-Gly, as can be seen from Fig. 2 and the following table.

Time	0	0.5	1	2	4	6	20 h
SerP-Gly	0	(27.9)	29.5	49.1	75.9 %	88	100 % hydrolysis
Gly-SerP	0	30.6	35.0	69.4	90.3 %	—	— »

In spite of the faster hydrolysis of Gly-SerP the amount of this compound formed by sequence inversion of SerP-Gly, is more than twice as large as the amount of SerP-Gly formed from Gly-SerP.

Fig. 2 also shows, that much more SerP is formed from Gly-SerP than from SerP-Gly, and that comparatively more ninhydrin colour is obtained from the dephosphorylated peaks (A) from Gly-SerP than from SerP-Gly. Since all the compounds concerned have ninhydrin colour values of 100 ± 0.05 (relative to leucine), calculation shows that peak A from Gly-SerP contains almost only the free amino acids (glycine and serine) while peak A from SerP-Gly contains large amount of dephosphorylated peptide (serylglycine) *. This was confirmed by isolation of peak A, followed by complete hydrolysis. These results show that Gly-SerP is hydrolysed mainly at the peptide bond yielding glycine and SerP, while SerP-Gly, apart from some hydrolysis at the peptide bond, to a large extent releases its phosphoric acid residue yielding serylglycine.

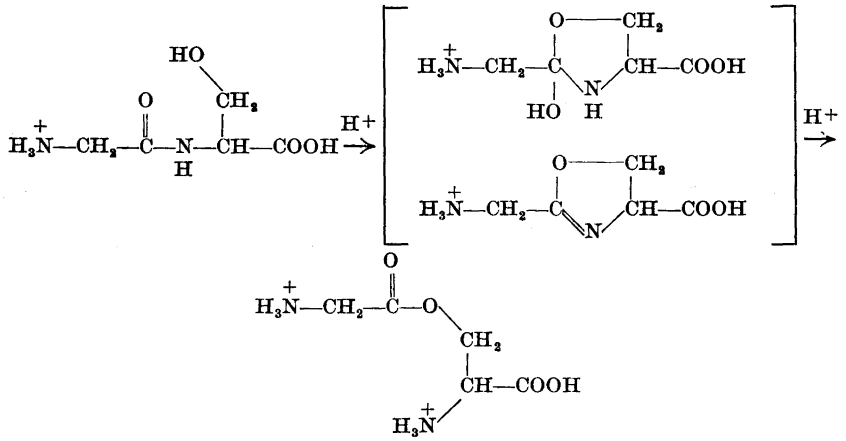
In conc. HCl, Gly-SerP is hydrolysed much faster than SerP-Gly:

Time	0	1	3	7	days
SerP-Gly	0	12.2	28.9	48.9	% hydrolysis
Gly-SerP	0	29.7	69.2	92.2	% »

Here also Gly-SerP is hydrolysed mainly at the peptide bond, while SerP-Gly affords a large amount of dephosphorylated peptide, as can be calculated from the colour yield. No sequence inversion was observed in conc. HCl.

DISCUSSION

Peptide bonds involving the amino groups of serine and threonine residues with their β-hydroxyl groups intact are known to be unusually labile to acid hydrolysis [1,20]. This lability is a consequence of an N→O acyl shift *via* an oxazolin [21] or, more likely, a hemiacetal [22] derivative:



* Glycylserine may be formed by sequence inversion, but should be hydrolysed very easily, see discussion.

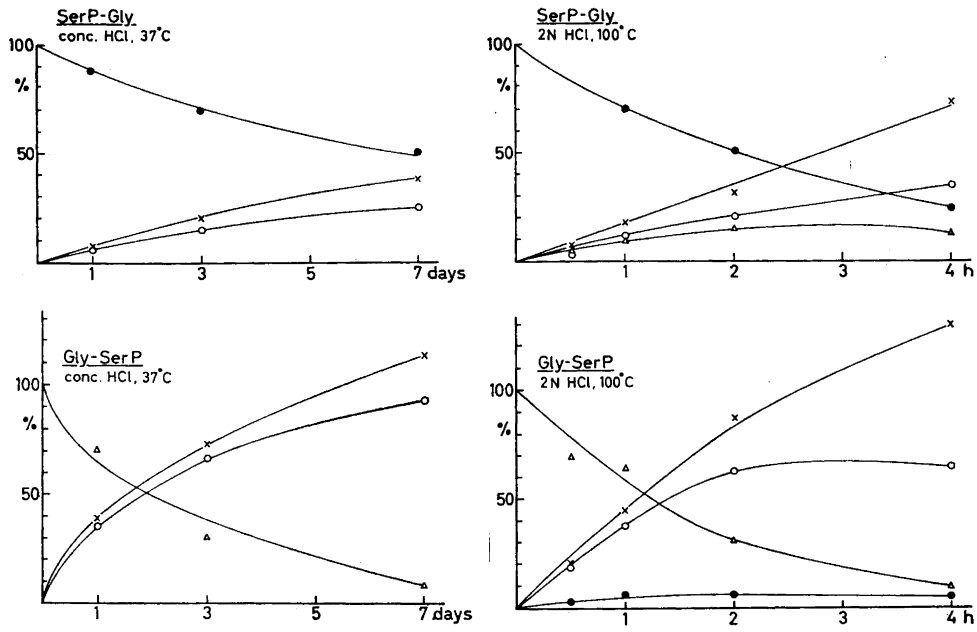


Fig. 2. Rates of hydrolysis of SerP-Gly and Gly-SerP, of formation of dephosphorylated amino acids and peptides and of SerP, and the formation of phosphopeptide with an inversed amino acid sequence. Measured as changes in ninhydrin colour; zero time colour = 100 %.

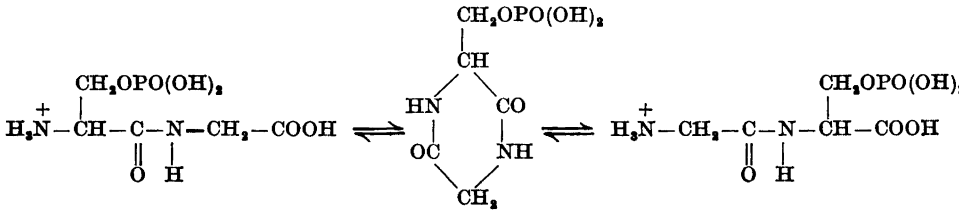
● — ● — ● SerP-Gly
△ — △ — △ Gly-SerP
○ — ○ — ○ SerP
× — × — × Unphosphorylated amino acids and peptides.

In SerP-Gly and Gly-SerP, the hydroxyl groups are esterified with phosphoric acid and, therefore, not available for this reaction. As Gly-SerP is hydrolysed almost exclusively to glycine and SerP, the acyl shift mechanism is not responsible for the higher sensitivity of this phosphopeptide to acid hydrolysis.

Martin has recently discussed the mechanism of the acid hydrolysis of dipeptides in aqueous solution, and the effects of the different side chains of the α-amino acids on the rate of hydrolysis [23]. According to Martin, the mechanism is the same as for amides in general. In the first, fast step, a proton is reversibly added to the peptide bond nitrogen atom, forming an amide cation. In the second, rate-controlling step, a water molecule is added to the carbonyl carbon atom in a bimolecular substitution. A consequence of this mechanism is, that substituents at the β-carbon atom of an N-terminal amino acid have only steric effects on the rate of hydrolysis, while substituents in the C-terminal amino acids produce mainly polar effects. According to this, Gly-SerP would be expected to be hydrolysed at the peptide bond appreciably faster

than SerP-Gly, as in fact was found experimentally. Firstly, the steric hindrance of the side chain of O-phosphorylserine should in the N-terminal position, as in SerP-Gly, keep water molecules from coming in contact with the carbonyl carbon atom of the intermediate amide cation to a much greater extent than the two hydrogen atoms of glycine in Gly-SerP; this effect is shown by the side chain of serine (Ref.[23], Table 3). Secondly, the electronattracting phosphate group of O-phosphorylserine in the C-terminal position as in Gly-SerP should increase the rate of hydrolysis as is found in the case of C-terminal dicarboxylic acid [23].

Schaffer *et al.* have shown [4] that SerP-Gly, during hydrolysis in 2 N HCl, undergoes sequence inversion to Gly-SerP to an appreciable extent. Thompson and Thompson have suggested [3] that this inversion, which is supposed to go *via* the diketopiperazine [1], leads to the more stable peptide sequence as in the conversion of glycylvaline to valylglycine [2]. However, the experimental results obtained here show, that SerP-Gly is at least as stable as Gly-SerP in hydrochloric acid, and that Gly-SerP also undergoes sequence inversion:



If the mechanism for the hydrolysis of dipeptides is also applicable to diketopiperazines, the intermediate above should show preferential ring-opening to give SerP-Gly. As in fact more Gly-SerP is formed by sequence inversion than SerP-Gly, the above diketopiperazine seems to be formed faster from SerP-Gly than from Gly-SerP.

The work was supported by grants from the *Swedish Medical Research Council* to Professor Olof Mellander.

Heat capacities of three nickel selenides with compositions $Ni_{0.95}Se$, $Ni_{0.875}Se$ and $Ni_{0.80}Se$, representing the $Ni_{1-x}Se$-phase with NiAs-like structure and cation vacancies, were measured in the range 5 to 350°K. No transitions or other heat-capacity anomalies were observed, except for slight upward trends in the heat-capacity values for $Ni_{0.875}Se$ and $Ni_{0.80}Se$ compared to those for $Ni_{0.95}Se$ above 250°K, which might possibly indicate the beginning of transitions. Values for the enthalpy function and entropy were calculated and tabulated for several temperatures. At 298.15°K the entropies are 8.754 eu for $Ni_{0.4872}Se_{0.5128}$ (*i. e.* $Ni_{0.95}Se$), 8.608 eu for $Ni_{0.4667}Se_{0.5333}$ (*i. e.* $Ni_{0.875}Se$ or Ni_7Se_8) and 8.506 eu for $Ni_{0.4444}Se_{0.5556}$ (*i. e.* $Ni_{0.80}Se$ or Ni_4Se_5).

The $Ni_{1-x}Se$-phase offers interesting possibilities for studying an order-disorder process as a function of composition and of temperature from a combined structural and thermodynamic point of view. It was shown by Alsén[1] that NiSe has a hexagonal structure of the NiAs-type in which each nickel atom is surrounded by six selenium atoms at the corners of a slightly irregular octahedron, or trigonal antiprism. These antiprisms are stacked on top of each other in the c-direction so that the nickel atoms form endless chains in this direction.

More recent work has shown[2] that the $Ni_{1-x}Se$-phase has a composition varying between $Ni_{0.98}Se$ and $Ni_{0.77}Se$ and that the stoichiometric 1:1 ratio is not included, at least not in the case of samples heat-treated at 550 and 400°C when examined by X-ray diffraction at room temperature. The structure is hexagonal only in the nickel-rich range, and additional, weak reflections are observed when $1-x$ is less than 0.91, indicating the presence of superstructure. For a sample with composition $Ni_{0.87}Se$ the superstructure was found to be orthorhombic with $A = a\sqrt{3}$, $B = 3a$ and $C = 3c$, where a and c are the dimen-

sions of the hexagonal unit. With further increase in the number of vacant Ni-positions below $Ni_{0.83}Se$, the basic structure changes from hexagonal to monoclinic, and at the composition $Ni_{0.80}Se$ the size of the unit cell is $A' = a\sqrt{3}$, $B' = a$, $C' = 2c$ and $\beta = 90.52°$.

A determination of the atomic arrangement in $Ni_{0.80}Se$ has ascertained[3] that there is a considerable degree of order among the vacancies after the 20 % missing nickel atoms. These vacancies are distributed in an ordered way in every other layer of metal atoms normal to the *c*-axis, while apparently almost no vacancies exist in the rest of the layers. Slight movements of nickel and selenium atoms in the vicinity of the vacancies are observed, but in general, the structure is little affected. The contraction in volume by the 5.32 % decrease in mass per unit cell is 5.26 %.

The $Ni_{1-x}Se$-phase shows metallic behavior, with a weak, almost temperature-independent paramagnetism. Thus its heat capacity behavior is expected to resemble that of the δ-phase in the nickel-tellurium system[4] which shows no magnetic transitions and rather small variations in heat capacity as a function of composition.

The nickel selenides are rather different from the iron selenides[5] in that no clear-cut separation into two-phase regions occurs within the $Ni_{1-x}Se$-phase. Therefore, it was thought of interest to carry out heat-capacity measurements on the nickel selenides in order to ascertain if the apparent absence of exsolution into phases of slightly different compositions is caused by failure of the nickel selenides to reach equilibrium (in contrast to what seems to be the case for the iron selenides), or by too small an entropy increment between ordered and slightly disordered states to cause such separation.

This requires studying a thermodynamic cycle involving free energy measurements as well as enthalpy and entropy measurements. The enthalpy of formation of the $Ni_{1-x}Se$-phase has been determined[6] at 775°C, and high-temperature heat-capacity measurements are presently in progress to study entropy changes accompanying the order-disorder process.

In this paper are reported the results of low-temperature heat-capacity measurements carried out on three single-phase samples within the homogeneity range of the $Ni_{1-x}Se$-phase, having compositions $Ni_{0.95}Se$, $Ni_{0.875}Se$ and $Ni_{0.80}Se$.

EXPERIMENTAL

A. *Preparation of the samples.* The nickel selenides were prepared by fusion of high-purity nickel and selenium. "Nickel oxide, low in cobalt and iron" from the British Drug Houses Ltd. was reduced with dry, purified hydrogen gas at 500°C for 5 h. The resulting, malleable nickel was broken into pieces and reduced again, this time at 1 000°C for 4 h. Spectrographic analysis showed the presence of the following impurities (in ppm): Al(100), Ba(1), Ca(10), Co(10), Cr(1), Cu(1), Fe(10), Mg(50), Mn(1), Si(50).

The high-purity selenium was a gift from Bolidens Gruvaktiebolag. According to their analysis it contained these impurities (in ppm): Cl(2), Fe(0.8), K(0.3), Na(0.4), non-volatile matter (12). The following elements were not detected (the numbers indicate the sensitivity limit in ppm): Ag(0.03), Al(0.3), As(1), Bi(0.1), Ca(1), Cr(0.3), Cu(0.1), Hg(0.5), Mg(0.3), Mn(0.1), Ni(0.3), Pb(0.3), S(5), Si(1), Sn(0.3), Te(1), Zn(1).

Accurately-weighed quantities of nickel and selenium corresponding to the compositions $Ni_{0.95}Se$, $Ni_{0.875}Se$ and $Ni_{0.80}Se$ were heated in evacuated and sealed vitreous silica tubes. The samples were fused for 2 h at 1 050, 1 000 and 950°C, respectively. They were

then cooled, fragmented and annealed at 550°C for seven days and cooled over a period of two more days. X-Ray powder photographs of the samples were identical to those obtained earlier[3].

B. *Cryostat and calorimeter.* The Mark I cryostat and technique employed in low-temperature adiabatic calorimetry will be described elsewhere[7]. Two different calorimeters were used, W-7 with a capacity of 40 cm³ was used for the $Ni_{0.95}Se$ and $Ni_{0.875}Se$ samples, while calorimeter W-17 with a capacity of 60 cm³ was used for the $Ni_{0.80}Se$ sample. Both calorimeters are gold-plated and have four and two vanes, respectively. Separate series of measurements were carried out to determine the heat capacities of the empty calorimeters, using the same thermometer and heater and exactly the same amount of indium-tin solder for sealing the calorimeter and Apiezon-T grease for thermal contact with the thermometer and heater. The heat capacity of the empty calorimeter W-7 represented from 17 to 25 % of the total heat capacity, and that of calorimeter W-17 from 16 to 21 %.

Temperatures were measured with a capsule-type platinum resistance thermometer (laboratory designation A-3) within an axial well in the calorimeter. The thermometer was calibrated by the National Bureau of Standards, and the temperatures were judged to correspond with the thermodynamic temperature scale within 0.1°K from 5 to 10°K, 0.03°K from 10 to 90°K and 0.04°K from 90 to 350°K. Precision is considerably better, and the temperature increments are probably accurate to 0.001°K after corrections for quasi-adiabatic drift.

The thermometer resistance and power input were measured with a calibrated White double-potentiometer, calibrated resistances and a calibrated standard cell. An electric timer, operated by a calibrated tuning fork and amplifier, was automatically started at the beginning of the heating period and stopped at the end.

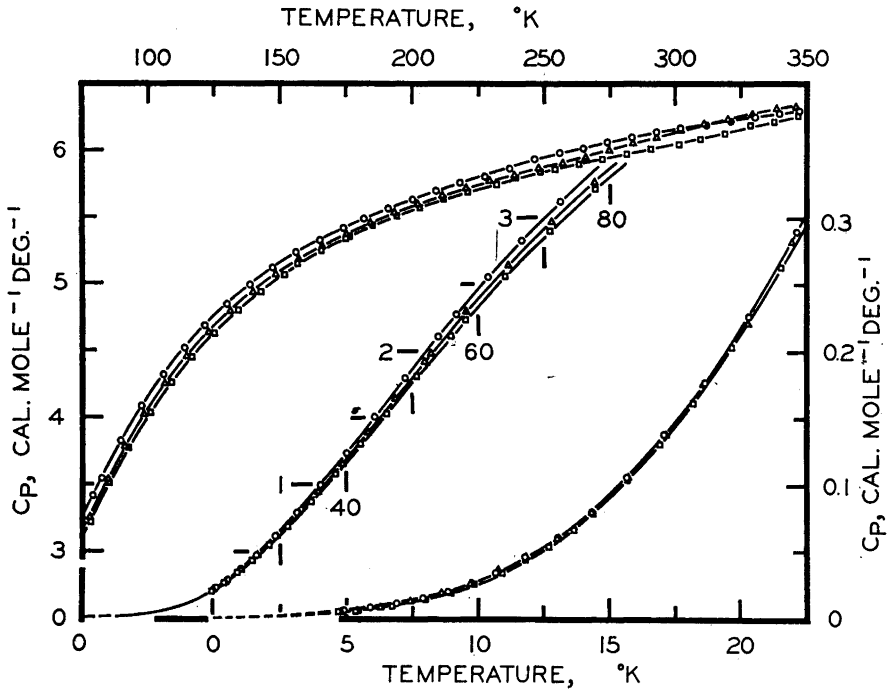

Fig. 1. Heat capacities of nickel selenides on a gram formula weight basis: O represents $Ni_{0.4872}Se_{0.5128}$, △ represents $Ni_{0.4667}Se_{0.5333}$ and □ represents $Ni_{0.4444}Se_{0.5556}$.

The calorimeter was loaded with sample and evacuated, and helium added at 5 cm Hg pressure at about 25°C to provide thermal contact between calorimeter and sample. It was then placed in the cryostat and cooled. The mass of sample used was 162.675 g $Ni_{0.95}Se$, 171.863 g $Ni_{0.875}Se$ and 172.998 g $Ni_{0.80}Se$.

RESULTS

The heat-capacity determinations are listed in Table 1 in chronological order, and expressed in terms of the thermochemical calorie, defined as 4.1840 abs joules. The ice point is taken to be 273.15°K and the atomic weights of nickel and selenium as 58.71 and 78.96, respectively. The data are expressed in terms of one mole of mixture, "mole", equivalent to the gram formula weight of Ni_ySe_{1-y}, *i.e.*, 69.09 g $Ni_{0.95}Se$, 69.51 g $Ni_{0.875}Se$ and 69.96 g $Ni_{0.80}Se$. An analytically-determined curvature correction for the finite temperature increments was applied to the observed values of $\Delta H/\Delta T$. The approximate temperature increments can usually be inferred from the adjacent mean temperature values in Table 1.

The heat capacity *versus* temperature curves are shown in Fig. 1. For $Ni_{0.95}Se$ it has the usual sigmoidal shape, with no anomalies or other irregular behavior up to 350°K. For $Ni_{0.875}Se$ and $Ni_{0.80}Se$ a slight relative increase in the values compared to those of $Ni_{0.95}Se$ is observed above 250°K. This might possibly indicate the beginning of transitions.

Values of C_p, $S_0°$ and $(H°-H_0°)/T$ for the three samples at selected temratures are listed in Table 2. No values for the free energy function are given because of the uncertainty about complete ordering of the atoms and holes, just as for the iron-selenides. The enthaply and entropy increments were computed by integration of the heat-capacity equation, obtained by successive approximations on an IBM 650 calculator. The heat-capacity values are considered to have a probable error of 1 % at 10°K and 0.1 % above 25°K. The estimated probable error in the entropy and enthalpy functions is 0.1 % above 100°K. Some of the data are given to an additional digit because of its significance when the entropies or enthalpies at different temperatures or compositions are compared. The effects of nuclear spin and isotopic mixing are not included in the entropy function.

The non-applicability of the Kopp-Neumann law is immediately evident, since the "molar" heat capacity, and also the entropy, decreases with inreasing selenium content, although the heat capacity and entropy of selenium is higher than for nickel. Within the homogeneity range of the Ni_{1-x} Se-phase reasonable interpolations could have been made, but even over this narrow range of compositions deviations from additivity are observed. These deviations suggest that interpolations should be made with great caution, and might aid in the resolution of the factors contributing to the heat capacities of phases with NiAs-like structure and cation vacancies.

Acknowledgment. The partial support of the *Division of Research, U. S. Atomic Energy Commission*, and of *Norges Almenvitenskapelige Forskningsråd* are gratefully acknowledged.

The authors thank Bolidens Gruvaktiebolag for a generous supply of high-purity selenium and Bruce Justice and Elfreda Chang for assistance in the calorimetric measurements and reduction of the data.

Studies on Succinic Acids

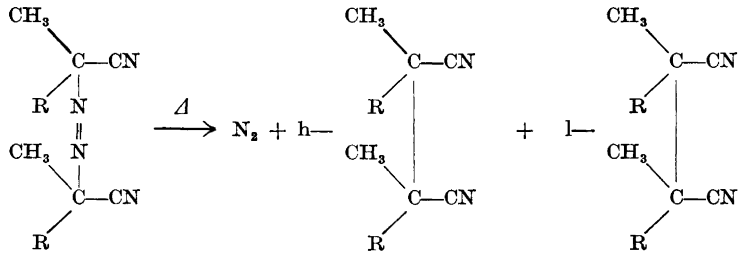
V. The Preparation and Properties of Diastereoisomers of Tetraalkylsuccinic Acids

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

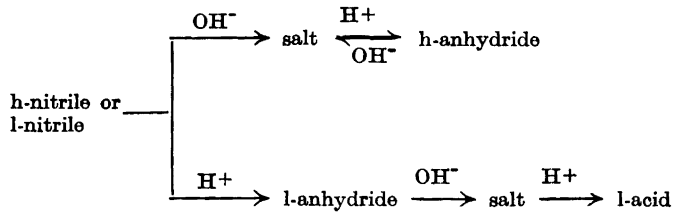
The diastereoisomers of three tetraalkylsuccinic acids containing two asymmetric centres, *viz.* α,α′-dimethyl-α,α′-diethyl-, α,α′-dimethyl-α,α′-dipropyl-, and α,α′-dimethyl-α,α′-di*iso*propylsuccinic acid, have been prepared. Their relative configuration is discussed on the basis of dissociation constant measurements, and in each pair the isomer with lower ratio between K_1 and K_2 is proposed to be the *meso* form.

Only a few tetraalkylsuccinic acids containing two asymmetric centres have been described in the literature [1–3]. Stefl [1] prepared α,α′-dimethyl-α,α′-diethyl- and α,α′-dimethyl-α,α′-dipropylsuccinonitrile (II, R = C_2H_5 and n-C_3H_7) by thermal decomposition of the corresponding bisazonitriles (I) and was able to isolate the diastereoisomers in a pure or almost pure state.



I II

(The letters h and l designate high- and low-melting, respectively). He studied the hydrolysis of these dinitriles and summarized the results in the following scheme:



i.e. on hydrolysis both dinitriles were converted into the same anhydride, in alkaline medium into the high-melting anhydride and in acid medium into the low-melting anhydride. Furthermore, he also concluded that the h-anhydride was isomerised to the l-anhydride by treatment with concentrated hydrochloric acid at 180° for 6 h or with acetic anhydride at the boiling temperature for 12 h, whereas the inverse reaction was claimed to occur on boiling the l-anhydride with 40 % aqueous potassium hydroxide for 2—3 days *.

Dox [3] synthesised α,α′-dimethyl-α,α′-diethylsuccinic acid by the bisazonitrile method and converted it into the anhydride and the imide but did not attempt to separate it into diastereoisomers.

The present author [2] has prepared α,α′-dimethyl-α,α′-diethylsuccinic acid and α,α′-diethyl-α,α′-di*iso*propylsuccinic acid by Kolbe electrolysis of the appropriate malonic monoesters, but could not separate them into diastereoisomers by fractional crystallisation. In the latter case the ease of formation of the anhydride from the acid both in solution and in the solid state made this procedure impossible.

It is now of course apparent that the isomerisations described by Stefl are not consistent with modern theories on the mechanism of inversion at an asymmetric carbon atom, since there is no mechanism for inversion at a quaternary carbon atom which does not involve scission and recombination of a carbon to carbon bond and this possibility seems very unlikely in view of the rather mild reaction conditions that Stefl used. Another point worthy of note is the failure to isolate the h-acid, the solution of the h-acid salt giving the h-anhydride directly on acidification. Tetraalkylsuccinic acids certainly have a very strong tendency to lose water forming anhydrides [2,4,5], but both tetraethyl- and tetrapropylsuccinic acid are liberated as the free acids by acidification of solutions of their salts. It is evident that some of the results must have been misinterpreted. The present paper deals with the problem of preparing pure diastereoisomers of some α,α′-dimethyl-α,α′-dialkylsuccinic acids and with evidence on the steric relationships between the acids obtained from dissociation constant measurements.

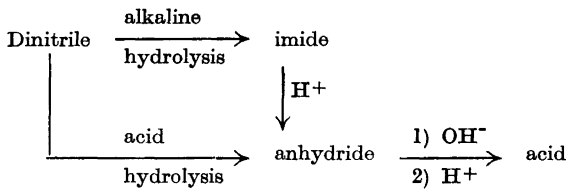
α,α′-Dimethyl-α,α′-diethylsuccinic acid

The product of hydrolysis of dimethyl α,α′-dimethyl-α,α′-diethylsuccinate by concentrated sulphuric acid was a liquid anhydride with rapidly dissolved in boiling 10 % aqueous sodium hydroxide solution [2]. On acidification this

* The present author was not able to duplicate the last-mentioned reaction with α,α′-dimethyl-α,α′-diethylsuccinic acid prepared in a different way [2].

gave a mixture of acids, m.p. 125—40°, which could not be separated by fractional crystallisation using several different solvents and solvent pairs. The acid slowly changes into the anhydride in solution, which complicates the separation procedure, since contamination by a small amount of anhydride considerably lowers the melting points of the acid. The melting point determinations must be done in sealed capillaries and the heating rate and time must be carefully controlled in order to obtain reproducible values [2,6].

An attempt was then made to prepare the acids by the bisazonitrile method since this permits the separation of the two forms at the dinitrile stage [1], and no inversion would be expected to occur during the hydrolysis. In fact the two nitriles were easily separated by fractional crystallisation from ligroin, and were then hydrolysed according to the following scheme:



In no case was any interconversion between the two diastereoisomeric series observed. The m.p's of the various compounds are listed in Table 1.

Table 1. Melting points of diastereoisomers of α,α'-dimethyl-α,α'-diethylsuccinic acid and their derivatives

	Imide, m.p.	Anhydride, m.p.	Acid, m.p.
High-melting dinitrile, m.p. 99—101°	97—99°	32—33°	189—192°
Low-melting dinitrile, m.p. 44—45°	92—95°	40—42°	182—184°

The melting point differences between the two series are rather small for the imides, anhydrides and acids, and it is difficult to identify the diastereoisomers by melting point determinations only. In the light of these findings the results reported by Stefl are quite understandable. The "h-anhydride" must actually have been the h- and l-imide, which were mistaken for the same compound. These imides dissolve in aqueous sodium hydroxide and are precipitated by acidification, which explains why the "h-acid" was never obtained. The apparent transformation of "h-anhydride" into "l-anhydride" by concentrated hydrochloric acid was a hydrolysis of the imides to the anhydrides. The "l-anhydride" apparently was either the h- or l-anhydride (or, as the dinitriles were not always separated from each other, a mixture of the anhydrides) and similarly the "l-acid" was either h- or l-acid (or a mixture). The small differences in melting point and solubility are probably responsible for Stefl's misinterpretation, especially as he never obtained the anhydrides in the solid state and the care necessary in m.p. determinations on the acids was not fully known at that time.

α,α'-Dimethyl-α,α'-dipropylsuccinic acid

This acid was best prepared by Kolbe electrolysis of monoethyl methylpropylmalonate. The succinic ester was easily hydrolysed by treatment with warm concentrated sulphuric acid, giving a mixture of anhydrides. The acid mixture obtained by alkaline hydrolysis of the anhydride and acidification was separated into two forms by fractional crystallisation from ethyl acetate, m.p. 173—175° and 166—167°, respectively. The corresponding anhydrides were liquid. The bisazonitrile method was also used but was not superior to the Kolbe method as the over-all yield of the dinitriles was low and they were impossible to separate by fractional crystallisation. The high-melting isomer was obtained in a pure state but the other fractions obtained were always mixtures of varying composition. It was established however that the high-melting dinitrile corresponded to the high-melting acid. Stefl's results with this acid can presumably be explained in the same way as for the α,α'-dimethyl-α,α'-diethylsuccinic acid.

α,α'-Dimethyl-α,α'-di*iso*propylsuccinic acid

This pair of acids was prepared by Kolbe electrolysis of monoethyl methyl-*iso*propylmalonate and subsequent treatment in the same way as for the *n*-propyl compound. The melting points of the acids were 175—177° (anhydride 65—66°) and 130—131° (anhydride 78—79°), respectively. Again the bisazonitrile method gave a low over-all yield of dinitriles, and only the high-melting compound was obtained pure, m.p. 67—68°. This isomer corresponded to the high-melting acid.

α,α'-Dimethyl-α,α'-di-(*tert.*-butyl)-succinic acid

The dimethyl ester of this acid has been prepared by Ansell *et al.*[7] It was not possible to hydrolyse the ester with concentrated sulphuric acid, and therefore the Kolbe method could not be used. The bisazonitrile method also failed because the intermediate radicals disproportionate instead of coupling. The reaction product on hydrolysis with strong sulphuric acid gave methyl-(*tert.*-butyl)-acetic acid in low yield.

DISCUSSION

The dissociation constants of the three acid pairs were determined in 50 % (by wt). aqueous ethanol by potentiometric titration [8]. The pK_1, pK_2, and ΔpK values are given in Table 2. Corresponding values for α,α'-diethyl-, α,α'-di*iso*propyl-, tetramethyl-, and tetraethylsuccinic acid have been included for comparison.

The dissociation constants of a number of *meso* and *racemic* α,α'-dialkylsuccinic acids and tetraalkylsuccinic acids and the K_1/K_2 ratios [8,9] for these compounds indicated that: Firstly, in an α,α-'dialkylsuccinic acid the alkyl

Table 2. Thermodynamic dissociation constants of alkylsubstituted succinic acids in 50 % (by wt.) aqueous ethanol

Succinic acid	pK_1	pK_2	ΔpK
α,α'-Dimethyl-α,α'-diethyl-, m.p. 189—92° [a]	5.73	9.66	3.93
α,α'-Dimethyl-α,α'-diethyl-, m.p. 182—4° [a]	4.45	10.44	5.99
α,α'-Dimethyl-α,α'-dipropyl-, m.p. 173—5°	5.73	9.99	4.26
α,α'-Dimethyl-α,α'-dipropyl-, m.p. 166—7°	4.56	10.86	6.30
α,α'-Dimethyl-α,α'-di*iso*propyl-, m.p. 175—7°	6.92	9.32	2.40
α,α'-Dimethyl-α,α'-di*iso*propyl-, m.p. 130—1°	3.20	13.13	9.93
Racem-α,α'-diethyl-[8]	4.76	9.22	4.46
Meso-α,α'-diethyl-[8]	5.37	7.43	2.06
Racem-α,α'-di*iso*propyl-[8]	3.66	11.44	7.78
Meso-α,α'-di*iso*propyl-[8]	5.98	8.10	2.12
Tetramethyl-[8]	4.84	10.13	5.29
Tetraethyl-[8]	4.78	11.42	6.64

[a] α,α'-Dimethyl-α,α'-diethylsuccinic acid prepared by the Kolbe method gave pK_1 and pK_2 values of 4.86 and 10.16 respectively [8]. Obviously this sample was a mixture of diastereoisomers.

groups have a tendency to take up positions *trans* to each other; in the *meso* acids this brings the carboxyl groups into a *trans* configuration and in the *racemic* acid into a *gauche* configuration. In the latter case a high K_1/K_2-ratio is obtained partly due to the formation of an internal hydrogen bond in the mono-anion, partly to increased Coulomb interaction between the carboxyl groups. Secondly, the accommodation of alkyl groups in, for instance, a tetraalkylsuccinic acid molecule introduces steric strain, which would be reduced in the cyclic hydrogen-bonded structure.

