Osmometric DP_n determinations. Osmometric determinations were made on the sodium salt of the acetylated xylan in 0.1 N sodium chloride [7] using "Ultrafein allerfeinst" membranes, supplied by Membranfiltergesellschaft Göttingen. Determinations of the DP_n of AMX and MX were carried out in chloroform and butyl acetate, respectively, using "Ultracellafilter allerfeinst" membranes supplied by the same firm.

Studies on Glucomannans from Norwegian Spruce

III *. Partial Hydrolysis

HANS MEIER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

An easily extractable polysaccharide fraction from Norwegian spruce, containing galactose, glucose and mannose residues, was subjected to partial hydrolysis. A number of oligosaccharides were isolated from the hydrolysate; among them were the four disaccharides and five of the eight trisaccharides that should be formed from a linear glucomannan with β-1,4-linkages and a random distribution of the hexose residues. In addition to these compounds, 6-O-α-D-galactopyranosyl-D-mannose (Ga $\xrightarrow[\alpha]{1\ 6}$ M) and a trisaccharide (Ga $\xrightarrow[\alpha]{1\ 6}$ M $\xrightarrow[\beta]{1\ 4}$ M) were also isolated, indicating that, in addition to the glucomannan, there was also present either a galactomannan of the type found in legume seeds or a galactoglucomannan.

Glucomannans containing glucose and mannose residues in proportions of between 1:3 and 1:4 have been isolated from several coniferous woods. Methylation studies have shown that these polysaccharides are essentially linear with β-1,4-linked hexose residues [1–7], though some indications of branching have been found [3,7,8]. In agreement with this type of structure partial hydrolyses of the glucomannans or of pulps enriched in them [1,5,6,9–12] have afforded 4-*O*-β-D-mannopyranosyl-D-mannose (M $\xrightarrow[\beta]{1\ 4}$ M), 4-*O*-β-D-glucopyranosyl-D-mannose (*G* $\xrightarrow[\beta]{1\ 4}$ M), 4-*O*-β-D-mannopyranosyl-D-glucose (M $\xrightarrow[\beta]{1\ 4}$ G), cellobiose (G $\xrightarrow[\beta]{1\ 4}$ G) and mannotriose (M $\xrightarrow[\beta]{1\ 4}$ M $\xrightarrow[\beta]{1\ 4}$ M).

Some authors [1,4,6,13,14] have obtained polysaccharide fractions which in addition to glucose and mannose residues also contained a high percentage of galactose residues, indicating the presence of a galactomannan or a galactoglucomannan. It was observed in this laboratory that quite high galactose contents in some glucomannan fractions could be reduced to a low value (1 %

or lower) if the polysaccharide material was delignified and precipitated with Fehling's solution [7]. It therefore seems probable that pine and spruce contain galactose-free glucomannans but that linkages between lignin and the polysaccharides make it impossible to separate material that has not been completely delignified, into its components. The most easily extracted, mannose-containing polysaccharide fraction has, however, not been dealt with in previous studies at this laboratory. The present paper describes an investigation of this fraction from Norwegian spruce (*Picea abies* Karst.).

Delignification of spruce wood by the chlorite method dissolves a large part of non-cellulose polysaccharides. This fraction (*A*, Table 1) was recovered by dialysis and was shown to consist mainly of polysaccharides containing mannose residues. To remove contaminating araboxylans, arabogalactans and galactans, *A* was purified by precipitation first with barium hydroxide [15] and then with Fehling's solution, giving fraction *B*. Galactans of the type recently isolated from compression wood [16] are precipitated by barium hydroxide but with Fehling's solution give little or no precipitate. Araboxylans and arabogalactans are not precipitated by either barium hydroxide or Fehling's solution. The material precipitated by barium hydroxide but not precipitated by Fehling's solution therefore contained a large proportion of galactose residues with lesser amounts of xylose and arabinose residues. The material precipitated by both barium hydroxide and Fehling's solution (fraction *B*, Table 1) was not free from lignin, so that contamination with other polysaccharides, *e.g.* a galactan, cannot be excluded, but it should consist essentially only of mannose-containing polysaccharides. *B* differed from other spruce polysaccharides containing mannose residues that have been studied in this laboratory [3,17], not only in its high content of galactose but also in the low ratio of glucose to mannose (1:7.4). *B* on electrophoresis on glass fibre sheets in borate buffer gave a single spot with considerable trailing.

Fraction *B* was subjected to partial hydrolysis, the yield of lower polysaccharides being improved by separation and further hydrolysis of the higher oligosaccharides. The oligosaccharides were then fractionated by carbon column chromatography, by chromatography and electrophoresis on thick filter paper and by chromatography on cellulose and carbon columns. Fifteen oligosaccharides (Table 2) were obtained in a state of purity. As can be seen from Table 2, the R_F values of some of these substances are very close, and separa-

Table 2. Oligosaccharides from the partially hydrolysed, mannose-rich fraction *B*.

[a] All linkages are β-1,4, except Ga → in *c* and *h*, which are α-1,6.
[b] Numbers of fractions combined from the first carbon column fractionation. Numbers in brackets indicate that a substance was present in more than one of the combined fractions.
[c] As the separation and purification of the compounds was often tedious and involved considerable losses, the yields are not representative of the amounts present in the hydrolysate. The yields given in brackets are those for the combined fractions given in brackets, in the cases where the substance was isolated from these.
[d] Paper chromatographic mobility relative to glucose in solvent ii.
[e] Paper electrophoretic mobility in 0.1 M borate buffer, pH 10.0, relative to glucose.

tion could hardly have been effected without the aid of all of these methods. The results of the carbon column chromatography are rather surprising, some disaccharides being eluted after some of the trisaccharides and even after mannotetraose.

Definite structures could be assigned to all exept one (*o*, Table 2) of the fifteen oligosaccharides isolated. Total hydrolysis before and after reduction with sodium borohydride, and chromatography of the hydrolysate gave information on the component sugars and the reducing end group. Partial hydrolysis was carried out on the tri- and tetrasaccharides and the components obtained were identified by paper chromatography and paper electrophoresis. The degree of polymerisation of the tri- and tetrasaccharides was determined by the metod of Peat *et al.* [18].

The disaccharides (*a-f*, Table 2) were all known, crystalline compounds.

The mannobiose, mannotriose and mannotetraose which were obtained, belong to a homologous series, as is shown by the linear relationships between R_M and n [19] (Fig. 1) and between $[M]_D/n$ and $\frac{n-1}{n}$ [20] (Fig. 2). The mannotriose was obtained in an amorphous state in the present investigation but has been obtained crystalline by Whistler and Smith [21]; the value for $[M]_D$ in Fig. 2 is calculated from their value for the specific rotation. Fig. 2 gave the specific rotation of a β-1,4-linked mannan by extrapolation as $-48°$ (in water), in good agreement with the value $-46°$ (in N sodium hydroxide), found for ivory nut mannan A, which is known to contain principally these linkages [22].

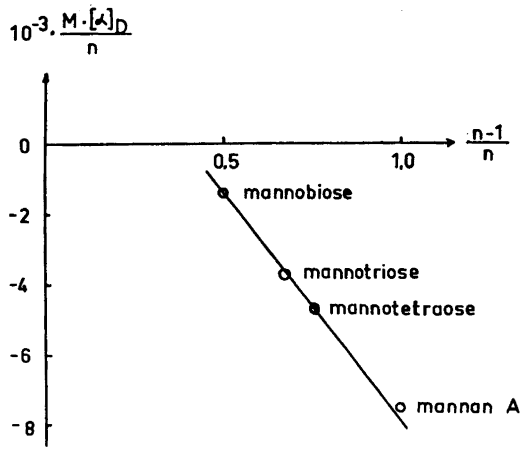

Fig. 2. Application of the Freudenberg-Blomquist relationship to mannose oligosaccharides (M = molecular weight, n = degree of polymerisation).

The galactobiose and galactotriose were obtained only in low yield and probably derive from a galactan of the type recently isolated from spruce compression wood [16].

The oligosaccharides containing both mannose and glucose residues obviously derive from a glucomannan of the ordinary type. The cellobiose may derive from contaminating cellulose, though this is less likely, especially as $G\xrightarrow[\beta]{1\quad 4}G\xrightarrow[\beta]{1\quad 4}M$ was also isolated. All of the disaccharides expected from a glucomannan and five of the eight theoretically possible trisaccharides were isolated. For statistical reasons, elements yielding cellotriose and to a lesser extent the trisaccharides with two glucose residues should be rare, but as glucosidic linkages are more resistant to acid hydrolysis than mannosidic, $G\xrightarrow[\beta]{1\quad 4}G\xrightarrow[\beta]{1\quad 4}M$ should be enriched compared to $M\xrightarrow[\beta]{1\quad 4}G\xrightarrow[\beta]{1\quad 4}G$ and $G\xrightarrow[\beta]{1\quad 4}M\xrightarrow[\beta]{1\quad 4}G$. Thus $G\xrightarrow[\beta]{1\quad 4}G\xrightarrow[\beta]{1\quad 4}M$ was the only trisaccharide with two glucose residues which was obtained in the present investigation. Oligosaccharides, derived from potential branching points in the glucomannan were looked for specially but were not observed. They would be present, however, only in small amounts and might easily have been overlooked.

Two oligosaccharides ($Ga\xrightarrow[\alpha]{1\quad 6}M$ and $Ga\xrightarrow[\alpha]{1\quad 6}M\xrightarrow[\beta]{1\quad 4}M$), containing an α-galactopyranosidic residue, linked to the 6-position in a mannose residue, were also obtained. Partical hydrolysis of the latter after reduction with sodium borohydride and identification of $Ga\xrightarrow[\alpha]{1\quad 6}M$ in the hydrolysate, eliminated the structure $Ga\xrightarrow[\alpha]{1\quad 6}M\xleftarrow[\beta]{4\quad 1}M$. The$Ga\xrightarrow[\alpha]{1\quad 6}M$ residue is known

as a structural element of the galactomannans from legume seeds, *e.g.* in locust bean gum and guaran[23]. These polysaccharides contain a linear chain of β-1,4-linked mannose residues, some of which are substituted in the 6-position by α-galactopyranosidic residues. It is therefore possible that the same type of polysaccharide occurs in spruce wood. These oligosaccharides could also be derived from a galactoglucomannan but the first possibility seems more attractive. If a more or less constant ratio of glucose to mannose of between 1:3.5 and 1:4 is assumed for the spruce glucomannans, then the carbohydrate composition of the present fraction (*B*) implies that it should contain about equal parts of glucomannan and galactomannan. The galactose to mannose ratio in the latter should be lower than 1:2.5, as there are indications that galactans are also present in fraction *B*. The isolation of the two polysaccharides in a state of purity should of course definitely prove this hypothesis, but the separation of a glucomannan and a galactomannan by present methods seems to be a most difficult task. The isolation of $G\xrightarrow[\beta]{1\quad 4}G$ and $G\xrightarrow[\beta]{1\quad 4}G\xrightarrow[\beta]{1\quad 4}M$ from the hydrolysate gives some support to the presence of a glucomannan (glucose:mannose, 1:4), since structural elements giving these oligosaccharides should be even more rare in a galactoglucomannan, in which the proportions of glucose to mannose are 1:7.4.

In methylation studies of mannose-rich polysaccharide fractions from Loblolly pine and Sitka spruce Ball *et al.*[1] and Dutton and Hunt [4] isolated 2,3,4,6-tetra-*O*-methyl-D-galactose and a di-*O*-methyl-D-mannose, believed to be the 2,3-dimethyl-ether. This is in good agreement with our results, which show the presence of galactose residues that are linked to 6-positions in mannose residues and are most probably terminal.

In a recent paper [24] Hamilton and Thompson have reported the isolation and a structural investigation of a polysaccharide, believed to be a galactoglucomannan, from southern pine.

EXPERIMENTAL

Melting points are corrected. Concentration of solutions was done under reduced pressure at a bath temperature of 40°.

Paper chromatography and paper electrophoresis. Whatman No. 1 and No. 3 MM papers were used. The chromatograms were run in the solvent systems (v/v):

i. ethyl acetate-acetic acid-water, 3:1:3 (upper layer)
ii. ethyl acetate-pyridine-water, 2:1:2 (upper layer)
iii. acetone-butan-1-ol-water, 7:2:1.

The method of Saeman *et al.*[25] was used for quantitative determination of monosaccharides. Paper electrophoreses were run in 0.1 M borate buffer of pH 10.

Isolation and fractionation of the polysaccharides. Norwegian spruce wood meal (1 000 g, 0.5—2.0 mm) was extracted with acetone and the residue was delignified by the chlorite method at 60° and pH 4.7. The product remaining after delignification was 71.8 % of the acetone-extracted wood. The combined chlorite solutions (30 l) were dialysed against tap water for five days and then concentrated to about 5 l. After acidification with acetic acid the hemicelluloses were precipitated with 20 l ethanol. The precipitate (*A*, Table 1) was washed with aqueous ethanol, ethanol and then ether and dried (yield 94 g, containing 16 % lignin, determined spectrophotometrically [26]). A sample of this material (70 g) was dissolved in water and saturated barium hydroxide solution was added until precipitation was complete. The precipitate was centrifuged, washed, dis-

solved in dilute acetic acid and the polysaccharides were reprecipitated with ethanol and washed. The product was dissolved in water, Fehling's solution was added, the precipitate formed was centrifuged, washed, dissolved in dilute acetic acid, and the polysaccharides (*B*, Table 1) were recovered by precipitation with ethanol (yield 25 g). The centrifugate, after addition of Fehling's solution, was acidified and dialysed, and the polysaccharides were precipitated with ethanol (yield 8 g). This fraction yielded, after hydrolysis, mainly galactose, with smaller amounts of arabinose, xylose and uronic acids.

Partial hydrolysis of B. A sample of *B* (15 g) dissolved in N sulphuric acid (1 000 ml) was heated on the steam bath for 30 min and then was cooled and neutralised with barium hydroxide. Barium sulphate was removed by centrifuging and the solution was shaken with activated carbon (400 g) and then filtered. The aqueous phase contained only monosaccharides and was discarded. The carbon was eluted first with 15 % and then with 50 % aqueous ethanol. The 15 % ethanol eluate contained monosaccharides and lower oligosaccharides. The second eluate contained higher oligosaccharides, which were subjected to further partial hydrolysis; the whole procedure was repeated twice. The 15 % ethanol eluates and the final 50 % ethanol eluate were combined, concentrated and added to the top of a carbon-Celite column (4 × 45 cm). Gradient elution with aqueous ethanol (6 l, 0—20 %) effected a partial separation of the components (Table 2). In addition to the substances listed in Table 2, some higher, unidentified oligosaccharides were observed in fraction 110 and later fractions. Similar fractions from the carbon column were combined giving eleven main fractions. A twelfth fraction was obtained by elution of the column with 50 % ethanol. Most of the main fractions were fractionated further by chromatography on cellulose columns or on thick filter paper. Sometimes a single separation was sufficient, but for some of the mixtures two successive fractionations in different solvent systems were necessary. For some mixture, *e. g.* substances *c* and *d*, electrophoresis on thick filter paper was also used for separation. The purification of *h* from contaminating *g*, was done by carbon column chromatography.

Identification of the oligosaccharides. The oligosaccharides were identified as described above.

Ga $\overset{1}{\underset{\alpha}{\longrightarrow}}\overset{6}{}$ M was compared with an authentic sample, kindly supplied by Professor Roy L. Whistler. The two samples were chromatographically and electrophoretically indistinguishable, gave an undepressed mixed m. p. and also gave identical X-ray powder diagrams. The lattice spacings in Å were: 6.57 (m), 6.33 (s), 5.22 (vs), 5.06 (m), 4.55 (m), 4.42 (vs), 4.28 (m), 4.18 (m), 4.05 (m-s), 3.69 (s), 3.52 (s).

Substance *f*, (G $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M) had a specific rotation +6° (in water). Similar values [5,27,28] and some higher values, +12° and +15° [11,29] have been reported for this substance.

Component *o* on hydrolysis yielded one part of glucose to three parts of mannose. After borohydride reduction and hydrolysis the proportions were one to two. A paper chromatographic and electrophoretic examination of a partial hydrolysate of *o* indicated the presence of G, M, G $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M, M $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M and G $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M. Even though M $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M was not detected, the structure G $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M $\overset{1}{\underset{\beta}{\longrightarrow}}\overset{4}{}$ M appears to be the most probable for this substance.

Acknowledgement. The author is much indebted to Professor Bengt Lindberg for his interest in this investigation.

An Electrophoretic Investigation of the Degradation of β-Casein by Crystalline Rennin

BÖRJE LINDQVIST and TORSTEN STORGÅRDS

The Central Laboratory of Mjölkcentralen, Stockholm, Sweden

An attempt was made to chart the primary course of the degradation of β-casein by crystalline rennet. The degradation follows distinctly different paths depending on the temperature, pH and other factors. Under conditions different from those under which the main experiments were made, the electrophoresis diagram shows that substances with mobilities in the range $u \times 10^5 = 0.5-11.5$ can be formed. In some cases only 2 or 3 of these substances with apparently arbitrary u-values may represent almost all of the degradation product.

In the profusion of degradation products derived from it and in the wide differences in the mobility of these products, β-casein differs considerably from α-casein. NPN formation during the degradation proceeds at only a third of the rate at which it is formed from α-casein and can almost be disregarded.

The enzymatic degradation of β-casein has been studied by Christensen[1], using trypsin, chymotrypsin and plasmin for the proteolysis and following the degradation by viscosimetry and NPN determinations. Lillevik *et al.*[2] have continued these investigations using chymotrypsin and following the degradation by alcohol titration. Peterson *et al.*[3] and Groves *et al.*[4] have studied the more or less stable degradation products that can be isolated after proteolysis. They used trypsin and followed the degradation with free electrophoresis, and pepsin together with paper electrophoresis, respectively.

The present investigation was carried out in order to obtain a picture of the earliest stages of the degradation of the β-casein by rennin as shown by changes in the electrophoretic curves. Some experiments were also made using other proteolytic enzymes under conditions that would produce the maximum variation in the appearance of the electrophoresis curves. The investigation followed more or less the same lines as the corresponding investigation on α-casein described previously (Lindqvist and Storgårds [5]).

METHODS

Preparation of β-casein. β-Casein was prepared according to Hipp *et al.*[6] by fractional precipitation from urea solution. The starting material used for the fractionation was the mother liquor left after precipitation of α-casein from a solution of whole casein.

The progress of the fractional precipitation of the β-casein was followed by electrophoresis and the precipitation procedure was adjusted as required to give a β-casein as free as possible from both α-casein and γ-casein. By adding greater or lesser amounts ammonium sulphate to the solution used to precipitate the β-casein the process can be varied to give the best conditions and only three or four reprecipitations are needed to give pure β-casein. When ammonium sulphate was not added, that is, using the original procedure of Hipp *et al.*, this could not be done nearly as readily.

The β-casein thus obtained was free from fat and other opalescent impurities and also from the proteolytic enzymes present in the milk. After freeze-drying the β-casein was stored in a tightly closed jar containing silica gel as a drying agent.

Two different preparations of β-casein were used in this investigation. One of these contained small amounts of degradation products from the β-casein. The other, much smaller batch was completely pure. The batch used in a certain experiment is indicated on the diagrams and electrophoresis curves given below. The presence of these impurities does not interfere with the evaluation of the results obtained or the conclusions drawn.

Enzymes. Rennin was prepared in a crystalline state as described in the preceding paper[5]. *Pepsin* was crystallised according to Northrop[7] from a commercial preparation with an activity of 1:10 000. *Pancreatin* corresponded to the standards of B.P. 1932. Partially *heatinactivated crystalline rennin* was obtained by the following procedure:

A concentrated solution of crystalline rennin (4 000 Ru/ml) * was mixed with an equal volume of 3 % β-casein solution containing 2 % NaCl and 1/15 M NaH_2PO_4 at pH 6.7. Within a few seconds after mixing 0.2 ml was introduced into 2 ml of the same β-casein solution as above. This 2 ml of solution was already placed in a water bath at the inactivation temperature required (60° or 65°). Through this procedure momentaneous heating of the rennin solution was obtained. After the required inactivation time (5 min to 1 h) the temperature was rapidly reduced by injection of a mixture of cold 3 % β-casein solution (20 ml) having a pH of 5.3. This solution was then kept at a temperature of 17° like the other reaction mixtures. It is at present not clear whether the proteolytic action of the partially inactivated material is due to undestroyed rennin, or whether the rennin contains some heat stable modification or whether some completely different enzyme is present in traces in the rennin crystals. Whatever the case the content as measured by the activity was only about 1 %.

The proteolyses with rennin, pepsin, and pancreatin were carried out in exactly the same way as described for the α-casein investigations. The amounts of acid used to obtain a given pH in the reaction mixtures were, however, different from those used in the previous experiments because of the different buffer capacities of the α- and β-caseins. The amount of acid added varied between 0 and 33 ml of N HCl per 125 ml of buffer solutions. When the buffer was mixed with three volumes of 4 % β-casein in water adjusted to pH 9.0 with NaOH the resultant buffered solutions had a pH between 2.4 and 6.1. In the solutions a loose coagulum was formed instead of the sticky precipitate formed in the α-casein experiments. This made it easier to dissolve the samples for analysis.

Analyses. The analyses were done in the same way as in the previous investigation. The non-protein nitrogen (NPN) was determined on a filtrate obtained after the addition of trichloroacetic acid (TCA) to a concentration of 2 %. Because of the limited amounts of β-casein available the determinations of total N och soluble N had to be restricted in order to allow a full electrophoretic investigation. The electrophoresis were run with phosphate buffer of pH 7.3 and ionic strength 0.1 for 120 min at 12 mA. Standard Spinco cells were used.

The β-casein was broken down quite rapidly compared with the α-casein and as a rule the length of the experiments could be limited to 1 week.

RESULTS

A. The formation of soluble nitrogen. The amount on non-protein nitrogen liberated ($NPN_{2\%TCA}$) was low throughout and in no case was greater then

* Ru = rennin units according to Berridge, see Ref.

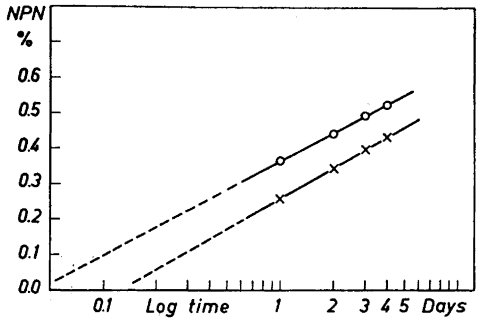

Fig. 1. Formation of NPN from β-casein in proteolysis with rennin. Mean reaction rate for the pH range 2.4—6.10.
O = β-casein containing 5 % of β-casein degradation products
× = pure β-casein

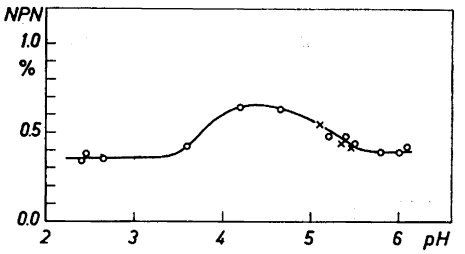

Fig. 2. Amount of NPN released from β-casein by rennin after 4 days at different pH values.

0.7 %. The values obtained showed a greater spread than the corresponding values obtained for α-casein but the tendency was the same — the NPN values plotted against log time gave straight lines starting from about 0.1 days on the time axis. This is shown in the curves in Fig. 1 for the two β-caseins preparations. The curve for the impure preparation showed a parallel displacement upwards caused by the more rapid formation of NPN from the impurities.

The points on the curves are mean values of results obtained in different experiments. Since the NPN formation was relatively independent of the pH, as is shown by Fig. 2, this should be not unreasonable. The pH optimum for NPN formation from β-casein by the action of rennin was the same as for the degradation of α-casein, pH 4.5.

B. Electrophoreses. The first stages of the β-casein degradation proceed very rapidly. It was necessary to take samples about an hour after adding the rennin but in spite of this it was not possible to obtain consecutive pictures demonstrating the details of the degradation. This would require samples to be taken perhaps every 10 min during the first few hours which was not technically feasible.

Fig. 3 gives an indication of the main lines of the degradation. The rule formulated for the degradation of α-casein also applies in this case — the primary cleavage gives only a few simple components with migration rates both higher and lower than that of the parent substance. On of these substances (βb in Fig. 6) had a migration rate of $u \times 10^5 = 0.5$ under the conditions used. Another substance with $u \times 10^5 = 6.8$ (βc) had a very short life and vanished completely within 24 h. A third main component (βa) was broken down fairly rapidly into two new parts (βa_1 and βa_2). One or both of these then underwent further degradation. The rates of degradation were very strongly dependent on the pH.

Table 1. Quantitative analysis of the electrophoresis diagrams shown in Fig. 3. Mean percentage distribution of the components of the reaction mixtures.

pH	βa_1	βa_2	βb	βc	βd	Notes
5.10	37.9	15.4	35.4	27.6	0	The values for βc are for a reaction time of 0.05 days; the values for βb are means for 0.05—4 days less the value for 0 days; other components are given as means for 1—4 days
5.35	42.0	22.5	26.8	30.6	8.6	
5.45	47.3	30.8	21.9	37.3	11.3	

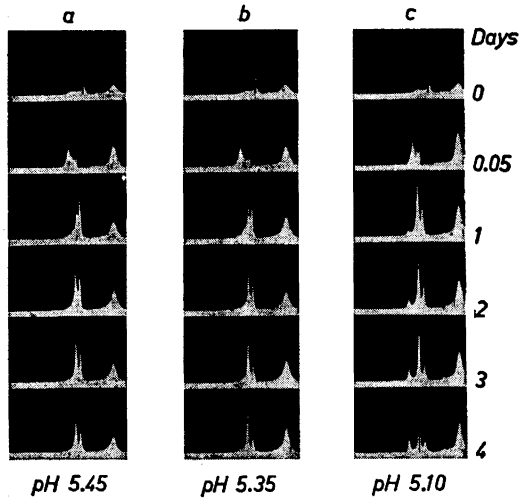

Fig. 3. Electrophoresis curves showing the course of the degradation of β-casein by rennin at three different pH values. The rate of formation and further degradation of the various components can vary widely for pH differences as small as 0.1 units. The purest β-casein was used.

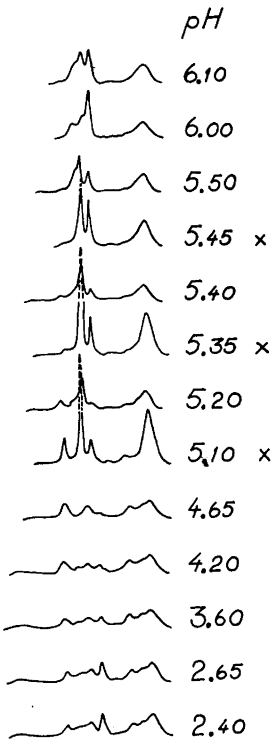

Fig. 4. Electrophoresis curves showing the final result (4 days) of the degradation of β-casein by rennin in the pH range 2.40—6.10. The maximum number of degradation products is shown at pH 4. Degradations using the pure β-casein are marked with ×.

The difficulties of quantitative estimation of the reaction products from the electrophoresis diagrams are considerable and an evaluation was possible in only a limited number of cases. Table 1 gives some measurements made on the components of the mixtures shown in Figs. 3 and 6. The values obtained confirm the subjective impression of the course of the degradation obtained by inspection of Fig. 3.

The final results of degradation varied considerably with the pH. At pH 4 and lower a large number of components are formed; at pH values above 5.4 there were only a few components. This is shown in Fig. 4. There was a certain amount of distortion of the curves when the less pure β-casein was used but this was not so large that it had to be taken into account when comparing the curves.

At pH 4.20 there were about 7—8 components, spread over the mobility range 0.5—11.5. A corresponding large spread of the components of the mixture of degradation products was also obtained at higher pH values when other enzymes were used. This is shown by a number of extreme cases given in Fig. 5. As is clear from this figure the main part of the degradation product may occur at any part of the mobility range and two or more principal components can also occur in apparently arbitrary combinations as shown in Fig. 5 B—G.

DISCUSSION

The tendency of β-casein on enzymatic degradation to give rise to substances with widely varying electrophoretic properties makes much more difficult

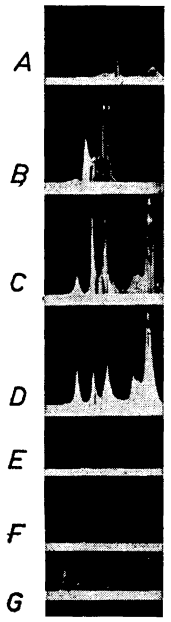

Fig. 5. Degradation of β-casein under different conditions. The electrophoresis curves shown here have been selected to show extreme variations in the distribution of the components.

A. Unaffected β-casein (starting material)
B. Degradation by partially inactivated rennin (heat-treated for 20 min at 65°. Incubated at pH 5.3 and 37° for 8 days)
C. As for B but inactivated for 20 min at 60°
D. As for B but inactivated for 5 min at 65°
E. Degradation by pepsin at pH 5.5 for 11 days at 17°
F. As for E but degradation continued for 18 days
G. Degradation by pancreatin at pH 5.5 for 8 days at 17°

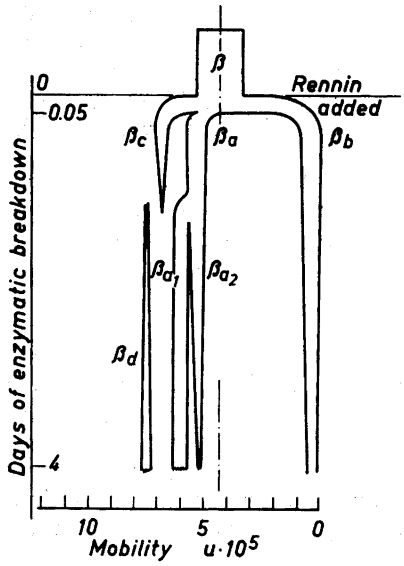

Fig. 6. Diagram of the course of the degradation of β-casein by rennin at pH 5.10 and 17°

the elucidations of the various paths of degradation under different conditions. It is not possible to give any generalised degradation curves covering the whole pH range. Fig. 6 gives a diagrammatic representation of the course of degradation as shown by the electrophoresis curves in Fig. 3 for pH 5.10. Corresponding diagrams are somewhat similar at higher pH values and during the early stages at low pH values.

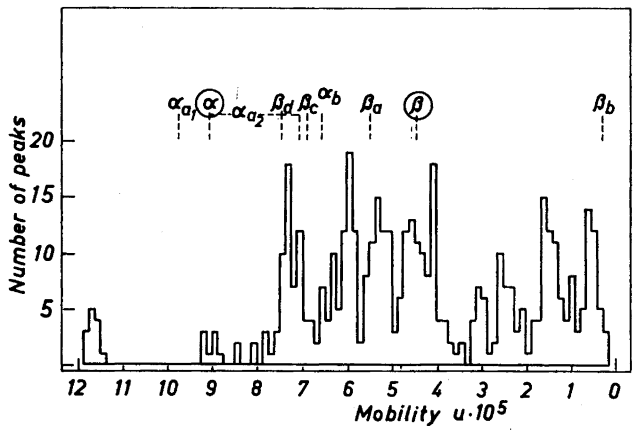

Fig. 7. Frequency of mobilities of approx. 470 peaks measured on electrophoresies from 90 degradation experiments. For comparison the mobilities of β-casein and of the degradation products observed previously för α-casein have also been marked. In this figure as in the preceding, the mobility scale has been placed with the zero point on the right so that the histogram agrees with the electrophoresis curves.

Table 2. The amino acid composition of α- and β-casein [8].

	Amino acid in g/100 g protein	
	α-casein	β-casein
Aspartic acid	8.4	4.9
Alanine	3.7	1.7
Tyrosine	8.1	3.2
Lysine	8.9	6.5
Arginine	4.3	3.4
Valine	6.3	10.2
Methionine	2.5	3.4
Leucine	7.9	11.6
Proline	8.2	16.0
Others	same within 10—15 %	

Fig. 7 gives another picture of the possible paths followed by the degradation in the form of a histogram showing the distribution of 470 peaks of various mobilities that were measured. The β-casein has a mobility in the middle of the mobilities of the group of degradation products. There was a surprisingly high content of substances that migrated very slowly at pH 7.3 and as in the case of α-casein the splitting off of a given substance usually gave a reduction in the mobility.

For comparison the positions of β-casein and its degradation products have been marked on Fig. 7. When a mixture of α- and β-casein is degraded the two sets of components partly overlap which could easily lead to misinterpretations of their origin.

The considerable differences between α- and β-casein in their reaction with proteolytic enzymes depends of course on the amino acid sequence in the two molecules. A comparison between the amino acid sequences of α- and β-casein should therefore give better information on the points of attack of the proteolytic enzymes than in proteolytic experiments with other proteins.

No investigations of this sort have as yet been published. However, a comparison of the amino acid compositions of α- and β-casein shows some points of difference. Some of the most marked of these are shown by the data in Table. 2 (Gordon *et al.*[8]).

Apart from the differences in the amino acid sequences, the major differences between α- and β-casein in potential paths of degradation on enzymatic proteolysis should be due for instance to the low content of aspartic acid and other acidic components and to the high content of proline, leucine, methionine and valine in β-casein.

In the degradation of β-casein as in that of α-casein, the formation of NPN and the cleavage of the β-casein molecule into a few simple parts have no direct connection. The formation of NPN is reasonably independent of pH and other factors but the electrophoresis curve is extremely dependent on the conditions used.

Acknowledgement. The authors wish to express their gratitude to the Scientific Council of Swedish Dairies' Association which made the investigation possible by placing the ultracentrifuge at their disposal.

Short Communications

The Structure of Some Salts of 2:6-Dimethyl-γ-pyrone (2:6-Dimethyl-4H-pyran-4-one)

HÅKON HOPE

Universitetets kjemiske institutt, Blindern-Oslo, Norway

It was first shown by Collie and Tickle [1] that 2:6-dimethyl-γ-pyrone (DMγP) has the property of uniting with various acids to form stable crystalline salts. Since this discovery a considerable amount of work has been done to determine the mechanism of the salt formation (for references see [2]). It is now a widely accepted theory that the proton from the acid is added to the carbonyl oxygen, and that at the same time the pyrone ring acquires an aromatic character. From X-ray data [3] it is known that the free DMγP ring may be described roughly as a system containing two C—C double bonds (C_2-C_3 and C_5-C_6) and two C—C single bonds.

Determination of the crystal structures of some of the DMγP salts will probably give the information which is needed to decide whether these ideas are correct or not. Structure analyses of some of the salts have therefore been started. Up to this time the salts DMγPHBr, DMγPHBr.H_2O, DMγPHBr.$2H_2O$, and DMγPHCl.H_2O have been investigated by X-ray methods.

The salts were prepared by adding dry HBr (HCl) to a solution of DMγP in benzene or ether [4]. The precipitate was collected on a glass filter and dried *in vacuo*. The anhydrous salts were found to be hygroscopic and had to be kept in a desiccator over a drying agent.

Anhydrous DMγPHBr was crystallized by cooling a solution in a mixture of ether and methanol (1:1). The description given by Collie and Tickle [1] is somewhat ambiguous, as the crystals prepared according to their method contain water of crystallization. The crystals are monoclinic, with a marked tendency towards twin formation.

Space group: $P2_1/c$
Cell dimensions: $a = 6.89$ Å; $b = 15.52$ Å;
$c = 15.51$ Å
$\beta = 94.9°$
$Z = 8$ gives $\varrho_{calc} = 1.65$ g/cm³
$\varrho_{obs} = 1.64$ g/cm³

The monohydrate DMγPHBr.H_2O was prepared by exposing anhydrous DMγPHBr to air until one mole of H_2O per mole of the salt had been taken up. It was crystallized in the same manner as the anhydrous salt. The crystals are triclinic plates, also with a tendency to twin formation.

Space group: $P\bar{1}$ (assumed)
Cell dimensions: $a = 7.00$ Å; $b = 8.33$ Å;
$c = 9.47$ Å
$\alpha = 109.9°$; $\beta = 92.9°$;
$\gamma = 106.0°$
$Z = 2$ gives $\varrho_{calc} = 1.50$ g/cm³
$\varrho_{obs} = 1.50$ g/cm³

A Fourier projection along the a axis has been completed, which confirms the assumed space group.

The dihydrate DMγPHBr.$2H_2O$ was prepared by evaporating a solution of the salt in methanol, to which a little water had been added. The crystals are orthorhombic plates. The chloride DMγPHCl.H_2O is isomorphous with the corresponding HBr salt, and was prepared in a similar manner.

More detailed structure determinations of the substances mentioned are under way.

Detailed ESR Spectra of the Free Radicals of FMN and FAD

ANDERS EHRENBERG

Department of Biochemistry, Nobel Medical Institute, Karolinska Institutet, Stockolm, Sweden

In the last years considerable attention has been paid to the properties of flavin radicals because of their possible role in enzymatic activity. Spectrophotometry [1-3] and electron spin resonance, esr, [4,5] have been used for the study of the free and protein bound flavin radicals. In the latter investigations it was not possible to detect any hyperfine structure of the esr spectra. Commoner *et al.*[6] claimed recently that there is a hyperfine splitting that consists of thirteen lines in the flavin radicals. By improved sensitivity and technique it has now been possible to study these spectra in more detail.

FAD and FMN were half reduced by $Na_2S_2O_4$ or Pd-H_2 and studied at room temperature in an X-band spectrometer equipped with a 100 kc field modulation.

The two coenzyme radicals gave identical spectra but the shape of the hyperfine splitting varied with pH as can be seen from Fig. 1. At both pH 0 and 7 the hyperfine spectrum consists of at least 32 symmetrically arranged lines. The spacing between consecutive resolved lines is not constant and varies at pH 0 from 1.3 to 2.1 gauss and at pH 7 from 1.2 to 1.7 gauss. The total splitting between the uttermost observable hyperfine lines increases with the acidity, being 46 gauss at pH 7 and 50 gauss at pH 0. The accompanying colour change from yellow-green to reddishbrown indicates that a proton dissociation is operable with a pK between these values. The attachment of the proton hence seems to influence the distribution of the odd electron in a way so that its absolute spin density is somewhat increased near the nuclei giving rise to the hyperfine splitting. The theoretical calculations available [7,8] suggest that all the four nitrogens in the *iso*alloxazine nucleus has to be accounted for in this interaction, possibly also the two unsubstituted hydrogens of the benzene part [7]. No direct influence can at present be ascribed to the nuclear magnetic moment of the dissociable proton.

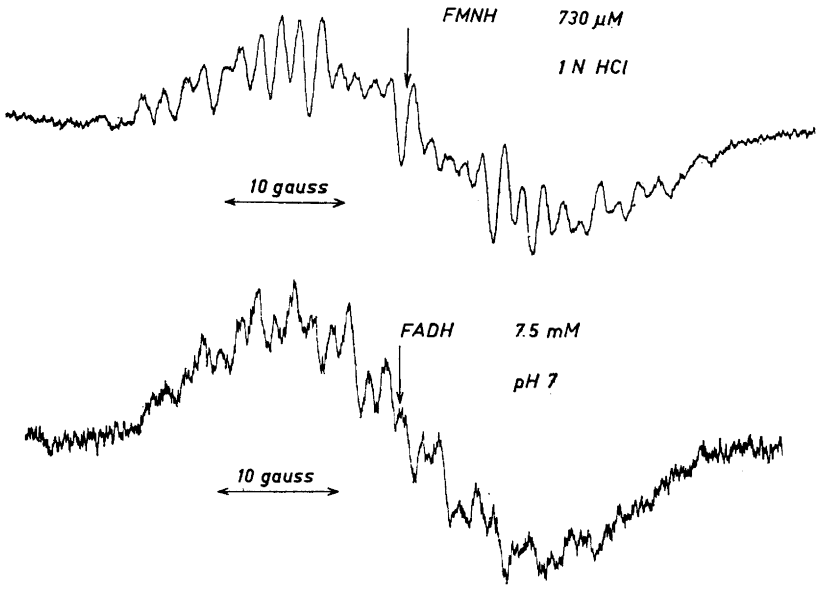

Fig. 1. Derivative records of the esr absorption of the free radicals of FMN at pH 0 (above) and of FAD at pH 7 (below).

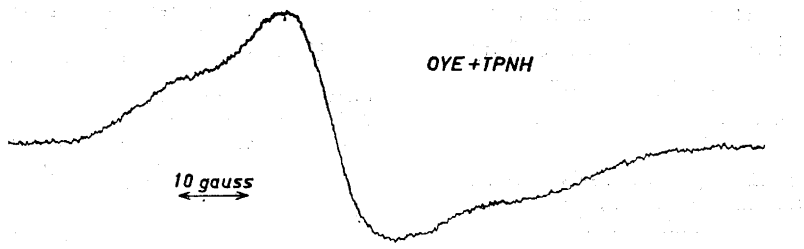

Fig. 2. Derivative record of the esr absorption of the free radicals formed in OYE upon reaction with TPNH.

The hyperfine spectra of Fig. 1 are superposed on broader lines with a width of about 21 gauss between the inflexion points Neither solution contained only radical molecules but were mixtures also containing radical dimers, oxidized and reduced molecules and possibly further complexes of these molecular species. An explanation for the broad underlying absorption might be that the lifetime of the radicals is shortened enough by the dynamic equilibrium established between the solute constituents, in analogy with the explanation forwarded by Ward and Weissman for the equilibrium between naphthalene and its negative ion [9]. The possibility to determine the mean lifetime of the radicals as well as the rate constant of the electron or hydrogen transfer process is now being investigated.

In the previous investigation on old yellow enzyme, OYE, Ehrenberg and Ludwig [4] could not detect any difference between the esr spectra of the FMN free radical and the radical formed in the reaction between OYE and TPNH. In order to achieve enough sensitivity for the detection of the radicals in the latter reaction it was at that time necessary to use a very wide field modulation, that made any search for hyperfine structure impossible, and only the g-values and mean widths of the signals could be compared. With the present technique there is still no hyperfine structure to be seen in the esr absorption of these radicals; see Fig. 2. The spectrum is unsymmetrical and shows only a weak structure consisting of a relatively sharp central peak with broader wings. This observation confirms that the free radicals formed in the reaction between OYE and TPNH really are bound to the protein. The rotational motion of the big protein molecule will be too slow to make the averaging of the anisotropic terms of the interaction between the electron and the magnetic nuclei effective, as it is for the more rapidly tumbling smaller molecules like FMN and FAD. As would be expected the coenzyme radicals give under certain conditions in frozen solutions esr spectra that are rather similar to that of the enzyme radical.

A more detailed report will be published later in this journal.

Über die Addition von Thioglykolsäure an S-Allyl-thioglykolsäure

ERIK LARSSON und BERNDT-OTTO OSBERG

Abteilung für organische Chemie, Chemisches Institut, Universität, Lund, Schweden

Etwa 90 % von allen in der Literatur beschriebenen Additionen von Mercaptoverbindungen RSH an Äthylenverbindungen $R'-CH = CH_2$ verlaufen in Gegenwart von Peroxyden unter Bildung von $R'-CH_2-CH_2-SR$. Dieses gilt für Mercaptoverbindungen wie Alkyl- und Arylmercaptane, Thioglykolsäure, Thioglykolsäureester und Thioessigsäure und für Äthylenverbindungen mit z.B. R' gleich Kohlenwasserstoffreste, CH_3OCH-, $Cl-$, $CN-$, $HOCH_2-$, $CN\cdot CH_2-$, C_2H_5O-, $n-C_4H_9O-$, $n-C_{12}H_{25}-S-CH_2-$, $CHO-$, $HOCO(CH_2)_n-$ mit n = 0, 1, 2, 8.

Wir sind seit einiger Zeit damit beschäftigt, Säuren von der allgemeinen Zusammensetzung $CH_2 = CH(CH_2)_n\cdot S\cdot(CH_2)_m\cdot COOH$ darzustellen und ihr Verhalten gegenüber verschiedenen Mercaptoverbindungen und anderen Addenden zu untersuchen. Im folgenden werden einige Resultate mit S-Allyl-thioglykolsäure und Thioglykolsäure beschrieben. Die S-Allyl-thioglykolsäure wird leicht aus Allylchlorid und Dinatriumthioglykolat in Wasser dargestellt. Sie reagiert nicht mit Thioglykolsäure in Gegenwart von Hydrochinon (ohne Lösungsmittel). Molare Mengen von Thioglykolsäure und S-Allyl-thioglykolsäure ergeben beim Zusatz von etwas Peroxyd (Benzoylperoxyd, Ascaridol) Trimethylen-*bis*-thioglykolsäure. Diese Säure stellt man aber leichter aus Trimethylenbromid und Thioglykolsäure dar [1]. Von präparativem Interesse ist dagegen, dass man aus S-Allyl-thioglykolsäure solche Verbindungen wie

$HOCO\cdot CH_2\cdot S\cdot CH_2\cdot CH_2\cdot CH_2\cdot S\cdot CH_2\cdot CH_2\cdot COOH$ und
$HOCO\cdot CH_2\cdot S\cdot CH_2\cdot CH_2\cdot CH_2\cdot S\cdot R$

darstellen kann, was in einer folgenden Arbeit gezeigt wird.

S-Allyl-thioglykolsäure [2]. 76,5 g (1 Mol) Allylchlorid wurden mit 92,0 g (1 Mol) Thioglykolsäure in 1 Liter 2,0 N Natronlauge geschüttelt, bis die Thioglykolsäure verbraucht war. Das Reaktionsgemisch wurde mit Äther ausgeschüttelt und dann mit Schwefelsäure im Überschuss versetzt. Die erneute Extraktion mit Äther ergab eine Ätherlösung, die bei Destillation 70–80 g (ber. 132 g) S-Allyl-thioglykolsäure vom Sdp 136–138° (15 mm) ergab. (Gef. C 45,7; H 6,1; S 24,4; Äquiv. Gew. 131,4. Ber. C 45,5; H 6,1; S 24,3; Äquiv. Gew. 132,1). d_4^{25} 1,137; n_D^{25} 1,5054; MR_D 34,4 (gef.), 34,4 (ber.).

Trimethylen-bis-thioglykolsäure. 6,6 g (0,05 Mol) S-Allyl-thioglykolsäure und 4,6 g (0,05 Mol) Thioglykolsäure wurden vermischt und mit 0,2 g Ascaridol versetzt. Das Gemisch wurde bei Zimmertemperatur aufbewahrt. Am nächsten Tage war es zu einer festen Krystallmasse erstarrt, die in Essigäther aufgelöst wurde. Mit Benzol wurde aus der Lösung 8,8 g Substanz ausgefällt, die beim Umkrystallisieren aus Essigäther + Petroläther 7,8 g Trimethylen-*bis*-thioglykolsäure vom Schmp. 69,5–70° und Äquiv.-Gew. 112,2 (gef.), 112,1 (ber.) ergab. Mischschmp. mit nach *Rothstein* [2] hergestellter Säure 69,5°. – Um eine gute Ausbeute an Trimethylen-*bis*-thioglykolsäure zu erhalten, muss man eine sorgfältig destillierte S-Allyl-thioglykolsäure verwenden.

Eingegangen am 28. März, 1960.

On the Crystal Structure of a Basic Aluminium Sulfate and the Corresponding Selenate

GEORG JOHANSSON, GEORG LUNDGREN, LARS GUNNAR SILLÉN and RUNE SÖDERQUIST

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, and Research Institute of National Defence, Dept. 4, Solna 8, Sweden

Solutions of aluminium chloride can be hydrolyzed by the addition of about 2.5 equivalents of alkali before a permanent precipitate of aluminium hydroxide is formed. The pH of the solution is then still < 7. Measurements of diffusion and freezing point depression seemed to indicate that such hydrolyzed solutions contain polynuclear complexes which may be built up from about six aluminium atoms [1]. Similar conclusions have been drawn from results of pH-measurements in hydrolyzed aluminium perchlorate solutions [2].

Now, the addition of sulfate ions to aged solutions having an Al:OH ratio of about 1:2.5 results in a precipitation of basic aluminium sulfates [3-5] which, under suitable conditions, can be obtained in a well-crystallized form [6]. Since the atomic arrangement in the crystals might give some information about the polynuclear complexes in the solution, an X-ray investigation on the structure of the crystals was initiated. This paper contains some preliminary results on the compounds

$$Na_2O \cdot 13Al_2O_3 \cdot 8SO_3 \cdot xH_2O \text{ and}$$
$$Na_2O \cdot 13\ Al_2O_3 \cdot 8SeO_3 \cdot xH_2O$$

with x apparently varying between 76 and 68. The sulfate has previously been described by formulae which can be written as "$(Al_2(OH)_5)_2SO_4$" [3,4,6] but the present investigation has shown that alkali metal ions are an essential constituent of the salts.

The crystals were prepared in the following way: An aluminium chloride solution was heated to 80°C and hydrolyzed by adding about 2.5 equivalents of sodium hydroxide. The solution was then kept at 80°C for about 30 min, after which the basic salts could be precipitated by the addition of sodium sulfate or selenate solutions. If the aluminium concentration was low (approximately 0.01—0.1 M) and the sulfate or selenate was added in excess, then the crystallization was slow and tetrahedral crystals, large enough for single crystal X-ray work, were formed after a few days.

For the analyses, crystalline samples dried in air were dissolved in dilute hydrochloric acid. *Aluminium* was determined by precipitation with 8-hydroxyquinoline. *Sodium* was precipitated and weighed as sodium magnesium uranyl acetate. The amount of sodium was also determined independently with a flame spectrophotometer using solutions containing known amounts of sodium, aluminium and sulfate as standards. *Sulfate* was precipitated and weighed as $BaSO_4$ or titrated with standard sodium hydroxide after passing the solution through a hydrogen-saturated cation exchange column. The *selenate* ions were reduced with sulfur dioxide and weighed as Se. In the sulfate compound, the *water* was determined by Hartwig-Bendig's modification of Brush and Penfield's method as described by Kolthoff and Sandell [7] but no independent analysis of the water content was made for the selenate compound.

A test for *chloride* in the crystals was negative (<0.01 %).

The *densities* of the crystals were determined by a flotation method (for the sulfate) and by the displacement of benzene (for the sulfate) or of carbon tetrachloride (for the selenate).

The results of the analysis were as follows:

	$Na_2O \cdot 13Al_2O_3 \cdot 8SO_3 \cdot xH_2O$			$Na_2O \cdot 13Al_2O_3 \cdot 8SeO_3 \cdot xH_2O$		
		$x = 76$	$x = 68$		$x = 76$	$x = 68$
	obs. %	calc. %	calc. %	obs. %	calc. %	calc. %
Al_2O_3:	38.7	39.02	40.75	35.8	35.14	36.53
$SO_3(SeO_3)$:	18.5	18.86	19.69	27.1	26.92	27.99
Na_2O:	1.6	1.82	1.90	1.5	1.64	1.71

	1.97	1.97	1.88	2.11	2.15	2.07 g/ml

The water content of the sulfate crystals has been found to vary. When the crystals were dried in air at 25°C, the analyses (given above) indicated $x = 76$ but, when the crystals were dried, also at 25°C, in a desiccator over silica gel for a week, they gradually lost weight and attained a water content of 37.5 % corresponding to an x-value of 68 at the end of the drying period. Single crystals picked out from both products all gave apparently identical rotation (around [001]) and Weissenberg photographs ($hk0$, $hk1$). The crystal structure should consequently be the same for both products and some of the water molecules in the air-dried crystals must be zeolitic. When standing in moist air, the desiccator-dried product slowly took up water reversibly. The same phenomenon was also observed for the selenate.

When the preparations were dried over silica gel for a long period the water content continued to decrease slowly. After six weeks' drying, it corresponded to $x \approx 52$. However, the crystals broke and became opaque. The lines in the powder photographs were also broadened and indicated the formation of an X-ray amorphous product. This process seems to start in the neighbourhood of $x = 68$.

Crystals were set with [001] and [110] as rotation axes and rotation and Weissenberg photographs ($hk0-hk7$ (sulfate), $hk0-hk8$ (selenate) and $hhl-h,h+6,l$ (selenate)) were taken with CuK radiation. The crystals were found to be cubic with $a = 17.9 \pm 0.1$ Å (sulfate) and $a = 18.0 \pm 0.1$ Å (selenate). There are two formula weights in the unit cell, *i.e.* 4 Na, 52 Al, 16 S(Se) and about 264 to 280 O (as O, OH and H_2O).

Piezo-electric tests on the crystals were positive, indicating that the atomic arrangement lacks a centre of symmetry. This is also suggested by the tetrahedral shape of the crystals.

The crystals were found to be optically isotropic with a refractive index n_D^{20} of 1.495 (sulfate) and 1.514 (selenate).

The Laue symmetry is $m3m$. For the sulfate crystals, the reflections systematically absent are $h00$ with h odd which is characteristic [8] only for the space group No. 208—$P4_232$. Moreover, all reflections with $h + k$, $h + l$, and $k + l$ = odd are weak. For the selenate crystals, these weak reflections could not be detected even on heavily exposed photographs and may be systematically absent. The selenate compound would then belong to one of the space groups No. 209—$F432$, No. 216—$F\bar{4}3m$ or No. 225—$Fm3m$.[8]

Of these, No. 225 is not in accordance with the piezo-electric tests and No. 216 is the only one offering point positions that would allow the aluminium and selenium atoms to be situated in completely occupied, definite point positions.

The Patterson projections along [001] have been calculated and a survey of possible arrangements of AlO_6-octahedra in accordance both with the Patterson projections and the space groups $P4_232$ (for the sulfate) and $F\bar{4}3m$ (for the selenate) has been made. However, using this information alone, the number of possible Al—O— frameworks is quite large. On the other hand, if we assume that the structure contains only one kind of discrete Al—O—OH—H_2O group, which the solution data seem to suggest, the number of possibilities can be reduced considerably. Thus, there are 52 aluminium atoms in the unit cell and the symmetry (pseudo-symmetry for the sulfate) of the atomic arrangement corresponds to a face-centered cubic cell. Since there are at least four crystallographically equivalent groups in an F-centered cell, there are at most $52/4 = 13$ aluminium atoms in each Al—O—OH—H_2O complex in the structure. But, with the assumption made, the number of aluminium atoms per complex ion could not be less than 13 since this is a prime number. The complexes with six aluminium atoms which have been proposed for perchlorate solutions [1,2] do not thus seem to be present in these crystals which, instead, should contain $Al_{13}O_x(OH)_y(H_2O)_z$ groups.

A complete structure determination of one of the compounds thus seemed to be of interest and a determination of the structure of the selenate has been carried out by one of us (G.J.). The results of that investigation confirm our assumption of discrete groups with 13 aluminium atoms. The groups are, however, built up from twelve AlO_6 octahedra and one AlO_4 tetrahedron instead of 13 AlO_6 octahedra as was at first expected. The formula of the complex ions in the crystals seems to be $Al_{13}O_{40}H_{48}^{7+}$ or $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$.

A detailed account of the results of the structure determination of the selenate will be published later [9]. Further studies on the sulfate are in progress (R.S.).

On the Crystal Structures of Some Basic Aluminium Salts

GEORG JOHANSSON

Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, California, U.S.A., Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

An aluminium chloride solution can be hydrolyzed by the addition of about 2.5 equivalents of alkali without the formation of a permanent precipitate of aluminium hydroxide. The addition of a suitable anion to this hydrolyzed solution precipitates basic salts, the structures of which are of a special interest since they might give some information about the polynuclear complexes that seem to exist in hydrolyzed aluminium salt solutions [1,2]. The structures of a number of them are being investigated and preliminary results of some of the structure determinations are given in this paper.

If the aluminium chloride solution is hydrolyzed by sodium hydroxide and sodium selenate is added, tetrahedral crystals can be obtained, which, when dried in air, have the composition $Na_2O{\cdot}13Al_2O_3{\cdot}8SeO_3{\cdot}xH_2O$ (with x in this case equal to about 74, *cf.* Ref.[3]. The crystals are cubic, with a_o = 18.0 Å and with two formula weights in the unit cell. The space group is $T_d^2-F\bar{4}3m$. Three-dimensional intensity data have been collected with Cu$K\alpha$-radiation. The structure has been solved from the tree-dimensional Patterson function and refined by means of three-dimensional Fourier maps *. At the present stage of the refinement the reliability index, R, is 0.11 for the 245 observed reflections, but the positions of the sodium atoms are still uncertain. The parameters are:

* All calculations were carried out on a Burroughs 205 computer at the California Institute of Technology.

Atom	Position	Positional parameters	Atom	Position	Positional parameters
48 Al_1	48(h)	$x = 0.057$	16 Se	16(e)	$x = 0.882$
		$z = 0.328$	48 O_5	48(h)	$x = 0.138$
4 Al_2	4(b)	—			$z = 0.968$
48 O_1	48(h)	$x = 0.047$	16 O_6	16(e)	$x = 0.828$
		$z = 0.677$	16 O_7	16(e)	$x = 0.663$
16 O_2	16(e)	$x = 0.441$	12 O_8	16(e)	$x = 0.190$
48 O_3	48(h)	$x = 0.069$	24 O_9	24(g)	$z = 0.960$
		$z = 0.223$			
48 O_4	48(h)	$x = 0.158$			
		$z = 0.447$			

The structure is built up from discrete aluminium-oxygen groups (Fig. 1) each containing 12 AlO_6 octahedra sharing O_1-O_1 and O_2-O_4 edges, and with an additional aluminium atom in the center of a tetrahedron of O_2 atoms. These large groups, which have the composition $Al_{13}O_{40}$, are not directly connected but are joined to the selenate groups by means of hydrogen bonds between O_3 of an aluminium-oxygen group and O_5 of a SeO_4 group. If the hydrogen atoms are located from the positions of hydrogen bonds and from Pauling's rule for the sum of the electrostatic bond strengths, the formula for the discrete aluminium-oxygen complexes seems to be $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$. The formula for the basic salt now being considered should then be written $Na[Al_{13}O_4(OH)_{24}(H_2O)_{12}](SeO_4)_4 \cdot 13H_2O$. It is interesting to note that both the rings of six AlO_6 octahedra, that can be distinguished in the hydrargillite structure, and the groups of three octahedra which, linked together by common edges and corners, build up the diaspore and boehmite structures, can also be seen in the $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$-groups (Fig. 1).

If the aluminium chloride solution is hydrolyzed with ammonia and ammonium sulfate is added to a high concentration, tetrahedral crystals of another kind can be obtained. They were first described by Bassett and Goodwin [4] who gave them the formula $6(NH_4)_2SO_4 \cdot 11Al_2O_3 \cdot 6SO_3 \cdot xH_2O$ (x = ca 72). The crystals are tetragonal with Laue symmetry $4/m$ and have the same kind of reflections systematically absent as the basic selenate. If a face centered unit cell is chosen the cell dimensions are $a = b = 19.8$ Å and $c = 19.6$ Å as determined from precession and Weissenberg photographs. The density is 1.86 g/cm³. According to these results and the analysis data given by Bassett and Goodwin [4] the following number of atoms should be present in the unit cell: Al: 52 (51.4), S: 28 (27.9), NH_4^+: 28 (28.0). The formula may therefore be written $(NH_4)_7[Al_{13}O_4(OH)_{24}(H_2O)_{12}](SO_4)_7 \cdot xH_2O$. The similarities to the basic selenate seem to be an indication that the same kind of discrete aluminium-oxygen groups are present in both compounds.

A monoclinic basic aluminium sulfate forming plate-like crystals also seems to be built up from the same kind of aluminium-oxygen complexes. It can be obtained from dilute hydrolyzed aluminium chloride solutions by the addition of sodium sulfate (for example from solutions that are about 0.01 M in Al^{3+} and 0.03 M in SO_4^{2-}). The composition is $13Al_2O_3 \cdot 6SO_3 \cdot xH_2O$ (x = ca 79) and the crystals seem to be identical with the compound $13Al_2O_3 \cdot 6SO_3 \cdot xH_2O$ described by Bassett and Goodwin [4]. The space group is C_{2h}^4 or C_s^2, with the intensity distribution favouring the centrosymmetric C_{2h}^4. The unit cell dimensions are: $a = 20.2$ Å, $b = 11.5$ Å, $c = 25.0$ Å, $\beta = 103°$ (symmetry $P2/a$ or Pa) but the crystals can also occur in a form with a unit cell of only half this size, with $a = 14.2$ Å, $b = 11.5$ Å, $c = 17.7$ Å, $\beta = 102.3°$ (symmetry $P2/n$ or Pn). This, however, can spontaneously switch over to the larger unit cell without any noticeable changes in the appearance of the crystal or of the sharpness of the spots on the Weissenberg photographs. Three-dimensional intensity data have been collected with Cu$K\alpha$ radiation from the crystals containing the smaller unit cell. About 3 200 reflections were observed. The three-dimensional Patterson function could be interpreted by assuming two aluminium-oxygen com-

plexes similar to those in the basic selenate to be present in the unit cell according to the symmetry $P2/n$. Three dimensional Fourier maps seem to confirm this assumption and also reveal the positions of four of the sulfate groups in a fourfold position; the remaining two sulfate groups, however, are apparently statistically distributed over two positions close to a center of symmetry in the unit cell. This result in connection with the fact that for some of the zonal data, for example the $h3l$-reflections, the intensity distribution is closer to one expected for a noncentrosymmetric space group seems to indicate the presence of small deviations from a centrosymmetric arrangement. The space group should then be Pn rather than $P2/n$. The refinement of the structure will be continued according to this space group.

The reliability index, R, assuming the space group to be $P2/n$, is at the present stage of the refinement 0.24 for all observed reflections. The parameters for the aluminium atoms in the aluminium-oxygen complexes are:

Atom	Parameters		
	x	y	z

Free Butyric Acid as a Possible Source of Off-Flavour of the Cow's Milk After Administration of Oestrogens

TORLEIV LUNAAS

Department of Sexual Physiology and Sexual Pathology, Veterinary College of Norway, Oslo, Norway

During investigations on the metabolism of oestrogens in the cow undertaken at this department[1] peculiar alterations of the milk after parenteral administration of the hormones were repeatedly observed[2]. To further explore the nature of these alterations 10 mg oestradiol-17β in 5 ml propyleneglycol was injected intramusculary to a non-pregnant cow producing 8 liters milk a day. Daily milk samples were frozen on the day of drawing and analysed in series immediately after thawing.

On the week after injection the milk produced per day gradually decreased to

plexes similar to those in the basic selenate to be present in the unit cell according to the symmetry $P2/n$. Three dimensional Fourier maps seem to confirm this assumption and also reveal the positions of four of the sulfate groups in a fourfold position; the remaining two sulfate groups, however, are apparently statistically distributed over two positions close to a center of symmetry in the unit cell. This result in connection with the fact that for some of the zonal data, for example the $h3l$-reflections, the intensity distribution is closer to one expected for a noncentrosymmetric space group seems to indicate the presence of small deviations from a centrosymmetric arrangement. The space group should then be Pn rather than $P2/n$. The refinement of the structure will be continued according to this space group.

The reliability index, R, assuming the space group to be $P2/n$, is at the present stage of the refinement 0.24 for all observed reflections. The parameters for the aluminium atoms in the aluminium-oxygen complexes are:

Free Butyric Acid as a Possible Source of Off-Flavour of the Cow's Milk After Administration of Oestrogens

TORLEIV LUNAAS

Department of Sexual Physiology and Sexual Pathology, Veterinary College of Norway, Oslo, Norway

During investigations on the metabolism of oestrogens in the cow undertaken at this department[1] peculiar alterations of the milk after parenteral administration of the hormones were repeatedly observed[2]. To further explore the nature of these alterations 10 mg oestradiol-17β in 5 ml propyleneglycol was injected intramusculary to a non-pregnant cow producing 8 liters milk a day. Daily milk samples were frozen on the day of drawing and analysed in series immediately after thawing.

On the week after injection the milk produced per day gradually decreased to

5 liters and showed a strong ability to foam when stirred. The most striking change in the milk was the development of an acrid, nauseous taste.

The following milk constituents were determined: sodium and potassium (flame photometry of trichloroacetic filtrates), calcium and magnesium (flame photometry after resp. oxalate and ammoniumphosphate precipitation), chloride (flame photometry after silver precipitation), lactose (polarimetry), fat (Gerber), citric acid (heating with acetic anhydride and pyridine) and free fatty acids (titration of ether-petroleum ether extracts [3]).

The maximal deviations were found to occur on the third day after injection when sodium had increased to 22 mequiv/l (from 15 mequiv/l), chloride to 42 mequiv/l (from 27 mequiv/l) and potassium decreased to 27 mequiv/l (from 38 mequiv/l) indicating a decreased diluting resp. concentrating ability of the mammary gland. At this time calcium had increased to 63 mequiv/l (from 40 mequiv/l), and fat to 5.5 % (from 3.8 %). A few determinations (biuret method) indicated increased protein content. The other constituents analysed showed minor variations in concentration except the extractable fatty acids which had increased 30-fold (see Table 1).

A sample of the milk drawn on the third day after injection was acidified with concentrated phosphoric acid, extracted 3 times with its equal volume of ether and the extracts titrated. After re-acidification the samples were submitted to gas liquid partition chromatography [4] for identification and titration of volatile fatty acids. In each of the three extracts butyric acid corresponding to about 10 % of the titre of the extracted acids was found and the total amount of butyric acid in the milk sample was roughly estimated to 1 g/l. No other volatile acids could be found.

It was therefore suspected that the butyric acid could be responsible for the off-flavour of the milk. This was substantiated by the strong aggravation of the off-flavour following acidification of the milk with mineral acids and by organoleptic comparison with normal milk to which butyric acid had been added.

Small increments of the free fatty acids were also found in connection with the two following natural heats and after an injection of 10 mg oestrone, but no corresponding off-flavour of the milk was perceptible. Injections of various oestrogens to 8 cows

in high yield (between 1 and 2 months after parturition) did not alter the concentration of free fatty acids of the milk.

It is a clinical experience that cows suffering from cystic ovaries may secrete an off-flavoured milk with a salty and bitter taste [5]. From the above described findings in the milk following parenteral administration of oestrogens and in connection with heat it seems justified to ascribe this milk abnormality to an altered oestrogen status of the cows. The stage of the lactation period seems, however, to be of importance. Milk of this kind, presumably with a high

lipase activity [6], may render large amounts of normal milk inpalatable when admixed prior to processing for consumption.

More systematic investigations are in progress.

The Fatty Acid Composition of Cerebrospinal Fluid Lipids

ROLF BLOMSTRAND

Swedish Medical Research Council, Unit for Biochemical Research Related to Atherosclerosis, University of Lund, Lund, Sweden

The study of the fatty acid composition of the different lipids of human cerebrospinal fluid (CSF) has not previously been possible due to the lack of suitable analytical methods which could be applied to the small amounts of lipid available. The CSF contains only 1–1.5 mg of total lipids [1] per 100 ml and ultramicrochemical techniques have to be applied to normal and abnormal fluids if neurochemical correlations are to be made. Through the use of the technique described below it has been possible to identify the fatty acid pattern of cholesterol esters, glycerides and phospholipids of normal human CSF.

Pooled normal CSF (140 ml) obtained from individuals without neurological symptoms was used for the analysis. The CSF was immediately centrifuged after lumbar puncture, the cell-free supernate was carefully removed and aliquots taken for determination of total protein. The rest of it was kept at −20°C until analyzed. All specimens used had normal white cell count and normal protein concentrations. The pooled CSF was concentrated by dialysis in a collodium bag under reduced pressure according to Mies [2] and extracted with 20 volumes of chloroform:methanol 2:1 and washed with water [3]. The total lipids (1.8 mg) were separated on a silicic acid column [4] (0.2 g) into cholesterol esters, glycerides + free fatty acids and phospholipids. The different lipid fractions were hydrolyzed and the fatty acids were isolated after saponification and acidification. The fatty acid composition was defined by gas-liquid chromatography according to James and Martin [5] using an Argon Pye chromatograph with an ionization chamber as detector. Because of the complexity of the fatty acid pattern, it was necessary to chromatograph the mixed methyl esters on two different stationary phases, a polar polyester (LHC–R–296) [6] and silicone oil. In addition chromatograms were obtained on the mixed esters after complete hydrogenation in order to obtain an accurate chain-length analysis. The analytical procedures used otherwise have been described earlier.[7]

The determination of the fatty acid composition of the different lipid components of human CSF is summarized in Table 1. For comparison the fatty acid composition of the different lipid classes of normal serum is also included in the table. Three characteristic fatty acid patterns are found in the cholesterol esters, glycerides + free fatty acids and phospholipids of human CSF. The fatty acid composition of the CSF resembles the serum lipids, but there are certain differences. Especially remarkable is the very low concentration of linoleic acid in the cholesterol esters of CSF compared with that of the serum cholesterol esters. Another interesting finding is the rather high concentration of palmitoleic acid in the glycerides + free fatty acid fraction and in the cholesterol esters. In the group C_{20-22}? several peaks were found among the phospholipid fatty acids. Significant amounts of a fatty acid with 24 carbon atoms were also found in the phospholipids of the CSF. Work is in progress to identify these fatty

The Preparation and the Kinetics of Solvolysis of Some Derivatives of β,β,β-Trichloroethanol

PENTTI SALOMAA and RAILI LINNANTIE

Department of Chemistry, University of Turku, Turku, Finland

In continuation of earlier investigations on the kinetics of alkoxy-substituted compounds [1-4], a number of compounds of the type $XCH_2OCH_2CCl_3$, where X is a chlorine atom, an alkoxyl group or an acyloxy group, were prepared from β,β,β-trichloroethanol. These compounds were of interest from the kinetic standpoint because they contain three electron-attracting chlorine atoms bound to one carbon atom, which combination was expected to lower greatly the rates of solvolysis (*cf.* Ref.[4]).

Experimental. β,β,β-Trichloroethanol (I) was prepared by reducing chloral according to the directions of Chalmers [5]. Derivatives of this alcohol, which have not been described previously, were synthesized by methods described below. The yields of the pure compounds varied from 30 to 70 %. The compounds and their physical constants are shown in Table 1. The values of the molecular refractivity in the last column were calculated using values of the group refractivities reported by Vogel [6] and the refractivity value 18.078 for three chlorine atoms attached to the same carbon atom. The purities of most of the compounds were also checked by volumetric analysis of formaldehyde liberated on their hydrolysis in 80 % sulphuric acid or, in the case of α-chloromethyl β,β,β-trichloroethyl ether, the formaldehyde and hydrogen chloride formed on hydrolysis of the compound by water, and by determining the molecular weights by cryoscopy in benzene solution. The results of the analyses were in satisfactory agreement with the theoretical values. Thus, for example, the molecular weight determinations of (III) gave the mean value 316 ± 8, whereas the true molecular weight is 311.

α-Chloromethyl β,β,β-trichloroethyl ether (II) was prepared from the trichloroethanol, paraformaldehyde and hydrogen chloride. Although the method of preparation was similar in principle to that employed when preparing other α-chloroethers (for references, see Ref.[1]), poor yields were obtained when the cooled mixture of alcohol and formaldehyde was saturated with hydrogen chloride. The reason for this was that the formal that is produced in a concurrent or intermediate reaction reacts very slowly with hydrogen chloride to form the α-chloroether. In addition, the stream of hydrogen chloride removes from the reaction mixture appreciable amounts of formaldehyde derived from paraformaldehyde evidently owing to the lower solubility of formaldehyde in trichloroethanol than in unsubstituted aliphatic alcohols. The influence of these factors was avoided by saturating the reaction mixture with hydrogen chloride and allowing it to stand about one week at −2°C with intermittent shaking and then resaturating it with hydrogen chloride. The volatilization of formaldehyde was prevented by covering the reaction mixture with concentrated hydrochloric acid before passing hydrogen chloride into the mixture.

Details of a typical synthesis are presented in the following. About 20 ml of concentrated hydrochloric acid was added to form a layer over a mixture of 47 g (0.31 mole) of trichloroethanol and 13 g (0.43 mole) of paraformaldehyde and the whole was cooled in an ice-water mixture and then saturated with hydrogen chloride gas over a period of 5 h. The reaction

Table 1. Boiling points, densities and refractive indexes of the compounds $XCH_2OCH_2CCl_3$.

	X	B.p. °C/mm Hg	d_4^{20}	n_D^{20}	R_D obs.	R_D calc.

(VII)	C_3HCOO	104–106/ 7	1.3784	1.4568	43.74	43.58

mixture was stored eight days at −2°C, during which the phases were mixed from time to time by shaking the flask. After the mixture had again been saturated with hydrogen chloride, the upper layer was removed and the lower layer containing the chloroether dried with anhydrous calcium chloride; the hydrogen chloride was removed with a current of carbon dioxide. The layer was then fractionally distilled under reduced pressure. After about 10 % of the distillate had passed over, the main fraction (about 60 %) distilled at 80−84°C and 24 mm Hg; then the temperature rose abruptly owing to the distillation of formal (III) formed as a side product.

Di-(β,β,β-trichloroethoxy)methane (III) was prepared by two different methods. In the first method, an equimolar mixture of (I) and (II) was kept at a temperature of 50°C for 10 h, during which carbon dioxide was passed through the mixture to expel the hydrogen chloride formed. The crude product was washed with sodium bicarbonate solution and water, dried with anhydrous sodium sulphate, and purified by fractional distillation under reduced pressure. In the second method, (I), formaldehyde (added as paraformaldehyde) and anhydrous zinc chloride in the molar ratio of 2:1:0.1 were allowed to react 24 h at 50−60°C. The formal (III) formed in the reaction was isolated by shaking the reaction product with a mixture containing one volume of water and 5 volumes of petroleum ether. The petroleum ether layer containing the formal was dried with sodium sulphate and distilled under reduced pressure. The former method gave the higher yield (about 60 % of theory) of pure product. An attempt was also made to synthesize the formal (III) by distilling a a mixture of di-*sec.*-propyl formal and trichloroethanol acidified with *p*-toluenesulphonic acid to remove the *sec.*-propanol formed in the reaction, but it was found that the replacement of the second alkyl group of di-*sec.*-propyl formal (the same was the case with di-*n*-propyl formal) by a β,β,β-trichloroethyl group took place so slowly that the method can be employed only to prepare asymmetric formals (see below).

Normal and secondary propyl-β,β,β-trichloroethyl formals, (IV) and (V), were prepared from the respective dipropyl formals and trichloroethanol. Equimolar amounts of the reactants were heated together in the presence of *p*-toluenesulphonic acid and the mixture was subjected to fractional distillation to remove the most volatile component, the propanol. Nearly quantitative yields of (IV) and (V) were obtained. When twice the amount of trichloroethanol relative to the dialkyl formal was employed in the first reaction (to prepare IV), only the asymmetric formal was produced. When an equimolar amount of trichloroethanol was added to (IV) or (V), no reaction was observed to take place when the mixture was heated, although the catalyst concentration was greatly increased, as no propanol distilled over during a period of several hours.

The β,β,β-trichloroethoxymethyl esters of formic and acetic acids, (VI) and (VII), were prepared from the chloroether (II) and anhydrous potassium formate or potassium acetate by a procedure similar to that previously employed to prepare alkoxymethyl esters [2-4].

The method of performing the kinetic measurements was the same as described previously [1].

The intention was to obtain kinetic data for a direct comparison with previously reported data on the solvolysis of alkoxymethyl compounds [4]. It was, however, possible to study only the ethanolysis of chloromethyl β,β,β-trichloroethyl ether (II) in ethanol and a 53.3 wt. % ethanol-dioxan mixture. All the compounds prepared in this work were so sparingly soluble in water that their hydrolysis reactions in this solvent could not be studied by customary methods.

The first-order rate coefficients measured for the ethanolysis of the chloroether (II) and the respective parameters of the Arrhenius equation are the following:

		15°	25°	35°	E (kcal/mole)	log A
Ethanol	10^5k(s^{-1})	6.19	17.6	47.7	18.44	9.77
53.3 wt.% ethanol-dioxan	»	1.56	3.95	9.62	16.43	7.64

A comparison of the values with previous data for α-chloroethers [4], $ROCH_2Cl$, reveals that the rate of ethanolysis diminishes rapidly (by a factor of 12−14 for each

chlorine substitution) in the sequence R = CH_3CH_2-, CH_2ClCH_2-, CCl_3CH_2- owing to a large increase in the activation energy. The activation energies in the ethanolysis of the first two compounds in 53.3 wt.% ethanol-dioxan are, respectively, 11.13 and 13.55 kcal per mole [1,4]. The logarithms of the frequency factor for the three compounds have values varying from 7.04 to 7.66 and hence the entropies of activation differ only insignificantly. The structural effects are thus consistent with the unimolecular carbonium ion mechanism of ethanolysis.

On the basis of the data presented it is possible to estimate the effect of the β,β,β-trichloroethyl group on the hydrolysis mechanism of the corresponding alkoxymethyl esters in dilute acid solutions. The polar substituent constant $\bar{\sigma}$ *, as defined in Ref.[4], for this group is + 2.87. From this value it can be estimated that the rate coefficient for the hydrolysis of β,β,β-trichloroethoxymethyl acetate (VII) by the unimolecular $A_{AL}1$ mechanism in dilute aqueous acid at 25°C should be about 7×10^{-7} l mole^{-1}s^{-1}. As this latter value is of a much lower order of magnitude than the rate coefficients relating to the normal type of acid-catalysed hydrolysis reactions of alkyl acetates (about 10^{-4} l mole^{-1}s^{-1}), *i.e.* reactions taking place by the bimolecular $A_{AC}2$ mechanism, it can be assumed that also the ester (VII) hydrolyses almost exclusively by the latter mechanism. In the case of the corresponding formate, (VI), the conditions for the unimolecular hydrolysis mechanism are even less favourable.

The Effect of Acetone Treatment on Vitamin A_1-Aldehyde Extracts from Herring Roe

OLAF R. BRÆKKAN, HAKON MYKLESTAD and LEIF REIN NJAA

Governmental Vitamin Laboratory, Norwegian Fisheries Research Institute, Bergen, Norway

Plack *et al.*[1] have demonstrated the presence of vitamin A_1 aldehyde in herring ova *(Clupea harengus)* and some other marine teleosts. They investigated several extraction methods, but found that extraction of the eggs with light petroleum followed by addition of ethanol to the blended mixture gave the best results. Pollard and Bieri [2] confirmed some of these findings, but reported that all their samples of herring roe contained only vitamin A_2 aldehyde. They extracted the ova several times with ethanol and isolated the vitamins by hexane extraction of the alcohol extracts.

During studies of the occurrence of vitamin A aldehydes in fish in our laboratory, we applied both the proposed extraction methods on the herring roe *(Clupea harengus)*, and found only vitamin A_1 aldehyde to be present. We were further only able to demonstrate the presence of vitamin A alcohol in these extracts but not the ester. Plack *et al.*[1] estimated the vitamin concentrations by the Carr-Price test, and reported for herring ova 2.4—5.7 μg vitamin A_1 aldehyde per g and 0.3—0.9 μg vitamin A_1 ester and alcohol per g. We have carried out the estimations by spectrophotometric measurements in the ultraviolet and found only 1 μg vitamin A_1 aldehyde and 0.3 μg vitamin A_1 alcohol per g herring roe. The absorption curves of the fractions were plotted, thus establishing the identity of the compounds.

Plack *et al.*[1] studied the effect of acetone treatment of the light-petroleum extracts. They found in liver storage tests in rats that only the acetone-soluble fraction contained biological activity, while the acetone-insoluble fraction showed no activity. In repeated experiments they could only recover about 40 % of the activity originally present in the extracts. This suggested a further investigation of the soluble portion, and the present communication reports some of the findings.

chlorine substitution) in the sequence R = CH_3CH_2-, CH_2ClCH_2-, CCl_3CH_2- owing to a large increase in the activation energy. Plack *et al.*[1] estimated the vitamin concentrations by the Carr-Price test, and reported for herring ova 2.4—5.7 μg vitamin A_1 aldehyde per g and 0.3—0.9 μg vitamin A_1 ester and alcohol per g. We have carried out the estimations by spectrophotometric measurements in the ultraviolet and found only 1 μg vitamin A_1 aldehyde and 0.3 μg vitamin A_1 alcohol per g herring roe. The absorption curves of the fractions were plotted, thus establishing the identity of the compounds.

Plack *et al.*[1] studied the effect of acetone treatment of the light-petroleum extracts. They found in liver storage tests in rats that only the acetone-soluble fraction contained biological activity, while the acetone-insoluble fraction showed no activity. In repeated experiments they could only recover about 40 % of the activity originally present in the extracts. This suggested a further investigation of the soluble portion, and the present communication reports some of the findings.

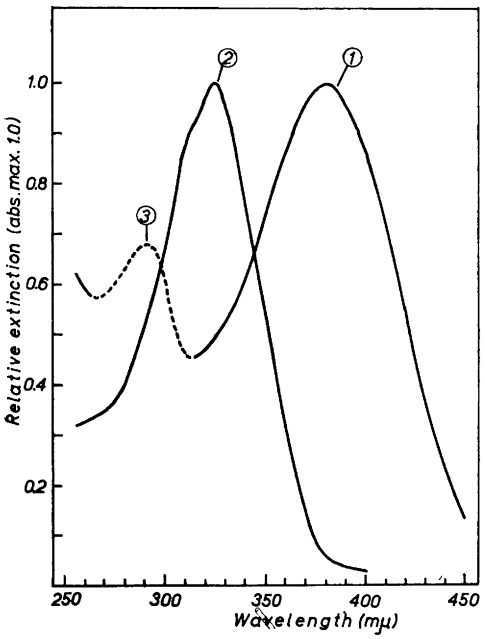

Fig. 1. Absorption curves of vitamin A_1-aldehyde extracted from herring ova (1), and its reduction product vitamin A_1 (2). The dotted band (3) is caused by the presence of α-tocopherol.

Extracts obtained by both the reported methods [1,2] were evaporated to dryness under reduced pressure. The residues were extracted with acetone as described by Plack *et al.*[1] or with the following modification: The residue was dissolved by heating with acetone, and then cooled by partial evaporation in vacuum, whereby a precipitate formed which was insoluble at room temperature. This precipitate was washed several times with cold acetone. The acetone extracts were combined and evaporated to dryness, dissolved in hexane and chromatographed on a soft Al_2O_3-column. The elution was carried out with 2 % (v/v) ethyl ether in hexane. As the aldehyde band approached the end of the column, 10 ml fractions were collected. These fractions were evaporated to dryness, dissolved in ethanol and measured in a Beckman DU spectrophotometer. The "aldehyde" fractions showed absorption curves with maxima between 390—400 mμ. The later fractions had absorption maxima at the highest wavelengths. By the normal procedure (without acetone treatment of the residue), a curve with absorption maximum at 380 mμ, corresponding to vitamin A_1-aldehyde, was observed. Unfortunately vitamin A_1-aldehyde and α-tocopherol present in the extracts move together on this type of column. Thus a band corresponding to α-tocopherol may be observed on the "aldehyde" absorption curves (Fig. 1).

When the different alcohol-solutions were reduced with sodium borohydride [1], the absorption maxima were shifted towards lower wavelengths. The reduction products were readily freed from α-tocopherol by chromatography on soft Al_2O_3. It may be mentioned that the reduction procedure employed did not influence the absorption maximum of α-tocopherol. Vitamin A_1 aldehyde gave a compound with absorption maximum at 325 mμ (vitamin A_1). For all the acetone treated extracts reduction resulted in compounds with absorption maxima at 340—360 mμ. Again the later frac-

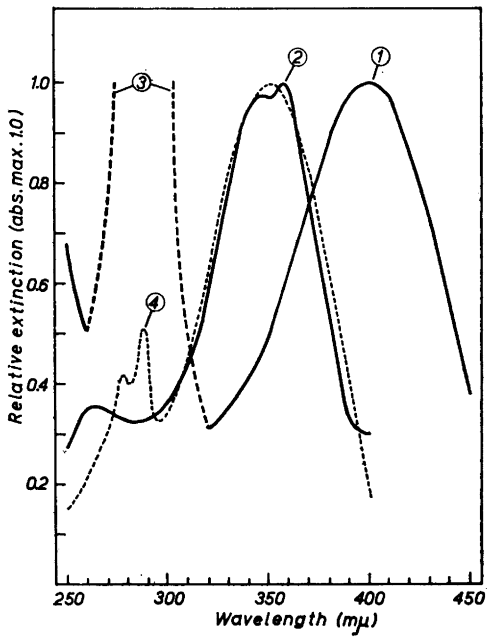

Fig. 2. Absorption curves of compound(s) isolated from acetone treated extracts from herring ova (1), and its reduction product(s) (2). The dotted band (3) is caused by the presence of α-tocopherol. For comparison is plotted vitamin A_2 after Lambertsen & Brækkan[10] (4).

tions showed absorption maxima at the higher wavelengths. A comparison of the fractions indicated the presence of a mixture of two compounds with similar chromatographic properties on the column used. The spectrophotometric data are summarized in Figs. 1 and 2.

The spectrophotometric properties of the fractions obtained were very similar to those reported for oxidation-products obtained by the Oppenauer reaction in the presence of acetone or diethyl ketone [3-5]. Apparently the compounds observed by us are axerophthylidene-acetone [3] and the so-called "C_{20}-aldehyde" [4,5], and their reduction products. In Table 1 are summarized data reported in the literature on the spectrophotometric properties of these compounds in ethanol and their reaction products with $SbCl_3$ in chloroform. The absorption maxima obtained for our compounds (Fig. 2) agree generally well with those reported in the literature, thus indicating the presence of both axerophthylidene-acetone and the C_{20}-aldehyde in our reaction. The possibility, however, of the presence of isomers of only one compound cannot be overlooked.

The treatment with acetone of pure vitamin A_1-aldehyde prepared from vitamin A_1-alcohol [1] caused no change in the retinine$_1$-molecule as judged by the U.V.-absorption curve. This is in agreement with the findings of Plack *et al.*[1]. When, however, vitamin A_1 aldehyde in concentrations equal to those present in herring roe was added to the acetone-treated residue, from which all retinine-like compounds had been removed, storage at room temperature over night resulted in it being transformed to a compound, with absorption maximum at 395 mμ. Reduction of this compound resulted in a substance with absorption maximum at 342 mμ. It thus seems that substances present in the hexane extracts from herring roe, but insoluble in acetone, are necessary for the reactions to take place which result in the formation of axerophthylidene-acetone and the C_{20}-aldehyde.

The absorption maxima for the reduction products, 340—360 mμ, suggested the presence of vitamin A_2 as one of these compounds. Haworth *et al.*[4] thus proposed a reduction of the C_{20}-aldehyde to an alcohol with a formula corresponding to the one at present accepted for vitamin A_2 [8]. Cama *et al.*[7] have discussed this possibility and pointed out that hydrogenation of the β-ionone ring in the second stage of the Oppenauer oxidation seems improbable. They discussed the possible structure for the C_{20}-compound, and suggested as one of the possibilities a *cis*-isomer of vitamin A_2 aldehyde. A reduction of this compound would result in an isomer of vitamin A_2. In this connection it should be born in mind that Haworth *et al.*[4] found the C_{20}-aldehyde to be biologically active, and Plack *et al.*[1] found approx. 40 % of the original activity of the hexane extracts in the acetone-soluble fraction, and no activity in the residue. The lack of the typical absorption maxima at 277 and 286 mμ [9,10]

weighed against the possibility of the presence of vitamin A_2 after reduction of our acetone extracts. The absorption maximum for the $SbCl_3$-reaction was at 700–720 mμ, compared with 693 mμ for vitamin A_2. We may, however, emphasize that very little is known with regard to all the possible isomers of vitamin A_2 and their spectrophotometric properties. The $SbCl_3$ colour of our "aldehyde"-fraction had a maximum slightly higher than that of the reduced compound.

The present investigation has thus confirmed the findings of Plack *et al.*[1] with regard to the presence of vitamin A_1 aldehyde in herring roe. We could not find vitamin A_2 aldehyde as reported by Pollard and Bieri [2]. The effect of the acetone treatment on vitamin A_1 aldehyde when the acetone-insoluble fraction of hexane extracts of herring roe was present, establishes a case where a natural product catalyses or takes part in the reaction between vitamin A_1 aldehyde and ketone-bodies. The reactions reported, when seen in relation to the chemical studies recorded [3-5], suggest as a possible pathway for the formation *in vivo* of vitamin A_2, that it is derived from vitamin A_1 *via* the retinenes.

Crystal Data of Nickel(II) dithiosemicarbazide-Sulphate

RITA GRØNBÆK and SVEND ERIK RASMUSSEN*

Chemistry Department A. Technical University of Denmark, Copenhagen, Denmark

K. A. Jensen [1] has described two forms of nickel(II)dithiosemicarbazide sulphate $(Ni(ThiO)_2SO_4$ which he proposed to be *cis-trans* isomers.

As very few examples of stereoismerism of nickel complexes have been definitely proved we have started an X-ray investigation in order to establish the complete structures of the two forms.

The *a* form crystallizes from water when mixing cold aqueous solutions of nickel sulphate and thiosemicarbazide. The product contains water of crystallization and the chemical analysis is consistent with the formula: $Ni(ThiO)_2SO_4$, 3 H_2O. The water is removed by heating the product to 110°C and is slowly taken up again at room temperature.

Oscillation, rotation and Weissenberg diagrams were taken of crystals of $Ni(ThiO)_2SO_4$, 3 H_2O using Cu-radiation.

The crystals are monoclinic with the following dimensions of the unit cell, unique axis b:

$$a = 6.91 \text{ Å}$$
$$b = 16.41 \text{ Å}$$
$$c = 6.32 \text{ Å}$$
$$\beta = 97°.7$$

The density of the crystal is approximately 1.84. Consequently there are two units of $Ni(ThiO)_2SO_4$, $3H_2O$ per unit cell.

The only systematic extinctions are $h\,k\,0$ when k is odd. The possible space groups are $P2_1/m$ and $P2_1$. A Patterson projektion $P(u, v)$ showed a large concentration of peaks at $v = \frac{1}{2}$. No other line exhibited extraordinary concentrations of peaks. Hence the space group $P2_1$ is established.

The β form is precipitated from hot aqueous solutions of nickel sulphate and thiosemicarbazide. It contains no water of crystallization. Its powder diagram is different from that of the *a* form. It was

Preliminary Note on the Configuration at C_{22} of *Solanum* Alkaloids

PER M. BOLL

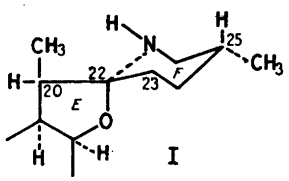
Royal Danish School of Pharmacy, Chemical Laboratory B, Copenhagen, Denmark

Tomatidine and 5α-solasodanol-(3β) are generally believed to represent two types of *Solanum* alkaloids (aminoketal alkaloids) related to each other in the same manner as the "neo" and "iso" steroid sapogenins, *i. e.* they differ in configuration at C_{25} by having an axial C_{25}-methyl group (structure II) and an equatorial C_{25}-methyl group (structure I), respectively.

Recently, Schreiber [1] and later Toldy [2] have suggested, however, that the two compounds differ in configuration at C_{22}. According to their formulation, tomatidine is a 22β-compound (structure III) and 5α-solasodanol-(3β) a 22α-compound (structure I). This difference in configuration at C_{22} will cause the methyl groups at C_{25} in both compounds to be equatorial.

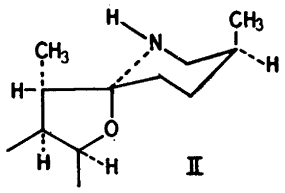
The work submitted in this preliminary note supports the idea that tomatidine and 5α-solasodanol-(3β) in fact differ in configuration at C_{22}. It was found that tomatidine forms an N-bromo as well as an N-chloro derivative, whereas 5α-solasodanol-(3β) only forms an N-chloro derivative.

With the object of estimating the space requirements for binding a halogen atom to the nitrogen atom of ring F the hydrogen:halogen separation distances were measured on Dreiding molecular models. These measurements indicate that the distance between the N-halogen atom and two of the hydrogen atoms of the C_{20}-methyl group in structure I is 2.4 Å. In



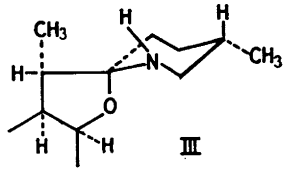
I

22α-iso



II

22α-neo



III

22β-iso

structure III the distance between the N-halogen and the hydrogen atom at C_{20} is 2.6 Å.

Assigning a van der Waals radius of 1.0 Å to hydrogen and radii of chlorine and bromine of 1.8 Å and 1.95 Å, respectively, the distances H ⟷ Cl and H ⟷ Br can be estimated to 2.8 Å and 2.95 Å, respectively. Although the measured distances H ⟷ Hlg in structure I and III only are 2.4 Å and 2.6 Å, respectively, one can easily see, remembering the experimental facts, that the difference in the measured distances is of an order of magnitude allowing the formation of an N-chloro derivative, but not the formation of an N-bromo derivative in the case of 5α-solasodanol-(3β). Furthermore, small distortions of the bond angles in rings E and F may increase the H ⟷ Hlg separation distances to values estimated using the van der Waals radii. Such distortions of bond angles are quite common [3].

Furthermore, small distortions of the bond angles in rings E and F may increase the H ⟷ Hlg separation distances to values estimated using the van der Waals radii. Such distortions of bond angles are quite common [3].

Table 1. Halogen derivatives of *Solanum* alkaloids.

Derivative	Halogen content * Calc.	Found	M. p., °C **	$[\alpha]_D^{24}$ ($CHCl_3$)
N-Chlorosolasodine	7.92	7.89	153	−114°
N-Chloro-5α-solasodanol-(3β)	7.89	7.97	183	− 59°
N-Chlorotomatidine	7.89	8.06	175	+ 35°
N-Bromotomatidine	16.17	16.18	208 ***	+ 51 ***

* The halogen content determined by iodometric titration.

** The m. p. reported are corrected. All four compounds melt under decomposition.

*** Toldy reports the m. p. 202–205°C and $[\alpha]_D^{20}$ −8.6 (dimethylformamide). However, N-bromotomatidine is quite unstable and decomposes to tomatidine hydrobromide ($[\alpha]_D^{24}$ −8.0 (CH_3OH)).

Fieser and Fieser [4] have suggested that 22β-steroid sapogenins are destabilized by steric interference between the two hydrogens at C_{22} and the hydrogens of the C_{20}-methyl group, these being only 1.8 Å apart. However, similar model considerations by the present author on a 22β-steroid sapogenin and a 22β-aminoketal alkaloid indicate that the above mentioned hydrogens are in fact 2.0 Å apart. This last distance is a permissable hydrogen:hydrogen separation distance.

Further details of this work will be submitted shortly.

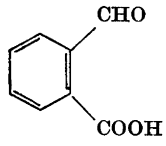
Structure of the *o*-Formylbenzoate Ion

ERLING BERNATEK

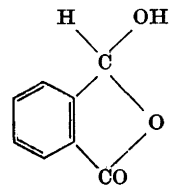
Universitetets Kjemiske Institutt, Blindern, Oslo, Norway

Phthalaldehydic acid exists in aqueous solutions as 3-hydroxyphthalide. This formula has an asymmetric carbon atom, but the acid is not optically resolvable by means of alkaloid salts since its anion only exists in the open (*o*-formylbenzoate) form where no asymmetry occurs. Infra-red absorption shows that this is the case in solid salts as well as in aqueous solution.

Phthalaldehydic acid (*o*-formylbenzoic acid) has been represented as having both an aldehyde group and a carboxyl group (I), but also the ring-tautomeric hydroxyphthalide form (II) has been considered.



I



II

Grove and Willis [2] using infra-red absorption spectroscopy concluded that phthalaldehydic acid in the solid state existed exclusively in the cyclic lactol form (II). This was inferred from the single C=O absorption band at 1 738 cm^{-1}, which is much closer to the five-ring lactone frequency of phthalide (1 750 cm^{-1}) than to the aromatic carboxylic acid (1 690 cm^{-1}) frequency of benzoic acid, and from the characteristic alcoholic OH absorption at 3 250 cm^{-1}. Some years later Wheeler, Young and Erley [3] reexamined phthalaldehydic acid and a long series of its functional derivatives. One of their main findings was that the cyclic lactol structure persisted also in aqueous solution. A water solution spectrum clearly indicated the presence of a lactol carbonyl absorption at 1 748 cm^{-1} and the antisymmetric C—O—C stretch of the ring was observed at about 1 090 cm^{-1}. Derivatives were prepared with alcohols, thiols, primary and secondary amines, acid amides, acid anhydrides, urea

and substituted ureas and carbamates. All of these substances existed in the solid state as phthalide derivatives. Esters of phthalaldehydic acid are of two types, normal and *pseudo*-esters (cyclic). These are readily distinguished by chemical methods, *e.g.*, the normal esters undergo a facile reaction with carbonyl reagents, a reaction which is absent in the *pseudo*-esters. Grove and Willis [2] investigated the infra-red absorption of the liquid normal methyl ester and the *pseudo*-ester (m.p. 46—47°) and could corroborate the chemical evidence.

From the cyclic formula (II) is seen that the carbon atom to which the hydroxyl group is linked is asymmetric. The question therefore arises whether a compound of this type is resolvable and in that case if the enantiomers have any degree of optical stability. Preliminary experiments were carried out where the strychnine and brucine salts of phthalaldehydic acid were subjected to fractional crystallisation. The salts were decomposed cautiously with mineral acid and the organic acid isolated, but in no case could any optical activity be observed. This negative result could have one or several causes. The active bases could have been ill-chosen if the diastereomers formed were of similar solubility, the acid itself or the *o*-formylbenzoate ion could have no optical stability, or the mentioned ion could exist entirely in the open non-cyclic form where the asymmetry of the carbon atom would disappear. To test the latter possibility solid state spectra of the strychnine and brucine salts were recorded. A main characteristic of these spectra was that no absorption band occurred between 1 700 and 1 800 cm^{-1}. This fact alone is decisive in ruling out a cyclic form of the *o*-formylbenzoate ion in the solid alkaloid salts. At 1 682 and 1 676 cm^{-1} strong carbonyl absorptions occurred, most likely due to the lactam grouping in strychnine and brucine, respectively. A shoulder on the latter absorption band at 1 690 cm^{-1} is probably due to the free aldehyde group in the *o*-formylbenzoate ion. Carboxylate ion absorption was observed at 1 575 and 1 555 cm^{-1}, but the other expected bands between 1 300 and 1 400 cm^{-1} could not be identified due to several skeletal vibrations in this region.

As a consequence of these observations it became desirable to investigate the infra-red absorption of aqueous solutions of phthalaldehydic acid at different pH (see Fig. 1).

In the spectrum of the free acid (A) is seen the ring carbonyl absorption at 1 756 cm^{-1} (Wheeler *et al.*[3] reported, as mentioned before, the value 1 748 cm^{-1}. Evidently due to less accurate matching of their cell pair this band occurred only as a minor excrescence on a broad water-absorption band. From curve A it is evident that the matching in our case is very good. Further the spectrometer was calibrated in connection with this work and we therefore place more faith in the higher value). At 1 082 cm^{-1} is observed a band, which is due to the C—O—C antisymmetric stretch of the ring. In this region, however, the cell material (calcium fluoride) begins to absorb strongly and the sensitivity of the apparatus is therefore somewhat diminished. In the curve B where the acid is half-way neutralised with sodium hydroxide the ring carbonyl and C—O—C stretch frequencies are still observed, but in addition there has emerged two conspicious bands at 1 565 and 1 392 cm^{-1} characteristic for the carboxylate ion. At about 1 695 cm^{-1} there is a smaller peak probably due to a free aldehyde group, but here the sensitivity of the spectrometer is

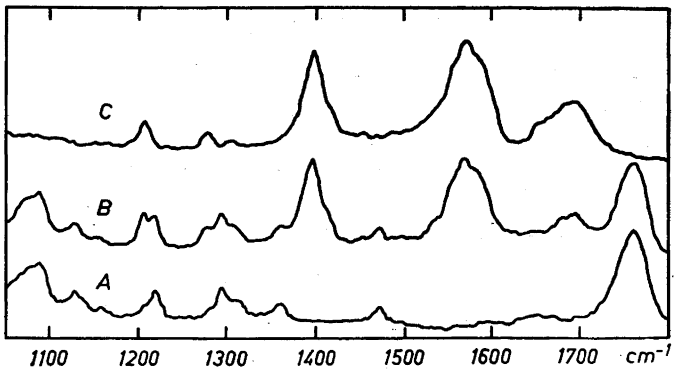


Fig. 1. Infra-red absorption in water of
A: Phthalaldehydic acid
B: Phthalaldehydic acid + half an equivalent of sodium hydroxide
C: Fully neutralised phthalaldehydic acid.

diminished due to strong water absorption. The fully neutralised acid (C) shows no ring carbonyl or ring C—O—C stretch frequencies, while the carboxylate ion and aldehyde group bands are conspicious. It must therefore be concluded that salts of phthalaldehydic acid in the solid state as well as in solution exist in the open form and hence no optical resolution of the acid can be effected through diastereomeric salts.

Phthalaldehydic acid undergoes the Cannizzaro reaction [4], reduces ammoniacal silver solution and forms an oxime. This has been taken as an indication that phthalaldehydic acid has some of the properties which would be expected of the open form [3]. From the present experiments it is clear that the two former reactions deal with the non-cyclic *o*-formylbenzoate ion and throw therefore no light on the structure of the acid itself. Oxime formation can take place in alkaline solution as is by now to be expected (see exptl. part), but also under the slightly acid conditions obtained where phthalaldehydic acid and hydroxylamine hydrochloride are dissolved in water. This may mean that in aqueous solution the acid exists as an equilibrium between the open and the cyclic form, strongly displaced towards the cyclic form. Very small amounts of the open form cannot be detected in the spectra due to the slight solubility of phthalaldehydic acid in water. The solid-state spectrum of the oxime has been recorded and it clearly indicates an open form of the derivative *viz.* benzaldoxime-*o*-carboxylic acid. No ring carbonyl band is observed between 1 700 and 1 800 cm^{-1} and in the region 1 000—1 100 cm^{-1} only one minor band is found, the intensity being far too low for an antisymmetric C—O—C ring stretch band. Carboxyl C=O absorption is found at 1 679 cm^{-1}, which is in the lower part of the region for aryl conjugated acids. There may exist a weak chelation between the carboxyl group and the oxime moiety, but at higher temperatures there must be stronger interaction as the oxime at 100° gradually loses water and is transformed into phthalimide probably through 2,3,1-benzoxaz-1-one and *o*-cyanobenzoic acid [5].

EXPERIMENTAL

Phthalaldehydic acid was prepared by oxidation of naphthalene and recrystallised from water. M. p. 99°.

Strychnine and brucine salts. These salts were prepared in the usual way by heating an aqueous solution of phthalaldehydic acid with an equimolecular amount of the finely ground alkaloid until a clear solution remained. The salts which separated from the filtered solution on cooling were subjected to repeated fractional crystallisations from water.

Phthalaldehydic acid oxime. Phthalaldehydic acid (1.5 g) was dissolved in aqueous sodium carbonate and hydroxylamine hydrochloride (0.7 g) added. The solution was left for 2 h and acidified with hydrochloric acid whereupon the oxime separated immediately (1.4 g). Recrystallised from water. M. p. ca. 125° (rapid increase of temperature).

Infra-red spectra. The spectrometer was a Perkin-Elmer double beam apparatus (Model 21).

Solid compounds were first dried *in vacuo* over phosphorus pentoxide, and the spectra were obtained in Nujol mulls between rock-salt plates. Spectra of the aqueous solutions were obtained in a matched pair of calcium fluoride cells (0.025 mm) compensated with water.

The solutions whose infra-red absorption is recorded in Fig. 1 were made up as follows:
A: 15 mg (0.1 mmole) phthalaldehydic acid per ml of water.
B: 30 mg (0.2 mmole) acid and 4 mg sodium hydroxide (0.1 m equiv.) per ml of water.
C: 15 mg (0.1 mmole) acid and 4 mg sodium hydroxide (0.1 m equiv.) per ml of water.

The author's thanks are due to mag. scient. Else Augdahl for the determination of the infra-red spectra.

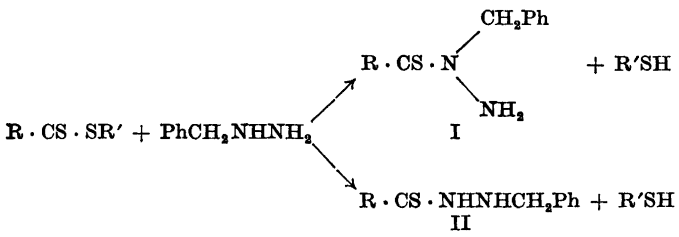
Reactions between Benzylhydrazine and Dithioesters

BJÖRN FORSGREN and JAN SANDSTRÖM

Department of Organic Chemistry, University of Lund, Lund, Sweden

The formation of pairs of isomeric thiohydrazides in reactions between benzylhydrazine and four different dithiocarboxylic esters has been investigated. The neutral isomers give thiohydrazones, and the acidic isomers thiadiazolines, in reactions with benzaldehyde. pK_a-values for the acidic thiohydrazides in aqueous ethanol are given. Separation of pairs of isomers by paper chromatography is described.

In the course of a current investigation of heterocyclic compounds derived from thiocarbohydrazide, it was considered desirable to prepare methyl 2-benzyldithiocarbazate (Ia). The reaction between benzylhydrazine and dimethyl trithiocarbonate was expected to provide a suitable route. However, the reaction product was found to consist of a mixture of only 20 % of the desired compound and 80 % of the 3-isomer (IIa).



a, R=CH_3S; b, R=Ph; c, R=CH_3O; d, R=$PhCH_2O$.

This result at first seemed somewhat surprising, since monosubstituted aliphatic hydrazines, and also benzylhydrazine, react with cyanic acid [1,2] and thiocyanic acid [3,4] and with their *iso*esters [2,5] as if the —NH-group were more nucleophilic than the NH_2-group, *i.e.* the products are 2-substituted semicarbazides and thiosemicarbazides. As has been pointed out by Greer and Smith [6], this is explained by the electron-donating properties of the alkyl group.

On the other hand, arylhydrazines give 1-arylsemicarbazides and 1-arylthiosemicarbazides [7] as stable products. This is explained by the interaction between the aromatic nucleus and the —NH-group, which makes the latter less nucleophilic than the NH_2-group. The same effects are taken into account to explain why methylamine is more basic and aniline less basic than ammonia [8]. The same difference in orientation is found when methylhydrazine and phenylhydrazine react with carboxylic acid chlorides [9] and with dithioesters such as carboxymethyl dithiobenzoate [10,11] and alkyl trithiocarbonates [12,13]. With methylhydrazine, 1-methyl-1-acyl(thioacyl)-hydrazines (III), and with phenylhydrazine, 1-phenyl-2-acyl(thioacyl)-hydrazines (IV) are formed.

However, there is evidence for the operation of a steric effect in the reactions between methylhydrazine and carboxylic esters. Von Brüning [14] has shown, that methylhydrazine and diethyl oxalate react readily to give 1,1'-oxalyl-bis-2,2'-methylhydrazine, $(CO{\cdot}NHNHCH_3)_2$ (V).

In a recent investigation, Hinman and Fulton [15] have shown, that methyl acetate, propionate, *iso*butyrate, and benzoate, react with methylhydrazine to give mixtures of 1-acylated (IIIb), and 2-acylated (IVb) methylhydrazine, where the latter isomer predominated. With the aliphatic esters both the yield of (IIIb) and the reaction rate fell off with increasing size of the acyl group. On the other hand, reactions between methylhydrazine and carboxylic acid anhydrides gave high yields of the 1-acyl-methylhydrazines (IIIb).

It seems as if dithioesters should occupy a position intermediate between, on the one hand carboxylic esters, and on the other hand cyanic acid and thiocyanic acid and their derivatives, with regard to sensitivity to steric effects in reactions with aliphatic hydrazines. Therefore, it was considered desirable to investigate the reactions of benzylhydrazine with a selection of dithioesters. Carboxymethyl dithiobenzoate, O,S-dimethyl xanthate, O-benzyl-S-carboxymethyl xanthate, and carboxymethyl dithiocarbamate were chosen, together with dimethyl trithiocarbonate. The carboxymethyl dithiocarbamate did not give definable products with benzylhydrazine, but the other esters reacted rapidly and gave mixtures of the possible isomers (I) and (II). The yields and ultra-violet absorption data are recorded in Table 1.

For separation of the isomers the reaction mixtures were dissolved in ether, and the solutions were extracted with a quantity of N NaOH equivalent to the total amount of thiohydrazide present. With the dithiocarbazate and thiobenzhydrazide mixtures one extraction was enough to transfer practically all of the acidic isomer (II) into the alkaline solution, but when the thioncarbazate mixtures were so treated, appreciable quantities of the acid forms

Table 1. Yields and ultraviolet absorption data for the compounds I and II.

Starting material	Yield %	λ_{max} mμ	ε_{max}
$CH_3S \cdot CS \cdot SCH_3$	Ia: 20	255	10 300
		276	11 100
	IIa: 74	277	10 800
$Ph \cdot CS \cdot SCH_2CO_2H$	Ib: 23	288	11 200
	IIb: 72	245	12 400
		298	6 500
$CH_3O \cdot CS \cdot SCH_3$	Ic: 25	—	—
	IIc: 70	250	12 000
$PhCH_2O \cdot CS \cdot SCH_2CO_2H$	Id: 76	252	15 000
	IId: 22	252	11 600

All spectra were taken in absolute ethanol, c, 5×10^{-5}, with a Beckman DU spectrophotometer.

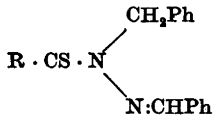
(IIc) and (IId) remained in the ether solution after the first extraction. The progress of the extraction could be followed by paper chromatographic examination of the ether solution after each extraction. For this purpose ordinary paper chromatography with water as the stationary phase was found unsuitable. In the solvents used by Hinman [16] these hydrazides travelled with the solvent front, and the same result was obtained with chloroform saturated with water, a system used with success by Kjær and Rubinstein [17] for substituted thioureas and thiosemicarbazides. Instead, the system developed by Wickberg [18], with dimethyl sulphoxide as the stationary phase and ethers or aliphatic hydrocarbons as the mobile phase, was found very useful. In all the four isomer mixtures obtained in this investigation the acidic isomer travelled slower than the neutral one, which is to be expected, since dimethyl sulphoxide has weakly basic properties [19].

By this method it could be shown that methyl 3-benzylthioncarbazate (IIc) was extracted by two succesive extractions with N NaOH beyond the limit of detection in the ether solution, but that the benzyl analogue (IId) could still be detected after six successive extractions. The partition of an acid between ether and aqueous alkali is governed by the partition coefficient, C, of the undissociated acid between ether and water, by the dissociation constant of the acid, and by the activities of the hydrogen ions and the anions of the acid in the aqueous phase. The partition observed, $P = \frac{[HA]_{ether}}{[HA]_{aq} + [A^-]_{aq}}$ can be expressed in the above quantities by inserting $\frac{K_a \times [HA]_{aq}}{a_{H^+} \times f_{A^-}}$ for $[A^-]_{aq}$ and C for $\frac{[HA]_{ether}}{[HA]_{aq}}$. In this way we obtain $P = \frac{C \times a_{H^+} \times f_{A^-}}{a_{H^+} \times f_{A^-} + K_a}$

The values of the dissociation constants, K_a (Table 2) were determined by electrometric titration with a glass electrode in 20 % and in 3 % aqueous ethanol (w/w). For reasons of solubility no determinations were made in pure water, but approximate values can easily be obtained by extrapolation. However, these can not be the same as in water saturated with ether. The coefficients of partition, C, of the acids between ether and pure water were determined

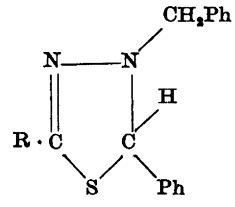
spectrophotometrically. This method could not be used in alkaline medium because of the rapid oxidation mentioned below. Instead, known quantities of the thioncarbazates were equilibrated between ether and aqueous NaOH, and P was determined by evaporating the ether solutions and weighing the dry residues. For a_{H^+} was inserted the expression $\frac{K_w}{([OH^-] - [A^-]) \times f_{OH^-}}$, where $[OH^-]$ is the concentration of hydroxyl ions in the aqueous phase before equilibration. The activity coefficients f_{A^-} and f_{OH^-} are not known with certainty, but their ratio should not differ much from unity. In solutions with $a_{H^+} < 10^{-12}$, the first term in the denominator of P can be neglected. The value of K_w is probably not the same in water as in water saturated with ether, but the ratio K_w/K_a should not be very much different in the two solvents. The values of C obtained from determinations of P with aqueous alkali were found to rise with pH. For the methyl thioncarbazate (IIc) the increase of C was moderate, but for the benzyl analogue (IId), which is much less soluble in water, the value of C rose steeply with pH (Table 2). This change of C with pH can be correlated with the diminishing mutual solubility of ether and water with increasing alkalinity [20]. Much more clear-cut conditions can be expected by using organic solvents, which are practically insoluble in water, but with benzene and *iso*propyl ether the partition coefficient C has so high values that the extraction from these solvents becomes much more tedious than from ether. Instead, ethanol was added to the aqueous phase in order to increase the mutual solubility of ether and water and to reduce the partition coefficient, and thereby the extraction was considerably facilitated. When the N NaOH used for extraction was diluted with ethanol to about 30 % (v/v), only three successive portions were neccessary for a complete extraction of the benzyl thioncarbazate (IId). From the expression for P and the values in Table 2 it is obvious that the extraction of the thiohydrazides (IIa) and (IIb) is favoured both by dissociation constants and by partition coefficients. The extraction of (IIc) is somewhat impeded by a low dissociation constant, and the extraction of (IId) is highly impeded by low dissociation constant and high partition coefficient.

Both types of thiohydrazides react with benzaldehyde. The neutral isomers (I) with free amino group give hydrazones (VI) and the acidic isomers (II) give thiadiazolines (VII).



VI

a — d as in (I)



VII

The recording of the ultra-violet absorption spectra of the acidic isomers (II) is complicated by a reaction in very dilute solution with formation of benzaldehyde hydrazones:

$$R \cdot CS \cdot NHNH \cdot CH_2Ph \xrightarrow{-2H} R \cdot CS \cdot NHN{:}CHPh$$

Table 2. pK_a-Values (thermodynamic) and partition coefficients (C) between ether and water for the thiohydrazides, R·CS·NHNHCH$_2$Ph.

	pK_a			C	
R	20 % ethanol	3 % ethanol (w/w)	water	0.1 N NaOH	0.5 N NaOH
CH_3S	7.66	7.56	35		
Ph	7.82	7.63	310		
CH_3O	9.38	9.24	260	330	800
$PhCH_2O$	9.26	9.16	2 400	17 000	39 000

The ether and water used for the partition experiments were saturated with respect to one another prior to measurements. Because of the uncertainties in Ka and Kw and the activity coefficients the values of C must be regarded as very approximate.

The oxidation products have been identified by paper chromatography and UV-spectrum. The change is particularly rapid in alkaline medium. The reaction can be illustrated by the spectra in Fig. 1.

The thiadiazoline (VIIb) is rather unstable and is oxidized by air to a compound $C_{21}H_{18}N_2OS$, probably the 2-hydroxy derivative of the thiadiazoline. Holmberg [10] has found a similar facile oxidation of the 3-methyl analogue.

..... CH_3S·CS·NHN:CHPh [21], 5 × 10^{-5} M solution in absolute ethanol.

The present investigation shows that different types of dithiocarboxylic esters react with benzylhydrazine to give mixtures of the two possible thiohydrazides. The discussion of a possible steric effect must await the results of an investigation of a wider selection of other closely related esters.

EXPERIMENTAL *

Benzylhydrazine and dimethyl trithiocarbonate. Dimethyl trithiocarbonate (2.8 g) was dissolved in a mixture of ethanol (25 ml) and ether (25 ml), and the solution was added to a solution of benzylhydrazine sulphate (4.6 g) in N NaOH (40 ml) and ethanol (50 ml). On the following day the crystals of sodium sulphate were removed by filtration, and the solvents were taken off *in vacuo*. The remaining oil was dissolved in ether (50 ml), and the solution was extracted with N NaOH (20 ml). The ethereal solution on evaporation gave a solid residue (0.7 g), which crystallized from a mixture of benzene and light petroleum (b.p. 40—60°) as colourless plates with m. p. 91—92°, consisting of *methyl 2-benzyldithiocarbazate* ** (Ia). (Found: C 51.0; H 5.70; N 13.0; S 30.0. Calc. for $C_9H_{12}N_2S_2$: C 50.9; H 5.70; N 13.2; S 30.2.)

Acidification of the alkaline extract from the crude reaction mixture gave a crystalline deposit (2.9 g), which crystallized from a mixture of benzene and light petroleum (40—60°) as colourless prisms, m. p. 58—59°, of *methyl 3-benzyldithiocarbazate* (IIa). (Found: C 50.8; H 5.64; N 13.1; S 30.1. Calc. for $C_9H_{12}N_2S_2$: C 50.9; H 5.70; N 13.2; S 30.2.)

The benzaldehyde hydrazones (VI) and the thiadiazolines (VII) were prepared by reacting the appropriate thiohydrazides with the calculated amount of benzaldehyde in ethanol with a catalytic amount of hydrochloric acid. When necessary, the products were precipitated by the addition of water and purified by recrystallization.

Methyl 2-benzyl-3-benzylidene-dithiocarbazate (VIa) crystallized from ethanol as colourless needles, m. p. 134—135°. (Found: C 63.9; H 5.47; N 9.37; S 21.4. Calc. for $C_{16}H_{16}N_2S_2$: C 64.0; H 5.37; N 9.33; S 21.3.)

2-Phenyl-3-benzyl-5-methylthio-Δ^4-1,3,4-thiadiazoline (VIIa) was too unstable to be recrystallized, but according to analysis the crude product, m. p. 60—62°, was fairly pure. (Found: C 64.2; H 5.47; N 9.27; S 21.2. Calc. for $C_{16}H_{16}N_2S_2$: C 64.0; H 5.37; N 9.33; S 21.3.)

Benzylhydrazine and carboxymethyl dithiobenzoate. Carboxymethyl dithiobenzoate [22] (2.1 g) in N NaOH (10 ml) was added to a solution of benzylhydrazine sulphate (2.2 g) in N NaOH (20.2 ml). The red colour rapidly disappeared, and a crystalline product (2.4 g) was deposited. It was dissolved in ether (50 ml) and the solution was extracted with N NaOH (10 ml). The ethereal solution on evaporation gave a solid residue (0.56 g), which crystallized from a mixture of toluene and light petroleum (80—100°) as colourless plates of *1-benzylthiobenzhydrazide* *** (Ib), m. p. 92—93°. (Found: C 69.8; H 5.93; N 11.5; S 13.1. Calc. for $C_{14}H_{14}N_2S$: C 69.4; H 5.82; N 11.6; S 13.2.)

The acidic isomer, *2-benzylthiobenzhydrazide*, (IIb), separated as pale yellow needles (1.75 g) when the alkaline extract from the crude reaction product was acidified with acetic acid. It crystallized from toluene as pale yellow needles, m. p. 146—147°. (Found: C 69.8; H 5.78; N 11.4; S 13.1. Calc. for $C_{14}H_{14}N_2S$: C 69.4; H 5.82; N 11.6; S 13.2.)

The correctness of structure (Ib) for the neutral thiohydrazide was further demonstrated by its deamination with nitrous acid to N-benzyl-thiobenzamide. The thiohydrazide (Ib) (0.25 g) was dissolved in a mixture of ethanol (5 ml) and N HCl (2 ml), and a solution of sodium nitrite (0.2 g) in water (5 ml) was added. Gas was evolved and an oil was deposited, which solidified to a crystalline material (0.19 g). This crystallized from light petroleum (80—100°) as pale yellow needles of *N-benzylthiobenzamide*, m. p. 86—87°. (Found: N 6.11; S 14.1. Calc. for $C_{14}H_{13}NS$: N 6.16; S 14.1.)

---

* All melting points are uncorrected and taken in capillary tubes in an electrically heated block.

** Numbering according to Chemical Abstracts (see Subject Index, Carbazic acid).

*** Numbering according to Holmberg [19].

This compound was also prepared by reaction between benzylamine and the sodium salt of carboxymethyl dithiobenzoate and was found to be identical with the compound described above. Levi [23] has described the preparation of N-benzylthiobenzamide by reaction between benzylamine and sulphur at 180°, and he reports m. p. 86°.

Benzaldehyde 1-benzylthiobenzhydrazone (VIb) crystallized from toluene-light petroleum (80—100°) as yellow, rhombic prisms, m. p. 116—117°. (Found: C 76.2; H 5.34; N 8.42; S 9.80. Calc. for $C_{21}H_{18}N_2S$: C 76.3; H 5.49; N 8.48; S 9.70.)

2,5-Diphenyl-3-benzyl-Δ^4-1,3,4-thiadiazoline (VIIb) was too unstable to be recrystallized, but according to analysis the crude product, m. p 65—67°, was fairly pure. (Found: C 76.4; H 5.38; N 8.48; S 9.82. Calc. for $C_{21}H_{18}N_2S$: C 76.3; H 5.49; N 8.48; S 9.70.)

The crude thiadiazoline (0.4 g) was dissolved in hot ethanol (8 ml). On cooling, pale yellow needles separated, m. p. 161—162°. (Found: C 72.7; H 5.30; N 7.97; S 9.10. Calc. for $C_{21}H_{18}N_2OS$: C 72.8; H 5.24; N 8.09; S 9.25.)

Benzylhydrazine and dimethyl xanthate. Dimethyl xanthate (6.2 g) in ethanol (150 ml) was added to a solution of benzylhydrazine sulphate (11 g) in 2 N NaOH (50 ml). On the following day the crystals of sodium sulphate were removed by filtration, and then the solvents were removed *in vacuo* at room temperature. The oily residue was dissolved in ether (50 ml), and the solution was extracted twice with N NaOH (each portion 50 ml). After the second extraction only one spot, corresponding to the neutral isomer, could be observed when the ethereal phase was examined with paper chromatography. The ethereal solution was evaporated and gave a non-crystallizing residue (2.5 g) of *methyl 2-benzylthioncarbazate* (Ic). It was not analyzed but only used for preparation of the benzylidene derivative (VIc).

The acidic isomer, *methyl 3-benzylthioncarbazate* (IIc), separated as a crystallizing oil, when the alkaline extract from the crude reaction mixture was acidified with acetic acid. The compound (6.9 g) crystallized from benzene-light petroleum (40—60°) as colourless rods, m. p. 45—46°. (Found: C 55.0; H 6.14; N 14.3; S 16.3. Calc. for $C_9H_{12}N_2OS$: C 55.1; H 6.16; N 14.3; S 16.3.)

Methyl 2-benzyl-3-benzylidene-thioncarbazate (VIc) crystallized from light petroleum (80—100°) as colourless prisms, m. p. 99—100°. (Found: C 67.5; H 5.77; N 9.74; S 11.2. Calc. for $C_{16}H_{16}N_2OS$: C 67.6; H 5.67; N 9.85; S 11.3.)

2-Phenyl-3-benzyl-5-methoxy-Δ^4-1,3,4-thiadiazoline (VIIc) crystallized from ethanol as colourless rods, m. p. 63—66°. (Found: C 67.5; H 5.62; N 9.93; S 11.2. Calc. for $C_{16}H_{16}N_2OS$: C 67.6; H 5.67; N 9.85; S 11.3.)

Benzylhydrazine and O-benzyl-S-carboxymethyl xanthate. O-Benzyl-S-carboxymethyl xanthate [24] (6.0 g) was dissolved in N NaOH (25 ml) and added to a solution of benzylhydrazine sulphate (5.5 g) in N NaOH (50 ml). A non-crystallizing reaction product separated rapidly, and it was dissolved in ether (100 ml) and extracted three times with aqueous ethanolic NaOH (each portion 25 ml N NaOH and 10 ml of ethanol). Then the ether solution on paper chromatography showed only one spot, corresponding to the neutral isomer (Id). The ether solution was evaporated to dryness, and the crystalline residue (5.1 g) crystallized from ethanol as colourless rods of *benzyl 2-benzylthioncarbazate* (Id), m. p. 47—48°. (Found: C 66.0; H 5.97; N 10.4; S 11.8. Calc. for $C_{15}H_{16}N_2OS$: C 66.1; H 5.92; N 10.3; S 11.8.)