It is evident that these two factors cannot always be easily distinguished. In the tetraalkylsuccinic acids of the type studied in this paper the molecule is highly strained due to the presence of the four alkyl groups, and it can be expected that the two more bulky alkyl groups will have the greater influence on the conformational equilibrium. In the hydrogen-bonded structure, for the *meso* acid mono-anion the methyl groups will lie on one side of the ring and the more bulky groups on the other side. In the other possible *meso* acid conformation all groups will be *trans* staggered and this would be energetically favoured if there was no interaction between the carboxyl groups.

In the *racemic* acid mono-anion with a cyclic structure the bulky alkyl groups will be situated *trans* to each other and this arrangement will therefore be less strained than that of the corresponding *meso* form. From these considerations it can be concluded that the *meso* acid should possess a lower K_1/K_2-ratio than the *racemic* acid since: (1) in the fully *trans* staggered conformation the Coulomb interaction between the carboxyl groups is less than that of the most favoured *racemic* acid conformation (which has the carboxyl groups *gauche*) and moreover the formation of an internal hydrogen bond is not possible, and 2) if a cyclic *meso* acid conformation is present in appreciable amounts, it must nevertheless be less stable than the corresponding *racemic*

form. On these grounds the acids with the lower ΔpK in Table 2 are ascribed the *meso* configuration. The m.p's and solubility relationships are in agreement with this.

EXPERIMENTAL

The analyses were done by the Department of Analytical Chemistry, Chemical Institute, University of Lund. Melting points were determined with a Kofler apparatus unless otherwise stated. M.p's in sealed capillaries (abbreviated s.c.) were done as described in paper II of this series.

α,α'-Dimethyl-α,α'-diethylsuccinic acid

A. *Bisazonitrile method.* Hydrazine sulphate (96 g) and sodium cyanide (75 g, 97—98 %) were dissolved in 1 500 ml of water in a three litre bottle. Methylethyl ketone (96 g) was added and the mixture was shaken for 48 h. The organic layer was then taken up in ether, the ether was removed by evaporation *in vacuo* at room temperature and the residue, a viscous oil (120 g) which did not crystallise even after standing for several days in a vacuum desiccator, was dissolved in 200 ml of acetic acid + 100 ml of concentrated hydrochloric acid. The mixture was cooled to 5°, and an equimolecular amount of bromine dissolved in 400 ml of 70 % aqueous acetic acid was added with vigorous stirring during the course of 2 min. Stirring was continued for half an hour and the reaction mixture was then poured into ice water (3 l). The precipitate was collected, washed thoroughly with water, and dried giving the crude bisazonitrile (93 g), m.p. 49—51°, m.p. after recrystallisation from light petroleum 50—51° (80 g). Stefl [1] reported m.p. 54—55°, Dox [3] 57°, and Overberger *et al.*[10] 49—51°.

The recrystallised, dry bisazonitrile (80 g) was decomposed by boiling in carbon tetrachloride (500 ml) for 20 h. The solvent was distilled off and the residue was subjected to fractional crystallisation from ligroin. The more insoluble fraction (30 g) had m.p. 70—90°. One recrystallisation from ligroin afforded pure high-melting α,α'-dimethyl-α,α'-diethylsuccinonitrile (25 g, 22 %), m.p. 99—101°. The low-melting isomer was isolated from the mother liquor, m.p. 44—45° after two recrystallisations from ligroin; the yield of pure low-melting α,α'-dimethyl-α,α'-diethylsuccinonitrile was 19.5 g (17 %). Stefl [1] reported m.p. 98—99° and 42—43°, respectively. For the high-melting form Overberger *et al.*[10] found m.p. 96—98°.

The high-melting α,α'-dimethyl-α,α'-diethylsuccinonitrile, 10 g, was hydrolysed by boiling with a mixture of concentrated sulphuric acid (50 ml), water (20 ml) and acetic acid (60 ml) for 20 h. The reaction mixture was poured into water, the organic layer was taken up in ether, the ether solution was washed with sodium carbonate solution and water, and finally the ether was distilled off. The residue was distilled *in vacuo*, b.p. 117—118°/10 mm. The main fraction (9.2 g) solidified on standing, m.p. 30—33°, and was recrystallised from light petroleum, m.p. 32—33°. According to the analysis it was an anhydride of α,α'-dimethyl-α,α'-diethylsuccinic acid. (Found: C 65.2; H 8.9; Calc. for $C_{10}H_{16}O_3$: C 65.2; H 8.8). The anhydride was dissolved in 10 % aqueous potassium hydroxide by boiling for 30 min. Addition of dilute hydrochloric acid precipitated the high-melting α,α'-dimethyl-α,α'-diethylsuccinic acid, which was crystallised from ethyl acetate, m.p. 189—192° (s.c.). (Found: C 59.5; H 9.2; equiv. wt 204. Calc. for $C_{10}H_{18}O_4$: C 59.4; H 9.0; equiv. wt 202).

The high-melting α,α'-dimethyl-α,α'-diethylsuccinonitrile was hydrolysed under alkaline conditions by boiling with 30 % aqueous potassium hydroxide for 48 h. The reaction mixture was extracted with ether to remove any remaining nitrile, and the aqueous layer was acidified with dilute hydrochloric acid. The crystalline material deposited was collected and recrystallised from ligroin, m.p. 97—99°; according to analyses this material was α,α'-dimethyl-α,α'-diethylsuccinimide. (Found: C 65.5; H 9.3; N 7.7. Calc. for $C_{10}H_{17}O_2N$: C 65.5; H 9.3; N 7.7). Dox [3] reported m.p. 93—4° for an imide of unspecified configuration. The imide was hydrolysed to the anhydride, m.p. 32—33°, by boiling for 8 h with concentrated sulphuric acid, water, and acetic acid in the same proportions as above.

Low-melting α,α'-dimethyl-α,α'-diethylsuccinonitrile (10 g) was hydrolysed in the same way as for the high-melting nitrile. The α,α'-dimethyl-α,α'-diethylsuccinic anhydride obtained (9.0 g), b.p. 124—126°/12 mm, m.p. 39—41°, was recrystallised from light petroleum, m.p. 40—42°. (Found: C 64.9; H 8.7. Calc. for $C_{10}H_{16}O_3$: C 65.2; H 8.7). Hydrolysis gave the low-melting α,α'-dimethyl-α,α'-diethylsuccinic acid, m.p. 182—184° (s.c.) after recrystallisation from ethyl acetate. (Found: C 59.3; H 9.0; equiv. wt 203. Calc. for $C_{10}H_{18}O_4$: C 59.4; H 9.0; equiv. wt 202).

Alkaline hydrolysis of the low-melting dinitrile in the same way as for the high-melting nitrile afforded an α,α'-diemethyl-α,α'-diethylsuccinimide of m.p. 92—95° after recrystallisation from ligroin. (Found: C 65.5; H 9.4; N 7.6. Calc. for $C_{10}H_{17}O_2N$: C 65.5; H 9.4; N 7.7). Acid hydrolysis of this imide gave the anhydride, m.p. 40—42°.

B. *Kolbe method.* A crude mixture of the two diastereoisomeric acids was prepared as described previously [2]. Fractional crystallisation was tried with ethyl acetate, benzene, ethyl acetate-benzene, and ethyl acetate-light petroleum, but no separation was achieved. The sample with highest m.p. melted at 173—176° (s.c.). The products isolated from the mother liquors were largely anhydrides.

α,α'-Dimethyl-α,α'-dipropylsuccinic acid

A. *Bisazonitrile method.* The bishydrazonitrile was prepared in the same way as for the methylethyl derivative from hydrazine sulphate (96 g), sodium cyanide (75 g), and methyl propyl ketone (115 g) in water (1 500 ml). The crude product (125 g) was oxidised directly with bromine in aqueous acetic acid as described above. The crystalline product obtained was contaminated with a strongly lachrymatory oil, which was removed by suction on a sintered glass-funnel. The nature of this product was not investigated. The product was recrystallised from light petroleum, m.p. 55—70°, yield 42 g. Stefl [1] reported m.p. 64° and Overberger *et al.* 73—74.5°. The bisazonitrile was decomposed by boiling in carbon tetrachloride for 24 h. The solvent was distilled off, and the residue was distilled *in vacuo*, b.p. 106—110°/0.5 mm. The main fraction (27 g, 21 %) solidified on standing over night, m.p. 40—70°. In spite of several attempts to separate the two isomers by fractional crystallisation from various solvents, only the high-melting, less soluble form was obtained in a pure state, m.p. 83—85° after three recrystallisations from ligroin. Stefl reported m.p. 84° for the high-melting form and that the other isomer was liquid. Overberger *et al.*[10] gave m.p. 83—83.5° for the high-melting form.

The mixture of dinitriles (10 g) was hydrolysed with sulphuric acid — water — acetic acid and the crude anhydride was directly hydrolysed in the same way as before. The dried acid was dissolved in the minimum of ethyl acetate and the solution was treated with decolorising carbon, filtered, and allowed to cool. The crystals were filtered off, m.p. 171—175° (s.c.) and recrystallised from ethyl acetate, m.p. 173—175° (s.c.). According to analyses this substance was an α,α'-dimethyl-α,α'-dipropylsuccinic acid. (Found: C 62.3; H 9.5; equiv. wt 228. Calc. for $C_{12}H_{22}O_4$: C 62.6; H 9.6; equiv. wt 230). The anhydride was prepared by treating the acid with excess acetyl chloride. Distillation gave the pure α,α'-dimethyl-α,α'-dipropylsuccinic anhydride, b.p. 114—116°/12 mm. (Found: C 67.7; H 9.6. Calc. for $C_{12}H_{20}O_3$: C 67.9; H 9.5).

The mother liquor from the above filtration was diluted with five volumes of light petroleum giving a precipitate of the low-melting α,α'-dimethyl-α,α'-diethylsuccinic acid, m.p. 158—162° (s.c.), which was recrystallised from acetic acid-ligroin (1:10), m.p. 166—167° (s.c.). (Found: C 62.4; H 9.4; equiv. wt 230. Calc. for $C_{12}H_{22}O_4$: C 62.6; H 9.6; equiv. wt 230). The anhydride was liquid, b.p. 115—118°/14 mm. (Found: C 67.9; H 9.5. Calc. for $C_{12}H_{20}O_3$: C 67.9; H 9.5). The amounts of pure acids isolated were 1.9 and 1.1 g, respectively, but the material could be recovered from the mother liquor as anhydride, for use in subsequent preparations.

The high-melting α,α'-dimethyl-α,α'-dipropylsuccinonitrile was found to correspond to the high-melting acid.

B. *Kolbe method.* The preparation and electrolysis of monoethyl methylpropylmalonate was done in the same way as before [2]. The product was obtained in 35 % yield, b.p. 119—120°/2 mm, n_D^{20} 1.4468, d_4^{20} 0.9704. According to analyses it was the diethyl ester. (Found: C 66.7; H 10.5; r_D 0.2752. Calc. for $C_{16}H_{30}O_4$: C 66.9; H 10.7; r_D 0.2777). The

ester was hydrolysed with concentrated sulphuric acid in the usual way, and the acids were prepared as described for the anhydride obtained from the dinitriles. The pure acids melted at 174—175° (s.c.) and 166—167° (s.c.), respectively.

α,α'-Dimethyl-α,α'-diisopropylsuccinic acid

A. *Bisazonitrile method.* The bishydrazonitrile was prepared in the same way as the methylethyl derivative from hydrazine sulphate (96 g), sodium cyanide (75 g), and methyl *iso*propyl ketone (115 g) in water (1 500 ml). The crude product (125 g) was oxidised directly as described above. In this case also a strongly lachrymatory oil was formed that had to be removed by suction on a sintered glass-funnel. The crystalline mass was recrystallised from ethanol, m.p. 64—69°, yield 44 g. Overberger *et al.* found m.p. 68.5—70°. The bisazonitrile was boiled over night in carbon tetrachloride (250 ml). Distillation yielded a mixture of dinitriles, (16.5 g, 13 %), b.p. 142—145°/14 mm, which partially solidified after standing for a few days. Attempts to separate the two forms failed, and only the high-melting α,α'-dimethyl-α,α'-di*iso*propylsuccinonitrile could be obtained pure, m.p. 67—68° after recrystallisation from light petroleum. (Found: C 74.7; H 10.4; N 14.8. Calc. for $C_{12}H_{20}N_2$: C 75.0; H 10.5; N 14.6).

The mixture of dinitriles (10 g) was hydrolysed as before. The anhydride obtained was purified by distillation, b.p. 110—111°/1.5 mm and this was converted to the acid in the usual way. The acid was dissolved in the minimum amount of boiling ethyl acetate as rapidly as possible. The high-melting α,α'-dimethyl-α,α'-di*iso*propylsuccinic acid which crystallised on cooling, was recrystallised from ethyl acetate, m.p. 169—172° (s.c.). (Found: C 62.4; H 9.6; equiv. wt 116. Calc. for $C_{12}H_{22}O_4$: C 62.6; H 9.6; equiv. wt 115). The anhydride was prepared and recrystallised from light petroleum, m.p. 65—66°. (Found: C 67.7; H 9.5; Calc. for $C_{12}H_{20}O_3$: C 67.9; H 9.5).

The mother liquor from which the high-melting acid had crystallised was rapidly evaporated to about one third of its original volume and then diluted with five volumes of light petroleum. This treatment precipitated the low-melting α,α'-dimethyl-α,α'-di*iso*propylsuccinic acid, m.p. 131—2° (s.c.), unchanged after a further recrystallisation from ethyl acetate-light petroleum (1:5). (Found: C 62.4; H 9.5; equiv. wt 229. Calc. for $C_{12}H_{22}O_4$: C 62.6; H 9.6; equiv. wt 230). The anhydride melted at 78—79° after recrystallisation from light petroleum. (Found: C 67.9; H 9.5. Calc. for $C_{12}H_{20}O_3$: C 67.9; H 9.5). The amounts of pure acids obtained were 1.0 g and 0.7 g, respectively, but the material could be recovered as anhydride from the mother liquor for use in subsequent preparations.

The high-melting α,α'-dimethyl-α,α'-di*iso*propylsuccinonitrile was found to correspond to the high-melting acid.

B. *Kolbe method.* The preparation and electrolysis of monoethyl methyl*iso*propylsuccinate was carried out as described previously [8]. The product was obtained in 24 % yield, b.p. 125—130°/4 mm, n_D^{20} 1.4558; d_4^{20} 1.0035. According to analyses it was the dimethyl ester. (Found: C 65.7; H 10.3; r_D 0.2708. Calc. for $C_{14}H_{26}O_4$: C 65.1; H 10.1; r_D 0.2722). The two acids were prepared from this ester in the usual way, m.p. 170—172° (s.c.) and 130—131° (s.c.).

Attempts to prepare α,α'-dimethyl-α,α'-di-(tert.-butyl)-succinic acid. The bisazonitrile from pinacolone was prepared according to Overberger *et al.*[11] Decomposition in carbon tetrachloride yielded a dark-brown liquid, which could not be distilled owing to the very vigorous foaming. It was therefore hydrolysed directly with sulphuric acid-water-acetic acid (4:1:3). The product was isolated by ether extraction and distilled, 90—93°/6 mm. The distillate soon solidified and was recrystallised from light petroleum, m.p. 53—57°. According to analyses it was methyl-(*tert.*-butyl)-acetic acid. (Found: C 64.5; H 10.8; equiv. wt 130.6. Calc. for $C_7H_{14}O_2$: C 64.5; H 10.9; equiv. wt 130.2). Newman *et al.*[12] reported m.p. 51—52°.

pK-measurements. The p*K* values for these acids were determined as described in paper III of this series [8].

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work. A grant from *Matematisk-naturvetenskapliga Fakulteten* is gratefully acknowledged.

The Activation of Phosphoprotein Phosphatase with Inorganic Phosphate and Surfactants

BO NORBERG

Chemical central laboratory, Sabbatsbergs sjukhus, Stockholm, Sweden

In the determination of the activity of phosphoprotein phosphatase as released inorganic phosphate, Pi, which can be precipitated with calcium at pH 9, the enzyme activity is dependent upon the concentration of Pi, so that the apparent activity approaches 0 in connection with falling Pi, attains a maximum at about 0.1 mM Pi, when the substrate is 1 % phosvitin, and sinks in connection with an even moderate excess of Pi. The enzyme activity is further increased by quaternary ammonium bases such as cetyltrimethylammonium bromide and other detergents. The activation is presumed to be connected with an increased tendency to reaction in the carbinol-group of the serine residue in the substrate.

In an earlier investigation [1] it was found that precipitation of the inorganic phosphate (Pi) released by the phosphoprotein phosphatase was necessary in order to get satisfactory reproducibility and proportionality between enzyme concentration and reaction rate. In the course of subsequent work, however, a number of apparently inexplicable irregularities were observed. Thus on one day fresh liver extract gave good activity with two casein substrates (2.17 and 3.86 units per gram liver), whereas much smaller values were obtained the next day (0 and 1.17 units per gram). Experiments with phosvitin [2] also gave unexpected results, adrenal extract giving higher activity, in 5 out of 6 experiments, than liver extract, as compared with the reverse relation when casein was used as substrate [1]. Parallel measurements of activity were then carried out with casein and phosvitin as substrate, and extract of adrenal glands, erythrocytes and liver from the rat, guinea-pig, rabbit, and cat as enzyme source. With liver in these experiments a higher apparent activity was obtained with casein substrate in 11 out of 13 tests. Adrenals and blood corpuscles, on the other hand, gave higher activity with phosvitin in 10 out of 15 experiments. Since inhibition of phosphoprotein phosphatase with Pi has been shown [1,3], and since liver is richer in Pi than are red corpuscles, the irregularities might possibly be due to the occurrence of Pi. Attempts to eliminate the excess Pi by dialysis, however, resulted regularly in a loss of activity. A more careful investigation of the effect of Pi was therefore indicated.

In the subsequent experiments human erythrocytes were chiefly used as source of enzyme. In a preliminary series with rat liver, an extract in 0.1 M acetate, of pH 5.8, gave activities of between 3.26 and 4.76 units per gram, on an average 4.07 with a standard deviation of 0.056, while an aqueous extract gave 3.88—4.87 units per gram, averaging 4.35. Systematic testing with erythrocyte extract showed optimal activity at an ionic strength of 0.04. Accordingly the erythrocytes, after 3 washings with isotonic sodium chloride were hemolyzed with distilled water, after which the hemolysate was diluted to 50 mg hemoglobin per ml and ionic strength 0.2, using sodium chloride and acetate buffer, pH 5.8. Phosvitin with about 1.1 mg protein nitrogen per ml (determined on trichloroacetic acid precipitate) was used as substrate.

Measurement of the enzyme activity was performed by incubating 1 ml extract and 4 ml substrate at 38°C, then stopping the enzyme effect with trichloroacetic acid and measuring the Pi released after precipitation with calcium at pH 9[1]. Apart from this standard method two alternatives were tried: a) direct determination of Pi in the trichloroacetic acid extract according to Fiske-Subbarow and b) extraction of directly obtained phosphomolybdate complex [4]. However, these alternative methods regularly gave lower values than did the standard method, especially at the optimal initial concentration of Pi. In 84 comparisons the standard technique gave on an average 1.61 ± 0.27 (standard deviation) times greater activity than did alternative a). The apparent difference in activity is referable to the higher blank value in the alternative methods. The preliminary explanation of this might be the occurrence of an acid-labile phosphorus linkage in the substrate. In subsequent testing only the standard technique was used.

The revovery of Pi which had been added to dialysed substrate was investigated at four phosvitin concentrations. It was found that in order to get a certain blank value more Pi was required the higher the phosvitin-content. This emerges clearly from Fig. 1, where increasing addition of phosphate does not give a rising blank value until after the addition of 100 μmole/l with approx. 1 % phosvitin, and of 200 μmole/l for 2 % phosvitin.

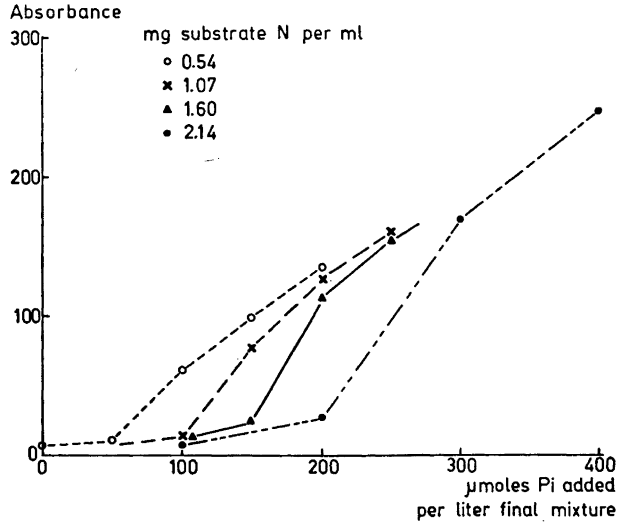

Fig. 1. Apparent inorganic phosphate (Pi, as absorbance) against total concentration of added Pi at increasing phosvitin concentrations.

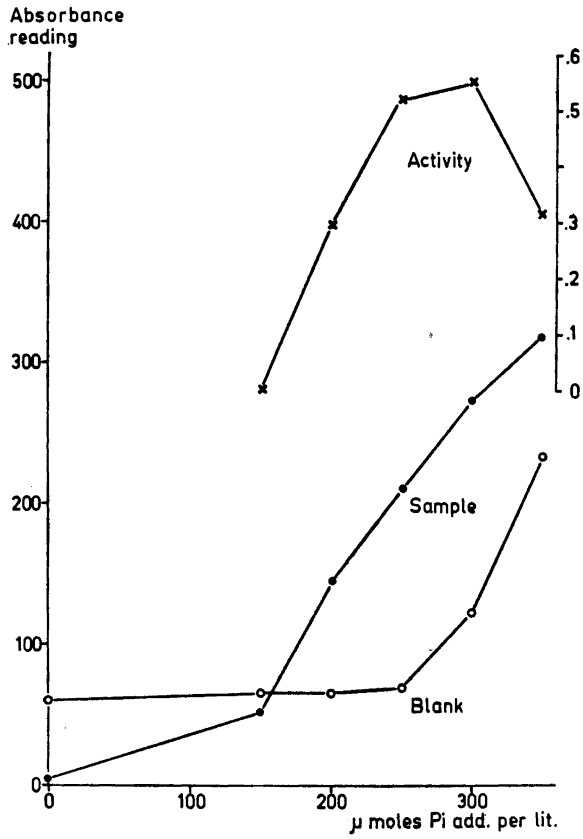

Fig. 2. Effect of addition of inorganic phosphate on blank reading and enzyme activity.

The *relation between enzyme activity and added Pi* is illustrated by the experiment shown in Fig. 2. On the addition of Pi corresponding to up to 0.15 mM no enzyme activity at all is obtained on incubation. On larger additions it increases however, reaching a maximum at the same time as the blank value begins to rise in response to a Pi-addition corresponding to a final concentration of 0.25 mM phosphate at 1.8 % phosvitin. Even slightly larger amounts of Pi result in inhibition.

In subsequent experiments 1 % phosvitin was usually used as substrate, and maximal enzyme activity was then obtained at a blank value of about 100 μM Pi. This appears from a series of experiments comprising 39 tests and reproduced in Fig. 3. When the actual concentration of Pi found in the blank value exceeds 150 μM, the activity is greatly reduced. If the initial Pi-value approaches 0, the enzyme activity disappears entirely. One must obviously determine the content of Pi in every enzyme sample and adapt the addition of Pi to the substrate so that the optimal concentration of Pi for the actual substrate is approximately reached; the interval between too little and too much is evidently very small.

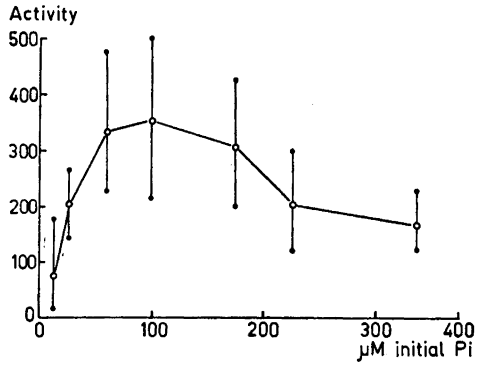

Fig. 3. Actual initial concentration of Pi at incubation and its effect on enzyme activity (mean value and range). Each mean represents 2 to 8 experiments.

Just how sensitive the enzyme reaction is to excess phosphate is shown in Fig. 4. With a rising incubation period an increasing concentration of Pi is obtained, which results in increasing inhibition; so that the apparent activity per 100 mg hemoglobin has fallen below 50 % of the highest value measured when the concentration of Pi has risen to no more than 0.4 mM. This striking sensitivity to phosphate in the incubation milieu shows clearly how difficult it is with *in vitro* experiments to throw light upon the activity of the enzyme *in vivo*.

In connection with the testing of casein as substrate, *quaternary ammonium bases* were also added in the dialysis, with the intention of preventing bacterial contamination of the substrate. This resulted, in the majority of the experiments in a not inconsiderable increase in the activity, as is exemplified in Table 1.

Similar results were also obtained with octylphenoxyethoxyethyldimethylbenzylammonium chloride ("Septin" Pharmacia, Uppsala) and cetyltrimethylammonium bromide, CTB, and also with ethylendiamine-tetraacetate, EDTA. The sensitivity of the enzyme to the phosphate ion concentration was not investigated however, and with the exception of some of these tests no attention was paid to this factor. The significance of the addition of phosphate for casein which had been dialyzed against 0.5 % CPBr with extract from fresh rat's liver as enzyme is shown in Table 2. In other casein substrates which had been dialyzed with or without addition of quaternary ammonium base an addition of phosphate corresponding to 0.12—1.05 mM Pi was required at the start of the incubation,with an average of 0.51 mM Pi for optimal effect (22 substrates with 20 mM organically bound phosphorus).

For testing with phosvitin CTB in a concentration of 10 mM was generally used. The effect of the detergent and of the addition of phosphate is shown in Table 3, which clearly indicates stimulation but also the dependence on the addition of phosphate both without and with CTB. To throw further light upon this, Table 4 shows the results of an experiment in which the phosvitin solutions were prepared directly in water and in 0.01 M CTB, respectively, without dialysis. Here the water substrate gives an apparently very low

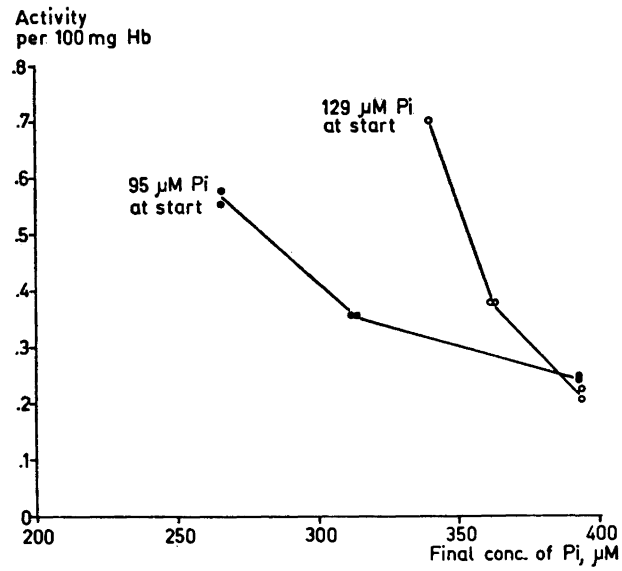

Fig. 4. Increasing inhibition of enzyme activity with rising concentration of Pi in digest. Initial concentration of Pi 95 μM (dots) and 129 μM (circles).

concentration of Pi. In the CTB-substrate, on the other hand, one obtains with increasing phosvitin-concentration a considerable Pi concentration. The optimal activity is obtained at an apparent concentration of 61 μM Pi in the substrate + 214 μM in the hemolysate. The activation, which apparently derives from the detergent, seems to be intimately connected with the Pi which is available, and at a higher substrate-concentration it turns into a faint but distinct inhibition. The interesting thing about this experiment is that the detergent appears to mobilize the labile phosphorus in the substrate, as there was no special addition of phosphate.

The results of the investigation appear to show that a certain minimal concentration of inorganic phosphorus is required to obtain the greatest possible activity with phosphoprotein phosphatase in the measuring system used. On the other hand, further inorganic phosphorus which is produced by the

enzyme or which exists from the outset, results in a striking inhibition. It is evident that this phosphatase activity can be regulated with great sensitivity by Pi. A further activation through detergents also seems to occur, and the experiments appear to indicate that this effect may consist in a loosening and breaking of covalent phosphorus linkages in the substrate.

The *in vitro* system applied cannot be considered comparable with the conditions obtaining *in vivo*, but it is an interesting coincidence that at the maximal activation of the enzyme the concentration of Pi coincides with the minimal concentration required for oxidative phosphorylation in respiring mitochondria [5-7]. In contradistinction to oxidative phosphorylation and phosphorolysis [8], where Pi is included as substrate component, the activating phosphate seems rather to act as a cofactor for the phosphoprotein phosphatase, as is the case in the transformation of serine to glycine [9]. The possibility that Pi is required to overcome a solubilization effect in the precipitation of calcium phosphate [10], which is included in the analytic procedure applied, cannot be ruled out, but it seems unlikely, since the phosphate effect exists, even if more faintly, in direct phosphate analysis. On the other hand, it is not inconceivable that through dialysis the substrate loses some phosphate, which is replaced

Table 3. Effect of added KH_2PO_4 on activity of erythrocyte phosphoprotein phosphatase on phosvitin prepared in water and in 0.01 M cetyltrimetylammonium bromide, CTB.

by added Pi. A simple and rapid exchange between serine-bound phosphorus and Pi has been shown [11], and, as has been adduced above, it is conceivable that the dertegence effect is connected with a further loosening of the phosphorus-serine linkage or with activation of the carbinol-group of the serine [12]. In view of the fact that surfactants prove as a rule to be enzyme-inhibitors [13] it is also more probable that the effect here starts on the substrate; this would entail an intensification of the affinity between enzyme and substrate [14]. The inhibition of excess Pi may be a competition for the active site of the enzyme.

On the Crystal Structure of $W_2O_3(PO_4)_2$

PEDER KIERKEGAARD

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

$W_2O_3(PO_4)_2$ possesses a monoclinic unit cell which contains four formula units and has the dimensions

$a = (7.83 \pm 0.01)$ Å
$b = (12.48 \pm 0.02)$ Å
$c = (7.76 \pm 0.01)$ Å
$\beta = (91.9 \pm 0.1)°$
$V = 758$ Å^3

A structure is proposed with the symmetry No. 11, $P2_1/m$. The positions of the wolfram and phosphorus atoms in the unit cell were determined from the Patterson and Fourier electron density functions. The parameters of the oxygen atoms were deduced from geometrical considerations, using interatomic distances from previoulsy determined structures. The arrangement arrived at may be considered as an idealized structure that should be slightly distorted in order to give an explanation of the very weak reflexions with k = odd.

In $W_2O_3(PO_4)_2$, there are WO_6 octahedra joined by PO_4 tetrahedra giving a three-dimensional arrangement, the groups being joined in such a way that, firstly, every WO_6 octahedron is linked to four PO_4 tetrahedra and one WO_6 octahedron and, secondly, every PO_4 tetrahedron is linked to four WO_6 octahedra.

During the course of crystal structure studies at this Institute on phosphorus-oxygen compounds of molybdenum and wolfram, reports have been published on the structures of the phases WOP_2O_7[1] and $Mo(OH)_3PO_4$[2]. According to Schulz [3], the WO_3-P_2O_5 system contains, in addition to the former compounds, a phase of the composition 2 WO_3·P_2O_5 which is insoluble in water, acids and dilute ammonia and slowly soluble in hot dilute sodium hydroxide. In solutions of 2 WO_3·P_2O_5, only orthophosphate ion could be proved — diphosphate or polyphosphate ions were not found.

This article will describe investigations on the structure of 2 WO_3.P_2O_5.

PREPARATION OF THE CRYSTALS

A viscous, colourless solution of WO_3 (10 g) in concentrated (14.5 M) H_3PO_4 (25 ml) was prepared at about 220°C. The solution was heated at about 475°C for several hours,

after which crystals satisfactory for X-ray work were obtained (the method according to Schulz [3]). After cooling, the crystals were washed with hot water and dried in air. Under the microscope, they were seen to be colourless rods.