The acidic isomer, *benzyl 3-benzylthioncarbazate* (IId), was obtained as a crystallizing oil, when the alkaline extract from the crude reaction mixture was acidified with acetic acid. The yield was increased when the ethanol was removed *in vacuo*. The product (1.5 g) crystallized from benzene-light petroleum (40—60°) at −30° as colourless rods, m. p. 51—52°. (Found: C 66.1; H 5.90; N 10.3; S 11.7. Calc. for $C_{15}H_{16}N_2OS$: C 66.1; H 5.92; N 10.3; S 11.8.)

Benzyl 2-benzyl-3-benzylidene-thioncarbazate (VId) crystallized from light petroleum (80—100°) as colourless rods, m. p. 92—93°. (Found: C 73.0; H 5.78; N 7.98; S 9.09. Calc. for $C_{22}H_{20}N_2OS$: C 73.3; H 5.59; N 7.77; S 8.89.)

2-Phenyl-3-benzyl-5-benzyloxy-Δ^4-1,3,4-thiadiazoline (VIId) crystallized from ethanol as colourless rods, m. p. 96—98°. (Found: C 72.9; H 5.79; N 7.90; S 9.05. Calc. for $C_{22}H_{20}N_2OS$: C 73.3; H 5.59; N 7.77; S 8.89.)

Paper chromatography. The impregnation of the papers with dimethyl sulphoxide was performed as described by Wickberg [18]. Before use the papers were stored in a desiccator over dimethyl sulphoxide and silica for at least 24 h to attain equilibrium. Mixtures of di-*n*-butyl ether and *n*-heptane were used as the mobile phase, and generally the R_F-

values rose with increasing proportion of ether in the solvent. The ascending technique was used, and 20 cm length of paper was in most cases enough to obtain a satisfactory separation of the isomeric pairs (I) and (II). The spots could be made visible by spraying the papers with an aqueous solution 0.1 N in $AgNO_3$ and $CuSO_4$ and 2 N in ammonia. The neutral isomers gave grey spots and the acidic ones brown spots. A more general spray reagent is the iodine-azide reagent [25], but it gave less distinct spots. The different compounds could also conveniently be localized by photographing the papers in UV-light.

Dissociation constants. Titration graphs were recorded with a glass electrode, Radiometer 202 B, against a calomel electrode in saturated KCl, when 0.05 N NaOH in 20 % and 3 % (w/w) aqueous ethanol was added to $3 \times 10^{-3} - 3 \times 10^{-4}$ M solutions of the thiohydrazides (II) in aqueous ethanol of the same composition. Before use the glass electrode was stored over night in the appropriate aqueous ethanol, and then it was calibrated with a standard buffer in water. From 6–9 points around the value for half-neutralization the dissociation constants were calculated and corrected for the activity of the anion.

Acknowledgments. The technical assistance of fil.kand. Lars Andersson, Miss Karin Göransson and Miss Ingeborg Leutiger is acknowledged. The investigation has been supported by grants from the *Swedish Natural Science Research Council*, from *Stiftelsen Lars Hiertas Minne*, and from *Kungliga Fysiografiska Sällskapet.*

The Chemistry of the Natural Order Cupressales

XXVII *. Heartwood Constituents of *Juniperus utahensis* Lemm.

JARL RUNEBERG

Organisk-kemiska institutionen, Kungl. Tekniska Högskolan, Stockholm 70, Sweden

From the heartwood of *Juniperus utahensis* there were isolated: thujopsene, cuparene, widdrol, "Widdringtonia diol", a yellow compound $C_{20}H_{20}O_5$, carvacrol, nootkatin, hinokiic acid as well as a hydroxy acid and a carbonyl containing compound, both probably of a sesquiterpene nature. The presence of β-thujaplicin was indicated by paper chromatography and that of α-cedrene by gas chromatography.

The available literature on juniper wood constituents deals mainly with the isolation and fractionation of essential oils and describes their physical constants. Only in a few cases have the various constituents present been identified. In a previous paper [1] in this series, however, an account was given of a more detailed chemical investigation of the Far Eastern species *Juniperus chinensis* in which a dozen of the heartwood constituents were identified. This paper deals with the constituents of the American desert juniper, *J. utahensis*.

The only previous investigation of this species that has been published was carried out by Adams and Billinghurst [2] who described an oil obtained by steam distillation of leaves and small twigs. They gave the physical constants of the oil but did not isolate or identify any of its constituents.

The wood used in the present investigation came from a tree grown at Grand Canyon, Arizona, U.S.A. It had been cut at least three years before it was worked up and was therefore rather dry.

The wood was extracted with acetone. The ether-soluble portion of the acetone extract was poured into a large volume of light petroleum giving a yellow crystalline precipitate.

On recrystallisation the compound melted with decomposition at 313° and analysed for $C_{20}H_{20}O_5$. The mass spectrum confirmed the molecular weight as 340. The compound contained no methoxyl group; the C-methyl determination gave 1.4 moles of acetic acid. The infrared spectrum (see Fig. 1) indicated

* Part XXVI. *Tetrahedron*. In the press.

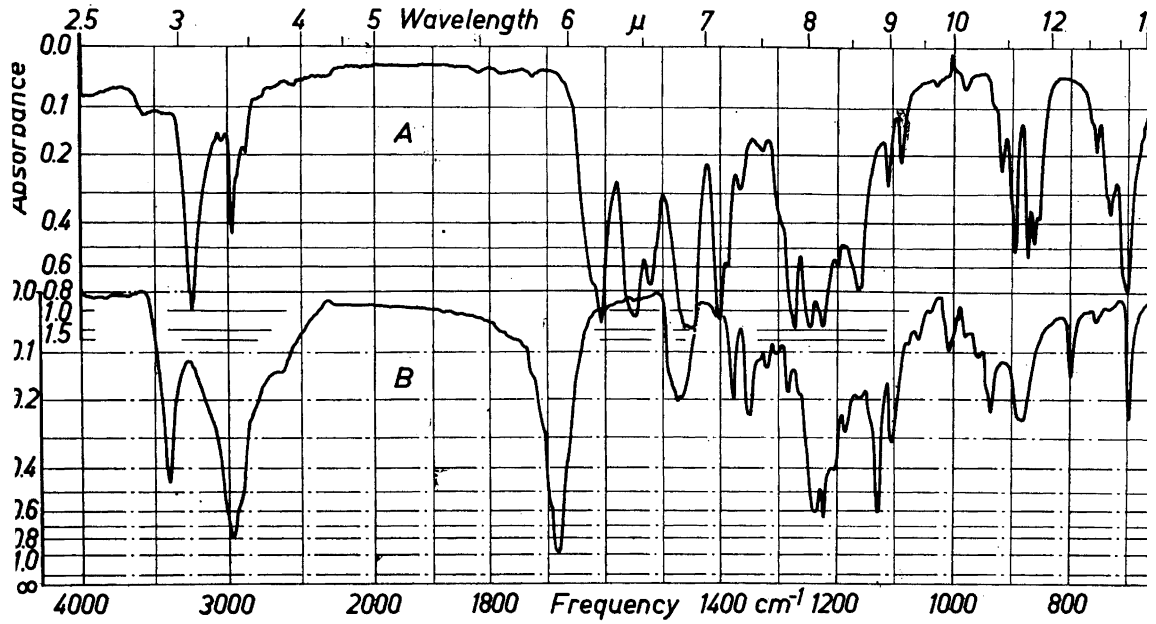

Fig. 1. Infrared spectra of utahin (A) and of hydroxy acid m. p. 181—187° (B) in potassium bromide.

the presence of at least one phenolic hydroxyl group (3 250 cm^{-1}). The absorption at 1 615—1 650 cm^{-1} and the broad, weak OH-absorption near 2 500 cm^{-1} may indicate the presence of a strongly hydrogen-bonded keto function in the molecule. The ultraviolet spectrum of the compound is given in Fig. 2.

Zinc dust distillation afforded a semi-solid product with ultraviolet absorption maxima at 245, 253 and 282 mμ. Selenium dehydrogenation gave a very small yield of a product with maxima at 274 and 277 mμ. Catalytic hydrogenation afforded only unidentifiable products. The compound gave a negative magnesium-hydrochloric acid test.

The name utahin is proposed for the above compound which to our knowledge has not previously been isolated.

Acetylation of utahin afforded a pale yellow di-acetate, $C_{24}H_{24}O_7$, m.p. 205° (decomp.), which was not found to be optically active. Its infrared spectrum showed no absorption band at 3 250 cm^{-1} but the absorption in the 1 615—1 650 cm^{-1} and 2 500 cm^{-1} regions was unchanged. The ultraviolet spectrum of utahin diacetate is given in Fig. 2.

Since the wood used in this investigation had been stored for several years it is possible that utahin may be an artefact formed by oxidation during storage. To check this possibility a large sample of fresh wood (grown near Ogden, Utah, U.S.A.) was obtained. This material also afforded utahin but in considerably lower yield (0.001 %, see below). It therefore seems likely that utahin

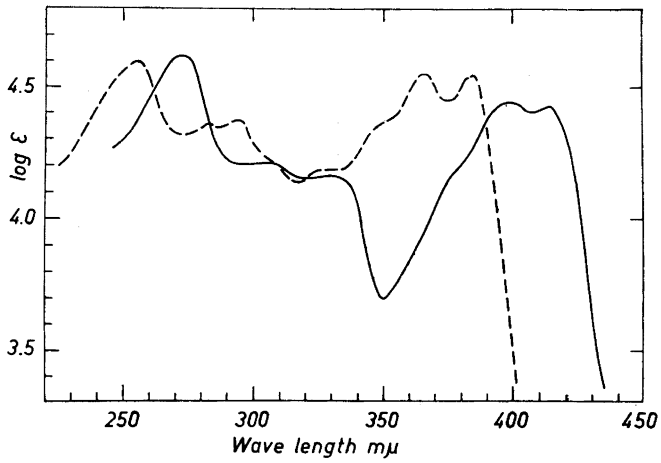

Fig. 2. Ultraviolet spectra of utahin (————) in chloroform and of utahin diacetate (- - - - - -) in ethanol (95 %).

is present in the fresh wood although the possibility that it may have been formed during working up cannot be excluded.

The diterpenes ferruginol, sugiol and xanthoperol have recently been isolated from *J. communis* [3-5]. The empirical formula and the C-methyl content of utahin suggest that it could be related to these diterpenes. Further work on utahin is in progress.

The light petroleum-soluble part of the acetone extract, on standing, gave a yellowish crystalline precipitate (C, see experimental part). The infrared spectrum of this material, except for additional carbonyl absorption (1 745 cm^{-1}) showed great resemblance to that of utahin but it has not yet been investigated.

The remaining light petroleum-soluble acetone extract was separated into neutral and acid fractions by extraction with alkali. The acidic material afforded two sesquiterpene acids.

One of these was hinokiic acid [6] which has also been found in *J. chinensis* [1] as well as in several other trees of the Cupressaceae.

The other acid was a new sesquiterpene hydroxy acid $C_{15}H_{24}O_3$, m.p. 181—187°; unchanged by further recrystallisation or sublimation. Since the acid could not be catalytically hydrogenated, the analysis suggests that the compound may be tricyclic. Except for a very weak maximum at 206 mμ ($\varepsilon = 63$), the ultraviolet spectrum showed no significant absorption in the 195—350 mμ region.

Although the compound itself melted over a wide range, it gave a sharp-melting methyl ester (m.p. 98.0—98.5°) with diazomethane. The ester was reduced to a diol which was dehydrogenated with selenium giving a product that, according to the ultraviolet spectrum, was mainly benzenoid in nature. The dehydrogenation product was chromatographed on alumina but

none of the fractions gave a crystalline picrate. The hydroxy acid was stable to chromic acid in pyridine at room temperature indicating that the alcoholic hydroxyl group is tertiary. Dehydration with formic acid yielded a product which gave a satisfactory analysis but had no sharp melting point and was probably a mixture of isomers. The ultraviolet spectrum showed only a maximum at 205 mμ indicating that the product did not contain an α-β-unsaturated acid. Further work on the structure of this hydroxy acid is in progress.

The remaining acidic material from the light petroleum-soluble acetone extract gave carvacrol on distillation. The tropolones were concentrated by precipitation with copper acetate and decomposition of the crude copper salts with hydrochloric acid. Chromatography of the product obtained gave nootkatin and paper chromatography indicated the presence of β-thujaplicin.

The neutral oil was distilled. Fraction 1 (Table 1) corresponded to a wide boiling point range and according to its infrared spectrum appeared to be a complex mixture of carbonyl compounds, hydrocarbons and alcohols. Fraction 2 consisted almost entirely of hydrocarbons and fraction 3 again showed hydroxyl absorption. Gas chromatography of the first three fractions indicated the following compositions (in percent), assuming complete resolution: Fraction 1 (Table 1), thujopsene [6] 55; α-cedrene 31; two unknowns 7 and 7. Fraction 2, thujopsene 62; α-cedrene 13; four unknowns 10, 8, 6 and 1. Fraction 3, thujopsene 16; cuparene [7] 34; two unknowns 34 and 16.

The major component of fraction 2 (Table 1) was shown to be thujopsene by conversion to the corresponding aldehyde (widdrenal) [6,8]. Fraction 3 (Table 1) was ozonised at low temperature and the material unaffected by ozone was identified as cuparene.

The next higher boiling fraction gave widdrol [8] but no cedrol was detected. However since α-cedrene is present it is not improbable that cedrol might also occur in the wood although in very small amount. The same fraction, on ozonolysis followed by chromatography, afforded a sesquiterpene diol, m.p 154°, previously isolated from *Widdringtonia juniperoides* [8].

Fraction 5 (Table 1) contained a crystalline carbonyl compound which is probably a sesquiterpene but gave a poor analysis.

The compounds isolated are listed below with very approximate estimates of the amounts present (as percentages of the air-dried wood). Total acetone extract 9.3, ether-soluble acetone extract 6.3, light petroleum-soluble acetone extract 1.8, sodium bicarbonate-soluble 0.084, sodium hydroxide-soluble 0.67, neutral 1.1, utahin 0.030, nootkatin 0.0002, β-thujaplicin 0.0001, carvacrol 0.0072, hinokiic acid 0.013, sesquiterpene hydroxy acid 0.070, α-cedrene 0.048, thujopsene 0.18, cuparene 0.047, widdrol 0.051, "Widdringtonia diol" m.p. 154°, 0.0003, high boiling carbonyl compounds 0.020.

EXPERIMENTAL

Rotations were measured in chloroform; melting points, taken on a hot stage, are corrected; boiling points are uncorrected. Light petroleum refers to the fraction b.p. 40–60°.

Isolation of the oils: The ground, air-dried heartwood (9.7 kg) was continuously extracted with acetone for 24 h. The acetone was evaporated and the remaining oil poured with stirring into ten volumes of ether. The ether solution was filtered (precipitate A, 312 g), evaporated and the residue was poured into ten volumes of light petroleum. After filtration (precipitate B, 437 g) the solution was evaporated almost to dryness. On standing for about one month a yellow crystalline precipitate formed (C, 0.373 g). This was removed by filtration. The filtrate was diluted with two volumes of light petroleum and extracted successively with a saturated solution of sodium bicarbonate and 2 N sodium hydroxide. On acidification and extraction with ether the sodium bicarbonate solution yielded a viscous oil (D, 8.1 g) which was not further investigated. The sodium hydroxide-soluble material (E, 65.3 g) was isolated in the same way by acidification and extraction with ether. The light petroleum solution was washed with water, dried and evaporated yielding neutral material (F, 104.0 g).

Precipitate B

Isolation of utahin. Precipitate B was dissolved in an equal amount of acetone. On standing a yellow precipitate (2.8 g) formed. It was separated by filtration, washed with acetone, recrystallised from a large volume of ethyl acetate and sublimed in a high vacuum, m.p. 313° (decomp.) (Found: C 70.6; H 6.2; CH_3O 0.1. $C_{20}H_{20}O_5$ requires C 70.6; H 5.9.) The melting point did not change on further recrystallisation and sublimation. (Found: C 70.9; H 6.0; O 23.3; CH_3-(C) 6.2. $C_{20}H_{20}O_5$ requires O 23.5; CH_3-(C) (one) 4.4.)

The mass-spectrum was recorded on an instrument with an all-glass, heated inlet system [9]. Only major peaks are given. The figures in brackets are intensities given as *per cent* of the strongest peak (m/e = 43). 340 (21), 312 (17), 284 (18), 270 (8), 269 (40), 253 (8), 128 (9), 127 (24), 115 (20), 105 (9), 91 (13), 77 (13), 69 (10), 67 (11), 63 (9), 57 (13), 55 (29), 53 (17), 51 (10), 45 (9), 44 (21), 42 (13), 41 (61), 39 (25), 29 (25), 28 (23), 27 (29), 18 (95), 17 (17) and 15 (10).

Utahin sublimed easily in a high vacuum and had a low solubility in most organic solvents except chloroform. It dissolved in concentrated sulphuric acid giving a pale greenish solution from which it could be recovered by addition of water. A solution in 95 % ethanol gave a brownish colour with aqueous iron (III) chloride. The compound does not dissolve in aqueous sodium hydroxide (2 N) but affords a bright orange salt with alkali. Utahin does not react with carbonyl reagents or with *o*-phenylene diamine in acetic acid.

Because of its very low solubility in ether, utahin was expected also to occur in the precipitate A. This was therefore extracted with chloroform, the extract was evaporated and the residue was dissolved in acetone (50 ml). Only a small amount of utahin (130 mg) precipitated on standing.

The wood remaining after acetone extraction was dried and extracted exhaustively with chloroform. Only a very small amount of utahin was obtained from the chloroform extract.

Utahin diacetate. Utahin (70 mg) in acetic anhydride (2 ml) was treated with perchloric acid (1 drop), the mixture was heated on a boiling water bath for 1 h and poured on to ice. The pale yellow crystalline material formed was separated and recrystallised from 95 % ethanol, m. p. 207° (decomp.), $[\alpha]_D$ 0. (Found: C 68.0; H 5.6; CH_3-CO- 19.7. $C_{24}H_{24}O_7$ requires C 67.9; H 5.7; CH_3-CO- (one) 10.6.)

Alkali-soluble fraction

Hinokiic acid. The alkali-soluble oil E on standing deposited a crystalline material (1.23 g). This was filtered off and recrystallised from light petroleum, m. p. 166.0–167.5° $[\alpha]_D$ −87° (*c* 1.6). It was identified as hinokiic acid [6] (mixed m. p., I.R.).

Hydroxy acid. The material remaining after separation of hinokiic acid from the oil E was dissolved in ether and extracted with aqueous sodium carbonate (2 N). The ether solution on evaporation gave an oil (G). The sodium carbonate solution on acidification and extraction with ether gave a product (36.4 g) which was mixed with light petroleum

and partly crystallised on standing for several months. The crystals (6.76 g) were separated by filtration (filtrate, oil [H], recrystallised several times from ligroin (b. p. 100—125°) and from ethanol-water and were then sublimed in a high vacuum, m. p. 181—187°, $[\alpha]_D$ −47° (*c*, 3.2). (Found: C 71.9; H 9.7; M (Rast) 250; M (titr.) 207; CH_3—(C) 7.4. $C_{15}H_{24}O_3$ requires C 71.4; H 9.6; M 252; CH_3—(C) (one) 6.0.) Further recrystallisation from these solvents and sublimation did not change the melting point (181—187°), (C 71.1; H 9.2).

Hydroxy acid methyl ester. The hydroxy acid (400 mg) was methylated with diazomethane. The ester was recrystallised from ethanol-water and sublimed in a high vacuum, m. p. 98.0—98.5, $[\alpha]_D$ −25° (*c*, 1.0). (Found: C 72.1; H 9.5; M (Rast) 252. $C_{16}H_{26}O_3$ requires C 72.1; H 9.8; M 266.)

Diol. A solution of the hydroxy acid methyl ester (595 mg) in absolute ether was added dropwise with stirring at 0° to a solution of lithium aluminium hydride (455 mg) in absolute ether. After 3 h at room temperature the excess reagent was destroyed with ethyl acetate. Hydrochloric acid (2 N) was added and the solution was extracted with ether. On evaporation the ether solution afforded a substance (518 mg) which was recrystallised from *cyclo*hexane and sublimed in a high vacuum, m. p. 130.0—131.0°, $[\alpha]_D$ +6° (*c*, 2.0). (Found: C 75.4; H 10.9. $C_{15}H_{26}O_2$ requires C 75.6; H 11.0.)

Attempts to hydrogenate the hydroxy acid. Hydroxy acid (60 mg) in 95 % ethanol (10 ml) or in acetic acid was shaken with a platinum oxide catalyst (6 mg) in a hydrogen atmosphere for 6 h. No hydrogen was absorbed and the starting material was recovered unchanged.

Attempted oxidation with chromic acid. Hydroxy acid (21 mg) was added to a solution of chromic acid (32 mg) in glacial acetic acid (2 ml) and dry pyridine (1 drop). After 15 h at room temperature methanol (0.3 ml) was added and the mixture left to stand for another 15 h. It was then acidified with sulfuric acid (2 N) and extracted with ether; the ether solution was washed with water, dried and evaporated. The residue, after recrystallisation from ethanol, afforded unchanged starting material.

Dehydration of the hydroxy acid. A mixture of the hydroxy acid (355 mg) and formic acid (90 %, 7 ml) was heated on a water bath for 2 h. Ether was added and the solution was extracted with aqueous sodium bicarbonate. The ether solution was evaporated affording a residue which was recrystallised from 95 % ethanol and sublimed in a high vacuum, m. p. 87—93°. (Found: C 77.1; H 9.2; CH_3—(C) 11.7. $C_{15}H_{22}O_2$ requires C 76.9; H 9.5; CH_3—(C) (one) 6.4.)

Carvacrol. A sample (17.8 g) of the sodium carbonate insoluble oil (G) was distilled through a spinning band column. The material distilled over a range of 108—170°/20 mm without giving any definite fraction of constant boiling point. The material boiling at 113—122°/20 mm was mainly carvacrol. This fraction was converted into carvacroxy acetic acid, m. p. 151—152°, undepressed by an authentic sample.

The sodium carbonate insoluble oil (G, 10.0 g) was dissolved in ligroin (b.p. 100—125°) and shaken with aqueous copper acetate (saturated). The liquid phases were removed by filtration and the copper salts remaining were washed with ligroin and water, decomposed with hydrochloric acid (2 N) and the product was extracted with ether. On evaporation of the ether solution a viscous oil (I, 481 mg) was obtained. This was chromatographed on silica gel. The silica gel was made iron-free by treatment with aqueous oxalic acid (saturated) and washing with water. It was then treated with a solution of the disodium salt of ethylene diamine tetra-acetic acid (0.002 M), washed with water and dried. The *iso*propyl ether-soluble part of the oil I (232 mg) was chromatographed on this pretreated silica gel (40 g) using *iso*propyl ether as eluent. 200 ml fractions were collected. Each fraction was evaporated and analysed by paper chromatography [10]. Fraction 1 consisted mainly of a yellow compound which was not further investigated, fraction 2 of a mixture of this compound and nootkatin, fraction 3 of nootkatin and a small amount of β-thujaplicin. The crystalline part of this fraction (4 mg) was recrystallised from light petroleum, m. p. 96.0, and identified as *nootkatin* (mixed m. p., I.R.). Fraction 4 consisted of β-thujaplicin, nootkatin and three further compounds with lower R_F values than the first two, fraction 5 mainly of *β-thujaplicin* which however could not be crystallised.

Neutral fraction

The neutral oil F was fractionally distilled through a one metre, vacuum-jacketed, packed column, giving the fractions listed in Table 1.

Table 1. Distillation of fraction F. Total distillate 81.7 g or 80 %.

Fraction	Weight (g)	B.p. (°C)	Pressure (mm Hg)	Rotation ($[\alpha]_D$)	Refractive index (n_D^{25})
1	11.3	101.0–126.5	14	−44.4	1.4933
2	14.9	126.5–135.0	14	−66.4	1.5040
3	12.8	135.0–155.5	14	+27.4	1.5094
4	12.0	155.5–156.0	14	+42.9	1.5079
5	17.8	156.0–160.5	14	+12.6	1.5117
6	12.9	up to 230°	2	+ 3.9	1.5202

Gas chromatographic examination of the sesquiterpene hydrocarbon fractions. A Pye Argon Chromatograph, Cat. No. 12 000, was used together with a Philips Automatic Compensator PR 2210 A/21. (Column length 1.20 m, internal column diameter 5 mm, stationary phase 100–115 mesh Silocel C 22 brick powder impregnated with 2,4-dinitrophenyl-2-naphthyl ether (15 %) and dibenzylpyridine (a mixture of 2,4- and 2,6-isomers, 0.75 %) [11], temperature 150°, charge 0.025 µl, argon flow rate 0.32 ml/sec.

The following peaks were obtained. Recorder deflection (mV) given as a function of time (min). Fractions refer to those in Table 1.

Fraction 1, 9 (17.8); 23 (24.9); 60 (27.2); 9 (29.6).

Fraction 2, 2 (17.8); 12 (24.9); 66 (27.2); 4 (34.7); 4 (39.2); 5 (42.7).

Fraction 3, 7 (27.2); 11 (42.4); 9 (48.9); 8 (60.0).

The peak at 24.9 min corresponded to synthetic *α-cedrene* prepared from cedrol, the peak at 27.2 min to pure thujopsene and the peak at 60.0 min to cuparene.

Thujopsene. Fraction 2 (Table 1, 2.1 g) in 95 % ethanol (40 ml) was refluxed with selenium dioxide (1.2 g) for 4 h. The product was filtered, evaporated to dryness and the residue distilled in a high vacuum. On standing a crystalline precipitate (372 mg) was formed; this was collected by filtration, recrystallised from light petroleum, m. p. 73.5–74.5° and identified as widdrenal [6,8] (mixed m. p., I.R.).

Cuparene. Fraction 3 (Table 1) was redistilled through a spinning band column. The fraction (1.36 g) showing the strongest absorption at 1 525 cm^{-1} was ozonised in methylene chloride at −70°C until an excess of ozone was indicated by the appearance of a blue colour. When the reaction mixture had reached room temperature, hydrogen peroxide (30 %, 4 ml) in potassium hydroxide (10 %, 1.5 ml) was added dropwise. A large quantity of ether was added, the organic phase was separated, washed with water and evaporated giving a viscous oil. This was chromatographed on basic alumina (40 g). The first 100 ml of light petroleum eluted a hydrocarbon (191 mg) which was distilled under reduced pressure. The fraction boiling at 115°/7 mm, n_D^{25} 1.5215, $[\alpha]_D$ +65° (*c*, 1.9) was identified with *cuparene* [7] by comparing its physical constants and infrared spectrum with those of an authentic sample.

Widdrol. Fraction 4 (Table 1) crystallised partly on standing. A sample of this fraction (7.0 g) was filtered, the crystals (684 mg) were washed with light petroleum and recrystallised from acetonitrile, m.p. 95.0–96.0°, $[\alpha]_D$ +103° (*c*, 2.1) identified as widdrol [8] (mixed m. p., I.R.).

Attempts to isolate cedrol. Crude widdrol obtained from fraction 4 (Table 1, 204 mg) was chromatographed on basic alumina. Light petroleum eluted a small quantity of hydrocarbon; 2 % ether in benzene gave an oil with an infrared spectrum different from that of cedrol; ether-benzene (1:1) eluted widdrol.

A sample (1.52 g) of the mother liquor obtained when widdrol was separated from fraction 4 (Table 1) was ozonised as described for cuparene (see above) and the product separated into acidic and neutral fractions with sodium carbonate (2 N). The neutral fraction was chromatographed on basic alumina but no cedrol could be detected. Crude widdrol (204 mg) obtained from fraction 4 (Table 1) was ozonised and chromatographed in the same way but no cedrol was obtained in this case either.

"*Widdringtonia diol.*" In the chromatography of the neutral part of the ozonisation product obtained from crude widdrol, elution of the column with methanol gave a crystalline compound (4 mg). This was recrystallised from light petroleum, m. p. 153—154° and identified (mixed m. p., I.R.) as a "diol" previously isolated from *Widdringtonia juniperoides* [8].

High boiling carbonyl compounds. A sample of fraction 5 (Table 1, 10.0 g) in 95 % ethanol containing 10 % acetic acid (30 ml) was refluxed with Girard D reagent (3.0 g) for 30 min. The reaction mixture was diluted with about five volumes of ice-water and extracted with ether. The aqueous phase was acidified with an equal volume of hydrochloric acid (4 N) and extracted with ether. The ether solution, on evaporation, afforded an oil (1.09 g) which partly crystallised on standing. The crystals (183 mg) were separated by filtration, washed with light petroleum, recrystallised from the same solvent and sublimed in a high vacuum, m. p. 107.5—108.0°, $[\alpha]_D$ +75 (*c*, 1.4). (Found: C 81.5, 81.1; H 10.5, 10.2; $C_{15}H_{24}O$ requires C 81.8; H 11.0.) 2,4-dinitrophenyl-hydrazone, m. p. 198—199°.

Acknowledgements. My thanks are due to Professor H. Erdtman for collecting the initial wood sample used and for his interest in this work, to Dr. Edward G. Locke, United States Department of Agriculture, Forest Service, Forest Products Laboratory, Madison, Wisconsin, for further gifts of material and to Ing. R. Ryhage, Karolinska Institutet, Stockholm, for determination of the mass spectrum of utahin.

I also wish to thank Miss G. Hammarberg for the infrared and ultraviolet spectra and the *Swedish Natural Science Research Council* for financial support.

Chromatographic Determination of Ascorbic Acid

INGOLF CROSSLAND

Statens Vitamin Laboratorium, Copenhagen, Denmark

A description is given of a quantitative, chromatographic method for the determination of ascorbic acid. According to this method ascorbic acid is separated from interfering substances by chromatography on a cellulose column and determined in the eluate by means of diazotised nitroanisidine. Determinations of ascorbic acid contents down to 1 mg per 100 g in various materials have been tabulated to show the applicability of the method.

A survey of the literature on chemical assay of ascorbic acid in biological materials shows that the specificity of most of the methods used is not very satisfactory.

Thus the method most widely used, *i.e.* titration with an oxidizing reagent, as for instance dichlorophenol-indophenol [1,2], depends solely on the power of reduction of ascorbic acid, and this has certainly proved to give reliable results in the assay of, for instance, most fresh vegetables and fruits, but too high results in the assay of many other materials, for instance dried foods, which contain foreign, reducing substances. Descriptions of methods endeavouring to overcome this difficulty, thereby improving the specificity of the method, abound in the literature (*cf.* review by Sebrell and Harris [3]), but since the chemical nature of the reducing substances concerned are often unknown, it will generally be impossible with absolute certainty to eliminate the process of reduction resulting from their presence.

Another method is to oxidize ascorbic acid to form dehydroascorbic acid and determine the resulting carbonyl function by means of 2,4-dinitrophenylhydrazine [4]. There is a risk, however, that other aldehydes and ketones, partly resulting from the process of oxidation, may react with the reagent, leading to falsely high ascorbic acid values.

A third method for chemical assay of ascorbic acid, devised by Schmall *et al.*[5], depends on the condensation of ascorbic acid with a diazotised *o*-nitroaniline derivative in acid solution and spectrophotometric measurement in alkaline solution of the resulting hydrazide of oxalic acid. Moor [6] has modified the method, adapting it for the determination of ascorbic acid in foods. In this laboratory it has been found, however, that Moor's method may fail when the extract is low in ascorbic acid while at the same time containing substances

which produce high blank values. In a few cases the extinction determined for the blank was found to be higher than the extinction determined for the analytical sample.

A generally applicable way of improving the specificity of the assay involves chromatographic purification of the ascorbic acid prior to the chemical assay. The literature contains many examples of paper-chromatographic separation of ascorbic acid from interfering substances [7-9], but it appears to be difficult to avoid loss of ascorbic acid during the fairly protracted chromatographic separations. Moreover, it is possible to use a limited volume of extract only for this chromatographic separation, since the paper cannot "carry" any large amount of accompanying substances or of the metaphosphoric acid required for the extraction. As a consequence the sensitivity obtained is not satisfactory.

According to the method described in the following these difficulties have been overcome. The method depends on the purification of the ascorbic acid by chromatography on a column, and this has made possible the determination of ascorbic acid contents as low as 0.4 mg ascorbic acid per 100 ml extract. The content of the ascorbic acid in the purified solution is determined according to a modified version of the method devised by Schmall *et al.*[5] mentioned above.

EXPERIMENTAL

Principle of method. The procedure consists in:

(1) extraction of ascorbic acid with metaphosphoric acid,

(2) preliminary treatment of the extract, enabling it to be transferred to a cellulose column,

(3) chromatography of the extract, elution with a mixture of butanol-water-acetic acid,

(4) determination of ascorbic acid in the eluate by means of diazotised 2-nitro-4-methoxyaniline, which interacts with ascorbic acid to form — after shaking with a sodium hydroxide solution — the disodium salt of oxalic acid 4-methoxy-2-nitro-phenylhydrazide, the extinction of which at 570 mμ is proportional to the content of ascorbic acid.

Reagents

(1) *Metaphosphoric acid, 5 %.* Dissolve 5 g "metaphosphoric acid", analytical grade (HPO_3 containing 50—60 % $NaPO_3$), in 100 ml water. Prepare fresh solution on the day of using.

(2) *Acetone,* pure grade.

(3) *Acetone, aqueous solution, 50 % v/v.*

(4) *Acetic acid,* analytical grade.

(5) *n-Butanol,* analytical grade.

(6) *Ethylenediamine-NNN'N'-tetraacetic acid, disodium salt, 10 %.* Dissolve 10 g ethylenediamine-NNN'N'-tetraacetic acid, disodium salt ($C_{10}H_{14}O_8N_2Na_2$, $2H_2O$) in 100 ml water.

(7) *Ethylenediamine-NNN'N'-tetraacetic acid, 0.2 %.* Mix 2 ml 10 % ethylenediamine-NNN'N'-tetraacetic acid (reagent 4) with 2 ml acetic acid and dilute to 100 ml with water. This solution is supersaturated with regard to the free ethylenediamine-NNN'N'-tetraacetic acid, but is good for one week.

(8) *Eluant.* Mix 5 ml ethylenediamine-NNN'N'-tetraacetic acid, 0.2 %, (reagent 7) with 14 ml water, 1 ml acetic acid and 100 ml *n*-butanol by shaking vigorously until the mixture is (apparently) homogeneous. Prepare on the day of using.

(9) *Ascorbic acid,* reference standard, 100 μg/ml. Dissolve 50.0 mg ascorbic acid in 0.2 % ethylenediamine-NNN'N'-tetraacetic acid (reagent 7) and dilute to 50 ml with

this reagent. To a 2 ml portion of this solution add 1 ml acetic acid and dilute with *n*-butanol to 20 ml. This may cause some ethylenediamine-NNN'N'-tetraacetic acid to precipitate.

(10) *Diazotised nitroanisidine.* Mix 1 ml of a solution of 4-amino-3-nitroanisole ($C_7H_8N_2O_3$; dissolve 190 mg in 6 ml acetic acid and dilute to 100 ml with 1 N hydrochloric acid) and 0.1 ml sodium nitrite solution (dissolve 800 mg $NaNO_2$ in 100 ml water). Dilute the colourless solution with 1 ml 96 % ethanol and 2 ml *n*-butanol with stirring. The reagent is now ready for use and will keep for about one hour.

(11) *Cellulose powder.* Whatmann Cellulose Powder, standard grade.

(12) *Sodium hydroxide, 2 %.*

PROCEDURE

Cellulose column for chromatography. The chromatographic tube (*cf.* Bro-Rasmussen and Hjarde [10]) is about 40 cm long (internal diameter 12 mm) with a widening at the top holding 20—30 ml eluant and at the bottom terminating in a capillary tube, about 1 cm long (internal diameter 1 mm, external diameter about 7 mm).

Suspend 10 g cellulose powder in about 100 ml acetone, transfer directly to the chromatographic tube and force through the latter by means of carbon dioxide (at about 0.5 atm). Whenever the capillary tube gets choked with cellulose powder, and a little powder has collected at the bottom, clean the capillary tube with a piece of wire, providing free passage for the acetone. When all the powder has been transferred to the column — using as much acetone as required for this purpose — and the acetone has been forced out without allowing air to enter the cellulose, force the following liquids through the column in the order stated: 2 ml 50 % acetone (reagent 3), 2 ml 10 % ethylenediamine-NNN'N'-tetraacetic acid (reagent 6), 2 ml 50 % acetone (reagent 3), and, finally, 25 ml eluant (reagent 8), each liquid being pressed down to the surface of the column before the next is transferred to the column.

Extraction. Accurately weigh out a sample of not more than 30 g, if necessary under a 5 % solution of metaphosphoric acid, transfer to a Waring blendor with 100 ml 5 % metaphosphoric acid, bubble carbon dioxide through the solution and homogenize. Fill up to 250 ml with water and centrifuge.

From this stage it is necessary to protect the ascorbic acid from daylight, the effect of which is to decompose ascorbic acid. This decomposition causes most trouble in highly diluted solutions.

Preliminary treatment of extract. For the chromatography use, preferably, a volume of extract that contains about 20 μg ascorbic acid. If 0.5 ml extract (or an even smaller volume) is sufficient, add 1 ml acetic acid and a little cellulose powder (up to 0.5 g) to the sample drawn, stir and dilute with 5 ml *n*-butanol.

If more than 0.5 ml extract is used for the analysis, evaporate to a volume which is less than 0.5 ml by means of a stream of electrically heated carbon dioxide, and continue as described above.

In case the volume of the extract sample is more than 0.5 ml, it may be necessary to add hydrochloric acid. As regards this, *cf.* comments on the method.

Chromatography. Stir the suspension carefully and transfer quantitatively to the column by means of a pipette. Begin measuring the volume of the collected eluate from the moment the sample is transferred to the column. Force the sample through the column by means of carbon dioxide (at about 0.5 atm) and wash with three to four 1—2 ml portions of eluant, the liquid being pressed down to the surface of the column following each transference of eluant. Any lumps of cellulose from the sample left in the column should immediately be disintegrated with a spatula. Following the quantitative transference of ascorbic acid material to the column, pour eluant directly into the chromatographic tube and collect the following fractions:

(a) 34 ml, which contains the liquid front and is discarded.
(b) 10 ml, which should not contain any ascorbic acid.
(c) 13 ml, main fraction, which should contain all the ascorbic acid present.
(d) 10 ml, which should not contain any ascorbic acid.

Transfer fractions b, c and d to 50 ml separatory funnels, washing down with 5, 2 and 5 ml eluant, respectively, the volume of liquid in the separatory funnels being thus, in all cases, 15 ml.

Determination of ascorbic acid. To each of the samples b, c and d and to a reference sample (15 ml eluant to which has been added 0.200 ml ascorbic acid standard solution (reagent 9)) in separatory funnels add 0.200 ml diazotized nitroanisidine (reagent 10) and mix by swirling the separatory funnels for 0.5 min following each addition. The period of reaction should not be less than 5 min. Then carefully add 10 ml 2 % sodium hydroxide solution from a pipette, running the solution along the wall of the separatory funnel so as to prevent the two phases from mixing before the subsequent shaking. Now, as quickly as possible, shake vigorously for about one minute. Run out the aqueous solution and centrifuge for 5 minutes. Measure the extinction in the spectrophotometer in a 5 cm cell at 570 mμ.

Since the content of ascorbic acid in the sample is proportional to the extinction measured, the content of ascorbic acid can be calculated from the extinctions of the reference standard and the main fraction, the mean value of the extinctions of the fractions immediately before and after the main fraction being used as blank, *cf.* Discussion.

COMMENTS

re extract. The problems connected with the extraction does not differ from those met with in other methods for ascorbic acid analysis. Metaphosphoric acid solution is now generally acknowledged to be the best extraction agent, oxalic acid, which is otherwise frequently applied, having proved to be unsuitable [11].

To ensure reproducibility of the chromatography, the pH of the extract must be adjusted at about 1, too high pH values resulting in too high retention volumes, while too low pH values (caused for instance by excess of strong acids as trichloroacetic acid) result in too small retention volumes, *i. e.* ascorbic acid will be present in the fractions immediately after or immediately before the main fraction. When the above procedure is followed for the preparation of the extract, the acidity of the latter will in most cases be as required, and the chromatography will proceed satisfactorily without ascorbic acid in the fractions before and after the main fraction. This applies to all the vegetables mentioned in Table 1. It has been found, however, that in the chromatography of a product as cod roe some ascorbic acid will be present in the fractions immediately after the main fraction (5 ml extract was reduced by evaporation before being chromatographed), which is presumably due to a too high pH value of the extract. For this reason 0.1 ml hydrochloric acid (about 3 N) was added per 5 ml extract. This addition is based on qualitative experiments which have shown that chromatography of pure ascorbic acid solutions to which had been added 100 mg "HPO_3" (an analytical preparation containing about 60 % $NaPO_3$) — which corresponds to the quantity of "HPO_3" present in 5 ml extract — results in complete separation, *i. e.* no ascorbic acid in the fractions before and after the main fraction. If about half of the $NaPO_3$ present is neutralized by means of 0.1 ml hydrochloric acid (about 3 N), the ascorbic acid will still be retained quantitatively in the main fraction. This means that whenever the pH of the extract is expected to be too high, it is possible to ensure complete separation by adding hydrochloric acid in the above quantities. Only in the case of extracts which required evaporation did it prove necessary to add hydrochloric acid.

A reasonable accuracy is ensured by transferring a quantity of extract which contains 10—30 μg ascorbic acid to the column. If less than this amount of ascorbic acid is present in 0.5 ml of the extract, a suitable volume must be withdrawn and evaporated to a volume which is less than 0.5 ml. Such evaporation is conveniently performed in a 10 ml sample tube by means of a slight stream of electrically heated carbon dioxide. Temperature and rate of flow must be adjusted so that the tube with the sample is just tepid to the touch. The quantity of extract which may be transferred to the column depends on the nature of the extract, as excessive quantities of extracted substances may in the first place impede the quantitative transference of the sample to the column, because after the butanol addition the cellulose powder may become very tacky, and, in the second place, delay the passage of the ascorbic acid so that traces of ascorbic acid may be present in the fractions following the main fraction. The aim of the abovementioned addition of

cellulose powder to the sample is to enable this cellulose powder to adsorb the components of the extract which are precipitated by the 5 ml *n*-butanol added. Qualitative experiments show that when using 100 mg glucose with 0.3 ml water, 100 mg "HPO_3" and 0.1 ml 3 N hydrochloric acid, the fractions before and after the main fraction will be free from ascorbic acid, while when 250 mg glucose is used instead of 100 mg, the fraction after the main fraction will contain traces of ascorbic acid. The sensitivity of the method depends on these factors. As it appears from Table 1, the volume of the largest sample withdrawn for evaporation and chromatography in the course of the present work was 5 ml.

re chromatographic column. The presence of ascorbic acid in the different fractions collected depends, of course, on the dimensions of the chromatographic tube. Experience has shown that the reproducibility is very good from chromatogram to chromatogram using the same chromatographic column. Whether the dimensions of the column are correct may be checked by measuring the length of the column of cellulose powder, which should be between 31 cm and 33 cm, and by test chromatography as described in the following.

Chromatograph 200 μl of the "strong" standard solution (reagent 9), which contains 200 μg ascorbic acid (adding 1 ml acetic acid, a little cellulose powder, and 5 ml *n*-butanol and pouring this mixture into the tube). Collect the following fractions: 1 (34 ml), 2 and 3 (2 × 5 ml), 4 (2 ml), 5 (5 ml), 6 (4 ml), 7 (2 ml), and 8 (5 ml). Discard fraction 1, and to each of the following add 200 μl diazotised nitroanisidine (reagent 10). Extract the dye by shaking with 1 ml 5 % sodium hydroxide solution. Fractions 5 and 6 should contain the ascorbic acid, while fractions 4 and 7 must show only faint traces of blue colour. If tubes of other dimensions are to be used, the procedure of this qualitative chromatographic separation should be modified to indicate the fractions in which the ascorbic acid occurs in this case.

When acetone is used for charging the tube with cellulose powder, a tightly packed and readily reproducible column will be obtained. Treatment with 2 ml of 10 % aqueous solution of the disodium salt of ethylenediamine-NNN'N'-tetraacetic acid prevents oxidation of the ascorbic acid in the column due to catalytic action of copper and, more-

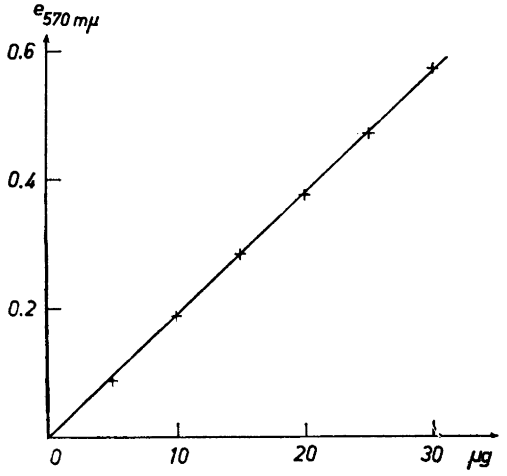

Fig. 2. Standard curve. Abscissa: μg ascorbic acid per 15 ml eluant. Ordinate: extinction at 570 mμ in a 5 cm cell.

over, due to its content of water, ensures that the cellulose powder is saturated with water, which is essential to obtain a reliable chromatographic separation.

re eluant. The eluant should be stabilized by means of ethylenediamine-NNN'N'-tetraacetic acid. The solubility of this substance in the butanol phase is very low, but the stabilizing effect appears clearly from the curve in Fig. 1. Ethylenediamine-NNN'N'-tetraacetic acid does not protect ascorbic acid against the action of light, and artificial illumination should therefore be used throughout. The eluant should be freshly prepared. All distilled water used in these experiments has been condensed in metal equipment and has not been redistilled.

The chromatographic separation is performed rapidly, only 30 min passing from the moment when the sample is transferred to the column and until the final fractions have passed out of the column.

re ascorbic acid determination. The reagent has been chosen with a view to ensure maximum specificity. Experience shows that the extinction of the interfering substances accompanying ascorbic acid in the chromatographic separation generally decreases with increasing wavelength in the range 400 mμ to 600 mμ, consequently a reagent should be chosen which forms a hydrazide of oxalic acid with absorption maximum at the greatest possible wavelength. From this point of view 2-nitro-4-methoxyaniline was the best reagent available.

The interaction of diazotised nitroaniline and ascorbic acid is not instantaneous, maximum yield is obtained by allowing 5—20 min for the reaction.

It is important to follow closely the instructions given with regard to the extraction of the reaction products by means of sodium hydroxide solution. If the mixing of the phases is effected by a slow and cautious shaking, the yield of hydrazide will be reduced.

The colour will not persist for an unlimited period. Following the procedure described, the reduction will be about 1 % per hour at an extinction of 0.400 (corresponding approximately to the 20 μg standard).

In the above description of the procedure the use of only one reference standard sample is prescribed. This has been shown to be justified, as the standard curve (see Fig. 2) has been found to be linear within the range 0—30 μg.

RESULTS AND DISCUSSION

Table 1 summarizes the results of determinations of ascorbic acid obtained by the chromatographic method and by titration with dichlorophenol-indophenol in various biological materials. The following discussion of the specificity and accuracy of the method is based on these measurements taken together with recovery experiments and chromatographic determinations of substances of special nature.

One of the requirements which must be fulfilled to obtain a correct determination of an ascorbic acid content by the chromatographic method is that the extinction determined at 570 mμ in the main fraction derives exclusively from the interaction between the reagent and ascorbic acid. Without a more thorough examination it is not possible to determine whether this is the case. There may be coloured substances in the extract which pass out together with ascorbic acid in the main fraction and is transferred from here to the sodium hydroxide phase, and there may be ascorbic acid analogs which are not separated by chromatography and which react with the reagent in the same way as ascorbic acid.

As it appears from the table illustrating the chromatographic separations performed (Table 1), experience shows, however, that the extinctions measured in the fractions before and after the main fraction are small in the case of nearly all materials. It has been assumed, therefore, that coloured substances

20.1	5 [b]	20.0	100

a. 5 ml extract of cod roe in 2 % metaphosphoric acid + 0.1 ml appr. 3 N hydrochloric acid + a solution of dichlorophenolindophenol until total oxidation of ascorbic acid. Excess of oxidizing agent is destroyed by allowing the acid solution to stand overnight. 20.0 μg of ascorbic acid is added and the solution is reduced by evaporation to a volume of less than 0.5 ml.

b. 5 ml of a solution of 2 % metaphosphoric acid to which 20.2 μg ascorbic acid is added, is evaporated till the volume is less than 0.5 ml.

fraction. As an exception may be mentioned the highly coloured beet root extract, in the case of which the extinction of the fraction after the main fraction is too high to be used as a blank, and that the ascorbic acid value found therefore must be considered merely to represent a maximum value. Incidentally, this very low value as compared to the titration value tends to confirm the results obtained by Somer *et al.*[12]

*Iso*ascorbic acid and glucoascorbic acid interact with the diazonium reagent and with sodium hydroxide to form the same hydrazide as ascorbic acid. It is impossible by chromatography to separate *iso*ascorbic acid and ascorbic acid, while glucoascorbic acid will follow immediately after ascorbic acid in the chromatogram, *i.e.* in the fraction after the main fraction. Consequently it is not possible according to this method to distinguish between ascorbic acid and *iso*ascorbic acid. Other substances, related to ascorbic acid, which might be expected to interfere in the analysis in this way have not been studied.

In addition to the condition mentioned in the above, which must be fulfilled to ensure correct results, the main fraction must not contain substances the presence of which results in a reduction of the yield obtained from the reaction.

Sulphur dioxide may interfere in this way, since it passes the chromatographic column together with ascorbic acid, resulting in too low ascorbic acid values. If thus the molar ratio of sulphur dioxide to ascorbic acid is as 1:1, the yield of hydrazide will be 5 % too low. However, sulphur dioxide may be removed from the acid extract by bubbling carbon dioxide through the solution.

The reliability of the method in general may be judged by comparing the results obtained when applying the titration method and the chromatographic

method to vegetables and fruits and also by the results of recovery experiments, as those represented in Table 2.

All ascorbic aid determinations hitherto made according to the described method have been included in Table 1. Agreement between the results obtained according to the two methods are seen to be fairly good with regard to most of the vegetables, while considerably lower values are found in the case of products of animal origin and dehydrated vegetables. It should be mentioned that the titrations have been performed by means of dichlorophenol-indophenol, if necessary after extraction with chloroform (a modification of the xylene method [13] generally used with coloured or turbid extracts), without any attempt at improvement of the specificity.

It will be seen that in the case of nearly all the samples the extinction values obtained from fractions before and after the main fraction are small; this applies also to the samples with regard to which chromatography of 5 ml extract was necessary.

It appears from the recovery experiments (Table 2) that the losses resulting both from chromatography and evaporation are very small. An experiment with cod roe extract, in which the ascorbic acid was first oxidized with dichlorophenol-indophenol before the addition of the 20 μg ascorbic acid, also shows that the content of ascorbic acid is maintained quantitatively throughout the procedure.

The sensitivity of the method depends on the nature of the sample and on the demands made as to accuracy. It appears from Table 1 that in protein-containing materials, as for instance cod roe, it is possible to determine ascorbic acid contents down to a concentration of about 3 mg per 100 g without reducing the demands as to a reasonably large deflection of the measuring instrument.

Note added in proof. Apples contain a colourless substance (or several substances) which very nearly follows ascorbic acid on the column and gives a reddish colour with the reagent, thereby interfering with the determination. The chemical nature of the substance has not been investigated.

The author wishes to thank Dr. phil. Willy Hjarde for his very kind interest in this study.

Studies on the Hydrolysis of Metal Ions

28. Application of the Self-medium Method to the Hydrolysis of Lead(II) perchlorate Solution

ÅKE OLIN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of Pb(II) has been studied at high Pb^{2+} concentrations, B, in order to enhance the relative amounts of species with a OH^-/Pb(II) ratio < 1. The equilibrium solutions measured had the general composition

B M Pb(II), H M H^+, $(3-2B-H)$ M Na^+, 3 M ClO_4^-

and the hydrolysis was followed to $Z = 0.15$ for $B = 1.490$, 0.990 and 0.500 M. Z is the average number of OH^- groups bound to each Pb(II). If it is assumed that the activity factors stay constant at low Z, the data up to $Z = 0.10$ may be interpreted by the following reactions and equilibrium constants

$4\,Pb^{2+} + 4H_2O \rightleftharpoons Pb_4(OH)_4^{4+} + 4H^+$; $\log \beta_{4,4} = -19.25$ ($B = 0.50$ M), -19.23 ($B = 0.99$ M), -19.28 ($B = 1.49$ M).

$2Pb^{2+} + H_2O \rightleftharpoons Pb_2OH^{3+} + H^+$; $\log \beta_{1,2} = -6.45$ ($B = 0.50$ M), -6.45 ($B = 0.99$ M), -6.34 ($B = 1.49$ M)

For higher values of Z deviations appear which may be due either to complexes other than Pb_2OH^{3+} and $Pb_4(OH)^{4+}$ or to variations in the activity factors.

In a previous study [1], where the hydrogen ion concentration and the concentration of Pb^{2+} in hydrolysed lead(II) perchlorate solutions were measured, evidence was presented for the formation of the species $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$, $Pb_6(OH)_8^{4+}$ and $PbOH^+$. At the highest Pb(II) concentrations then studied (0.080 M and 0.040 M) there were indications of complexes with a OH^-/Pb(II) ratio < 1 at small degrees of hydrolysis. However the concentrations of these complexes were so small that their formulas could not be found. The self-medium method recently used by Hietanen and Sillén [2] in studies on the hydrolysis of Th^{4+} and UO_2^{2+} seemed to be useful for solving the present problem. The concentration of the unknown species could be expected to be favored by a high metal ion concentration.

When we are dealing with complicated equilibria in solution it is desirable to keep the activity factors constant so that concentrations can be used instead of activities in the law of mass action. Usually this is brought about by the addition of a large amount of a neutral salt. This method has been termed the inert medium method. However if only a minor part of the ions in for example a concentrated metal salt solution is converted to other species by complex formation one might hope that the ionic invironment would be but slightly changed and that therefore as a good approximation concentrations could be used instead of activities. Future experience with the method will show how far this approximation can be used. In the following we shall assume that the activity factors stay constant in the Z range studied here.

The more common symbols used are listed below for reference.

B total concentration of Pb(II)
b concentration of Pb^{2+}
H analytical hydrogen ion concentration (often negative)
h actual hydrogen ion concentration
Z average number of OH^- groups bound per Pb(II) atom
$\beta_{p,q}$ equilibrium constant for the reaction $qPb^{2+} + pH_2O \rightleftharpoons Pb_q(OH)_p^{(2q-p)+} + pH^+$

$y(x)_v$ y as a function of x at constant v
All concentrations are expressed in mole/l (M).

EXPERIMENTAL

Method and apparatus. In the present study we have made a minor alteration in the original method and decided to add $NaClO_4$ to our solutions so that they were always 3 M in ClO_4^-. At the highest total lead(II) concentration studied, 1.490 M, the compositions of the solutions corresponded to the self-medium idea but for the lower values of B the compositions of the solutions approached the inert medium method, but with the restriction that Z was allowed to reach a value of *ca* 0.1 only. The limit set for Z is quite arbitrary. The highest value of Z for which the approximation of constant activity factors may be used, is probably dependent on what species are formed. It may also be dependent on B.

The general composition of the solutions, S, investigated was

B M Pb(II), H M H^+, $(3-2B-H)$ M Na^+, 3 M ClO_4^-

The values of B used were 1.490, 0.990 and 0.500 M. B was kept constant in each run and H was varied by the addition of NaOH. The experiments were carried out as potentiometric titrations in an oil thermostat at 25.0°C. Log h was measured with a calibrated glass electrode using the cell

$$(-) \text{ ref / S / glass } (+) \quad \text{(I)}; \; E = E^0 + 59.15 \log h + E_j \qquad (1)$$

The reference half-cell used was

$$\text{ref} = 3 \text{ M } ClO_4^-, \; (3-2B) \text{ M } Na^+, \; B \text{ M Pb(II) / Pb–Hg}$$

The emf of cell (I) was registered on a Radiometer valve potentiometer (PHM4) to ± 0.2 mV.

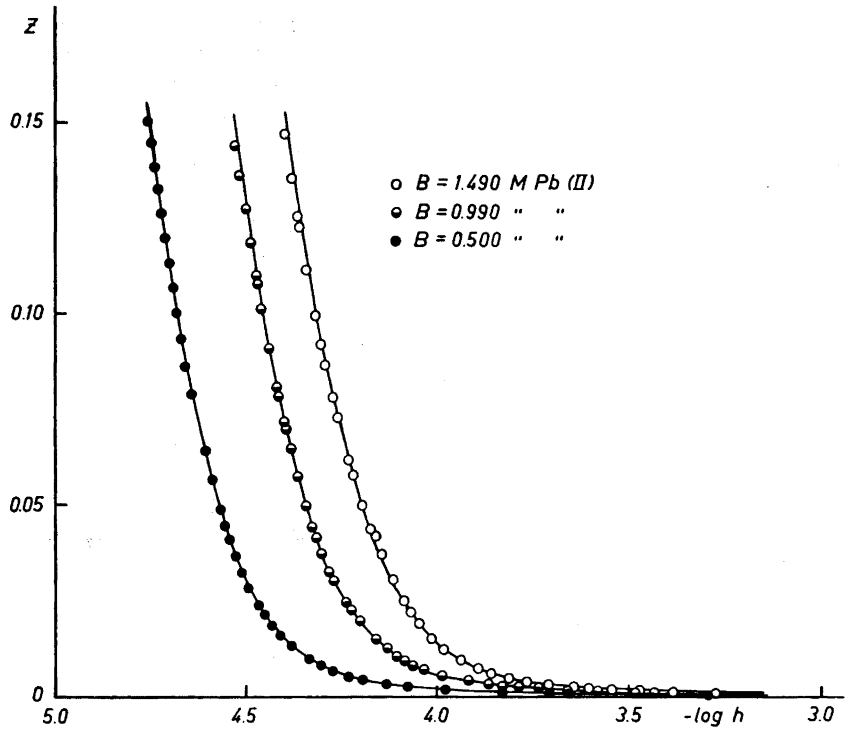

Fig. 1. Z, average number of OH^- bound per Pb(II) atom as a function of log h. Drawn curves have been calculated with the equilibrium constants given in the text.

Experimental details. The liquid junction potential, E_j, in cell (I) was determined in acid solution for $0.005 < h < 0.025$ M by replacing the glass electrode by a lead amalgam electrode. E_j was calculated from the emf's by the procedure described by Biedermann and Sillén [3]. The values thus found could be represented by $E_j = -(18 \pm 3)\,h$. The experimental accuracy did not allow us to determine the coefficient more accurately than this. For the calculations of our experimental quantities, E°, log h and Z this uncertainty was without importance. The numerical value of the coefficient is reasonable considering the value -16.7 found with 3 M $(Na)ClO_4$.

The starting solution contained B M Pb(II) and *ca.* 0.025 M $HClO_4$ in 3 M $(Na)ClO_4$. Equal volumes of NaOH solution and a solution of $Pb(ClO_4)_2$ of concentration $2B$ in 6 M $(Na)ClO_4$ were added from two burets thus keeping $[Pb(II)] = B$ and $[ClO_4^-] = 3$ M during a run. The first few points for $H > 0.01$ M were used to determine E° and the analytical hydrogen ion concentration of the starting solution by a Gran extrapolation [4]. This provided us with a check, since this concentration was also known from the analysis of the stock solutions used to prepare the starting solution.

Two NaOH solutions of different strengths were employed in each titration. The first solution (*ca* 0.15 M) was used to determine E° and to study the hydrolysis for $Z < 0.02$. The second base solution (at least 0.75 M) was then introduced and Z followed to 0.15. We had to use such a strong base in order to limit the volume of solution to a reasonable amount. When the strong base was added a large amount of precipitate was formed. On shaking the precipitate immediately dissolved without leaving any residue. At least three titrations were made for each value of B.

The equilibria were rapidly established. Within 10 min after each addition of base the emf of the glass electrode showed a constant value.

The $NaClO_4$, $HClO_4$ and NaOH solutions used in the present investigation were prepared and analysed as described previously [1].

The $Pb(ClO_4)_2$ solution was prepared by dissolving PbO (Baker, p.a.) in $HClO_4$ (Kebo, p.a.). The following procedure was used. The oxide was first repeatedly washed with distilled water and then dissolved in acid using an excess of the oxide. This gave us a slightly alkaline solution which was left standing for a week in order to precipitate foreign metal ions as the hydroxides. After filtration the solution was analysed to determine the deficit of hydrogen ions, and a calculated amount of $HClO_4$ was added in order to give the solution the analytical composition $Pb(ClO_4)_2$. Upon addition of the acid the solution turned light brown from the presence of tetravalent lead. The PbO_2 was destroyed by adding platinum black and bubbling with H_2 gas for a few hours. The solution so prepared was optically blank (reference H_2O) for $\lambda > 2\,800$ Å. At $\lambda \sim 2\,800$ Å Pb(II) started to absorb light as indicated by a very rapid increase in the optical density of the solution.

The analysis of the solution was done as described previously [1].

RESULTS AND CONCLUSIONS

The data are presented giving Z as a function of $\log h$ in Fig. 1 and Table 1. Z is the average number of OH^- groups bound per lead(II) atom.

The hydrolysis was followed till Z reached *ca* 0.15. Our basic assumption will be that the activity factors stay constant at low values of Z. However we do not know the value of Z above which this ceases to be true.

We shall start our attempt to interpret the data by comparing the experimental $Z(\log h)_B$ with theoretical curves calculated on the assumption that only one of the complexes $(PbOH^+)_n$ with $n = 1, 2, \ldots$ is formed. From such a comparison we get an idea of how many OH^- groups are present in the complexes formed. The choice of a ratio $OH^-/Pb(II) = 1$ in the complexes is quite arbitrary, but since the number of metal atoms in the complex is less important than the number of OH^- groups in fixing the shape of the $Z(\log h)_B$ curve, a not too large change in this ratio would not alter our conclusions.

The 0.500 M titration fits well the theoretical $Z(\log h)$ curve for $Pb_4(OH)_4^{4+}$ at high values of Z. At lower values of Z the experimental curve is less steep than the theoretical curve. Complexes with $n = 4$ are thus indicated at high Z. At low Z complexes with < 4 OH^- must also be present.

The 0.990 M titration for high values of Z showed agreement with the theoretical $Z(\log h)$ curve for $Pb_3(OH)_3^{3+}$. However if the theoretical and experimental curves were made to fit at high Z values, the experimental curve became steeper than the theoretical curve at intermediate values of Z; this is an impossible result. At low Z the reverse is true. The same statements hold for the 1.490 M titration. From these two titrations we may draw the conclusion that at low Z complexes with < 3 OH^- are formed. It would appear unlikely that both $Pb_3(OH)_3^{3+}$ and $Pb_4(OH)_4^{4+}$ are present simultaneously in comparable amounts. If such were the case the deviations from the theoretical $Z(\log h)_B$ curve for $Pb_4(OH)_4^{4+}$ would have been most pronounced for $B = 0.500$ M, since a lower value fo B favors the formation of $Pb_3(OH)_3^{3+}$ relative to $Pb_4(OH)_4^{4+}$. No evidence for $Pb_3(OH)_3^{3+}$ was found in the previous work with 3 M $(Na)ClO_4$ medium.

It would be very reasonable if $Pb_4(OH)_4^{4+}$ it the main complex formed at high Z. This complex has been shown in a previous work [1] to predominate for lower B values in the Z region now investigated. The position of the $Z(\log h)_B$ curves on the log h axis is also in agreement with the value of $\log \beta_{4,4} = -21.25$ found earlier.

Now we turn to the data for very low Z. Whereas at low Z practically no information can be obtained from a single $Z(\log h)_B$ curve about the number of metal atoms in a complex, we can group the complexes with regard to the number of OH^- groups they contain. Also we are allowed to put $b \simeq B$. Thus we get

$$Z = \Sigma\, \beta_{1,q}\, B^{q-1}h^{-1} + 2\,\Sigma\, \beta_{2,q}B^{q-1}h^{-2} + \ldots p\,\Sigma\, \beta_{p,q}B^{q-1}h^{-p} \qquad (2)$$

If complexes with a certain value of p predominate we find

$$(\partial \log Z/\partial \log h)_B = -p \qquad (3)$$

A plot of log Z *versus* log h should then yield a straight line and p is found from the slope of this line. The presence of complexes with different values of p would give a curved line.

Provided that the changes of the activity factors are not too large on going from one value of B to another, information on the value of q can be found

from $(\partial \log Z/\partial \log B)_h$. For the case that complexes with one value only for q are present the difference quotient is equal to $(q-1)$.

Owing to the large value of the formation constant for $Pb_4(OH)_4^{4+}$, as estimated from the upper parts of the $Z(\log h)_B$ curves, the term for this complex in eqn. (2) is small only if $Z < 0.003$. Therefore it is necessary to substract the term for this complex in order to get a reasonably broad range in Z and $\log h$ from which to determine p.

The term for $Pb_4(OH)_4^{4+}$ was calculated with $b = B$ and assuming $\log \beta_{4,4} = -19.25$ which is the value found from the measurements with 3 M (Na)ClO_4. The choice is somewhat arbitrary but from the 0.500 M titration a value close to -19.25 was indicated by "curve fitting" against a normalized $Z(\log h)$ curve. The Z corrected for $[Pb_4(OH)_4^{4+}]$ will be denoted by Z_c. The calculations were performed only for $Z < 0.01$. The correction at this value of Z is *ca.* 0.005.

The $\log Z_c(\log h)_B$ plots did not deviate much from linearity, and the best straight lines were drawn through the points. The values of the slopes of these lines $(= -p)$ were, $B = 0.500$ M, $p = 1.1$; $B = 0.990$ M, $p = 1.0$; $B = 1.490$, $p = 1.1$. Since p must be a whole number we may conclude $p = 1$. The average value of $(\Delta \log Z_c/\Delta \log B)_h$ was 1.2. This would indicate $q = 2$.

From the above considerations it seems likely that the complex Pb_2OH^{3+} is formed at low Z. This complex has a ratio $OH^-/Pb(II) = 0.5$ whereas the ratio $OH^-/Pb(II) = 1$ in $Pb_4(OH)_4^{4+}$. The quotient $[Pb_2OH^{3+}]/[Pb_4(OH)_4^{4+}]$ would thus be expected to increase with B keeping Z constant. This is in agreement with the experimental results. The deviation of the experimental curves from the calculated $Z(\log h)_B$ curve for $Pb_4(OH)_4^{4+}$ is most pronounced for $B = 1.490$ M. Since the value of q is uncertain we shall briefly discuss other possibilities. For $q = 1$ we would have $PbOH^+$. This complex cannot predominate at low Z because the deviations from the theoretical curve should then be most pronounced for $B = 0.500$ M. From the value of $\log \beta_{1,1} = -7.9$ obtained with 3 M (Na)ClO_4 medium one would also expect the concentration of $PbOH^+$ to be very small. Values of $q > 2$ seem increasingly less likely from the geometry of the complexes. We will thus try to explain our data on the assumption that $Pb_4(OH)_4^{4+}$ and Pb_2OH^{3+} are the only important complexes formed.

Hietanen and Sillén [2] have outlined a method by which two equilibrium constants can be determined by fitting the experimental $Z(\log h)_B$ curves to a family of normalized curves. The shape of each normalized curve is determined by a parameter containing the two equilibrium constants. When the normalized curve has been found which fits the experimental curve best one equilibrium constant is found from the difference between the coordinates on the $\log h$ axes and the other from the parameter. This method has the advantage that it is based on a direct comparison of the experimental $Z(\log h)_B$ with the normalized curves. Therefore its is easier to judge if differences observed between the experimental and normalized curves are reasonable or not.

Now we shall derive the expression for our set of complexes Pb_2OH^{3+} and $Pb_4(OH)_4^{4+}$.

$$B = b + 2\beta_{1,2}b^2h^{-1} + 4\beta_{4,4}b^4h^{-4} \quad (4)$$

$$BZ = \beta_{1,2}b^2h^{-1} + 4\beta_{4,4}b^4h^{-4} \quad (5)$$

It will prove convenient to introduce

$$v = 4B\beta_{1,2}h^{-1} \text{ and } l = \beta_{4,4}/(4B\beta_{1,2}^4) \quad (6), (7)$$

Eliminating b we find

$$Z = v^{-1}(\sqrt{1 + v(1-Z)} - 1)^2 + l(\sqrt{1 + v(1-Z)} - 1)^4 \quad (8)$$

We were not able to express Z as a function of v explicitly. The $Z(-\log v)_l$ curves had to be calculated by successive approximations for each value of l tested. These calculations proved to be very timeconsuming. Therefore it was decided to determine preliminary values of $\beta_{1,1}$ and $\beta_{4,4}$ first. It may be noted, as can be seen directly from eqn. (8), that $Z(\log [h(1-Z)^{-1}])_B$ curves can be normalized explicitly. However we preferred a direct comparison with the experimental $Z(\log h)_B$ data.

Determination of preliminary values of $\beta_{1,2}$ and $\beta_{4,4}$. If approximate values of the equlibrium constants are known we can calculate l from eqn. (7). Then we know beforehand for what values of l our family of normalized curves can be expected to fit the experimental curves thus reducing the number of $Z(-\log v)_l$ curves which need to be calculated.

We shall determine the preliminary values of $\beta_{1,2}$ and $\beta_{4,4}$ from a projection map described by Biedermann and Sillén [5] (See also Ref.[6]). The formulas derived in Ref. [5] were used for calculations on systems where a transition from mononuclear to polynuclear complexes takes place. However analogous formulas can be derived for the case in which one polynuclear complex changes to another complex which is also polynuclear. In the present study we have a transition from Pb_2OH^{3+} to $Pb_4(OH)_4^{4+}$.

$$Z = \frac{\beta_{1,2}bh^{-1} + 4\beta_{4,4}b^3h^{-4}}{1 + 2\beta_{1,2}bh^{-1} + 4\beta_{4,4}b^3h^{-4}} \quad (9)$$

The following substitutions are introduced

$$k^3 = 4\beta_{4,4}; \quad u = kbh^{-4/3}; \quad v = \beta_{1,2}bh^{-1} \quad (10), (11), (12)$$

As the coordinates for the experimental data we shall use

$$x = \log B - \log h \quad (13)$$

$$y = \log B - 4/3 \log h \quad (14)$$

and as the corresponding coordinates for the projection map we shall use

$$X = x + \log \beta_{1,2} \quad (13a)$$

$$Y = y + \log k \quad (14a)$$

It is easily verified that

$$X = \log v + \log (1 + 2v + u^3) \quad (15)$$

$$Y = \log u + \log (1 + 2v + u^3) \quad (16)$$

$$Z = \frac{v + u^3}{1 + 2v + u^3} \quad (17)$$

Thus we can calculate $Y(X)_Z$ curves for different values of Z as the parameter. These curves are then fitted to the experimental $y(x)_Z$ curves and the equilibrium constants found from the differences between the coordinates on the axes. Cuts were made at $Z = 0.01$, 0.02, 0.03, 0.04 and 0.05. Since each $Z(\log h)_B$ curve has to be treated independently the $y(x)_Z$ curve degenerates to a single point. The method, in fact, is closely related to that given in Ref [7].

Final adjustment of $\beta_{1,2}$ *and* $\beta_{4,4}$. With l found from the values of $\beta_{1,2}$ and $\beta_{4,4}$ determined by means of the projection map, normalized curves were calculated. In addition curves were constructed also for values of l somewhat smaller and higher than those obtained from the preliminary $\beta_{1,2}$ and $\beta_{4,4}$.

It was not possible to find constants which could reproduce the data up to $Z = 0.15$ for the two highest values of B. The equilibrium constants given in the table account for the data to 0.001 Z unit or better in the Z range given in the fourth column.

B	$\log \beta_{1,2}$	$\log \beta_{4,4}$	Z
0.500 M	-6.45 ± 0.1	-19.25 ± 0.1	<0.15
0.990 M	-6.45 ± 0.1	-19.23 ± 0.1	<0.12
1.490 M	-6.34 ± 0.1	-19.28 ± 0.1	<0.10

We do not know the reason for the bad agreement at high Z for the two largest values of B. Beside experimental errors as an explanation it may be suggested either that complexes other than Pb_2OH^{3+} and $Pb_4(OH)_4^{4+}$ are also present or that the change in the ionic medium is too large for the activity factors to remain constant. The change of the ionic medium is larger the larger B is and one would expect the variations of the activity factors to show up for $B = 1.490$ M first. On the other hand the relative concentrations of complexes with a OH^-/Pb(II) ratio < 1 increase with B. We have not tried to achieve a better fit by introducing more complexes than those already considered because of the uncertainty of the activity factors.

The values of E^o obtained by putting $h = H$ in eqn. (1) for $0.010 < H < 0.025$ M may be slightly in error. Actually $h = H + [Pb_2OH^{3+}] + 4[Pb_4(OH)_4^{4+}]$. From the equilibrium constants we find that $[Pb_2OH^{3+}]$ would make h somewhat larger than H. $[Pb_4(OH)_4^{4+}]$ is very small and can be neglected. The error in E^o thus introduced is 0.2 mV at most. Practically this error is without importance for our conclusions and would only mean that the $Z(\log h)_B$ curves are slightly displaced along the log h axis.

Another error is caused by the neglect of the liquid junction potential between the hydrolysed solution and the solution in the reference half-cell. Using Henderson's equation and unpublished conductance data by G. Biedermann E_j was calculated to be *ca* 0.2 mV for the solutions of highest Z. Thus the error introduced by neglecting E_j is small.

The close agreement between the numerical values of the equilibrium constants for the different lead(II) concentrations is intriguing considering the differences in the cat-ionic part of the medium. The reason might be that the ratios of the activity factors in the law of mass action expression for the formation of these complexes stay constant, even though the individual activity factors vary. Hietanen and Sillén [2] have observed that the differences

between the numerical values of equilibrium constants which have been determined both with the inert medium method and with the self-medium method are of the order of 0.1 logarithmic unit. This appears to hold also for the formation constant of $Pb_4(OH)_4^{4+}$.

As was mentioned in the introduction previous measurements [1] with 3 M $(Na)ClO_4$ medium indicated the presence of complexes with a $OH^-/Pb(II)$ ratio < 1 at low Z and $B = 0.080$ M and 0.040 M from the fact that the experimental $OH^-/Pb(II)$ ratio was somewhat smaller than 1. The main complex in these solutions was identified as $Pb_4(OH)_4^{4+}$ but the concentrations of the other complexes with a $OH^-/Pb(II)$ ratio < 1 were so small that their formulas could not be found. Assuming $\beta_{1,2}$ to have the same value in 3 M $(Na)ClO_4$ medium as found here the concentration of Pb_2OH^{3+} was calculated from the previously published data. Except for the 0.080 M and 0.040 M titrations at low Z, $[Pb_2OH^{3+}]$ was found to be very small and, for these concentrations, to be consistent with the experimentally found $OH^-/Pb(II)$ ratios.

The formation of complexes of the general composition Me_2OH appears to be quite common. From measurements on hydrolysed $Pb(NO_3)_2$ solutions Pedersen [9] has earlier found evidence for Pb_2OH^{3+}. The value of log $\beta_{1,2}$ (extrapolated to zero ionic strength) found by him was -7.3. Other metal ions for which hydrolysis data have indicated such complexes include Be^{2+} (Ref.[8]), Cu^{2+} (Ref.[10]), UO_2^{2+} (Ref. [11]), and Th^{4+} (Ref. [2]). For the last three ions the complex only is present in appreciable concentrations for high values of B.

A New Method of Investigating the Enzymatic Inversion of Sucrose

BJØRN ANDERSEN and THOR A. BAK

Universitetets Fysisk-Kemiske Institut, Copenhagen

A new way of investigating the enzymatic inversion of sucrose is described. The reaction is followed by measuring the optical rotation of the solution, but instead of taking out samples in which the reaction can be stopped and measuring the optical rotation after the mutarotation of glucose and fructose has stopped, the measurements are performed directly on the reacting solution and a correction for the mutarotation is applied. The expression for the correction term is derived as a second order differential equation which is solved numerically by a step by step integration. The mutarotation constants for glucose and fructose have been determined and using these values and an assumed value for the optical rotation of β-fructofuranose it is shown that the correction term is in accord with experiments.

It is well known that sucrose is hydrolyzed in the presence of acids or the enzyme invertase. During the process the optical rotation (sodium light, 589 mμ) of the solution changes sign and the process is therefore known as the inversion of sucrose.

The classical investigation of the acid catalyzed inversion is due to Wilhelmy [1] who showed it to be a first order reaction or rather deduced the mathematical expression for a first order reaction from the experiments. Since then this reaction has been investigated several times and the mechanism is well known. Contrary to this the mechanism for the enzymatic hydrolysis which takes place at pH 4—7 is not known with certainty, although the reaction has often been investigated.

The results of the many experiments on the enzymatic inversion described in the literature are not all consistent with each other. This is probably due to the fact that the conventional method of following the reaction consists of taking out samples in which the reaction can be stopped and then measuring the optical rotation after the mutarotation has ceased If one does not add base which catalyses the mutarotation it is necessary to wait a long time before the measurements are performed. If on the other hand base is added the measurement must be performed very rapidly since fructose decomposes in alkaline solution.

The first of these possibilities (*i.e.*, stopping the reaction without catalysing the mutarotation) was used by Kjeldahl [2], who investigated the influence of temperature on the enzymatic inversion. He stopped the reaction by adding mercuric chloride which does not affect the mutarotation. In his papers he does not mention how long time he waited before he measured the optical rotation of the samples. The necessary time turns out to be in this case approximately 5 hours [3].

Among the other classical investigations we mention the work of Henri [4]. He used direct measurements of the reaction in the polarimeter tube and obtained in this way a perfectly reproducible curve for the apparent degree of reaction as a function of time, which he took to be an expression for the rate of inversion of sucrose alone. He furthermore found that a first order reaction constant calculated from the experimental data increased rapidly with time and concluded that the reaction is not a first order reaction in contrast to the result found earlier by O'Sullivan and Tompson [5]. The last mentioned authors incidentally were the first to use the above described technique in which mutarotation is catalyzed by the addition of base.

Hudson has discussed the work of O'Sullivan and Tompson critically as well as that of Henri [6,7]. Furthermore he repeated the measurements using the technique of O'Sullivan and Tompson (with Na_2CO_3 instead of KOH) and obtained results which were in agreement with their work.

This technique for measuring the reaction, *i.e.* taking out samples in which the reaction is stopped and the mutarotation is catalyzed, has been used in all subsequent papers such as those by Michaelis and Menten [8], Nelson and Hitchcock [9] and Christiansen and Bergthorsson [12]. It is clear that in this method there are a number of possibilities for making errors for instance in measuring the time when the reaction is stopped or in the dilution of the sample which takes place when the reaction is stopped and during which CO_2 is evolved. Apart from this the method is rather tedious and requires large amounts of enzyme since each sample is about 20 ml. It should be said, however, that the results of Nelson and Hitchcock and those of Christiansen and Bergthorsson are in excellent agreement.

A direct method in which the degree of reaction can be found without stopping the reaction is much to be preferred, but in that case one must take into account that the optical rotation of the solutions is not only a function of the degree of advancement for the reaction

$$S \rightarrow F_\beta + G_\alpha \tag{1}$$

but also depends on how far the reactions

$$F_\beta \rightleftharpoons F_\alpha \tag{2}$$

$$G_\alpha \rightleftharpoons G_\beta \tag{3}$$

have progressed. In these expressions S stands for sucrose G_α means α-glucose and G_β means β-glucose. F_β stands for β-fructofuranose and F_α for the form of fructose which is formed from F_β in solution. The following argument is completely independent of whether F_α is a sixmembered ring or just an optical isomer of F_β.

Below we shall derive an expression for the correction one must apply in order to convert the apparent degree of advancement φ defined as

$$\varphi = (a(t) - a(0))/(a(\infty) - a(0))$$

where $a(t)$ is the optical rotation of the solution at time t, to the true degree of advancement

$$\xi = (S(t) - S(0))/(S(\infty) - S(0))$$

where $S(t)$ denotes the concentration of sucrose at time t. The corrected curve will thereafter be compared with experiments made in the classical way.

EXPERIMENTAL

All polarimetric measurements were performed at 25.0°C in a Zeiss "Kreis-polarimeter 0.01°" using a 40 cm polarimeter tube in a thermostated jacket. The kinetic experiments were made in solutions which contained 10 g of sucrose * in 100 ml of solution. The solution was 0.005 M with respect to sodium acetate and 0.005 M with respect to acetic acid. In two experiments samples were taken out and the reaction was stopped by means of 2 ml 0.2 M Na_2CO_3; in two experiments the reaction was followed directly in the polarimeter tube. Fig. 1 shows a curve for the average of the last two experiments and the average points obtained by the first method.

The rate constants for mutarotation of glucose and fructose were also determined by dissolving the two sugars in the same buffer as above and measuring the optical rotation as a function of time. The slope of the line which is obtained by plotting the natural logarithm of the rotation minus final rotation *versus* the time is the sum of the rate constants for the forward and backward first order reactions. For these sums which are the so called mutarotation constants we obtained

(Fructose) $k_F = 0.2750$ min^{-1}

(Glucose) $k_G = 0.02473$ min^{-1}

as an average of two determinations which deviated less than one in thousand.

THE CORRECTION FORMULA

In order to derive the relation between the two degrees of advancement discussed above, we use that instead of considering the reactions

$$F_\beta \rightleftharpoons F_\alpha \qquad \text{and} \qquad G_\alpha \rightleftharpoons G_\beta$$

we may consider the reactions

$$F_1 \rightarrow F_2 \qquad \text{and} \qquad G_1 \rightarrow G_2$$

in which F_1 denotes F_β and F_2 the equilibrium mixture of F_β and F_α. Similarly G_1 denotes α-glucose and G_2 the equilibrium mixture of α and β-glucose. The last equation simply expresses that instead of considering the approach to equilibrium as the net result of two opposing first order reactions we may (formally) consider it as an irreversible transformation of a pure compound to an equilibrium mixture. The first order rate constants for the latter processes are the sums of the rate constants for the opposing reactions $\alpha \rightleftharpoons \beta$. The rate constants for the reactions $F_1 \rightarrow F_2$ and $G_1 \rightarrow G_2$ are therefore the first order mutarotation constants k_F and k_G which we have determined experimentally.

* The sucrose was a high grade product kindly given to us by "De Danske Sukkerfabrikker".

We have therefore the equations

$$S \rightarrow F_1 + G_1$$
$$F_1 \rightarrow F_2$$
$$G_1 \rightarrow G_2$$

and using the same symbols for concentration we have the differential equations

$$\dot{F}_1 + k_F F_1 = -\dot{S}$$
$$\dot{G}_1 + k_G G_1 = -\dot{S}$$

with the initial values $S(0) = S_0$, $G_1(0) = G_2(0) = F_1(0) = F_2(0) = 0$. These equations are first order linear equations with the formal solution

$$F_1 = -S + S_0 e^{-k_F t} + k_F e^{-k_F t} \int_0^t S e^{k_F t} dt$$

$$F_2 = S_0(1 - e^{-k_G t}) - k_G e^{-k_G t} \int_0^t S e^{k_G t} dt$$

and analogous expressions for G_1 and G_2.

The total optical rotation of the reaction mixture is

$$\alpha(t) = \alpha_S S + \alpha_1 F_1 + \alpha_2 F_2 + \beta_1 G_1 + \beta_2 G_2$$

where the α's and β's are the optical rotations of the different species in arbitrary units. Using that $\alpha(0) = S_0 \alpha_S$ and $\alpha(\infty) = (\alpha_2 + \beta_2) S_0$ we can form the expression for the apparent degree of advancement defined as

$$\varphi = (\alpha(t) - \alpha(0))/(\alpha(\infty) - \alpha(0))$$

We obtain

$$\varphi = (1-a_1-a_2)\xi + a_1 k_1 e^{-k_1 t} \int_0^t \xi e^{k_1 t} dt + a_2 k_2 e^{-k_2 t} \int_0^t \xi e^{k_2 t} dt$$

where $\xi = 1 - S/S_0$ is the true degree of advancement and

$$a_1 = (\alpha_1 - \alpha_2)/(\alpha_S - \alpha_2 - \beta_2)$$
$$a_2 = (\beta_1 - \beta_2)/(\alpha_S - \alpha_2 - \beta_2)$$

The value of a_2 ($a_2 = 0.544$) can be calculated from data in the literature about the specific rotation of the sugars, but a_1 cannot be calculated *a priori* since the specific rotation of the form of fructose which is liberated from sucrose is not known.

The above integral equation giving φ in terms of ξ is not useful since φ is the quantity which is easy to measure. Differentiating the equation once and twice with respect to time and eliminating the remaining integrals between the three equations we can, however, obtain a differential equation expressing ξ in terms of φ. It is

$$(1-a_1-a_2)\ddot{\xi} + (k_1+k_2-a_1k_2-a_2k_1)\dot{\xi} + k_1k_2\xi = \ddot{\varphi} + (k_1 + k_2)\dot{\varphi} + k_1k_2\varphi$$

Table 1. The table shows the agreement between the experimental values of ξ (t) and the calculated values. The figures in brackets have been used to determine the initial slope of $\xi_{expt}(t)$.

t (min)	5	10	15	20	40	70
ξ_{expt}	0.065	0.127	0.188	0.242	0.453	0.682
ξ_{theor}	(0.065)	(0.127)	(0.188)	0.238	0.461	0.670

When φ is known as a function of t this equation can be integrated numerically to give ξ. Since φ is found experimentally it will be necessary to use smoothed out values of it to get reasonable values for its derivatives. In the actual experiment φ was measured every minute in the larger part of the experiment and we used smoothing by fives to get a table of φ with five minute intervals. Even then the second derivative was rather erratic and we therefore introduced the new variable $z = \varphi - (1-a_1-a_2)\xi$ obtaining the equation

$$\ddot{z} + \frac{k_1+k_2-a_1k_2-a_2k_1}{1-a_1-a_2}\dot{z} + \frac{k_1k_2}{1-a_1-a_2}z = \frac{k_1a_1+k_2a_2}{1-a_1-a_2}\dot{\varphi} + \frac{k_1k_2(a_1+a_2)}{1-a_1-a_2}\varphi$$

in which the second derivative is absent on the right hand side. Using the smoothed out values for φ the derivative was calculated using a five point differentiation formula.

Had a_1 been known the procedure would now have been to use a power series expansion for φ in the neighbourhood of $t = 0$ obtained by least square curve fitting to obtain a power series expansion for ξ near $t = 0$. From this a sufficient number of ξ values could be obtained to start a step by step integration of the equation for z. Such an integration could for instance follow the method of Milne [10,11] which we used in the calculations described below.

As it is, a_1 is not known and we have therefore used the initial slope of the curve $\xi = \xi(t)$ to determine a_1. Using this value $a_1 = 0.228$ the corrected curve

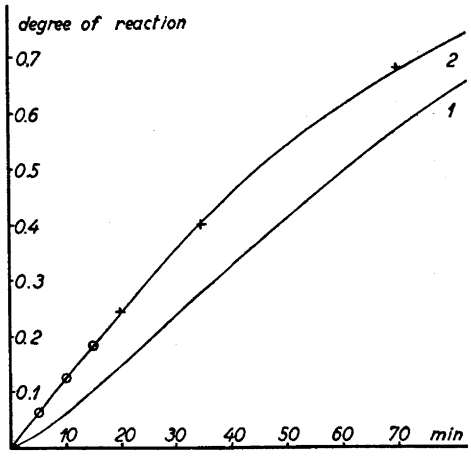

Fig. 1. Curve No. 1 shows the experimental values of $\varphi(t)$, curve No. 2 shows $\xi_{theor}(t)$ calculated using curve No. 1. O are the values of ξ_{expt} which have been used in determining the initial slope of $\xi_{expt}(t)$, + are the other values of ξ_{expt}.

on Fig. 1 has been calculated. Since this curve has been fitted to the experimental data near the origin it is not surprising that it gives a good fit there, but even for $\xi \simeq 0.7$ the disagreement between the calculated values as given in Table 1 and the experimental points is only about 2 % which is only slightly more than the experimental uncertainty. By using a_2 as a parameter which is fitted to give the best agreement on the average the disagreement could be made even smaller and furthermore this would lead to a more precise determination of a_2 and thereby of the optical rotation of fructose as it is formed from sucrose. Such calculations would require calculating facilities which are not at our disposal at the present time but we hope to return to the problem later. Here our primary aim has been to show that a correction of this type is possible but as a byproduct we have obtained a possibly not very accurate value for the optical rotation of β-fructofuranose which from the value of $a_1 = 0.228$ is found to be $-70.8°$ in contrast to the rotation $-95.75°$ found for the equilibrium mixture.

In using this method it is of the utmost importance that φ is known with great accuracy so that its derivatives can be determined with reasonable accuracy. When this is achieved on the other hand, our method presents several advantages. Firstly it is more accurate than the classical method since all errors due to stopping the reaction and diluting the samples are avoided, and more experimental points can be obtained. Secondly the experimental part of it is much quicker so that the method will be faster, provided calculating facilities are available. Finally the method is far less enzyme-consuming than the previous methods. Since earlier experiments always were carried out using enzyme mixtures which were easily obtained the problem of enzyme consumption was not serious. When one wants to use highly purified invertase as we plan to do later the problem becomes important, however, and this has indeed been one of the reasons for developing this method.

We are indebted to Professor J. A. Christiansen for encouragement and advice. B. A. gratefully acknowledges economic support from the *Carlsberg Foundation* and from *Statens Almindelige Videnskabsfond.*

Crystal Structure of *Cyclo*hexane-1a,3a,5a-thiophosphoric Acid Ester

PER ANDERSEN and K. E. HJORTAAS

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

An X-ray investigation of the thiophosphoric acid α-floroglucitol ester has been carried out. The space group is $Pna2_1$ and the cell dimensions are a 11.45 ± 0.05 Å; b 7.28 ± 0.04 Å; c 9.47 ± 0.05 Å, with 4 molecules in the unit cell. The structure shows that the three ester oxygen atoms are in axial positions in the *cyclo*hexane ring. The space group of the corresponding phosphoric acid ester is Cc with cell dimensions a 11.37 Å; b 6.25 Å; c 11.74 Å; β 118°, and 4 molecules in the cell.

The esters formed by α-floroglucitol and phosphoric acid and thiophosphoric acid, respectively, were synthesised by Stetter and Steinacker in 1951 [1] and the reactions were shown to be:

$$C_6H_9(OH)_3 + OPCl_3 = C_6H_9O_3PO + 3HCl$$

and

$$C_6H_9(OH)_3 + SPCl_3 = C_6H_9O_3PS + 3HCl$$

They assumed configurations as shown in Fig. 1 and could conclude that α-floroglucitol was the *cis* form of *cyclo*-hexane-1,3,5-triol. This had been proved earlier by an X-ray investigation of the dihydrate of α-floroglucitol [2]. The hydroxygroups were in equatorial rather than in axial positions in this crystal structure, however.

The 1,3-carbon-carbon distance in *cyclo*hexane is 2.51 Å and the Cl—Cl distance in both $OPCl_3$ and $SPCl_3$ is 3.23 Å. Even if these distances are somewhat unfavourable the proposed structure is reasonable when compared with the hydroxy-oxygen distances in phosphoric acid [3] which are 2.50—2.52 Å. The proposed structure should therefore be expected to exhibit undistorted axial bonds.

CRYSTALLOGRAPHIC DATA

The X-ray data were obtained from oscillation and Weissenberg photographs using unfiltered Cu$K\alpha$ radiation. Multiple film technique was employed with visual estimation of the intensities using an experimental intensity scale

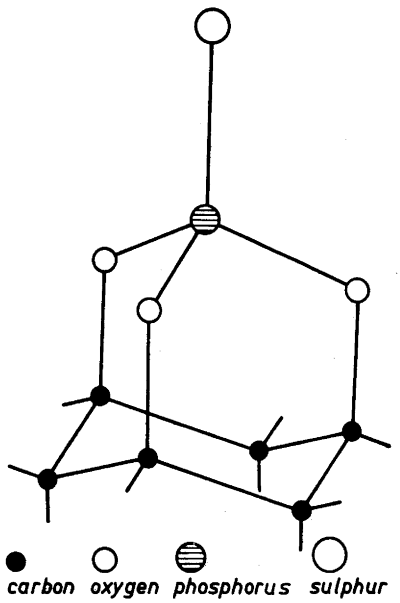

Fig. 1. A model of the molecule.

for comparison. The intensities were corrected in the ordinary way to obtain $|F_o|$ values. The space groups were determined both for the sulphur and oxygen compound, but a structure determination was only carried out for the former.

The thiophosphoric acid ester is orthorhombic with the following unit cell dimensions:

$$a\ 11.45 \pm 0.05\ \text{Å};\quad b\ 7.28 \pm 0.04\ \text{Å};\quad c\ 9.47 \pm 0.05\ \text{Å}$$

The experimental density was found equal to 1.64 g cm^{-3} which gives four molecules in the cell. The systematic extinctions show that reflexions in the $(0kl)$ zone are present only when $k + l = 2n$ and in the $(h0l)$ zone when $h = 2n$. The possible space group could therefore be either $Pnam$ or $Pna2_1$. Both space groups are equally acceptable as the fourfold positions in $Pnam$ require the point symmetry m and the proposed model has the symmetry $3m$. Patterson projections combined with the trial and error computations showed that $Pna2_1$ was the correct space group.

The phosphoric acid ester is monoclinic and has the cell dimensions:

$$a\ 11.37\ \text{Å};\quad b\ 6.25\ \text{Å};\quad c\ 11.74\ \text{Å};\quad \beta\ 118°$$

The density was found to be 1.60 g cm^{-3} which gives four molecules per unit cell. The systematic extictions show that (hkl) reflexions are present when $h + k = 2n$ and $(h0l)$ reflexions for $l = 2n$. This leads to two possible space groups $C2/c$ and Cc. As the fourfold positions in $C2/c$ has the point symmetry 2 or $\bar{1}$ it must be assumed that Cc is the correct space group.

H_9	0.64	0.46	4.0	0.64	−0.09	4.0

It was decided to carry out a structure determination of the sulphur compound because of the higher symmetry in the space group, as in *Cc* not even one projection has a center of symmetry.

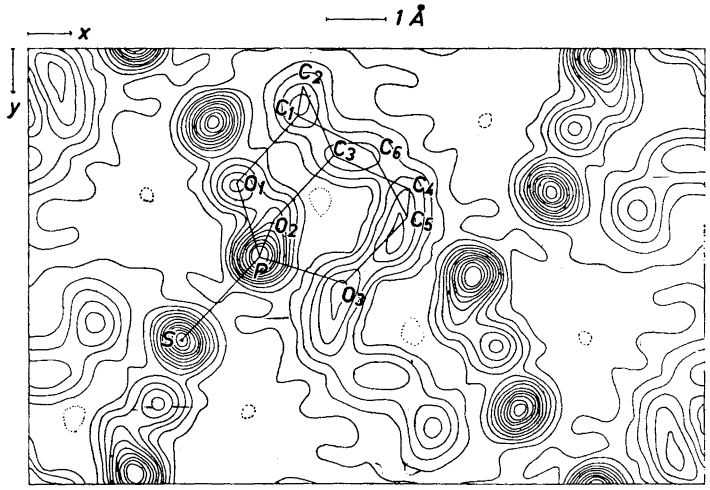

Fig. 2. Projection along [001]. Interval of contour lines 2e Å^{-2}. Zero line dotted.

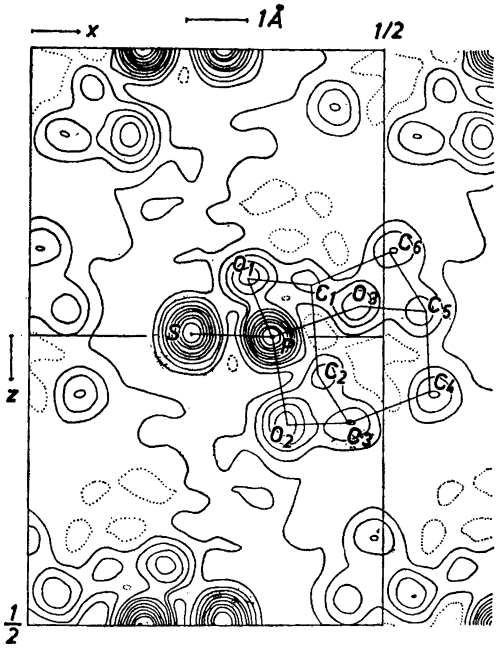

Fig. 3. Projection along [010]. Interval of contour lines 2e Å^{-2}. Zero line dotted.

STRUCTURE DETERMINATION

The Patterson projections $P(u, v)$ and $P(u, w)$ did not give any conclusive indications as to the position or orientation of the molecule. The assumption that the molecule as a whole is roughly spherical (except for the sulphur atom) combined with trial and error computations and informations from the Patterson projections finally lead to a structure which could be refined. One could thus unequivocally exclude the more symmetrical space group *Pnam*.

The structure was refined in the [001] and the [010] projection using $(F_o - F_c)$ difference syntheses. The hydrogens were introduced in the final stage for reflexions with ξ values less than about 0.6 and by assuming the C—H bond to be 1.09 Å. In the [001] projection the R factor in the end was 0.13 with an isotropic temperature factor $B = 3.2$ Å^2 for all atoms. The corresponding values for the [010] projection were $R = 0.14$ and $B = 3.6$ Å^2. In calculating R the (002) and (201) reflections are omitted because of extinction. In calculating $\Sigma||F_o|-|F_c||$ unobserved reflections are given the minimum observable value $|F'_o|$ when $|F_c| > |F'_o|$, but are omitted when $|F_c| < |F'_o|$. In either case they are excluded from $\Sigma\,|F_o|$. The difference syntheses in both projec-

tions indicated that individual damping should be used. The phosphorus atom should be damped less and the sulphur atom more. This is also what one should expect from an inspection of the structure.

A least squares refinement carried out on a Ferranti Mercury computer for the two projections in question gave the correlation factors $R = 0.09$ and $R = 0.07$, respectively, for the [001] and [010] projection. The contribution from the hydrogen atoms is here included in all structure factors. The coordinates and the individual isotropic temperature factors are listed in Table 1. Figs. 2 and 3 show the two Fourier projections based on the phases calculated from these parameters. The standard deviations calculated from the equation derived by Cruickshank [4] are listed in Table 2, the values are doubled in the non-centrosymmetrical projection [5]. The interatomic distances and valency angles within the molecule and their standard deviations are listed in Table 3.

DISCUSSION

Orientation of the molecule in the cell is such that the S—P bond lies approximately in the *xy* plane and the axial bonds of the *cyclo*hexane ring are roughly parallel to this plane which is not far from being a plane of symmetry. The closest intermolecular approaches are listed in Table 4. They have all values which are compatible with accepted van der Waals radii.

The structure determination shows that the configuration proposed by Stetter and Steinacker is the correct one, and all distances and angles are within the limits of error those to be expected from an ideal model. The three oxygen atoms are in axial positions and the O—O distances are in good agreement with those computed for axial positions. Both the P—O distance and the O—P—O angle are in good agreement with those found in phosphoric acid [3].

Thanks are due to Dr. H. Stetter for placing samples of the two substances mentioned in this paper at the disposal of the Physical Chemistry Department.

On the Stability of Ozonides

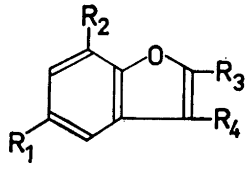
ERLING BERNATEK and METTE HVATUM

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

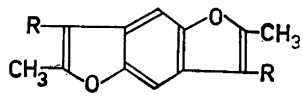
Thermal decomposition in benzene of three ozonides has been followed iodometrically. The first half of the reaction is strictly first-order with no induced decomposition. Activation energies have been calculated. The rate-controlling step is probably a homolytic cleavage of the O—O bond. It seems probable that an ozonide can transfer active oxygen to a suitable substrate.

For some time we have been concerned with the ozonolysis of certain benzofurans and benzodifurans [1,2], during which work the formation of stable ozonides has been a matter of great interest.

Isolation of the ozonides in a pure crystalline state has been achieved with varying ease in the different cases chiefly due to great variations in their stability. One of the structural factors guiding the stability is the nature of the substituents at both ends of the double bond. Criegee has made a statement at variance with this[3], but had perhaps only hydrocarbon substituents in mind.



I:	$R_1 = CH_3COO$;	$R_2 = H$;	$R_3 = CH_3$;	$R_4 = COOH$
II:	$R_1 = CH_3COO$;	$R_2 = H$;	$R_3 = CH_3$;	$R_4 = COOCH_3$
III:	$R_1 = CH_3COO$;	$R_2 = H$;	$R_3 = CH_3$;	$R_4 = COOC_2H_5$
IV:	$R_1 = CH_3COO$;	$R_2 = H$;	$R_3 = CH_3$;	$R_4 = COOC_3H_7$
V:	$R_1 = CH_3COO$;	$R_2 = H$;	$R_3 = CH_3$;	$R_4 = COCH_3$
VI:	$R_1 = CH_3COO$;	$R_2 = R_3 = CH_3$;		$R_4 = COOC_2H_5$
VII:	$R_1 = CH_3COO$;	$R_2 = R_3 = CH_3$;		$R_4 = COCH_3$
VIII:	$R_1 = R_2 = H$;		$R_3 = COOCH_3$;	$R_4 = H$



IX: R = $COOC_2H_5$
X: R = $COCH_3$
XI: R = H

Stable ozonides have on previous occasions been prepared in this laboratory from the substances III, VI and IX. An isolable, but rather unstable ozonide was obtained from X, while ozonides from V, VII and XI were too unstable to be isolated. In the experimental section of this work is described the preparation of two new benzofuran derivatives (II and IV) and their stable, monomeric ozonides. Attempts to prepare isolable ozonides from I and VIII met with no success.

Summarising these results it is seen that if only one end of the double bond in the furan ring is substituted, no ozonide can be isolated. This is in agreement with the findings that only 2,3-disubstituted indoles form stable ozonides. Furthermore, a free carboxyl group is evidently detrimental to the stability of an ozonide while an ester group enhances the stability more than does an acetyl group.

Small changes in the substituents therefore bring about great differences in stability. To get a clearer picture of their (thermal) stabilities, absolutely as well as relatively to each other, we have investigated the degradation of three closely related and easily accessible ozonides, *viz.* those of II, III and IV, at elevated temperatures.

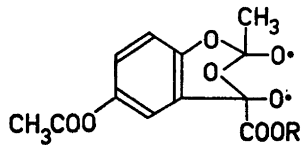
The kinetic runs were performed in benzene solution, but some degradation experiments in xylene and decalin will be discussed later in this paper. Analytically the reactions were followed by determining iodometrically the decreasing content of active oxygen. The validity of our kinetic results (*i.e.* that they truly represent the decomposition of the ozonide) is therefore based on the assumption that the rupture of the O—O bond is a rate-controlling step and that no transfer of active oxygen to the solvent or to reaction products take place. Justification of these assumptions is found in the strict adherence of the degradation to first order kinetics (however, see below), and in the rather high activation energies. The relevant kinetic results are summarised in Table 1.

The first-order rate-constants are all calculated from the first half of the reactions. From that point onwards serious deviation from first-order kinetics began to develop in the form of distinct retardation of the reaction. This may be a true kinetic effect, *i.e.* the reaction products exert a negative catalysis or it may be an analytical artefact in the sense that we are no longer measuring the real content of ozonide in solution. Such a situation could arise if the ozonide was able to transfer its active oxygen to any of the reaction products, supposing that the new peroxidic products were more stable that the ozonide itself.

Table 1. First-order rate-constants for the thermal decomposition of benzofuran ozonides in benzene.

Ozonide from	Temperature °C	$C_o \times 10^3$ in mole/l	k in h^{-1}
II	100.0	0.633	0.140
II	100.0	1.962	0.131
II	100.0	3.217	0.142
II	79.65	1.962	0.0147
III	100.0	0.633	0.132
III	100.0	1.962	0.126
III	100.0	3.217	0.122
III	90.0	1.962	0.0436
III	79.15	1.962	0.0127
IV	100.0	0.633	0.134
IV	100.0	1.962	0.124
IV	100.0	3.217	0.130
IV	79.15	1.962	0.0124

No significant changes in the rate-constants at 100° were observed on increasing the concentration of the reactant about five times. First-order kinetics is thus further vindicated and induced decomposition ruled out. We believe that the rate-determining step in the thermal decomposition is a homolytic splitting of the O—O bond producing a diradical like XII. Due to the special



XII

steric situation in this diradical recombination must be frequent. The further reactions are probably of the usual radical type transformations, *viz.* decomposition, rearrangements and attack on substrates. The complexity and partly polymeric nature of the reaction products from our experiments substantiate the belief that several modes of reaction are operative. If the concept of active oxygen transfer is true, even the initial homolytic cleavage may not be entirely homogeneous but mixed with small amounts of another reaction where the O—O bond is preserved. From our kinetic data the following activation energies are calculated: Ozonide of II 28.2 kcal/mole; ozonide of III 28.7 kcal/mole; ozonide of IV 28.8 kcal/mole. These figures are well within the range of activation energies for thermal decompositions of peroxides and therefore compatible with a homolytic cleavage of an O—O bond.

In the initial search for a suitable inert solvent for the decomposition experiments xylene (*o*, *m*-, *p*-mixture) was tried. Surprisingly the content of active oxygen increased when a solution of ozonide in xylene was heated at 100° for some hours. Xylene is known to have a slight tendency to autoxidation and the amount of oxygen in the air in the ampoules was sufficient to explain the

increase in active oxygen. Controls with xylene alone, however, showed only a weak autoxidation under the experimental conditions, so the presence of an ozonide or its immediate decomposition products must be able to catalyse this process. According to our figures the reaction is accelerated at least ten times. Direct transfer of active oxygen from ozonide to the solvent can not be inferred with certainty from these experiments. Decalin has far greater tendency to formation of peroxides than xylene and some runs were made in this solvent under an oxygen-free nitrogen atmosphere. The rate of decomposition at 100° was in this case only about one third of the measured in benzene. This difference is far to large to be explained by general solvent effect, but must be due to the formation of decalin peroxides by the action of the ozonide.

EXPERIMENTAL

Methyl 2-methyl-5-acetoxybenzofuran-3-carboxylate (II). To a continuously agitated solution of anhydrous zinc chloride (35 g) in dry acetone (50 ml) and glacial acetic acid (3 ml) kept at 75°, was added during 8 h a solution of *p*-benzoquinone (27 g) in methyl acetoacetate (100 ml) and acetone (100 ml). The reaction mixture was concentrated in a stream of warm air and placed in a refrigerator when a greyish crystalline product separated which was washed with small amounts of ice-cold methanol. Yield 24.2 g (47 %). Recryst. four times from aqueous acetone (charcoal), m.p. 146.5°. (Found: C 64.1; H 5.2; OCH_3 15.4. Calc. for $C_{11}H_{10}O_4$: C 64.1; H 4.9; OCH_3 15.1.) The product (10 g) was dissolved in acetyl chloride (50 ml), boiled for 15 min and poured into ice-water (2 l) when a dark oil separated. After about 0.5 h this solidified, was broken up and washed thoroughly with water. Recrystallised from aqueous acetone, m.p. 83°. (Found: C 63.1; H 5.0; OCH_3 12.1. Calc. for $C_{13}H_{12}O_5$: C 62.9; H 4.9; OCH_3 12.5.)

n-Propyl 2-methyl-5-acetoxybenzofuran-3-carboxylate (IV). The ethyl ester I (R_1 = OH) (17.5 g) was dissolved in dry propanol-1 (300 ml), saturated at room temperature with hydrogen chloride, and refluxed for 8 h. The main part of the propanol (250 ml) was distilled off and the residue poured into ice-water (1 l) when a crystalline substance separated (18.3 g, 98 %). Recrystallised twice from aqueous acetone and four times from benzene, m.p. 105°. (Found: C 66.6; H 6.2. Calc. for $C_{13}H_{14}O_4$: C 66.7; H 6.0.) Acetylation as for the methyl ester. Recrystallised thrice from aqueous acetone (charcoal), m.p. 45—46°. (Found: C 65.4; H 5.9. Calc for $C_{15}H_{16}O_5$: C 65.2; H 5.8.)

Ozonisation. The ozone generator produced at an oxygen flow of 30 l/h, 2.4 g O_3/h. Methyl ester (II) (9 g) was dissolved in ethyl acetate (250 ml) and ozonised at 0° for 52 min. Most of the ethyl acetate was removed in a stream of air and the remainder *in vacuo*. The residue consisted of yellow, somewhat sticky crystals which were washed with aqueous acetic acid (1:1). Yield 8.7 g (81 %). Recrystallised twice from aqueous acetic acid (8:2) and twice from alcohol. White crystals, m.p. 88—89°. (Found: C 52.7; H 3.9; act. O 5.4; M 294 (benzene). Calc. for $C_{13}H_{12}O_8$: C 52.7; H 4.1; act. O 5.4; M 296). The propyl ester was ozonised in the same way, but at a lower temperature (solid carbon dioxide — acetone). The ozonide had m.p. 68°. (Found: C 55.1; H 4.7; act. O 5.0; M 317 (benzene). Calc. for $C_{15}H_{16}O_8$: C 55.6; H 5.0; act.O 4.9; M 324).

Ozonolysis of 2-methyl-5-acetoxybenzofuran-3-carboxylic acid (I). The acid (5 g) was dissolved in ethyl acetate (200 ml) and ozonised at low temperature (solid carbon dioxide — acetone) for 30 min. To the reaction mixture was added light petroleum until turbidity occurred and a yellow oil which contained active oxygen separated. The solvent mixture was decanted and the last traces removed *in vacuo*. As soon as the oil reached about room temperature it began to decompose with evolution of gas. The residue soon solidified to a yellow crystalline mass which did not contain any active oxygen. Recrystallised from an ether-ligroin mixture (charcoal), m.p. 117—122°, white crystals. Hydrolysis with 2 N hydrochloric acid afforded white needles, recrystallised from water (charcoal), m.p. 198—200°. Blue colour with ferric chloride. Mixed m.p. with an authentic sample of gentisic acid showed no depression.

Kinetics. The purified ozonides were dissolved in reagent grade benzene at room temperature and 10 ml aliquots transferred to glass ampoules which were sealed and placed in a thermostat bath at the appropriate temperature. For analysis the ampoules were rapidly cooled and broken in a tall beaker whereupon glacial acetic acid (15 ml) was added. Pieces of solid carbon dioxide were placed in the mixture and sodium iodide (1 g) added. The beaker was closed with a lid and kept in a dark cupboard for 0.5 h. Recently boiled water (100 ml) was added and the heterogeneous mixture titrated under vigorous stirring with standard (0.01 N) thiosulphate. Controls with samples of the ozonide of III gave results better than 99.5 % of the theoretical value. The starting point in the runs was always a titration value of an actual sample rather than a figure calculated from the weighed amount of ozonide.

Decomposition in xylene and decalin. Ozonide of III was dissolved in pure xylene (free from active oxygen) and 10 ml aliquots were transferred to ampoules and sealed as before. In a typical run the titration value increased from 9.03 ml 0.01316 N sodium thiosulphate to 13.33 ml in 2 h 20 min. Roughly estimated the volume of air in the ampoules was 10 ml, *i.e.* 2 ml of oxygen. This is 0.18 mequiv. (calculated as routed through a hydroperoxide and determined iodometrically) corresponding to a consumption of 13.5 ml 0.01316 N sodium thiosulphate. Ampoules with xylene only were heated 2 h 20 min. Air volume approximately as before. Mean titration value: 0.37 ml of the usual thiosulphate.

The runs in decalin were performed in a reflux apparatus kept in a thermostat at 100° through which a stream of dry oxygen-free nitrogen (washed with alkaline pyrogallol solution) was led. Decalin is a rather poor solvent for the ozonide (of III) and the reaction mixture was therefore made up by saturating the decalin with ozonide at room temperature. Samples of ca 25 ml were withdrawn and cooled to room temperature and from this 20 ml samples were pipetted and analysed. The reaction was not pure first order, but if calculated as such, the average rate-constant was 0.05 h^{-1}.

Thiamine and Thiamine Diphosphate in Liver and Brain from Rats Treated with CCl_4

KARL-HEINZ KIESSLING and KARIN TILANDER

Institute of Zoophysiology, University of Uppsala, Sweden

The amount of thiamine and thiamine diphosphate in liver and brain of rats and their distribution in liver cytoplasm fractions has been studied.

The supernatant (including the microsomal fraction) contains nearly twice as much thiamine diphosphate as the mitochondria, while thiamine is present almost exclusively in the supernatant.

In rat livers with fatty infiltration, obtained by injections of CCl_4, the amount of thiamine diphosphate is slightly reduced. The decrease happens mainly in the mitochondria. An increased decomposition of thiamine diphosphate is found in fatty infiltrated liver homogenates as compared with normal ones.

No significant difference is found in thiamine diphosphate concentration between brains from normal and CCl_4-treated rats. The amount of thiamine is very low in either case.

Fatty infiltration of the liver is easily obtained in rats by injections of CCl_4 or white phosphorus, or by feeding them with a diet deficient in choline. Fatty liver may be obtained also by giving rats alcohol for a long time. In rats suffering from fatty liver caused by CCl_4 or white phosphorus, or by feeding on a choline deficient diet the liver mitochondria are morphologically changed in the same way as when treated with hypotonic medium [1]. They also contain less than normal amounts of thiamine diphosphate [2], cytochrome c, pyridine nucleotides, and adenylnucleotides [3-5].

In the present communication the content of thiamine diphosphate and thiamine in liver and brain are analysed and evidence is put forward for an increased decomposition of thiamine diphosphate * in fatty liver produced by CCl_4 treatment as compared with normal conditions.

* Abbreviations used: TDP thiamine diphosphate, T thiamine, P_i inorganic phosphate.

EXPERIMENTAL

Male rats from the same litter and weighing about 200 g were used for the experiments. In each experiment two rats were used parallelly, one with fatty infiltration obtained by CCl_4 treatment and the other a control rat. Fatty infiltration was obtained by daily intraperitoneal injection of CCl_4 (0.2 ml of a 20 % solution in olive oil).

The rats were killed by decapitation, the livers immediately removed and chilled on ice, weighed, minced with a pair of scissors in cold isotonic sucrose, washed twice, and homogenized in a Potter-Elvehjem homogenizer in five volumes of cold 0.25 M sucrose. The homogenisations of the tissues from all animals were performed as uniform as possible, *i.e.* the same homogenizer was used, the pistel was moved with the same rapidity, and the time was always the same. From the homogenate samples were taken for incubation with TD^{32}P or T and $^{32}P_i$ in order to study the decomposition and synthesis of TDP as described elsewhere [6]. From the remaining part of the homogenate mitochondria and supernatant (soluble and microsomal fraction being taken together) were prepared.

Free thiamine was determined as thiochrome according to Hjarde [7], TDP manometrically as described by Westenbrink and Steyn-Parvé [8], and with the thiochrome method as the difference between total and free thiamine. TDP isolated by paper chromatography (*iso*butyric acid—versene—NH_3 [9] followed by propanol — HAc—H_2O [10]) was used as standard in the manometric method. Generally the values for TDP obtained with the thiochrome method were slightly lower than with the manometric method. In the tables the values for TDP obtained with the latter method are given. For determination of protein the Biuret method of Cleland and Slater [11] was used.

RESULTS

Table 1 gives figures about the content and distribution of TDP and T in the liver cells from normal and fatty infiltrated rat livers. The figures are mean values from six experiments, all determinations having been performed in duplicate. To avoid leakage of T and TDP from mitochondria to supernatant during the preparation of the cell fractions the tissues were homogenized very cautiously in a Potter-Elvehjem homogenizer. Our figures for the TDP concentration in mitochondria and supernatant are therefore very low as compared with those for liver given by Goethart [12] and Dianzani and Dianzani Mor [2]. In our experiments about 50 % of the TDP was recovered in the fraction removed by low speed centrifugation, and which contains mainly intact liver cells, blood corpuscles, and nuclei.

When, however, nuclei from rat liver were isolated according to Logan, Ficq, and Errera [13], the content of TDP in this purified fraction was found to be only 0.03 μg TDP per gram of normal liver.

Thus our figures in Table 1 for TDP and T in mitochondria and supernatant (soluble and microsome fraction) only intend to supply an idea about the relative distribution of the two compounds in the cell fractions, and to show the ratio between them. The latter agrees with that obtained by Goethart and Dianzani and Dianzani Mor, *i.e.*, in normal liver the TDP content of mitochondria is about half that of the supernatant. In fatty infiltered liver the mitochondrial TDP is reduced.

Compared with TDP the amount of T in the liver cells is low (Table 1), and is found mainly in the supernatant. In fatty infiltrated liver T is reduced, but since also TDP is reduced, the ratio between T and TDP is nevertheless the same as in normal liver.

Table 1. Content and distribution of thiamine and thiamine diphosphate in normal and fatty infiltered rat liver (T and TDP are mean values from 6 expts., total lipids from 4).

		TDP		T		$\frac{T}{TDP}$	Total lipids mg/g wet weight
		μg/g liver	μg/10 mg prot.	μg/g liver	μg/10 mg prot.		
Normal liver	Homogenate	8.96 ±0.55	0.38 ±0.03	0.59 ±0.01	0.026 ±0.001	$\frac{1}{16}$	41
	Supernatant	3.08 ±0.23	0.23 ±0.02	0.51 ±0.04	0.049 ±0.02	$\frac{1}{6.2}$	
	Mito-chondria	1.64 ±0.18	0.76 ±0.05	0.03 ±0.007	0.012 ±0.001	$\frac{1}{63}$	
Fatty liver	Homogenate	7.17 ±0.34	0.36 ±0.02	0.36 ±0.01	0.019 ±0.002	$\frac{1}{20}$	77
	Supernatant	2.43 ±0.31	0.27 ±0.02	0.38 ±0.03	0.044 ±0.004	$\frac{1}{6.8}$	
	Mito-chondria	0.98 ±0.16	0.48 ±0.06	0.03 ±0.005	0.012 ±0.002	$\frac{1}{42}$	

Table 2 gives figures for the amount of TDP and T in the brain from normal and CCl_4-treated animals. With regard to TDP no obvious differences are found. The amount of T in normal brain is only 1/20 of that in liver, and is still lower in CCl_4-treated animals.

The decomposition of TDP in homogenates from normal and fatty infiltrated rat livers has been investigated by means of radioactive TDP added to the homogenates. The amount of TDP decomposed after 60 min at 37°C is signi-

Table 2. Thiamine and thiamine diphosphate in brain from normal and CCl_4 treated rats (mean value from 6 expts.).

	TDP		T		$\frac{T}{TDP}$
	μg/g liver	μg/10 mg protein	μg/g liver	μg/10 mg protein	
Normal rat	3.68 ± 0.36	0.23 ± 0.04	0.03	0.0025	$\frac{1}{77}$
CCl_4 treated rat	3.61 ± 0.22	0.27 ± 0.02	<0.03	<0.0025	$< \frac{1}{77}$

Table 3. Synthesis and decomposition of thiamine diphosphate in homogenates from normal and fatty infiltered rat livers. Homogenate from 1/5 of a gram of liver has been used. (The values represent the mean of 6 expts.)

	Synthesis (per cent of added ^{32}P)	Decomposition (per cent of added $TD^{32}P$)
Normal liver	2.06 ± 0.25	5.92 ± 0.55
Fatty liver	2.25 ± 0.30	17.14 ± 1.61

ficantly higher in fatty infiltrated liver homogenates than in normal ones (Table 3). The same table shows that the ability to synthesize TDP from added T is uninfluenced by CCl_4 treatment.

DISCUSSION

The figures for TDP in rat liver homogenates (Table 1) are rather low as compared with those given by Goethart [12] and by Dianzani and Dianzani Mor [2], but are more in agreement with those obtained by Siliprandi and Siliprandi [14] and by Ochoa [15]. Possibly the differences can be ascribed to different rat strains.

The total amount of TDP in fatty infiltrated rat livers, produced by injections of CCl_4, is only slightly less than in normal livers (Dianzani and Dianzani Mor [2] and Table 1 in the present paper). The decrease is mainly localized to the mitochondria. Christie and Judah [16], in a study of the mechanism of action of CCl_4, advanced the opinion that the primary locus of action were the membranes of the liver mitochondria. This action is, according to Dianzani and Dianzani Mor, comparable with the displacement of TDP from swollen mitochondria as a consequence of hypotonic treatment.

However, no corresponding increase of the TDP concentration in the supernatant occurs (Table 1). Our results even show a slight decrease also in the supernatant from fatty liver (calculated as μg TDP/g liver).

Table 3 shows that in liver homogenates from CCl_4-treated rats, as compared with normal ones, the decomposition of TDP is increased. This increase of the phosphatase acting on TDP may explain the decrease of TDP in the supernatant and in the mitochondria. In this connection it may be of interest to point to an increased mitochondrial ATP-ase activity observed recently by Recknagel and Anthony [17] in CCl_4-treated rat liver.

On the other hand, an increased decomposition of TDP to thiamine, should result in an increased thiamine level. This is, however, not the case (Table 1). This can be explained by the assumption that tissues are capable of retaining only a limited amount of free thiamine. Thus when the amount is enhanced by increased dephosphorylation of TDP, the excess of thiamine is eliminated by excretion or decomposition.

As CCl_4 is thought to be a hepatotoxin only, no differences in TDP should occur in tissues other than liver. The only tissue, apart from liver, studied by us is brain, where CCl_4 is found to be without effect on the TDP level.

On the Oxidation of Cholesterol in Liver Mitochondrial Preparations

Bile Acids and Steroids 99

HENRY DANIELSSON

Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

The oxidation of 4-^{14}C- and 26-^{14}C-cholesterol has been studied in mitochondrial preparations of mouse and rat liver. The simultaneous occurrence of autoxidation and enzymatic oxidation of the added labeled cholesterol, indicated by experiments on the metabolism of cholesterol in different cellfractions of liver and in mitochondria of heart and kidney, has been ascertained by analyses of the labeled products formed under non-enzymatic and "enzymatic" conditions. Among autoxidatively formed products 3β, 5α, 6β-trihydroxycholestane, 7α-hydroxycholesterol, 7β-hydroxycholesterol and 7-ketocholesterol have been identified. Two major enzymically formed compounds both retaining the C_{27}-side-chain, have been isolated. One is less polar than 7α-hydroxycholesterol but more polar than 7-ketocholesterol, while the other shows chromatographic properties similar to a neutral trihydroxy-C_{27}-sterol. This latter compound is metabolized to chenodeoxycholic but not cholic acid in the bile-fistula rat.

Cholesterol is catabolized by the liver *in vivo* to bile acids, which represent the major end-products of cholesterol metabolism in the animal body. The individual steps in this chain of reactions, which entail elimination of the terminal *iso*propyl-group and modifications of the nucleus by saturation of the Δ^5-double bond, reversal of the configuration of the hydroxyl-group at C_3 and introduction of hydroxyls in C_7 and C_{12} or C_6, have not been fully established. The work of Bergström and Lindstedt [1-4] on the metabolism in the bile-fistula rat of possible intermediates between cholesterol and cholic acid has yielded important informations on the likely sequence in this process. Thus, all available evidence makes it probable that the nucleus is hydroxylated, first at C_7 and then, at least in this species, at C_{12} prior to the completion of the side-chain degradation, and that one of the early steps is the introduction of the 7α-hydroxyl-group.

Studies of the metabolism of cholesterol *in vitro* appear a promising approach to further investigations on the individual steps in the degradation

of cholesterol to bile acids. Such investigations have also been undertaken by several groups of workers. Meier *et al.*[5] reported in 1952 on the formation of labeled CO_2 from 26-^{14}C-cholesterol in rat liver slices. Anfinsen and Horning [6,7] demonstrated the same reaction in mouse liver mitochondria in presence of AMP *, DPN and boiled liver juice. Gurin and coworkers [8,9] have reported similar findings and also the formation of labeled 25-dehydrocholesterol, a labeled C_{27}-acid and aldehyde from 26-^{14}C-cholesterol in a solubilized rat liver mitochondrial system.