Analysis. A sample was fused with sodium potassium carbonate in a platinum crucible and the cake was dissolved in boiling water. From an ammoniacal solution, the *phosphorus* was precipitated (according to Kolthoff and Sandell [4]) with a magnesium solution. The precipitate was filtered off, washed with water, dissolved in hot 1 M HNO_3 and from this solution the phosphorus was finally precipitated with ammonium molybdate and weighed as $(NH_4)_3PO_4 \cdot 12\ MoO_3$. The amount of *wolfram* in the filtrate — made neutral — was determined gravimetrically by precipitation with mercury(I)nitrate according to Cumming and Kay [5] and weighing, after ignition, as WO_3. The methods of analysis were tested carefully on samples with known compositions and the errors were found to be very low.

The *density* of the crystals was determined from the apparent loss of weight in benzene.

	Calculated for $2\ WO_3 \cdot P_2O_5$	Found	
% WO_3	75.56	76.3	76.5
% P_2O_5	23.44	23.3	23.5
Density	5.30	5.02 ±	0.01

The density is calculated for 4 formula units per cell.

UNIT CELL AND SPACE GROUP

From rotation and Weissenberg photographs (*hk*0—*hk*4; *h*0*l*—*h*6*l*, 0*kl*—4*kl*), taken with CuK radiation, of small crystals of different shapes (one needle about 0.1 mm in length and about 0.04 mm in diameter rotated around the needle axis, [010], and one cube-like body with an edge of only about 0.06 mm rotated around [100] and [001]), it was concluded that the crystals are monoclinic and that the dimensions of the unit cell are about 7.7_7 Å, 12.5_3 Å, 7.8_3 Å and that the monoclinic angle is about 91°.

The reflections were recorded photographically using the multiple film technique and the relative intensities were estimated visually by comparison with an intensity scale obtained by photographing a reflection with different exposure times. The F^2 values were then calculated using the nomograms given by Lu[6]. No correction was applied for the absorption.

More accurate values for the unit cell dimensions were calculated from a powder photograph taken with strictly monochromatized Cu$K\alpha_1$ radiation in a focusing camera of Guinier type. KCl was used as an internal standard (see Table 1, p. 671).

$$a = (\ 7.83 \pm 0.01)\ \text{Å} \qquad \beta = (91.9 \pm 0.1)^\circ$$
$$b = (12.48 \pm 0.02)\ \text{Å} \qquad V = 758\ \text{Å}^3$$
$$c = (\ 7.76 \pm 0.01)\ \text{Å}$$

The value (5.02) found for the density gives $3.8 \approx 4$ formula units in the unit cell.

The reflections with k = odd are very weak but the only ones systematically absent are

$$0k0 \text{ with } k = \text{odd}$$

This is characteristic of the space groups No. 4 $P2_1$ and No. 11 $P2_1/m$. The absence of the piezo-electric effect is consistent with the latter space group and the investigation was started by examining whether the structure was consistent with this space-group with the higher symmetry.

In No. 11 $P2_1/m$, the following point positions are possible

2(*a*):000; $0\frac{1}{2}0$; 2(*b*): $\frac{1}{2}00$; $\frac{1}{2}\frac{1}{2}0$; 2(*c*): $00\frac{1}{2}$; $0\frac{1}{2}\frac{1}{2}$;
2(*d*): $\frac{1}{2}0\frac{1}{2}$; $\frac{1}{2}\frac{1}{2}\frac{1}{2}$; 2(*e*): $\pm(x\frac{1}{4}z)$;
4(*f*): $\pm(xyz)$; $\pm(x,\frac{1}{2}-y,z)$

POSITIONS OF THE WOLFRAM AND PHOSPHORUS (P_1) ATOMS

Patterson projections. In order to find the eight wolfram positions, the three Patterson projections *P*(*uvp*), *P*(*pvw*) and *P*(*upw*) were calculated (Figs. 1 and 2).

The eight wolfram atoms in the unit cell must occupy either two fourfold positions ($2 \times 4(f)$) or combinations of the twofold positions and the fourfold position or four of the twofold positions. Now, if the wolfram atoms occupy any twofold position 2(*a*)—(*e*), we will get this as a special case of the general point position 4(*f*). Therefore, we will start the examination assuming that the eight wolfram atoms occupy point positions 4(*f*).

In the point position 4(*f*), the interatomic vectors are:

$\pm[2x$	$2y$	$2z]$ weight 1
$\pm[2x$	$\frac{1}{2}$	$2z]$ » 2
$\pm[0$	$2y-\frac{1}{2}$	$0]$ » 2

By comparing this table with *P*(*uvp*) in Fig. 1, we see that at $u = 0$ there is (besides the origin maximum) only one high maximum at $v = \frac{1}{2}$, and thus we find that the *y*-coordinates will be ≈ 0 or 1/4. Now, in *P*(*uvp*) there are also pronounced peaks at $v = 1/4$ (A and B in Fig. 1). These maxima certainly correspond to W—W vectors and the position at $v = 1/4$ will exclude the possibility that all of the wolfram atoms have the same *y* coordinate. Thus we conclude that the *y*-coordinates of the wolfram atoms are 0 and 1/4, which will give

4 W_1 in 4(*f*) with $x = x_1$ $y \approx 0$ $z = z_1$
2 W_2 in 2(*e*) » $x = x_2$ $y = 1/4$ $z = z_2$

The W—W distances would then be

$\pm[0$	$\frac{1}{2}$	$0]$	weight 2
$\pm[2x_1$	$1/4 \pm 1/4$	$2z_1]$	» 2
$\pm[2x_2$	$\frac{1}{2}$	$2z_2]$	» 1
$\pm[x_1 \pm x_2$	$\pm 1/4$	$z_1 \pm z_2]$	» 2

Now in *P*(*uvp*) and *P*(*pvw*) (Fig. 1), we see that all peaks at $v = 0$ are nearly identical with the maxima at $v = \frac{1}{2}$. This is not in agreement with the

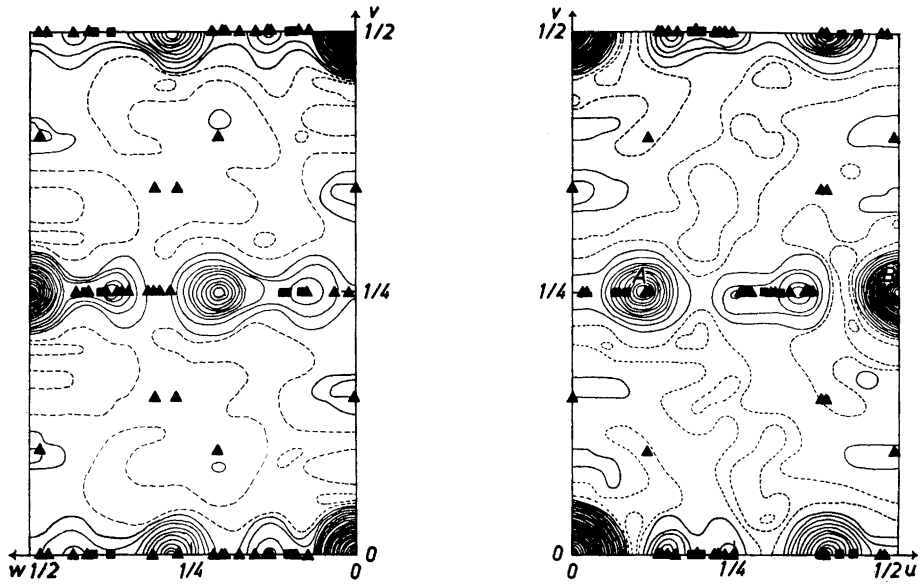

Fig. 1. The Patterson projections *P(uvp)* and *P(pvw)*. The W—P (■) and W—O (▲) vectors have been indicated for the final structure. Dashed lines indicate negative values.

table above. The only way to explain this is that the remaining two wolfram atoms (W_3) are situated in the point position 2(*e*) with $x \approx -x_2$ and $z \approx -z_2$. Thus we have

$$2\ W_3 \text{ in } 2(e) \text{ with } x \approx -x_2 \quad y = 1/4 \quad z \approx -z_2$$

The W—W distances would then be:

$\pm[0$	$\frac{1}{2}$	$0]$ weight 4
$\pm[2x_1$	$1/4 \pm 1/4$	$2z_1]$ » 2
$\pm[2x_2$	$1/4 \pm 1/4$	$2z_2]$ » 2
$\pm[x_1 \pm x_2$	$\pm 1/4$	$z_1 \pm z_2]$ » 4

The Patterson projection on the *uw* plane should therefore show (besides the origin maximum) the following maxima

I	$\pm[2x_1$,	$2z_1]$	weight 4
II	$\pm[2x_2$,	$2z_2]$	» 4
III	$\pm[x_1 + x_2$,	$z_1 + z_2]$	» 8
IV	$\pm[x_1 - x_2$,	$z_1 - z_2]$	» 8

There are two high peaks in *P(upw)* at $u = 0.39_0$, $w = 0.27_4$ (C in Fig. 2) and at $u = 0.61_4$, $w = 0.31_2$ (D in Fig. 2) and, in addition, two peaks at

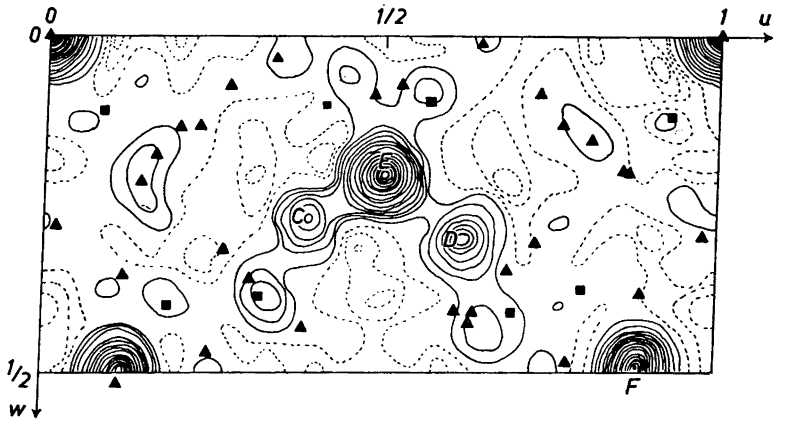

Fig. 2. The Patterson projection $P(upw)$. The positions of the vectors for the final structure have been marked as in Fig. 1. For the largest maxima (00) and (10), only every second contour has been marked. Dashed lines indicate negative values.

$u = 0.49_7$, $w = 0.20_7$ (E in Fig. 2) and at $u = 0.88_8$, $w = 0.48_1$ (F in Fig. 2) whose heights are about double those of the former. (All maxima have been located by the interpolation table given by Booth [7]). These maxima certainly correspond to the W—W wectors I—IV so the peak C must correspond to the vector I or II (and D to II or I) and the peak E to the vector III or IV (and F to IV or III). By calculating the vectors I—IV for all possible combinations of x_1, x_2, z_1 and z_2, the following two alternatives were found for the arrangement of the wolfram atoms (it is sufficient to consider the range $0 \leq x \leq \frac{1}{2}$, $0 \leq z \leq 1$):

Alt. a:	4 W_1 in	4(*f*) with	$x \approx 0.19_5$	$y \approx 0$	$z \approx 0.13_7$
	2 W_2 »	2(*e*) »	$x \approx 0.31_0$	$y = 1/4$	$z \approx 0.65_3$
	2 W_3 »	2(*e*) »	$x \approx 0.69_0$	$y = 1/4$	$z \approx 0.34_7$
Alt. b:	4 W_1 »	4(*f*) »	$x \approx 0.31_0$	$y \approx 0$	$z \approx 0.65_3$
	2 W_2 »	2(*e*) »	$x \approx 0.19_5$	$y = 1/4$	$z \approx 0.13_7$
	2 W_3 »	2(*e*) »	$x \approx 0.80_5$	$y = 1/4$	$z \approx 0.86_3$

These two sets of wolfram parameters will give identical W—W vectors and the values obtained checked well with the Patterson projections $P(uvp)$ and $P(pvw)$ in Fig. 1. The positions and heights of the maxima in these projections were found to be in good agreement with the claculated W—W-distances. The parameters obtained from $P(upw)$ should, however, be more accurate since, in the calculation of this projection, more F^2 values were used and since less overlapping occurs in this projection.

Thus, from the Patterson projections we get two alternatives for the arrangement of the wolfram atoms and, at this state of the investigation, it was not possible to rule out one of them.

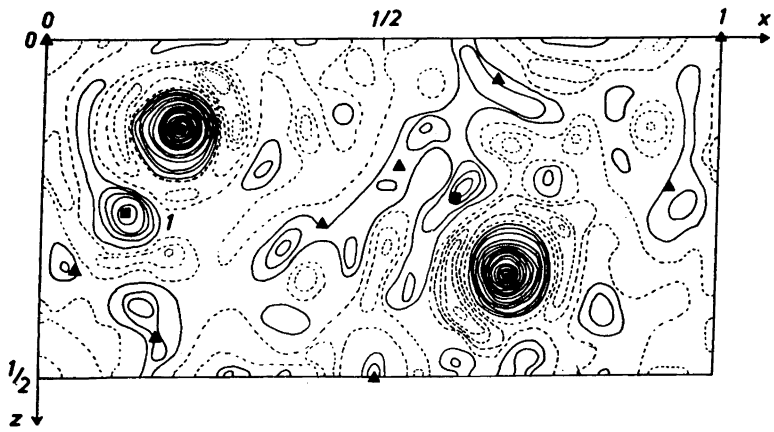

Fig. 3. Electron density projected on the *xz* plane. The final positions of the phosphorus (■) and oxygen atoms (▲) have been marked. In the wolfram peaks, only every second contour has been marked. Dashed lines indicate negative values.

However, in the Patterson projections there are, in addition to peaks corresponding to the W—W vectors, several lower maxima which perhaps could be ascribed to the W—P distances. In the unit cell, there are eight phosphorus atoms situated in 4(*f*) and/or 2(*a*)—(*e*) and consequently the corresponding possible W—P distances were calculated. From the positions of the lower maxima, situated at $v = 0$, 1/4 and ½ in Fig. 1, 2(*a*)—(*d*) can at once be ruled out as possible point positions if the peaks are real and correspond to W—P vectors. Thus the phosphorus atoms must occupy 2(*e*) and/or 4(*f*). It should now be possible to obtain possible alternatives for the parameters of the phosphorus atoms but it would be preferable to determine their sites from a map giving electron density since such a map gives maxima that are sharper and less in number than those of the corresponding vector map.

Electron density projection. For a compound of this type, the electron density projections can easily be calculated since the signs of all the F_{hkl} values can be determined from the contributions given by the wolfram atoms because of their dominant scattering factors. In this case, the projection $\varrho(xpz)$ should be favourable for calculation since the two alternatives for the wolfram arrangement will give equal F_{h0l} values. In this way, $\varrho(xpz)$ was calculated and the result is given in Fig. 3. We see that the wolfram atoms are clearly indicated at $x = 0.195$, $z = 0.137$ and at $x = 0.690$, $z = 0.347$.

Besides the very high wolfram maxima in the calculated electron density projection, there is a lower peak in ϱ (xpz) at $x = 0.12$, $z = 0.26$ (1 in Fig. 3). If this lower peak is a real maximum, and not a false one due to diffraction effects or inadequate intensity data, it is possible that two overlapping phosphorus atoms could give a peak of this height. As mentioned above, the point positions 2(*e*) and 4(*f*) were possible for the arrangement of the phosphorus atoms. If four phosphorus atoms are situated in 4(*f*), two phosphorus maxima overlap

in the *xz* projection of the electron density. Since the projection $\varrho(xpz)$ really shows one rather distinct maximum (1 in Fig. 3), which could be ascribed to overlapping phosphorus atoms, we may conclude that this peak, if real, gives the position of four phosphorus atoms (4 P_1) in 4(*f*). Now all W—P_1 distances were calculated and the lower maxima in the Patterson projections were compared with the W—P_1 vectors. From Fig. 1, we see that most of the lower peaks outside $v = \pm 1/4$ are situated in or close to the planes $v = 0$ and $\frac{1}{2}$. From this we immediately obtain $y_{P_1} \approx 0$ and thus we may conclude

$$4\ P_1 \text{ in } 4(f) \text{ with } x \approx 0.12 \qquad y \approx 0 \qquad z \approx 0.26$$

For the arrangement of the wolfram atoms we have already found two possible sets of parameters (see p. 661) and consequently we obtain two alternatives for the W—P vectors

$$\left.\begin{aligned} u &= \pm (0.195 \pm 0.12) \\ w &= \pm (0.137 \pm 0.26) \end{aligned}\right\} \quad \begin{aligned} v &= 0 \text{ and } \tfrac{1}{2} \text{ if alt. a} \\ &= 1/4 \text{ and } 3/4 \text{ if alt. b} \end{aligned}$$

$$\left.\begin{aligned} u &= \pm (0.310 \pm 0.12) \\ w &= \pm (0.653 \pm 0.26) \end{aligned}\right\} \quad \begin{aligned} v &= 1/4 \text{ and } 3/4 \text{ if alt. a} \\ &= 0 \text{ and } \tfrac{1}{2} \text{ if alt. b} \end{aligned}$$

Thus it should be possible, from the positions of the maxima corresponding to the vectors above, to decide which alternative for the wolfram coordinates is the correct one. The vectors were therefore compared with $P(uvp)$ and $P(pvw)$ in Fig. 1 and it was found that the two alternatives seemed to be about equally plausible, even if the agreement might be a little better for b than for a.

Three-dimensional Patterson calculations. By introducing three dimensional Patterson calculations, it should, however, be possible to decide which of the two sets gives the correct wolfram position in the unit cell. Therefore $P(u0w)$ and $P(u1/4w)$ were calculated using all reflexions (975) obtained with Cu*K* radiation. In order to obtain more reflexions and in this way reduce the cutting-off effects, trials were also made with Mo*K* radiation but it was found that these experiments gave no additional information. However, the data obtained with Cu*K* radiation should be sufficient, even if it would have been advantageous to get reflexions with higher *h* and *l* values than nine which was the highest index in these directions obtained with Cu*K* radiation. The results are given in Fig. 4 ($P(u0w)$) and Fig. 5 ($P(u1/4w)$).

In $P(u0w)$ there are, besides the maxima due to W—W vectors, two maxima at $w = 0.19_2$, $w = 0.41_0$ (1 in Fig. 4) and at $u = 0.56_1$, $w = 0.09_2$ (2 in Fig. 4). In $P(u1/4w)$ there are also, besides the high "wolfram" peaks, two maxima at $u = 0.32_3$, $w = 0.38_5$ (3 in Fig. 5) and at $u = 0.92_9$, $w = 0.11_9$ (4 in Fig. 5). All these maxima certainly correspond to the W—P_1 wectors given above since the positions and heights of the peaks are in good agreement with calculated data and, moreover, from the position of the peaks 1 and 2 at $v = 0$ (and 3 and 4 at $v = 1/4$) we obtain immediately that the alternative b will give the correct position of the wolfram atoms. Thus we may conclude (the values are weighted means of the parameters found in the calculated functions):

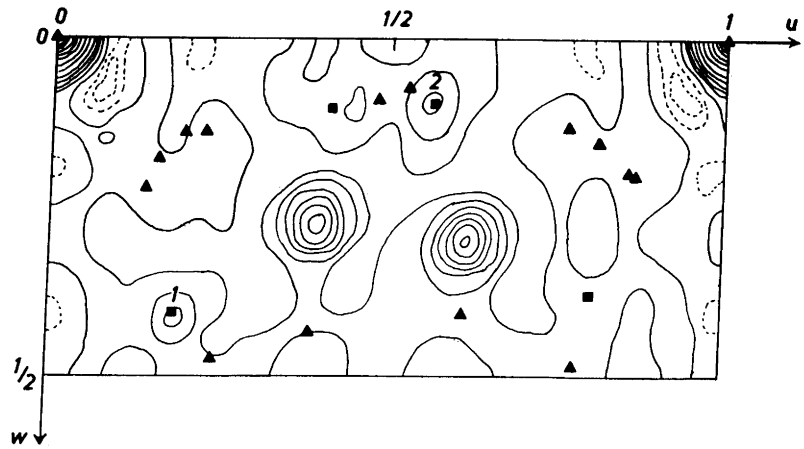

Fig. 4. The Patterson function $P(u0w)$. The positions of the vectors for the final structure have been marked as in Fig. 1. For the maxima at (00) and (10), only every second contour has been marked. Dashed lines indicate negative values.

4 W_1	in	$P2_1/m$	4(f)	with	$x = 0.310$	$y = 0$	$z = 0.653$
2 W_2	»	»	2(e)	»	$x = 0.195$	$y = 1/4$	$z = 0.137$
2 W_3	»	»	2(e)	»	$x = 0.805$	$y = 1/4$	$z = 0.863$
4 P_1	»	»	4(f)	»	$x = 0.12$	$y = 0$	$z = 0.25$

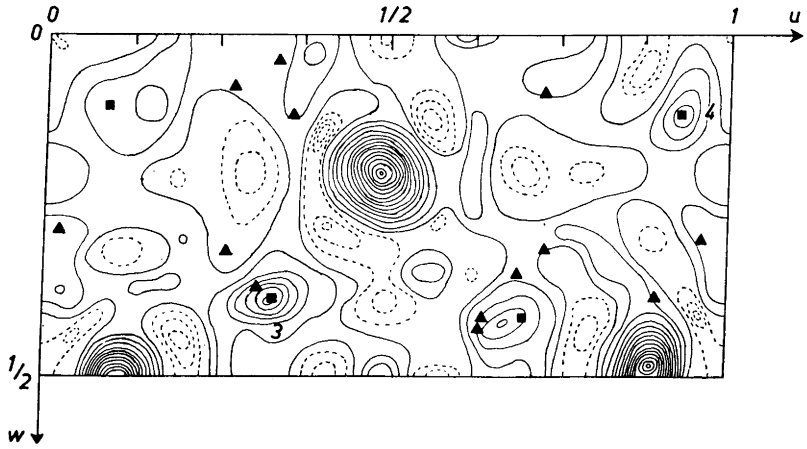

Fig. 5. The Patterson function $P(u1/4w)$. The positions of the vectors for the final structure have been marked as in Fig. 1. For the two largest maxima, only every second contour has been marked. Dashed lines indicate negative values.

Using these parameters, W—P_1 distances were calculated and these vectors have been indicated in Figs. 1 and 2. The agreement between observed and calculated data is quite good thus indicating that the coordinate values are reasonably correct.

The remaining maxima in the Patterson functions and electron density projection may correspond to W—P and W—O vectors or phosphorus and oxygen atom positions but, at this stage of the investigation, they were not considered since these peaks are about the same height as the false maxima.

POSITIONS OF THE OXYGEN ATOMS

General remarks. The light oxygen atoms do not make any appreciable contribution to the intensities of the reflections and their positions had thus to be found from considerations of the interatomic distances. The following assumptions were made:

1. The W—O distance was assumed to be not less than that found [8-10] in WO_3 and related compounds, *i.e.* 1.8_5 Å.

2. Each phosphorus atom was assumed to be surrounded by four oxygen atoms giving a tetrahedron with the bond lengths within the limits: P—O = 1.4_5 — 1.6_5 Å and O—O = 2.4_8 — 2.6_8 Å (these distances are limits for those published [11-13]).

3. The distance between two oxygen atoms not belonging to the same PO_4-group was assumed to be not less than 2.6_0 Å.

With these assumptions, the space free for oxygen atoms will be deduced as follows.

There are two symmetry planes in the unit cell at $y = \pm 1/4$. If an oxygen atom is not situated exactly in a symmetry plane, it must be at a distance of at least 1.3_0 Å (1.2_4 Å if belonging to the same PO_4-group) from it. Accordingly, the y coordinates of the atoms should be either $y = 1/4$ and $y = 3/4$ or within the limits $-0.14_5 \leq y \leq 0.14_5$, $0.35_5 \leq y \leq 0.64_5$ Moreover there are eight symmetry centres per unit cell (the point positions $2(a)-(d)$). If an oxygen does not coincide with a symmetry centre, it must be situated outside a sphere of radius 1.3_0 Å around it. For the same reason, spheres of radii 2.6_0 Å around each oxygen atom which has been located and of radii 1.8_5 Å around each wolfram atom enclose domains forbidden for the centres of other oxygen atoms.

Positions of the oxygen atoms around the phosphorus atoms (P_1). The four phosphorus atoms, the positions of which have been found above, are surrounded by four wolfram atoms at the distances: P_1-W_2; $W_2-2\,P_1 = 3.2_9$ Å; P_1-W_3, $W_3-2\,P_1 = 3.2_9$ Å; $P_1-2\,W_1$, $W_1-2\,P_1 = 3.4_2$ Å, 3.4_7 Å. The angles, W—P—W, between the phosphorus and the four neighbouring wolfram atoms are 104°, 101°, 100° and 143°. Now it seems very probable that the four oxygen atoms around the phosphorus atom P_1 will be strongly attracted by the wolfram atoms and, with the assumptions made above and from the calculated angles and W—P_1 distances, we see that it is possible for all oxygen atoms belonging to the same PO_4 tetrahedron to be in contact with four different wolfram atoms. Assuming this, which seems to be very probable, the following coordinates are obtained

4 O_1	in	$P2_1/m$	4(f)	with	$x = 0.20$	$y = 0.10_0$	$z = 0.14$
4 O_2	»	»	»	»	$x = 0.20$	$y = 0.90_0$	$z = 0.14$
4 O_3	»	»	»	»	$x = 0.17$	$y = 0$	$z = 0.44$
4 O_4	»	»	»	»	$x = 0.93$	$y = 0$	$z = 0.22$

Positions of the oxygen atoms O_5 and O_6. In this structure, the wolfram atoms are situated in pairs, W_1-W_1 and W_2-W_3, with the distances 3.8_7 Å or 3.6_6 Å. Now, in several oxygen compounds of wolfram, a similar value, about 3.75 Å, has been found [8,9,14] for the distances between wolfram atoms joined by oxygen atoms. It seems therefore very probable that the wolfram atoms mentioned above are also joined in the same way; *i.e.* by oxygen atoms. Assuming this, the parameters of the oxygen atoms O_5 and O_6 would be

2 O_5	in	$P2_1/m$	2(d)	with	$x = \frac{1}{2}$	$y = 0$	$z = \frac{1}{2}$
2 O_6	»	»	2(e)	»	$x = 0$	$y = 1/4$	$z = 0$

Positions of the oxygen atoms O_7-O_{14}. For the remaining 24 oxygen atoms in the unit cell we note, as before for the oxygen atoms O_1-O_6, that they must be strongly attracted by the wolfram atoms and, consequently, should be situated as close to them as possible. Now we have found contacts W—3 O and if all of the remaining 24 oxygen atoms are in contact with wolfram, we obtain the coordination W—6 O. A higher coordination number is excluded since spatial reasons will prevent the latter O atoms being in contact with more than one W atom. Now, in most of the oxygen compounds of wolfram the same coordination number has been reported [9,14,15] and thus, it seems very reasonable that the coordination W—6 O also occurs in $2WO_3 \cdot P_2O_5$. We must therefore investigate the possibility that all of the remaining oxygen atoms in the unit cell are in contact with wolfram. Now, the wolfram atoms W_2 and W_3 are situated in the symmetry planes ($y = \pm 1/4$) and each of them is in contact with three oxygen atoms (O_1, O_2 and O_6). Two of these oxygen atoms (O_1 and O_2) are situated outside the symmetry planes and, with the assumptions made above (see p. 665), we get immediately that the only possibility for obtaining the coordination W_2—6 O and W_3—6 O is with 12 oxygen atoms in the point position 2(e). Reasonable interatomic distances were only obtained assuming:

2 O_7	in	$P2_1/m$	2(e)	with	$x = 0.05$	$y = 1/4$	$z = 0.34$
2 O_8	»	»	»	»	$x = 0.95$	$y = 1/4$	$z = 0.66$
2 O_9	»	»	»	»	$x = 0.42$	$y = 1/4$	$z = 0.27$
2 O_{10}	»	»	»	»	$x = 0.58$	$y = 1/4$	$z = 0.73$
2 O_{11}	»	»	»	»	$x = 0.67$	$y = 1/4$	$z = 0.06$
2 O_{12}	»	»	»	»	$x = 0.33$	$y = 1/4$	$z = 0.94$

From the positions given above for the oxygen atoms O_3, O_4 and O_5 — which atoms are in contact with the wolfram atoms W_1 and situated in the same planes ($y = 0$ and $\frac{1}{2}$) — we obtain at once that the only possibility for obtaining the coordination W_1—6 O is if the remaining twelve oxygen atoms

are situated in the point position 4(*f*). It is now easy to calculate the coordinates of those atoms so that reasonable O—O and W—O distances are obtained. Thus we get

4 O_{13}	in	$P2_1/m$	4(*f*)	with	$x = 0.47$	$y = 0$	$z = 0.83$
4 O_{14}	»	»	»	»	$x = 0.31$	$y = 0.15_0$	$z = 0.65$
4 O_{15}	»	»	»	»	$x = 0.31$	$y = 0.85_0$	$z = 0.65$

POSITIONS OF PHOSPHORUS ATOMS P_2 AND P_3

Now when the positions of all oxygen atoms have been determined, the parameters of the four remaining phosphorus atoms should be obtainable. It was assumed above that the coordination figure around the phosphorus atoms is a tetrahedron. Thus it should be possible using the known oxygen positions to find the remaining phosphorus positions so that each of these atoms will be surrounded by four oxygen atoms in a tetrahedral arrangement and with the P—O distances within the limits assumed above (p. 665).

Since a PO_4-group has not a centre of symmetry as would be required in 2(*a*)—(*d*), the four phosphorus atoms must occupy the positions 4(*f*) or 2 × 2(*e*). Now, in the Patterson projections in Fig. 1, we see that most of the maxima are situated at $v = 0$, 1/4 and ½ and from this we conclude that, if the phosphorus atoms are situated in 4(*f*), the *y*-coordinate ≈ 0. Otherwise, we would have pronounced peaks due to W—P vectors outside these planes. As a matter of fact, the low maxima situated outside the planes ($v = 0$, 1/4 and ½) were found to correspond to W—O vectors (see p. 670). However, at $y = 0$ through the unit cell, there are only two tetrahedral interstices of the kind described above *viz.* those coinciding with the positions of the phosphorus atoms P_1. Thus the remaining four phosphorus atoms must be situated in the symmetry planes ($y = \pm 1/4$), *i.e.* in the position 2(*e*). The *x* and *z* coordinates of these phosphorus atoms — situated with $y = 1/4$ — are easy to determine since there are also in this section through the unit cell only two possible phosphorus positions. Thus we obtain

2 P_2	in	$P2_1/m$	2(*e*)	with	$x = 0.61$	$y = 1/4$	$z = 0.26$
2 P_3	»	»	»	»	$x = 0.39$	$y = 1/4$	$z = 0.74$

REFINEMENT OF THE PARAMETERS

The parameters found above will only give an idealized structure since the weak reflections with odd *k* remain unexplained. The appearance of these reflections could be explained by assuming a distortion of the structure in such a way that some or all of the atoms are displaced from the positions given above. A refinement of the structure was therefore started.

In order to eliminate the diffraction effects as much as possible and get more reliable *x* and *z* coordinates for the phosphorus atoms, the wolfram atoms were subtracted from the Fourier image in Fig. 3. The structure factors were then corrected by an exponential factor, $e^{-0.28 \sin^2 \Theta}$, obtained in the

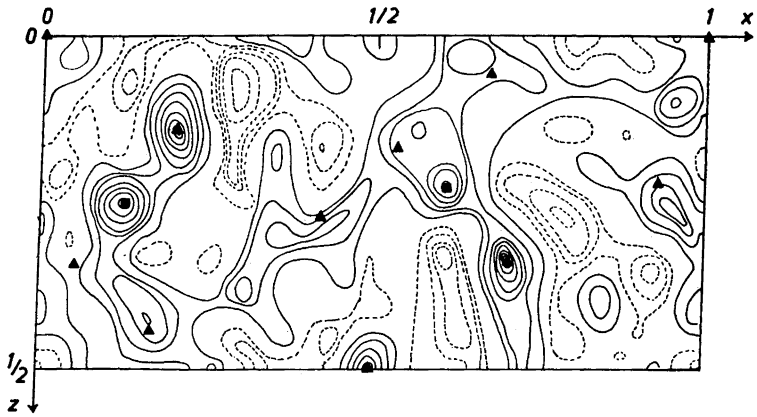

Fig. 6. Electron density projected on the *xz* plane with the wolfram atoms subtracted. The final positions of the phosphorus and oxygen atoms have been indicated as in Fig. 3. Dashed lines indicate negative values.

ordinary way for the determination of temperature factors. From Fig. 6, which shows this new electron density projection, we see the phosphorus atoms P_1 at $x = 0.11_8$, $z = 0.25_4$ and $P_2 + P_3$ at $x = 0.60_6$, $z = 0.23_7$. The four overlapping oxygen atoms are also clearly indicated at $x = 0.20$, $z = 0.15$ (O_1 and O_2) and at $x = 0.70$, $z = 0.34$ (O_{14} and O_{15}). The positions of these peaks are in good agreement with the corresponding parameters given above except for the *z*-parameter of the phosphorus atoms P_2 and P_3 which should be changed from 0.26 to 0.23 according to this new electron density projection. The positions of the oxygen atoms, belonging to the tetrahedra around P_2 P_3, consequently had to be shifted a little in order to get reasonable P—O distances. It is remarkable that most of the remaining maxima — although rather diffuse and about the same heigh as the false maxima — were found to coincide fairly well with oxygen positions. However, by means of this calculation, it was not possible to obtain any deviations which could explain the double *b* axis even if the maximum formed by the overlapping atoms P_2 and P_3 is a little elongated, indicating perhaps that x_{P_2} and z_{P_2} not are exactly equal to $\bar{x}_{P_2}$ or $\bar{z}_{P_2}$ as assumed above. An attempt to solve the structure by trial and error methods assuming a displacement of these phosphorus atoms and of the surrounding oxygen atoms was however, without success.