Fredrickson and Ono [10,11] analyzed the products formed from 4-^{14}-C-cholesterol in the mouse liver mitochondrial system of Anfinsen and Horning and found that of the 25 % of cholesterol metabolized 15 % was present as acidic compounds not identical with cholic or deoxycholic acid, 7 % as 25- and 26-hydroxycholesterol and the remainder as cholesterol esters. In a preliminary communication Danielsson and Horning [12] have reported on the formation of an unknown compound both from 4-^{14}C- and 26-^{14}C-cholesterol in essentially the same mouse liver mitochondrial system. This compound, which had chromatographic properties similar to a trihydroxylated neutral C_{27}-sterol, was metabolized in the bile-fistula rat to chenodeoxycholic acid and to two acids with chromatographic mobilities identical with those of the 6β-hydroxylated acids formed from chenodeoxycholic acid.

Such *in vitro* studies of the oxidation of cholesterol might conceivably be complicated by the well-known fact that cholesterol is easily autoxidized in colloidal solutions in the presence of air. The products of autoxidation are formed by introduction of oxygen functions in the 5,6,7-positions of the cholesterol molecule.

In a thourough study of the autoxidation of cholesterol in aqueous colloidal solutions Bergström and Wintersteiner[13–15] demonstrated the formation of 7-ketocholesterol and the two epimeric 7-hydroxycholesterols. The oxidation proceeded equally well at 37° as at 85°, although slower, reaching completion after 24 h at 37° compared to 3 h at 85°. After this period of time about 60 % of the cholesterol had been transformed into the 7-oxygenated compounds. Later, Mosbach *et al.*[16] could isolate in low yield 3β, 5α, 6β-trihydroxycholestane from samples of autoxidized cholesterol and Schwenk *et al.*[17] detected small amounts of 3β-, 5α-dihydroxy, 6-ketocholestane in samples of cholesterol-extracts from liver.

In the present work the products formed from labeled cholesterol in presence of rat and mouse liver mitochondria have been isolated and partly identified and the conditions under which the products are formed have been investigated.

EXPERIMENTAL

Labeled compounds. 4-^{14}C-cholesterol (60 μC/mg) was obtained from the Radiochemical Centre, Amersham, England. 26-^{14}C-cholesterol (250 μC/mg) was purchased from New England Nuclear Corp., Boston, Mass., USA. Prior to use the labeled cholesterol was checked for absence of autoxidation products by chromatography [18].

* Abbreviations used are: AMP = adenosine-monophosphate: DPN = diphosphopyridine nucleotide; Tris = tris (hydroxymethyl)aminomethane: EDTA = ethylenediaminetetraacetic acid.

Reference compounds. *7-Ketocholesterol* (m.p. 169—170°; reported [15] 170°—172°) was prepared from cholesteryl acetate by oxidation with *t*-butyl chromate according to Heusler and Wettstein [19], followed by hydrolysis with potassium carbonate [20]. *7β-Hydroxycholesterol* (m.p. 172—173°, $[\alpha]_D^{25}$ +5°; reported [24] m.p. 178°, $[\alpha]_D$ +7°) was obtained by lithium aluminum hydride reduction of 7-ketocholesteryl acetate and purified by formation of the dibenzoate [21]. *7α-Hydroxycholesterol* was prepared according to Henbest and Jones [22,23]. Cholesteryl benzoate was treated with N-Br-succinimide in boiling carbon tetrachloride for 5—6 min. The resulting 7α-Br-cholesteryl benzoate was treated with sodium formate to yield 7α-formoxycholesteryl benzoate, purified by chromatography on aluminum oxide (Merck, Darmstadt, Germany) and the free sterol was then obtained by saponification. The resulting 7α-hydroxycholesterol had a m.p. of 184—85°, $[\alpha]_D^{25}$ —92°; reported [23,24] 185° $[\alpha]_D$ —86.6° and 91.6°. *3β, 5α, 6β-Trihydroxycholestane* (m.p. 228—231°; reported [25,26] 229—233° and 237—239°) was prepared according to Fieser *et al.*[26] by treatment of cholesterol with hydrogen peroxide in formic acid. 3β, 5α-Dihydroxy, 6-ketocholestane (m.p. 230—233°; reported [26] 231—232°) was obtained by treatment of cholesterol in methanol with N-Br-succinimide, as described by Fieser *et al.*[26].

Preparation of homogenates. White male mice of the Danish State Serum Institute strain weighing approx. 25 g and white male rats of the Sprague-Dawley strain weighing approx. 150 g were used. 10 or 33 % (liver wet weight/volume) homogenates were prepared in 0.25 M sucrose containing 3.6 mg nicotinamide/ml with a tight-fitting Teflon Potter-Elvehjem homogenizer. Mitochondria were isolated by centrifugation for 10 min at 10 000 × *g* and then washed once with the homogenizing medium. Microsomes were spun down in the Spinco preparative ultracentrifuge at 100 000 × *g*, 60 min. Boiled liver juice was prepared from the supernatant of the 10 000 × *g* centrifugation of mouse liver homogenates by heating for 10 min at 85—95° followed by centrifugation for 20 min at 20 000 × *g* to remove denatured protein. In some cases boiled liver juice was prepared according to Horning *et al.*[7] The boiled liver juice was kept at —15° for not more than 4—6 weeks prior to use.

Mitochondria and microsomes were resuspended in a few ml of the nicotinamide-sucrose medium by homogenization with a loose-fitting pestle 10—20 sec and then diluted to suitable volumes. The composition of the incubations, in which mitochondria, AMP, DPN (purchased from the Sigma Chemical Co., St. Louis, USA and Boehringer, Mannheim, W-Germany, respectively) and boiled liver juice were used simultaneously, was as follows:

Mitochondria from 15 g of liver in 10 ml nicotinamide-sucrose medium
Boiled liver juice 9 ml
0.01 M DPN 1.5 ml
0.04 M AMP 1.5 ml
0.05 M Tris buffer, pH 7.8, 5 ml
Serum albumin suspension of labeled cholesterol 1—2 ml

When less or more mitochondria were used the amounts were proportionally changed. When boiled liver juice was omitted no change in the concentrations of the other components was made. In incubations with microsomes, these were suspended in the amount of solution used for suspending mitochondria.

The labeled cholesterol was added to the incubation mixtures as an emulsion with serum albumin, prepared by dissolving the sterol in 0.1—0.2 ml ethanol and adding 0.9—1.8 ml of a 1 % solution of bovine serum albumin (Armour Lab., Kankakee, Ill. USA) in distilled water. In some instances the cholesterol emulsion was prepared with Tween 20 (Atlas Powder Co., Wilmington, Delaware, USA) as described by Meier *et al.*[5]

Incubations were conducted aerobically at 38° for 4 h with shaking in 50 ml Erlenmeyer-flasks containing each not more than 5—7 ml of the incubation mixture. The incubations were terminated by addition of 3—4 volumes of ethanol.

Analyses of the incubation mixtures. The precipitate formed by the addition of ethanol was removed through filtration and the ethanol was evaporated. The aqueous residue was acidified with hydrochloric acid and then extracted twice with water-saturated *n*-butanol. The combined butanol-extracts were washed with water until neutral and

then taken to dryness. The residue was chromatographed in the reversed phase partition systems earlier described. Phase systems I and III [17] were employed for separation of neutral steroids and systems C1 and F1 [27] for acidic steroids. Hyflo Supercel or Hostalene, prepared as earlier described [18,28], were used as supporting material for the stationary phase.

Phase systems:

	Moving phase	ml	Stationary phase	ml
I	*Iso*propanol:water	165:135	chloroform:heptane	10:40
III	» »	150:150	» »	15:60
C1	Methanol:water	150:150	chloroform:*iso*octanol	15:15
F1	» »	165:135	chloroform:heptane	45:5

Chromatograms were run at constant temperature of 23°. Radioactivity was determined in infinitely thin layers with an automatic end-window counter or in a window-less methane gas-flow counter (Frieseke and Hoepfner, Erlangen, Germany, FH 49 and FH 51, respectively). $^{14}CO_2$ was trapped in 2 N KOH, precipitated with 1.5 M $BaCl_2$ and counted in an infinitely thick layer of $BaCO_3$.

RESULTS

Fractionation of homogenates and optimal conditions for oxidation of 4-^{14}C-cholesterol

In this section experiments are described where the conversion of cholesterol to more polar products was analyzed by chromatography first on phase system I to separate cholesterol from the more polar products (Fig. 1) and then on phase system III (Fig. 2) to separate the more polar products into three fractions, one "acidic" (A Fig. 2), one "trioxy neutral" (B Fig. 2) and one "dioxy neutral" (C Fig. 2).

Fractionation of liver homogenates, which were prepared either as 10 or 33 % homogenates, by differential centrifugation in the usual manner, demonstrated (Table 1) that the oxidation of cholesterol to more polar products

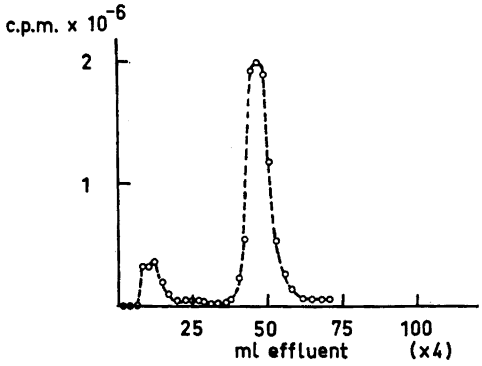

Fig. 1. Chromatogram of the butanol-extract from an incubation of 4-^{14}C-cholesterol with mouse liver mitochondria + boiled juice, AMP and DPN, 18 g Hostalene. Phase system I.

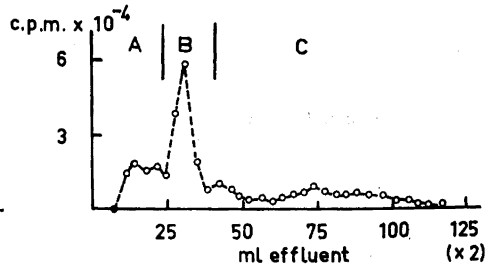

Fig. 2. Rechromatography of first peak in the chromatogram shown in Fig. 1. A = "acidic" fraction; B = "trioxy neutral" fraction; C = "dioxy neutral" fraction. 9 g Hostalene. Phase system III.

Table 1. Oxidation of cholesterol in different cellfractions of mouse and rat liver. 33 % homogenate.

	% conversion to more polar products	
	Rat	Mouse
Mitochondria	3	4.7
Microsomes	0.7	2.5
Supernatant	0.7	2
Mitochondria + supernatant	5	10
Mitochondria + microsomes + supernatant		5.5
Microsomes + supernatant	0.5	3.3

occurred most easily in presence of mitochondria isolated from mouse as well as rat liver. The addition of 100 000 × *g* supernatant (hereafter called supernatant) to mitochondria doubled the conversion. The oxidation was considerably slower in presence of microsomes and the addition of microsomes to mitochondria plus supernatant depressed the oxidation. Supernatant alone was capable of a small transformation of added cholesterol to more polar products. Use of boiled liver juice (prepared in either of the two ways described in the experimental part) instead of fresh supernatant in combination with mouse liver mitochondria resulted in the highest conversion of cholesterol to more polar products (10—15 %) and it was found that this magnitude of conversion could easily be reproduced from experiment to experiment. The extent of conversion was examined at various intervals during a 4 h incubation with this system (Fig. 3) and the oxidation was found to proceed in two phases, one rapid with leveling off after 1 h of incubation and afterwards one linear phase.

This system, mouse liver mitochondria plus boiled liver juice, is the same as the one described for achieving maximal $^{14}CO_2$-production from 26-^{14}C-cholesterol except that in the latter case there is a requirement for DPN and AMP. Using the amount of more polar products formed from 4-^{14}C-cholesterol as index of oxidation, as has been done in this investigation, the addition of DPN and/or AMP to the system had no influence on the magnitude of the oxidation nor could any effect be observed, when these cofactors, alone or in combination, were added to mitochondria alone (Table 2).

Incubation with boiled liver juice only resulted in 2—3 % oxidation of the added 4-^{14}C-cholesterol, easily reproduced in a number of experiments.

Table 2. The effect of cofactors on the oxidation of cholesterol in mouse liver mitochondria. 33 % homogenate.

	% conversion to more polar products

Boiled juice	3.3	3
Mitochondria (kidney)	0.7	1
» + boiled juice	2	
Mitochondria (heart)	2	1

Oxidation of cholesterol in presence of a deproteinized liver extract must be attributed to autoxidation. This finding is not entirely surprising in view of the long recognized sensitivity of cholesterol to autoxidation in colloidal solutions. Considering the appreciable autoxidation occurring in presence of boiled liver juice it was conceivable that at least part of the oxidation taking place in the optimal system (mouse liver mitochondria plus boiled liver juice) or even in mitochondria alone was due to autoxidation. One possible way of establishing if autoxidation occurred in presence of mitochondria alone was thought to be a study of the oxidation, if any, of cholesterol in mitochondria isolated from other organs, *e.g.* heart or kidney, which in the present state of knowledge can be regarded as unlikely sites of cholesterol catabolism *in vivo*. The extent of oxidation in heart or kidney mitochondria isolated from rat or mouse varied from 0.7 to 2 % (Table 3). Judging from the chromatographic behaviour of the polar products formed, these consisted of autoxidation products. It appears likely, therefore, that a certain degree of autoxidation of cholesterol occurs in mitochondrial systems.

Using the analytical procedure outlined at the beginning of this section, a consistent difference in the ratio "trioxy neutral" to "dioxy neutral" fraction was obtained when experiments using the complete system were compared with experiments using boiled liver juice only. Thus, under "enzymatic" conditions, *i.e.* using the full system, this ratio in the isolated products was 1.5—1.8, while non-enzymatic incubations, *i.e.* using boiled liver juice, yielded much less "trioxy neutral" steroids, resulting in a ratio of about 0.5—0.7. After incubations with mouse liver mitochondria alone roughly equal amounts of "trioxy neutral" and "dioxy neutral" steroids were isolated, and with rat liver mitochondria somewhat more of the "dioxy neutral" fraction was formed.

As it seemed apparent that part of the more polar products was formed by autoxidation of the added labeled cholesterol, to be described in more detail in the following section, it was conceivable that the mode of suspending the cholesterol could be a factor to be taken into account. Accordingly several experiments were performed using Tween 20 emulsions, a method that has been widely used for dispersing water-insoluble steroids in aqueous media. However, it was found, that the general pattern of polar products formed in the full system from Tween-emulsified cholesterol did not differ from that obtained when albumin-suspensions of cholesterol were used.

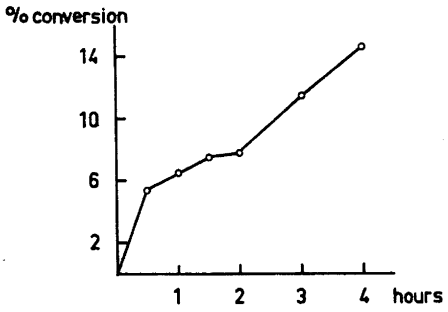

Fig. 3. Time curve of oxidation of cholesterol in mouse liver mitochondria + cofactors.

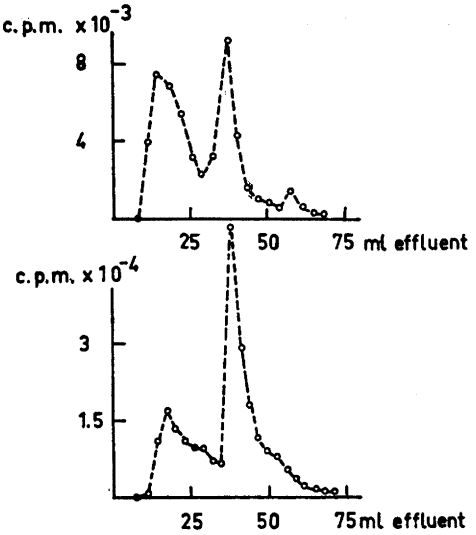

Fig. 4. Rechromatography of "acidic" and "trioxy neutral" fractions from incubation A (upper curve) and C (lower curve). 4.5 g hydrophobic Hyflo Supercel. Phase system III.

In view of the stability of cholesterol towards autoxidation *in vivo*, it appeared possible that the observed occurrence of autoxidation in the mitochondrial system might be due to incomplete penetration of the mitochondrial membrane by the extramitochondrially added cholesterol. As circumstantial evidence for such a concept could be taken the fact that efforts of procuring weighable amounts of the different more polar products by incubating mitochondria from several hundred rat livers did not yield the amounts that could be calculated from the magnitude of conversion of the labeled cholesterol added in these incubations and the amount of endogenous cholesterol present in the mitochondria. Experiments on the distribution of the added cholesterol between the mitochondria and the suspending medium would appear at first sight a more direct approach to this problem. After the termination of a usual 4 h incubation, the mitochondria were isolated again by centrifugation and the amounts of labeled cholesterol and conversion products were assayed both in the mitochondria and in the supernatant fluid. About 75—80 % of the total activity was found associated with the mitochondria. The percentage of more polar products of the total radioactivity was approximately the same in the mitochondria as in the supernatant fluid. Experiments on the rate of association of the added labeled cholesterol with the mitochondria demonstrated that after 15 min incubation 25 %, after 1 h 50 % and, as stated above, after 4 h 75—80 % of the originally added radioactivity was recovered from the mitochondria. That so much of the label was associated with the mitochondria when isolated after a 4 h incubation is by no means any proof, that the label

actually is present inside the mitochondria, as it might just as well be partly or wholly on the surface of the mitochondria. At this time no comparatively simple means of differentiating between these two possibilities could be visualized.

The presence of cupric ions has been shown to be an absolute requirement for the autoxidation of cholesterol in aqueous colloidal solutions [15] and the use of heavy metal complex formers in the incubation mixtures could conceivably reduce the autoxidation occurring in the mitochondrial system. Attempts to achieve a reduction of autoxidation merely by preparing the homogenate and cofactors in redistilled water and carrying out the incubations in flasks carefully rinsed with redistilled water were unsucessful. This is not unexpected since heavy metal ions already occur in the liver. However, in the presence of 10^{-3} M EDTA in the incubation mixture, a considerable reduction of the autoxidation occurred. The conversion to more polar products was in this case 6.4 % compared to 10.8 % in a parallel incubation without EDTA. The distribution of the more polar products between the "acidic", "trioxy neutral" and "dioxy neutral" fractions were in both instances approximately the same, but when the "trioxy neutral" fractions were further analyzed a marked difference was observed. This fraction, as described in detail below, contains 3β, 5α, 6β-trihydroxycholestane, which is the major autoxidation product formed in the present experiments. The content of the cholestanetriol in the "trioxy neutral" fraction from the incubation with EDTA present was only a third (16 %) of that (44 %) found when no EDTA had been added. The used of 10^{-3} M CN^- or 10^{-3} M phenanthroline did not result in the same reduction of autoxidation as the use of EDTA.

Isolation and partial identification of the products of oxidation of cholesterol under non-enzymatic and "enzymatic" conditions

Before undertaking the experiments described below, and the analyses of the products formed in these, a number of testruns and testanalyses were performed. The same chromatographic pattern of products was obtained, whether mitochondria isolated from a 10 % or a 33 % homogenate were employed in incubations with 4-^{14}C-cholesterol together with boiled juice prepared from a water extract of whole liver or from the supernatant fluid obtained after removal of mitochondria. As it was found more practicable to use a 33 % homogenate and boiled juice isolated after spinning down the mitochondria, this method was employed in experiments aiming at isolation of products. When this system was tested in a few experiments for $^{14}CO_2$-production from 26-^{14}C-cholesterol, negligible amounts of labeled CO_2 could be recovered. Chromatography of such incubations demonstrated the presence of the same products found in 4-^{14}C-cholesterol incubations. Two incubations, kindly performed by Dr. M. G. Horning, were run with 26-^{14}C-cholesterol with the aim of also analyzing for $^{14}CO_2$ using a 10 % homogenate and boiled juice from a water extract of whole liver. The yield of labeled CO_2 was 2.5 and 0.4 %, respectively. Due to the use of too small an amount of 26-^{14}C-cholesterol in the first experiment, the conversion products could not be isola-

ted. In the second experiment the conversion to polar products was 10 %. Chromatography of this material did not demonstrate any noticeable difference in the pattern of products compared to, *e.g.*, the ones isolated in the experiments described below.

Isolation and partial identification of products formed from 4-^{14}C-cholesterol under non-enzymatic and "enzymatic" conditions were performed on four separate incubations using: A, cofactors only (boiled juice, AMP and DPN); B, mouse liver mitochondria; C, mouse liver mitochondria plus cofactors; D, rat liver mitochondria. Analyses were performed in the same manner for all four incubations unless otherwise stated.

Chromatography of the butanol-extracts on phase system I allowed calculations of the amount of the more polar products and of cholesteryl esters formed, which latter are retained in the stationary phase. The conversions are given at the top of Table 4. The amount of cholesteryl esters in incubation B was 0.2 %, in C 1.6 % and in D 0.7 %. The more polar products were saponified with 10 % methanolic potassium hydroxide for 1 h. This procedure, which facilitates the further isolation of the products, does not appear to change the chromatographic properties of these. After saponification the polar material was chromatographed on phase system III to separate it into the three fractions earlier discussed. Some 20 % of the radioactivity was retained in the stationary phase and was found to consist of cholesterol as shown by rechromatography on phase system I. An explanation for the presence of cholesterol in this eluate could be that a small part of the cholesterol in the original

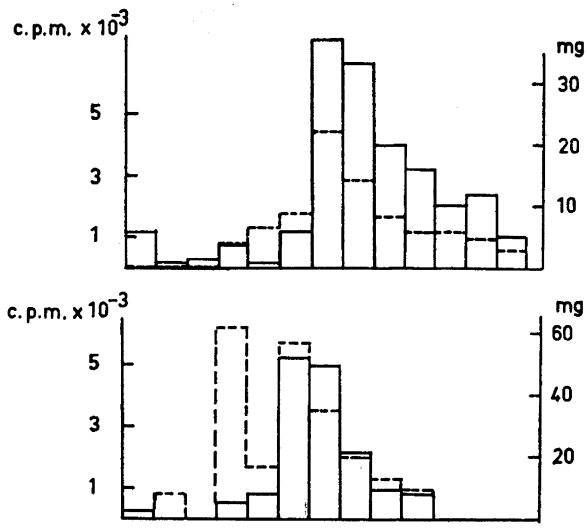

Fig. 5. Chromatography of acetylated "trioxy neutral" fractions of A and C together with unlabeled 3β, 5α, 6β-trihydroxycholestane. *Cf.* Fig. 4. 100 ml fractions. Each bar represents one fraction. 20 g Woelm I. Broken line: radioactivity. Solid line: weight.

butanol-extract was in the form of a complex with lipid material of such a polarity, that it is eluted early with phase system I. After saponification this complex would dissociate and the free cholesterol formed is retained in the stationary phase of the chromatogram with phase system III.

The "acidic" and the "trioxy neutral" fractions were combined and rerun to obtain a more distinct separation of these fractions. This chromatogram is shown in Fig. 4. The upper curve is the one obtained from incubation A (cofactors only) and the lower from incubation C (full system). All subsequent figures will also each show chromatograms from incubation A (upper curves) and C (lower curves).

"*Acidic*" *fraction.* The acidic material was chromatographed together with unlabeled cholic acid with phase system C1. In all cases there was a front peak. In material from incubations B, C and D there was also obtained a peak appearing shortly after cholic acid. The eluates of these columns containing any dihydroxy- and monohydroxy acids were chromatographed together with unlabeled chenodeoxycholic acid on phase system F1. In all four chromatograms two radioactive bands appeared after the titration curve of the added carrier.

"*Trioxy neutral*" *fraction.* The "trioxy neutral" fractions were acetylated together with 200 mg 3β, 5α, 6β-cholestanetriol each and chromatographed on aluminium oxide (Woelm, Eschwege, W-Germany, grade 1) using increasing concentrations of ethyl acetate (from 0 to 5 %) in benzene as eluant. In the chromatograms of this fraction from incubation C, as shown in Fig. 5, a large radioactive peak, designated in Table 4 as Ia, appears before the 3,6-diacetate

of the carrier is eluted. Comparatively small amounts of activity is eluted at this place in the chromatogram of the same fraction from incubation A, *cf.* Fig. 4. The same early radioactive peak, although smaller, was observed in chromatograms of B and D. Radioactivity was in all cases eluted together with the carrier. At the end of the peak of the carrier the specific activity per mg carrier rose, and to find out if this represented another radioactive compound than the cholestanetriol, the carrier peaks were divided into two fractions, that were crystallized separately to constant specific activity (four crystallizations from methanol/water, acetone/water, hexane and methanol/water). It was found that the late increase in specific activity of the carrier observed in the chromatogram represented radioactive material, designated in Table 4 as Ib, not identical with the 3,6-diacetate of the cholestanetriol. As this occurred also in A, it was thought that this material might be the 3-acetate of 3β-, 5α-dihydroxy-6-ketocholestane, but cocrystallization of the radioactive material with this compound failed to establish any such identity. As Ib represented only a small amount of the total "trioxy neutral" fraction any further characterization was not pursued.

Some information on the structure of compound Ia was obtained by its metabolism in the bile-fistula rat. When injected intraperitoneally it was rapidly excreted, 60—70 % the first 24 h, and had been transformed into chenodeoxycholic acid, the identity of which was established by cocrystallization with unlabeled chenodeoxycholic acid, and into two other acids with chromatographic properties identical to those of the 6β-hydroxylated acids formed from chenodeoxycholic acid.

"Dioxy neutral" fraction. The "dioxy neutral" fraction was subjected to additional chromatography on Hyflo Supercel columns using phase system III. By this method of chromatography this fraction could be separated into two distinct peaks in the case of B, C and D, while A yielded only one main peak, *cf.* Fig. 6. The material in the first peak, present in A, B, C and D, had the same elution volume as 7α- and 7β-hydroxycholesterol, which are difficult to separate with this phase system. The method of choice for achieving a separation of these epimers appears to be to form the dibenzoates, which are reported to be separable by chromatography on aluminium oxide [21] and which in addition are easier to crystallize than the free sterols, anyway in the case of the β-epimer. Accordingly the radioactive material was diluted with 100 mg of unlabeled 7β-hydroxycholesterol and benzoylated in the usual manner. The ether extract of the benzoylation mixture was distributed between hexane and 70 % aqueous methanol, a procedure that was found to remove byproducts, which seriously interfered with the chromatography. The hexane-phase containing the hydroxycholesterol dibenzoates was evaporated to dryness and the residue chromatographed on aluminium oxide. In spite of considerable efforts to separate the epimers by careful chromatography on both Woelm, grade I, and Merck aluminium oxide, no such separation could be obtained. However, it was found that in B and C, but not in A (D was lost in an earlier chromatogram), a radioactive peak appeared in the chromatogram just before the elution of the hydroxycholesterol dibenzoates, but whether this early peak represented some unknown compound or just by chance a partial separation of the α-epimer from the β-epimer cannot be stated at present. All material

eluted in respective columns was combined and crystallized to constant specific activity (from methanol once and acetone/water twice) and the amount of 7β-hydroxycholesterol could thus be calculated. The first mother liquor containing the α-epimer, was then diluted with 80 mg unlabeled 7α-hydroxycholesterol dibenzoate and crystallized to constant specific activity (from methanol once and acetone/water twice) giving the amount of this epimer in the original mixture. Isotope dilution as analysis for the two hydroxycholesterol dibenzoates in a mixture of both has been used earlier by Dauben and Payot [25]. In the case of A there remained 20 %, in B 36 % and in C 30 %, of the original radioactivity not accounted for as the 7-hydroxycholesterol dibenzoates. During the course of the attempts to separate the epimeric dibenzoates, it was observed that limited hydrolysis of the dibenzoates occurred, especially when the chromatograms had to be run over several days. Whether the radioactivity not identified as 7α- and 7β-hydroxycholesterol dibenzoate could be accounted for as partly or wholly saponified dibenzoate or represented a new compound(s) was not further investigated with this material.

In the chromatograms of the "dioxy neutral" fraction (*cf.* Fig. 6), as mentioned earlier, another compound, designated as III in Table 4, was eluted after the 7α- and 7β-hydroxycholesterol in B, C and D. The formation of this unknown metabolite has been observed only in "enzymatic" incubations and its nature and further metabolism is presently being studied.

In all four chromatograms of the "dioxy neutral" fraction on Hyflo Supercel columns (Fig. 6) part of the radioactivity was retained in the stationary

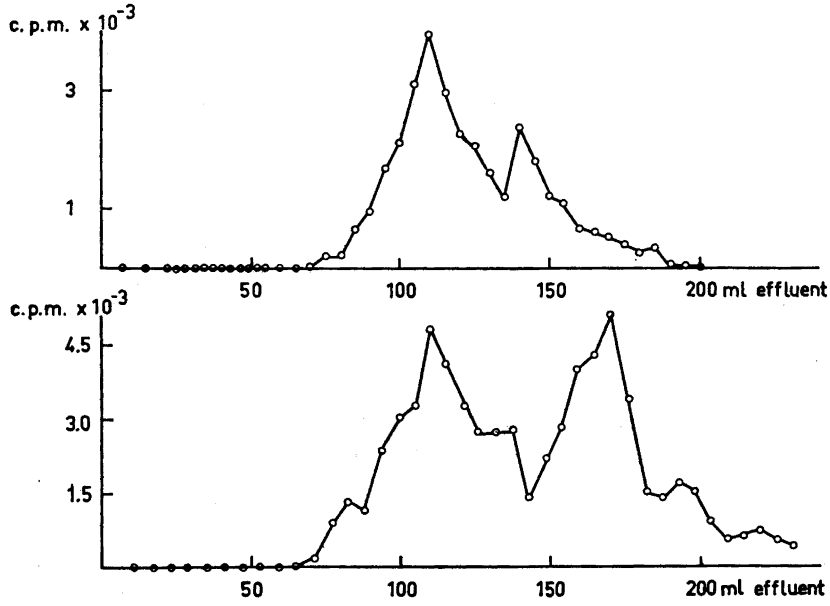

Fig. 6. Chromatograms of "dioxy neutral" fractions of A and C. *Cf.* Fig. 4. 4.5 g hydrophobic Hyflo Supercel. Phase system III.

phase. This material was rechromatographed on phase system I and found to have the same elution volume as 7-ketocholesterol. The identity of the labeled material with 7-ketocholesterol was established by isotope dilution.

DISCUSSION

Prior to the present work only one investigation, that by Fredrickson [10], on the oxidation of 4-^{14}C-cholesterol in a fortified mouse liver mitochondrial system has been published. The results obtained in the two studies are entirely at variance with each other and no explanation can be offered. While Fredrickson found products that appeared to have arisen by enzymatic oxidation only, the results now presented, corroborated by further analyses of the experiments reported by Danielsson and Horning [12], emphasize first of all that a considerable degree of autoxidation of the added 4-^{14}C-cholesterol indubitably occurs. Thus, there appears to be no reason to invoke enzymatic action as an explanation for the formation of such compounds as 3β, 5α, 6β-cholestanetriol, 7β-hydroxycholesterol and 7-ketocholesterol, which were formed in all incubations examined. These compounds are all typical autoxidation products and would be illogical and improbable intermediates in the catabolism of cholesterol to bile acids, which latter have normally a 7α-hydroxyl-group and invariably lack a hydroxyl at position 5. The possibility that 7α-hydroxycholesterol in part was formed enzymatically should not be excluded expecially as the evidence so far available makes it a highly probable early intermediate in the formation of bile acids from cholesterol [3]. On the other hand, it must also have been formed by autoxidation, which yields both epimers. Any possibility of establishing if 7α-hydroxycholesterol was formed partly by enzymatic action on cholesterol in the present experiments appears remote.

Based on the nature of the polar products and the respective amounts of these the extent of autoxidation in the fortified mouse liver mitochondrial system amounted to approximately 50 % of the total amount of labeled cholesterol oxidized.

Although the occurrence of autoxidation in the mitochondrial system cannot be regarded as unexpected in view of the well-documented instability of cholesterol in polar solvents upon exposure to oxygen *, it would seem possible that the mode of solubilizing the cholesterol could be of importance. Attempts to reduce autoxidation by emulsifying with Tween instead of serum albumin were not successful. Recently Avigan [29] published a method for preparing cholesterol solutions with the aid of serum lipoproteins and this method merits to be tested as a possible means of reducing autoxidation in the mitochondrial system. Another possibility could be to run short time incubations. The shape of the time curve was such (Fig. 3) that it had some resemblance to that of an enzymatic process in mitochondria or microsomes during the first 2 h of incuba-

* The radiation of ^{14}C in ^{14}C-labeled cholesterol stored in the dry state in presence of air for long periods of time, 1 month—2 years, has been shown [25] to induce autoxidation proceeding in a manner identical with that of unlabeled cholesterol in colloidal suspensions. The contribution, if any, of the radiation of ^{14}C in the labeled cholesterol to the magnitude of autoxidation in the present experiments was not investigated.

tion. However, some preliminary analyses of polar products formed during this early phase of the incubation did not reveal any striking differences.

A more direct approach to the problem of reducing autoxidation seems to be to incubate in the presence of heavy metal complex formers, as the autoxidation of cholesterol in aqueous colloidal solutions has been shown to require the presence of cupric ions [15]. The use of 10^{-3} M EDTA in the incubation mixture resulted in a considerable but not total reduction of the autoxidation. Further work is needed in order to be able to closer evaluate the possibilities in this method.

The emphasis should, however, not be put only on the occurrence of autoxidation of the added labeled cholesterol in the mitochondrial preparations. Approximately half of the products isolated must have been formed by the action of enzymes. As basis for this conclusion is taken that products formed only in the presence of mitochondria are enzymatic products. The two main enzymatically formed products were Ia, which is identical with the compound earlier reported on by Danielsson and Horning [12], and III (*cf.* Table 4). As earlier stated both compound Ia and III must have a C_{27}-side-chain, as they were formed also from 26-^{14}C-cholesterol, but the detailed structures of these have not been established. Ia had chromatographic properties similar to those of a trihydroxylated neutral C_{27}-sterol both on reversed phase and as acetylated on aluminium oxide columns. It forms probably a triacetate. as it had the same mobility on aluminium oxide as the triacetate of 3α, 7α, 27-trihydroxycoprostane. The manner it was metabolized in the bile-fistula rat, yielding chenodeoxycholic but not cholic acid, indicated that the hydroxyls could be in positions 3, 7 and 27, as 3α, 7α-dihydroxycoprostane is metabolized to both cholic and chenodeoxycholic acid, while 3α, 7α-dihydroxycoprostanic acid gives chenodeoxycholic but not cholic acid [30], *i.e.* the presence of oxygen functions in the side-chain of a steroid with a 3,7-hydroxylated nucleus makes a 12-hydroxylation in the rat impossible.

Compound III showed chromatographic properties similar to those of a saturated dihydroxy neutral C_{27}-sterol or of an unsaturated hydroxyketone with considerably greater polarity than 7-ketocholesterol. Work on the structure and further metabolism of this compound is in progress and will be the subject of a future communication.

Among the acidic products at least one acid, the one which was eluted shortly after cholic acid with phase system C1, was an enzymatic product, but no further characterization of this acid has been carried out. The presence of labeled acidic compounds in the non-enzymatic incubations was unexpected, as such products have not been demonstrated earlier in autoxidized cholesterol. Further work on the nature of these must be done before their chromatographic counterparts in the "enzymatic" incubations can be studied.

In discussing the labeled enzymatic products formed from labeled cholesterol in the mitochondrial preparations, it must be stressed that there is no evidence, either for or against, that these compounds are formed *directly* from cholesterol, as they just as well could be enzymatically transformed autoxidation products, in the case of Ia and III most probably from 7α-hydroxycholesterol and in the case of the acidic compound(s) from any of the autoxidation products.

Whether or not any $^{14}CO_2$ was formed from 26-^{14}C-cholesterol, the same general pattern of polar products was obtained. The results presented therefore have the same bearing on incubations performed with 26-^{12}C-cholesterol as with 4-^{14}C-cholesterol. There can be no doubt that the formation of $^{14}CO_2$ from 26-^{14}C-cholesterol is an enzymatic process but the nature of the substrate in this oxidation is in more doubt, anyway as judged from the results of this investigation. Using only $^{14}CO_2$-formation from 26-^{14}C-cholesterol as an assay it appears that results of studies of the *quantitative* aspects on the conversion of cholesterol to bile acids should be interpreted with caution, especially in incubations of long duration.

Acknowledgments. The skillful technical assistance of Miss Birgitta Holmberg and Miss Electra Pascalides is gratefully acknowledged.

Substituted 1,3-Diamino-2-propanols

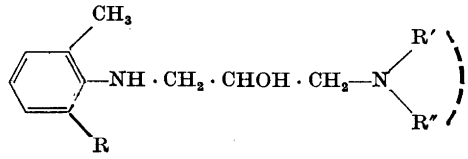
RICHARD DAHLBOM* and ALFONS MISIORNY

Research Laboratories, AB Astra, Södertälje, Sweden

A series of 1,3-diamino-2-propanols of the general formula $R-CH_2 \cdot CHOH \cdot CH_2-Am$ where R is a 2,6-disubstituted anilino residue and Am is an alkylamino group were synthesised. Some compounds were also made with R a benzhydrylamino or 10-phenothiazinyl group.

1,3-Diamino-2-propanols of the general formula $R-CH_2 \cdot CHOH \cdot CH_2-Am$, where R is an unsubstituted or monosubstituted anilino residue and Am is a lower mono- or dialkylamino group were first prepared by Fourneau *et al.*[1,2] in connection with their investigations on antimalarial drugs. Further compounds of this type have been described by Ludwig, West and Farnsworth [3], who stated that these compounds possessed striking convulsant properties.

In connection with work on local anesthetics it was of interest to prepare and study compounds of this type containing a 2,6-disubstituted anilino residue. A number of compounds were synthesised with the general formula



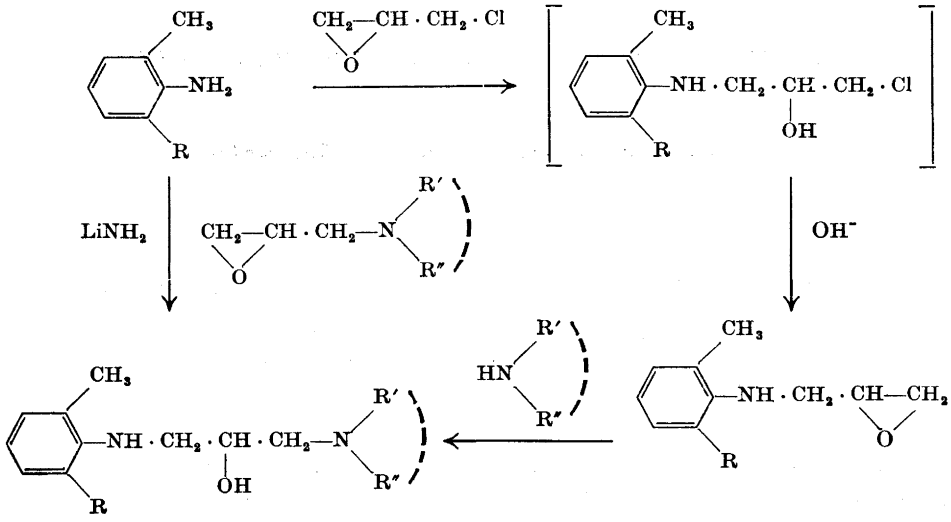
in which R is methyl or chlorine and R′ and R″ are hydrogen, alkyl groups or two connected alkyl groups forming a heterocyclic ring. These compounds were prepared by two methods:

(*A*) Condensation of a 2,6-disubstituted aniline with an N-(2,3-epoxypropyl)-dialkylamine in the presence of lithium amide. Attempts to effect this condensation without a condensing agent gave very poor yields even at elevated temperatures.

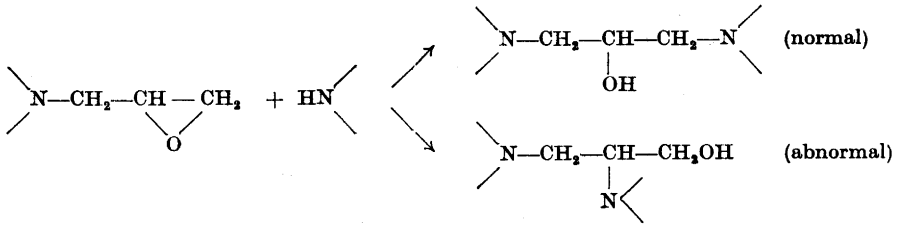
---

* Present address: Royal Institute of Pharmacy, Stockholm, Sweden.

(*B*) Treatment of a 2,6-disubstituted aniline with epichlorohydrin giving a 1-anilino-3-chloro-2-propanol, followed by treatment of the product, without isolation, with a large excess of alkali in order to reform an epoxide ring and reaction of the N-(2,3-epoxypropyl)-aniline obtained with a primary or secondary amine.



Theoretically the opening of an unsymmetrically substituted epoxide ring can give rise to two structural isomers:



However, there is considerable evidence [4-6] that if the reaction as in this case is a nucleophilic displacement on carbon, the nucleophilic reagent entirely or predominantly attacks the least substituted carbon atom ("normal" ring-opening). We have therefore presumed that the compounds described in this paper are 1,3-diamino-2-propanols and not the isomeric 2,3-diamino-1-propanols which would be the products, if the ring-opening were "abnormal". The compounds (1—20) and their properties are listed in Table 1.

The new compounds were tested for local anesthetic action on rabbit cornea, using Xylocaine as standard. They all had a marked anesthetic effect (usually 1—5 times that of Xylocaine). The *cyclo*hexylamino compounds 7 and 15 were about 15—20 times as active as Xylocaine. The lowest activity

was shown by the compounds containing a morpholino or piperazine residue as amino component. The compounds were usually somewhat more toxic than Xylocaine and moreover had convulsant properties. Some of them had a favourable therapeutic index, but their usefulness as local anesthetics was precluded by the strong irritating properties displayed by all compounds in this series.

Several of the compounds had hypnotic or sedative effects. Attempts were therefore made to enhance this effect by replacing the anilino group by a benzhydrylamino, *p*-chlorobenzhydrylamino or a 10-phenothiazinyl residue (compounds 21—27 in Table 1). Compounds 23 and 27 are of special interest as these compounds bear a certain structural resemblance to hydroxyzine, N-(*p*-chlorobenzhydryl)-N'-[2-(2-hydroxyethoxy)-ethyl]-piperazine, and perphenazine, N-[3-(2-chloro-10-phenothiazinyl)-propyl]-N'-(2-hydroxyethyl)-piperazine, respectively, which are used clinically as ataraxic agents. However, compounds 21—27 had very little or no ataraxic properties in pharmacological tests.

EXPERIMENTAL

2,3-Epoxypropylamines

N-(2,3-Epoxypropyl)-diethylamine and *N-(2,3-epoxypropyl)-piperidine* were prepared from diethylamine and piperidine, respectively, by reaction with epichlorohydrin according to the method of Gilman *et al.*[7]

N-(2,3-Epoxypropyl)-morpholine was prepared in the same way but with some small modifications owing to the greater solubility of the morpholino compound in water. Yield 50 %. B. p. 89—90°/10 mm; n_D^{25} 1.4670. (Found: C 58.8; H 9.07; N 9.86. Calc. for $C_7H_{13}NO_2$: C 58.7; H 9.15; N 9.78.)

N-Methyl-N'-(2,3-epoxypropyl)-piperazine was prepared by the same method from N-methylpiperazine and epichlorohydrin. Yield 22 %. B. p. 95—96°/12 mm; n_D^{25} 1.4727. (Found: C 61.5; H 10.3; N 17.9. Calc. for $C_8H_{16}N_2O$: C 61.3; H 10.4; N 18.1.)

N-(2,3-Epoxypropyl)-2,6-dimethylaniline. A solution of 2,6-dimethylaniline (121 g, 1.0 mole) and epichlorohydrin (102 g, 1.1 mole) in toluene (150 ml) was refluxed for 6 h. After cooling to room temperature, powdered sodium hydroxide (75 g) was added in small portions with stirring and external cooling. After half an hour water (300 ml) was added, the stirring was continued for a further half hour. The toluene layer was separated, washed with water and dried over sodium sulphate. The solvent was evaporated *in vacuo* and the residue distilled giving a colourless oil (76 g, 43 %), b. p. 90—92°/0.3 mm; n_D^{20} 1.5415. (Found: C 74.2; H 8.43; N 8.20. Calc. for $C_{11}H_{15}NO$: C 74.5; H 8.53; N 7.90.)

N-(2,3-Epoxypropyl)-2-chloro-6-methylaniline was prepared in the same way. However, 2-chloro-6-methylaniline reacted rather sluggishly with epichlorohydrin and the reaction was therefore carried out by heating the components in diethylbenzene (mixture of isomers of b.p. 175—181°) at 160—170° for 6 h. Yield 38 %. B. p. 109—111°/1.0 mm; n_D^{20} 1.5562. (Found: C 61.3; H 6.24; N 6.89. Calc. for $C_{10}H_{12}ClNO$: C 60.8; H 6.12; N 7.09.)

N-(2,3-Epoxypropyl)-benzhydrylamine. Benzhydrylamine (216 g, 1.18 mole) was added with stirring in small portions during one hour to epichlorohydrin (111.2 g, 1.20 mole) to which had been added some water (3.6 ml). During the addition the temperature rose to 28°. Stirring was continued for 8 h, during which time the temperature rose slowly to 35° and then decreased.

The reaction product separated gradually as a thick oil. The reaction mixture was allowed to stand overnight and then benzene (150 ml) was added followed by a solution of sodium hydroxide (56 g) in water (90 ml) added with stirring over half an hour. Stirring

was continued for one hour. Ether (100 ml) was then added and the organic layer was separated and dried over sodium sulphate. The solvent was evaporated under reduced pressure and the residue, a viscous oil (280 g) which did not crystallise was used as starting material for syntheses without further purification. Attempts to distill the oil led to decomposition.

1,3-Diamino-2-propanols

Method A. Lithium amide (0.11 mole) was added to a solution of the aromatic amine (0.1 mole of 2,6-dimethylaniline, 2-chloro-6-methylaniline, phenothiazine, *etc.*) in benzene (150 ml) and the reaction mixture was refluxed with stirring for 1.5 h. After cooling the appropriate N-(2,3-epoxypropyl)-dialkylamine (0.1 mole) was added, and the mixture was refluxed with stirring for a further 2.5 h. After cooling the benzene solution was washed with water and extracted with 2 N hydrochloric acid. The acid extract was then made alkaline with conc. ammonium hydroxide. The reaction product usually separated as an oil that soon crystallised and was purified by recrystallisation. When it was impossible to obtain the product in crystalline form, it was extracted with ether, the ether was evaporated and the residue distilled *in vacuo*. Some of the compounds were converted to a salt and purified by recrystallisation.

In the preparation of the phenothiazine compounds 24—27 the reaction time after the addition of the epoxide was prolonged to 5 h.

Compound 23 was prepared by condensation of *p*-chlorobenzhydrylamine and N-methyl-N′-(2,3-epoxypropyl)-piperazine in boiling xylene for 6 h and it was therefore not necessary to use lithium amide as condensing agent in this case. Compound 23 contains two asymmetric carbon atoms and should be able to give two racemates. No attempts were made to separate these racemates. Method *A* was used for compounds 1, 3, 4, 11, 13, 19, 20 and 23—27.

Method B. A solution of the appropriate N-(2,3-epoxypropyl)-aniline (0.1 mole) and a mono- or dialkylamine (0.2 mole of diethylamine, *n*-propylamine, pyrrolidine, *etc.*) in xylene (50 ml, mixture of isomers of b.p. 138—142°) was refluxed for 6 h. The xylene was washed with water and extracted with 2 N hydrochloric acid. The reaction product was then isolated as described for method A. Method *B* was used for compounds 1, 2, 5—10, 12, 14—18, 21 and 22.

Physical constants and analytical data are collected in Table 1.

The Constitution of an Araboxylan from Scots Pine (*Pinus silvestris* L.)

PER J. GAREGG and BENGT LINDBERG

Svenska Träforskningsinstitutet, Träkemiska avdelningen, Stockholm Ö, Sweden

Pine (*Pinus silvestris* L.) chlorite holocellulose after extraction first with dimethyl sulphoxide and water gives an araboxylan on extraction with 14 % potassium hydroxide. From the results of methylation studies it is concluded that this araboxylan has a backbone of 1,4-linked β-D-xylopyranose residues and that every fifth to sixth xylose residue is substituted in the 2-position with 4-*O*-methyl-D-glucopyranosyluronic acid residues, while every seventh to eighth xylose residue is substituted in the 3-position with L-arabofuranose residues.

The isolation of an araboxylan from Scots pine (*Pinus silvestris L.*) has been described in a previous communication from this Institute [1]. Pine chlorite holocellulose [2] was extracted successively with dimethyl sulphoxide, hot water, 14 % aqueous potassium hydroxide, 14 % aqueous potassium hydroxide containing 3 % boric acid and finally with 24 % aqueous potassium hydroxide containing 3 % boric acid. The hemicellulose extracted with 14 % potassium hydroxide on fractionation first with Fehling's solution and then with aqueous barium hydroxide [3] yielded an araboxylan substantially free from other polysaccharides.

The present paper deals with the results of methylation studies on the araboxylan. The molar ratio arabinose: xylose: 4-*O*-methylglucuronic acid was 1 : 7.7 : 1.5, and the $\overline{DP}_n$ estimated by osmometry in aqueous solution [4] was 133.

The araboxylan was methylated with dimethyl sulphate in sodium hydroxide solution and then treated five times with methyl iodide and silver oxide in dimethyl formamide [5]. The product (methoxyl 38.1 %, $\overline{DP}_n$ 115) was subjected to acid hydrolysis and the acidic and neutral fragments were separated on an anion exchange resin. The acidic portion containing the methylated aldobiouronic acid together with a smaller amount of the methylated uronic acid, after esterification and glycosidation, was reduced with lithium aluminium hydride and then hydrolysed.

The monomeric sugars in the two hydrolysates were fractionated on carbon-Celite columns and estimated quantitatively. The 2-*O*- and 3-*O*-methyl-D-xyloses in the neutral fraction of the hydrolysate from the methylated polysaccharide were incompletely separated on the column; their relative proportion was determined by quantitative paper electrophoresis in borate buffer [6] and a preparative fractionation was done on a carbon-Celite column

Table 1. Methyl ethers (mole %) obtained from methylated araboxylan from pine wood.

Component	Mole %
Xylose	0.4
2-*O*-Methylxylose	9.9
3-*O*-Methylxylose	13.7
"Dimethylarabinose"	0.9
2,3-Di-*O*-methylxylose	49.8
2,3,4-Tri-*O*-methylxylose	1.3
2,3,5-Tri-*O*-methylarabinose	9.7
2,3,4-Tri-*O*-methylglucose	14.3

Table 2. Fractionation of neutral monosaccharides from a hydrolysate of methylated araboxylan. Gradients: 0—12 % aqueous ethanol (3 l), 12—35 % aqueous ethanol (3 l), 35 % aqueous ethanol-35 % aqueous *n*-propanol. Fractions collected: 25 ml.

Tube No.	Component	Millimoles	Mole %
42— 50	Xylose	0.0212	0.5
70— 75	3-*O*-Methylxylose	0.0622	1.5
76—116	2-*O*- and 3-*O*-Methylxylose	0.655	16.0
117—132	"Dimethylarabinose"	0.0596	1.5
133—220	2,3-Di-*O*-methylxylose	2.70	66.0
250—274	2,3,5-Tri-*O*-methylarabinose	0.524	12.8
275—298	2,3,4-Tri-*O*-methylxylose	0.0685	1.7

The ratio 2-*O*- : 3-*O*-methylxylose in fraction 76—116 was 4.5:1.

Table 3. Fractionation of the hydrolysate from the acidic part of the methylated araboxylan hydrolysate. Gradient: 0—50 % aqueous ethanol (5 l). Eluted with 50 % aqueous ethanol. Fractions collected: 25 ml.

Tube no.	Component	Millimole	Mole %
24—80	3-*O*-Methylxylose	0.434	42.0
Remainder	2,3,4-Tri-*O*-methylglucose	0.600	58.0

by gradient elution with borate buffer [7]. The results of the fractionations are summarised in Table 1. In correlating the proportions obtained in the two fractionations (see Tables 2 and 3) to get the values given in Table 1, the ratio of the total amount of monomers in each of the two fractionations was adjusted to give the same uronic acid content as that present in the original araboxylan.

The hydrolysate obtained from the acidic fragments of the methylated polysaccharide hydrolysate contained only 3-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-glucose. The aldobiouronic acid from the pine wood thus clearly is 2-*O*-(4-*O*-methyl-D-glucuronopyranosyl)-D-xylose which is the usual aldobiouronic acid fragment found in wood xylans [8–15]. There were no indications of 3-*O*-(4-*O*-methyl-D-glucuronopyranosyl)-D-xylose residues the presence of which has been reported in hydrolysates from *Pinus radiata* D. Don [16] and various grasses [17]. The aldobiouronic acid was isolated from a partial hydrolysate of the araboxylan and was converted to the crystalline methyl-2-*O*-(methyl 2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucuronopyranosyl)-3,4-di-*O*-acetyl-D-xylopyranoside according to Timell [18]. Some 3-*O*-methyl-D-xylose was found in the hydrolysate from the neutral portion of the methylated polysaccharide. This probably arises from partial hydrolysis of the methylated aldobiouronic acid fragment, as the yield agreed well with the excess of 2,3,4-tri-*O*-methyl-D-glucose from the acid portion. The L-arabofuranose residues therefore appear to be attached exclusively to the 3-positions of the anhydroxylose residues. This is substantiated by the relative proportions of 2-*O*-methyl-D-xylose and 2,3,5-tri-*O*-methyl-L-arabinose. The results give no indication whether the L-arabofuranose residues are linked directly to the anhydroxylose back-bone or are the terminal residues of side-chains of β-1,4-linked xylose units. From the results of previous investigations [19,20], however, it seems likely that the L-arabofuranose residues are linked directly to the anhydroxylose back-bone. The amount of the fraction containing 2,3,4-tri-*O*-methyl-D-xylose (1.3 mole %) appears somewhat higher than that required by a $\overline{DP}_n$ of 115 (0.9 mole %). This fraction did, however, contain a smaller amount of 2,3,5-*O*-tri-methyl-arabinose, and there is therefore little indication of any branching in the β-1,4-linked anhydroxylose back-bone.

Previous studies of the hemicelluloses of coniferous wood have indicated the presence of a xylan composed only of 4-*O*-methyl-glucuronic acid and xylose [9,11,14,15]. This arabinose-free xylan has been extracted directly with alkali from finely ground wood and the hemicelluloses have been fractionated to yield the xylans [9,15]. Fractionation of alkaline holocellulose extracts has also yielded arabinose-free xylans [11,14]. The yields have usually been of the order of 1 % or less of the wood. Xylans containing arabinose residues have been isolated from Norway spruce [21], Western hemlock [10,22] European larch [23] and Sitka spruce [12]; the constitutions of those from Western hemlock [22] and European larch [23] have been investigated and found similar to that of the araboxylan examined in the present work. Structural investigation of the xylans present in Southern pine pulps [24] has indicated a similar structure for the native araboxylan in this case also. The xylan in the present investigation represents 80 % of the total xylan in the wood which amounted to 9—10 % of the dry extractive-free wood. In view of the results of previous investigations, the

presence in the pine wood of an arabinose-free xylan cannot be excluded, but it seems however probable that if present it constitutes only a minor part of the xylan in the wood.

EXPERIMENTAL

All melting points are corrected. Evaporations were done under reduced pressure at a bath temperature below 40°.

Chromatography. Papers: Whatman No. 1. Solvents: A. Ethyl acetate-acetic acid-water 3:1:3. B. Butanol-ethanol-water 10:3:5. C. *Iso*propyl ether-light petroleum (40—60°) 1:1 (on dimethyl sulphoxide-impregnated paper [25]).

Paper electrophoresis. Papers: Whatman No. 1, Schleicher and Schüll 602hP. Buffers: 0.1 M borate buffer at pH 10, 0.1 M acetate buffer at pH 4. Spray reagents: Aniline hydrogen phthalate, anisidine hydrochloride.

Isolation of the araboxylan. The araboxylan was extracted from Scots pine (*Pinus silvestris* L.) chlorite holocellulose. It was obtained in a substantially pure form by the fractionation techniques previously described [1]. OCH_3 2.6 %; 4-*O*-methylglucuronic acid 20.7 %; the ratio galactose:glucose:mannose:arabinose-xylose was trace:trace:nil:12.7:87.3; $\overline{DP}_n$ 133 (in aqueous solution [4]), $[\alpha]_D^{20}$ −59° (*c*, 1.2 in water).

Methylation of the araboxylan. The araboxylan (5 g) was first methylated with methyl sulphate in aqueous sodium hydroxide and then treated five times with methyl iodide and silver oxide in dimethyl formamide [5,26]. Yield 4.4 g, $[\alpha]_D^{20}$ −50°. (*c*, 1 in chloroform), OCH_3 38.1 %, (calculated methoxyl content for a fully substituted araboxylan with 20.7 % methyluronic acid is 38.1), $\overline{DP}_n$ 115.

Hydrolysis of the methylated araboxylan and separation of acid and neutral components. The methylated araboxylan (1.3 g) was hydrolysed first with 72 % sulphuric acid (10 ml) at room temperature for 0.5 h and then with 8 % sulphuric acid (90 ml) at 100° for 2 h. The hydrolysate was neutralised with barium carbonate, filtered and passed through Amberlite IR 120 (H^+ form). The acidic components were absorbed on Dowex 2 (acetate form), 1.5 × 12 cm, the column was eluted with water (1.5 l) and the eluate concentrated to give the neutral fraction (950 mg). The acids were displaced from the column with 3 N acetic acid (500 ml); the eluate was concentrated to give the acidic fraction (275 mg). Paper chromatograms of the two fractions using solvent B indicated a complete separation of neutral and acidic material; the neutral fraction contained methylxylose, dimethylxylose, trimethylarabinose and probably some trimethylxylose; the acid fraction contained two components, probably methylated uronic acid (minor component) and methylated aldobiouronic acid (major component). Paper electrophoresis in the acetate buffer gave two spots with slightly lower mobilities than those of 4-*O*-methyl-D-glucuronic acid and 2-*O*-(4-0-methyl-D-glucuronopyranosyl)-D-xylose, respectively.

Glycosidation, esterification and reduction of the acidic components. The acidic fraction (275 mg) was refluxed with 2.1 % dry methanolic hydrogen chloride for 8 h and the solution was then neutralised with silver carbonate, filtered and concentrated to dryness. The product was reduced with lithium aluminium hydride (1 g) in refluxing ethyl ether (50 ml) for 4 h. Excess hydride was destroyed with anhydrous ethanol and the alcoholates were decomposed with water. Aluminium hydroxide was removed by centrifuging and the supernatant solution was neutralised with sulphuric acid. Lithium sulphate was removed by filtration of the product in ethanolic solution and the filtrate was concentrated to a syrup (260 mg).

Hydrolysis of the reduced acidic fraction. The reduced acidic components (260 mg) were hydrolysed overnight at 100° with 0.5 N sulphuric acid (20 ml), neutralised with barium hydroxide, filtered and concentrated to dryness. Paper chromatography in solvent B and paper electrophoresis in the borate buffer indicated the presence of 3-*O*-methyl-xylose and 2,3,4-tri-*O*-methyl-glucose.

Fractionation of the hydrolysates from the neutral and acidic components. The neutral components (950 mg) from the hydrolysate of the methylated araboxylan were fractionated on a carbon-Celite (1:1) column (4 × 46 cm) by gradient elution [27]; the hydrolysate from the acidic components (260 mg) was fractionated on a carbon-Celite column (3.3 × 25 cm) in the same way. The amount of reducing sugar in each of the combined

fractions was determined by hypoiodite oxidation [28]. 2-*O*- and 3-*O*-methyl-D-xylose were incompletely separated and the relative proportions of these components in the combined mixed fraction were determined by quantitative paper electrophoresis in borate buffer [6]. A preparative fractionation was done on a carbon-Celite (1:1) column (3.3 × 25 cm) using borate buffer [7] (0.1 M; pH 10) and gradient elution (3 l 0—10 % aqueous ethanol). 3-*O*-methyl-D-xylose was eluted first. The results of the fractionations are summarised in Tables 2 and 3.

Characterisation of components

D-*Xylose.* Characterised only by paper chromatography. Indistinguishable from D-xylose in solvents A and B.

2-O-*Methyl*-D-*xylose.* Crystallised from acetone, m. p. 130—132°, undepressed on admixture with authentic material. Indistinguishable from authentic material on paper electrophoresis in borate buffer and on paper chromatography in solvent B.

3-O-*Methyl*-D-*xylose.* Crystallised from acetone and methyl ethyl ketone, m. p. 95—97°, undepressed on admixture with authentic material. Indistinguishable from authentic material on paper electrophoresis in borate and on paper chromatography in solvent B.

"*Dimethylarabinose*" (Table 2). Only examined by paper chromatography. This fraction contained a main component with a mobility slightly lower than that of 2,3-di-*O*-methylxylose, as well as some methylxylose and 2,3-di-*O*-methylxylose. Demethylation indicated arabinose and a smaller amount of xylose.

2,3-*Di*-O-*methyl*-D-*xylose.* The anilide had m. p. 133—135°, undepressed on admixture with authentic material.

2,3,4-*Tri*-O-*methyl*-D-*xylose.* Demethylation indicated xylose and a small amount of arabinose. The methyl sugar and its anilide failed to crystallise. The methyl sugar was indistinguishable from authentic material on paper chromatography in solvent C.

2,3,5-*Tri*-O-*methyl*-D-*arabinose.* Demethylation gave arabinose only. The 2,3,5-tri-*O*-methyl-L-arabonamide had m. p. 135—137°, undepressed on admixture with authentic material.

2,3,4-*Tri*-O-*methyl*-D-*glucose.* The 1,6-diazobenzoate crystallised from ligroin-chloroform (25:1) m. p. 162—164, undepressed on admixture with authentic material.

A crystalline derivative of the aldobiouronic acid. The araboxylan (2 g) was hydrolysed with 0.5 N sulphuric acid (160 ml) at 100° for 3 h and the hydrolysate was neutralised with 0.5 N barium hydroxide, filtered and concentrated to a small volume. Barium ions were removed by passage through Amberlite IR 120 (H^+ form) and the uronic acids were absorbed on Dowex 2 (acetate form). Neutral sugars were eluted with water (2 l), the acids with 3 N acetic acid (500 ml) and then with water until the eluate was neutral. Concentration yielded the acid fraction (0.45 g). Paper chromatography in ethyl acetate-formic acid-acetic acid-water 19:1:3:4 and ethyl acetate-pyridine-water 2:1:2 indicated that the acid fraction contained the aldobiouronic acid slightly contaminated with aldotri- and tetrauronic acids but no spots corresponding to 4-*O*-methylglucuronic acid were observed. The aldobiouronic acid was indistinguishable from 2-*O*-(4-*O*-methyl-D-glucuronopyranosyl)-D-xylopyranose. The crystalline methyl-2-*O*-(methyl 2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucuronopyranosyl)-3,4-di-*O*-acetyl-D-xylopyranoside prepared according to Timell [18] crystallised from ethyl ether and was recrystallised from ethyl ether-ethanol 1:1, $[\alpha]_D^{20}$ +103° (*c*, 0.5 in chloroform), m. p. 202—203° undepressed on admixture with authentic material kindly supplied by Dr. T. E. Timell, Montreal.

Osmometric $\overline{DP}_n$ *determinations.* Osmometric $\overline{DP}_n$ determinations on the araboxylan were done on the sodium salt in 0.1 N aqueous sodium chloride [4] using "Ultrafein feinst" membranes supplied by Membranfiltergesellschaft, Göttingen. The $\overline{DP}_n$ of the methylated araboxylan was determined in butyl acetate solution using "Ultrazellafilter allerfeinst" membranes supplied by the same firm.

Action of Strong Acids on Acetylated Glycosides

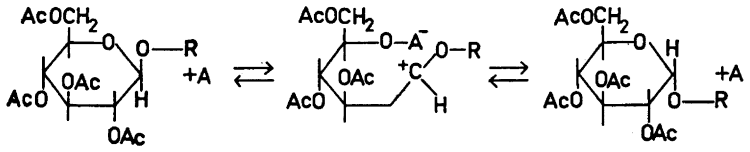
XIII *. Studies on the Mechanism of the Anomerisation Reaction **

JAN JANSON and BENGT LINDBERG

Institutionen för träkemi, Kungl. Tekniska Högskolan, Stockholm Ö, Sweden

The anomerisation of some acetylated glycosides in sulphuric acid-acetic anhydride-acetic acid has been studied. Replacement of the 2-*O*-acetyl group of *iso*propyl-tetra-*O*-acetyl-β-D-glucopyranoside with a methyl group results in a higher rate of reaction. Thus participation of the 2-*O*-acetyl group does not seem to facilitate the reaction. For a 2-deoxy-glucopyranoside and a galactofuranoside the acetolysis was so fast that no anomerisation could be observed.

The anomerisation of acetylated glycosides, a reaction of considerable preparative interest, is known to be catalysed by strong acids in the generalised sense, *e.g.* titanium tetrachloride and boron trifluoride. The mechanisms of this and similar reactions have recently been discussed by Lemieux [1]. The anomerisation is known to be intramolecular [2,3] and two alternative mechanisms have been suggested. Lindberg [2] assumed that the acid (A) coordinates with

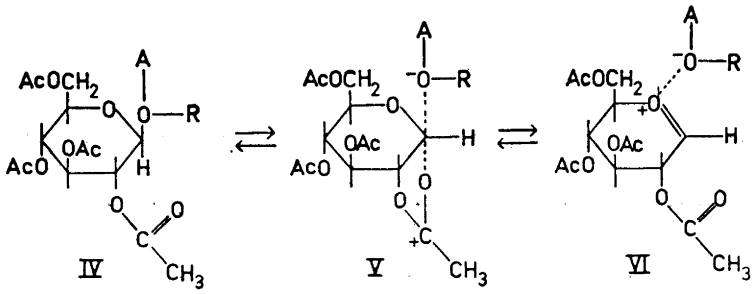


I II III

the ring oxygen in (I) and that the open chain intermediate (II) could reclose to give either of the anomeric glycosides (I or III) while Lemieux on the other hand has assumed that the acid coordinates with the oxygen of the aglycone group (IV). In this case the bond between $C_{(1)}$ and OR is further weakened by participation of the *O*-acetyl group at $C_{(2)}$ (V). When it is finally broken

* Part XII. *Acta Chem. Scand.* 6 (1952) 949.

** Presented at Tionde Nordiska Kemistmötet, Stockholm, 1959.



the two ions are not dissociated but exist as an ion pair, formulated as VI. This ion pair can then collapse, giving either the *α*-or the *β*-anomer.

The postulated participation of the neighbouring *O*-acetyl group could be studied by investigating the anomerisation of glycosides in which there is no such group. The anomerisation of *iso*propyl-tetra-*O*-acetyl-*β*-D-glucopyranoside in acetic anhydride-acetic acid (10:3), catalysed by sulphuric acid, is known to proceed 50—60 times faster than the anomerisation of penta-*O*-acetyl-*β*-D-glycopyranose. The corresponding glycoside of 2-*O*-methyl-D-glucose was prepared and its anomerisation studied under the same conditions. The velocity constant for the reaction was about twice that of the glucoside indicating that participation of the 2-*O*-acetyl group does not facilitate the reaction. The acetylated 2-*O*-methyl-*α*-D-glucopyranoside was isolated from the reaction mixture.

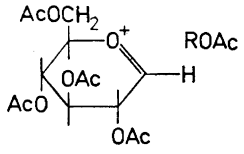
There is a remote possibility that the methoxyl group at $C_{(2)}$ might also participate. In a 2-deoxy-glycoside however, participation from a $C_{(2)}$ substituent is eliminated, and *iso*propyl-tri-*O*-acetyl-2-deoxy-*β*-D-glucopyranoside was therefore prepared and investigated in the acetic anhydride-acetic acid-sulphuric acid system. However, the acetolysis of this substance was too fast to allow a study of its anomerisation. A substance, m.p. 111—112°, $[\alpha]_D$ + 104° (chloroform) was isolated from the reaction mixture. It analysed for a tetra-acetate of 2-deoxy-D-glucose, and gave 2-deoxy-D-glucose on deacetylation. The same acetate was also obtained by treating tetra-*O*-acetyl-2-deoxy-*β*-D-glucopyranose with sulphuric acid in acetic anhydride-acetic acid. Overend *et al.*[4] have reported the preparation of two acetates of 2-deoxy-D-glucose. One, m.p. 91°, $[\alpha]_D$ + 12° (ethanol), claimed to be the *α*-acetate, was prepared by acetylation of 2-deoxy-D-glucose with acetic anhydride in pyridine. The other, m.p. 75—78°, $[\alpha]_D$ + 30° (ethanol), claimed to be the *β*-acetate, was prepared by acetylation with acetic anhydride and sodium acetate. On repeating these acetylations using the conditions described by Overend *et al.* the same substance m.p. 91—93°, $[\alpha]_D$ −2° (chloroform) was obtained with both acetylating agents. This substance is apparently tetra-*O*-acetyl-2-deoxy-*β*-D-glucopyranose while the compound with the high optical rotation, + 104°, is the corresponding *α*-acetate, and the product, m.p. 75—78°, reported by Overend *et al.*[4], is a mixture. On these assumptions,there is good agreement between the optical rotations of the anomeric acetates of D-glucose and 2-deoxy-D-glucose (Table 1) and between the methods of preparation.

Table 1. Optical rotations of acetylated pyranosidic D-glucose and 2-deoxy-D-glucose.

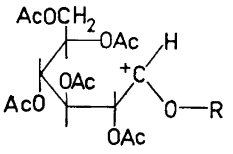
Parent sugar	Anomeric form	$[\alpha]_D$ in chloroform
D-Glucose	α	+ 101°
D-Glucose	β	+ 4°
2-Deoxy-D-glucose	α	+ 104° a) + 12° b)
2-Deoxy-D-glucose	β	− 2° a) + 30° b)

a) Present investigation.
b) Ref.[4], optical rotation in ethanol.

If $CH_3\overset{+}{C}O$ is the catalyst in the acetic anhydride-acetic acid-sulphuric acid system, which seems plausible (*cf. e.g.* Refs.[5,6]) then the mechanism proposed by Lemieux becomes less probable. When the acetyl ion is added to the glycosidic oxygen and the linkage between this oxygen and $C_{(1)}$ is broken, the product would be not an ion pair but an ion (VII) and an alkyl acetate, the recombination of which seems most improbable. If the acetyl ion adds to the



VII



VIII

ring oxygen, the opening of the ring to VIII and the re-formation of either of the forms is possible. As previously suggested [2,7] this theory also acounts for the formation of the open chain acetates that are known to be formed during these reactions. According to this mechanism a furanoside would give the same intermediate as a pyranoside, and it should therefore be possible to convert an acetylated furanoside into the pyranoside by treating it with sulphuric acid in acetic anhydride-acetic acid. When this experiment was done with ethyl-tetra-*O*-acetyl-β-D-galactofuranoside, acetolysis was very rapid and the furanosidic β-acetate of galactose was the only product isolated from the reaction mixture. In contradistinction to the behaviour of the galactopyranosides the β-form thus seems to be the most stable furanosidic acetate. Bearing in mind the ease with which 2-deoxyglycosides and furanosides are hydrolysed in acids, the fast acetolysis of these products is not surprising.

Acid-catalysed hydrolysis, the formation of glycosides and the interconversion of pyranosides and furanosides, recently discussed by Shafizadeh [8], involve protonation of the sugar and the rate determining step should involve the formation of a carbonium ion. These reactions are thus similar to the anomerisations of acetylated glycosides with acids in the generalised sense,

and in neither case has it been possible to decide between the cyclic or the acyclic route. The interconversion of pyranosides and furanosides however is best interpreted by a mechanism involving an acyclic intermediate though it may well be that for all these reactions both pathways are possible and that one or the other predominates, depending on the substances in question and the conditions of the reaction.

EXPERIMENTAL

All melting points are corrected. Concentrations were done under reduced pressure at a bath temperature of 50° or less.

Isopropyl-tri-O-*acetyl-2*-O-*methyl-β*-D-*glucopyranoside.* Tri-*O*-acetyl-2-*O*-methyl-α-D-glucopyranosyl bromide [9] (6.5 g) was dissolved in benzene (20 ml) and *iso*propyl alcohol (15 ml), silver carbonate (8 g) and Drierite (4 g) were added. The mixture was shaken for 3 h at room temperature and allowed to stand overnight. After filtration and concentration a syrup was obtained, which was dissolved in ether and extracted with water. The ether solution was concentrated and the residue was crystallised from aqueous ethanol. The crystals (2.2 g) melted at 64–69°. Further crystallisation raised the m. p. to 67–69°, $[\alpha]_D^{26}$ +1° (*c*, 2.0, chloroform). (Found C 53.2; H 7.2. Calc. for $C_{16}H_{26}O_9$: C 53.0; H 7.2.)

Isopropyl-tri-O-*benzoyl-2-deoxy-β*-D-*glucopyranoside.* Tri-*O*-benzoyl-2-deoxy-α-D-glucopyranosyl bromide [10] (10.4 g) was dissolved in toluene (100 ml) and *iso*propyl alcohol (75 ml), silver carbonate (9 g) and Drierite (10 g) were added. The mixture was shaken for 3 h and left overnight. After filtration the solution was concentrated and crystallised from ether-light petroleum yielding the pure substance (6.0 g), m. p. 107–108°. Further crystallisation raised the m. p. to 108–109°, $[\alpha]_D^{23}$ −57° (*c*, 2.4, chloroform). (Found: C 70.0; H 5.7. Calc. for $C_{30}H_{30}O_8$: C 69.5; H 5.8.)

Isopropyl-2-deoxy-β-D-*glucopyranoside.* The benzoylated glycoside (5.0 g) was debenzoylated with alkali in the usual way and the product (1.4 g) was crystallised twice from butanone. M. p. 120–122°, $[\alpha]_D^{20}$ −51° (*c*, 2.4, water). (Found: C 52.7; H 8.6. Calc. for $C_9H_{18}O_5$: C 52.4; H 8.8.)

Isopropyl-tri-O-*acetyl-2-deoxy-β*-D-*glucopyranoside.* The debenzoylated product (1.3 g) was treated with acetic anhydride and pyridine and then worked up in the usual way. The product (1.9 g), was crystallised from ether-light petroleum. M. p. 67–68°, $[\alpha]_D^{23}$ −37° (*c*, 2.7, chloroform). (Found: C 54.8; H 7.2. Calc. for $C_{15}H_{24}O_8$: C 54.2; H 7.2.)

Ethyl-tetra-O-*acetyl-β*-D-*galactofuranoside* was prepared by acetylation of ethyl-β-D-galactofuranoside [11] with acetic anhydride and pyridine. Its m. p. 55–57° and optical rotation, −52° in chloroform, agreed with the values previously reported [12].

Kinetic experiments. The measurements were made as previously described [2]. Velocity constants were calculated for first order reactions (time in minutes) and expressed in Brigg's logarithms. The values obtained are summarised in Table 2.

Table 2.

Acetylated sugar	M. H_2SO_4	$\alpha_{initial}$	$\alpha_{max.}$	10^3 k	$K_{rel.}$
*Iso*propyl-β-D-glucopyranoside	0.037	−1.24	5.79	52.2	52
β-D-Glucopyranose	0.037	−0.37	4.93	1.00	—
*Iso*propyl-2-*O*-methyl-β-D-glucopyranoside	0.037	−0.14	5.48	103	110
β-D-Glucopyranose	0.037	−0.37	4.93	0.94	—
*Iso*propyl-2-deoxy-glucopyranoside	0.018	−1.50	7.05	—	—
Ethyl-β-D-galactofuranoside	0.018	−1.27	0.58	—	—

Isopropyl-tri-O-*acetyl-2*-O-*methyl-α*-D-*glucopyranoside*. The reaction mixture from the anomerisation of *iso*propyl-tri-*O*-acetyl-2-*O*-methyl-*β*-D-glucopyranoside (0.50 g) yielded a product (0.20 g), m. p. 152—154°, $[\alpha]_D^{25}$ +151° (*c*, 1.0, chloroform) which was obviously *iso*propyl-tri-*O*-acetyl-2-*O*-methyl-α-D-glucopyranoside. (Found: C 53.4; H 7.1. Calc. for $C_{16}H_{26}O_9$: C 53.0, H 7.2.)

Tetra-O-*acetyl-2-deoxy-α*-D-*glucopyranose*. The reaction mixture from attempted anomerisation of *iso*propyl-tri-*O*-acetyl-2-deoxy-*β*-D-glucopyranoside (0.20 g) yielded a product (0.034 g), m. p. 111—112°, $[\alpha]_D^{24}$ +104° (*c*, 1.6, chloroform). (Found: C 50.6; H. 5.8 Calc. for $C_{14}H_{20}O_9$: C 50.6; H 6.1.)

Penta-O-*acetyl-β*-D-*galactofuranose*. The reaction mixture from attempted anomerisation of ethyl-tetra-*O*-acetyl-*β*-D-galactofuranoside (0.25 g) yielded penta-*O*-acetyl-*β*-D-galactofuranose (0.03 g), with m. p. 97—98°, $[\alpha]_D^{24}$ —40° (*c*, 2.3, chloroform) in good agreement with the values reported for that substance [13].

Rapid Paper Chromatography of Carboxylic Acids

GURLI HAMMARBERG and BÖRJE WICKBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

C_1 to C_{14} straight chain fatty acids have been separated by chromatography on dimethyl sulphoxide impregnated paper. The acids migrated as almost round spots and a complete separation was obtained within less than 2 hours. The method was also found to be useful with alicyclic and higher dicarboxylic acids.

In the course of an investigation on the paper chromatography of sugar acetates, using dimethyl sulphoxide (DMS) as the polar, stationary phase [1], it was found that the normal fatty acids in the range formic to myristic acid could be separated in a similar way. The present investigation includes the separation of normal fatty acids and some alicyclic and dicarboxylic acids (Table 1). When compared to other solvent systems used for the paper chromatography of these acids, those containing DMS seem to give a good resolution in quite a short time.

The papers were usually first impregnated with DMS, the samples were then added as solutions of the free acids and the chromatograms developed with light petroleum, *iso*propyl ether or a solution of DMS in ethyl ether. The spots were detected by spraying with an indicator solution. The total time required for the separation of fatty acids was about 45 min to 2 h.

As is to be expected, the R_F values increase with the number of carbon atoms in an homologous series, with the polarity of the eluant and with the moisture content of the paper. Of monocarboxylic acids having the same number of carbon atoms, those with a straight chain carbon skeleton seem to move faster than those having a cyclic structure. There is a significant difference between normal and *iso*butyric acid (Table 1), but not between the isomeric valeric acids.

To obtain predictable results it is essential to control the moisture content of the papers (see experimental part); it is usually most convenient to run the chromatograms under dry conditions, but slightly moist conditions will sometimes improve the separation (*e.g.* of (+)camphonanic and hinokiic acid, Table 1). The spots are generally almost circular or only very slightly tailing. A conceivable explanation is that the acids in DMS solution are not appreciably dissociated or dimerised. If tailing occurs, this may be caused by too high a

water content in the solvents, by insufficient impregnation with DMS, by the application of too large amounts of samples or by crystallisation of the samples on the paper. Evaporation of volatile acids from the chromatograms becomes apparent only on prolonged development. Thus formic, acetic, butyric and valeric acids (*ca* 20 μg of each) could still be detected on chromatograms after 5 h development with light petroleum.

Preparative separations of sesquiterpenic acids have been made on thick filter paper or silica gel columns impregnated with DMS [2]. With silica gel — DMS, adsorption effects may occur as has been indicated by current work at this institute on the resolution of a tropolone—phenol mixture from plant material.

EXPERIMENTAL

Paper. Whatman No. 1 filter paper was cut into strips 23 or 46 cm long, with the starting line 5 or 7 cm, respectively, from the upper end.

Solvents. DMS was of a technical quality * (99.5 % purity) with less than 0.3 % of water. Other solvents were of reagent grade.

Impregnation of papers. The papers were passed at an even rate through a 25 % v/v solution of DMS in toluene, uniformly blotted between layers of filter paper and dried at 60° for 1 min to remove the toluene. This process was repeated once and the papers were then immediately placed between glass plates leaving only the starting line and the paper above it uncovered. (After application of the samples, the papers were transferred to the chromatogram tanks in such a manner that absorption of moisture was avoided.)

When the reproducibility is unimportant, the impregnation may be simplified, *e. g.* by blowing off the toluene with hot air.

Application of samples. Usually 1—2 μl of 2 % solutions of the acids in ethyl ether were applied on the paper, placing the spots at least 1.5 cm from the paper edges and 1 cm from each other on short papers; on long papers the corresponding distances were 2 and 1.5 cm, respectively. 5—100 μl samples of acetic acid have been run on short papers using the ethyl ether — DMS eluant. Normal chromatograms of acetic acid have also been obtained by applying 1—2 μl of aqueous sodium acetate to the starting line before the impregnation with DMS. After impregnation acetic acid was liberated by adding enough of a saturated solution of oxalic acid in acetone-ethyl ether (1:1) to cover the acetate spot.

Development. All chromatograms were developed by the descending technique. The following solvents were used:

Light petroleum, b. p. 60—71° (Skellysolve B), not purified.

*Iso*propyl ether, sodium dried.

Ethyl ether (sodium dried) containing 4 % v/v of DMS.

When light petroleum was used as the eluant, the papers were 46 cm long and the chromatogram tanks were equipped with wire gauze bags containing silica gel impregnated with DMS or DMS-water to obtained standardised moisture conditions. With silica gel impregnated with DMS-water (9:1) there was only a little tailing, but this became very pronounced with DMS-water (8:2).

For safety reasons all experiments with ethyl or *iso*propyl ether were done in small chromatogram tanks using papers 23 cm long. The tanks contained no drying agent but were frequently cleaned and filled with fresh solvent.

Detection of spots. The spots were detected by spraying with the mixed indicator of Duncan and Porteous [3]: Methyl red (200 mg) and bromothymol blue (200 mg) dissolved in formalin (100 ml) and ethanol (400 ml). The pH is adjusted as required below by adding dilute sodium hydroxide solution. Without drying, the chromatograms were briefly exposed to ammonia vapours, then evenly sprayed with indicator solution, treated with ammonia as before and finally sprayed with more indicator till red or orange spots were obtained against a stable green background. The spots were usually stable for more than an hour. If the indicator is too acid, the background colour will not be stable, and if it is too alkaline trace amounts of acids will not be detected. (Duncan and Porteous recommend pH 5.2 and several ammonia treatments after spraying only once with indicator.) It is advisable to mark faint spots as soon as they appear. Strong, blurred spots become sharper if more indicator is applied or if the indicator is more alkaline.

Acknowledgement. One of us (B.W.) would like to thank W. Roos' fund for a grant.

Esters of Aminoacylamido Substituted Methylphenylcarbamic Acids I

CLAËS TEGNÉR and NILS-ERIK WILLMAN

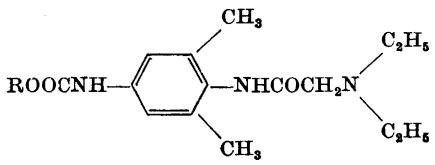
Research Laboratories, AB Astra, Södertälje, Sweden

A series of new aliphatic and alicyclic 4-diethylaminoacetamido-3,5-dimethylphenylcarbamates have been prepared and tested for local anesthetic activity. Some of these compounds showed a high surface anesthetic effect.

In the search for new local anesthetics several variations of the structure of α-diethylamino-2,6-dimethylacetanilide (Xylocaine®) have been tried [1]. Amongst others, investigations on changes in the local anesthetic activity by the introduction of different groups into the *para* position of the aromatic nucleus have been carried out. Thus Büchi *et al.*[2] have examined the effect of a butoxy group and Löfgren and Tegnér[3] have evaluated the influence of hydroxy, methoxy, butoxy and butyryloxy groups. The anesthetic properties of the *p*-hydroxy derivative of Xylocaine has also been reported by Krantz, Lu and O'Malley[4]. Recently Dahlbom, Tegnér and Willman[5] have described the preparation and the local anesthetic activity of some acyl and alkyl derivatives of Xylocaine while a series of *p*-alkoxycarbonyl derivatives has been investigated by Löfgren, Tegnér, Willman and Dahlbom[6].

Since some alkoxycarbonylamino substituted local anesthetics * have been described [8,9] and reported to show favourable anesthetic properties, a study of the influence of inserting an imino group between the alkoxycarbonyl group and the aromatic nucleus in the alkoxycarbonyl derivatives of Xylocaine seemed to be of interest, *i.e.* the preparation of alkyl 4-diethylaminoacetamido-3,5-dimethylphenylcarbamates.

The present paper describes the synthesis of esters of 4-diethylaminoacetamido-3,5-dimethylphenylcarbamic acid of the following general formula



* For a review of earlier investigations on local anesthetics containing the carbamate grouping, see Soehring and Rautmann [7].

where R is a *cyclo*pentyl, *cyclo*hexyl or an alkyl radical containing from two to eight carbon atoms (compounds II–XV, Table 1).

The compounds II and IX were prepared by the reaction of an alkyl chloroformate with α-diethylamino-4-amino-2,6-dimethylacetanilide [5]. Compounds III–V, VII, VIII, XIV and XV were synthesised by transesterification of ethyl 4-diethylaminoacetamido-3,5-dimethylphenylcarbamate (II) by heating under slightly reduced pressure with the appropriate alcohol, using sodium as catalyst.

During the isolation of compound V, a high-melting base, only slightly soluble in ether, was obtained in low yield. The infrared spectrum of this base did not show any urethane band at 1 725 cm^{-1} (KBr disc). It was identified as 1,3-bis(4-diethylaminoacetamido-3,5-dimethylphenyl) urea by comparison of its infrared spectrum and melting point with that of synthetic material [10]. A mixed melting point showed no depression.

Compounds VI and X–XIII were synthesised by reaction of α-diethylamino-4-amino-2,6-dimethylacetanilide with phosgene in toluene solution, and treatment of the precipitate formed, without purification, with the appropriate alcohol to give the desired carbamate.

The chlorine content of the precipitate formed in the reaction between the 4-amino derivative and phosgene indicated the formation of the hydrochloride of the chlorocarbonylamino compound. Attempts to purify this compound and to convert it into the *iso*cyanato derivative failed.

The local anesthetic activity of the compounds II—XV was tested on rabbit cornea, by the method of Wiedling [11]. The toxicity (LD50 value) of each compound was determined by subcutaneous injection in white mice. The results of these tests are given in Table 2. Irritation tests [12] carried out with most of the compounds showed that those containing a carbon chain more than five carbon atoms long in the alkoxycarbonylamino group were strongly irritant while those with five carbon atoms or less gave only slight or no irritation *.

EXPERIMENTAL

Iso*hexyl chloroformate (I)*. For the synthesis of compound IX *iso*hexyl chloroformate was prepared from *iso*hexanol [13] as described for benzyl chloroformate [14]. The ester was fractionated in a Vigreux column and the fraction b.p. 57—58°/8 mm was collected. Yield 82 %. (Found: C 51.1; H 7.77. Calc. for $C_7H_{13}ClO_2$: C 51.1; H 7.96.)

4-Diethylaminoacetamido-3,5-dimethylphenylcarbamates. The following three general methods were used for the preparation of compounds II—XV (see Table 1). A typical example is given of each method.

Method A. A solution of α-diethylamino-4-amino-2,6-dimethylacetanilide [5] (15 g, 0.060 mole) in benzene (250 ml) was treated with ethyl chloroformate (6.5 g, 0.060 mole) added dropwise with stirring and the reaction mixture was kept at 40—50° for 1 h. It was then extracted with water and the aqueous extract was made alkaline by the addition of ammonia. The oil that separated soon crystallised and was filtered off. Recrystallisation from aqueous ethanol (1:1) gave colourless crystals, m. p. 124—126° (13 g, 67 %).

* Thanks are due to Dr. S. Wiedling for performing the biological tests.

Table 2. Local anesthetic activity and toxicity of compounds II-XV.

XIV	n-C_7H_{15}—	1.5	50
XV	n-C_8H_{17}—	1.8	70

* *cf.* p. 889 for explanation.

Method B. A small piece of sodium (0.3 g) was dissolved in n-pentanol * (30 g, 0.34 mole) by heating. Ethyl 4-diethylaminoacetamido-3,5-dimethylphenylcarbamate (II) (20 g, 0.062 mole) was added to this solution and the mixture was heated on a water bath at 80° under slightly reduced pressure (~135 mm). After 3 h the excess pentanol was removed under vacuum (8 mm) and the residue was washed with water. The residual crystalline mass was dissolved in benzene and the solution was filtered, dried over sodium sulphate and then passed through an Al_2O_3 column. The base separated on evaporation and was recrystallised from ethanol-water (3:1), colourless needles, m. p. 95—97° (20 g, 89 %).

The filtration of the benzene solution gave a rather insoluble product (~1 g) which was crystallised from chloroform-ethanol, m. p. 261—264°. It was insoluble in water, and bases but soluble in acids. Infrared spectra ** were recorded of this compound and, for comparison, of n-pentyl 4-diethylaminoacetamido-3,5-dimethylphenylcarbamate and 1,3-bis(4-diethylaminoacetamido-3,5-dimethylphenyl) urea[10]. The following strong bands were observed:

Compound m. p. 261—264°: 3 250, 1 665, 1 605, 1 540, 1 495, 1 405, 1 315 and 1 205 cm^{-1}.

n-Pentyl 4-diethylaminoacetamido-3,5-dimethylphenylcarbamate: 3 210, 2 830, 1 725, 1 670, 1 610, 1 550, 1 495, 1 225 and 1 088 cm^{-1}.

1,3-Bis(4-diethylaminoacetamido-3,5- dimethylphenyl) urea: 3 250, 1 665, 1 605, 1 540, 1 495, 1 405, 1 315 and 1 205 cm^{-1}.

As can be seen the compound showed no band at 1 725 cm^{-1} (urethane); comparison with the urea derivative showed that they were identical. A mixed melting point of the two compounds showed no depression.

Method C. α-Diethylamino-4-amino-2,6-dimethylacetanilide [5] (25 g, 0.10 mole) dissolved in dry toluene (400 ml) was added dropwise with stirring to a 10 % (v/v) solution

* As carbamates prepared from the commercial n-pentanol showed a broad melting point interval the alcohol was purified by fractional distillation and the fraction b. p. 138.5—139°, $n_D^{20} = 1.4097$ was collected for use.

** The infrared spectra were recorded with a Perkin-Elmer model 21 spectrophotometer. All compounds were run in KBr discs.

of phosgene (30 g, 0.30 mole) in toluene. The temperature of the reaction mixture was held at 40° by external heating. After standing overnight at this temperature, the precipitate formed was collected and dried in a desiccator. Attempts to purify this compound by recrystallisation caused discolouration and evolution of hydrogen chloride. No *iso*cyanate could be obtained by heating under reflux in an inert solvent (toluene). The chlorine content of the precipitate was determined by titration (Mohr) as 19.8 % indicating the formation to a large extent of the chlorocarbonylamino compound (calc. for $C_{15}H_{23}Cl_2N_3O_2$: Cl 20.4). When heated with 2 moles of ethanol in benzene solution a 92 % yield of the ethyl carbamate derivative was obtained. The precipitate was therefore used for synthesis without purification.

A suspension of the above precipitate in a mixture of dry toluene (150 ml) and *cyclo*hexanol (20 g, 0.20 mole) was heated on a water bath for 2 h. The solution was then diluted with absolute ether and the precipitate formed was filtered off and dissolved in water. The solution was extracted once with ether and then made alkaline by the addition of ammonia. The base liberated was collected and recrystallised from benzene, m. p. 143—146° (33 g, 88 %).

Methods of preparation, yields, solvents for recrystallisation, melting points and analytical data of the bases thus prepared are given in Table 2.

X-Ray Investigation on Rhodium Phosphides. The Crystal Structure of Rh_4P_3

STIG RUNDQVIST and ALLAN HEDE

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The rhodium-phosphorus system has been investigated in the range 0–75 atom per cent phosphorus using X-ray and chemical analytical methods. Four intermediate phases have been found, *viz.* Rh_2P, Rh_4P_3, RhP_2 and RhP_3. The structure of Rh_2P is of the anti-fluorite (*C* 1) type, $a = 5.498$ Å, and RhP_3 of the skutterudite (*D* 2) type, $a = 7.996$ Å. The crystal structure of Rh_4P_3 has been determined and refined by single-crystal X-ray methods. The space group is *Pnma*; $a = 11.662$ Å; $b = 3.317$ Å; $c = 9.994$ Å, and the unit cell contains sixteen rhodium atoms and twelwe phosphorus atoms on seven 4(*c*) positions. The structure is related to the Fe_2P (*C* 22) and Co_2P (*C* 23) structures.

The binary system rhodium-phosphorus has been earlier investigated using tensimetric and X-ray powder methods by Faller, Strotzer, and Biltz [1]. They reported four intermediate phases with the following compositions: Rh_2P, $RhP_{0.8}$, RhP_2 and RhP_3. Zumbusch [2] found that the structure of Rh_2P was of the anti-fluorite type. One of the present authors (S.R.) earlier [3] reported the structure of RhP_3 (*D* 2 type), and confirmed the anti-fluorite structure of Rh_2P.

The present paper gives an account of phase-analytical observations on the Rh-P system, and in addition describes the crystal structure determination of the phase Rh_4P_3, which has not been previously characterized properly.

EXPERIMENTAL

The alloys were prepared by heating rhodium metal powder (Heraeus, purity 99.95 %) and red phosphorus (purity 99 % or higher) in evacuated and sealed silica tubes at temperatures between 900°C and 1 100°C. The alloys were prevented from contacting the silica tube walls by placing them in small crucibles of pure aluminium oxide.

Chemical analyses were made at the Department of Analytical Chemistry of this Institute. The analytical work, directed by the head of the department, Dr. F. Nydahl, was performed in the following manner.

The samples were dissolved in hydrochloric acid-chlorine by heating in sealed glass tubes at 300°C for 24—48 h [4-7] (*cf* Ref. [8]). Perchloric acid was used as oxidant for the evolution of chlorine. 1—2 g of sodium chloride was added to the solution, which was evaporated to dryness in order to remove traces of silicic acid. The residue was taken up in hydrochloric acid and filtered. Rhodium was precipitated as sulphide, fired and reduced to metal in hydrogen [8]. In the filtrate from the rhodium sulphide, the phosphoric acid was precipitated after evaporation as ammonium molybdophosphate and weighed as $P_2O_5.24MoO_3$ according to Nydahl [9].

X-Ray powder photographs were taken with Guinier-type focussing cameras using Cu$K\alpha$ and Cr$K\alpha_1$ radiation ($\lambda_{CuK\alpha} = 1.5418$ Å; $\lambda_{CrK\alpha_1} = 2.2896$ Å). Each powder film used for lattice parameter measurements was calibrated with either silicon ($a = 5.4306$ Å) or calcium fluoride ($a = 5.4630$ Å) as an internal standard. The accuracy of the lattice parameter determinations is greater than 0.05 %.

Single crystal intensity data were obtained with an ordinary Weissenberg camera and niobium-filtered MoK radiation. The multiple-film technique was used with thin iron foils between successive films, and the intensities were estimated visually with the aid of a standard intensity scale. The single-crystal specimen of Rh_4P_3, picked from a crushed, arc-melted alloy, was roughly cylindrical and of radius 0.025 mm. An intensity correction for the absorption was applied, the single-crystal being regarded as a perfect cylinder.

Fourier series summations, structure factor calculations, and calculations of interatomic distances were made with the electronic digital computer BESK, using programs developed by M. Edstrand and S. Åsbrink, G. Blomqvist and S. Westman [10]. Atomic scattering factors f_i were introduced as analytical expressions of the type;

$$f_i = A_i \exp\left(-\frac{a_i}{\lambda^2}\sin^2\Theta\right) + B_i \exp\left(-\frac{b_i}{\lambda^2}\sin^2\Theta\right) + C_i \exp\left(-\frac{c_i}{\lambda^2}\sin^2\Theta\right).$$

The constants A_i, B_i, C_i, a_i, b_i and c_i, are based on the atomic scattering factor tables given by Thomas and Umeda [11] for Rh and by Tomiie and Stam [12] for P, and were calculated by Appel [13]. No corrections for dispersion were made. The following constants were used:

	A	B	C	a	b	c
Rh	15.520	16.977	12.024	0.237	2.600	20.057
P	1.447	7.971	5.588	0.001	1.528	37.194

PHASE ANALYSIS AND X-RAY POWDER DATA

The phase-analytical investigation showed that there are four intermediate phases with compositions close to Rh_2P, Rh_4P_3, RhP_2 and RhP_3. Within

Table 1. Phase-analytical data of alloys containing Rh_4P_3.

Alloy	Chemical analysis (weight per cent) Rh	P	Phases detected in powder photographs

experimental error, (0.05 %), the phases did not show any lattice parameter variations. Some phase-analytical data are given in Table 1 for alloys containing Rh_4P_3. These data show that the composition of the pure phase is $RhP_{0.75}$ rather than $RhP_{0.80}$ as reported by Faller, Strotzer and Biltz [1].

No signs of transitions in the solid state at temperatures between 800°C and 1 100°C were observed in quenched alloys. Some alloys were subjected to higher temperatures by heating in an argon-filled arc furnace. Alloys with a phosphorus content higher than about 50 atom per cent evolved phosphorus vapour on heating, but alloys having phosphorus contents lower than about 40 atom per cent could be melted without serious phosphorus losses. Single-crystals of Rh_4P_3 were obtained from such melts.

The anti-fluorite structure [2] of Rh_2P was confirmed by inspection of the X-ray powder photographs. Measurements of the unit cell edge gave the value 5.498 Å, corresponding to the following interatomic distances: Rh—6 Rh 2.749 Å; Rh—12Rh 3.888 Å; Rh—4P 2.381 Å.

The structure of $Rh_4P_3$was determined by employing single-crystal methods (*vide infra*). Powder data for Rh_4P_3 are presented in Table 2. The unit cell is orthorhombic with the dimensions $a = 11.662$ Å; $b = 3.317$ Å; $c = 9.994$ Å.

Attempts to prepare single-crystals of RhP_2 and RhP_3 were unsuccessful and the powder pattern of RhP_2 could not be interpreted. The powder photographs of RhP_3 could be indexed with the cubic unit cell $a = 7.996$ Å. It seems very probable that RhP_3 is isostructural with $CoAs_3$ (*D* 2 type), the structure of which was determined by Oftedal [14]. According to this author, the structure of $CoAs_3$ is based on the space group $Im3$ (No. 204) with eight cobalt atoms in the 8(*c*) position, and twentyfour arsenic atoms in the 24(*g*) position, having the parameters $y = 0.35$; $z = 0.15$. Assuming that RhP_3 has the *D* 2 structure, a satisfactory agreement between observed and calculated intensities was reached with the parameter values $y = 0.34_7$; $z = 0.13_7$ for the phosphorus atoms. Intensity data are given in Table 3. These parameter

values for the phosphorus atoms cannot be considered very accurate, but the following approximate interatomic distances may be given:

shortest Rh—P distance 2.33 Å,

shortest P—P distances 2.19 and 2.45 Å.

DETERMINATION OF THE STRUCTURE OF Rh_4P_3

Weissenberg photographs of Rh_4P_3 crystals showed that the symmetry is orthorhombic. The unit cell volume is 386.6 Å^3, indicating a unit cell content of sixteen rhodium atoms and twelve phosphorus atoms. The calculated density is 8.67 g.cm^{-3}. An inspection of the intensity data from the layer lines 0 through 3 around the *b*-axis, showed that the reflexions $hk0$ with $h = 2n + 1$ and $0kl$ with $k + l = 2n + 1$ were absent. The space groups *Pnma* and $Pn2_1a$ were thus probable. Due to the short *b*-axis, the position 8(*d*) in space group *Pnma* must be eliminated. Further inspection of the intensity data showed that the intensity sequences in the 0 and 2 layer lines were equal (allowing for the normal intensity decrease), and the same was true for the 1 and 3 layer lines.

The Patterson sections $P(x0z)$ and $P(x\frac{1}{2}z)$ were calculated. It was possible to explain all maxima in these sections with a structure model based on the space group *Pnma* with sixteen rhodium atoms in four 4(*c*) positions, and twelwe phosphorus atoms in three 4(*c*) positions. Due to extensive overlapping it was difficult to obtain accurate atomic parameters from the Harker peaks alone. However, an analysis of the whole Patterson function using the method

described by Lindqvist [15], provided atomic parameters sufficiently accurate for the determination of a satisfactory number of structure factor signs.

The atomic parameters were refined from electron density projections and difference syntheses in the *ac*-plane. After the last refinement, the *R*-value was found to be 0.105 for the 229 observed $|F(h0l)|$-values. An isotropic, overall temperature factor with $B = 0.20$ Å^2 was applied *. The final structure of Rh_4P_3 is as follows:

Space group *Pnma* — (D_{2h}^{16}), No. 62.
$a = 11.662$ Å; $b = 3.317$ Å; $c = 9.994$ Å; $U = 386.6$ Å^3; $Z = 4$. All atoms on 4(*c*) positions:

The standard deviation for the rhodium positions, calculated from Cruickshanks [16] formula, is 0.001_9 Å, and for the phosphorus positions 0.007_3 Å. Interatomic distances are listed in Table 4.

DESCRIPTION AND DISCUSSION OF THE Rh_4P_3 STRUCTURE

A projection of the structure onto the *ac*-plane is shown in Fig. 1. The coordination of the phosphorus atoms is shown in greater detail in Fig. 2 a, b and c. The phosphorus atoms are situated at the centres of triangular prisms with rhodium atoms at the corners. This type of nonmetal atom coordination is common with transition metal phosphides, *e.g.* in the (revised) *C* 22 (Fe_2P), and *C* 23 (Co_2P) structures, as well as in transition metal borides and silicides. Each rhodium atom is surrounded by five close phosphorus neighbours, with an average Rh—P distance of 2.41 Å. In the Fe_2P [17] and Co_2P [18] structures, half of the metal atoms are surrounded by four phosphorus atoms in a distorted tetrahedral configuration, and the other half of the metal atoms have five phosphorus neighbours. The rhodium atoms in Rh_4P_3 have on average nine close rhodium contacts with a mean Rh—Rh distance of 3.11 Å.

In transition metal phosphides with a metal content larger than 50 atom per cent, there is no tendency for P—P bond formation [19]. The difference between transition metal phosphides and borides, with respect to the nonmetal-nonmetal bond formation, is clearly illustrated by a comparison of the Rh_4P_3 structure with the orthorhombic Ni_4B_3 structure [20]. The structure of orthorhombic Ni_4B_3 is based on the same space group as Rh_4P_3, the unit cell containing sixteen nickel atoms and twelwe boron atoms distributed on seven 4(*c*) positions. The coordination of the nickel atoms at the corners of triangular prisms around the boron atoms, resembles the coordination of rhodium atoms around the phosphorus atoms in Rh_4B_3; (compare Figs. 1 and 2 in the present paper with Figs. 1 and 3 in Ref.[20]). However, whereas there are no P—P contacts closer than 3.18 Å in Rh_4P_3 two thirds of the boron atoms in Ni_4B_3 are connected in infinite chains with B—B distances of approximately 1.9 Å. Furthermore, each nickel atom in Ni_4B_3 is surrounded by ten or eleven nickel neighbours at an average distance of 2.71 Å, compared with the average coordination of nine rhodium atom neighbours around each rhodium atom in Rh_4P_3 at an average distance of 3.11 Å.

Heats of Hydrolysis of N-Acetylated Imidazole, 1,2,4-Triazole and Tetrazole

INGEMAR WADSÖ

*Thermochemistry Laboratory *, University of Lund, Sweden*

The heats of hydrolysis of N-acetylated imidazole, 1,2,4-triazole and tetrazole have been determined calorimetrically at 25°C. For the idealized hydrolysis reaction

$$RNAc(s) + H_2O(l) \rightarrow RNH(s) + HOAc(l)$$

the enthalpy changes were found to be: -4.83 ± 0.05 kcal/mole for RNH = imidazole, -7.29 ± 0.06 kcal/mole for RNH = 1,2,4-triazole and -10.31 ± 0.09 kcal/mole for RNH = tetrazole.

Heats of solution in acetone have been determined for the compounds participating in the hydrolysis reaction. From the heats of solution obtained, heats of hydrolysis referring to the reaction RNAc(acetone) + H_2O(acetone) → RNH(acetone) + HOAc(acetone) have been calculated to be: -7.52 ± 0.07 kcal/mole for R = imidazole, -9.03 ± 0.07 kcal/mole for R = 1,2,4-triazole and -12.35 ± 0.10 kcal/mole for R = tetrazole.

Free energy changes in transacetylation from tetrazole → 1,2,4-triazole → imidazole, have been briefly discussed.

During recent years a considerable amount of evidence has accumulated, that the imidazole ring of histidine forms an essential part of the active centre of some hydrolytic enzymes **. These hydrolysis processes in which esters or amides are involved, have been considered as two-step reactions. In the first step an imidazole group in the enzyme is believed to be acylated, after which follows a rapid hydrolysis. The kinetics of these reactions as studied on model substances have been extensively investigated. However, very little attention has been paid to the energetic relationships between substrate, enzyme intermediate, and the products. Therefore, in connection with earlier calorimetric work on acetylated compounds [2-5], it was felt desirable to determine the heat of hydrolysis of N-acetyl imidazole as well as that of N-acetyl 1,2,4-triazole and N-acetyl tetrazole.

* Sponsored by *The Swedish Natural Science Research Council* and by *The Swedish Technical Research Council.*

** See, *e.g.*, the reference list given in Ref.[1]

The compounds participating in the idealized hydrolysis reaction V are in condensed states, being solids and liquids. The derived standard heats of hydrolysis, therefore, are not closely comparable. As heats of vaporisation data are not available, heats of solution in acetone, which is believed to be an inert solvent for these compounds have been determined.

Some years ago the kinetics of the hydrolysis of these N-acetyl compounds were studied by Staab [6], which investigations will be supplemented by some enthalpy data given in this paper.

EXPERIMENTAL

Materials. Imidazole was prepared from D-tartaric acid and hexamethylenetetramine[7], and the crude product was recrystallized from benzene. After sublimation colourless crystals, melting at 88.7—89.4°C, were obtained. Imidazole was acetylated by acetyl chloride in benzene solution [6]. After removing the solvent in vacuum, the colourless crystalline residue was recrystallised from a benzene-ligroin mixture (1:1) and the product obtained was washed with petrol ether (boiling range 40—60°C) and dried in vacuum. After sublimation the melting point of the ester was 103.0—104.0°C. Potentiometric titration on the acetic acid formed by hydrolysis, gave an equivalent weight corresponding to a purity of 99.7 %.

1,2,4-Triazole was prepared from formamide and hydrazine hydrochloride [8], and the crude product was recrystallized from ethyl acetate. After sublimation colourless crystals melting at 120.2—120.9°C were obtained.

Acetylation of the triazole by acetyl chloride was performed in benzene solution [6]. After removing the solvent in vacuum, a white crystalline residue melting at about 37°C was obtained. In the further purification use was made of the exceptionally high vapour pressure of N-acetyl 1,2,4-triazole. The crystalline mass was put in a glass bulb fitted with a 30 cm tube. The tube was connected to a vacuum system for *ca* 10 min, after which it was sealed off. The bulb was placed on a sand bath maintained at a temperature slightly below the melting point of the substance, with the tube in a vertical position and after a week, most of the substance had sublimed into the tube, where it formed big colourless crystals. The process was repeated, after which the melting point was 39.7—40.7°C. Potentiometric titration indicated an equivalent weight equal to the theoretical.

Tetrazole was prepared from cyanogen and hydrazoic acid [9] and the crude product was sublimed to give white crystals melting at 153.5—155.0°C. Potentiometric titration indicated the purity to be 99.5 %.

N-Acetyl-tetrazole was prepared from the silver salt of tetrazole by reaction with acetyl chloride in benzene solution [6]. The light yellow product was recrystallised from a benzene-ligroin (8:2) solution, to give colourless needles. After sublimation the substance melted at 58.0—59.0°C. Equivalent weight, obtained by potentiometric titration with sodium hydroxide in aqueous solution, corresponded to a purity of 99.6 %.

Acetone used in the solution experiments was treated with potassium permanganate [10], dried with Drierite and distilled through a 10-plate column.

The heterocyclic acetates are rapidly hydrolyzed in the air and thus special precautions had to be taken. After the final sublimation, all handling of them, including the filling into ampoules for the calorimetric experiments, was carried out in a "dry air box" fitted with rubber gloves.

Apparatus. The reactions were carried out in a metal "isothermal" calorimeter, which has been described in detail elsewhere (Type D in Ref.[11]).

Calibration. The heat equivalent of the calorimeter, including its content, was determined electrically by passing a known current for a given time (300 sec) through the heating element. The calibrations were performed on the system after the reaction had taken place. The result of each calibration experiment was adjusted to give the heat equivalent of a "standard system", ε°, in which the calorimetric liquid contained the reaction products from a certain amount of substance. The actual heat equivalent values, ε, were obtained from ε°, by applying a small correction for the variations in the amount of substance used.

Calorimetric procedure. The calorimeter was charged with 100 ml of liquid, either 0.8 N aqueous sodium hydroxide solution or acetone. The heats of hydrolysis measurements were supplemented by determination of heats of solution in order to obtain the standard enthalpy changes of the hydrolysis reactions.

All reactions were very rapid, the reaction period was 5 min, and the initial and final thermistor resistance values could therefore be graphically evaluated.

Corrections to the standard states: The idealized, isothermal hydrolysis reaction V is obtained from eqns I—IV, which correspond to the reactions taking place under experimental conditions.

I	$RNAc(s) + H_2O(soln) \rightarrow RNH(soln) + HOAc(soln)$	ΔH_1
II	$RNH(s) \rightarrow RNH(soln)$	ΔH_2
III	$HOAc(l) \rightarrow HOAc(soln)$	ΔH_3
IV	$H_2O(l) \rightarrow H_2O(soln)$	ΔH_4
V	$RNAc(s) + H_2O(l) \rightarrow RNH(s) + HOAc(l)$	ΔH^0

$$\Delta H^\circ = \Delta H_1 - \Delta H_2 - \Delta H_3 + \Delta H_4$$

Units of measurements. The results of the calorimetric experiments are expressed in terms of the defined calorie, equal to 4.1840 abs. joules, and refer to the isothermal process at 25°C, and to the true mass. The molecular weights were computed from the 1951 table of international atomic weights [12].

RESULTS

The experimental results are summarised in Tables 1—4. In the tables the following symbols have been used:

$\log R_i/R_f$ the expression proportional to the temperature change: R_i and R_f are the corrected thermistor resistance values at the start and the end, respectively, of the main period.

ε the heat equivalent of the actual system in calories per unit of $\log R_i/R_f$.

Heats of hydrolysis

From five calibration experiments the standard heat equivalent (referring to 200 mg of substance) was calculated to be 9 071 $\pm$ 5 * cal/unit of $\log R_i/R_f$. Results from heats of hydrolysis measurements are given in Table 1. The amount of N-acetyl imidazole and -tetrazole participating in the reactions was corrected with regard to the analysis performed.

Results from the heats of solution measurements performed in 0.8 N aqueous solution of sodium hydroxide are given in Table 2.

Table 3 contains a summary of data connected with eqns I—V. The uncertainties given in Table 3 do not include possible systematic errors. As the accuracy of the titrations, by which the purity of the N-acetyl compounds and acetic acid was tested, cannot be considered to be better than $\pm$ 0.2 %, the true uncertainties are somewhat greater. Taking this into consideration, the standard enthalpy changes will be taken as $-$ 4.83 $\pm$ 0.05, $-$7.29 $\pm$ 0.06 and $-$10.31 $\pm$ 0.09 kcal/mole for the hydrolysis of N-acetylated imidazole, 1,2,4-triazole and tetrazole, respectively.

* When five or more determinations are performed, the uncertainties are given as the standard deviation of the mean. Otherwise they are the average deviation of the mean.

the given standard heat of hydrolysis, enthalpy changes referring to reaction VI were obtained.

VI RNAc(acetone) + H_2O(acetone) → RNH(acetone) + HOAc(acetone) ΔH_6

ΔH_6 was calculated to be −7.52 ± 0.07 kal/mole, −9.03 ± 0.07 kcal/mole and −12.35 ± 0.10 kcal/mole for RNH = imidazole, 1,2,4-triazole and tetrazole, respectively.

DISCUSSION

From the heats of hydrolysis data referring to reaction VI, the heats of transacetylation, in acetone solution, from N-acetyl-tetrazole to 1,2,4-triazole, and from N-acetyl 1,2,4-triazole to imidazole, are calculated to be -3.32 ± 0.12 kcal/mole and -1.51 ± 0.10 kcal/mole, respectively. Considering the symmetry of these transacetylation reactions and the absence of phase changes, the entropy changes must be very small. The standard free energy changes, therefore, should be almost the same as the corresponding enthalpy changes. The given data thus indicate, that from an energetic point of view, the transacetylation reactions are favourable only in the direction N-acetyl-tetrazole → 1,2,4-triazole → imidazole. This conclusion is in agreement with the observations made by Staab [6]. Some heats of aminolysis of the N-acetylated compounds investigated here have also been determined. They will be presented in connection with other aminolysis data in a forthcoming paper.

A Contribution to the Study of the Configuration of Anomeric Sugars

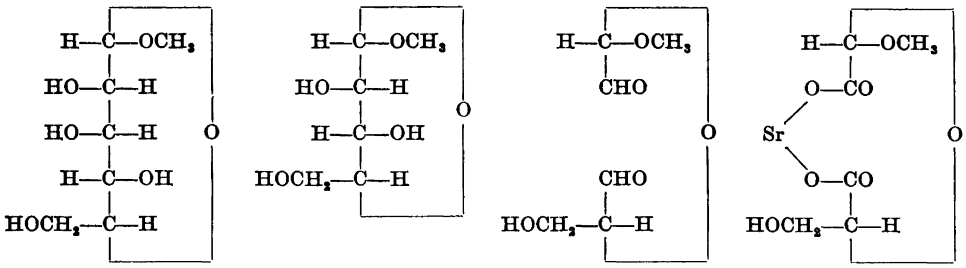
ENDRE BERNER and OVE KJØLBERG

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The following methyl aldopentofuranosides have been oxidized by means of periodic acid: α-D-arabofuranoside, α- and β-L-arabofuranosides, α-D-xylofuranoside, and β-D-ribofuranoside. The oxidation of an α-D-pentofuranoside gave the same product as obtained by Jackson and Hudson on oxidation of an α-D-hexopyranoside and corresponding results were arrived at when the β-D- as well as the α-L- and the β-L-forms of the two ring-types of glycosides were oxidized. The correlation between the configuration at carbon atom 1 in the anomeric forms of these types of glycosides is thus established. Reduction of the primarily obtained oxidation products led to enantiomeric diglycols because the asymmetry at carbon atom 4 in this way was eliminated. On discussing the configuration the importance of the use of X-ray methods for determination of the absolute configuration of the anomeric forms is underlined. It is further emphasized that a rational nomenclature for anomeric sugars and their derivatives ought to be worked out and eventually accepted by international agreement.

Jackson and Hudson [1] introduced the method of periodate oxidation in determining the ring structure and alpha-beta configuration of methyl glycosides. By the oxidation of an α-methyl-D-aldohexopyranoside (I) two moles of periodic acid were consumed resulting in the formation of one mole formic acid and a substance III designated D'-methoxy-D-hydroxymethyl-diglycolaldehyde and having the specific rotation +121°. It was found that all the four α-D-aldohexopyranosides which were investigated gave the same diglycolaldehyde with rotation +121°. The dialdehyde could be oxidized to a dibasic acid with the rotation +26° which was transformed into a strontium salt (IV) with rotation −53°. As the configuration at carbon atoms 1 and 5 of the glycoside were retained during these processes, it could be inferred that the configuration also at carbon atom 1 must be the same in all α-D-aldohexopyranosides.

As could be expected the β-methyl-D-aldohexopyranosides gave a dialdehyde different from that obtained from the anomeric α-forms. On the other



I II III IV

hand Jackson and Hudson found that periodate oxidation of the anomeric forms of methyl aldopentopyranosides led to enantiomeric dialdehydes, a result which is in accordance with the fact that carbon atom 5 in this case is not asymmetric. The mentioned authors also showed that α-methyl-D-arabofuranoside (II) gave an oxidation product identical with that obtained from the α-methyl-D-aldohexopyranosides and that therefore the configuration at carbon atom 1 in this furanoside must be the same as in the α-D-hexopyranosides. We have found that this holds also for other aldopentofuranosides as will be described below.

Smith and co-workers [2] showed that the dialdehydes could be reduced to diglycols either by hydrogenation in the presence of Raney nickel catalyst or by the action of sodium borohydride in aqueous solution. Because the asymmetry of carbon atom 5 in this way is eliminated, enantiomeric diglycols are obtained and consequently also in the case of the aldohexopyranosides the anomers of the D-series can be correlated to those of the L-series.

On the whole the application of the periodate oxidation method to the glycosides has demonstrated a definite correlation between anomers within the series of the aldohexopyranosides, the aldopentopyranosides, and the aldopentofuranosides, and also correlated the anomers of the aldopentofuranosides with those of the aldohexopyranosides. It has, however, not established a correlation between anomers of the aldohexopyranosides and those of the aldopentopyranosides and it does not, of course, give any proof of the absolute configuration at carbon atom 1.

The question of the configuration at carbon atom 1 is of considerable interest and has been the object of many papers. Especially interesting are those of Sørensen and Trumpy [3] and of Riiber and Sørensen [4]. The tentative configuration at C_1 which has in fact been generally accepted as correct is based mainly upon the application of Hudson's rules of isorotation and the displacement rules of Freudenberg and Kuhn, but partly also upon some chemical evidences such as the electric conductivity of glucose solutions to which boric acid has been added, the molecular refraction and the rate of hydrolysis of anomeric glycosides as compared with those of *cis-trans* isomeric diols investigated by Vavon, and further the predominant occurrence of certain glycosides by the addition of methanol to 1,2-oxides of sugars. For sugars belonging to the glucose and galactose series the application of these methods are mostly in agreement with the tentatively accepted configuration. On the other hand,

as especially shown by Riiber [5], molecular refractions and rates of hydrolysis in the case of sugars belonging to the mannose series (mannose, rhamnose, and lyxose) lead to an opposite configuration of that obtained by means of the rules of isorotation and displacement. This anomaly in the mannose series has not yet found an explanation. It would, however, seem reasonable to believe that it has bearing on the various conformations in which the pyranoses and pyranosides can occur. It has been shown in this institute [6] that in the case of the furanosides in which the molecules are supposed to be more or less plane no anomaly is found in the rates of hydrolysis of those of mannose as compared with those of sugars belonging to the glucose and galactose series.

Even if the periodate oxidation method and the other physical and chemical methods mentioned above would indicate a certain configuration at carbon atom 1 in the anomeric sugars and their derivatives this would not represent a strict proof of the configuration. It is therefore of considerable importance that the application of X-ray methods during the later years seems to prove conclusively the correctness of the tentatively accepted configuration at carbon atom 1. Thus Furberg [7] in 1950 showed that the β-D-ribofuranoside which is built into the cytidine molecule has *trans*-position of the groups bound to carbon atoms 1 and 2. The same author [8] has later shown that β-D-arabopyranose contains the hydroxyl groups at C_1 and C_2 in *cis*-position. (It should be remarked that the nomenclature used is based upon the application of the rules of isorotation and displacement mentioned above.) McDonald and Beevers [9] established the *cis*-position of the hydroxyl groups at C_1 and C_2 in α-D-glucopyranose and McGeachin and Beevers [10] the *trans*-position of the same groups in α-L-rhamnopyranose monohydrate.

Although the absolute configuration of the anomeric forms of the sugars and their derivatives can be established by means of X-ray investigations the question of a rational nomenclature is still open. As already emphasized by Riiber and Sørensen [4] it must be hoped that this will be taken up and settled by international agreement.

By means of column chromatography several crystalline methyl aldofuranosides have been prepared in this institute [6], amongst them the one used by Jackson and Hudson: α-methyl-D-arabofuranoside. Our sample of the latter which had the specific rotation +128° on oxidation with periodate gave a dialdehyde with rotation + 120° in good agreement with the values 120—121° obtained by the oxidation of the α-methyl-D-aldohexopyranosides. Jackson and Hudson starting from a slightly impure arabofuranoside (rotation + 123°) found the rotation of the dialdehyde to be + 117.3°. The other aldopentofuranosides which we have oxidized are the α- and β-methyl-L-arabofuranosides, the α-methyl-D-xylofuranoside, and the β-methyl-D-ribofuranoside. (The results of the oxidation of some aldohexofuranosides will be given in another paper.) The present results are collected in Table 1 from which it will be seen that the configuration at carbon atom 1 is the same in the α-D- and β-D-forms, respectively, as in the corresponding froms of the D-aldohexopyranosides and that there accordingly is the same relationship in the case of the L-methylosides.

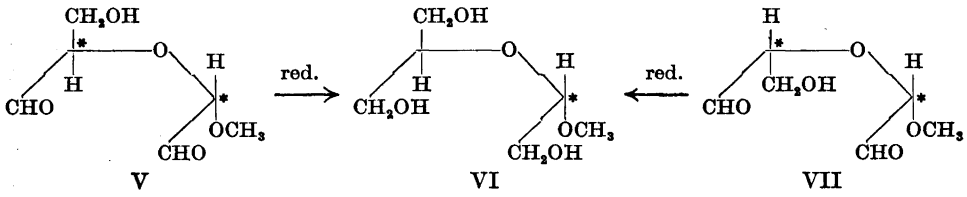
Owing to the small quantities of furanosides at our disposal only the dialdehyde from α-methyl-D-xylofuranoside was oxidized further. This dialdehyde, according to Jackson and Hudson called D'-methoxy-D-hydroxymethyl-

Table 1. Oxidation of some methyl-aldopentofuranosides.

Substance	Methyl-furanoside $[\alpha]_D^{20}$	Dialdehyde $[\alpha]_D^{20}$	Sr-salt of dibasic acid $[\alpha]_D^{20}$	Diglycol $[\alpha]_D^{20}$
α-Methyl-D-arabofuranoside	+128°	+120.1°		−13.3°
α-Methyl-L- »	−128°	−121.2°		+12.5°
β-Methyl-L- »	+118°	+150.6°		−11.1°
α-Methyl-D-xylofuranoside	+182°	+119.7°	−53.3°	−10.5°
β-Methyl-D-ribofuranoside	− 49.8°	−152.5°		+15.0°

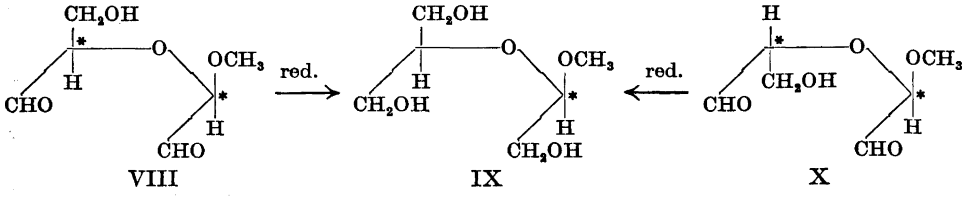
diglycolaldehyde, on oxidation with strontium hypobromite gave the crystalline strontium salt of D′-methoxy-D-hydroxymethyl-diglycolic acid. The composition of the salt was controlled by analysis and it had a specific rotation of −53.3° in good agreement with that of the strontium salt obtained from the α-D-aldohexopyranosides.

As will be seen from the formulae below reduction of the dialdehydes should lead to enantiomeric diglycols because the asymmetry at carbon atom 4 is eliminated. The specific rotations of the diglycols given in Table 1 show that within the limit of the experimental error, unavoidable by the small quantities used, this is the case. Sodium borohydride was found to be most suitable for the reduction of small quantities of the dialdehydes. The process was carried out in aqueous solution at room temperature and took place very rapidly. The reduction product, a methoxy-hydroxymethyldiglycol, was easily hydrolyzed in mineral acid to glycerol, glycolaldehyde, and methanol. After removing the methanol by evaporation, glycerol was identified as the tris-O-*p*-nitrobenzoate, m.p. 197−98°. From the hydrolysate the glycolaldehyde could not be isolated as a hydrazone as it would directly give the osazone. We therefore proceeded in this way that the trihydric alcohols (VI, IX) were



V VI VII

D′-Methoxy-D-hydroxymethyl-diglycolaldehyde — D′-Methoxy-hydroxymethyl-diglycol — D′-Methoxy-L-hydroxymethyl-diglycolaldehyde



VIII IX X

L′-Methoxy-D-hydroxymethyl-diglycolaldehyde — L′-Methoxy-hydroxymethyl-diglycol — L′-Methoxy-L-hydroxymethyl-diglycolaldehyde

transformed into the tris-O-benzoates in which the acetal linkings could be opened by treatment with N hydrochloric acid in acetic acid without remowing the benzoyl groups. On addition of 2,4-dinitrophenylhydrazine the crystalline hydrazone of glycolaldehyde-O-benzoate separated which was identified by analysis and comparison with an authentic specimen. Keeping the hydrazone in contact with the hydrazine solution for some time resulted in the formation of the osazone of glyoxal.