It was thought that three-dimensional Patterson calculations would perhaps solve the problem. Such calculations were therefore performed, firstly, in order to discover any deviation from the space group considered and, secondly, to investigate displacements like those proposed above for P_2 and P_3 or distortions produced when some of the atoms are not situated exactly in the planes $y = 0$ or $1/4$ ($\frac{1}{2}$ or $3/4$) as obtained — except in the case of the oxygen atoms O_1, O_2, O_{14} and O_{15} — in the structure investigation given above. However, all these attempts to perform a complete structure determination were in vain. Neither was it possible to solve the structure by calculating the generalized

Patterson functions using the observed values of $|F_{h1l}|^2$, $|F_{h3l}|^2$ or $|F_{h5l}|^2$. This was probably due to the poor experimental intensity material from the weak zones, *h*1*l*, *h*3*l* and *h*5*l*, obtained with Cu*K* radiation (as to Mo*K* radiation *cf.* p. 663).

Finally, attempts to solve the structure by trial and error methods assuming that the weak reflections were due to the displacement of the wolfram and some of the oxygen atoms were also without success.

FINAL STRUCTURE PROPOSITION

Thus, in spite of all the attempts to make a complete structure determination, we must restrict our conclusions to the following idealized structure for 2 $WO_3.P_2O_5$.

Space group No. 11 $P2_1/m$. Four formula units per unit cell. Atomic positions:

		x	*y*	*z*
4 W_1	in 4(*f*)	0.310 ± 0.003	0	0.653 ± 0.003
2 W_2	in 2(*e*)	0.195 ± 0.003	1/4	0.137 ± 0.003
2 W_3	in 2(*e*)	0.805 ± 0.003	1/4	0.863 ± 0.003
4 P_1	in 4(*f*)	0.12	0	0.25
2 P_2	in 2(*e*)	0.61	1/4	0.24
2 P_3	in 2(*e*)	0.39	1/4	0.76
4 O_1	in 4(*f*)	0.20	0.10_0	0.14
4 O_2	in 4(*f*)	0.20	0.90_0	0.14
4 O_3	in 4(*f*)	0.17	0	0.44
4 O_4	in 4(*f*)	0.93	0	0.22
2 O_5	in 2(*d*)	½	0	½
2 O_6	in 2(*e*)	0	1/4	0
2 O_7	in 2(*e*)	0.05	1/4	0.34
2 O_8	in 2(*e*)	0.95	1/4	0.66

The accuracy of the parameters for the phosphorus and the oxygen atoms is estimated to be about ± 0.02. Using these parameters, all the structure factors *hk*0—*hk*4, 0*kl*—4*kl* and *h*0*l*—*h*6*l* were calculated, multiplied by the factor $e^{-0.28 \sin^2 \Theta}$ (*cf.* above) and compared with the observed ones. Some of the results are shown in Table 2 where the values for *hk*0, *h*0*l*, *h*2*l* and 0*kl* for even values of *k* have been listed. All the *observed* structure factors with odd *k* from *hk*0, 0*kl* and *h*1*l* have been listed in Table 3. As is seen from Table 2,

there is quite a good agreement between the observed and calculated data. The reliability index according to Booth (see Ref.[5], p. 101) was found to be 0.18 for *hk*0, 0.16 for *h*0*l* and 0.17 for 0*kl* (absent reflections not included) and 0.22, 0.21 and 0.22 for the same reflections calculated without the phosphorus and oxygen atoms. This shows that the structure should be essentially correct as regards the heavy atoms and also indicates that the proposed coordinates for the phosphorus and the oxygen atoms will give a better agreement between observed and calculated intensities than that obtained when the phosphorus and oxygen atoms are omitted from the calculations. The coordinates were also checked against the Patterson functions and the electron density projections. The positions of all W—P and W—O vectors have been indicated in Figs. 1, 2, 4 and 5 and the positions of the phosphorus and oxygen atoms have also been market in Figs. 3 and 6. From the figures, we see that the agreement between calculated maxima and observed peaks is fairly good, which also seems to indicate the coordinate values to be plausible.

In the structure determination described above, we have assumed that the structure is consistent with the space group $P2_1/m$ having the higher symmetry and, since nothing was found against this, the asumption may be correct. Nevertheless, it is of course possible that all or some of the atoms are arranged according to the low-symmetry space group $P2_1$ and this has also in part been considered since all calculations made for the structure determination are independent of the space group assumption. However, it does not seem possible to get any essential difference for the atom arrangement even if the space

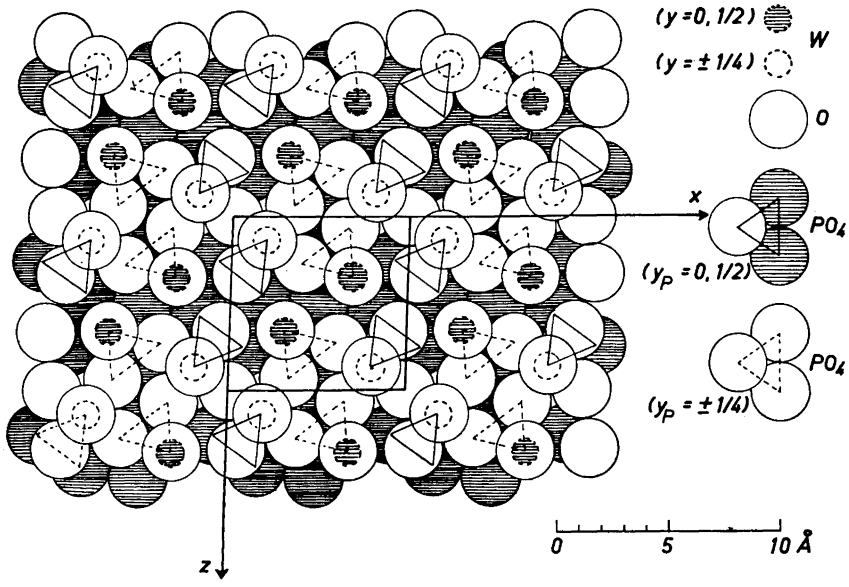

Fig. 7. Projection on the *xz* plane of the structure of $W_2O_3(PO_4)_2$.

group $P2_1$ is considered. This will perhaps increase the errors in the parameters since all of the coordinates are therefore obtained from overlapping peaks.

DESCRIPTION OF THE STRUCTURE

The structure of $2WO_3.P_2O_5$ may be described as built up of WO_6-octahedra and PO_4-tetrahedra. Every wolfram atom is in contact with four PO_4-groups and every PO_4-group with four wolfram atoms. Every wolfram atom is also in contact with one oxygen atom (O_{7-8}; O_{13}), which is bound only to this wolfram atom, and one oxygen atom (O_{5-6}) that is shared by two wolfram atoms. In this way, the crystals are built up of plane W_2O_3-groups parallel to the *xz* plane and joined by PO_4-tetrahedra so that every tetrahedron links together four W_2O_3-groups giving a threedimensional arrangement. The building principle might be expressed by the formula $W_2O_3(PO_4)_2$ and the compound should then be written according to this rather than $2WO_3 \cdot P_2O_5$. A further discussion of the structure will be given later on in a separate article.

The *xz* projection of the structure is shown in Fig. 7.

Table 1. Powder photograph of $2WO_3 \cdot P_2O_5$. Cu$K\alpha_1$-radiation. Reflections systematically absent in space group $P2_1/m$ have been omitted. KCl (a = 6.2930 Å) has been used as an internal standard.

Optical Resolution of some Auxin-active Thiocarbamates

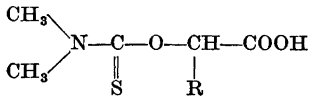
MAGNUS MATELL

Research Laboratory, Mo och Domsjö AB, Örnsköldsvik, Sweden *

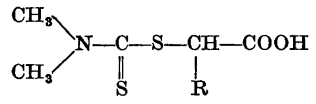
Several thiocarbamyl-derivatives of α-hydroxy- and α-thiocarboxylic acids have been synthesized and some of them resolved into optical antipodes. The compounds are of plant physiological interest and some of them show stereochemical specificity. The structural requirements for auxin activity have been modified to fit the results of the present investigation.

An interesting type of racemization has been observed. The acids are stable in the solid state but are rapidly racemized on melting. The theoretical considerations involved in this phenomenon will be discussed in a subsequent paper.

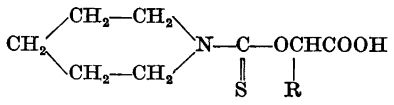
A few years ago a new type of plant growth regulators was discovered by van der Kerk and coworkers [1]. The structures of the new compounds, thiocarbamic esters of glycolic acid (I) or thioglycolic acid (II) are in part identical with the well-known α-aryloxyalkanoic acids (V). The fundamental



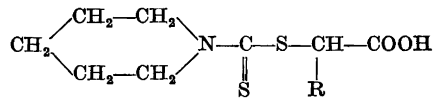
I



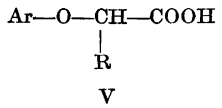
II



III



IV



V

difference is the absence of a cyclic system in I and II; this is notable, as such a system, with a polar side-chain in a definite spatial position, has been generally accepted as a necessary requirement for auxin-activity [2].

* Present address: Berol AB, Göteborg 14, Sweden.

It has been found that the aryloxyalkanoic acids show stereochemical specificity, *i.e.* the auxin-activity is associated with a definite configuration (D—)[3-5]. It was thus of interest to find out whether the new compounds behaved in a similar way.

In the present study some acetic acids (R = H) and propionic acids (R = CH_3) of type I—IV have been synthesized. The propionic acids of type I—III have been resolved into optical antipodes. The growth-regulating properties have been studied by Professor B. Åberg. The acids of type I and II not only give typical auxin responses in several tests, but the propionic acids also show stereochemical specificity [6]. This fundamental physiological similarity between compounds of type I—II and type V may be regarded as evidence that they are all taking part in identical or similar reaction mechanisms within the cell. This view is further supported by the fact that the auxin activity is lowered when the C—O—C link in I is replaced by C—S—C. A similar lowering of the auxin activity has been found when the ether oxygen in α-(2-naphthoxy)propionic acid is replaced by sulphur [4].

In view of these facts a revision of the ring structure requirement seems to be inevitable. In fact van der Kerk *et al.* have pointed out that the C—N bond is likely to acquire some double-bond character due to internal electron shifts. A partial ring system is thus formed, with the side-chain in a distinct spatial position [1]. This argument has ben verified by infra-red investigation of a number of dithiocarbamates [7]. Some structurally similar O-alkylxanthates have been found to give physiological responses in spite of the fact that in these compounds resonance is much less probable [8]. However, the responses reported seem not to be of a true auxin type.

It is thus possible to apply the current structure-activity requirements to the new types of growth regulators, provided the ring requirement is stated as: A ring system or a partial ring system with the side-chain in a distinct spatial position.

The piperidylderivatives III and IV did not show auxin responses and the steric effects of the propionic acids were weak. For that reason the optical resolution was completed only for one of the acids.

During the optical resolution of the acids now investigated it was found that the optical activity increased very little or even decreased from one recrystallization to the next. These irregularities could be derived from thermal instability of the optically active forms. The behaviour of the antipodes was studied by melting point microscopy. In most cases new crystals were rapidly formed in the melt at a temperature just above the primary melting point. The phenomenon was not due to isomorphism, since the new crystals were optically inactive. Further, the melting points coincided with the melting points of the corresponding racemates, with which they are identical as proved by lack of melting point depression of mixtures. This racemization is rather rapid in the melt but seems not to occur in the crystalline state as the melting point is sharp and independent of the heating time. Even if racemization occurred to such a slight extent as a few percent it should be possible to detect by microscopy the formation of some eutectic melt at the lower, eutectic temperature. A racemization of this type seems not to have been reported previously. A theoretical discussion will appear in a paper to follow.

[a] based on α-chlorocarboxylic acid in method A, on amine in method B. [b] hot stage microscope, corr. [c] Ref.[12] gives 116−117°C (uncorr.). [d] Ref.[12] gives 145−146°C (uncorr.). [e] Ref.[12] gives 145—147°C uncorr.). [f] Ref.[12] gives 134−135°C (uncorr.).

EXPERIMENTAL

The racemic acids were synthesized by one of the general procedures A and B, which are given below [9,12]. Further experimental details are found in Table 1.

Method A. An aqueous solution of 1 mole of an α-chlorocarboxylic acid is refluxed for 4 h with excess sodium carbonate in order to form the α-hydroxycarboxylic acid. After cooling to room temperature potassium hydroxide (1.2 mole) and carbon disulphide (1 mole) are added and the mixture shaken for 24−40 h. Excess carbon disulphide is removed *in vacuo* and 1 mole of chloroacetamide is added to the clear red solution. The mixture is stirred at room temperature for 6−7 h, filtered and carefully acidified with sulphuric acid. The yellow, crystalline intermediate is collected and added to an aqueous solution of 1 mole of the appropriate amine. After about 24 h at room temperature the solution is filtered and acidified with dilute hydrochloric acid to pH 2−3. The product is sometimes precipitated as an oil, which crystallizes rapidly on scratching.

Method B. Carbon disulphide (1 mole) is added to an aqueous solution of the amine (1 mole) cooled in ice. A concentrated aqueous solution of sodium hydroxide (1 mole) is added, followed by a neutralized solution of the α-chlorocarboxylic acid added at such a rate that the temperature is kept below 40°C. The solution is stirred for 2−4 h at room temperature and is then acidified. The product may come out as an oil which crystallizes on scratching.

Optical resolutions. Preliminary experiments were carried out with the following bases:

Strychnine	Quinidine	Cinchonidine
Brucine	Morphine	(+)-α-Phenethylamine
Quinine	Cinchonine	(−)-β-Phenylisopropylamine [10]

Ethyl acetate alone or with a small quantity of methanol was found to be the most effective solvent. The salt of the acid to be resolved with the optically active base was recrystallized several times. After each recrystallization a small sample of the salt was decomposed with hydrochloric acid, the acid isolated and the rotatory power determined.

Further details on the resolutions are found in Tables 2−6. The (+)-form of N-pentamethylenethiocarbamyllactic acid was obtained *via* the same base, brucine, as the (−)-form, which is notable. A small quantity of water (25 ml) was added to the mother liquor from crystallization No. 1a. A further crop of crystals was thus obtained (yield 18 %)

Table 2. Recrystallization of the (−)-β-phenyl*iso*propylamine salt of N,N-dimethylthiocarbamyllactic acid. Initial quantity: 0.07 mole.

and it was found to contain an almost pure (+)-acid ($[\alpha]_D$ = + 74.5°). The salt was recrystallized twice from ethyl acetate containing 2−5 % water. The rotatory power of the acid was + 81.3° and + 80.3°. Crystallization at −10°C gave a semi-solid salt but at room temperature the product was crystalline. The pure salts were analyzed, as may be seen from Table 7.

Table 7. Analyses of the pure salts.

Thermal racemization. All melting points were determined with a hot stage microscope according to Kofler and Kofler [11]. On melting the optically active acids new crystals were usually formed in the melt. The recrystallization tendency increased in the following order: Pentamethylenethiocarbamyl $-<$Dimethylthiocarbamyl$-<$Dimethyldithiocarbamyllactic acid. Recrystallization of the last one was so rapid that the primary melting point could not be determined accurately.

After complete crystallization of the melt, the melting point of the new crystals was determined and found to be the same as the melting point of the corresponding racemic acid within 1°C. The optical activity had also disappeared and the melting point depression for a mixture of the racemate and the crystals from the melt was less than 1°C.

Acknowledgements. The author is much indebted to Dr S. Lindenfors for syntheses of the racemic acids and to Professor N. Hellström for all facilities put at the author's disposal at the Royal Agricultural College, Uppsala, where this work was started. The completion of this investigation was made possible by the benevolent support of Mo och Domsjö AB, which is gratefully acknowledged. Part of the expenses involved has been defrayed by a grant from *Jordbrukets Forskningsråd.*

X-Ray Investigations on Cellulose II and Mixtures of Cellulose I and II

1. A Method for Characterizing and Determining the Relative Contents of the two Modifications

JON GJØNNES and NICO NORMAN

Central Institute for Industrial Research, Oslo, Norway

The previously reported method for characterizing samples of cellulose I by width and position of the peaks in the X-ray diffractograms is extended to include cellulose II and mixtures of cellulose I and II. Procedures for determination of the ratio between the two modifications as well as an estimate of their crystalline order is described. The methods are based on measurements of intensity and width of the $(10\bar{1})$ and (002) diffraction lines of cellulose II and the (002) line of cellulose I.

In a previous paper [1] it was shown that for the same crystalline modification of cellulose, variations in the state of order is clearly reflected in a corresponding change in width of the peaks in X-ray diffractograms of the samples. This suggests the width of the predominating lines in the diffractograms to be the most convenient X-ray parameters describing the state of order in the specimens, as previously utilized [2] for samples of cellulose I. However, the height and the shape of a peak will be strongly influenced by the presence of other modifications, since in this case a superposition of peaks takes place. Mixtures of the most common cellulose modifications, I (native) and II (regenerated), frequently occur both in commercially dissolving pulps [3] and after treatment of native cellulose with swelling reagents. In the hitherto reported X-ray methods for determining the relative contents of the different cellulose modifications no attention has been paid to the state of order in the sample [3–5]. It is the purpose of the present paper to demonstrate how an estimate of crystalline order and a determination of the ratio between the two modifications may be obtained from X-ray diffractograms of the samples, where in the ratio determination the degree of order is taken into account.

The main goal has been to establish a procedure based on parameters which lend themselves readily to measurements. It has been found most practical

to employ the intensity distribution in the region $2\Theta = 18°$ to $24°$ (referred to Cu$K\alpha$ radiation) which usually displays two peaks. The one at $2\Theta = 20°$, consists of the $(10\bar{1})$-line of cellulose II and the (021)-line of cellulose I, the other at $2\Theta = 22°-22.7°$ receives contributions from the (002)-lines of both modifications. For simplicity we shall designate the two peaks $(10\bar{1})$ and (002).

As parameters sensitive to composition both the centre of gravity of the two peaks and the ratio between the peak intensities ($I_{10\bar{1}}/I_{002}$) have been tried. These two parameters display, however, essensially the same features. In the following we shall restrict ourselves to the peak intensity ratio, as this quantity is the one which is most readily measured.

The peak intensity ratio as well as the centre of gravity will to some extend depend on the degree of orientation in the specimens, particularly due to the (021)-reflection of cellulose I. Hence measurements have been carried out both on unoriented samples and pressed sheets. The latter type of specimens has been found most convenient in practice, especially for pulp samples which usually are presented as sheets. Pressed specimens have therefore mainly been used in the experiments.

EXPERIMENTAL PROCEDURE

Transmission diffractograms of the samples were prepared in the manner described previously [2]. For the pressed samples the applied pressure was about 2 500 kg/cm^2. A microphotometer curve for a mixture of cellulose I and II is reproduced in Fig. 1, displaying the cellulose II $(10\bar{1})$-peak and the composite (002)-peak. The sharp peak at 20.88° is the quartz (100) reference line. The parameters used for characterization of the samples are indicated in the figure. The angles refer to Cu$K\alpha$ radiation.

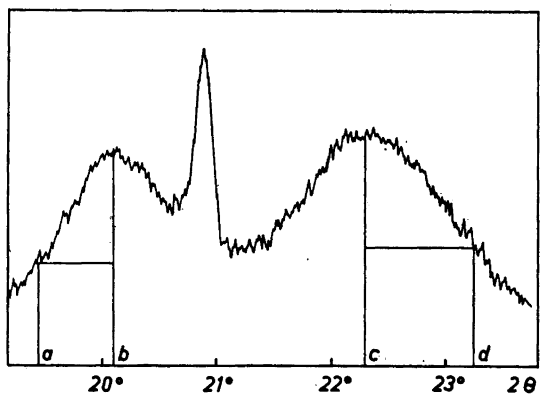

Fig. 1. Microphotometer curve for a sample consisting of a mixture of cellulose I and II. The letters a, b, c, and d indicate the $(10\bar{1})$ inner half value intersection, the $(10\bar{1})$ peak position, the (002) peak position, and the (002) outer half value intersection respectively.

RESULTS

The investigations included two different qualities of each of the two modifications I and II, a number of laboratory mixtures prepared from these samples in known ratios, and finally a series of cotton samples treated with hydrochloric acid for 1 to 4 h. The results are given in Table 1.

Table 1. Peak angles, half value intersections and peak intensity ratio $I_{10\bar{1}}/I_{002}$. Cu$K\alpha$ radiation.

From the 47 samples of specimen 1—12 the following mean standard deviations were found: Peak angles 0.035°, half value intersections: 0.03°, intensity ratio: 0.02.

DISCUSSION

The composition-sensitive parameter $I_{10\bar{1}}/I_{002}$ is seen to depend not only on the contents of cellulose I and II but also on the crystalline order in the two modifications. Corrections for the dependence on crystalline order must therefore be applied in order that the peak intensity ratio can be used for composition determination. Such a correction may apparently be based on the half widths of the peaks. For reasons which will be explained below, the angular position of the half value intersections (see Fig. 1) was preferred.

In Fig. 2 the (002) outer intersection is plotted *versus* the peak intensity ratio. As an approximation straight lines through points corresponding to the same composition with respect to crystalline modification may be considered representative for the specific composition. The plot clearly illustrates the magnitude of the corrections which have to be applied to the measured intensity ratio in order to obtain the correct value for the contents of the two cellulose modifications. For samples containing a high percentage of cellulose II the ($10\bar{1}$) half value intersection can be used as ordinate in the calibration chart. It has to be emphasized that the measurements used for constructing the calibration chart in Fig. 2 refer to samples with comparable crystalline order in the two modifications. Measurements on mixtures where the two components differ widely in crystalline order indicate that the correction method applies as well when cellulose I is the most crystalline fraction. When the cellulose II fraction is much more ordered than the cellulose I-fraction, the correction parameter appears to be measured too low, leading to an overestimation of the cellulose II-contents.

Fig. 2 has been used as a calibration chart to determine the cellulose II-contents of the acid-treated samples 13—17, leading to the values given in the first line of Table 2.

Table 2. Contents of cellulose II and estimated half widths for the samples 13—17.

Sample	13	14	15	16	17
per cent cellulose II, pressed sheets	38	50	76	79	73
per cent cellulose II, unoriented samples	39	50	72	81	72
Half width ($10\bar{1}$), degrees	>2.5	2.5	1.5	1.20	1.35
» » (002), »	<1.75	<1.75			

A plot very similar to Fig. 2 except for a translation to the left of the straight lines was obtained from peak intensity ratios measured for unoriented specimens. Cellulose II-contents for samples 13—17 determined by means of this plot and peak intensity ratios for unoriented specimens of these samples are given in the second line of Table 2.

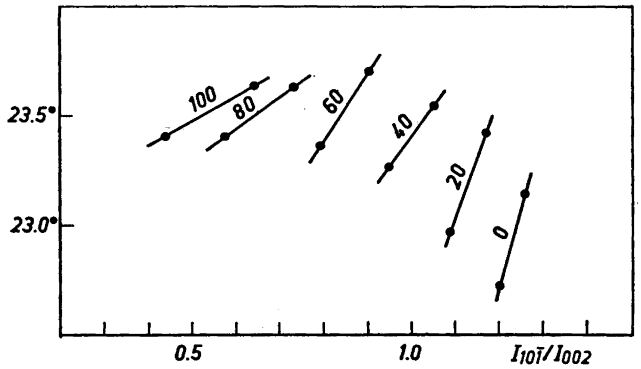

Fig. 2. The (002) outer half value intersection plotted as a function of the peak intensity ratio $I_{10\bar{1}}/I_{002}$ for series of mechanical mixtures of cellulose I and II (See Table 1). The numbers in the figure indicate the percentage of cellulose I in the samples.

An estimation of the half width of the diffraction lines for the major constituent in the mixture may also be done. From Fig. 2 it is seen that the (002) half value intersection for samples of cellulose with the same degree of crystalline order vary very slowly with composition when cellulose I is the main fraction. A similar feature is displayed by the ($10\bar{1}$) half value intersection for samples with cellulose II as the greater part. The position of the peaks, on the other hand, is very sensitive to composition. Thus it appears most reasonable to calculate half widths from the measured intersections and the peak angles corresponding to pure samples of cellulose I and II. This idea is also supported from studies of composite theoretical profiles. It is found that a neighbouring peak will produce a rather small displacement on the half value intersection at the side furtherst away from the interfering peak. For instance will the displacement vanish for the outher half value intersection of two Cauchy peaks separated through a distance equal to their half widths. This corresponds fairly to the influence of the cellulose II ($10\bar{1}$)-peak on the (002)-peak of cellulose I for samples 9—12. The influence of neighbouring peaks on the same side as the intersection may, however, be considerable. Thus it is seen that measurement of cellulose II ($10\bar{1}$) half value intersection may be worthless and in some cases even impossible due to the influence of the neighbouring (101) and ($10\bar{1}$) peaks for cellulose I (samples 11 and 12).

From such considerations the half widths given in Table 2 for samples 13—17 have been estimated, taking the cellulose II ($10\bar{1}$) and cellulose I (002) reflection angles to be 20.08° and 22.70° respectively. Due to great difference in line width between the two components in samples 13 and 14 the (002) line width for cellulose I is probably overestimated, the correct value may not be greater than the value 1.54° found for native cellulose [2]. The half widths of the ($10\bar{1}$) and (002) lines for pure cellulose II samples can be obtained in a similar way, leading to the values 1.18° and 1.13° for the acid treated samples, and 2.78° and 2.70° for the mercerized sample.

CONCLUSION

In the present paper the previously reported method [2] for characterizing samples of cellulose I by width and position of the lines in their X-ray diffractograms is extended to include cellulose II and mixtures of cellulose I and II. The application so far indicate that the method is well suited to detect and to describe structural differences between samples within the same modification as well as the ratio between cellulose I and cellulose II in mixtures. When mixtures of the two modifications are considered, a reliable line width parameter indicating the state of order in the sample can only be ascribed to the major constituent, and there will be some ambiguity for mixtures close to 50—50 %.

The interpretation of the measured widths must take into account both the lateral dimensions and crystalline order of the microfibril. At least for the mercerized samples the crystalline order seems to be the more important factor. The lateral order in cellulose II will be dealt with in a subsequent paper [6]. A thorough discussion of the hydrolysis experiments is given elsewhere [7].

The authors wish to express their thanks to Mrs. L. Bryn and Mrs. T. L. Rolfsen for their help in preparing the diffractograms. This investigation is part of a research program on the structure of cellulose carried out at the Central Institute for Industrial Research and The Norwegian Pulp and Paper Research Institute. Financial support from the *Royal Norwegian Council* for *Scientific and Industrial Research* is gratefully acknowledged. One of the authors (J.G.) is indebted to the *Norwegian Research Council* for *Science* and the *Humanities* for financial support.

X-Ray Investigations on Cellulose II and Mixtures of Cellulose I and II

2. Lateral Order in Cellulose II

JON GJØNNES and NICO NORMAN

Central Institute for Industrial Research, Oslo, Norway

The origin of broadening and displacement of the lines of cellulose II is discussed and related to the lateral order in the micelles.

In the preceding paper [1] a method is devised for characterizing samples of cellulose II and mixtures of cellulose I and II by suitable parameters measured from their X-ray diffractograms. It is the purpose of this paper to discuss the interpretation of the parameters describing the cellulose II-fraction, in particular their relation to the structure and lateral order of the micelles.

Table 1. Peak angles and half widths for samples of cellulose II. Cu$K\alpha$-radiation.

Specimen	($10\bar{1}$) reflection		(002) reflection	
	Peak angle (degree)	Half width (degree)	Peak angle (degree)	Half width (degree)
1. Mercerized cotton treated with 39 % HCl for 3 h	20.08	1.24	22.16	1.12
2. Mercerized acetate grade wood pulp	20.16	2.86	21.59	3.10

The half widths of the reflection ($10\bar{1}$) and (002) obtained from the measurements described in the preceding article are presented in Table 1. As is well known, the X-ray line widths depend both on the size and lattice perfection of the reflecting crystallites. It is seen, however, that the data presented in Table 1 display no differences in line width of the reflections ($10\bar{1}$) and (002)

for the same sample. This is quite remarkable, as the crystallites of cellulose II are commonly accepted to be ribbon shaped with the largest surface parallel to the (101) planes. If the particle size was the most predominant factor in determining the line widths, one would expect considerable differences in widths of the different reflections (*h0l*) from planes parallel to the chain axis, the (10$\bar{1}$)-line being by far the narrowest. We are thus led to the conclusion that at least the width of the (10$\bar{1}$) line to a great extent is determined by other factors, in particular lattice disorder. From the measured half widths *lower limits* for the particle size may be computed, leading to the values 30 Å for the mercerized pulp and 85 Å for the hydrolyzed sample.

There is additional evidence that the actual dimensions of the crystallites may be appreciably greater than the above mentioned values. Thus the line widths obtained for the mercerized pulp also seem to apply to mercerized samples prepared from cotton, which in the native state is reported to have lateral dimensions [2] of 50—80 Å. A particularly illustrative example of the alterations in line width of the cellulose II reflections resulting from chemical treatment is offered when cotton is treated with hydrochloric acid [1,3]. At first when cellulose II is formed there is a pronounced increase in line width, whereas prolonged acid treatment results in a gradual sharpening of the lines leading to a half width still lower than for the original native sample. It seems highly improbable that these variations in line width reflect changes in the lateral dimensions of the micelles. It can therefore be concluded that transformation of native cellulose into cellulose II by mercerization or acid treatment increases lattice disorder, whereas prolonged acid treatment leads to an improvement of the lattice order. This increase in lateral order is far more pronounced than what has been found in the cellulose I fraction after chemical treatments [3,4].

To obtain the best possible interplanar spacings for the investigated pure cellulose II-samples, the peak positions of the (10$\bar{1}$) and (002) reflections were corrected for the effect of overlapping peaks. The correction assumed Cauchy profile for the contribution from the neighbouring peaks and was based upon the half widths given in Table 1. The resulting interplanar spacings are tabulated in Table 2 together with (101)-spacings obtained from peak angles measured above an oblique linear background in the angular region $2\Theta = 10°-15°$.

These results which display considerable anisotropy in the variation of cell dimensions normal to the chain axis is in conformity with other measure-

Table 2. Interplanar spacings for samples of cellulose II.

Specimen	d_{101}(Å)	$d_{10\bar{1}}$(Å)	d_{002}(Å)
1. Mercerized cotton treated with 39 % HCl for 3 h	7.22	4.42	4.01
2. Mercerized acetate grade wood pulp	7.27	4.42	4.05

ments of interplanar spacing of cellulose II [6-8]. It is a general feature that the (10$\bar{1}$) spacing is found to be almost constant, even when cellulose is swelled to form hydrates. The other equatorial reflections, particularly (101) show pronounced variations. According to the currently accepted structure of cellulose II the intermolecular hydrogen bonds are mainly pointing in the direction of the [101] cell diagonal, and the structure can be described as a packing of hydrogen bonded sheets of cellulose chains parallel to the (10$\bar{1}$) planes [9].

It is thus seen that the best ordered cellulose II-samples display a shorter interchain distance within the sheets than the less ordered one, and one may tentatively suggest these differences to reveal variations in the strength and ordering of the hydrogen bonds. Another explanation is to assume the least ordered samples to possess somewhat more inter-crystalline water than the best ordered ones, leading to a greater average interchain distance.

If the above considerations hold true, it is evident that the lateral order concept outlined by Howsmon and others [10,11] and related to the strength and distribution of hydrogen bonds will be most intimately connected with the lattice disorder in the [101] direction. The (10$\bar{1}$) line width will, on the other hand, depend on disorder in the packing of the hydrogen bonded sheets. The nature of this disorder can not be stated from our present knowledge. A tempting explanation may be to assume some of the sheets to be incomplete, implying edge dislocations to be contained in the micelles and taking (101) as the slip plane. Assuming cellulose II to occur in a swollen state in the strong hydrochloric acid [3] this model can apparently account for the ordering resulting from acid treatment.

It should be pointed out, however, that the X-ray measurements within rather narrow limits give the same line width for all reflections from planes containing the chain axis, indicating the combined effect of disorder or distortion and possible particle size on the line width to be of the same magnitude in all directions normal to the chain axis.

Estimation of the Activity Coefficients in a Liquid Mixture of Na_2CO_3 and Na_2S

ERIK ROSÉN and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Activity coefficients for the components in Na_2CO_3—Na_2S liquid mixtures are calculated from the freezing point data of Courtois [2], assuming the solutions to be "regular solutions".

We have recently studied [1] the thermodynamics of equilibria on gasification of sodium-base pulping liquors. We then showed that under certain conditions, the condensed phase at equilibrium would be likely to consist mainly of a liquid mixture of Na_2CO_3 and Na_2S. For an accurate calculation of the equilibrium composition of the gas phase and condensed phase obtained, it was desirable to have an estimate of the activity coefficients of the two components, Na_2CO_3 (= 1) and Na_2S (= 2).

The experimental data on the system Na_2CO_3—Na_2S are rather meagre. Courtois [2] has given the temperature of solidification for various mixtures (circles in Fig. 3). He found no intermediate phase, and a simple eutectic equilibrium at 1 068°K. There is no evidence for solid solutions. From his work we may take the melting points to be 1 125°K for Na_2CO_3 and 1 453°K for Na_2S. These values are in good agreement (± 2°) with the work of other investigators [3–5].

Tammann and Oelsen [10] have also measured the freezing point curve. They give fewer points which agree well at low x_2 but deviate seriously at high x_2. We have decided to use Courtois' values; an experimental reinvestigation is however desirable.

The heat of fusion of Na_2CO_3, $L_{f1} = 7.3$ kcal mole^{-1}, has been determined calorimetrically by Ginzburg [3]. The heat of fusion for Na_2S, $L_{f2} \approx 1.6$ kcal mole^{-1}, has been estimated by Kubaschewski and Evans [6]. We have not been able to find any other data, such as heats of mixing, that could be used in the calculation of the activity coefficients of Na_2S and Na_2CO_3.

The two components Na_2S and Na_2CO_3 have the cation in common, and anions of the same charge and roughly the same "ionic radius". It seems likely that the Temkin [7] model can be used for such a mixture, as a good approximation; in this case, it means that the anions are randomly mixed. Then

$$s_1 - s_1^0 = -R \ln x_1; \qquad s_2 - s_2^0 = -R \ln x_2 \tag{1}$$

Let us now assume that the melts behave as "regular solutions" according to Hildebrand [8], which means that eqn (1) is valid and also that the molar heat of mixing is

$$\Delta H = bx_1x_2 \tag{2}$$

Then we can derive, from the definitions of partial molar quantities

$$h_1 - h_1^0 = bx_2^2; \qquad h_2 - h_2^0 = bx_1^2 \tag{3}$$

From the definitions of the thermodynamic quantities, with eqns (1) and (3) we may prove

$$RT \ln f_1 = bx_2^2; \qquad RT \ln f_2 = bx_1^2 \tag{4}$$

These are the well-known relationships for regular solutions [8]; the symbols have their usual significance: s_1, s_2 partial molar entropies; h_1, h_2 partial molar enthalpies; x_1, x_2 molar fractions ($x_1 + x_2 = 1$);

$$f_1 = a_1/x_1; \qquad f_2 = a_2/x_2 \tag{4a}$$

are activity coefficients, and the superscript "0" refers to the standard state, which is the pure liquid in our case.

The constant b is assumed to be independent of temperature, so that a knowledge of this constant makes it possible to calculate f_1 and f_2 for all temperatures. We shall now set out to calculate the constant b, using the available experimental data.

In those parts of the phase diagram where a liquid is in equilibrium with the solid substance 1, we have

$$1 \text{ (solid)} \rightleftharpoons 1 \text{ (liquid, activity } a_1); \; K = a_1; \; \Delta H = L_{f1} \tag{5}$$

where K is the equilibrium constant. By integrating van't Hoff's equation

$$\int_K^{K=1} \mathrm{d} \ln K = R^{-1} \int_T^{T_{f1}} L_{f1} \frac{\mathrm{d}T}{T^2}$$

and assuming L_{f1} to be approximately constant over the interval studied, we obtain

$$RT \ln K = -L_{f1}(1 - TT_{f1}^{-1}) \tag{6}$$

Here, T_{f1} is the melting point for pure Na_2CO_3. From eqns (4), (4a), (5), and (6) we find

$$bx_2^2 + RT \ln x_1 = -L_{f1}(1 - TT_{f1}^{-1}) \tag{7}$$

which may be rewritten in the form

$$T = (L_{f1} + bx_2^2)[L_{f1}T_{f1}^{-1} - R \ln (1 - x_2)]^{-1} \tag{8}$$

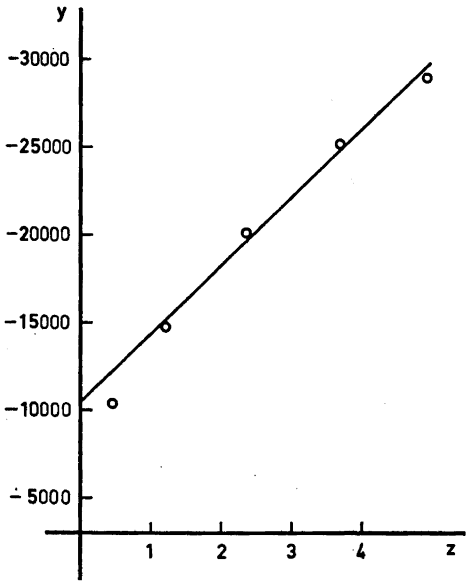

Fig. 1. Plot according to eqn (9). Circles calculated from data of Courtois [2]. Straight line calculated with $L_{fl} = 10.50$ kcal mole^{-1}, $b = 3.84$ kcal mole^{-1}.

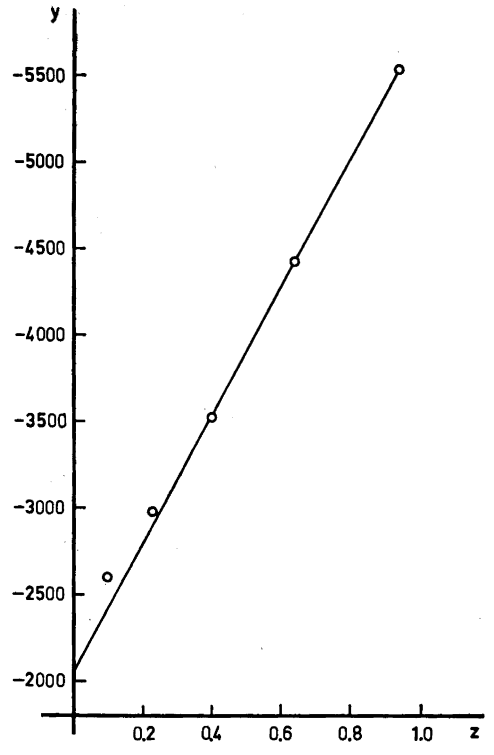

Fig. 2. Plot according to eqn (9) with indices 1 and 2 exchanged. Points calculated from data of Courtois [2]. Straight line calculated assuming $b = 3.69$ kcal mole^{-1} and $L_{f_2} = 2.05$ kcal mole^{-1}.

If b, L_{fl} and T_{fl} are known, we may thus give T as a function of x_2. In the present case, this function is approximately known[2]; in order to calculate the unknown constants b and L_{fl} we may transform eqn (7) to the form

$$L_{fl} + y + bz = 0 \qquad (9)$$

where

$$y = RTT_{fl}(T_{fl} - T)^{-1} \ln (1 - x_2)$$

$$z = T_{fl}(T_{fl} - T)^{-1} x_2^2$$

Eqn (9) has been used by Flood, Förland and Roald [9] for calculating the heat of fusion of $CaCO_3$, from the melting diagram. If y is plotted as a function of z, one will obtain b and L_{fl} from the slope and intercept of the straight line. — One may easily derive equations that are symmetrical to eqns (8) and (9), with 1 and 2 exchanged.

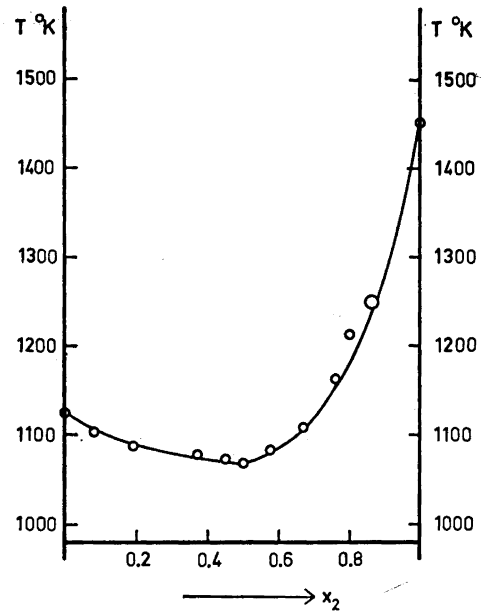

Fig. 3. Freezing point diagram $T(x_2)$ for system Na_2CO_3—Na_2S. Points: data of Courtois [2]. For the larger circle, Courtois gives a higher uncertainty than for the rest. Curve calculated from eqn (8) and its symmetrical form with 1 and 2 reversed, assuming $b = 3.75$ kcal mole^{-1}, $L_{f1} = 10.50$ kcal mole^{-1} and $L_{f2} = 2.00$ kcal mole^{-1}.

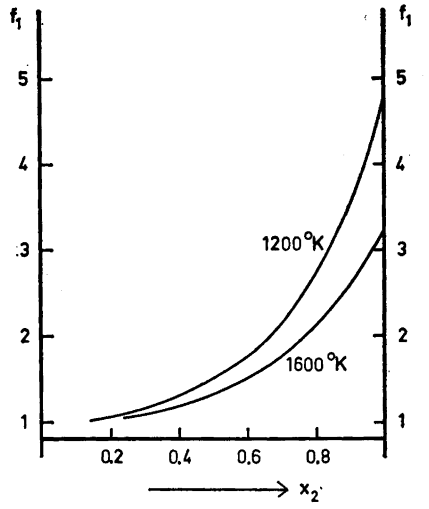

Fig. 4. Activity coefficient f_1 of Na_2CO_3 in melts Na_2CO_3—Na_2S, calculated by means of eqn (4), assuming $b = 3.75$ kcal mole^{-1}.

Fig. 1 gives a linear plot of Courtois' data according to eqn (9); it leads to the values $L_{f1} = 10.50$ kcal mole^{-1} and $b = 3.84$ kcal mole^{-1}. A plot of the symmetrical function is given in Fig. 2; it leads to $L_{f2} = 2.05$ kcal mole^{-1} and $b = 3.69$ kcal mole^{-1}.

Fig. 3 gives the diagram $T(x_2)$ calculated using eqn (8) and its symmetrical analog, with the average value of $b = 3.75$, and the value $L_{f1} = 10.50$ kcal mole^{-1}, and $L_{f2} = 2.00$ kcal mole^{-1}. Here, L_{f2} has been slightly adjusted to give a somewhat better agreement with the (anyway somewhat crude) experimental data.

The good agreement of the values for b obtained from the two independent diagrams (Figs. 1 and 2), and the good agreement of $T(x_2)$ with the experimental data indicate that the "Temkin regular solution" may be used as an approximate model for the melts of $Na_2CO_3 + Na_2S$.

Finally, Fig. 4 gives the activity coefficient, f_1, as a function of x_2, calculated by means of eqn (4), for temperatures 1 200°K and 1 600°K. For 1 200°K, values for f_1, when $x_2 > 0.8$ cannot be obtained experimentally since Na_2S(s) crystallizes.

Studies on Cobaltammines

III. Some Evidence on the Association of Thiocyanate and Perchlorate Ions with the *trans*-Dithiocyanatobis(ethylenediamine) Cobalt(III) Ion

RAGNAR LARSSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The extraction of *trans*-[Co $en_2(SCN)_2$]SCN from aqueous solutions of varying NH_4SCN concentration into a SCN^--saturated anion-exchange resin and also into a mixture of *cyclo*hexanone and 2-octanol has been recorded. In both cases a maximum of the extraction quotient was found at about $C_{NH_4SCN} = 1$ M. This is interpreted as an indication of outer-sphere complex formation.

By a conventional solubility method the first association constant for the reaction between the SCN^- and *trans*-Co $en_2(SCN)_2^+$ ions has been determined at an ionic strength of 3 M ($NaClO_4$). $\beta_1 = 0.3_0$ M^{-1} This result is discussed in relation to a hypothesis of competing associa- of SCN^- and ClO_4^- ions with the complex ion.

Some extraction experiments from solutions of varying concentrations of $NaClO_4$ into two different ketonic solvents are also recorded. These results are not conclusive in regard to the question of perchlorate outer-sphere complexes.

Several reports on the formation of "outer-sphere complexes" have recently been compiled [1,2]. However, some authors seem to regard this kind of association as an "ion-pairing" in the sense of Bjerrum [3]. This point of view is rather trivial in that effects thus described could equally well be accounted for by a calculation of the coefficients of activity of the reacting ions from the equation deduced by Gronwall, LaMer and Sandved [4] or by any still more elaborated treatment.

Therefore it was considered important to demonstrate the existence or non-existence of association in water between some univalent and rather large ions, where "ion-pairs" are not likely to be formed, *i.e.*, where the high order terms in the equation of Gronwall *et al.*[4] can be ignored. Such ions are even less expected to form "triple ions" in the sense of Fuoss and Kraus [5].

As such a system *trans*-Co $en_2(SCN)_2^+$ and SCN^- has been chosen.

The investigation has been pursued along two different lines. The first one has been to decide whether anionic complexes are formed or not. The second one has been an attempt to determine at least the first association constant at a constant ionic strength.

DETECTION OF ANIONIC THIOCYANATO COMPLEXES

Methods and Notations

It has been shown by Fronæus [6,7] that anionic complexes can be detected with the help of anionic exchange resins. If the distrubution of metal between the resin, saturated with the ligand, and the aqueous phase is determined as a function of the ligand concentration in the aqueous phase, then a maximum of that function will indicate the formation of at least one anionic complex.

The detailed deductions are found in the papers referred to. We emply the following symbols:

M	=	*trans*-Co $en_2(SCN)_2^+$
B	=	SCN-
C_M	=	total concn. of M in the aqueous phase
C_{MR}	=	» » » M » » resin »
C_B	=	» » » B » » aqueous »

What we intend to measure is thus $\varphi_R = \frac{C_{MR}}{C_M}$ as a function of C_B.

Likewise, if the distribution of metal between an organic solvent and the aqueous phase is determined at various C_B, then a maximum might be obtained. If it is assumed that only the neutral complex is extracted, this maximum may be taken as an indication of the existence of anionic complexes in the aqueous phase. Activity changes in the organic phase may, however, make the interpretation uncertain. It was found that a mixture of equal volumes of *cyclo*hexanone and 2-octanol was a good extracting solvent for *trans*-Co $en_2(SCN)_2$ SCN. If C_{MS} is the concentration of M extracted into this solvent mixture we will measure $\varphi_S = \frac{C_{MS}}{C_M}$ as a function of C_B.

Measurements

Chemicals used. *Trans*-Co $en_2(SCN)_2ClO_4$ was prepared from analytical grade chemicals following Werner and Bräunlich [8], with the modification that the perchlorate was precipitated by concentrated perchloric acid from the mixture of *cis*- and *trans*-isomers. It was found rather unexpectedly that the *cis*-isomer was precipitated with very great difficulty, so that an apparently pure *trans*-Co $en_2(SCN)_2ClO_4$ was obtained after two reprecipitations. The crystal mass was washed acid-free with ethanol and ether and air-dried. The absorption spectrum of the product compares rather well with the data of Shimura[9,10]. ($\lambda_{max_1} = 510$ mμ, $\varepsilon_{max_1} = 2.82 \times 10^2$; $\lambda_{max_2} = 315.5$ mμ, $\varepsilon_{max_2} = 3.08 \times 10^3$). The equivalent weight was determined alkalimetrically *via* an acid-saturated cation exchange resin; calc. 395; found 392. Cobalt content [11]: calc. 14.93 %; found 14.89 %.

Ammonium thiocyanate solutions were prepared as before [12].

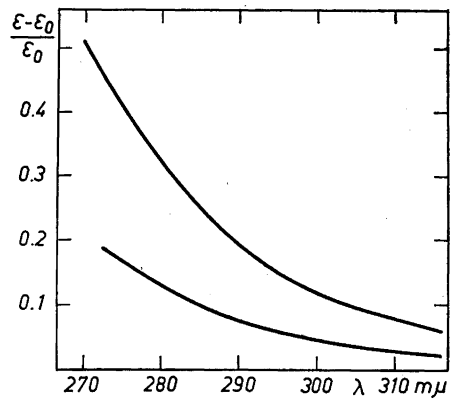

Fig. 1. The relative change of the extinction coefficients in UV. Upper curve: 0.1 mM $MClO_4$ + 1.5 M NaSCN (ε) compared to 0.1 mM $MClO_4$ + 1.5 M $NaClO_4$ (ε_0). Lower curve: 0.15 mM $MClO_4$ + 0.5 M NH_4SCN + 0.5 M NH_4ClO_4 (ε) compared to 0.15 mM $MClO_4$ + 1.0 M NH_4ClO_4 (ε_0).

The *anionc exchange resin* was Dowex 1, with 4 % cross-linking. It was converted into the thiocyanate form by percolating a concentrated solution of potassium thiocyanate, corresponding to ten times the exchange capacity, through a column of the resin, which was afterwards well rinsed with distilled water and air-dried.

*The extracting solvent. Cyclo*hexanone only cannot be used as an extracting solvent because of its tendency to dissolve large quantities of water and ammonium thiocyanate whereby the two-phase character of the system vanishes at rather low thiocyanate concentrations. Therefore an equal volume of 2-octanol was added to the *cyclo*hexanone.

Cyclohexanone (Riedel-de Haën A.-G., *rein*) was purified by distillation at 153.5—7°C and *2-octanol* (Eastman P 66) was distilled at 176—178°C.

Procedure. Ten milliliters of a solution of the composition C_B M NH_4SCN and C'_M M Co $en_2(SCN)_2ClO_4$ were shaken in glass-stoppered bottles together with w g of the resin (where w was kept about 1.5 g) or 10 ml of the extracting solvent. The shaking was performed in a water-thermostat at 20.0°C. The shaking was carried out for two days in the ion-exchange experiments and for about 15 h in the extraction experiments. In order to prevent any photochemical decomposition of the complex the bottles were coated with black paint on the outside. (The photolysis was found to be strongly dependent on the thiocyanate concentration; *cf.* Adamson and Sporer [13].) When equilibrium was reached, which was ascertained by prolonged shaking, the phases were rapidly separated — after centrifugation in the extraction case.

In the ion-exchange experiments the aqueous phase was sucked off as completely as possible with a filter-stick of large porosity. Thereafter the resin was rinsed rapidly in the shaking bottle with two 15 ml portions of distilled water, whereafter 20 ml of water were added and the bottles were subjected to renewed shaking. Then, as the thiocyanate concentration in the aqueous phase must be very low, the cobalt complex sorbed by the resin was almost quantitatively re-extracted. — This procedure was justified by preliminary experiments, that showed the elution process to be a slow one.

Determination of C_M. A photometric determination of C_M was deemed expedient in view of the intense colour of the complex. It was then necessary to investigate the influence of the thiocyanate concentration on the light absorption spectrum of the complex.

It was to be expected [14], that — regardless of the degree of outersphere complex formation — this influence would be small, especially in the region of long wave lengths. This was also found to be the case. There was no variation at constant ionic strength at the 510 mμ maximum within the limits of the experimental error. (The variation recorded in column 3 of Table 3 must be an "ionic strength effect".) Fig. 1 gives the relative change of the extinction coefficient in the ultraviolet wave length region.

The measurements of the absorption spectra and the C_M determinations in the ion-exchange experiments were made with a Beckman Model DK-1 Recording Spectrophotometer.

In the extraction experiments C_M was determined (at 510 mμ) with a Hilger Uvispek H 700 Spectrophotometer. In these experiments the aqueous phase only was examined; C_{MS} was determined by difference. In order to free the solutions from an eventual opalescence caused by small drops of the organic solvents separating at a possible temperature fall, one fifth of the solutions' volume of ethanol was added immediately after phase separation. This ethanol addition was found to cause an increase in the extinction coefficient of 3.7 %.

Determination of φ_R.

E' = optical density at the position of the 510 mμ maximum of a solution of composition C'_M M Co $en_2(SCN)_2ClO_4$ and C_B M NH_4SCN.

E_1 = optical density (at the 510 mμ maximum) of the same solution when 10 ml of it had been shaken with w g of the resin.

E_2 = optical density at the position of 316 mμ maximum of the solution obtained from the re-extraction from the resin (d = 1 cm).

We can now calculate φ_R in two different ways:

1.
$$C_{MR} = \text{const.} \frac{E'-E_1}{w} \times 10^{-2} \text{ mole/g} \quad (1)$$

$$C_M = \text{const. } E_1 \text{ mole/l} \quad (2)$$

$$\therefore \varphi_{R1} = \left(\frac{E'}{E_1} - 1\right) \times \frac{10^{-2}}{w} \text{ l g}^{-1} \quad (3)$$

2.
$$C_{MR} = \frac{10^{-2} \times 2\ E_2}{3.08 \times 10^3 \times w} \text{ mole/g} \quad (4)$$

$$C_M = C'_M - \frac{2\ E_2}{3.08 \times 10^3} \text{ mole/l} \quad (5)$$

$$\varphi_{R2} = \frac{10^{-5} \times 2\ E_2}{3.08\ w \left(C'_M - \dfrac{10^{-3} \times 2\ E_2}{3.08}\right)} \text{ l/g} \quad (6)$$

The factor 2 in eqn (4) originates from the fact that the volume of the solution which was used to extract the complex from the resin was 20 ml compared to the original solution of 10 ml. 3.08×10^3 is, as previously stated, the extinction coefficient of the complex at the second absorption maximum.

Determination of φ_S.

E_3 = optical density of the aqueous phase with an additional one fifth of ethanol measured at 510 mμ.

We easily obtain

$$C_M = \frac{6}{5} \cdot \frac{E_3}{d \times 1.037 \times \varepsilon} \quad (7)$$

where ε is the extinction coefficient at 510 mμ (2.82×10^2) and d is the thickness of the cell (2 cm).

C_{MS} is, however, not so easily obtained as there is still, in spite of the addition of 2-octanol to the *cyclo*hexanone, a tendency for the organic solvent to extract water and NH_4SCN, whereby the volume of the organic phase (V_S) increases and the volume of the aqueous phase (V) decreases. For $C_B > 1$ M it was necessary to make a correction for this effect. Defining $q = V_S/V$ and assuming that the total volume of the two phases is constant, which was apparently true, it is easily deduced

$$C_{MS} = \frac{0.5\ C'_M(1 + q) - C_M}{q} \quad (8)$$

Hence with a knowledge of q, we obtain $\varphi_S = \dfrac{C_{MS}}{C_M}$.

Determination of q. The quantity q was determined simply by shaking equal volumes of the organic solvent mixture and NH_4SCN-solutions in a stoppered, graduated centri-

Table 1. The variation of the volume quotient q with C'_B.

C'_B M	V	Vs	q	log $(q-1)$	log C'_B
2.730	4.20	5.7_9	1.38	-0.42_0	0.436
3.00	3.9_1	6.0_9	1.56	-0.25_2	0.477
3.60	2.7_6	7.2_4	2.62	0.20_0	0.556

fuge tube and reading the volumes. If C'_B means the thiocyanate concentration before equilibration, it was found (Table 1) that q could be related to C'_B by the relation

$$\log(q-1) = -2.7_4 + 5.2_5 \log C'_B \quad (9)$$

Results

The measurements are recorded in Tables 3 and 4. The values of φ_R as well as those of φ_S were reproducible within 1—2 %.

The value of C_B, the ligand concentration after equilibration, was determined as a function of C'_B, the original ligand concentration, by Volhard titration of the aqueous phase.

In the ion-exchange experiments the difference was found to be negligible; for the extraction system $C'_B - C_B$ is given in Table 2.

Table 2. The variation of C_B with C'_B.

C'_B M	C_B M	$\frac{C'_B - C_B}{V C'_B}$
0.2000	0.1916	0.0188
1.000	0.882	0.118
1.800	1.516	0.212
3.000	2.376	0.360

The values obtained in Table 2 were rationalized to the relation

$$C_B = C'_B - 0.119\ (C'_B)^{3/2} \quad (10)$$

which was used for calculation of C_B in Table 4.

From Fig. 2 it follows that the two curves describing φ_{R_1} and φ_{R_2} do not coincide, but that the former one lies always above the latter. This might be explained by assuming that part of the complex sorbed by the resin is adsorbed

on its surface only, and that this part is easily washed away and does not enter into the calculation of φ_{R_2}. The adsorption seems to be more pronounced at those ligand concentrations where the neutral complex is formed to a large part.

It is of interest to note that the φ_{R_1}-values determined for C'_M = 2.52 mM are all smaller than those corresponding to C'_M = 2.11 mM.

Although the effect is small it is concordant with the surface adsorption analogue of the criterion on complex formation by the resin put forward by Fronæus [7], *i.e.*, the smaller C'_M is the higher will φ be.

It is also observed that the functions φ_R and φ_S exhibit maxima at almost the same value of C_B. This may, however, be fortuitous; the ion-exchange measurements should be regarded as the significant ones. The position of the

maximum in the extraction case may depend on factors such as the mutual solubility of the solvents and the extraction of NH_4SCN into the organic phase.

MEASUREMENTS AT CONSTANT IONIC STRENGTH

Method and Formulae

In 3 M $NaClO_4$ the solubility of Co $en_2(SCN)_2ClO_4$ is rather low (0.6 mM). Hence there is a possibility of studying the complex formation by solubility measurements.

The following notations are used

$$\beta_n = \frac{[MB_n]}{[M][B]^n} \tag{11}$$

$$X = \sum_{n=1}^{n} \beta_n [B]^n \tag{12}$$

$$L = [M][C] \tag{13}$$

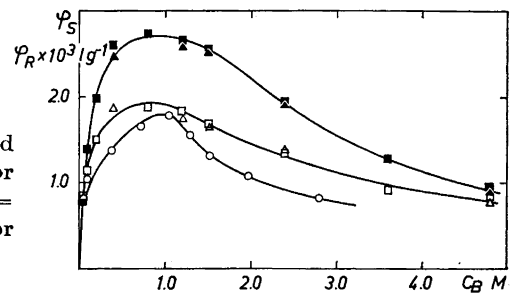

Fig. 2. The distribution quotients φ_R and φ_S. φ_{R1} for $C'_M = 2.52$ mM (▲); φ_{R1} for $C'_M = 2.11$ or 2.03 mM (■); φ_{R2} for $C'_M = 2.52$ mM (△) and φ_{R2} for $C'_M = 2.11$ or 2.03 mM (□). φ_S is marked by (○).

In eqn (13) the abbreviation C stands for ClO_4^-. This notation will be used throughout this paper. We then have

$$C_M = [M](1 + X) \tag{14}$$

From eqns (13) and (14) we obtain

$$1 + X = C_M \cdot [C]/L \tag{15}$$

Now

$$L = [M]_o[C]_o = (C_M)_o[C]_o \tag{16}$$

where indices mean $C_B = 0$. Thus

$$1 + X = \frac{C_M \cdot [C]}{(C_M)_o[C]_o} \tag{17}$$

In the following the approximations $[B] = C_B$ and $[C] = C_C$ will be used, because of the small value of C_M. Hence, by measuring C_M, we can obtain X as a function of C_B. If the coefficients of activity of the ionic species concerned could have been regarded as constant we might have been able to calculate β_1, β_2, ... by conventional methods. However, as the complexity is very weak it was necessary to use large ligand concentrations and thus the salt medium is changed to such a degree as to invalidate the supposition of constant activity coefficients.

The best we can hope for then is to be able to calcuate β_1 from

$$\beta_1 = \lim_{C_B \to 0} \left(\frac{C_M \cdot C_C}{(C_M)_o \cdot (C_C)_o} - 1 \right) \cdot \frac{1}{C_B} \tag{18}$$

C_B M NaSCN
$3.00 - C_B$ M $NaClO_4$
C'_M M $Coen_2(SCN)_2ClO_4$

were shaken in the same black-painted bottles as before. After some time a precipitation of Co $en_2(SCN)_2ClO_4$ was formed. From time to time samples of the solutions were withdrawn with a filterstick of fine porosity and were analyzed as before by measurement of the optical density at 510 mμ using the Hilger instrument and 2 cm quartz cells.

Chemicals used. Sodium perchlorate was prepared from analytical grade sodium carbonate and perchloric acid. *Sodium thiocyanate* was of analytical grade. The stock solutions were checked by ion-exchange-alkalimetric titration and Volhard titration, respectively.

Results

Unfortunately, equilibrium was very slowly reached. Experiments where solid Co $en_2(SCN)_2ClO_4$ was added in excess to solutions of the above composition did not give reproducible results. The probable explanation may be slow rearrangements in the solid phase.

Table 5. Solubility measurements: Optical densities of the saturated solutions (d = 2 cm; λ = 510 mμ). Calculation of X/C_B.

C_B M	E					$1+X$	X/C_B
	259 h	427 h	619 h	788 h	Mean		
0	0.354	0.345	0.340	0.339	0.345		*0.30*
0.3	0.428	0.419	0.418	0.411	0.419	1.093	0.31
0.43	0.472	0.459	0.456	0.451	0.459	1.140	0.33
0.60	0.520	0.511	0.510	0.507	0.512	1.187	0.31
0.90	0.645	0.637	0.639	0.635	0.639	1.297	0.33
1.20	0.835	0.822	0.819	0.815	0.823	1.431	0.36
$\beta_1 = 0.30 \pm 0.03$ M^{-1}							

In Table 5 are given the results of a representative set of experiments, the precipitation formed from the supersaturated solutions with C'_M = 3.00 mM.

The calculations have been performed on the mean of the determinations at the four different times reported. If the shaking had been further prolonged, the hydration of the complex might have caused undesirable effects. It must be observed, however, that this hydration, the velocity of which is very low at 20°C [15], would cause an *increase* of solubility. Also a *cis-trans* isomerization [15] would have the same effect. Furthermore, if X is calculated from any of the separate sets of solubilities we obtain, within the experimental errors, the same value of $\lim_{C_B \to 0} X/C_B$ as that reported here, *i.e.*, 0.30 M^{-1}.

SEARCH FOR PERCHLORATE COMPLEXES

For reasons put forward in the following discussion it was deemed necessary to investigate also the eventual formation of perchlorate complexes of Co $en_2(SCN)_2^+$. As the sorption of Co $en_2(SCN)_2ClO_4$ on a perchlorate-saturated anion exchange resin was too small to permit a reliable analysis, only the solvent extraction technique was used. In order not to base judgment on one set of measurements only, two different extracting solvents were used, *viz.*, the *cyclo*hexanone-2-octanol mixture and in the second case acetophenone.

Measurements

The measurements were performed as in the thiocyanate extractions.

The *acetophenone* used was a Merck preparation of the "wasserhell" quality. It was used without further purification.

The $NaClO_4$ concentration of the aqueous phase was determined alkalimetrically *via* a cation exchange resin in the acid form.

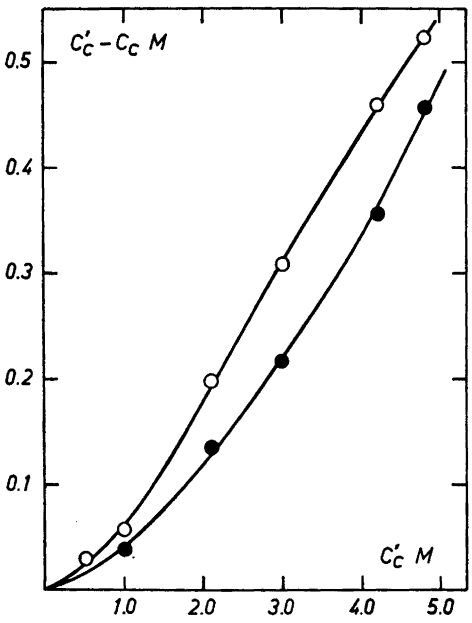

Fig. 3. Change of C_{NaClO_4} due to extraction. *Cyclo*hexanone—2-octanol mixture (O); acetophenone (●).

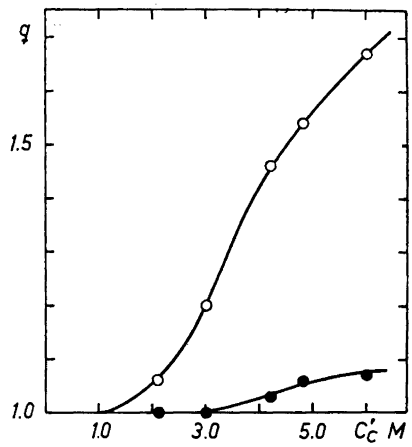

Fig. 4. Change of volume quotient q. *Cyclo*hexanone—2-octanol mixture (O); acetophenone (●).