EXPERIMENTAL

α-Methyl-D-xylofuranoside

Oxidation with periodic acid. To a solution of 0.1649 g (1.01 mmole) of the furanoside in 2.1 ml water 6.6 ml 0.3524 M H_5IO_6 (2.32 mmole) were added. After 100 min the optical rotation became constant $a_D^{20} = +2.18°$ in a 10 cm tube. The concentration of the dialdehyde was calculated to be 1.83 % and the specific rotation accordingly +119.7°. The consumption of periodic acid was determined in samples of 1 ml solution. After dilution with water (10 ml) sodium bicarbonate was added to basic reaction and then 5 ml 0.2016 N sodium arsenite and 0.1 g potassium iodide. After 15 min the solution was retitrated with 7.30 ml 0.1011 N KI_3. This corresponds to 1.10 mole H_5IO_6 per mole xyloside. The dialdehyde was isolated as described by Jackson and Hudson.

Oxidation of the dialdehyde. A quantity of 0.35 g dialdehyde collected from several experiments was oxidized with 1 ml bromine in the presence of 6 g strontium carbonate. The crystalline strontium salt obtained was recrystallized three times by dissolving in hot water and adding hot ethanol until precipitation began. Yield 0.3 g strontium D'-methoxy-D-hydroxymethyl-diglycolate dihydrate. After drying in a vacuum until constant weight the rotation was $[\alpha]_D^{20} = -53.3°$ (*c* 2.5 w). The dihydrate was used for analysis. (Found: C 22.54; H 3.67. Calc. for $C_6H_8O_7Sr \cdot 2H_2O$: C 22.81; H 3.80; Sr 27.76.) For determination of Sr 0.0836 g strontium diglycolate was dissolved in water till 50 ml. To parallels of 10 ml were added 2 ml conc. ammonia, 5 drops 0.1 % phthalein purpur, 10 ml 0.00955 M EDTA and 10 ml ethanol. Retitrated until light blue colour with 4.20 and 4.23 ml 0.00199 N strontium nitrate. Found 28.06, 27.90 % Sr.

Reduction of the dialdehyde. To 0.103 g of the dialdehyde dissolved in 10 ml water 0.1 g sodium borohydride was added in the course of one hour. After standing for another hour excess of borohydride was destroyed by bubling carbon dioxide through the solution until pH 7. The solution was then treated with active carbon after which the rotation in a 10 cm tube was $a_D^{20} = -0.11°$. As the concentration was calculated to be 1.05 % diglycol the specific rotation was −10.5°. In order to isolate the reduction product the solution was evaporated at reduced pressure (bath 35°) and the last trace of water removed in a vacuum desiccator above calcium chloride. The residue was extracted three times with 20 and three times with 10 ml cold anhydrous ethanol. After treatment with active carbon the ethanolic solution was concentrated *in vacuo* (bath 30°) giving about 0.07 g of a not quite pure syrup.

Determination of the glycolaldehyde. The syrup (0.07 g) was dissolved in 5 ml pyridine, benzoyl chloride (0.05 ml) added and the solution heated on the steam bath 40 min. After cooling the solution was poured on 15 ml ice-water saturated with sodium bicarbonate and then extracted three times with chloroform. The chloroform solution was washed thouroughly with water, dried with calcium chloride and the chloroform evaporated *in vacuo*. In order to remove the pyridine the temperature of the bath was in the end raised to 50−60°. The resulting syrup did not crystallize. Dissolved in 5.5 ml glacial acetic acid the rotation in a 10 cm tube was −0.16°. On addition of 0.5 ml conc. hydrochloric acid the optical rotation disappeared in the course of 10 min. After 20 min 2,4-dinitrophenylhydrazine (0.05 g) was added and dissolved easily on stirring. Shortly afterwards a crystalline orange-coloured substance separated which after washing with ethanol was

recrystallized by adding light petroleum (60—70°) to a warm solution of the hydrazone in chloroform. M. p. 187—88° and no depression on mixing with 2,4-dinitrophenylhydrazone of glycolaldehyde-O-benzoate prepared from erythritol [11]. (Found: C 52.46; H 3.55; N 16.07. Calc. for $C_{15}H_{12}O_6N_4$: C 52.32; H 3.51; N 16.27.)

If the hydrazone were left in the mother liquor for some days (or heated with it) the colour changed to dark red indicating that the hydrazone had been transformed into the osazone. Recrystallized from nitrobenzene, m. p. 310—315° (d). (An osazone prepared from glyoxal had the same appearance and melting point.) (Found: C 40.06; H 2.50; N 26.46. Calc. for $C_{14}H_{10}O_8N_4$: C 40.20; H 2.41; N 26.79.)

α-Methyl-D-arabofuranoside

To a solution of 0.2636 g (1.61 mmole) furanoside 5 ml 0.430 M H_5IO_6 (2.15 mmole) was added. After 100 min the optical rotation became constant, $\alpha_D^{20} = +1.93°$ in a 10 cm tube. As the concentration of dialdehyde was calculated to be 1.61 % the specific rotation was +120.1°. Analysis carried out as described for the xylofuranoside showed that 1.01 mole periodic acid had been consumed per mole arabofuranodide. The dialdehyde isolated (0.12 g) was dissolved in 10 ml water and reduced with 0.1 g sodium borohydride. After reduction the rotation of the solution was $\alpha_D^{20} = -0.16°$ and as the concentration of diglycol was calculated to be 1.2 % the specific rotation was −13.3°. The 2,4-dinitrophenylhydrazone of glycolaldehyde-O-benzoate prepared in the same way as described above had m. p. 184—86°.

α-Methyl-L-arabofuranoside

α-L-Arabofuranoside: 0.1607 g (0.98 mmole) in 7 ml water; added 3.0 ml 0.430 M H_5IO_6 (1.29 mmole). After 90 min $\alpha_D^{20} = -1.90°$. Concentration of dialdehyde calculated to 1.57 % and the specific rotation accordingly −121.2°. Analysis showed that 1 mole furanoside had consumed 0.97 mole periodic acid. The dialdehyde (0.088 g) reduced as above gave a solution with $\alpha_D^{20} = +0.11°$. As the concentration of diglycol was 0.88 % the specific rotation was +12.5°. The 2,4-dinitrophenylhydrazone of glycolaldehyde-O-benzoate had m. p. 185—87°.

β-Methyl-L-arabofuranoside

β-L-Arabofuranoside: 0.1219 g (0.74 mmole) in 4.8 ml water; added 2.2 ml 0.408 M H_5IO_6 (0.898 mmole). After 180 min rotation constant $\alpha_D^{20} = +2.56°$. Concentration of dialdehyde 1.70 % and specific rotation accordingly +150.6°. Analysis showed that 1 mole furanoside had consumed 1.04 mole periodic acid. Two experiments gave in all 0.072 g dialdehyde which dissolved i 8 ml water was reduced with 0.05 g sodium borohydride in the course of 10 min. The solution which contained 0.90 % diglycol had $\alpha_D^{20} = -0.10°$ and the specific rotation was accordingly −11.1°. The quantity of the hydrazone of glycolaldehyde-O-benzoate was in this case to small to be recrystallized. It had m. p. 179—181°.

β-Methyl-D-ribofuranoside

β-D-Ribofuranoside: 0.1307 g (0.80 mmole) in 5 ml water; added 3 ml 0.430 M H_5IO_6 (1.29 mmole). After 20 min the rotation became constant $\alpha_D^{20} = -2.44°$. Concentration of dialdehyde 1.60 % and specific rotation −152.5°. One mole of ribofuranoside consumed 1.02 mole periodic acid. The dialdehyde from two experiments (0.16 g) was dissolved in 10 ml water and reduced in 90 min with 0.1 g borohydride. The solution containing 1.60 % of diglycol had $\alpha_D^{20} = +0.24°$ and the specific rotation +15.0°. The diglycol isolated (0.12 g) was transformed into a 2,4-dinitrophenylhydrazone with m. p. 187—88°.

Amides of 4-Diethylaminoacetamido-3,5-dimethylphenylcarbamic Acid

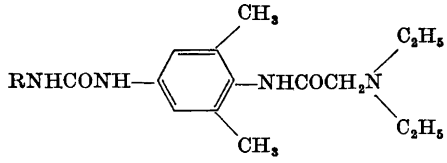
CLAËS TEGNÉR and KARL-ERIK DOMEIJ

Research Laboratories, AB Astra, Södertälje, Sweden

Five new amides of 4-diethylaminoacetamido-3,5-dimethylphenylcarbamic acid have been prepared and tested for local anesthetic activity.

Only a few derivatives of urea have been tested for local anesthetic activity. Thus Chabrier, Najer and Giudicelli [1] have described the properties of some ureas and others have been reported by Koelzer and Wehr [2], who also give a review of earlier investigations. The results of the investigations are, however, contradictory with regard to the value of the urea grouping in local anesthetics.

Some esters of 4-diethylaminoacetamido-3,5-dimethylphenylcarbamic acid have been shown to have a high local anesthetic activity when tested on rabbit cornea [3]. Because of the close similarity of the imino group to an oxygen atom it was of interest to study the effect of replacing one of the oxygen atoms in these carbamates by an imino group, *i.e.* to study amides of the general formula



In the present investigation a series of compounds of this formula has been synthesised with R = *n*-C_4H_9— (I), *n*-C_5H_{11}— (II), *n*-C_6H_{13}— (III), C_6H_5— (IV) and 4-[$(C_2H_5)_2N{\cdot}CH_2{\cdot}CO{\cdot}NH$] -3,5-$(CH_3)_2{\cdot}C_6H_2$— (V). The compounds I—IV were prepared by reaction of the appropriate *iso*cyanate with α-diethylamino-4-amino-2,6-dimethylacetanilide [4] in benzene solution. Two of the *iso*cyanates required (*n*-pentyl and *n*-hexyl) were prepared *via* their corresponding azides and Curtius degradation. This method yielded pure compounds but attempts to prepare the *iso*-cyanates by other methods gave impure products.

[a] A = ethanol; Aq = water; Bu = *n*-butanol; Chl = chloroform; Me = methanol.

For the preparation of compound V 1 mole of α-diethylamino-4-amino-2,6-dimethylacetanilide was reacted with 0.5 mole of phosgene. The hydrochloride of the α-diethylamino-4-chlorocarbonylamino-2,6-dimethylacetanilide is formed as an intermediate.

The compounds I—V were tested * for local anesthetic activity on rabbit cornea using xylocaine as a standard [5]. Compounds I, II and III were respectively 1.6, 3 and 9 times more active than xylocaine and IV showed the same activity as xylocaine but V was inactive. The subcutaneous toxicities of the compounds I—V, determined as LD50 values in white mice were 0.45, 0.57, > 1.0 **, > 1.0 ** and and > 0.5 *** g base/kg bodyweight. Compared with the corresponding esters [3] I—III had a lower anesthetic activity. As the amides were all found to be irritants no further tests were carried out.

* Thanks are due to Drs. S. Wiedling and A. Åström for carrying out the biological tests.

** LD50 values of more than 1.0 g/kg were not determined.

*** Owing to the low solubility of the compound higher dosages could not be tested.

EXPERIMENTAL *

n-Butyl and phenyl *iso*cyanates, which are commercially available, were purified by fractional distillation and the fractions b.p. 114—115° and 165—166°, respectively, were used for synthesis. The *n*-pentyl [6] and *n*-hexyl [7] *iso*cyanates were both prepared *via* their azides as described for the preparation of undecyl *iso*cyanate [8]. An *n*-pentyl *iso*cyanate fraction b.p. 138—139.5° and an *n*-hexyl *iso*cyanate fraction b.p. 162—163° were used.

The compounds I—IV (see Table 1) were prepared as described for the following example:

α-Diethylamino-4-amino-2,6-dimethylacetanilide [4] (5.6 g, 0.020 mole) was dissolved in dry benzene (50 ml), a solution of *n*-butyl *iso*cyanate (2.2 g, 0.022 mole) in dry benzene (15 ml) was added and the mixture was heated on a water bath for 1.5 h. The solvent was then evaporated and the residue was recrystallised from methanol-water (3:1) giving colourless crystals, m. p. 141—143°.

For the yields, solvents used for recrystallisation, melting points and analytical data for the individual compounds I—IV, see Table 1.

1,3-Bis(4-diethylaminoacetamido-3,5-dimethylphenyl)urea (V). α-Diethylamino-4-amino-2,6-dimethylacetanilide [4] (12.5 g, 0.050 mole) was added to a 10 % (v/v) solution of phosgene (25 g, 0.025 mole) in toluene and the solution was boiled under reflux for 8 h. After standing over night the mixture was shaken with 2 N sodium hydroxide and the precipitate was collected and dried in a desiccator. It was then treated with hot chloroform (50 ml) and filtered. Recrystallisation of the residue from chloroform-ethanol (3:1) gave colourless crystals, m. p. 261—264° (8.5 g, 65 %). (For analyses, see Table 1.)

* All melting points are corrected.

Magnetic Phase Transitions in Stoichiometric FeS Studied by Means of Neutron Diffraction *

ARNE F. ANDRESEN

Institutt for Atomenergi, Kjeller, Norway

Stoichiometric FeS has been examined by means of neutron diffraction in order to study the phase transitions and the orientation of the magnetic moments in the two antiferromagnetic phases. The magnetic moments are found to point along the c-axis below T_α and perpendicular to the c-axis above T_α. The superstructure derived by Bertaut for the low temperature antiferromagnetic phase has been confirmed only with a larger displacement of the Fe atoms.

According to susceptibility measurements by Haraldsen [1] two phase transitions are taking place in stoichiometric FeS. The α-transition occurring at $T_\alpha \approx 140°C$ is a transition between two antiferromagnetic phases, while the β-transition at $T_N = 325°C$ is a transition between an antiferromagnetic and a paramagnetic phase. Despite continuous efforts the nature of the first transition is not yet fully understood. However, several significant contributions have been made.

X-Ray investigations by Hägg and Sucksdorff [2] revealed slight structural changes at the transition. Above T_α the structure is of the regular NiAs-type with a hexagonal unit cell of dimensions $a_o = 3.44$ Å and $c_o = 5.88$ Å. Below this temperature weak superstructure reflections appear indicating a larger unit cell. Bertaut [3] succeeded in deriving an atomic arrangement to account for this superstructure. However, the small atomic displacements derived by him can not explain the large anomaly in the specific heat, 550 cal/mole, observed by Hirone *et al.*[4]

Recently electrical and magnetic measurements on single crystals of FeS by Kamigaichi *et al.*[5] and Hirahara *et al.*[6] showed a marked anisotropy in the electrical and magnetic properties with abrupt changes at the transition temperature. They interpret their results as indicating a change in the spin direction at the transition. Below T_α the spin is assumed to be parallel to and above T_α perpendicular to the c-axis. In the last case their data are consistent

with a model in which the moments take up two or more fixed directions in the *c*-plane.

By neutron diffraction it is possible to determine directly the orientation of the magnetic moments on the individual lattice sites. This was utilized by Sidhu [7] in determining the direction of the magnetic moments in pyrrhotite (FeS_{1+x}). He found here the magnetic moments to be perpendicular to the *c*-axis. Being unaware of the work of Kamigaichi *et al.* and Hirahara *et al.*, but anticipating some change in the spin system at the α-transition of the stoichiometric compound, we undertook a neutron powder diffraction investigation of $FeS_{1.0}$.

Low Temperature Antiferromagnetic Phase

A room temperature diffraction diagram of FeS obtained with the automatic diffractometer at the Kjeller reactor JEEP is shown in Fig. 1. The peaks observed can be well accounted for on the basis of the hexagonal super cell derived by Hägg and Sucksdorff [2]. The axes of this cell are related to those of the small NiAs-type cell mentioned above by $a = a_0\sqrt{3} = 5.97$ Å and $c = 2c_0 = 11.74$ Å.

In Fig. 2 is given the *c*-axis projection of this unit cell, the dotted lines indicating a NiAs-type cell. To account for the observed superstructure Bertaut [3] has suggested small displacements of the atoms from the NiAs positions. The directions of the displacements of the Fe atoms are indicated by the small arrows in the figure. The Fe atoms are displaced only in the *x* and *y* directions while the sulphur atoms are displaced along the *c*-axis. One can visualize the Fe atoms forming triangles of which some are contracted and some dilated. The sulphur atoms situated above or below the center of these triangles are displaced away from contracted triangles and in towards dilated triangles. The atomic positions are given in Table 1.

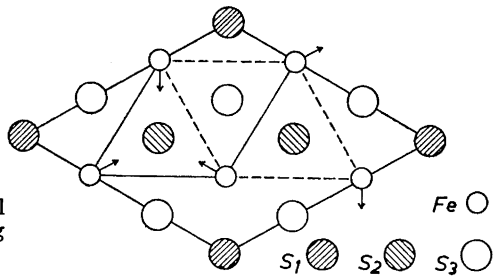

Fig. 2. c-Axis projection of the super cell derived by Bertaut; dotted lines indicating the NiAs-type unit.

From this model nuclear intensities were calculated using the coherent nuclear scattering amplitudes $b_{Fe} = 0.96 \times 10^{-12}$ cm and $b_S = 0.31 \times 10^{-12}$ cm taken from the compilation by Shull and Wollan [8]. By normalizing the observed intensities to the calculated ones for the outer reflections where the magnetic contribution is negligible due to the form factor fall-off, the amount of the inner reflections due to magnetic scattering could be estimated.

The only strong magnetic contribution was found for the reflection $(11\bar{2}2)$ corresponding to the $(10\bar{1}1)$ reflection from the NiAs-type cell (Table 2). This is compatible with an antiferromagnetic alignment of the magnetic moments in which the moments are parallel within each (0001) plane and antiparallel in neighbouring planes, provided the moments point along the c-axis.

where γ is the neutron magnetic moment, $S = 2$ the spin of the iron atoms and f the magnetic form factor. As this we have used the values from the curve for Mn^{2+} derived by Corliss *et al.*[9] F is the geometric structure factor, B_S the Brillouin function for spin S, and $q = \sin a$ where a is the angle between the scattering vector and the direction of the magnetic moment. A Debye-Waller temperature factor with $B = 0.7$ Å^2 was applied. This value was obtained assuming a Debye temperature of approximately $\Theta \approx 344$°K derived from the specific heat measurements of Grønvold *et al.*[10]

Using the parameters given by Bertaut the calculated intensities of the superstructure reflections came out much too low indicating larger displacements. The best fit was obtained with a displacement of the iron atoms of

magnitude $\varepsilon = 0.050 \pm 0.005$ compared to Bertaut's value $\varepsilon = 0.035$. As for the sulphur atoms, their contribution was too small to decide anything about their displacements.

The calculated intensities are given in Table 2 together with the normalized observed values. The fit is seen to be very good leading to a percentage mean error in the integrated peaks of 2.9 %. The (0001) reflection has been omitted. It is calculated zero, but a small peak still exists. This is possibly due to slight impurities or incomplete transition from the high temperature phase. The size of the peak varied from sample to sample and also completely vanished.

High Temperature Investigation

For high temperature runs the sample was placed in an evacuated quartz tube surrounded by a heating coil. A thermocouple protruding from the bottom of the cylinder had its junction near the center just below the irradiated part. A diagram obtained at 177°C, well above the α-transition, is shown in Fig. 3, instrumental background subtracted. Here no superstructure peak is visible and all the reflections can be indexed on the small NiAs-type cell previously described.

The most striking difference from the room temperature diagram is the appearance of a strong (0001) reflection. This must be of magnetic origin since the nuclear reflection is extinguished. However, with an antiferromagnetic alignment of the moments along the c-axis, a magnetic contribution may still occur. At room temperature it was negligible due to the q factor which is zero when the moments point along the scattering vector. Since the reflection now appears, the magnetic moments must have turned away from the c-direction. According to formula (1) the intensity of this reflection varies as $\sin^2\alpha$ with the angle α which the moments make with the c-direction.

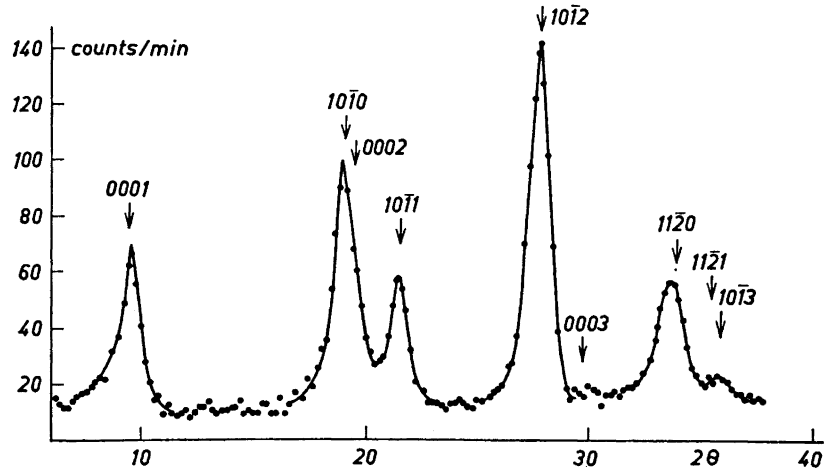

Fig. 3. Neutron diffraction diagram of $FeS_{1.0}$ at 177°C, instrumental background subtracted ($\lambda = 1.03$ Å).

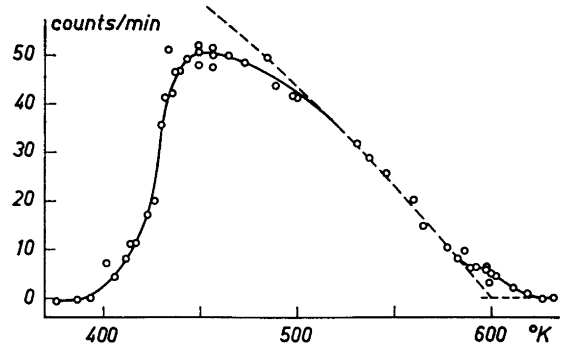

Fig. 4. Peak height of the (0001) reflection as a function of temperature. Dotted line derived from Brillouin function with $S = 2$.

As the (0001) reflection is also completely magnetic, it lends itself remarkably well to a study of the magnetic phase transitions. We have therefore recorded the intensity of this reflection as a function of temperature from room temperature up to 632°K. A close examination of the peaks did not reveal any change in their width with temperature which could be detected with our experimental conditions. We therefore take the peak value as representative of the intensity and this is plotted in Fig. 4 as a function of temperature.

We see that the α-transition starts already at 390°K (117°C) and a maximum is reached at 450°K (177°C). From here on the intensity starts to fall due to the temperature motion of the atoms and reaches zero at 627°K (354°C). Assuming a Néel temperature of $T_N = 600$°K (327°C) the larger part of the slope can be fitted to the Brillouin function with $S = 2$ (dotted line in the figure). The heel on the curve can be ascribed to the critical magnetic scattering which peaks at the Néel point as demonstrated by McReynolds and Riste [11]. Here some broadening of the peaks is expected, but this was not detected due to the low intensity compared to the background scattering.

High Temperature Antiferromagnetic Phase

The diagram shown in Fig. 3 was obtained at the temperature (450°K) corresponding to the maximum of the transition curve (Fig. 4). Still the magnetic intensity has clearly not reached its full value, but is reduced because of the broadness of the α-transition and its close proximity to the Néel point. Extrapolating back from the Brillouin curve, the magnetic intensities at 450°K were found to be reduced by the factor 0.41.

Utilizing this factor and assuming the antiferromagnetically aligned moments to point perpendicular to the c-axis, we find the calculated intensities given in Table 3. A Debye-Waller temperature factor with $B = 1.0$ Å^2 deduced from the Debye temperature $\Theta \approx 344$°K has been applied. The fit to the normalized observed values is seen to be good leading to a percentage

mean error in the integrated peaks of 8 %. The direction of the moments within the c plane can as pointed out by Shirane [12] not be determined from neutron powder diffraction data alone.

Table 3.

$10\bar{1}3$	15.4	10.2	32.4	28.9	3.5

DISCUSSION

The results of this investigation is largely in agreement with those derived by other methods. At the α-transition the direction of the magnetic moments change from pointing along the c-axis to pointing perpendicular to it. In the low temperature phase the superstructure is well explained by the arrangement proposed by Bertaut if the displacements of the iron atoms are made somewhat larger. While the β-transition at 327°C is rather well defined and corresponds well with the temperature given by Haraldsen, 325°C, the α-transition is rather broad and varies somewhat from sample to sample both with respect to sharpness and position. This might be due to slight variations in the composition and differences in preparation.

It is interesting to note the close similarity between FeS and α-Fe_2O_3. In the last case there is a transition between two antiferromagnetic states at approximately −20°C, and also here the magnetic moments are found to point along the trigonal axis below the transition and perpendicular to it above the transition (Shull *et al.*[13]). The iron atoms are in both cases surrounded by nearly regular octahedra of sulphur and oxygen atoms, respectively. No attempt will be made here to correlate the slight structural changes observed with the change in the orientation of the magnetic moments.*

Acknowledgements. The author would like to acknowledge the kind cooperation of F. Grønvold and P. Thurmann Moe of the University of Oslo in supplying the samples and much valuable information. He is also indebted to J. A. Goedkoop and T. Riste for illuminating discussions.

* After this investigation was completed the author has become aware of a more extensive investigation of the FeS_{1+x} system by neutron diffraction being carried out at Lawrence Radiatoin Laboratory, University of California, by J. T. Sparks, W. Mead, A. J. Kirschbaum and W. Marshall.

ACTA CHEMICA SCANDINAVICA 14 (1960) 927–932

1-(2′-Thiazolylazo)-2-Oxyaryl Compounds as Complexometric Metal Indicators

BROR SKYTTE JENSEN

Danish Atomic Energy Commission, Risø, Denmark

By the coupling of diazotized 2-aminothiazole with β-naphthol β-naphthol-6-sulphonic acid, *p*-cresol, resorcinol, orcinol and *m*-dimethylaminophenol a series of 1-(2′-thiazolylazo)-2-oxyaryl compounds have been prepared. Their properties as metal-indicators for Th^{4+}, La^{3+}, UO_2^{2+}, Pb^{2+}, Hg^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Mg^{2+} and Ca^{2+} ions have been investigated. The compounds seem to be especially suited for the direct titration of Cu^{2+}, Co^{2+} and Ni^{2+} ions with ethylenediaminetetraacetic acid (EDTA) in acid solutions.

The complexometric metal-indicator PAN (1-(2′-pyridylazo)-β-naphthol) was introduced by Cheng and Bray [1] who applied the dye to a few complexometric metal determinations. Later its great versatility as a metal-indicator was confirmed by works of Flaschka *et al.*[2,3] and Cheng *et al.*[4,5] Recently a number of new pyridylazo-dyes have been prepared which also show promise as metal-indicators and colorimetric reagents [6-10].

PAN acts as a tridentate ligand which accounts for the rather high stabilities of its metal-complexes.

By the replacement of the pyridine nucleus in PAN by a thiazole nucleus it should be possible to obtain a chelating agent with similar chelating properties. Hence the dye 1-(2′-thiazolylazo)-β-naphthol (TAN) has been prepared and investigated as a metal-indicator in complexometric titrations (Fig. 1).

By the coupling of diazotized 2-aminothiazole with β-naphthol-6-sulphonic acid, *p*-cresol, resorcinol, orcinol and *m*-dimethylaminophenol the following compounds were also prepared for further investigations.

1-(2′-thiazolylazo)-β-naphthol-6-sulphonic acid	TAN-6-S
2-(2′-thiazolylazo)-*p*-cresol	TAC
6-(2′-thiazolylazo)-resorcinol	TAR
6-(2′-thiazolylazo)-orcinol	TAO
6-(2′-thiazolylazo)-1-oxy-3-dimethylaminobenzene	TAM

The diazotization of 2-aminothiazole took place at 0 C° in *ca.* 6 N hydrochloric acid. The diazotate is so reactive that the couplings with the phenols

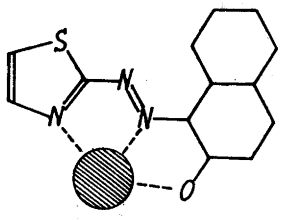

Fig. 1. Shows how 1-(2′-thiazolylazo)-β-naphthol may act as a tridentate ligand.

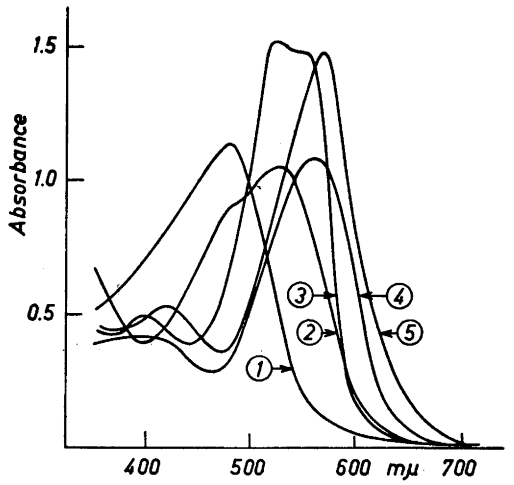

Fig. 2. Spectra of *ca.* 10^{-4} M solutions of TAN-6-S in acid (1) and in basic (2) solutions together with the spectra of its chelates of Zn (3), Pb (4) and Cu (5) in slightly acid solution.

had to be performed in cold acetic acid solutions or in 4 N hydrochloric acid solutions producing the dyes in crystalline form immediately.

Coupling of the diazotate with the phenols under alkaline conditions as is the normal case, produced large amounts of dark coloured by-products and only very low yields of the pure compounds could be obtained.

The pure compounds were obtained be recrystallizations from methanol or ethanol. The dye TAN-6-S was isolated as its sodium salt which was easily salted out from water by sodium chloride.

Previously only TAN and TAR seem to have been prepared.[11]

All the compounds form intensively coloured metal chelates in neutral or slightly acid solutions with Th^{4+}, La^{3+}, UO_2^{2+}, Hg^{2+}, Pb^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+} and Cd^{2+} ions.

The spectra of TAN-6-S alone and in combination with some metal ions are shown in Fig. 2. The effect of complex-formation seems to be a shift towards longer wave-lengths.

The dyes are also pH indicators. Only TAR and TAO do not change colour in an ammonia-buffer (pH = 10) indicating that their pK_a values are larger than 10. For TAN-6-S the pK_a value has been determined to 7.9 [12].

With the exeption of TAN-6-S the compounds are only slightly soluble in water but show appreciable solubility in water-ethanol or water-dioxane mixtures.

The dyes were tested as metal-indicators in complexometric titrations of several metal ions with 0.1 M EDTA solutions. Acetate-acetic acid, pyridine pyridinium chloride and ammonia-ammonium chloride buffers were used. The

changes of their colour at satisfactory endpoints were noted and are listed in Table 1. The amount of indicator used in the titrations was 4—5 drops of a 0.1 % solutions of the dye in methanol.

With all the compounds sharp end-points were obtained in direct titrations of Cu^{2+}, Co^{2+} and Ni^{2+} ions in acetate and in pyridine buffers. The Co^{2+} and Ni^{2+} ions, however, reacted satisfactorily only in hot solutions. The addition of methanol or ethanol often improved the colour changes with TAN, TAC, TAR, TAO and TAM because of the increased solubility of the indicators in the mixed solvents.

No direct complexometric titrations of Co^{2+} and Ni^{2+} ions in acid solutions seem to have been reported in the literature until now.

The direct titrations of Zn^{2+} and Pb^{2+} ions were easily performed in the pyridine buffer but not in the acetate buffer. The direct titration of the Cd^{2+} ion in those two buffers was unsatisfactory.

In pyridine buffer the Th^{4+}, Zr^{4+} and UO_2^{2+} ions formed intensively coloured chelates with all the compounds. However they could not be titrated with EDTA as larger amounts of the titrant were needed to change the colour of the indicator than that corresponding to equivalence.

With TAN, TAN-6-S and TAR the colour changes at the endpoints of the titrations were easily observed with all the metal ions mentioned. With TAO and TAC especially the endpoints in the Cu^{2+} ion titrations were good. When TAM was used as an indicator the colour changes were difficult to observe as the changes usually were from red-violet to pink.

It was found possible to increase the number of metal ions which could be titrated directly by the use of a Cu^{2+} ion-EDTA-dye combination as an indicator. A similar Cu^{2+} ion-EDTA-PAN indicator combination has been described by Flaschka.[3]

One drop of a Cu-salt solution was added to the buffer-indicator mixture and then so much EDTA solution that the indicator just changed colour. The metal ion solution to be determined was pipetted into the mixture where the Cu^{2+} ion was displaced from its EDTA complex in amounts large enough to reverse the colour change of the indicator. Depending on the buffer system used and the metal ion added the accurate determination of the latter was often possible by titration with EDTA to a new colour change.

In Table 2 some succesful titrations are shown which have been made in this way with TAN-6-S, TAR and TAO.

Owing to the small pK_a value of TAN-6-S (7.9 [12]) this indicator could not be used in the ammonia buffer (pH = 10) and therefore it could not be used in the determination of Mg^{2+}, Ca^{2+} and Cd^{2+} ions. With TAR and TAO these ions were succesfully titrated in an ammonia buffer.

The 1-(2′-thiazolylazo)-2-oxyaryl compounds are also useful as colorimetric reagents. A detailed procedure for the determination of uranium with TAN and TAM will be published in the near future [13].

Recently the synthesis of 2-(2′methylthiazolylazo)-*p*-methoxyphenol and its colour reactions with several metal ions have been described [14].

Table 1.

Compound	Metal ion	Buffer	Colour-change
TAN	Cu	Acetate	blue to orange to yellow
	Co	or	violet to orange to yellow
	Ni	pyridine	violet to orange to yellow
TAR	Cu		violet to yellow-green
	Co		violet to dirty yellow
	Ni		red-violet to yellow
TAO	Cu		red to yellow
	Co		red to yellow
	Ni		red to yellow
TAC	Cu		Blue-green to yellow
	Co		smoke to yellow
	Ni		blue-green to yellow
TAM	Cu		red-violet to pink
	Co		red-violet to pink
	Ni		red-violet to pink
TAN-6-S	Cu		blue to yellow-green
	Co		violet to dirty yellow
	Ni		violet to yellow
TAN	Zn	Pyridine	pink to yellow
	Pb		violet to yellow
TAR	Zn		pink to yellow
	Pb		violet to yellow
TAO	Zn		smoke to yellow
	Pb		blue-green to yellow
TAM	Zn		
	Pb		
TAN-6-S	Zn		red-violet to yellow
	Pb		blue-violet to yellow

Table 2.

Compound	Metal ion	Buffer
TAN-6-S	Hg, Zn, Pb La	Acetate or pyridine
TAR	Mg, Ca, Mn Cd	Ammonia
TAO	Mg, Ca, Mn Cd	

EXPERIMENTAL

All the compounds were prepared by essentially the same method. The synthesis of TAM will serve as an example. Owing to the possibility of coupling in positions 2 and 4 with *m*-dimethylaminophenol only a rather low yield of TAM was obtained.

6-(2'-Thiazolylazo)-3-dimethylaminophenol (TAM). 5 g of 2-aminothiazole were dissolved in 40 ml of 6 N hydrochloric acid and cooled in ice. 3.5 g of sodium nitrite were dissolved in a small amount of water. After the addition of crushed ice to both solutions the nitrite solution was slowly poured into the other solution while stirring with a glass spatula. The mixture was left in an icebath for 10 min. The solution of the diazotate was then poured slowly while stirring into a well cooled solution of 7 g of *m*-dimethylaminophenol in 100 ml of 4 N hydrochloric acid (or in acetic acid). An intense colour immediately developed in the mixture and soon yellow-brown crystals of the hydrochloride of TAM were formed.

After 1/2 h in the refrigerator 100 g of sodium acetate in 300 ml of water were added. The colour changed into intense red-violet and after 2—3 h the precipitate formed was filtered with suction on a Büchner-funnel. The filtrate which was almost pure red in colour was discarded. The filter cake was recrystallized from an acetic acid-water mixture yielding the pure product as dark violet needles. Yield 6.3 g (53 %), m. p. 216°C. (Found: C 53.22; H 4.87. Calc. for $C_{11}H_{12}N_4OS$: C 53.45; H 5.09.)

1-(2'-Thiazolylazo)-β-naphthol (TAN). Yield 75 %, m. p. 140°C. (Found: C 61.17; H 3.55. Calc. for $C_{13}H_9N_3OS$: C 61.30; H 3.57.)

1-(2'-Thiazolylazo)-β-naphthol-6-sulphonic acid, sodium (TAN-6-S). Yield 50 %, m. p. (decomp.). (Found: C 41.55; H 2.83. Calc. for $C_{13}H_8N_3O_4S_2Na$, H_2O: C 41.65; H 2.68.)

6-(2'-Thiazolylazo)-resorcinol (TAR). Yield 35 %, m. p. 235°C (decomp.). (Found: C 48.87; H 3.19. Calc. for $C_9H_7N_3O_2S$: C 49.00; H 3.38.)

6-(2'-Thiazolylazo)-orcinol (TAO). Yield 47 %, m. p. 250°C (decomp.). (Found: C 51.06; H 3.85. Calc. for $C_{10}H_9N_3O_2S$: C 51.00; H 3.93.)

2-(2'-Thiazolylazo)-p-cresol (TAC). Yield 57 %, m. p. 129°C. (Found: C 54.79; H 4.13. Calc. for $C_{10}H_9N_3OS$: C 54.70; H 4.18.)

Titrations. The 0.1 M solutions of the metal salts were prepared by dissolving calculated amounts of analytical grade metal nitrates or chlorides in water. The 0.1 M EDTA solution was prepared according to standard procedures [7]. The buffers were made by mixing 1 M solutions of the acids and bases in the proper ratios.

In the titration experiments 5—10 ml of the metal salt solution were pipetted into 30—40 ml of a buffer solution and diluted to ca. 100 ml distilled water. 4—5 drops of a 0.1 % solution of the indicator in methanol were added.

The titrant was added from a 10 ml burette, rapidly at first but dropwise near the expected end-point.

The end-point was taken as the point where further addition of titrant did not change the colour.

A titration was regarded as satisfactory when the experimental endpoint did not deviate more than 1 % from the calculated.

All melting-points were measured on a Kofler hot-bench. The spectra were taken with a Perkin-Elmer Spectracord 4 000 recording spectrophotometer.

Short Communications

Fluorometric Observations of Binary and Ternary Complexes Formed with Malic Dehydrogenase, Coenzyme, and D-Malic Acid

HUGO THEORELL and THOMAS A. LANGAN *

Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

Following the observation by Boyer and Theorell [1] of a change in the fluorescence spectrum of DPNH ** on binding to horse liver alcohol dehydrogenase, enzyme-reduced pyridine nucleotide complexes have been detected fluorometrically with yeast alcohol dehydrogenase[2], lactic[3], glutamic[4], and *iso*citric dehydrogenase [5]. With several of these enzymes fluorometric changes also occur on formation of ternary complexes of enzyme, reduced coenzyme, and substrate analogues. These phemomena have now been observed with malic dehydrogenase by Pfleiderer *et al.*[6,7] and independently in this laboratory. This communication is a report of the changes which occur in the fluorescence spectrum of DPNH on binding to malic dehydrogenase, and on formation of ternary complexes of malic dehydrogenase, DPNH, and D-malic acid. The binding of coenzyme and malic acid in binary and ternary complexes has been studied quantitatively by means of these changes.

Experimental. The fluorometric observations were carried out in the spectrofluorometer previously described [8], and calculations were made using equations based on those employed earlier in this laboratory [8,9]. All measurements were made at 23.5°C in 0.1 μ phosphate buffer containing 10^{-3} M EDTA. The pH was 7.15 unless otherwise noted. Titrations were followed using a measuring wavelength of 420 mμ and an activation wavelength of 352 mμ. Emission and excitation maxima are uncorrected for variations with wavelength in the intensity of the exciting light and sensitivity of the photocell. The correction would move the maxima about 15 mμ towards shorter wavelengths on this apparatus. Pig heart malic dehydrogenase was the product of C. F. Boehringer and Soehne, G.m.b.H. * and was assayed according to Ochoa [10]. DPN and DPNH were obtained from Sigma Chemical Co. and D- and L-malic acid from the California Corp. for Biochemical Research.

Results and discussion. Fig. 1 shows the changes in the fluorescence spectrum of DPNH on binding to malic dehydrogenase, and the further change in the spectrum on the addition of D-malic acid. In the presence of enzyme the observed emission maximum of DPNH shifts from 478 mμ to 470 mμ and doubles in intensity. On addition of 50 mM D-malate the maximum shifts further to 440 mμ and is increased an additional three fold. Changes in the fluorescence of enzyme-bound DPNH produced by substrate analogues or reduced substrates were originally observed with

Curve (1): 3.6×10^{-4} units of malic dehydrogenase. Curve (2): 3.3×10^{-6} M DPNH. Curve (3): 3.3×10^{-6} M DPNH plus 3.6×10^{-4} units of malic dehydrogenase. Curve (4): 3.3×10^{-6} M DPNH, 3.6×10^{-4} units of malic dehydrogenase, and 5×10^{-2} M D-malate. Activating wavelength 352 mμ. Buffer, 0.1 μ phosphate, pH 7.15, containing 10^{-3} M EDTA. Final volume, 2 ml. Temp., 23.5°C.

lactic dehydrogenase [3], and have since been detected with a number of other dehydrogenases [3,4,11,12]. Kinetic and equilibrium data [9,12] have supported the view that the fluorescence changes result from the formation of ternary complexes of enzyme, coenzyme and substrate analogue.

Addition of L-malate to the malic dehydrogenase-DPNH complex produced no change in fluorescence. However, L-malate competitively displaced D-malate from the ternary complex, producing a return to the original DPNH-enzyme spectrum when added in large excess. Small changes in the fluorescence of the enzyme-DPNH complex were produced by succinate and malonate.

The activation spectra for the fluorescence of the DPNH and D-malate complexes are shown in Fig. 2. The excitation maximum for DPNH fluorescence is seen to increase from 352 mμ to 362 mμ on combination with the enzyme. This is in contrast to the changes which have been observed with other complexes, in which the activation maximum decreases [4,5,14] or is unchanged [12]. On the addition of D-malic acid, there is a decrease in the excitation maximum to 345 mμ, a value below that of free DPNH.

Previous studies on horse liver alcohol dehydrogenase by Theorell and Winer [8,9] have utilized fluorescence changes for the quantitative study of coenzyme binding and ternary complex formation. This technique now has been applied to malic dehydrogenase. The enzyme was found to bind 4.4 moles of DPNH per mole, based on the turnover number of 38 000 moles of DPNH per mole enzyme per min reported by Wolfe and Neilands [15] for the conditions of the assay used in this work *. The binding of DPNH and DPN was competitive. No significant deviations from simple monovalent dissociation were observed, indicating that the binding sites act independently and equally. At pH 7.15, $K_{E,R}$ was 1.0 μM and $K_{E,O}$ 280 μM. From titrations in the presence of D-malate, $K_{EI,R}$ was found to be 0.4 μM, $K_{ER,I}$ 6 000 μM and $K_{E,I}$ 15 000 μM. At high concentrations of D-malate, 80 to 160 mM, $K_{EI,R}$ increased 30 to 50 %, apparently due to the effect of ionic strength. The mutual stabilizing effect of DPNH and D-malate on the binding of one another, shown by the fact that $K_{EI,R} < K_{E,R}$ and $K_{ER,I} < K_{E,I}$, indicates that a ternary complex, in which the bound molecules interact, is formed. D-Malate interacted specifically with DPNH. DPN and D-malate were bound to the enzyme without interaction, since the values found for $K_{EI,O}$, 299 μM, and $K_{EO,I}$, 14 900 μM, are in close agreement with $K_{E,O}$ and $K_{E,I}$. L-Malate apparently has the opposite specificity. It was without effect on the dissociation of DPNH, although it presumably interacts in the binding of DPN in the enzymatically active complex.

Preliminary measurements have been carried out at pH 6.0 and 8.0. The changes in the dissociation constants of the binary

* Pfleiderer has reported [6,7] that his malic dehydrogenase preparations bind one mole of DPNH per 40 000 g of protein, the molecular weight according to Neilands [15].

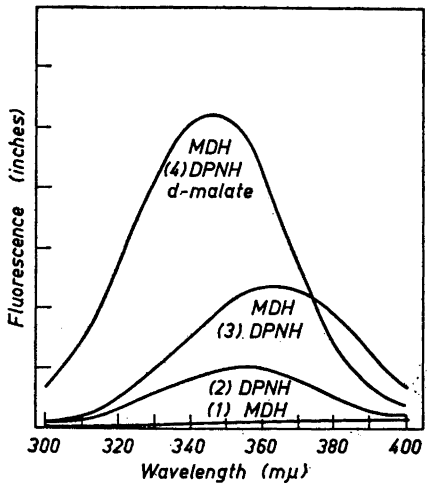

Fig. 2. Activation spectrum for fluorescence of DPNH, DPNH-malic dehydrogenase complex, and the ternary complex of malic dehydrogenase, DPNH, and D-malic acid. Curve (1): 3.6×10^4 units of malic dehydrogenase. Curve (2): 3.3×10^{-6} M DPNH. Curve (3): 3.3×10^{-6} M DPNH plus 3.6×10^4 units of malic dehydrogenase. Curve (4): 3.3×10^{-6} M DPNH, 3.6×10^4 units of malic dehydrogenase, and 5×10^{-2} M D-malate. Fluorescence was measured at the appropriate emission maximum for each system. Buffer, 0.1 μ phosphate, pH 7.15, containing 10^{-3} M EDTA. Final volume, 2 ml. Temp., 23.5°C.

coenzyme complexes are qualitatively similar to those observed with liver alcohol dehydrogenase [8]. The ratio $K_{E,O}/K_{E,R}$ decreases from about 1 400 at pH 6.0 to 100 at pH 8.0. $K_{E,O}$ decreases sharply from pH 6.0 to 7.15, indicating that a group with a pK in this region is involved in the binding of DPN. The mutual stabilization in the binding of D-malate and DPNH is also observed at pH 6 and 8, although $K_{EI,R}$, $K_{E,R}$, $K_{ER,I}$ and $K_{E,I}$ each increase with increasing pH. These studies are being completed and extended and a detailed report will be published.

Changes in the Fluorescence Spectrum of Reduced Triphosphopyridine Nucleotide on Binding to *Iso*-citric Dehydrogenase

THOMAS A. LANGAN*

Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

In 1956, Boyer and Theorell [1] reported a shift to shorter wavelengths and an intensification in the fluorescence spectrum of DPNH ** on binding to horse liver alcohol dehydrogenase. Subsequently, similar changes in DPNH fluorescence have been observed when DPNH combines with yeast alcohol dehydrogenase [2], lactic [3], glutamic [4] and malic dehydrogenase [5,6]. A fluorescence change of the type originally observed with liver alcohol dehydrogenase thus appears to be a general phenomenon in the binding of DPNH to the "alcohol" type [7] of dehydrogenase, and has proved valuable in the quantitative study of coenzyme binding [8-11]. Whether this phenomenon extends also to the case of TPN dependent dehydrogenases of this type has not been previously investigated. The present communication is a report of a change in the fluorescence spectrum of TPNH on combination with *iso*citric dehydrogenase which is similar in essential respects to the changes which have been observed on formation of the DPNH complexes. The fluorescence change is being utilized in a study of coenzyme, substrate and metal binding to the enzyme.

Experimental. The fluorometric observations were carried out in the spectrofluorometer previously described [8], and calculations were made using equations based on those employed earlier in this laboratory [8,9]. All measurements were made at 23.5°C in 0.1 μ Tris-chloride buffer, pH 7.1. Emission and excitation maxima are uncorrected for variations with wavelength in the intensity of the exciting light and sensitivity of the photocell. The correction would move the maxima about 15 mμ towards shorter wavelengths on this apparatus. Pig heart *iso*citric dehydrogenase was prepared and assayed according to the method of Moyle and Dixon [12]. Small amounts of flavin present in this material were removed by adding sufficient calcium phosphate gel in the last step to absorb most of the activity and eluting the enzyme with 0.05 M Tris, pH 7.3, 20 % saturated with ammonium sulfate. EDTA, 10^{-3} M, was included in all solutions from step 3 on. Preparations free of flavin fluorescence with a specific activity of up to 2 100 units/mg were obtained in this way. For the fluorometric experiments the following series of dialyses was employed to remove sulfate ions from the enzyme solution to the point where no cloudiness was visible on addition of $BaCl_2$: 18 h *vs.* 0.1 μ Tris pH 7.1, containing 1 M NaCl and 10^{-3} M EDTA; 24 h *vs.* 0.1 μ Tris pH 7.1; three 3 h periods *vs.* 0.1 μ Tris pH 7.1. These dialyses caused up to 70 % loss of activity. Shorter periods of dialysis gave material of higher specific activity but did not completely remove ammonium sulfate, which had a marked dissociating effect on the binding of coenzymes.

TPN and TPNH were products of Sigma Chemical Co. DL-isocitric acid lactone was obtained from Sigma and from the California Corp. for Biochemical Research. These products assayed enzymatically 47 to 48 % D-isocitric acid after hydrolysis at 60 to 100° in the presence of excess NaOH.

Results and discussion. The changes in the fluorescence spectrum of TPNH on binding to *iso*citric dehydrogenase are shown in Fig. 1. The emission maximum of TPNH is 478 mμ as observed in the apparatus used. In the presence of a stoichiometric amount of *iso*citric dehydrogenase the maximum is shifted towards the ultraviolet to 455 mμ and increased in intensity approximately three fold. Shifts of fluorescence to shorter wavelengths accompanied by an intensification are characteristic of the changes which have been observed on formation of DPNH complexes with "alcohol" dehydrogenases. The close similarity of the fluorescence changes which occur on binding of reduced pyridine nucleotides to this group of enzymes may be an indication of common structures in the region of the binding sites.

Fig. 2 shows the changes in the excitation spectrum for TPNH fluorescence on binding to *iso*citric dehydrogenase. The 352 mμ excitation maximum observed for

* Postdoctoral Fellow of the (U.S.) National Science Foundation.

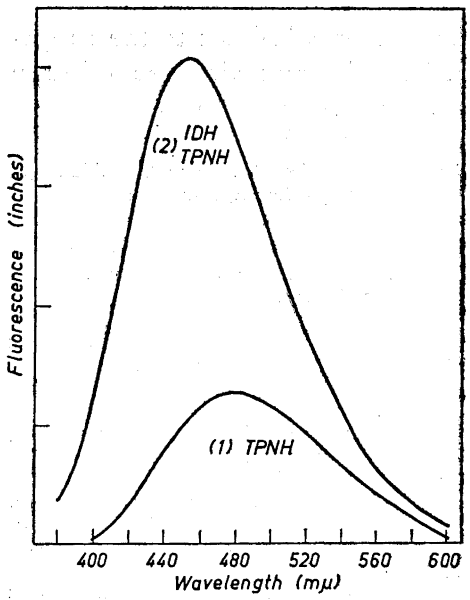

Fig. 1. Fluorescence emission spectrum of TPNH and TPNH-*iso*citric dehydrogenase complex. Curve (1): 2×10^{-6} M TPNH. Curve (2): 2×10^{-6} M TPNH plus 1 500 units of *iso*-citric dehydrogenase. Activating wavelength, 352 mμ. Buffer, 0.1 μ Tris pH 7.1. Final volume, 2 ml. Temp., 23.5°C. The curves are corrected for fluorescence due to buffer and enzyme.

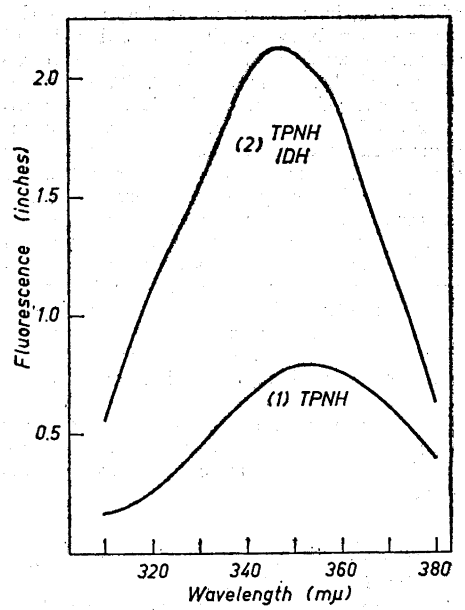

Fig. 2. Activation spectrum for fluorescence of TPNH and TPNH-*iso*citric dehydrogenase complex. Curve (1): 1×10^{-6} M TPNH. Curve (2): 1×10^{-6} M TPNH plus 615 units of *iso*citric dehydrogenase. Measuring wavelength. 460 mμ. Buffer, 0.1 μ Tris, pH 7.1. Final volume, 2 ml. Temp., 23.5°C. Curves corrected for fluorescence of buffer and enzyme.

TPNH fluorescence is seen to shift to 347 mμ in the presence of enzyme. In DPN dependent enzymes, no consistent pattern is evident in the effect of enzyme on the excitation maximum. Shifts to shorter wavelengths have been observed with liver alcohol dehydrogenase [4] and lactic dehydrogenase [13], and to longer wavelengths with malic dehydrogenase [5], while yeast alcohol dehydrogenase has no effect [14].

No difference between the fluorescence properties of unbound TPNH and DPNH has been observed.

The coenzyme binding capacity of *iso*citric dehydrogenase preparations, determined by following fluorescence changes at 410 mμ during titration with TPNH, was found to be 1 mole of coenzyme per 3.8×10^{11} units of enzyme, corresponding to a turnover number of 1 850 moles of TPN per min per mole of coenzyme binding sites. This value was constant over a three fold range of purity of the *iso*citric dehydrogenase. Assuming a molecular weight of 60 000 [15] the specific activity of the material obtained by Siebert *et al.*[15] indicates that the *iso*citric dehydrogenase molecule binds at least two molecules of TPNH. Since there is some evidence of inhomogeneity in this material [15], the binding capacity may be higher than two.

The titrations indicate an extremely tight binding of TPNH, the dissociation constant being on the order of 10^{-8} M. The binding of TPN was competitive with TPNH, with a dissociation constant approximately 200 times larger. A looser binding of the oxidized form of the coenzyme has been observed with other pyridine nucleotide dependent dehydrogenases [10,11,16]. DL-*Iso*citric acid was also found to block competitively the binding

of TPNH, in a manner analogous to the competition between DPNH and reduced substrate analogues in binding to horse liver alcohol dehydrogenase [9]. The competition is a reflection of the fact that complexes of the type *enzyme-reduced coenzyme-reduced substrate* are not formed by *iso*citric dehydrogenase, and emphasizes the role of coenzyme in determining the substrate binding properties of the enzyme. The effectiveness of DL-*iso*citric acid in displacing TPNH was markedly increased in the presence of 10^{-4} M Mn++ ions indicating that Mn++ is involved in the binding of *iso*citric acid. Further studies of this system are being carried out and will be reported in a detailed publication.

The author would like to thank Professor Hugo Theorell for his interest and for many helpful discussions during the course of this work.

Experiments Related to the Preparation of Pyridoxine from Furan

JØRGEN TORMOD NIELSEN*, NIELS ELMING** and NIELS CLAUSON-KAAS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

Pyridoxine (X) has previously been prepared from furan by a six-step reaction [1]. A number of variations of this method have been tried by us (*cf.* Ref. [2]), but have so far not lead to any appreciable improvements of the method. However, in the course of the work eight new compounds were prepared, and it was found worth while to publish directions for their preparation, since they at any time may become of use for synthetic work in this field. The reactions in question are summarized below. Compounds II—VIII and XI are new. Their structures follows from the syntheses and from analyses.

Since 2-(α-acetamidoethyl)-furan (I) is obtained from furan in a 44 % yield [3-5], the overall yield of pyridoxine from furan along the route described here is 10 %, as compared to 23 % of the route published previously.

Experimental. Microanalyses by E. Boss and K. Glens.

2-(α-Acetamidoethyl)-3, 4-dicarbethoxyfuran (IV). 2-(α-Acetamidoethyl)-furan [3] (17.2 g, 0.112 mole) and diethyl acetylenedicarboxylate (20.1 g, 0.118 mole) were mixed and heated to 100° for 3.5 h. After cooling, the reaction mixture was dissolved in acetone (120 ml) and shaken with 10 % palladium on carbon catalyst (0.62 g) at room temperature under 1 atm. of hydrogen until about 2 500 ml of hydrogen had been taken up. After filtration the solvent was removed by distillation and the light-brown residue decomposed in an oil bath (190—200°) under 13 mm during 1 h. The reaction mixture was crystallized from ether. Hereby 19.4 g of IV [white crystals, m. p. 51—53° (Hershberg apparatus, corr.)] was obtained (Found: C 56.9; H 6.4; N 4.7; OC_2H_5 30.5; $COCH_3$ 14.8. Calc. for $C_8H_6O_3N(OC_2H_5)_2(COCH_3)$ (297.3): C 56.6; H 6.4; N 4.7; OC_2H_5

* Present address: Chemical Laboratory of the University of Copenhagen, Copenhagen, Denmark.

** Present address: A/S Pharmacia, Copenhagen, Denmark.

of TPNH, in a manner analogous to the competition between DPNH and reduced substrate analogues in binding to horse liver alcohol dehydrogenase [9]. The competition is a reflection of the fact that complexes of the type *enzyme-reduced coenzyme-reduced substrate* are not formed by *iso*citric dehydrogenase, and emphasizes the role of coenzyme in determining the substrate binding properties of the enzyme. The effectiveness of DL-*iso*citric acid in displacing TPNH was markedly increased in the presence of 10^{-4} M Mn++ ions indicating that Mn++ is involved in the binding of *iso*citric acid. Further studies of this system are being carried out and will be reported in a detailed publication.

The author would like to thank Professor Hugo Theorell for his interest and for many helpful discussions during the course of this work.

Experiments Related to the Preparation of Pyridoxine from Furan

JØRGEN TORMOD NIELSEN*, NIELS ELMING** and NIELS CLAUSON-KAAS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

Pyridoxine (X) has previously been prepared from furan by a six-step reaction [1]. A number of variations of this method have been tried by us (*cf.* Ref. [2]), but have so far not lead to any appreciable improvements of the method. However, in the course of the work eight new compounds were prepared, and it was found worth while to publish directions for their preparation, since they at any time may become of use for synthetic work in this field. The reactions in question are summarized below. Compounds II—VIII and XI are new. Their structures follows from the syntheses and from analyses.

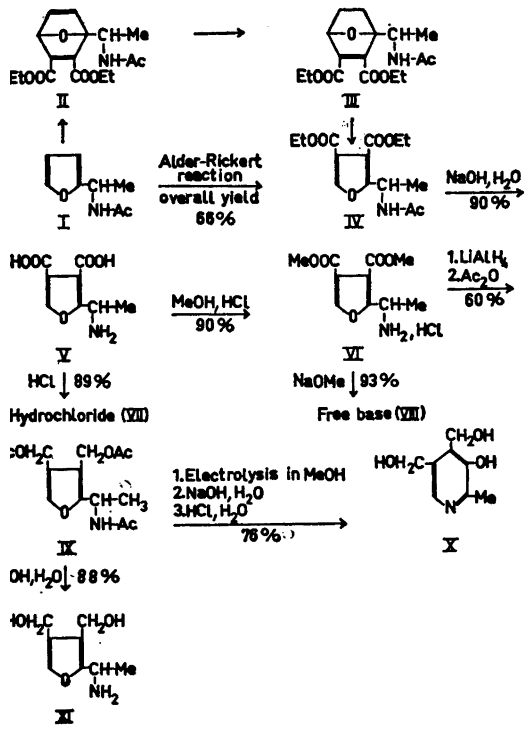
Since 2-(α-acetamidoethyl)-furan (I) is obtained from furan in a 44 % yield [3-5], the overall yield of pyridoxine from furan along the route described here is 10 %, as compared to 23 % of the route published previously.

Experimental. Microanalyses by E. Boss and K. Glens.

2-(α-Acetamidoethyl)-3, 4-dicarbethoxyfuran (IV). 2-(α-Acetamidoethyl)-furan [3] (17.2 g, 0.112 mole) and diethyl acetylenedicarboxylate (20.1 g, 0.118 mole) were mixed and heated to 100° for 3.5 h. After cooling, the reaction mixture was dissolved in acetone (120 ml) and shaken with 10 % palladium on carbon catalyst (0.62 g) at room temperature under 1 atm. of hydrogen until about 2 500 ml of hydrogen had been taken up. After filtration the solvent was removed by distillation and the light-brown residue decomposed in an oil bath (190—200°) under 13 mm during 1 h. The reaction mixture was crystallized from ether. Hereby 19.4 g of IV [white crystals, m. p. 51—53° (Hershberg apparatus, corr.)] was obtained (Found: C 56.9; H 6.4; N 4.7; OC_2H_5 30.5; $COCH_3$ 14.8. Calc. for $C_8H_6O_3N(OC_2H_5)_2(COCH_3)$ (297.3): C 56.6; H 6.4; N 4.7; OC_2H_5

* Present address: Chemical Laboratory of the University of Copenhagen, Copenhagen, Denmark.

** Present address: A/S Pharmacia, Copenhagen, Denmark.



30.3; $COCH_3$ 14.5.) Another 2.6 g of analytically pure IV was isolated by distillation of the mother liquor (b.p. $_{0.1}$ 178—186°) followed by crystallization from ether (m. p. 49—51°), thus bringing the total yield of IV up to 22.0 g (66 %).

In a separate experiment the intermediate compound II was isolated in a 45 % yield; white crystals from ether, m. p. 129—130° (Found: C 59.5; H 6.3; N 4.7; OC_2H_5 27.8; $COCH_3$ 13.8. Calc. for $C_{10}H_9O_3N(OC_2H_5)_2(COCH_3)$ (323.3): C 59.4; H 6.6; N 4.3; OC_2H_5 27.9; $COCH_3$ 13.3.)