Results

The results are reported graphically only, as the calculations were very similar to those of the thiocyanate extractions. In Fig. 3 is given the decrease of sodium perchlorate concentration due to extraction into the organic phase. Fig. 4 shows the change in the volume quotient as the electrolyte concentration increases. Fig. 5 gives the final result. The quotient φ was reproducible to within about 1 %. C'_M was kept low to avoid precipitation at the highest perchlorate concentrations.

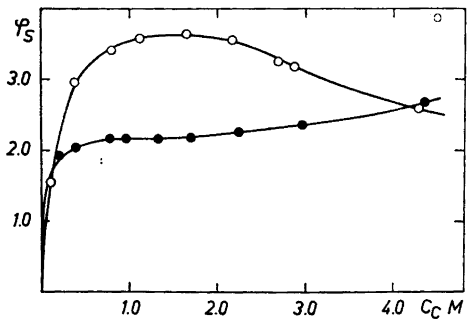

Fig. 5. Distribution quotient φ_S. *Cyclo*hexanone—2-octanol mixture (O); acetophenone (●).

C'_M = 0.5 and 2 mM (*cyclo*hexanone-2-octanol)
C'_M = 2 and 3 mM (acetophenone).

Only at C'_C = 4.8 M, C'_M = 3 mM was precipitation encountered. This point was then omitted.

DISCUSSION

If it is true, as infra-red data [16,17] suggest, that hydrogen-bonding makes an important contribution to the effects causing outer-sphere complexity, then the relation between the complexity constants will depend almost exclusively on electrostatic and statistical factors. Thus if we start from the experimental value of β_1, we can calculate the successive constants $\beta_2 \ldots \beta_n$ from the statistical relation

$$\frac{b_{n+1}}{b_n} = \frac{(N-n)n}{(N-n+1)(n+1)} \tag{19}$$

where

$$b_n = \frac{\beta_n}{\beta_{n-1}} \; ; \quad b_1 = \beta_1 \tag{20}$$

given by Bjerrum (Ref.[18], p. 24). These values must be maximum values, because of the neglect of the increasing electrostatic repulsion of negatively charged entities. In the present case, this neglect is certainly forgivable because we have chosen the large ions so as to minimize the electrical work.

In order to make use of eqn (19), we must make some assumption on the maximum coordination number N. It seems reasonable to assume that in this case $N = 8$, corresponding to the eight faces of an octahedron.

The calculation based on $\beta_1 = 0.3$ M^{-1} gave as result

$$\beta_2 = 0.04 \text{ } M^{-2}; \qquad \beta_3 = 0.003 \text{ } M^{-3}; \qquad \beta_4 = 0.0001 \text{ } M^{-4};$$

Then, from the well-known formula for $\bar{n}$ (Ref.[18], p. 21) we obtain for [B] = 1 M $\bar{n} = 0.28$, $\bar{n} = 0.29$ and $\bar{n} = 0.29$ if only the two, three and four first complexes are considered, respectively.

This result is in obvious variance with the result of the extraction experiments, which indicate, that $\bar{n} \approx 1$ when [B] = 1 M.

Some of this disagreement certainly arises from the fact that we compare measurements made at different ionic strengths and in solutions of ammonium and sodium salts, respectively.

However, it seems to the present author that a rather probable explanation is that there might be a perchlorate complexity too, which is of a strength comparable in magnitude to the thiocyanate complexity.

If this is the case, it must be entirely wrong to compare results from measurements in a perchlorate-rich medium with such obtained in a perchlorate-free one.

In consequence of this assumption we must re-formulate the treatment of the solubility measurements.

The following notations are introduced:

$$\beta_{nB} = \frac{[MB_n]}{[M][B]^n} \tag{21a}$$

$$\beta_{nC} = \frac{[MC_n]}{[M][C]^n} \tag{21b}$$

meaning the "true" complexity constants in the sense of Leden (Ref.[19], p. 40). We will assume in the following calculation that only the first two perchlorate complexes are formed in appreciable amounts. Then the only mixed complex to be considered is MBC, the complexity constant of which is defined as

$$\beta_{2BC} = \frac{[MBC]}{[M][B][C]} \tag{21c}$$

It may be assumed from energetical considerations that

$$2 \log \beta_{2BC} = \log \beta_{2B} + \log \beta_{2C} \tag{22}$$

or

$$\beta_{2BC} = \sqrt{\beta_{2B} \cdot \beta_{2C}} \tag{22a}$$

Hence eqn (14) turns into

$$C_M = [M](1 + X_B + X_C + \sqrt{\beta_{2B} \cdot \beta_{2C}} \cdot [B][C]) \tag{23}$$

Remembering that, in the actual case, $[B] + [C] = 3$, and combining eqn (23) with eqns (21) and (13) we obtain after trivial calculations

$$\frac{C_M \cdot [C]}{C_{M_0} \cdot [C]_0} = 1 + \frac{\beta_{1B} - \beta_{1C} - 6\beta_{2C} + 3\sqrt{\beta_{2B} \cdot \beta_{2C}}}{1 + 3\beta_{1C} + 9\beta_{2C}}[B] +$$

$$+ \frac{\beta_{2B} + \beta_{2C} - \sqrt{\beta_{2B} \cdot \beta_{2C}}}{1 + 3\beta_{1C} + 9\beta_{2C}}[B]^2 + \frac{\beta_{3B}}{1 + 3\beta_{1C} + 9\beta_{2C}}[B]^3 + \ldots . \tag{24}$$

Now the coefficient of the linear term of this expression must correspond to β_1 of eqn (18), *i.e.*, the experimentally determined quantity $\beta_1 = 0.3\ M^{-1}$. Thus we have

$$0.3(1 + 3\beta_{1C} + 9\beta_{2C}) = \beta_{1B} + 3\sqrt{\beta_{2C}} \cdot \sqrt{\beta_{2B}} - \beta_{1C} - 6\beta_{2C} \tag{25}$$

However,

$$\sqrt{\beta_{2B}} = \sqrt{\frac{b_2}{b_1}} \cdot \beta_{1B} \tag{26}$$

where $\frac{b_2}{b_1}$ is given by eqn (19).

Combining eqns (25) and (26) we finally obtain

$$\beta_{1B} = \frac{\beta_{1C} + 6\beta_{2C} + 0.3(1 + 3\beta_{1C} + 9\beta_{2C})}{1 + \frac{\sqrt{7}}{4}\sqrt{\beta_{2C}}} \tag{27}$$

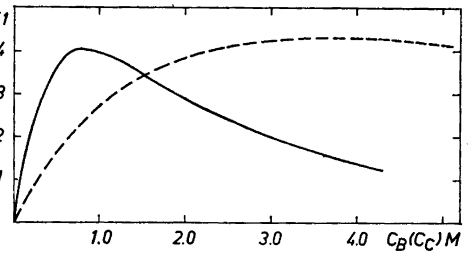

Fig. 6. Solid curve: α_1 of the thiocyanate system, calculated from the constants $\beta_{1B} = 1.4_2$ M^{-1}, $\beta_{2B} = 0.8_8$ M^{-2} and $\beta_{3B} = 0.3_1$ M^{-3}. Broken curve: α_1 of the perchlorate system, calculated from the constants $\beta_{1C} = 0.4$ M^{-1} and $\beta_{2C} = 0.07$ M^{-2}.

From a value of β_{1B} one can calculate β_{2B} *etc.*, from eqns (19) and (20).

We can then *illustrate* the interrelation of the thiocyanate and perchlorate complexity constants with a *numerical example:*

If we *assume* $\beta_{1C} = 0.4$ M^{-1}, eqns (19) and (20) give $\beta_{2C} = 0.07$ M^{-2}. Introducing these quantities in eqn (27) we obtain $\beta_{1B} = 1.4_2$ M^{-1}. Hence $\beta_{2B} = 0.8_8$ M^{-2} and $\beta_{3B} = 0.3_1$ M^{-3}. From these we may calculate $\bar{n}$ for [B] = 1 M.

Then we obtain $\bar{n} = 1.1_4$ if all three complexes are taken into account. Furthermore, a close examination of the φ_R-curves of Fig. 2 indicates that the maximum occurs at $C_B \approx 0.85$ M. For this ligand concentration and the constants calculated above we obtain $\bar{n} = 1.0_1$.

Indeed, we can calculate α_1 for any concentration (Fig. 6). This quantity [7] is directly related to φ_R, and the agreement between the two quantities is very good. (At low concentrations the constants derived here are no longer valid, but should be greater so as to give a steeper rise of φ_R, which is actually found.)

As the curves of activity coefficients for $NaClO_4$ and NaSCN (Ref.[20]) have rather broad minima in the region 1—3 M the variation of the value of the complexity constants with ionic strength may be negligible, which has been assumed above.

It is certainly not neccessary to stress the arbitrary points in the above calculations. The purpose has been only to illustrate the composite problems encountered in the investigations of systems of such an elusively weak complexity.

The extraction experiments in perchlorate solutions were undertaken in an effort to prove the existence of perchlorate complexes. The results are, however, disappointing in this respect.

As these experiments are not a major part of the present investigation only the following may be said:

With systems where the mutual solubility of the two phases is as great as here one might expect large changes in the activity coefficients. These changes make any interpretation of the results very difficult. Reference might be made to the findings of Johnson and Brubaker [21] that *cyclo*hexanone seems to enhance any tendency of anionic complex formation that may exist in the aqueous phase.

Comparison of Figs. 3 and 4 shows that it is not so much the extraction of $NaClO_4$ as the difference in mutual solubility (represented by different q) that causes the different shapes of the φ-curves.

It is interesting to note that if we calculate α_1 from the values of the complexity constants used above, $\beta_{1C} = 0.4\ M^{-1}$ and $\beta_{2C} = 0.07\ M^{-2}$, a very flat maximum is obtained at $C_C = 3.8$ M; *cf.* Fig. 6. (Apart from activity effects causing changes in the parameters involved, α_1 should be related to φ_S in the same way [7] as it is to φ_R.)

Summing up, we may state that there seems to be a definite tendency of thiocyanate ions associating with the *trans*-Co $en_2(SCN)_2^+$ ion, and that the measurements can be correlated semi-quantatively on the basis of the hypothesis of a slight perchlorate complexity of this ion.

The author is indebted to Professor S. Fronæus for a stimulating criticism of this work.

Studies on the Hydrolysis of Metal ions

Part 29. The Hydrolysis of the Silver Ion, Ag^+, in Acid Self-medium *

GEORGE BIEDERMANN and SIRKKA HIETANEN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of the Ag^+ ion has been investigated at 25°C by measuring the hydrogen ion concentration in the self-medium [3] 1 M $Ag^+(NO_3^-)$ with a glass electrode. The data, which indicate an extremely slight hydrolysis at log $[H^+] \geqq -6.3$, can be explained by the equilibrium $Ag^+ + H_2O \rightleftharpoons AgOH + H^+$ with log $*K_1 \leqq -11.1$; the effect may also be due to polynuclear complexes. No evidence was found for the presence of appreciable amounts of polynuclear hydrolysis products proposed previously [1].

Little data can be found in the literature which throw light on the hydrolysis equilibria of the Ag^+ ion. In 1933 Johnston, Čuta and Garrett [1] concluded that about 40 % of the dissolved silver in a saturated solution of Ag_2O is present as positively charged polynuclear ions such as Ag_2OH^+. Their argument is based on a comparison of the analytically determined total silver concentration with the conductometrically measured ionic concentration. Evidence was found by these authors that the concentration of the uncharged species AgOH cannot exceed 0.01 $[Ag(I)]_{total}$.

In 1954 Faucherre [2] studied the hydrogen ion concentration of $AgNO_3$ solutions in the ionic medium 0.2 M NO_3^- with a glass electrode. He explained the increase of log $[H^+]$ from −6 to −5, as log [Ag(I)] varied from −2 to −1, by assuming the equilibrium

$$Ag^+ + H_2O \rightleftharpoons AgOH + H^+ \; ; \; *K_1 = [AgOH]h[Ag^+]^{-1}$$

with log $*K_1 = -9.7$.

The hydrolysis equilibrium of Ag^+ is not easy to investigate because the Ag^+ ion is a very weak acid and the solubility product of Ag_2O is low (pK_s is about 7.7). As a result the acidity range where appreciable hydrolysis occurs but no precipitate is formed is narrow. If solutions dilute in $[Ag^+]$ are investigated, the useful acidity range can be made wider. This was attempted several years ago in this laboratory, but due to the low buffer capacity of dilute silver

* This work is dedicated to the sixtieth birthday of Professor W. Feitknecht, Bern, Switzerland.

solution and to the premature precipitation of Ag_2O no conclusive results could be obtained. In any case the study of dilute solutions can only yield information on mononuclear products.

METHOD OF INVESTIGATION

Recently a method has been proposed by Hietanen and Sillén [3] — the self-medium method — which is particularly suitable for studying the hydrolysis equilibria of such a weak acid as the Ag^+ ion. In the self-medium method the equilibrium concentration of hydrogen ions is measured in solutions containing, at a high and constant concentration, one of the reacting ions and a counter ion which does not take part in the reaction to be studied. The solutions may also contain a small amount of an inert (*i.e.* non protolyzing) cation or anion in order to keep the counter ion concentration constant when the acidity is varied.

In a series of measurements, which may be carried out conveniently as a potentiometric titration, the acidity is changed by replacing the inert ion with H^+ or OH^- ions. If the acidity changes are small and therefore only a small part of the reacting ions is transformed to the hydrolysis products, the composition of the solution is altered only slightly, so that the activity factors may be considered as constants. The advantage of the self-medium method is that the presence of hydrolysis products $Me_q(OH)_p$ (Me = metal ion) with high q/p can easily be detected under conditions when the solutions have an appreciable buffer capacity.

This paper summarizes our hydrogen ion concentration measurements using a glass electrode in a series of 1 M $AgNO_3$ solutions of varying acidity. $AgNO_3$ was chosen because it can be easily purified by recrystallization, in contrast to $AgClO_4$. It is essential to use as pure reagents as possible when the hydrolysis of weak acids is to be studied.

The solutions were prepared by mixing one ("S_0") of low acidity with another one ("T") containing about 0.02 M HNO_3. The results obtained in this work, as well as those found in solutions of 3 M ClO_4^-, show that the hydrolysis of Ag^+ is negligible for $\log [H^+] > -4$, consequently in the 0.02 M HNO_3 + 1.00 M $AgNO_3$ solution, "T", the hydrogen ion concentration h is equal to the analytical excess of hydrogen ions $H = [NO_3^-] - [Ag^+]$.

The starting solution S_0 of low acidity had to be prepared in a special way because addition of dilute NaOH to 1 M $AgNO_3$ always caused a precipitation of Ag_2O, which redissolved very slowly, whatever precautions were taken to avoid a local excess of OH^-. The CO_2-free 1 M $AgNO_3$ solution to be used as the starting solution was passed through a tube containing about 20 g Ag_2O to remove the minute amounts of excess hydrogen ions. This procedure ensures that the solution comes into intimate contact with the Ag_2O particles so that excess hydrogen ions are removed without the introduction of foreign ions. The solubility of Ag_2O is so low that the total silver concentration remains practically unchanged.

In all experiments we have found the analytical excess of hydrogen ions in the starting solution, H_0, to be negative, which indicates that the method used to prepare partially hydrolyzed solutions is an effective one. It is common

experience in this laboratory that equilibrium is established much more rapidly between a solid and a liquid by passing the liquid through a column of the solid than by shaking.

The hydrogen ion concentration at equilibrium was measured by using the cell

$$- \text{ GE} \mid \text{solution S} \mid \text{SE} +$$

where GE denotes the glass electrode, SE is the reference half-cell

$$\mid 1.000 \text{ M } KNO_3 \mid 0.990 \text{ M } KNO_3, \; 0.0100 \text{ M } AgNO_3 \mid AgCl, \; Ag.$$

Solution S had the general composition (neglecting the very small correction for H_o, see below)

$$H \text{ M } H^+, \; 1.000 \text{ M } Ag^+_{aq}, \; (1.000 + H) \text{ M } NO_3^-;$$

In all experiments H was kept below 0.01 M.

The emf of this cell can be written at 25°C

$$E = E_o - 59.15 \log h + E_j \qquad (1)$$

where E_o is a constant and E_j is the liquid junction potential between solution S and 1 M KNO_3. E_j was determined by measuring E in the h range 0.01 to 0.1 M where the hydrolysis is quite negligible. The equation $E_j = 52\ h$ mV was found to describe the data to a good approximation.

The liquid junction potential of the junction h M H^+, $(1.000-h)$ M Na^+, 1.000 M ClO_4^- | 1 M $NaClO_4$ has been previously measured in this laboratory (G. Biedermann unpublished work); up to $h = 0.1$ M the data could be represented by the equation $E_j = 64\ h$ mV, which is reasonably close to the E_j values found for the junction studied in this work.

A series of measurements ("titration") was started with a known volume, V_o ml, of a partially hydrolysed solution with an initially unknown deficit of H^+ ($- H_o$). To this solution an increasing amount V_T ml of an acid solution T (1 M $AgNO_3$, H_T M HNO_3) was added.

For each point H is given by the equation

$$H = \frac{V_T H_T + V_o H_o}{V_T + V_o} \qquad (2)$$

In a first approximation we neglected H_o, obtaining the approximate value

$$H_1 = \frac{V_T H_T}{V_o + V_T} = H - \frac{H_o V_o}{V_o + V_T} \qquad (3)$$

As H_1 increases, $(H_1 - H)/H_1$ decreases and

$$E + 59.15 \log H_1 - E_j(H_1) \qquad (4)$$

tends to E_o.

For each point of a series of measurements (4) was calculated and for $H_1 > 0.005$ M was found to be constant within $\pm$ 0.1 mV; this constant value for (4) was accepted as the correct E_o. We could then calculate h from (1) for each point.

The difference between the free and analytical hydrogen ion concentration is

$$h - H = BZ \tag{5}$$

where B is the total silver concentration and Z is the average number of OH bound per silver ion.

From (2), (3), and (5) we find

$$\left(\frac{V_o + V_T}{V_o}\right)(h - H_1) = BZ\left(\frac{V_o + V_T}{V_o}\right) + H_o \tag{6}$$

The left hand side can now be calculated from known quantities; it tends to H_o as the hydrolysis is suppressed. Indeed, a constant value was obtained within the limits of experimental uncertainty in our experiments in the log h range -5 to -3.5 indicating that hydrolysis is negligible for log $h > -5$. This value was taken to be equal to H_o. For a log h higher than about -3.5 $(h - H_1)$ could not be obtained with sufficient accuracy because the absolute uncertainty increases both for h and H_1. On the other hand, the relative uncertainty is constant, we have estimated a maximal error $\Delta h/h = 0.01$ and $\Delta H_1/H_1 = 0.001$.

EXPERIMENTAL DETAILS

$AgNO_3$ solutions were prepared from $AgNO_3$ p.a., Merck, which was purified by recrystallization and then dried at 140°C. Care was taken to avoid contamination with dust. *Ag_2O* was made by adding 0.1 M $Ba(OH)_2$ dropwise to 0.1 M $AgNO_3$ at 60–70°C; both solutions were prepared by dissolving the purified substances in CO_2-free water. The precipitated Ag_2O was washed with hot CO_2-free water until the washings gave no reaction for Ba^{2+}. The precipitation, washing and the transfer of Ag_2O to the column were made in a specially constructed apparatus in a purified nitrogen atmosphere.

HNO_3 solutions were made from 65 % HNO_3 p.a. Merck. They were standardized to an accuracy of 0.1 % against $KHCO_3$, and *via* NaOH solution against hydrazinium sulfate. *$Ba(OH)_2$* solutions were prepared from $Ba(OH)_2(H_2O)_8$ p.a. Merck, which was made carbonate- and chloride-free by double recrystallization. A 0.25 M $Ba(OH)_2$ solution had a scarcely perceptible turbidity, indicating that the carbonate content was very low. *Nitrogen* from a cylinder was purified by passing through 1 M H_2SO_4 and 1 M NaOH. Doubly distilled water, made CO_2-free by passing N_2 through it for several hours, was used to prepare all the solutions, which were stored and transferred in a nitrogen atmosphere.

The measurements were carried out employing the technique usual in this laboratory [4]. E was determined with a valve potentiometer PHM 4, Copenhagen, which was calibrated against a Leeds & Northrup compensator of the type K3; the reading accuracy of the valve potentiometer was 0.1 mV. A Beckman glass electrode of type No. 1190–80 was employed, which attained a constant potential within about 10 min and which remained constant within ± 0.1 mV for several hours.

All measurements were made in a paraffin-oil thermostat at 25.0 ± 0.1 °C.

RESULTS

Three series of measurements were made, and each time a fresh Ag_2O preparation was used to react with the starting solution. A typical series is shown in Table 1; the additions below 3 ml were made with a weight burette. It may be inferred from the table that the experimental conditions were chosen adequately to obtain the constants E_o and H_o with a satisfactory accuracy.

$E_o = 139.2 \pm 0.1$ mV $\qquad H_o = (-1.6 \pm 0.1) \times 10^{-5}$ M

Table 2 summarizes the results of our measurements.

Table 2.

No. of series	$H_o \times 10^5$	$\log h$	$Z \times 10^5$	$\log {}^*K_1$	$\log {}^*\beta_{12}$	$\log {}^*\beta_{22}$
(1)	(-1.0 ± 0.1)	(-5.82)	(1.15 ± 0.1)	(-10.8)	(-10.8)	(-16.9)
(2)	-1.7 ± 0.1	-6.33	1.7 ± 0.1	-11.10	-11.10	-17.73
(3)	-1.6 ± 0.1	-6.30	1.6 ± 0.1	-11.10	-11.10	-17.70

The H_o and Z values obtained in series (1) — which are set in brackets — are somewhat less accurate than those determined in the two others because at first no weight burette was used for the small additions.

In each series only the first point could be utilized to calculate Z because Z values less than 10^{-5} could not be obtained with satisfactory accuracy.

To explain the $Z(\log h)$ data we shall try what seems to be the three simplest assumptions on the main reaction

$$Ag^+ + H_2O \rightleftharpoons AgOH + H^+ \qquad {}^*K_1 = [AgOH]h[Ag^+]^{-1} \approx Zh$$
$$2\,Ag^+ + H_2O \rightleftharpoons Ag_2OH^+ + H^+ \qquad {}^*\beta_{12} = [Ag_2OH^+]h[Ag^+]^{-2} \approx ZhB^{-1}$$
$$2\,Ag^+ + 2\,H_2O \rightleftharpoons Ag_2(OH)_2 + 2\,H^+ \qquad {}^*\beta_{22} = [Ag_2(OH)_2]h^2[Ag^+]^{-2} \approx \tfrac{1}{2}Zh^2B^{-1}$$

Although great pains were taken to avoid contamination of the solutions we do not feel justified to claim that the extremely small Z values are not partly due to the presence of some impurity. We can therefore only conclude

$$\log {}^*K_1 \leqq -11.1; \log {}^*\beta_{12} \leqq -11.1; \log {}^*\beta_{22} \leqq -17.7$$

In the light of the present results it does not seem likely as suggested by Johnston, Čůta and Garrett [1] that the difference claimed between the analytically and conductometrically determined silver concentrations in a saturated solution of Ag_2O is due to the presence of Ag_2OH^+. If the saturated solution of Johnston *et al.* had contained 5.8×10^{-5} M Ag^+, 1.39×10^{-4} M OH^- and 8.1×10^{-5} M Ag_2OH^+, as they seem to suggest, one would calculate $\log {}^*\beta_{12} = -5.76$ and for the equilibrium

$$\tfrac{1}{2}Ag_2O(s) + \tfrac{1}{2}H_2O + Ag^+ \rightleftharpoons Ag_2OH^+$$

$\log K = 0.15$*. If these values were correct in our solution with $[Ag(I)]_{tot} = 1$ M, $\log h = -6.3$ we would calculate $Z \sim 0.35$ whereas we find 1.7×10^{-5}. It would moreover have been possible to dissolve Ag_2O in 1 M $AgNO_3$ to a value $Z \sim 0.37$.

In a following paper [6] a critical survey of the data on the solubility equilibria of Ag_2O will be given. On the basis of this survey we believe that the inconsistency between the analytical and conductance data of Johnston, Čůta and Garrett [1] is to be ascribed to the presence of minute amounts of impurities, *e.g.* CO_2, which may seriously influence the composition of a solution of such a low buffer capacity as a saturated solution of Ag_2O.

The $\log {}^*K_1$ value obtained in this work is considerably lower than that found by Faucherre [2]. This author assumed the analytical excess of hydrogen ions to be negligible in a CO_2-free solution of $AgNO_3$. However, according to our experience a minute amount of HNO_3 is inevitably occluded in the crystal; the HNO_3 impurity cannot be removed below the melting point of $AgNO_3$.

We are indebted to Professor Lars Gunnar Sillén for his great interest in this work and for his valuable criticism.

Studies on the Hydrolysis of Metal Ions

Part 30. A Critical Survey of the Solubility Equilibria of Ag_2O

GEORGE BIEDERMANN and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

On the basis of recalculation of the data available in the literature (Table 1) the most probable values of the constants of the following equilibria have been estimated at 25°C:

$\frac{1}{2}\,Ag_2O(s) + \frac{1}{2}\,H_2O \rightleftharpoons Ag^+ + OH^-$ $\quad \log K_{s0} = -7.71 \pm 0.03$
$\frac{1}{2}\,Ag_2O(s) + \frac{1}{2}\,H_2O \rightleftharpoons AgOH$ $\quad \log K_{s1} = -5.75 \pm 0.25$
$\frac{1}{2}\,Ag_2O(s) + \frac{1}{2}\,H_2O + OH^- \rightleftharpoons Ag(OH)_2^-$ $\quad \log K_{s2} = -3.72 \pm 0.03$

For the complex formation OH^--Ag^+ these data give

$\log K_1 = \log [AgOH][Ag^+]^{-1}[OH^-]^{-1} = 2.0 \pm 0.3$;
$\log \beta_2 = \log [Ag(OH)_2^-][Ag^+]^{-1}[OH^-]^{-2} = 3.99 \pm 0.05$

The different experimental methods which were employed to study these equilibria have been discussed in some detail.

In three preceding papers the hydrolysis equilibria of the Ag^+ ion were studied in acid [1], moderately alkaline [2] and highly alkaline [3] solutions by a group of workers in this laboratory. The data obtained by these investigators could be explained by assuming the formation of the species AgOH and $Ag(OH)_2^-$, and no evidence was found for the presence of appreciable amounts of polynuclear products which were claimed by several previous authors [4,5].

As a consequence of these results the solubility equilibria of Ag_2O may be written

$\frac{1}{2}\,Ag_2O(s) + \frac{1}{2}\,H_2O \rightleftharpoons Ag^+ + OH^-$ $\quad K_{s0} = \{Ag^+\}\{OH^-\}\{H_2O\}^{-\frac{1}{2}}$ (1)
$\frac{1}{2}\,Ag_2O(s) + \frac{1}{2}\,H_2O \rightleftharpoons AgOH$ $\quad K_{s1} = \{AgOH\}\{H_2O\}^{-\frac{1}{2}}$ (2)
$\frac{1}{2}\,Ag_2O(s) + OH^- + \frac{1}{2}\,H_2O \rightleftharpoons Ag(OH)_2^-$ $\quad K_{s2} = \{Ag(OH)_2^-\}\{OH^-\}^{-1}\{H_2O\}^{-\frac{1}{2}}$ (3)

where the symbol {} denotes activity. The present paper is devoted to a discussion of the available data concerning equilibria (1), (2) and (3). On the basis of the discussion an attempt has been made to estimate the most probable values at 25°C of K_{s0}, K_{s1} and K_{s2}, which are collected in the Synopsis.

It is believed that the conclusions reached in this work might find a general interest for the study of equilibria involving slightly soluble metal oxides and hydroxides.

ON THE SOLUBILITY PRODUCT OF Ag_2O, K_{s0}

Four methods have been applied to determine K_{s0}: (A) emf measurements (B) study of the equilibrium

$$AgCl(s) + OH^- \rightleftharpoons \tfrac{1}{2}Ag_2O(s) + \tfrac{1}{2}H_2O + Cl^-; K_4 = \{Cl^-\}\{H_2O\}^{1/2}\{OH^-\}^{-1} = \frac{K_{s0}(AgCl)}{K_{s0}(Ag_2O)} \quad (4)$$

(C) conductance measurements and (D) chemical analysis of the saturated solution.

As will be clear from the following discussion K_{s0} may be determined in a straightforward manner by methods (A) and (B), when the measurements are made in solutions of $[OH^-] \geq 0.01$ M which have an appreciable buffer capacity. Methods (C) and (D) require on the other hand the study of a saturated solution of Ag_2O containing no added electrolyte. Since the solubility product of Ag_2O is rather low ($\log K_{s0}$ is about -7.7) the composition of the saturated solution is influenced considerably by the presence of slight amounts of protolyzing impurities, *e.g.* CO_2 or substances dissolved from glass.

Using methods (C) and (D) therefore the nature and concentration of the impurities must be known and their effect on the data must be taken into account. By a correct treatment of the conductance and the analytical data the uncertainty caused by the presence of impurities may become unappreciable, as it is shown by the fact that the results derived from the experiments of the most careful workers are in agreement with those found by the methods (A) and (B), (see Table 1).

(A) Emf measurements with the half-cell $OH^-/Ag_2O(s),Ag$

Previous workers [6-8] had difficulty in obtaining constant and reproducible emf values with Ag_2O,Ag electrodes. More recently, however, Makolkin [9] and Hamer and Craig [10] were able to find the experimental conditions in which the Ag_2O,Ag electrodes function reversibly.

The cell studied by Makolkin had the composition

$$H_2/Ba(OH)_2\ I\ M/Ba(OH)_2\ I\ M/Ag_2O,Ag\ (25°C) \quad (I)$$
$$E(p_{H_2} = 1\ atm) = e°(H^+/Ag_2O,Ag) - 29.58 \log \{H_2O\} \quad (5)$$

and he found

$$E = 1\ 171.9 \pm 0.8\ mV_{int} = 1\ 172.3 \pm 0.8\ mV_{abs}*$$

The cell of Hamer and Craig was

$$Hg,HgO/NaOH\ I\ M/NaOH\ I\ M/Ag_2O,Ag\ (25°C) \quad (II)$$
$$E = e°(H^+/Ag_2O,Ag) - e°(H^+/HgO,Hg) \quad (6)$$

and they obtained

$$E = 244.0 \pm 0.5\ mV_{abs}$$

* The conversion to mV_{abs} was made by the present authors.

Here e° denotes the standard potential referred to the hydrogen scale.

Cells I and II may be expected to yield highly accurate values for K_{s0}. The solubilities of Ag_2O and HgO are so low that the liquid junction potential is quite negligible for $I \geq 0.01$ M. Both these investigators used solutions of $I \geq 0.1$ M, therefore small amounts of CO_2 and substances dissolved from glass, which can hardly be avoided, do not influence appreciably the composition of the solutions. Moreover since the $[OH^-]$ is practically the same in both half-cells the effect of the impurities on the emf will be cancelled out.

The correctness of the assumed cell reaction may be tested, *e.g.* by changing I. Hamer and Craig have found that the emf of cell II remains constant within $\pm$ 0.5 mV as $[OH^-]$ is varied from 1.3 to 10 M.

Since

$$e^\circ(H^+/Ag_2O,Ag) = e^\circ(Ag^+/Ag) + 59.15 \log \frac{K_{s0}}{K_w} \qquad (7)$$

where K_w is the ionic product of water, we need in order to calculate K_{s0} the values of the constants K_w, $e^\circ(Ag^+/Ag)$ and with cell II also $e^\circ(H^+/HgO, Hg)$. We shall use $pK_w = 13.997$; the most probable values for the standard potentials will be taken from a critical survey [11] made in this laboratory: $e^\circ(Ag^+/Ag) = 799.4 \pm 0.2$ mV_{abs} and $e^\circ(H^+/HgO, Hg) = 926.1 \pm 0.3$ mV_{abs}. The term containing $\{H_2O\}$ in (5) has been neglected, since Harned and Mason [12] have shown that in 0.1 M $Ba(OH)_2$ (the concentration presumably used by Makolkin) it is less than 0.05 mV.

With the constants selected Makolkin's data give $-\log K_{s0} = 7.70 \pm 0.02$ and those of Hamer and Craig 7.73 ± 0.02; the difference does not exceed significantly the experimental uncertainty.

(B) Determination of $K_4 = \dfrac{K_{s0}(AgCl)}{K_{s0}(Ag_2O)}$

Since at 25°C the solubility product of AgCl, $K_{s0}(AgCl)$, is about $0.01 \times K_{s0}(Ag_2O)$ the analytical determination of the ratio $[Cl^-]\,[OH^-]^{-1}$ in a solution which is in equilibrium with solid Ag_2O and AgCl may be carried out with a fair degree of accuracy. Two sets of data are available — the measurements of Noyes and Kohr [13] and those of Newton [14], which are in a satisfactory agreement. These investigators have found that equilibrium is established at 25°C within a few hours, so that the attack of OH^- on the glass surface may not introduce an appreciable error.

No systematic trend can be detected in the $[Cl^-]\,[OH^-]^{-1}$ values as $[OH^-]$ varies from 0.05 to 0.35 M. This fact indicates that in these solutions $f(Cl^-)\,f^{-1}(OH^-)$ is equal to unity within the narrow limits of experimental uncertainty. The deviation of $\{H_2O\}$ from unity is certainly negligible. We can thus set $K_4 = [Cl^-][OH^-]^{-1}$.

From the data of Newton [14] the average value of pK_4 is calculated to be 2.045 ± 0.015 and from those of Noyes and Kohr [13] 2.02 ± 0.02. On the basis of a critical examination of the available data Sillén [15] gave as the most probable value of $pK_s(AgCl)$ 9.752 ± 0.005. Introducing this value into (4) we find $pK_{s0} = 7.71 \pm 0.03$ from Newton's results, and 7.73 ± 0.05 from those of Noyes and Kohr; the agreement with the figures deduced from the emf measurements is satisfactory.

(C) Conductance measurements

The conductance of a saturated solution of Ag_2O was determined at 25°C with a high accuracy by Böttger [16] and Laue [17]. Both these investigators employed a Ag_2O preparation of high purity and used as solvent "conductivity water" which denotes pure water kept in contact with air. Böttger evaluated K_{s0} by the classical method; he set $10^3(\varkappa - \varkappa_w) = \sqrt{K_{s0}}\,(\lambda_{Ag^+} + \lambda_{OH^-})$ where $\varkappa$ is the conductance of the saturated solution, $\varkappa_w$ is that of the conductance water and λ denotes ionic conductance.

Laue [17] realized that the chief impurity in conductance water is carbon dioxide at such a high concentration (about 10^{-5} M) that a considerable error is made when in the saturated solution $[Ag^+]$ is set equal to $[OH^-]$. Laue has given a correct treatment of his data and obtained $pK_{s0} = 7.71$. The general principles used by this author form the basis of our approach which is somewhat more simple.

The computation of K_{s0} consists of two steps. First α) the total carbon dioxide content, $[CO_2]_{tot}$, of the conductance water is calculated from $\varkappa_w$, then β) the composition of the saturated solution is obtained from $[CO_2]_{tot}$ and $\varkappa$.

Since the ionic strength of a saturated solution is about 10^{-4} M we have assumed the activity factors of all species present to be unity and we have neglected the variation of the ionic conductances with concentration.

α) $[CO_2]_{tot}$ was calculated from $\varkappa_w$ by combining

$$10^3\varkappa_w = h\lambda_{H^+} + [HCO_3^-]\lambda_{HCO_3^-} = h(\lambda_{H^+} + \lambda_{HCO_3^-}) \tag{8}$$

with

$$K_{a1} = \frac{h[HCO_3^-]}{[H_2CO_3 + CO_2]} \tag{9}$$

and $$[CO_2]_{tot} = [H_2CO_3 + CO_2] + [HCO_3^-] \tag{10}$$

Kolthoff and Elmquist [18] have found that $\varkappa_w$ is decreased by no more than about 90 % if CO_2 is removed by purified air from a conductance water. These experiments indicate that it can be regarded only as a rough approximation if we ascribe $\varkappa_w$ entirely to $[CO_2]_{tot}$ because conductance water contains also non-volatile impurities. However the error introduced by calculating $[CO_2]_{tot}$ with (8) does not exceed the uncertainty of the $\varkappa$ measurement.

β) In a saturated solution of Ag_2O the concentrations of the ionic species present are related by the equation

$$[Ag^+] = [OH^-] + [HCO_3^-] + 2[CO_3^{2-}], \tag{11}$$

the specific conductance is given by

$$10^3\varkappa = [Ag^+]\lambda_{Ag^+} + [OH^-]\lambda_{OH^-} + [HCO_3^-]\lambda_{HCO_3^-} + 2[CO_3^{2-}]\lambda_{CO_3^{2-}} \tag{12}$$

and since $\log h$ is about -10

$$[CO_2]_{tot} \cong [HCO_3^-] + [CO_3^{2-}] \tag{13}$$

By taking into account the equilibrium

$$OH^- + HCO_3^- \rightleftharpoons CO_3^{2-} + H_2O; \frac{K_{a2}}{K_w} = \frac{[CO_3^{2-}]}{[OH^-][HCO_3^-]} = K' \qquad (14)$$

insertion of (11) and (13) into (12) yields

$$10^3\varkappa = x(\lambda_{OH^-} + \lambda_{Ag^+}) + \frac{[CO_2]_{tot}}{1 + K'x}[\lambda_{Ag^+} + \lambda_{HCO_3^-} + 2K'x(\lambda_{CO_3^{2-}} + \lambda_{Ag^+})] \qquad (15)$$

where $[OH^-]$ is denoted by x for convenience. The unknown $[OH^-]$ is obtained by a short series of successive approximations from (15) and the known, $[CO_2]_{tot}$, K' and the λ's, then $[HCO_3^-]$ and $[CO_3^{2-}]$ are calculated using (14) and (13). $[Ag^+]$ is found from (11).

The following numerical values were used: $pK_{a1} = 6.352$ [19], $pK_{a2} = 10.329$ [20]; $\lambda_{H^+} = 349.8$, $\lambda_{Ag^+} = 61.92$, $\lambda_{OH^-} = 197.6$, $\lambda_{HCO_3^-} = 44.5$ [21] and $\lambda_{CO_3^{2-}} = 74.0$ [22].

Application of this calculation to the $\varkappa_w$ and $\varkappa$ data of Böttger has given $pK_{s0} = 7.69 \pm 0.02$ while Laue's figures give 7.71 ± 0.02.

The agreement with the pK_{s0} values found in sections (A) and (B) shows that conductance measurement is also capable of giving accurate results in such an unfavorable system as that discussed.

(D) Chemical analysis

The attempts of workers prior to Laue to determine $[Ag(I)]_{tot}$ in a saturated solution of Ag_2O had the purpose of getting only approximate values. Laue [17] and Johnston *et al.*[4] were able to work out electroanalytical and potentiometric methods suitable for determining a silver concentration of about 10^{-4} M with an accuracy of a few percent. The results of these very careful workers differ considerably. Laue found that in paraffinized flasks the solubility equilibrium is established at 25°C within an hour and he obtained $[Ag(I)]_{tot} = (1.51 \pm 0.10) \times 10^{-4}$ M. According to Johnston *et al.* at least ten days were required to attain equilibrium and they found $[Ag(I)]_{tot} = (2.22 \pm 0.04) \times 10^{-4}$ M.

We have reason to assume that Johnston's value for $[Ag(I)]_{tot}$ was high, because some OH^- reacted with small amounts of carbon dioxide in the conductance water ($\varkappa_w \sim 1.2-2 \times 10^{-5}$) and with the surface of the pyrex flask (which was in contact with an alkaline solution for many days) forming silicates, aluminates and borates.

Assuming that $[Ag(I)]_{tot} = [Ag^+]$ we may give a rough estimate of the amount of OH^- ions which by reacting with glass might have caused the high results of Johnston *et al.* These authors used a water of $\varkappa_w = 1.2 \times 10^{-6}$ corresponding to $[CO_2]_{tot} = 2.4 \times 10^{-5}$ M. With this value and with $pK_{s0} = 7.70$ we estimate that their solution with $[Ag^+] = 2.22 \times 10^{-4}$ M contained also $[OH^-] = 9 \times 10^{-5}$, $[HCO_3^-] = 1.7 \times 10^{-5}$, $[CO_3^{2-}] = 7 \times 10^{-6}$ and $[SiO(OH)_3^-] + [Al(OH)_4^-] + [B(OH)_4^-] = 1 \times 10^{-4}$ M. According to experiences in this laboratory such a value for $[SiO(OH)_3^-] + [Al(OH)_4^-] + [B(OH)_4^-]$ does not seem to be unreasonable.

The apparently slow attainment of the solubility equilibrium may also be explained by reaction of OH^- with glass. As the $[OH^-]$ is decreased more Ag_2O

Table 1. Survey of the calculated pK_{s0} values.

Author	Method	Auxiliary data	pK_{s0}
1. Makolkin [9]	emf of the cell $H_2/Ba(OH)_2$ *I* M/Ag_2O, Ag	$e^o(Ag^+/Ag) = 799.4 \pm 0.2$ mV_{abs}	7.70 ± 0.02
2. Hamer and Craig [10]	emf of the cell Hg, HgO/NaOH *I* M/Ag_2O, Ag	$e^o(Ag^+/Ag) = 799.4 \pm 0.2$ mV_{abs} $e^o(H^+/HgO,Hg) = 926.1 \pm 0.3$ mV_{abs}	7.73 ± 0.02
3. Noyes and Kohr [13]	*K* for $\frac{1}{2}Ag_2O + \frac{1}{2}H_2O + Cl^- \rightleftharpoons AgCl + OH^-$	$pK_s(AgCl) = 9.75_2 \pm 0.005$	7.73 ± 0.06
4. Newton [14]	as 3.	as 3.	7.71 ± 0.03
5. Böttger [16]	conductance	$\varkappa_{H_2O} = 1.15 \times 10^{-6}$	7.69 ± 0.02
6. Laue [17]	conductance	$\varkappa_{H_2O} = (1.35$ and $1.53) \times 10^{-6}$	7.71 ± 0.02
7. Laue [17]	chemical analysis	$\varkappa_{H_2O} = 1.2 \times 10^{-6}$	7.75 ± 0.05

will dissolve until $[Ag^+]\,[OH^-]$ becomes again equal to K_{s0}. Dissolution of glass in alkaline solutions is known to be rapid at first, but after prolonged contact the reaction becomes very slow. Thus after a period the increase of the $[Ag^+]$ is expected to be unappreciable.

Recent experimental results on the hydrolysis of the Ag^+ ion [1] have given no support to the hypothesis of Johnston *et al.* that the high solubility is to be explained by the formation of the species Ag_2OH^+.

Laue's data may be used to get an approximate value of K_{s0}. We have assumed $[Ag(I)]_{tot}$ to be equal to $[Ag^+]$. The discussion presented in the next section indicates that the error so made is less than the experimental uncertainty. First $[CO_2]_{tot}$ was calculated from (8) using $\varkappa_w = 1.2 \times 10^{-5}$ as given by Laue, then $[OH^-]$ was obtained from (14) and (11) by successive approximation. This treatment gave $pK_{s0} = 7.75 \pm 0.05$.

The results of our calculations are summarized in Table 1; this indicates a substantial agreement between the pK_{s0} values based on different assumptions and experimental procedures. As the most probable value we would propose the weighted average $\log K_{s0} = -7.71 \pm 0.03$.

ON THE SOLUBILITY OF Ag_2O IN ALKALINE SOLUTIONS

Johnston *et al.*[4] made an extensive and highly accurate study on the solubility of Ag_2O in NaOH, KOH and $Ba(OH)_2$ solutions at 25°C. A few data in NaOH solutions have also been obtained by Laue [17]. It should be pointed out that as $[OH^-]$ exceeds about 0.01 M the solutions attain such a high buffer

capacity that the carbon dioxide content of the conductance water and the dissolution of oxides from the glass surface have a negligible influence on the solubility equilibrium.

Both authors explained their data by equilibrium (3); Laue obtained log $K_{s2} = -3.70$ and Johnston *et al.* found log $K_{s2} = -3.71$. The latter authors gave moreover log $K_{s1} = -5.60$. The validity of the assumption that exclusively mononuclear hydrolysis products are formed was verified only recently by distribution [2] and emf [3] studies carried out in this laboratory.

We have recalculated both sets of data by a more exact method than was done previously, and we have employed the curve fitting technique [23] which may yield a more reliable estimate of the uncertainties of the computed constants. No attention was paid to the results found in solutions of $[OH^-] \leq 0.01$ M because these may be expected to be not quite reliable.

The water activity and the ratio of the activity factors of OH^- and $Ag(OH)_2^-$ were assumed to be unity; the error made seems to be negligible compared with the experimental uncertainty. We calculated from the vapor pressure measurements of Robinson and Stokes [24] $\frac{1}{2}$ log $\{H_2O\}$ to be -0.0075 at [NaOH] = 1 M; this was the highest $[OH^-]$ considered.

We have also assumed in the following calculation that $f(Ag^+)\ f\ (OH^-) = f_\pm^2 = 1$; this seems to be permissible because, at the $[OH^-]$ values where $f_\pm$ is expected to deviate appreciably from unity, $[Ag^+] = \dfrac{K_{s0}}{f_\pm^2[OH^-]}$ becomes much less than the uncertainty in the $[Ag(I)]_{tot}$ determination.

We started from the equation

$$[Ag]_{tot} = [Ag^+] + [AgOH] + [Ag(OH)_2] = \frac{10^{-7.71}}{[OH^-]} + K_{s1} + K_{s2}[OH^-] \qquad (16)$$

(16) can be rearranged to

$$\log\left([Ag]_{tot} - \frac{10^{-7.71}}{[OH^-]}\right) = \log K_{s1} + \log\ (1 + \frac{K_{s2}}{K_{s1}}\ [OH^-]) \qquad (17)$$

If the data $\log\left([Ag]_{tot} - \dfrac{10^{-7.71}}{[OH^-]}\right) = f(\log\ [OH^-])$ are superimposed on the calculated curve $\log(1 + X) = f(\log X)$ the vertical displacement required to make them coincide yields log K_{s1} and the horisontal one log $\dfrac{K_{s2}}{K_{s1}}$. We have found in this way

$$\log K_{s1} = -5.75 \pm 0.25$$

and

$$\log K_{s2} = -3.72 \pm 0.03,$$

which agree well with the previously determined values.

The solubility equilibria of Ag_2O are visualized in Fig. 1; the curve was calculated with the constants given in the Synopsis. The deviations of the data at log $[OH^-] < -2$ illustrate the great difficulties encountered when poorly buffered solutions are studied.

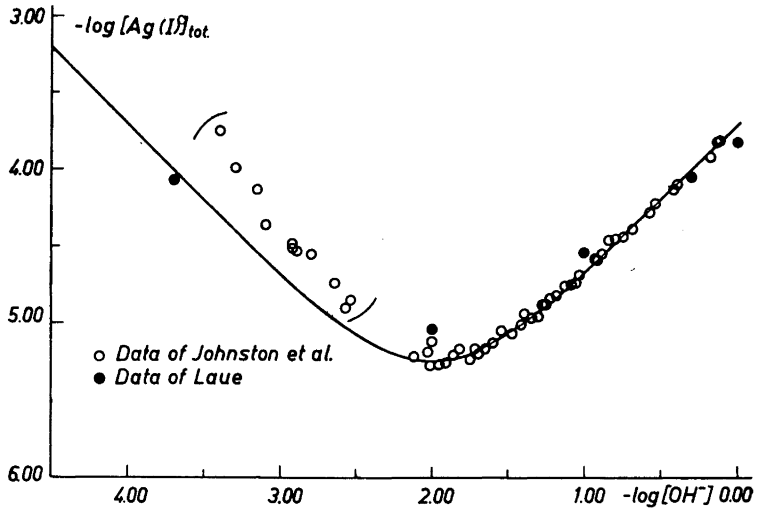

Fig. 1. The solubility equilibria of Ag_2O. log $[Ag(I)]_{tot}$ as a function of log $[OH^-]$. O measurements of Johnston *et al.*[4], ●: measurements of Laue [17]. The curve represents the equation $\log [Ag(I)]_{tot} = \log ([Ag^+] + [AgOH] + [Ag(OH)_2^-] = \log \left(\frac{1.95 \times 10^{-8}}{[OH^-]} + \right.$ $\left. + 1.8 \times 10^{-6} + 1.90 \times 10^{-4}[OH^-] \right)$

For the complex formation $OH^- - Ag^+$ these data give $\log K_1 = \log \{[AgOH]\,[Ag^+]^{-1}\,[OH^-]^{-1}\} = 2.0 \pm 0.3$ and $\log \beta_2 = \log\{[Ag(OH)_2^-]\,[Ag^+]^{-1}\,[OH^-]^{-2}\} = 3.99 \pm 0.05$, which means that $K_1 \sim K_2$.

The corresponding acidity constants of Ag^+ are then both around $10^{-12.0}$ (since $\log K_w = 14.00$ at 25°C), thus Ag^+ is another of the aquo ions with first and second acidity constant of the same order of magnitude.[25]

Note added in proof. After this work was submitted to publication Professor Reino Näsänen has kindly informed us on an investigation recently carried out in his laboratory. Näsänen and Meriläinen has determined K_{s0} at 25°C by emf measurements using a glass electrode, and they obtained $pK_{s0} = 7.74$. This value is in excellent agreement with those calculated by the present authors.

This investigation was financially supported by *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)*.

The Crystal Structure of $(TiCl_4 . POCl_3)_2$

CARL-IVAR BRÄNDÉN and INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structure of $(TiCl_4 \cdot POCl_3)_2$ has been determined from three-dimensional X-ray data. The structure is built up of dimeric molecules $(TiCl_4 \cdot POCl_3)_2$ with double chlorine bridges between the two titanium atoms of the dimer. The coordination around the titanium atom is octahedral. The oxygen atom in $POCl_3$ functions as donor atom. The approximately tetrahedral structure of $POCl_3$ is preserved.

Titanium tetrachloride is a strong Lewis acid and forms a great number of addition compounds with different donor molecules (Lewis bases). The mole ratio acceptor molecule to donor molecule is 1:1 or 1:2. The phase diagram $TiCl_4$—$POCl_3$ shows the existence of both types of compounds between $TiCl_4$ and $POCl_3$.[1] Sheldon and Tyree [2] have concluded from the shifts in the phosphoryl bond stretching frequency (measured in infrared) that phosphoryl chloride functions as a donor molecule through the oxygen atom. The present study was undertaken as a part of our investigations of the coordination and of the chemical bonds in addition compounds of different oxychlorides.

PREPARATIONS

Single crystals of the very hygroscopic compound were prepared in sealed capillary tubes by a method of zone melting. In most preparations the compound studied in this paper was obtained. Two other compounds appeared, however, in some cases. The unit cell volumes of those two crystals show simple ratios to the unit cell volume of the crystals usually prepared *(vide infra)*. They therefore probably represent other modifications. Preparations from carbon tetrachloride solutions give only the most common modification. We have not further studied the conditions of preparation of the two less common modifications.

CRYSTAL DATA

The unit cell dimensions of the orthorhombic crystals were determined by an extrapolation method used earlier by Hermodsson and Strandberg [3]. The values are $a = 12.42 \pm 0.02$ Å, $b = 12.76 \pm 0.05$ Å and $c = 13.51 \pm 0.02$ Å. The extinctions $h0l$ for l odd, $0kl$ for k odd and $hk0$ for h odd lead to the spacegroup *Pbca*.

This is in agreement with the data published earlier [1,4] except for some small corrections and improvements in accuracy. They also showed that there are eight units of $TiCl_4 \cdot POCl_3$ in the unit cell.

The other two modifications are monoclinic with the following approximate unit cell dimensions:

$a = 9.9$ Å, $b = 8.7$ Å, $c = 12.3$ Å and $\beta = 98°$
$a = 13.9$ Å, $b = 12.1$ Å, $c = 19.1$ Å and $\beta = 105°$

The cell volumes are very nearly one and three halves respectively of the orthorhombic unit cell volume (0.48 and 1.43).

The single crystal was rotated around the *b*-axis and Weissenberg photographs were taken. Nine zones (0—8) were recorded with Ni-filtered Cu-*K* radiation using multiple-film technique. Connection between the zones was obtained using a method described by Magnéli [5].

The 785 independent intensities were estimated visually. The relative $|F|^2$ values were obtained after correction using the chart of Lu [6]. No correction was made for absorption errors. The capillary tube used had an inner diameter of 0.10 mm. The linear absorption coefficient is 236.0 cm^{-1} for Cu-$K\alpha$ radiation.

DETERMINATION OF THE ATOMIC POSITIONS

After some unsuccessful attempts to solve the structure by means of Harker sections a three-dimensional Pattersson synthesis was calculated on the Hägg-Laurent machine [7]. Most of the maxima in this function were rather broad due to overlapping of several peaks of almost equal height. A method suggested by Lindqvist [8] was used to interpret the Pattersson function.

All atoms of the formula unit $TiCl_4 \cdot POCl_3$ are in the general position 8 (*c*) of space group *P b c a*. Between two crystallographically different atoms there are 8 vectors within the asymmetric unit of the cell, related by the following coordinates for the vectors in Pattersson space.

x_1,y_1,z_1; $\frac{1}{2}-x_1$, $\frac{1}{2}-y_2,z_2$; x_2, $\frac{1}{2}-y_1$, $\frac{1}{2}-z_2$;
$\frac{1}{2}-x_2,y_2$, $\frac{1}{2}-z_1$; x_2,y_2,z_2; $\frac{1}{2}-x_2$, $\frac{1}{2}-y_1,z_1$;
x_1, $\frac{1}{2}-y_2$, $\frac{1}{2}-z_1$; $\frac{1}{2}-x_1$, y_1, $\frac{1}{2}-z_2$.

By combining the maxima in the Pattersson function in groups according to this relation, it proved possible to determine approximate coordinates for seven atoms, Ti, O and 5 Cl.

Using these coordinates, signs were determined for F $(0,k,l,)$, F $(h,0,l,)$ and F $(h,k,0)$. The corresponding Fourier projections were calculated and from these the remaining three atoms could be located. Three successive sets of Fourier projections along all three axes were calculated. From the parameters thus obtained the signs were determined for 550 observed F (h,k,l). This and the following calculations were made on the electronic computer BESK in Stockholm. The atomic scattering factors were evaluated by a two-term expansion of Gaussian functions with constants given by Vand *et al.*[9]

Table 1. Final atomic parameters and their standard deviations.

Atom	x	y	z	$\sigma(x)$ Å	$\sigma(y)$ Å	$\sigma(z)$ Å
Ti	0.0629	0.3616	0.4986	0.005	0.006	0.005
P	0.1875	0.4353	0.2819	0.008	0.009	0.008
O	0.1075	0.4124	0.3564	0.020	0.020	0.016
Cl_1	0.1062	0.5507	0.5424	0.007	0.009	0.007
Cl_2	0.2364	0.3205	0.5231	0.008	0.009	0.008
Cl_3	0.0098	0.2107	0.4306	0.008	0.010	0.008
Cl_4	0.0092	0.3285	0.6506	0.008	0.010	0.007
Cl_5	0.2852	0.5483	0.3130	0.010	0.011	0.011
Cl_6	0.2769	0.3103	0.2522	0.009	0.010	0.008
Cl_7	0.1207	0.4706	0.1548	0.009	0.011	0.008

Two successive three-dimensional Fourier synthesis were carried out, the last one giving a broad and miss-shaped maximum for one of the chlorine atoms, indicating an errouneous assumed position for this atom. All other maxima were sharp and well-defined.

In order to get a better position for this atom signs were determined for F (h,k,l) using the other nine atomic positions. Bounded Fourier projections along the a-axis between the planes $x = 0$ and $x = \frac{1}{2}$ as well as along the c = axis with boundaries $z = 0$ and $z = \frac{1}{2}$ were calculated. These projections gave only one extra well-defined maximum besides maxima at the assumed atomic positions.

At this stage the structure was tested against the three-dimensional Pattersson synthesis. The overlap was very large but all maxima were explained.

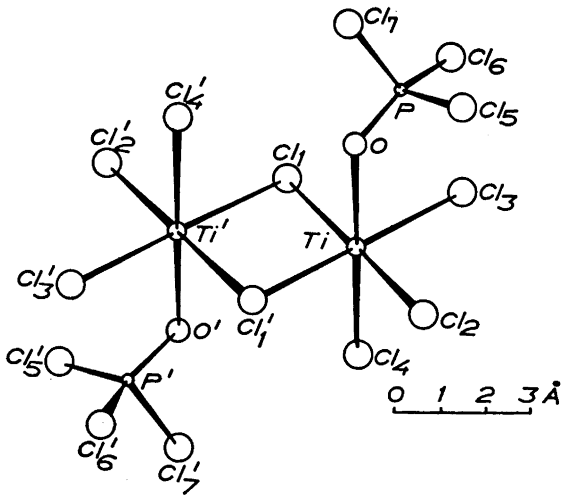

Fig. 1. The molecule of the addition compound $(TiCl_4 \cdot POCl_3)_2$.

REFINEMENT AND ASSESSMENT OF ACCURACY

Two successive three-dimensional Fourier synthesis were computed, in the last one the signs were determined for all F (h,k,l).

Two three-dimensional back-shift corrections were then carried out. To obtain an estimate of the standard deviations in the atomic coordinates Cruickshank's method [10] was used. The second back-shift correction gave smaller shifts than the standard deviation.

The standard deviations obtained with the calculated structure-factors after the back-shift corrections are given in Table 1 together with the final parameters. Using a temperature factor of 4.30 Å^2, the reliability index $R = \Sigma \mid |F_o| - |F_c| \mid / \Sigma |F_o|$ for all observed reflexions is 0.18.

A copy of the observed and calculated F-values can be obtained from this Institute by request.

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

The structure of one adduct molecule is shown in Fig. 1 and the bond lengths and bond angles are given in Table 2 together with their standard deviations.

The molecule is a dimer and the compound should be written $(TiCl_4 \cdot POCl_3)_2$ and named di-μ-chloro-hexachlorobis(phosphorylchloride) dititanium (IV). The double chlorine bridge has not been found earlier in addition compounds of titanium tetrachloride but it has been recognized as a common feature in the adducts of many other acceptor molecules studied by Mann and his school [11]. One example is $(PdBr_2 \cdot Me_3As)_2$. No accurate structure determination has been made of such compounds however.

Table 2. Bond distances and bond angles in $(TiCl_4 \cdot POCl_3)_2$ and their standard deviations.

Distance	(Å)	S.D. (Å)	Angle	(°)	S.D. (°)
Ti — Cl_1	2.44	0.01	Cl_1 — Ti — Cl_1'	78.5	0.3

			Cl_2 — Ti — O	87.4	0.6
			Cl_3 — Ti — O	88.1	0.6
			Cl_4 — Ti — O	173.0	0.6
			Cl_3 — Ti — Cl_1'	167.5	0.4
			Cl_2 — Ti — Cl_1	165.0	0.4
			Ti — O — P	151.8	1.3
			O — P — Cl_5	115.6	0.9
			O — P — Cl_6	111.3	0.9
			O — P — Cl_7	111.5	0.9
			Cl_5 — P — Cl_6	107.0	0.6
			Cl_5 — P — Cl_7	106.6	0.6
			Cl_6 — P — Cl_7	104.1	0.5

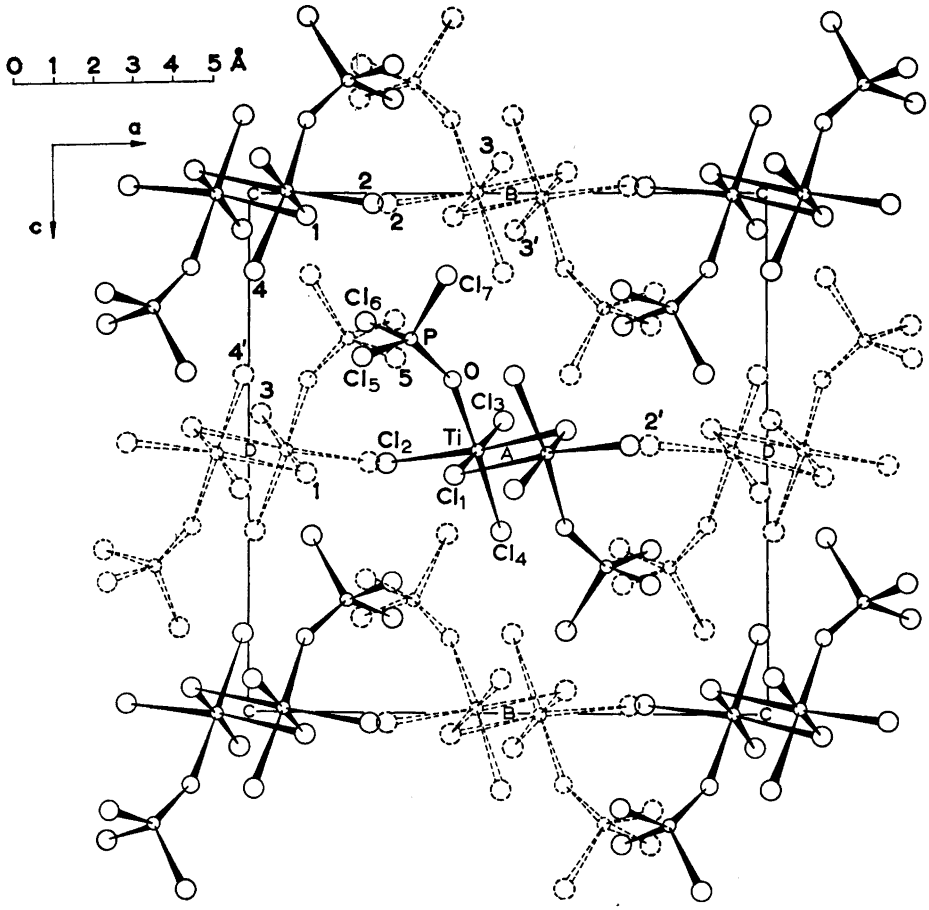

Fig. 2. Projection of the structure along [010], showing different Cl—Cl contacts. The dotted molecules have their centre of symmetry at $y = 1/2$, the other molecules at $y = 0$.

The possible existence of different geometrical isomers in such dimeric molecules was also discussed by Mann and Wells [11]. The present compound has a symmetrical *trans* configuration but the other two modifications found by us may represent other possible geometrical isomers.

The $POCl_3$ molecule has not changed much by the adduct formation and has a structure very similar to free $POCl_3$ [12] and to $POCl_3$ in $SbCl_5 \cdot POCl_3$ [13] (averaged values): P—O 1.44, 1.45 and 1.46 Å; P—Cl 1.96, 1.995 and 1.96 Å; O—P—Cl 112.8°, 114.9° and 112.0°; Cl—P—Cl 105.9°, 103.5° and 106.4°.

The acceptor molecule $TiCl_4$ has changed its co-ordination from tetrahedral to octahedral. The Ti—Cl bond lengths have increased from 2.18 ± 0.04 Å in free $TiCl_4$ [14] to 2.20—2.24 Å ± 0.02 Å for the non-bridging chlorine atoms and the significantly larger values 2.44 and 2.54 ± 0.02 Å for the bridging

Table 3. Packing distances in $(TiCl_4 \cdot POCl_3)_2$.
(*Cf.* Fig. 2.)

	Distance (Å)
$Cl_7(A) - Cl_1$ (C)	3.73
$Cl_7(A) - Cl_2$ (C)	3.66
$Cl_7(A) - Cl_3'$ (B)	3.65
$Cl_6(A) - Cl_1$ (C)	3.65
$Cl_6(A) - Cl_2$ (B)	3.55
$Cl_6(A) - Cl_4'$ (D)	3.63
$Cl_6(A) - Cl_5$ (D)	3.53
$Cl_5(A) - Cl_3$ (D)	3.65
$Cl_5(A) - Cl_4$ (C)	3.72
$Cl_4(A) - Cl_3$ (B)	3.81
$Cl_3(A) - Cl_2'$ (D)	3.48
$Cl_2(A) - Cl_1$ (D)	3.96

chlorine atoms. Such an increase in bond length by bridge formation is to be expected but is easily obscured because of lacking accuracy in the structure determination. Even quite weak bridge interaction is reflected in a bond length increment [15].

The Ti—O bond length of 2.10 Å is almost the same as the Sn—O bond length of 2.12 Å found in $SnCl_4 \cdot 2SeOCl_2$,[16] while the short Ti—Cl bond lengths are appreciably shorter than the corresponding Sn—Cl bond lengths: 2.20—2.24 Å compared with 2.36—2.41 Å. These results will be discussed in a following paper.

Gillespie and Nyholm [17] have suggested that the electronegativity difference between oxygen and the neighbour atoms will determine the bond angle at a bridging oxygen atom. The two known structures of $POCl_3$ addition compounds are in agreement with this idea. Titanium is less electronegative than antimony and the bond angle Ti—O—P is accordingly larger than Sb—O—P: 151.8° compared with 143.7°.

The packing of the molecules is indicated in Fig. 2. All packing distances less than 4.0 Å between different molecules are collected in Table 3.

In the discussion of the structure of another adduct molecule $SeOCl_2 \cdot 2NC_5H_5$[15] it was pointed out that the generally used concepts of covalent and ionic bonds cannot profitably be applied to compounds of this type. A detailed discussion of the conditions will be given in a following paper [18].

We wish to thank Professor G. Hägg for all facilities put at our disposal and Mr Y. Hermodsson for stimulating discussions. These investigations have been sponsored by a grant from the *Air Force Office of Scientific Research and Development Command, United States Air Forces*, through its European Office under Contract No. AF 61 (052)-43. This grant is greatfully acknowledged.

Borides of Rhenium and the Platinum Metals

The Crystal Structure of Re_7B_3, ReB_3, Rh_7B_3, $RhB_{\sim 1.1}$, $IrB_{\sim 1.1}$ and PtB

B. ARONSSON and (in part) E. STENBERG and J. ÅSELIUS*

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Some features of the binary systems of boron with rhenium and the platinum metals are reported. Re_7B_3 and Rh_7B_3 are isomorphous with Ru_7B_3 (Th_7Fe_3 ($D10_3$)-type). The structure of ReB_3 is closely related to those of Mo_2B_5 and W_2B_5. $RhB_{\sim 1.1}$ and PtB crystallize in the anti-NiAs structure, and a phase with the approximate composition $IrB_{\sim 1.1}$ is isomorphous with $ThSi_2$ (C_c-type).

As mentioned in an earlier communication [1] studies on the borides of the platinum metals are in progress at this Institute. In the previous paper the crystal structure of Ru_7B_3 was dealt with. In this paper we shall discuss some general features of the binary systems of boron with rhenium and the platinum metals and also described the crystal structures of Re_7B_3, ReB_3, Rh_7B_3, $RhB_{\sim 1.1}$, $IrB_{\sim 1.1}$ and PtB.

EXPERIMENTAL

Rhenium, ruthenium, rhodium and osmium (powder) were obtained from Heraeus (Hanau, Germany) and iridium and platinum from Johnson, Matthey & Co (London). Crystalline boron powder was kindly donated by Borax Consolidated (London). The manufactures have given the following information about their products:

Re : ca. 99.8 %
Ru : ca. 99.9 % – 99.95 %, traces of Cu, Fe, Ca, Mg and Si
Rh : ca. 99.95 %, traces of Ru, Fe, Ca and Mg
Os : ca. 99.5 %, main impurity: oxygen, traces of alkali and Fe
Ir : min. 99.8 %
Pt : min. 99.9 %
B : 99.0–99.7 %, main impurities: Fe, Si, O.

All phases reported in this paper were prepared by arc melting weighed amounts of metal and boron powders. Some borides of ruthenium, rhodium, and platinum were also synthesized by sintering in crucibles of recrystallized alumina (Degussit Al 23 from Degussa, Frankfurt).

* *Note on authorship.* E. Stenberg and J. Åselius have collaborated with the main author in the crystal structure determinations of Rh_7B_3, $RhB_{\sim 1.1}$, $IrB_{\sim 1.1}$ and PtB.

No chemical analyses were made. Since the vapour pressures of boron and the metals involved are not very different, we believe that the compositions are not changed much when the samples are melted.

Powder photographs were taken in cameras of the Guinier type (Cu$K\alpha$-radiation) with CaF_2 (a = 5.4630 Å) and NaCl (a = 5.6401 Å) as internal standards. Since the expression for the intensities of powder lines is somewhat different for cameras of the Guinier type than for the ordinary Debye-Scherrer cameras we have also given the calculated $p|F|^2$ values. Single crystals of the phases $RhB_{\sim 1.1}$, $IrB_{\sim 1.1}$ and PtB were examined in Weissenberg cameras. We used Mo$K\alpha$ radiation and the multiple film technique with thin iron foils between the films. The intensities were visually estimated by comparison with an intensity scale. The structure factors of Re_7B_3 and Rh_7B_3 were computed on the digital electronic computer BESK with a program devised by Åsbrink *et al.* [2]. The scattering factors were computed with the formula:

$$f_i = A_i \exp\left(-\frac{a_i}{\lambda^2}\sin^2\Theta\right) + B_i\exp\left(-\frac{b_i}{\lambda^2}\sin^2\Theta\right) + C_i \exp\left(-\frac{c_i}{\lambda^2}\sin^2\Theta\right) + D_i$$

The following constants A_i, B_i, C_i, a_i, b_i and c_i were calculated by Dr. K. Appel at the Quantum Chemistry Group of this University on basis of the scattering factor tables by Tomas and Umeda [3] (rhenium, rhodium) and Ibers [4] (boron):

	A	B	C	a	b	c
Re	25.854	28.303	19.925	0.170	1.885	15.175
Rh	15.520	16.977	12.024	0.237	2.600	20.057
B	1.644	0.406	2.878	0.6069	4.5832	33.019

In the calculations of the structure factors of ReB_3, $RhB_{\sim 1.1}$ and $IrB_{\sim 1.1}$ we used the mentioned scattering factor tables [3,4].

No corrections for dispersion (D_i) absorption or thermal movement were made.

RESULTS

A great number of intermediate phases were observed in the arcmelted alloys. We could characterize some phases by determining their crystal structures or unit cells (Table 1). We have confirmed the observation of Buddery and Welch [5] that many borides of the platinum metals are also easily prepared by sintering in silica tubes. Thus, Ru_7B_3, $RuB_{\sim 1.0}$, Rh_7B_3, $RhB_{\sim 1.1}$, and PtB

were successfully synthesized in alumina crucibles which had been inserted in evacuated and sealed silica tubes. As pointed out by Rundqvist and Jellinek [6] and also ourselves [7] borides prepared in this way may be contaminated through reactions with the silica tubes. It seems as if the risk of contamination is

reduced when direct contact between sample and silica is avoided, but without complete chemical analyses we can make no quantitative statements on this point.

The lattice parameters (l.p.) of rhenium, ruthenium, rhodium, osmium, iridium and platinum in two-phase metal-boron alloys were not significantly (that is not more than 0.05 %) different from those reported for the pure metals. This indicates that the solubility of boron is small in the solid phases of the metals mentioned.

In arc-melted rhenium-boron alloys only three rhenium borides were observed. Their unit cells are given in Table 1. We could not detect the tetragonal phase Re_2B which Neshpor *et al.*[8] reported to exist in sintered alloys. The other binary systems certainly contain several more intermediate phases than those in Table 1. We have confirmed the observation [5] that the powder photographs of $RuB_{\sim 1.0}$ and $OsB_{\sim 1.0}$ could be indexed with a cubic unit cell. As far as we are aware the other phases of Table I have not been properly characterized before.

The formulæ of Re_7B_3, ReB_3, Ru_7B_3, Rh_7B_3 and PtB are based on the structures of these phases but seem to agree well with their real compositions. The ideal structural formulae of $RhB_{\sim 1.1}$ and $IrB_{\sim 1.1}$ are RhB (or possibly RhB_2) and IrB_2 respectively. In both cases, other phases not yet characterized may have the same ideal composition. It is suggested that the notations $RhB_{\sim 1.1}$ and $IrB_{\sim 1.1}$ be used until the Rh-B and Ir-B systems have been clarified.

The l.p. variations of the phases of Table 1 are small. The largest variations (0.1—0.2 %) were observed for $RhB_{\sim 1.1}$ and PtB. Thus, the reported phases probably have narrow ranges of homogeneity.

The crystal structures of Re_7B_3, ReB_3, Rh_7B_3, $RhB_{\sim 1.1}$, $IrB_{\sim 1.1}$ and PtB: The powder photographs of Re_7B_3 and Rh_7B_3 were very similar to that of Ru_7B_3. When we assumed the atomic parameters to be the same in Re_7B_3 and Rh_7B_3 as in Ru_7B_3 we obtained good agreement between observed and calculated intensities (Tables 2 and 3). Thus, Re_7B_3 and Rh_7B_3 are isomorphous with Ru_7B_3.

The powder photograph of ReB_3 (Table 4) could be indexed with a hexagonal cell. From the size of the unit cell we concluded that it contained two rhenium atoms. The only systematic extinction was observed for $hh\bar{2}hl$ reflexions which only appeared for l even. Thus, the possible space groups are: $P6_3/mmc$ $P\bar{6}2c$, $P6_3mc$, $P\bar{3}1c$ and $P31c$. Assuming the rhenium atoms to occupy two-fold positions 1/3, 2/3, 1/4 (or 1/3, 2/3, z) excellent agreement between observed and calculated intensities is obtained (Table 4). Because of the

great differences in scattering power of rhenium and boron, the boron atoms have to be located from space considerations. If we make the plausible assumptions that Re-B distances are > 2.2 Å and B-B distances > 1.6 Å, six boron atoms can be situated in one four-fold position 1/3, 2/3, z and one two-fold position 0,0,0 (or 0,0,z). The only other boron arrangement which does not seem very improbable is to place the boron atoms in one six-fold position x,0,0 ($x \sim 1/3$). In this second alternative the shortest B—B distances have the normal value of 1.68 Å but the shortest Re—B distance is only 2.10 Å. Therefore, the first proposed structure is considered to be the most probable one. This structure has the symmetry of space group $P6_3/mmc$ with the following atomic positions:

2 Re in 2(c)
4 B_I in 4(f) with $z = 0.55$
2 B_{II} in 2(a)

Interatomic distances are given in Table 5. [The second, less probable structure has the symmetry of space group $P\bar{6}2c$ with two rhenium atoms in 2(c) and six boron atoms in 6(g) with $x \sim 1/3$].

Table 6. Power photographs of arcmelted alloys with the nominal compositions $RhB_{1.5}$ and PtB, respectively. (Cu$K\alpha$ radiation.) Since the relative values of I_{calc} are very similar for $RhB_{\sim 1.1}$ and PtB, they have only been computed for $RhB_{\sim 1.1}$.

Table 7. Interatomic distances in $RhB_{\sim 1.1}$ and PtB (in Å).

Rh — 12 Rh : 2,85 (6); 3.31 (6).		Pt — 12 Pt : 2.81 (6); 3.36 (6)	
— 6 B : 2.18 (6).		— 6 B : 2.19 (6).	
B — 6 Rh : 2.18 (6).		B — 6 Pt : 2.19 (6).	
— 2 B : 2.21 (2).		— 2 B : 2.03 (2).	

The powder photographs of $RhB_{\sim 1.1}$ and PtB were very similar indicating that these phases were isomorphous. From the systematic extinction of $h\,h\,\bar{2}\bar{h}l$ reflexions with l odd and the unit cell dimension we suspected that the structure of these phases was of the anti-NiAs ($B8$) type. With this assumption (space group $P\bar{6}_3/mmc$, two metal atoms in 2(c) and two boron atoms in 2(a)), good agreement between observed and calculated intensities was obtained (Table 6). A single crystal of each of $RhB_{\sim 1.1}$ and PtB was also studied. The agreement between observed and calculated structure factors for $h\,0\,\bar{h}\,l$ reflexions is satisfactory — the R value was 9.4 % (45 observed reflexions) for $RhB_{\sim 1.1}$ and 10.0 % (29 observed reflexions) for PtB. Interatomic distances are given in Table 7. (In a preliminary communication [5] we described the structure of $RhB_{\sim 1.1}$ and PtB using the orthorhombic space-group $C\,m\,c\,m$. We have found, however, that there are no significant deviations from hexagonal symmetry.)

The single crystal and powder photographs of $IrB_{\sim 1.1}$, finally, could be indexed with a tetragonal unit cell. Since $h\,k\,l$ reflexions were only observed when $h + k + l = 2n$ and $2k + l = 2n + 1$ or $4n$, the only possible space group was $I4_1/amd$. In order to adhere to convention we have chosen the

origin at $\bar{4}m2$. From the size of the unit cell we concluded that it contained four iridium atoms which were placed in 4(*a*). As in the case of ReB_3 the boron atoms had to be located from space considerations. It seems unlikely that the boron atoms occupy the positions 4(*b*), 8(*c*) or 8(*d*) since with boron in any of these positions Ir—B distances of about 2.0 Å or shorter would be formed. The most probable boron position is in 8(*e*) with $z = 0.41_8$. The agreement between observed and calculated intensities for the proposed structure is good (Table 8). With the boron atoms in 8(*e*), $IrB_{\sim 1.1}$ is isomorphous with $ThSi_2$[9] (C_c type according to the handbooks of Smithells [10] and Pearson [11]). Interatomic distances are shown in Table 9.

DESCRIPTIONS OF THE STRUCTURES AND COMMENTS

The Ru_7B_3 structure was discussed at some length in the previous paper [1]. Somewhat unexpectedly the Me_7B_3 borides are isomorphous with Th_7Fe_3[12] (*D* 10_2-type [10,11]). (In this connection we wish to point out that the structure [12] of ThCo is also isomorphous with a common boride structure, namely the CrB structure).

The rhenium skeleton of ReB_3 is built up of close packed layers arranged in a close packed hexagonal structure (*ABAB* . . .). The shortest intermetallic distance within the layers is 2.90 Å whereas atoms of neighbouring layers only have a remote contact (4.10 Å) with each other. Between the metal layers there are slightly puckered hexagonal sheets of boron atoms with the shortest B—B distances 1.71 Å and 1.83 Å. The distances between atoms of neighbouring boron layers are also quite large (> 3.0 Å). Thus the cohesion in the *c*-direction must be mainly due to metal-boron bonds.

The structures which Kiessling [13] has suggested for W_2B_5 and Mo_2B_5 contain the same building elements as ReB_3. In addition to the puckered boron sheets there are also plane boron layers in W_2B_5 and Mo_2B_5. With the usual notations the sequences of close packed hexagonal metal layers in ReB_3, W_2B_5 and Mo_2B_5 are: *ABAB* . . ., *AABBAABB* . . ., and *AABBCCAABBCC*..., respectively. If, following Kiessling, we denote the puckered boron sheets with *K* and the plane boron sheets in W_2B_5 and Mo_2B_5 with *H*, the complete stacking sequences along the *c* direction of the three structures are as follows:

ReB_3 : *AKBK* . . .
W_2B_5 : *AHAKBHBK* . . .
Mo_2B_5 : *AHAKBHBKCHCK* . . .

Thus, these structures are very closely related.

$IrB_{\sim 1.1}$ is of interest because of its apparent deviation from the ideal formula IrB_2. It should be noted that other compounds with structures closely related to that of $ThSi_2$ also show deviations from the ideal formula. Thus, Perri *et al.*[14] found that a gadolinium silicide with the ideal formula $GdSi_2$ had the composition $GdSi_{1.4}$.

Position of the *O*-Acetyl Groups in Birch Xylan *

HANS O. BOUVENG, PER J. GAREGG and BENGT LINDBERG

Svenska Träforskningsinstitutet, Träkemiska avdelningen, Stockholm Ö, Sweden

A xylan containing 11.8 % uronic acid and 16.9 % *O*-acetyl has been isolated from birch holocellulose by extraction with dimethyl sulphoxide. Methylation studies of the acetyl xylan itself and of a deacetylated sample have shown that the *O*-acetyl groups are attached to the xylose residues mainly in the 3-position and only to a lesser extent in the 2-position.

Birch wood xylan, the predominating hemicellulose in birch wood, has been shown to consist of a chain of 1,4-linked β-D-xylose residues, with every tenth to fifteenth residue substituted in the 2-position with a 4-*O*-methyl-α-D-glucopyranosyluronic acid residue [1-3]. Acetic and formic acids have been isolated from several woods [4] but Timell in an examination of birch wood found only acetic acid [5]. The isolation from birch wood of a partly acetylated xylan [6] localised at least part of the acetic acid in the wood.

In the present investigation the acetylated xylan was isolated by extraction with dimethyl sulphoxide (DMSO) from birch wood holocellulose which had been prepared by chlorination and treatment with ethanolic ethanolamine from a mixture of *Betula verrucosa* Ehrh. and *B. pubescens* Ehrh. The holocellulose was subsequently extracted with hot water and 12 % potassium hydroxide. The yield and composition of the different fractions are given in Table 1. The DMSO extract represented about 50 % of the xylan in the wood and xylose formed about 96 % of the aldose residues of the extract. The present results are thus substiantially different from those obtained with birch chlorite holocellulose [6] from which only about 15 % of the acetylated xylan could be extracted by this method. By osmometry according to Pals and Hermans [7] the $\overline{DP}_n$ of the acetylated xylan was estimated as 200 ± 10.

The positions of the *O*-acetyl groups in the acetylated xylan were investigated by two series of methylations. In the first series the acetylated xylan was fully methylated by a slightly modified version [8] of the method described by Kuhn *et al.*[9] The product (*O*-acetyl, 10.1 %; methoxyl, 28.1 %) was reduced with lithium aluminium hydride to yield a partially methylated glucoxylan

* Preliminary results of this investigation have been published in *Chem. and Ind., 1958*, 1727; the results were presented at the 136th meeting of the American Chemical Society, Atlantic City, New Jersey, September 1959. Abstract 3 E.

Table 1. Yield and composition of extracts from birch holocellulose (%).

	Yield	Lignin	CH_3CO	Uronic acid	OCH_3 %	Aldose residues				
						Galactose	Glucose	Mannose	Arabinose	Xylose
Birch holocellulose	—	7.2				0.9	61.0	2.9	1.1	33.9
DMSO extract	15.0	2	16.9	11.8	1.77	0.8	3.1	—	—	96.2
Hot water extract	0.55	5	4.0	42.7	2.58	19.1	18.2	3.5	8.0	49.6
12 % KOH extract	15.6	3	—	14.6	1.57	1.1	3.2	1.6	1.6	92.0
Residue			—			0.9	88.9	3.5	0.7	6.0

(AMX; $\overline{DP}_n$, 60). In the second series the xylan was methylated with simultaneous deacetylation and then after reduction was converted to a fully methylated glucoxylan (MX; $\overline{DP}_n$, 43) by further methylation. The low $\overline{DP}_n$ values for the two methylated xylans indicate that considerable depolymerisation occurred during the methylations.

The two methylated polysaccharides were hydrolysed and the monomeric sugars obtained were separated on a carbon-Celite column and estimated quantatively. 2-*O*- and 3-*O*-methyl-D-xylose were incompletely separated on the column and were separated for quantitative estimation by paper electrophoresis in borate buffer;[10] fractionation on a preparative scale was done on a carbon-Celite column by gradient elution in the presence of borate buffer [11]. The results of the fractionations are summarised in Table 2.

The presence of 2-*O*-methyl-D-xylose in the hydrolysed MX cannot be unequivocally accounted for. It is known from studies on cellulose [10,12] that hydroxyl groups in different positions show considerable differences in reactivity on methylation. It is also known from investigations at this Institute (unpublished results) that 2,3-di-*O*-methyl-D-xylose is demethylated to a small extent under the conditions employed for the hydrolysis of AMX and MX, but without

Table 2. Methyl ethers (in mole %) obtained from methylated xylans from birch wood.

Methyl ether	Acetylated methylated xylan (28.1 % OMe)	Deacetylated methylated xylan (37.4 % OMe)
Xylose	5.4	0.1
2-*O*-Methylxylose	17.5	2.5
3-*O*-Methylxylose	9.1	6.3
2,3-Di-*O*-methylxylose	58.1	78.3
2,3,4-Tri-*O*-methylxylose	—	5.2
2,3,4-Tri-*O*-methylglucose	9.8	4.0
2,3,4,6-Tetra-*O*-methylglucose	—	3.7

any preferential demethylation at either the 2- or the 3-position. Thus the presence in the hydrolysate from MX of 2-*O*-methyl-D-xylose which is often found in hydrolysates from methylated xylans (*cf. e.g.* Ref.[2]) might be explained either by incomplete methylation or by demethylation during hydrolysis. Another possibility is the occurrence of some branching points in the original polysaccharide, which might be correlated with the proportion of 2,3,4-tri-*O*-methyl-D-xylose (5.2 mole %) which is higher than that required by a straight chain of about 40 xylose residues (2.3 mole %). This matter however requires further investigation. Aspinall and Das Gupta have recently obtained evidence for a branched xylose chain in a similar xylan from jute.[13] The 2-*O*-methyl-D-xylose in the hydrolysed MX could also be accounted for by the presence of 3-*O*-(4-*O*-methyl-D-glucuronopyranosyl)-D-xylose residues which have been found in *Pinus radiata* D. Don [14] and various grasses.[15] However, a paper chromatographic investigation of a partial hydrolysate did not reveal the presence of this aldobiouronic acid.

The virtual absence of 2,3,4-tri-*O*-methyl-D-xylose from hydrolysed AMX indicates that most of the terminal non-reducing xylose residues carry *O*-acetyl groups.

The results show that the *O*-acetyl groups in the methylated acetylated xylan are attached to the xylose residues mainly at the 3-position and only to a lesser degree at the 2-position. However, the 30 % of the *O*-acetyl groups that is replaced by methoxyl groups is not accounted for. No indications were found of *O*-acetyl groups on the uronic acid residues. As the conditions during methylation [16] and possibly also in the isolation of the polysaccharide favour the migration of acetyl groups it is not possible to extrapolate the results obtained back to the native polysaccharide. In naturally occurring 1-*O*-acetyl-D-mannitol [17] and 6-*O*-acetyl-D-glucose [18] the *O*-acyl groups occupy the most readily acetylated position. No conclusion can be drawn from the present investigation as to whether this is also the case for the acetylated xylan.

EXPERIMENTAL

All melting points are corrected. Evaporations were done under reduced pressure at a bath temperature below 40°.

Chromatography. Papers: Whatman No. 1 and 3MM. Solvents: A. Ethyl acetate-acetic acid-water, 3:1:3. B. Butanol-ethanol-water 10:3:5. C. *Iso*propyl ether-light petroleum (40–60°), 1:1 (on DMSO-impregnated paper [19]).

Paper electrophoresis. Papers: Whatman No. 1, Schleicher and Schüll 602 hP. Buffers: 0.1 M borate buffer at pH 10, 0.1 M acetate buffer at pH 4. Spray reagents: Aniline hydrogen phthalate, anisidine hydrochloride.

Preparation of birch wood holocellulose. Acetone-extracted birch wood (a technical mixture of *Betula verrucosa* Ehrh. and *B. pubescens* Ehrh.) of particle size 1–2 mm (462 g) was treated with chlorine in ice-water and extracted with 3 % ethanolic ethanolamine according to Timell and Jahn [20], yielding birch holocellulose (373 g). Yields and analytical data for the holocellulose and the extracts described below are given in Table 1.

Extraction of the holocellulose. The holocellulose (300 g) was extracted twice with redistilled dimethyl sulphoxide (3 l) at room temperature. After filtration the combined solutions were acidified with acetic acid and the hemicellulose was precipitated by adding two volumes of ethanol and removed by centrifugation. It was obtained as a powder after reprecipitation from aqueous solution with ethanol, washing with ethanol and ether and drying in a vacuum. The hemicellulose had $\overline{DP}_n$ 200 ± 10 and $[\alpha]_D^{20}$ −69° (*c*, 1.0 in water).

Table 3. Distillation at constant volume of the volatile acid from birch wood xylan and of some known acids.

Distillate ml	Formic acid %	Acetic acid %	Propionic acid %	Acid from xylan
25	17	27	46	28
50	31	46	70	46
75	41	60	82	59
100	50	69	89	68
125	56	76	93	75
150	62	81		80
175	66	85		84
200	70	88		87
225	74	90		90

The residual holocellulose was extracted twice with boiling water for 2 h and then twice with 12 % aqueous potassium hydroxide under nitrogen overnight at room temperature. The extracts were worked up as described above. The lignin in the holocellulose was estimated as Klason lignin, that in the hemicellulose fractions by measuring the absorption at 280 mμ [21]. Uronic acid contents were determined according to Johansson *et al.* [22], and quantitative paper chromatography on aldoses in the hemicellulose hydrolysates was done according to Saeman *et al* [23].

Identification of the O-*acetyl groups.* The acetic acid was identified by Dyers method [24]. The xylan (0.25 g) was heated in N sodium hydroxide at 100° for 15 min. The solution was acidified and the volatile acid was removed by distillation. After neutralisation with sodium hydroxide and concentration the solution containing the acetate was passed through Amberlite IR-120 (H^+), made up to 50 ml and distilled at constant volume. The distillate was collected in 25 ml fractions which were titrated with 0.01 N sodium hydroxide. Solutions with comparable concentrations of authentic formic, acetic and propionic acid were distilled in a similar manner. The results are summarised in Table 3 which shows that only acetic acid was obtained from the xylan.

Methylation of acetylated birch wood xylan. DMSO-extracted xylan (4 g) was dissolved in dry dimethyl formamide (150 ml). Methyl iodide (10 ml) and silver oxide (9 g) were added in small portions over 5 h and the solution was stirred vigorously and cooled externally. The reaction was allowed to proceed for a further 20 h and the product was then isolated as previously described [8]. The product was methylated in the same way a further three times. Yield 1.55 g, OCH_3 28.1 %, CH_3CO 10.1 %. (The calculated methoxyl content for a fully substituted xylan with 10.1 % *O*-acetyl is 28.4 %). This material is referred to as AMX.

Methylation with deacetylation of birch xylan. The xylan (4 g) was first methylated with simultaneous deacetylation using methyl sulphate in aqueous sodium hydroxide and then methylated three times with methyl iodide and silver oxide in dimethyl formamide. Yield 3.32 g, OCH_3 37.4 % (theoretical value 38.3 %). This material is referred to as MX.

Reduction of AMX and MX. AMX (1.5 g) was reduced with lithium aluminium hydride (2 g) in boiling, anhydrous tetrahydrofuran (100 ml) for 4 h. After addition of water to destroy excess reducing agent and neutralisation with sulphuric acid, the reaction mixture was filtered and concentrated to dryness. The product was extracted with chloroform and precipitated in light petroleum from benzene solution. Yield 1.4 g. MX (1.3 g) was reduced similarly to yield 1.2 g of product. This was then methylated twice with methyl iodide and silver oxide in the usual manner. Yield 1.1 g, OCH_3 37.9 %.

Hydrolysis of reduced AMX and MX. Reduced AMX (1 g) was treated with formic acid at 100° for 8 h and then with 0.5 N hydrochloric acid at 100° overnight. The solution was passed through Amberlite IR 4B (free base) and concentrated to a syrup. Yield 0.85 g.

Reduced MX (0.80 g) was hydrolysed in a mixture of 20 ml acetic acid and 40 ml 0.5 N sulphuric acid at 100° overnight. The hydrolysate was treated with barium hydroxide, filtered and concentrated to a small volume. After extraction with ethanol and concentration the mixture of monomeric sugars was obtained as a syrup (0.81 g).

Table 4. Fractionation of hydrolysed AMX. *Gradients:* 0 → 12 % aqueous ethanol (3 l), 12 → 35 % aqueous ethanol (3 l). 20-ml fractions were collected.

Tube No.	Component	Millimole	Mole %
21—38	Xylose	0.198	5.4
41—44	3-*O*-Methylxylose	0.112	3.0
45—88	2-*O*- + 3-*O*-Methylxylose	0.870	23.6
108—166	2,3-Di-*O*-methylxylose	2.14	58.1
Residue	2,3,4-Tri-*O*-methylglucose	0.360	9.8

Ratio: 2-*O*-: 3-*O*-methylxylose in fraction 45—88 was 2.9:1.

Fractionation of hydrolysed AMX and MX. The hydrolysates were fractionated on a carbon-Celite column (4 × 46 cm) by gradient elution with aqueous ethanol [25]. The column was subsequently washed with 50 % acetone. The amount of reducing sugar in each of the combined fractions was determined by hypoiodite oxidation [26]. The fractions containing both 2-*O*- and 3-*O*-methyl-D-xylose were analysed for each component by quantitative paper electrophoresis in borate [10] while fractionation on a preparative scale was done on a carbon-Celite column (2.8 × 30 cm) by gradient elution (2 l 0—6 % aqueous ethanol) in the presence of borate (0.1 M, pH 10); 3-*O*-methyl-D-xylose was eluted first. The results of the fractionations are summarised in Tables 4 and 5.

Characterisation of components

D-*Xylose.* Table 4: Crystallised from ethanol-water, m. p. and mixed m. p. 143—145°. Table 5: Characterised by paper chromatography.

2-O-*Methyl*-D-*xylose.* Table 4: Crystallised from acetone, m. p. 131—133°. Table 5: The ether was indistinguishable by paper electrophoresis from an authentic specimen, kindly supplied by Dr. T. E. Timell, Montreal.

Table 5. Fractionation of hydrolysed MX. *Gradients:* 0 → 12 % aqueous ethanol (3 l), 12 → 30 % aqueous ethanol (2 l), 30 % aqueous ethanol → 30 % aqueous acetone (3 l), 30 % → 50 % aqueous acetone (2 l). 25 ml fractions were collected.

Tube No.	Component	Millimole	Mole %
24— 42	Xylose	0.031	0.1
54— 71	3-*O*-Methylxylose	0.203	4.9
72—120	2-*O*- + 3-*O*-Methylxylose	0.163	3.9
134—224	2,3-Di-*O*-methylxylose	3.25	78.1
230—254	2,3,4-Tri-*O*-methylglucose	0.166	4.0
255—284	2,3,4-Tri-*O*-methylxylose	0.216	5.2
Residue	2,3,4,6-Tetra-*O*-methylglucose	0.154	3.7

Ratio: 2-*O*- : 3-*O*-methylxylose in fraction 72—120 was 1.8:1.

3-O-Methyl-D-xylose. Tables 4 and 5: Crystallised from acetone and methyl ethyl ketone, m. p. and mixed m. p. 96—98°. The ether was indistinguishable from authentic material on paper electrophoresis.

2,3-Di-O-methyl-D-xylose. Table 4: $[\alpha]_D^{20}$ +23° (*c*, 1.5 in water). The anilide had m. p. 124—126°. Table 5: $[\alpha]_D^{20}$ +23.5° (*c*, 1.5 in water). The anilide had m. p. 126—128°. These values are in good agreement with those previously reported [27].

2,3,4-Tri-O-methyl-D-xylose. $[\alpha]_D^{20}$ +18° (*c*, 1.1 in water). The anilide after crystallisation from ligroin had m. p. and mixed m. p. 99—101°. The ether was indistinguishable from authentic material by paper chromatography on DMSO-impregnated paper in solvent C.

2,3,4-Tri-O-methyl-D-glucose. The ether was in both cases indistinguishable from an authentic sample on paper chromatography in solvents A, B and C. Attempts to crystallise the aniline derivative failed; on paper chromatography in solvent C it gave two spots corresponding to the α and β forms, both of which were indistinguishable from the spots given by 2,3,4-tri-*O*-methyl-D-glucopyranosyl-N-phenylamine.

2,3,4,6-Tetra-O-methyl-D-glucose. Demethylation gave glucose only. The ether was indistinguishable from an authentic sample on paper chromatography in solvent A, B and C.

Partial hydrolysis of birch wood xylan. Xylan (5 g) from the 12 % potassium hydroxide extract was dispersed in water (300 ml) and 2 N sulphuric acid (100 ml) was added. The mixture after keeping at 100° for 3 h gave a clear solution. After neutralisation with barium hydroxide and filtration, the solution was concentrated to a small volume. Paper chromatography in the ethyl acetate-pyridine-water, 2:1:2 solvent indicated the presence of at least two acidic components together with xylose and small amounts of other sugars. The barium salts of the acids were precipitated with ethanol. From the supernatant liquid further amounts of barium salts of acids were obtained after concentration and repeated precipitation. The precipitates were washed with ethanol and reprecipitated. The free acids (0.76 g) were obtained after removal of the cations with Amberlite IR-120 (H^+) and concentration to dryness.

Fractionation of the acidic components. The acidic fraction (0.76 g) was adsorbed on a cellulose column, 2.5 × 35 cm, and eluted with ethyl acetate-acetic acid-formic acid-water 19:3:1:4 (3 l). 25 ml fractions were collected. Suitable fractions were combined, evaporated to dryness and examined by paper chromatography in ethyl acetate-acetic acid-water 3:1:1, in ethyl acetate-acetic acid-formic acid-water 19:3:1:4 and by paper electrophoresis in borate and acetate buffer.

Fraction 1 (75 mg) contained mainly 4-*O*-methyl-D-glucuronic acid together with a smaller amount of 2-*O*-(4-*O*-methyl-α-D-glucuronopyranosyl)-D-xylose, both indistinguishable from authentic specimens.

Fraction 2 (250 mg) contained 2-*O*-(4-*O*-methyl-D-glucuronopyranosyl)-D-xylose and a trace of a component of lower R_F-value on paper chromatography. The aldobiouronic acid was indistinguishable from authentic material on chromatography and on electrophoresis.

Fraction 3 (320 mg) consisted of a mixture of higher acids and oligosaccharides and was not examined further. No aldobiouronic acid was observed corresponding to 3-*O*-(4-*O*-methyl-D-glucuronopyranosyl)-D-xylose, which is reported to move faster than 2-*O*-(4-*O*-methyl-D-glucuronopyranosyl)-D-xylose on paper chromatography in ethyl acetate: acetic acid:formic acid-water, 19:3:1:4 [14].