In another separate experiment the other intermediate compound (III) was isolated from pure II in a 89 % yield; white crystals from ether, m. p. 109—110°. (Found: C 58.9; H 7.1; N 4.7; OC_2H_5 27.6; $COCH_3$ 13.2. Calc. for $C_{10}H_{10}O_3N(OC_2H_5)_2(COCH_3)$ (325.4): C 59.1; H 7.1; N 4.3; OC_2H_5 27.7; $COCH_3$ 13.2).

2-(α-Aminoethyl)-3,4-dicarboxyfuran (V). IV (10.0 g, 0.034 mole) and sodium hydroxide (3 N, 115 ml, 0.34 mole) were heated under reflux (24 h). After cooling the mixture was brought to pH 8.7 by addition of concentrated hydrochloric acid. A small amount of a voluminous white precipitate was removed by filtration. The filtrate was brought to pH 5.0 by further addition of hydrochloric acid. Hereby 5.42 g of white crystals of V separated. Another 0.56 g of V was obtained by evaporation of the mother liquor to 60 ml. The total yield of V (5.98 g) corresponds to 90 %; m. p. 292—296° after darkening at about 280° (Kofler stage, corr.). (Found: C 48.3; H 4.6; N 7.0. Calc. for $C_8H_9O_5N$ (199.2): C 48.2; H 4.6; N 7.0.)

The hydrochloride of V (VII) was prepared in a 89 % yield in the usual way; white crystals, m. p. 195—200° (decomp.). (Found: C 40.7; H 4.4; N 6.2; Cl 14.5. Calc. for $C_8H_{10}O_5NCl$ (235.6): C 40.8; H 4.3; N 5.9; Cl 15.0.)

2-(α-Aminoethyl)-3,4-dicarbomethoxyfuran hydrochloride (VI). V (5.93 g) and anhydrous methanol (95 ml) were mixed and treated with hydrogen chloride until 4.5 g was absorbed. The pale yellow solution was heated under reflux (10 h). After cooling Drierite was added, the mixture shaken (2 h) and the Drierite removed by filtration. Methanol and excess hydrogen chloride were removed by distillation under vacuum and the residue dried under vacuum in a dessicator over potassium hydroxide. Dissolution in anhydrous methanol (15 ml) and precipitation with anhydrous ether gave 7.10 g (90 %) of VI; white crystals, m. p. 167—169° (decomp.). (Found: C 45.8; H 5.7; N 5.5; Cl 13.6; OCH_3 23.5. Calc. for $C_8H_8O_3NCl(OCH_3)_2$ (263.7): C 45.5; H 5.4; N 5.3; Cl 13.4; OCH_3 23.5.)

The free base of VI (VIII) was prepared from VI and sodium methoxide in methanol in a 93 % yield in the usual way; colorless oil, n_D^{25} 1.4952. (Found: C 52.9; H 5.7; N 6.5; OCH_3 27.1. Calc. for $C_8H_7O_3N(OCH_3)_2$ (227.2): C 52.9; H 5.8; N 6.2; OCH_3 27.3.)

2-(α-Acetamidoethyl)-3,4-bis(acetoxymethyl)-furan (IX). VI (3.27 g, 0.0124 mole) dissolved in anhydrous methanol (12 ml) was transformed into the free base (VIII) as described above. The base was dissolved in anhydrous ether (25 ml) and the solution added with stirring to a mixture of lithium aluminum hydride (0.94 g, 0.025 mole) in ether (40 ml) during 15 min. Stirring was continued for 1 h and the mixture heated under reflux for another hour. After cooling acetic anhydride (40 ml) was added dropwise with stirring at —20°. The ether was evaporated and the residue heated under reflux (30 min). After cooling ether (150 ml) was added, the mixture filtered and distilled from an oil bath. The yield was 2.21 g (60 %) of IX; pale yellow liquid, b. p. $_{0.1}$ 180—190°, n_D^{25} 1.4914; previously found b. p. $_{0.05}$

175–187°, n_D^{25} 1.4905. (Found: C 56.6; H 6.7; N 4.9; $COCH_3$ 42.7. Calc. for $C_8H_{10}O_3N(COCH_3)_3$ (297.3): C 56.6; H 6.4; N 4.7; $COCH_3$ 43.4.) Crystallization from ether gave white crystals, m. p. 89–92°; previously found 95–96° [1].

The transformation of IX into pyridoxine hydrochloride in a 76 % yield has been described previously [1].

2-(α-Aminoethyl) - 3,4-bis(hydroxymethyl)-furan (XI). IX (5.95 g, 0.020 mole) and sodium hydroxide (3 N, 67 ml, 0.20 mole) were mixed and heated under reflux (24 h). After cooling the light brown mixture was continuously extracted with ether (3 days). The etheral extract was distilled from an oil bath. Hereby 3.02 g (88 %) of XI was obtained as a pale yellow oil; b. p. $_{0.05}$ 165–171°, n_D^{25} 1.5304. (Found: C 56.3; H 7.9; N 8.5. Calc. for $C_8H_{13}O_3N$ (171.2): C 56.1; H 7.7; N 8.2.)

Two Fractions of Melanocyte Stimulating Hormone in Urine

BRUNO DAHLBERG

Womens' Clinic, General Hospital, Malmö, Sweden

One of the hormones secreted from the pituitary is the Melanocyte Stimulating Hormone (MSH). Two different melanocyte stimulating substances have been isolated from porcine pituitary (Lerner and Lee [1]; Lee and Lerner [2]), one is alpha-MSH which has an isoelectric point at pH 10.5–11.0, the other is beta-MSH which has an isoelectric point at pH 5.5.

Other investigators found similar substances with isoelectric points around pH 5 but could not find any activity at pH 11. (Porath *et al*[3]; Benfey and Purvis [4]; Geschwind and Li [5]).

MSH is excreted in the urine of normal men and women (Shizume and Lerner [6]; Dahlberg [7]), as well as during pregnancy (Shizume and Lerner [6]; Dahlberg [8]).

Owing to the inadequate methods for extraction of MSH from urine it has previously been difficult to estimate the excretion in the urine of normal subjects.

As MSH is a pituitary hormone a method for determination of the excretion in urine was thought to give information on certain pituitary functions. A biological assay has therefore been elaborated.

For the determination of the hormone hypophysectomized frogs, *Rana Esculenta*, were used. In the method of extraction used an active melanocyte stimulating substance was found at pH 4.0. In recovery experiments 45.4 % ± 6.4 of a known amount of added MSH could be retrieved.

As the degree of accuracy thus seemed rather low it was thought that part of the hormone might remain in solution. In order to investigate this problem extractions were carried out at both pH 4.0 and pH 11.5 on the urine of normal women. The usual activity was found at pH 4.0, *but in the fraction at pH 11.5 activity was also found.* There are thus *two fractions of melanocyte stimulating hormone in the urine of homo.*

Recovery experiments with a known amount of added MSH yielded the following results:

At pH 4.0 = 40–45 %,
at pH 11.5 = 55–60 %

On the Transfer of Thiocyanate from Fodder to Milk

ARTTURI I. VIRTANEN and ROLF GMELIN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In connection with our studies on goitrogenic factors in crucifers, especially those belonging to the *Brassica* species and varieties, the enzymatic formation of the thiocyanate ion SCN^- from some mustard oil glucosides was found [1]. It has been known that SCN^- inhibits iodine uptake by the thyroid gland, and there is reason to assume that SCN^- is one member of the *Brassica* factor which causes goitre in experimental animals.

An important question is to what extent the SCN^- which is formed when the cows chew the fodder is transferred from the rumen to the milk. In order to elucidate this problem we have performed feeding experiments with cows by giving them different amounts of potassium- and ammonium thiocyanate mixtures.

According to our determinations about 0.2 mg % of SCN^- is generally found in the mixed milk during the indoor freeding from the big dairies in Southern Finland. In this area stable feeding commonly consists of hay (mostly timothy, often mixed with red clover), oats, silage (AIV) made of red clover-grass mixtures or sugar beet tops, and sugar beet pulp. If beets are used in the feeding, they are mainly mangels or fodder sugar beets. Marrow kale is still grown to a comparatively small extent. The growing of swedes is also slight.

If the daily feeding of the cows contains about 30 kg of marrow kale or the same amount of swedes, the SCN^- content of the milk is about 0.5 to 0.8 mg % according to our determinations. As already mentioned, the feeding of marrow kale is not general in Finland, and on the farms which grow it, it is restricted to October—November. Swedes again may be fed all the winter, but the daily rations are small on those relatively few farms on which they are grown. It is probable that the growing of marrow kale will increase in Finland. In Northern Finland, up to the polar circle and even beyond it, winter rape and turnip rape will probably become important raw material for silage on the basis of experiments and the experience obtained during the last years. The thiocyanate content of the milk will thus increase in this large area.

Determination of SCN^- in milk and in urine. A modification of Barker's method [2], essentially as described by Michajlovskij and Langer [3], was used for the determination: 10 ml of 20 % trichloroacetic acid was added to 10 ml of milk. 5 ml of the clear filtrate was treated with Fe^{3+}-reagent. The red brown coloration was measured in a Klett-Summerson photometer with filter 50 and compared with a standard SCN^- curve. 5 ml of milk filtrate + 1 ml of water, and 1 ml of Fe-reagent + 5 ml of water was used for background correction.

In the case of urine, exact determinations of SCN^- values were not possible since phenolic substances disturb the Barker method as well as the Aldridge method. The excretion of SCN^- was followed by subtraction of the colorimetric values in parallel experiments, *i. e.* in urines of cows fed with SCN^-, and cows which had received identical feeding but without addition of SCN^-. The found values can therefore be regarded only as approximative values.

First feeding experiment. On January 16, 1960, a mixture of 2 g of NH_4SCN and 2 g of KSCN was fed to the Ayrshire cow Häyri (calved on March 17, 1959) at 7.20 and 17.20; total amount of SCN^-, 5.46 g. The first milk sample was taken just before the feeding of thiocyanate. 0.24 mg % of SCN^- was found in it. The milking times were regularly at 6.30 and 17.10, and a milk sample was taken each time for the determination of SCN^-. Twelve days after the feeding of thiocyanate, a milk sample was taken only once a day for analysis, and after fifteen days only now and then. During the whole test period, the milk production of the cow was mostly 6.5 to 7.5 kg in the morning and 5.0 to 6.0 kg in the evening. The daily production ranged from 11 to 13 kg of milk with 3.5 % of fat. The SCN^- content of the milk is shown in Fig. 1.

The results show that 10 h after the first portion of thiocyanate, the SCN^- content of the milk has risen from the initial value of 0.24 mg % to 0.9 mg %. The feeding of the second portion in the same evening raised the SCN^- content of the following morning milk to 1.4 mg %, after which the content decreased in 24 h to about 0.7 mg %, where it remained for over ten days. The original SCN^- content of the milk was reached only after about four weeks after the feeding of thiocyanate. The total milk

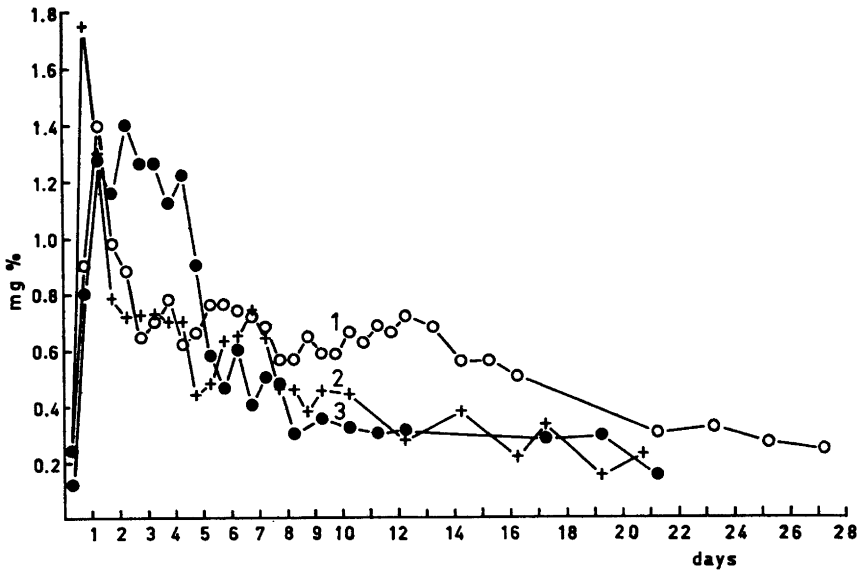

Fig. 1. SCN^- content of milk from cows fed different doses of thiocyanate. 1, Cow Häyri, fed 5.46 g of SCN^- in two doses on January 16, 1960; 2, Cow Häyri, fed 6 g of SCN^- in one dose on February 29, 1960; 3, Cow Mila, fed 24 g of SCN^- during four days in eight doses.

yield was about 315 kg during this time. About 1 000 mg or some 18 % of the 5.46 g of SCN^- fed was excreted in the milk. No SCN^- determinations were performed on the urine.

Second feeding experiment. A mixture of 1.95 g of NH_4SCN and 2.5 g of KSCN, corresponding to 3.0 g of SCN^-, was fed twice a day at 7.00 and 17.00, in total 8 × 3 g = 24 g of SCN^-, to the Ayrshire cow Mila (calved on September 26, 1958). The first milk sample was taken just before the feeding of thiocyanate was begun. 0.12 mg % of SCN^- was then found in the milk, *i. e.* half of Häyri's initial value, although the feeding of both cows was the same: 4 kg of oats, 4 kg of hay, 20 kg of AIV silage made of a red clover-grass mixture, and 2 kg of oat straw. The SCN^- content of the milk yields are shown in Fig.1.

The SCN^- content of Mila's milk also rose to 1.4 mg %, remaining at about this level during the four days in which the thiocyanate preparation was fed. A decreasing tendency appeared, however, already at the fourth day of the feeding. In spite of the fact that Mila got altogether well four times more SCN^- than Häyri, the SCN^- content of Mila's milk decreased more rapidly, reaching 0.3 mg % already after eight days from the beginning of the feeding experiment. Obviously SCN^- was more rapidly oxidized in Mila's organism than in Häyri's. The extremely low initial value of 0.12 mg % of SCN^- in Mila's milk was possibly due to this fact. The daily milk production ranged from 10 to 11.5 kg with 4.7 % of fat. About 900 mg of SCN^-, or less than 4 %, of the 24 g of SCN^- fed was excreted in the milk. The total milk yield was about 220 kg during the three weeks in which the SCN^- content exceeded the initial value. Also in this case no SCN^- determinations were performed on the urine.

The amounts of thiocyanate fed to the cows in the experiments related above were so high that cattle can hardly get larger or even as large ones when plenty of crucifers are used in the feeding. We have found that about 10 mg % of SCN^- is formed in crushed marrow kale, and hence a daily dose of 6 g of SCN^- would theoretically presuppose a ration of 60 kg of marrow kale a day, which is hardly eaten by a cow. Daily rations of more than 30 kg a day are usually not recommended because of the danger of diarrhea.

Table 1. Excretion of SCN^- in urine. On February 2, at 7.00 the cow Häyri was given 6 g of SCN^- (as KSCN + NH_4SCN) in one dose.

date	time	amount of urine/l	SCN^- mg/100 ml of urine	total SCN^- in urine/mg
29.II	10.55	2.0	7.8 (−6)	156 (36)
29.II	15.50	1.5	23.2 (−6)	348 (258)
29.II	22.30	1.5	58.0 (−6)	870 (780)
29.II	23.55	2.2	12.2 (−6)	268 (136)
1.III	01.16	2.7	8.0 (−6)	216 (54)
1.III	02.56	3.0	9.2 (−6)	276 (96)
1.III	04.24	2.1	8.6 (−6)	181 (55)
1.III	05.45	0.8	13.8 (−6)	110 (62)
		15.8 1/24 h		2 425 mg

(1 477 mg SCN^-/15.8 l of urine)

Third feeding experiment. The cow Häyri, the test animal in the first experiment, was given 3.9 g of NH_4SCN and 5 g of KSCN, corresponding to 6 g of SCN^-, in one dose on February 29, 1960 at 7.00. In this experiment the SCN^- content of the urine was also determined during 24 h after the feeding of thiocyanate. The SCN^- content of the milk before the start of the experiment was 0.24 mg %, *i. e.* the same as at the beginning of the first experiment. Ten hours after the feeding of thiocyanate, the SCN^- content of the milk had risen to 1.75 mg %. The SCN^- content of the milk is shown in Fig. 1, and that of the urine in Table 1.

Before the feeding of thiocyanate, the SCN^- content of the cows' urine was on the average about 6 mg of SCN^- per 100 ml. When this amount was subtracted from the SCN^- found in Häyri's urine after the feeding of thiocyanate, it was established that about 1.5 g of SCN^- was excreted in the urine during 24 h. The urine was not collected after this, but the SCN^- content of it had decreased so rapidly during the first day that an excretion of SCN^- in urine over 2 g, *i. e.* one third of the thiocyanate fed, is not probable. Since about 800 mg of the SCN^- fed was excreted in the milk, about half the amount fed has obviously been oxidized in the organism. This is of course only a rough estimation. In experiments with dogs Boxer and Rickards [4] found that about 30 % of SCN^- are metabolized in the body to CO_2.

On the basis of the above results, it does not seem probable that the SCN^- content of cow's milk could rise much above 1 mg % in practice, even when large amounts of crucifers are included in the feeding of cattle. This is in agreement with the results of Wokes *et al.*[5] who found SCN^- values between 0.01 and 1 mg % in a large number of milk samples. The feeding of the cows was probably unknown to the authors (it is not mentioned in the paper), but obviously the samples analysed also included milk from herds fed with marrow kale which is a relatively common fodder plant on farms in England.

With normal feeding Wright [6] found 0.8 mg % of SCN^- and with kale feeding 4.6 mg % in goat's milk. Obviously goat's milk contains about four times more SCN^- than cow's milk, even if its chemical composition is very similar to that of cow's milk.

This investigation is a part of a research project under U. S. Public Law No. 480, 83rd Congress.

Studies on Peroxy Compounds

V. The Introduction of the *t*-Butoxy Group into Tetrahydrofuran

SVEN-OLOV LAWESSON, CURT BERGLUND and SUSANNE GRÖNWALL

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Uppsala, Sweden

The benzoyloxy group may be introduced into olefins by the copper salt catalyzed decomposition of *t*-butyl perbenzoate, according to the Kharasch-Sosnovsky [1,2] method whereby the benzoyloxy group enters exclusively the allylic position without the occurrence of isomerisation. Denney *et al.* have proposed a mechanism based on studies with *t*-butyl perbenzoate (carbonyl ^{18}O) and Lawesson and Berglund have found that the benzoyloxy group is introduced into benzyl ethers [4,5] and benzyl sulphides [6] without fragmentation or dimerisation of the respective substrates. In our further studies of the Kharasch-Sosnovsky reaction with various types of ethers we have found that under suitable conditions tetrahydrofuran gives 2-*t*-butoxy tetrahydrofuran. (Found: C 66.57; H 10.93. Calc. C 66.63; H 11.18), b. p. 127°C, $n_D^{20} = 1.4194$. That the *t*-butoxy group enters mainly (possibly exclusively) the 2-position is inferred by the chemical and physical evidence, details of which will be given in a subsequent publication. Contrary to tetrahydrofuran, 1,4-dioxane gives 2-benzoyloxy-1,4-dioxane. (Found: C 63.57; H 5.84. Calc. C 63.45; H 5.81), m. p. 51–52°C and di-*n*-butyl ether gives 2-benzoyloxy-di-*n*-butyl ether. (Found: C 72.25; H 8.91. Calc. C 71.97; H 8.86), b. p. 97–98°C/0.3 mm Hg, $n_D^{20} = 1.4837$. Although there are indications that the benzoyloxy group is first introduced also into tetrahydrofuran, the main product isolated is the *t*-butoxy compound.

At this juncture, we do not want to discuss any theoretical or other aspects of this reaction; however, by extending this work, we are exploring the Kharasch-Sosnovsky reaction more fully and any detailed discussion will be postponed until further experimental work has been completed.

On the Crystal Structures of $(BiO)_2SeO_4 \cdot H_2O$, $(BiO)_2SO_4 \cdot H_2O$, $BiOHCrO_4$ and $BiOHSeO_4 \cdot \frac{1}{2}H_2O$

BENGT AURIVILLIUS, OLOV von HEIDENSTAM and INGRID JONSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

In the bismuth oxide salts whose structures have hitherto been reported, a characteristic structural element is frequently present, *viz.* infinite two-dimensional layers of the composition Bi_2O_2. The layers consist of sheets of oxygen atoms which are arranged to form squares. The bismuth atoms are situated alternately above and below the centres of the latter as illustrated in Fig. 1. Each oxygen atom of the sheets is thus tetrahedrically surrounded by four bismuth atoms. The arrangement can also be described geometrically as built up of OBi_4 tetrahedra linked together to form the Bi_2O_2 layers by sharing four edges.

The bismuth oxide compounds reported to contain Bi_2O_2 layers include several bismuth oxide halides [1], some bismuth oxide salts of fatty acids [2], several mixed oxides of bismuth and titanium, niobium or tantalum [3] and one oxide carbonate of bismuth [4].

The present study was undertaken in order to find out whether the Bi_2O_2 layers are also present in compounds containing tetrahedral anions.

Since only preliminary determinations have been made of the positions of the

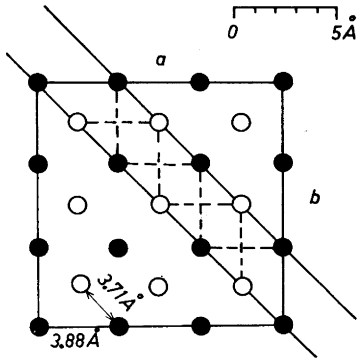

Fig. 1. Projection of the bismuth atom positions in a Bi_2O_2 layer on the *ab* plane. Circles and filled circles mark Bi atoms at the heights zero and 2.50 Å respectively. The Bi-Bi distances are given for BiOCl.

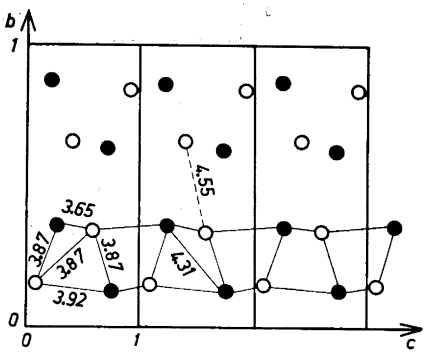

Fig. 2. Projections of the bismuth atom positions in $(BiO)_2SeO_4 \cdot H_2O$ on the *bc* plane. Circles and filled circles denote the positions of the atoms Bi_1 and Bi_2.

oxygen atoms, the formulae given in the title must as yet be regarded as empirical. However, from the positions found for the Bi atoms, the following conclusions can be drawn:

1. The arrangement of the bismuth atoms in $(BiO)_2SO_4 \cdot H_2O$ and $(BiO)_2SeO_4 \cdot H_2O$ have features in common with their arrangement in Bi_2O_2 layers. In fact, in these compounds, idealized bismuth atom positions can be deduced from their arrangement in these layers.

2. The arrangements of the bismuth atoms in $BiOHCrO_4$ and $BiOHSeO_4 \cdot \frac{1}{2} H_2O$ are not compatible with that in Bi_2O_2 layers.

$(BiO)_2SeO_4 \cdot H_2O$ and $(BiO)_2SO_4 \cdot H_2O$

The compounds $(BiO)_2SeO_4 \cdot H_2O$ and $(BiO)_2SO_4 \cdot H_2O$ are isostructural. Space group: $P2_1/c$ (No. 14). The unit cells contain four formula units. The following point positions and parameters were derived:

$(BiO)_2SeO_4 \cdot H_2O$;

4 Bi_1 in 4(*e*):
$\pm(x,y,z)$; $\pm(x,\frac{1}{2}-y,\frac{1}{2}+z)$;
$x = \overline{0.034}$, $y = 0.156$, $z = 0.087$
4 Bi_2 in 4(*e*):
$x = 0.299$, $y = 0.134$, $z = \overline{0.235}$
4 Se in 4(*e*):
$x = 0.366$, $y = 0.634$, $z = 0.087$

$(BiO)_2SO_4 \cdot H_2O$;

4 Bi_1 in 4(*e*):
$x = \overline{0.037}$, $y = 0.155$, $z = 0.088$
4 Bi_2 in 4(*e*):
$x = 0.310$, $y = 0.135$, $z = \overline{0.218}$

Cell dimensions:

$(BiO)_2SeO_4 \cdot H_2O$;
$a = 7.92$ Å, $b = 14.04$ Å, $c = 5.64$ Å, $\beta = 108.8°$
$(BiO)_2SO_4 \cdot H_2O$;
$a = 7.67$ Å, $b = 14{,}00$ Å, $c = 5.70$ Å, $\beta = 109.2°$

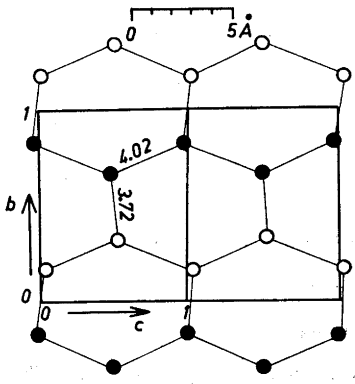

Fig. 3. Projection of the bismuth atom positions in $BiOHCrO_4$ on the *bc* plane. Circles and filled circles mark Bi atoms at $x = 0.16$ and $x = \overline{0.16}$, respectively.

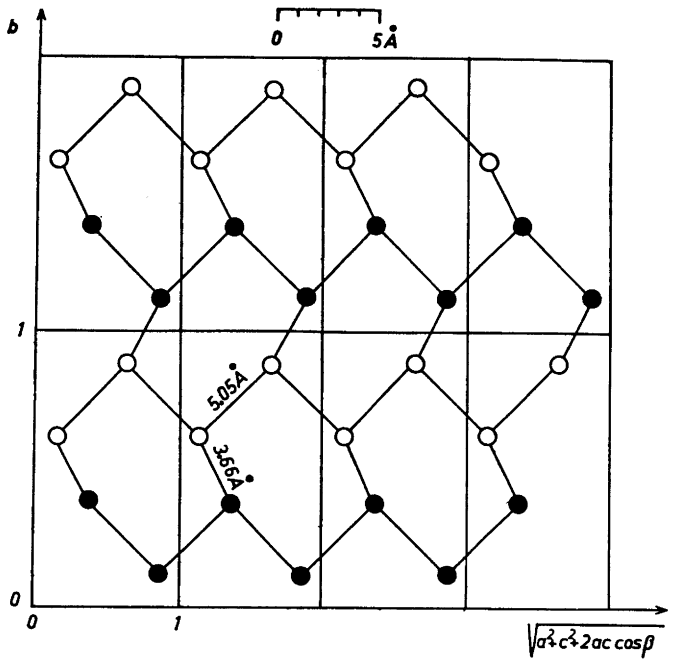

Fig. 4. Projection of the bismuth atom positions of one layer in $BiOHSeO_4 \cdot \frac{1}{2}H_2O$ on the plane (101) along the line [10$\bar{1}$]. The bismuth atoms occur at two heights along [10$\bar{1}$], the difference in the heights being 0.68 Å. Circles and filled circles representent bismuth atoms at different levels.

The bismuth atom positions projected on the *bc* plane are shown in Fig. 2. As seen, the bismuth atoms form double chains along the *c* axis of the unit cell. These chains can be described as being formed by linked tetrahedra, each sharing two opposite edges. A corresponding chain of Bi atoms occurs in the Bi_2O_2 layers and is marked in Fig. 1. Thus the arrangements of the bismuth atoms in $(BiO)_2SeO_4 \cdot H_2O$, $(BiO)_2SO_4 \cdot H_2O$ and in Bi_2O_2 layers are quite similar. In the structures of this selenate and sulphate, OBi_4 tetrahedra with reasonable distances O—Bi are geometrically possible.

$BiOHCrO_4$

Space group: $P2_1/c$ (No. 14). The unit cell contains four formula units. The following point positions and parameters were arrived at for the bismuth and chromium atoms:

4 Bi in 4(*e*):

$\pm(x,y,z)$; $\pm(x,\frac{1}{2}-y,\frac{1}{2}+z)$;
$x = 0.162$, $y = 0.170$, $z = 0.014$

4 Cr in 4(*e*):

$x = 0.270$, $y = 0.580$, $z = 0.177$

Cell dimensions:

$a = 5.61$ Å, $b = 9.54$ Å, $c = 7.44$ Å, $\beta = 93.15°$

The projection of the bismuth atom positions on the *bc* plane is given in Fig. 3. As seen, the bismuth atoms form puckered sheets made up of hexagons along the *bc* planes. The shortest distance between bismuth atoms belonging to different sheets is 5.61 Å. A tetrahedral arrangement OBi_4 with reasonable distances O—Bi is not possible in this structure and the arrangement of the bismuth atoms does not seem to have any relation to the bismuth arrangement occuring in Bi_2O_2 layers.

Judging from the Bi—Bi distances, there seems to exist a weak tendency for the bismuth atoms to form pairs in this structure.

$BiOHSeO_4 \cdot \frac{1}{2} H_2O$

Space group: $P2_1/n$ (No. 14). The unit cell contains four formula units. The following point positions and parameters were derived for the bismuth and selenium atoms:

4 Bi in 4(*e*):
$\pm(x,y,z)$; $\pm(\frac{1}{2}+x,\frac{1}{2}-y,\frac{1}{2}+z)$;
$x = 0.586$, $y = 0.118$, $z = 0.151$
4 Se in 4(*e*):
$x = 0.094$, $y = 0.165$, $z = 0.165$
Cell dimensions:
$a=6.64$ Å, $b=13.60$ Å, $c=6.08$ Å, $\beta=112.2°$

The bismuth atoms form nearly planar sheets parallel to the plane (101). The sheets are made up of hexagons with the edges 3.66 Å and 5.05 Å (Fig. 4). The shortest distances between bismuth atoms in adjacent layers is 5.77 Å. The arrangement of the bismuth atoms in $BiOHSeO_4 \cdot \frac{1}{2}H_2O$ does not bear any resemblance to the quadratic layers of bismuth atoms in the Bi_2O_2 sheets. The tendency of pair formation for the bismuth atoms is more pronounced in this structure than in $BiOHCrO_4$.

These investigations will be continued in order to refine the parameters and to determine the positions of the oxygen atoms. A full account will be published later.

These studies form part of a research program on bismuth oxide salts financially supported by the *Swedish Natural Science Research Council.*

Electrophilic Replacement of Bromine by Hydrogen

Debromination of 2,4,6-Tri-*t*-butylbromobenzene

PHILIP C. MYHRE*

Nobel Institute of Chemistry, Stockholm 50, Sweden

When 2,4,6-tri-*t*-butylbromobenzene (*I*) is heated in the presence of a strong acid a mixture of products including 1,3,5-tri-*t*-butylbenzene (*II*) and 3,5-di-*t*-butylbromobenzene is formed. If an acceptor for Br+ such as bromide ion is present in the acid and the resulting bromine is entrained from the solution, *II* is the chief product. In principle, any compound which formally serves as a reducing agent for Br+ and is otherwise inert is suitable for use as an acceptor. Reactive aromatic hydrocarbons prove to be very efficient for this purpose. Trifluoroacetic acid has been used in most experiments because of its high acidity and relatively good solvent properties; however, the reaction occurs with a variety of acids.

The debromination of *I* is viewed as an electrophilic replacement of bromine by hydrogen or the reverse of aromatic bromination. That *I* should undergo electrophilic debromination was by no means unexpected. The observed strong isotope effect in the "positive" bromination [1] of *II* coupled with the known facts about other electrophilic substitutions by hydrogen [2] led us to investigate this reaction possibility. The isotope effect in the bromination of *II* has been explained in terms of steric effects which cause the velocity of step 2 to become less than that of step -1. It is apparent that steric repulsion energy increases as this reaction proceeds towards products. As a result, the energy differ-

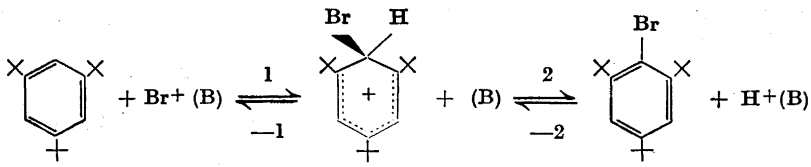
Reactive aromatic hydrocarbons prove to be very efficient for this purpose. Trifluoroacetic acid has been used in most experiments because of its high acidity and relatively good solvent properties; however, the reaction occurs with a variety of acids.

The debromination of *I* is viewed as an electrophilic replacement of bromine by hydrogen or the reverse of aromatic bromination. That *I* should undergo electrophilic debromination was by no means unexpected. The observed strong isotope effect in the "positive" bromination [1] of *II* coupled with the known facts about other electrophilic substitutions by hydrogen [2] led us to investigate this reaction possibility. The isotope effect in the bromination of *II* has been explained in terms of steric effects which cause the velocity of step 2 to become less than that of step -1. It is apparent that steric repulsion energy increases as this reaction proceeds towards products. As a result, the energy differ-

* U.S. National Science Foundation Postdoctoral Fellow, 1958—1960.



ence between the products and the transition state would be expected to be less for a highly hindered compound such as *I* than for a less hindered alkylbromobenzene. Consequently, one would predict that the reverse reaction, debromination, would become energetically more favorable in highly hindered systems. It should be stressed that the existence of an isotope effect in the bromination of *II* does not imply that the reaction is reversible. However, steric effects serve to explain both the isotope effect and the facile debromination.

Since there are numerous examples in the literature of acid-induced dehalogenations of highly reactive unhindered aromatic compounds such as amines and phenols [3,4], it is important to establish that the lowering of the free energy of activation for the debromination of *I* is in a large measure due to the above mentioned steric effects and not simply to a general activation of the aromatic ring by the alkyl group substituents. Consequently, the possible debromination of 2-bromomesitylene (*III*), a compound whose substituents have as a first approximation similar electron releasing properties but greatly reduced steric hindrance, was investigated. No debromination could be detected when *III* was subjected to conditions which caused extensive debromination of *I* (refluxing trifluoroacetic acid and excess bromide ion). In the course of this work it has been shown that mesitylene is a far better acceptor of Br+ than bromide ion. Therefore, it could be argued that debromination of mesitylene would be difficult to detect because of the rapid back reaction (bromination). A more conclusive test was devised. An equimolar mixture of mesitylene-α-H_1^3, specific activity 228, and inactive 2-bromomesitylene was heated at reflux in trifluoroacetic acid for one hour; this is approximately one half-life for the debromination of *I*. The specific activities of the isolated mesitylene and bromomesitylene were 226 and 3, respectively. From these results it is concluded that *III* does not appreciably debrominate under conditions which lead to extensive debromination of *I*. The results also preclude the exchange of hydrogen in the methyl groups of mesitylene under the reaction conditions.

The facile debromination of *I* led us to investigate the possibility that the reported [5] failure of the iron catalyzed bromination of *II* to yield *I* (only 3,5-di-*t*-butylbromobenzene has been isolated) was due to two competing reactions: the first, a readily reversible bromination at an aromatic carbon bearing a hydrogen; the second, an irreversible bromination at an aromatic carbon bearing a *t*-butyl group. A necessary condition of this proposed scheme is that *I* be converted to 3,5-di-*t*-butylbromobenzene under iron catalyzed bromination conditions. This conversion has been shown to take place. It remains to be shown that *I* is transiently formed in this bromination reaction.

The Ternary Compound $SbCl_5 \cdot TiCl_4 \cdot 3POCl_3$

GÖRAN ADOLFSSON, RAGNAR BRYNTSE and INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

In the system $SbCl_5-TiCl_4-POCl_3$ a compound is formed which has a higher melting point than any of the compounds $SbCl_5 \cdot POCl_3$, $TiCl_4 \cdot POCl_3$ or $TiCl_4 \cdot 2POCl_3$. It is rather difficult to obtain the compound pure from excess $SbCl_5$, $TiCl_4$ or $POCl_3$ (depending upon the mole ratios of the original mixture), but all such experiments indicate a composition $SbCl_5 \cdot TiCl_4 \cdot 3POCl_3$. (The high melting point shows that it cannot be a mixture of $SbCl_5 \cdot POCl_3$ and $TiCl_4 \cdot 2POCl_3$). We therefore tried to prepare a pure specimen by dissolving $SbCl_5$ and $TiCl_4$, in the mole ratio 1:1, in ethylene chloride and adding an excess of $POCl_3$. The volatile components were then removed by evacuation, the solid residue was further purified by sublimation and the resulting crystals were analyzed. (Found: Cl 67.5; Ti 5.00; P 10.0. Calc. Cl 67.3; Ti 5.05; P 9.8.)

Titanium was determined spectrophotometrically by the peroxide method with an excess of phosphoric acid in order to make the determination insensitive to the amount of phosphoric acid in the dissolved sample.

Phosphorus was determined by precipitation as $MgNH_4PO_4 \cdot 6H_2O$ in the presence of EDTA and hydrogen peroxide (to keep titanium in solution) and titration by EDTA of the magnesium content in the washed precipitate.

Antimony did not interfere in these determinations.

The crystals sublime before melting at about +200°C.

The high melting point indicates that the ternary compound cannot be a loose addition compound between $SbCl_5 \cdot POCl_3$ and $TiCl_4 \cdot 2POCl_3$. Since co-ordination around Sb and Ti is already as large as possible in those two addition compounds, however no halogen bridged compound of the same type as in $[TiCl_4(OPCl_3)]_2^1$, containing Sb as well as Ti, can therefore have formed. A more probable alternative would be the formation of $SbCl_6^-$ and $[TiCl_3(OPCl_3)_3]^+$ ions.

The latter suggestion has been tested by measurements of the specific conductances of 0.9 M solutions of $SbCl_5 \cdot POCl_3$, $TiCl_4 \cdot 2POCl_3$ and $SbCl_5 \cdot TiCl_4 \cdot 3POCl_3$ in ethylene chloride. The values are approximately (at +21°C):

2.4×10^{-5} ohm^{-1} cm^{-1} ($SbCl_5 \cdot POCl_3$)
3.7×10^{-4} ohm^{-1} cm^{-1} ($TiCl_4 \cdot 2POCl_3$)
6.3×10^{-3} ohm^{-1} cm^{-1} ($SbCl_5 \cdot TiCl_4 \cdot 3POCl_3$)

The evidence so far is thus in accord with the idea that the ternary compound is actually $[TiCl_3(OPCl_3)_3](SbCl_6)$. Conclusive proof is, however, still lacking.

In the systems $SbCl_5-SnCl_4-POCl_3$ and $SbCl_5-AsCl_3-POCl_3$ no ternary compound could be found. The increase in specific conductance is obtained, however, but the magnitude of the conductances is smaller than with $TiCl_4 \cdot 2POCl_3$:

3.6×10^{-5} ohm^{-1}cm^{-1} ($SnCl_4 \cdot 2POCl_3$)
6.1×10^{-4} ohm^{-1}cm^{-1} ($SbCl_5 \cdot POCl_3 + SnCl_4 \cdot 2POCl_3$)

The greater tendency of $TiCl_4$ to act as a chloride ion donor in these systems is in agreement with the active base strength of $TiCl_4$ as determined by potentiometric measurements [2].

Bacterial Carotenoids

VI. A Note on the Constitution of Bacterioruberine *α*

SYNNÖVE LIAAEN JENSEN

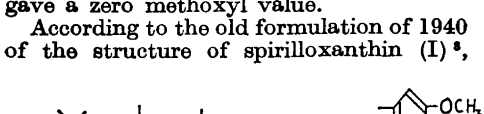
Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

This paper gives a preliminary report on the chemical constitution of bacterioruberine *α* — the main carotenoid pigment of certain red, rod-shaped, obligate and extremely halophilic bacteria for which Volcani [1] have suggested the genus name *Halobacterium*.

In 1932 Petter [2] isolated two crystalline carotenoids named bacterioruberine *α* (abs. max. 460, 490, 528 mμ in methanol) and bacterioruberine *β* (abs.max. 452, 482, 522 mμ in methanol) from a bacterium which she named *Bacterium halobium*, and which undoubtedly belongs to the genus *Halobacterium* (Volcani). From the same source Lederer [3] could isolate only crystalline bacterioruberine *α* (abs.max. 460, 495, 528 mμ in methanol). The absorption spectrum was found to be similar to that of rhodoviolascin [4], later shown to be identical with spirilloxanthin [5]. Bacterioruberine *α*, however, had a pronounced hypophasic character, and Lederer suggested that this carotenoid possibly was a di-demethylated spirilloxanthin.

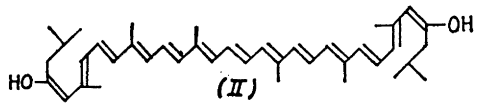
A carotenoid with absorption spectrum similar to that of bacterioruberine *α* was present also in cells of an obligate, halophilic bacterium studied by Spruit and Pijper [6]. An interesting chromatographic survey of the carotenoids of a number of halophilic bacteria has recently been given by Baxter [7], again stating that bacterioruberine *α* is the main carotenoid of several red *Halobacterium* species. A sample of bacterioruberine *α* of unreported purity gave a zero methoxyl value.

According to the old formulation of 1940 of the structure of spirilloxanthin (I) [8],



(I)

Lederer's suggestion of 1938 that bacterioruberine *α* was a di-demethylated spirilloxanthin would imply the structure (II) for this carotenoid with two enolic



(II)

hydroxyl groups. This has not been confirmed by the present investigation.

In the present investigation bacterioruberine *α* was isolated as the major carotenoid from a *Halobacterium* sp. (Strain No. 1, from the Department of Biochemistry, this University). The carotenoid was extracted with acetone and purified by chromatography of the unsaponifiable matter on deactivated alumina.

Bacterioruberine *α* crystallised with difficulty as the all-*trans* isomer from acetone-petroleum ether solution in mauve-violet, shiny, needles, m. p. 182°C (evacuated tube). Consistent micro combustion analyses could not be obtained. The crystalline carotenoid was readily soluble in pyridine and acetone, fairly readily soluble in methanol, chloroform and carbon disulphide, fairly soluble in benzene and diethyl ether and nearly insoluble in petroleum ether. Absorption maxima in various solvents as recorded immediately after dissolution with a Zeiss PMQ2 calibrated spectrophotometer is presented in Table 1 together with similar data reported for spirilloxanthin [5]. The agreement in absorption maxima for the two carotenoids falls within the experimental errors for different samples and instruments. The shape of the absorption spectra in the utilised solvents was further identical and showed pronounced fine-structure. It appears therefore that bacterioruberine *α* and spirilloxanthin have identical chromophores, that is 13 conjugated carbon-carbon double bonds in an aliphatic chain.

Quantitative extinction coefficient determinations carried out in acetone gave as a maximum value $E^{1\%}_{1\,cm} = 2\,620$ at 499 mμ, a value within the expected range for a di-demethylated spirilloxanthin. Spirilloxanthin in hexane has $E^{1\%}_{1\,cm} = 2\,540$ at 493 mμ [5].

A stereochemical investigation of bacterioruberine *α* was performed by means of a paper-chromatographical method previously reported [9]. Bacterioruberine *α* was found to exhibit a greater stereochemical lability than any other carotenoid so far reported. It might be mentioned that after 24 h in darkness at room temperature the all-*trans* isomer had isomerized spontaneously to Neo U to an extent of 42 % as colorimetrically determined after ra-

Table 1. Absorption maxima in various solvents for all-*trans* bacterioruberine *a* and spirilloxanthin [5].

Carotenoid	Abs.max. in mμ in				
	Pet.ether *	Benzene	Acetone	$CHCl_3$	CS_2
Bacterioruberine *a*	369	378	374	380	
	385	398	389	397	418
	461	481	466	475	500.5
	494	511	499	506	533.5
	528	549	533.5	544	572

* b.p. 60—70°C.

pid chromatographic separation. After 24 h exposure to indirect daylight at room temperature of a solution of the pure *trans* isomer, only 37 % *trans* remained, whereas gross stereoisomerisation to Neo U, Neo A and Neo B had occurred. The composition of the iodine catalyzed equilibrium mixture is presented in Table 2.

The two first maxima give the position of the *cis*-peak, which is very weak for the *trans* isomer and strongest for the Neo U isomer. R_F-values for the different stereoisomers have been published previously [9].

Quantitative partition tests according to the method of Zechmeister and Petracek [10] gave the following partition ratios:

Pet.ether/95 % methanol	1:99
Pet.ether/85 % methanol	3:99

Bacterioruberine *a* is seen to be strongly hypophasic even with 85 % methanol, thus indicating the presence of two or more hydroxy groups in the molecule.

Upon prolonged treatment with acetic anhydride in pyridine bacterioruberine *a* was completely recovered; whereas bacterioruberine *a* was very unstable towards freshly distilled acetyl chloride in pyridine, yielding only decomposition products. The failure of bacterioruberine *a* to yield an acetate indicated that all hydroxyl groups present were tertiary. This was confirmed by the IR-spectrum (KBr) which showed a strong absorption band for the hydroxyl stretching frequency at 3 320 cm^{-1}, no absorption band around 1 030 cm^{-1} characteristic of secondary hydroxyl groups [11], but a fairly strong band typical of tertiary hydroxyl groups at 1 142 cm^{-1} as in chloroxanthin [11], rhodopin [11] and rhodovibrin [12].

$HCl—CHCl_3$-treatment [13] gave no product with extended conjugated chain. Allylic hydroxyl groups are therefore not likely to be present.

Table 2. Composition of the iodine catalyzed equilibrium mixture of bacteriorubine *a*.

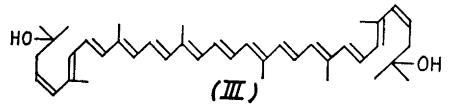
Member of the stereoisomeric set	Abs.max. in mμ in		% of total colorimetr. determined *
	pet.eth. bp. 60—70°C	acetone	
Neo B	369, 385, 463, 492, 522	374, 389, 470, 498, 526	1
Neo A	369, 385, 454, 483, 516	374, 389, 460, 489, 522	20
all-*trans*	369, 385, 461, 494, 528	374, 389, 466, 499, 533.5	37
Neo U	369, 385, 460, 490, 522	374, 389, 466, 496, 527	42

* The same extinction coefficient was used for calculating the actual amount of each stereoisomer.

The stability of the chromophore of bacterioruberine *a* in neutral as well as in basic media further refuted the presence of enolic hydroxyl groups [14]. The absence of enolic hydroxyl groups was supported also by the lack of a relatively intense IR-absorption band around 1 660 cm^{-1} attributed by Rosenkrantz and Gut [15] to the grouping $-CH=C-O-$.

The IR-spectrum further showed that no methoxyl groups or carbonyl functions were present in bacterioruberine *a*.

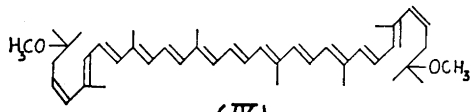
Combining the evidence of a chromophore of 13 conjugated carbon-carbon double bonds in an aliphatic system with the presence of at least two non-allylic, non-enolic, tertiary hydroxyl groups, it seems that only one structure (III) is probable for bacterioruberine *a*.



(III)

The presence of no more than two hydroxyl groups was further confirmed by quantitative determination of active hydrogen. (Found: Active H 0.39 %. Calc. for $C_{40}H_{54}(OH)_2$: 0.35 %; for $C_{40}H_{52}(OH)_3$: 0.51 %.)

From the new spirilloxanthin structure (IV) [14, 16] it is thus seen that bacterioruberine *a* should be a di-demethylated spirilloxanthin in agreement with Lederer's [3] original suggestion.



(IV)

Bacterioruberine *a* is another example of a bacterial carotenoid with tertiary hydroxyl groups in addition to chloroxanthin [17, 11], rhodopin [11], rhodovibrin [12] and OH-spirilloxanthin [18] from photosynthetic bacteria. This appears to be a characteristic feature so far not reported for carotenoids from higher organisms. The position of the hydroxyl group in chloroxanthin has not yet been established, but is for the rest of the carotenoids mentioned above invariably located in 1-positions.

This work will be published in more detail elsewhere.

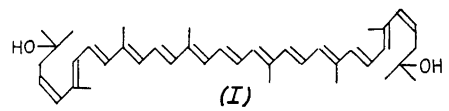
Bacterial Carotenoids

VII. A Partial Synthesis of Spirilloxanthin and OH-Spirilloxanthin

SYNNÖVE LIAAEN JENSEN

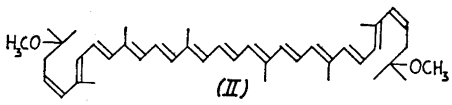
Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

From the structure (I) ascribed to bacterioruberine *a* in the previous paper[1] it



(I)

is seen that bacterioruberine *a* represents a di-demethylated derivative of spirilloxanthin (II)[2,3].



(II)

It is obvious that a mutual support for these structures could be obtained if dimethylated bacterioruberine *a* and spirilloxanthin were shown to be identical.

Bacterioruberine *a* was isolated from a *Halobacterium* sp. (Strain No. 1, from the Department of Biochemistry, this University) as previously described[1]. Several procedures were tried to methylate this carotenoid. The instability of bacterioruberine *a* towards heat and acid catalysts restricted the number of useful methods. Treatment with diazomethane in methanol-ether[4], dimethylsulphate and potassium carbonate in dry acetone[5] or the usual method with potassium *t*-amyloxylate and methyl iodide[6] failed to give any methylation products. This was to be expected in view of the non-enolic, tertiary character of the hydroxyl groups of bacterioruberine *a*.

The careful method reported by Kuhn *et al.*[7] for the methylation of N-acetylglucosamine derivatives with methyl iodide and silver oxide in dimethylformamide proved, however, to be successful also in this case. Following this method mono- and dimethyl-derivatives of bacterioruberine *a* were obtained in maximum yields of 12 % and 2.4 %, respectively, in fourteen different methylation experiments besides unchanged starting material. The reaction was carried out at room temperature, in darkness, under nitrogen and with magnetic stirring. The methylation process was followed paper chromatographically[8] and usually interrupted after about 70 h. The carotenoids were transferred to benzene and separated by chromatography on deactivated alumina. The yields could not be significantly increased by lowering or increasing the reaction temperature, by using dry dimethylformamide or by exchanging the silver oxide for barium oxide[9], and were in any case not well reproducible.

The methylation products could only be isolated in amounts insufficient for crystallization and were characterized by means of absorption spectra in visible light, column and paper[8] chromatography of the main stereoisomers and quantitative partition tests according to Zechmeister and Petracek[10].

The properties of mono-methoxy-bacterioruberine *a* are presented in Tables 1 and 2 together with the corresponding properties of the so-called OH-spirilloxanthin, a minor pigment

Table 1. Absorption maxima for the main stereoisomers of mono-methoxy-bacterioruberine *a* and OH-spirilloxanthin.

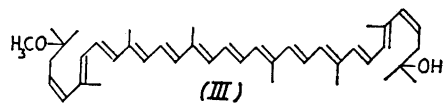
present in cells of *Rhodospirillum rubrum* [11, 12] in the exponential growth stage and in *Rhodopseudomonas palustris* [13]. These bacteria were used as sources for the isolation of chromatographically pure fractions of OH-spirilloxanthin.

The absorption spectra of the corresponding stereoisomers of mono-methoxy-bacterioruberine *a* and OH-spirilloxanthin further had analogous shapes. Co-chromatography of the *trans* isomers of the two pigments gave one zone which could not be resolved on kiselguhr paper. The solvents required for elution from deactivated alumina also were similar. The partition tests indicate the presence of one hydroxyl group in both pigments. Both pigments gave the same products upon HCl—$CHCl_3$ treatment [14].

The data presented for mono-methoxy-bacterioruberine *a* and OH-spirilloxanthin strongly suggest that these pigments are identical, leading to a structural formula (III) for OH-spirilloxanthin



(III)

as a mono-demethylated spirilloxanthin — in good agreement with the previous tentative assumption [11] and the kinetic data for its biosynthesis in *Rhodospirillum rubrum* [12] from rhodovibrin (OH—P481) [15] and as a spirilloxanthin precursor.

** acetone in pet.ether b.p. 60—70°C.

Similar properties for di-methoxy-bacterio-ruberine *a* and spirilloxanthin are presented in Tables 3 and 4. Spirilloxanthin was isolated from the same source as OH-spirillo-xanthin as previously described[8]. The shape of the absorption spectra of the corresponding stereoisomers of the two carotenoids were very similar.

Co-chromatography of the *trans* isomers on kiselguhr paper gave one zone which could not be resolved. Di-methoxy-bacterioruberine *a* and spirilloxanthin further required similar solvents for elution from deactivated alumina.

The data presented are greatly in favour of identity of di-methoxy-bacterioruberine *a* and spirilloxanthin, a fact that strengthens the suggested structures for bacterio-ruberine *a* (I) and spirilloxanthin (II).

This work will be published in more detail elsewhere.

The Crystal Structures of Zr_5Sn_3 and Zr_3Sn

GUNNAR GRAN AND STEN ANDERSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

In the zirconium-tin system, four intermediate phases have been reported to exist, *viz.* Zr_4Sn, Zr_5Sn_3, ZrSn and $ZrSn_2$ (Refs. [1,2]). Crystal structures have been given only for $ZrSn_2$ (of $C54$ type) and for Zr_5Sn_3 (Ref. [2]). The latter is described as being of the $D8_8$ type but no structural details have hitherto been given.

In the present study, which was undertaken in order to complement the existing knowledge concerning this system, metallic zirconium and tin of 99.95 % purity were used as starting materials. Alloys of several compositions were prepared by melting pressed tablets of the metals in an electric arc furnace under argon atmosphere. The samples were then sealed in evacuated silica tubes and annealed for about two months at 900°C. Tantalum foils protected the alloys from reacting with the silica.

X-Ray powder patterns were registered in a Guinier focusing camera with strictly monochromatized CuKa_1 radiation. Single crystal data were obtained with a Weissenberg camera using CuK radiation.

Rod-formed single crystals were obtained from a sample of a composition close to $ZrSn_{0.5}$. Complete single-crystal data were registered while rotating the crystal around the rod axis, the unit length of which was found to be 5.8 Å. The symmetry proved to be hexagonal and the unit cell dimensions as obtained from the powder pattern were found to be:

$$a = 8.46 \text{ Å}, \qquad c = 5.78 \text{ Å}$$

It was confirmed that the structure was of the $D8_8$ type, as had previously been observed. The space group is thus $P6_3/mcm$ (No. 193) and all the atoms occupy positions 6 (g) (x, 0, ½ etc.). From the electron density projection (x, y, p), the following atomic parameters were obtained:

	Zr	Sn
x	0.245	0.609

Table 1. Powder pattern of the sample $ZrSn_{0.6}$ containing two phases of Zr_5Sn_3 type.

Table 2.

Composition	X-Ray evidence
$ZrSn_{0.4}$	$Zr_3Sn + Zr_5Sn'_3$
$ZrSn_{0.5}$	$Zr_5Sn'_3$
$ZrSn_{0.6}$	$Zr_5Sn'_3 + Zr_5Sn''_3$
$ZrSn_{0.7}$	$Zr_5Sn''_3 + ZrSn$

However, it was evident that this phase was not of the ideal composition Zr_5Sn_3. When the tin content was increased, extra lines appeared close to the original lines. The sample remained two-phasic after additional heat treatment. The new lines could be indexed in the same way as the former with the following unit cell parameters:

$$a = 8.50 \text{ Å}, \qquad c = 5.81 \text{ Å}$$

An indexed powder pattern of the sample $ZrSn_{0.6}$ is given in Table 1. The existence of two phases of Zr_5Sn_3 type has thus been found.

The symbols $Zr_5Sn'_3$ and $Zr_5Sn''_3$ used in Table 2 designate the ones low and high in tin, respectively. Further studies at the critical compositions of the two phases and concerning the type of defect are contemplated.

At a composition $ZrSn_{0.4}$, the Guinier powder pattern photograph showed, in addition to the pattern of the defective Zr_5Sn_3, a number of strong, extra lines. Assuming a cubic unit cell, these extra lines could be indexed with $a = 5.634$ Å. The structure was found to be of the well-known β-wolfram structure type and should thus be given the formula Zr_3Sn.

Synthesis of Benzyl 4-*O*-Methyl-β-D-Xylopyranoside

PER J. GAREGG

Svenska Träforskningsinstitutet, Träkemiska avdelningen, Stockholm Ö, Sweden

Previous studies of a naturally occurring acetylated xylan [1] in birch wood have raised the question of whether the *O*-acetyl groups are attached to the most readily acetylated free hydroxyl groups in the β-1,4-linked anhydroxylose chains. In an attempt to investigate which of the two free hydroxyl groups at the 2- and 3-position is the most readily acetylated, benzyl 4-*O*-methyl-β-D-xylopyranoside was selected as a suitable model for partial acetylation. The synthesis of this substance, by a sequence of reactions given below is analogous to that described by Hough and Jones [2] for the synthesis of the corresponding methyl glycoside, is reported in the present paper. The final product and all the intermediates were obtained in a crystalline form and the overall yield from D-arabinose was 10 % of the theoretical.

Experimental. All melting points are corrected. Evaporations were done under reduced pressure at a bath temperature below 40°.

Benzyl 3,4-isopropylidene-2-tosyl-β-D-arabinopyranoside, II. Benzyl-3,4-*iso*propylidene-β-D-arabinopyranoside (81 g, m. p. 55—57°, $[\alpha]_D^{20}$ —195°), prepared from 100 g D-arabinose according to Ballou [3] was dissolved in pyridine (500 ml) and treated with *p*-toluenesulphonyl chloride (112 g). The solution was allowed to stand at room temperature during 48 h and then poured on ice. The mixture was extracted with chloroform and the chloroform solution was dried over anhydrous sodium sulphate, filtered and concentrated to dryness. The syrup obtained was used directly in the next step; a small quantity which was set aside crystallised from 96 % aqueous ethanol, m.p. 62—64° unchanged on further recrystallisation, $[\alpha]_D^{20}$ —194° (*c* 1.0 in chloroform). (Found: C 61.14; H 5.96; O 26.20; S 6.84. Calc. for $C_{22}H_{26}O_7S$: C 60.81, H 6.03; O 26.78; S 7.38.)

Benzyl 2-tosyl-β-D-arabinopyranoside, III. The above product was dissolved in boiling acetone (900 ml) and 0.1 N formic acid (1 800 ml) was added over a period of 20 h under reflux. Concentration yielded a syrup which crystallised from aqueous ethanol. Recrystallisation from ethanol/*iso*propyl ether yielded benzyl 2-tosyl-β-D-arabinopyranoside (70 g) with m. p. 120—123°. The pure substance had m. p. 123.5—124.5°, $[\alpha]_D^{20}$ —156° (*c* 0.8 in chloroform). (Found: C 57.40; H 5.52; O 27.94; S 7.88. Calc. for $C_{19}H_{22}O_7S$: C 57.86; H 5.62; O 28.39: S 8.13.)

Benzyl 2,3-anhydro-β-D-ribopyranoside, IV. Benzyl 2-tosyl-β-D-arabinopyranoside (70 g) was dissolved in methanolic sodium methoxide (1 l, made from 13 g sodium) and allowed to stand overnight. The solution was diluted with water (500 ml) and neutralised with sulphuric acid, the methanol was removed by vacuum distillation and the aqueous solution was extracted with chloroform. The combined chloroform solutions were dried over anhydrous sodium sulphate, filtered and the filtrate was concentrated to dryness. Spontaneous crystallisation occurred giving benzyl 2,3-anhydro-β-D-ribopyranoside (29 g) with m. p. 64—76°. Recrystallisation from *iso*propyl ether gave 25 g with m. p. 74—76°. The pure substance had m. p. 76—77°, $[\alpha]_D^{20}$ —67° (*c* 0.8 in chloroform). (Found: C 64.60; H 6.13; O 29.04. Calc. for $C_{12}H_{14}O_4$: C 64.85; H 6.35; O 28.80.)

Benzyl 4-O-methyl-2,3-anhydro-β-D-ribopyranoside, V. Benzyl 2,3-anhydro-β-D-ribopyranoside (25 g) was methylated with methyl iodide (38 ml) and silver oxide

At a composition $ZrSn_{0.4}$, the Guinier powder pattern photograph showed, in addition to the pattern of the defective Zr_5Sn_3, a number of strong, extra lines. Assuming a cubic unit cell, these extra lines could be indexed with $a = 5.634$ Å. The structure was found to be of the well-known β-wolfram structure type and should thus be given the formula Zr_3Sn.

Mean Amplitudes of Vibration of *Cyclo*propane from Electron Diffraction and Spectroscopic Calculations

A. ALMENNINGEN, O. BASTIANSEN, S. J. CYVIN and P. N. SKANCKE

Universitetets kjemiske institutt, Blindern; Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

In a previous work [1] values for the mean amplitudes of vibration (u) for the bond distances of *cyclo*propane were reported. The values were obtained a) from electron diffraction studies of the molecule in the gaseous state and b) from theoretical computations based upon spectroscopic data. The values reported were obtained using approximation calculations. In the present work a more rigorous calculation has been carried out using the same two methods.

Electron diffraction calculations. New u values for the bond distances and for the non-bonded C—H distance have been calculated. The following procedures were used: 1. Approximating the radial distribution curves with sums of Gaussian peaks. 2. Using least squares calculations on the intensity curve. 3. Studying the areas under the sinusoidal curve for the outer part of the intensity curve. The last procedure leads to the determination of the u value for the C—C distance. It was found advisable to study the u value for the C—H distances after the subtraction of the contribution from the C—C distance. Attempts were made to determine the error limits of the u value determination. The results of these studies are presented in the last column of Table 1. The resulting u value for C—C is a trifle larger than that obtained earlier. The error estimations indicate that the earlier rough evaluation of the accuracy of the u value for the C—H bond was a little too optimistic.

Spectroscopic calculations. While an electron diffraction study is unable to determine the u values of the H—H distances with any reasonable accuracy, calculations from spectroscopic data yield useful values for all six amplitudes of vibration associated with the various interatomic distances of the *cyclo*propane molecule. The results of the spectroscopic calculations are given in Table 1 computed both for the zero point and for 298°K.

Table 1. Mean amplitudes of vibration (u) in Å units.

Atom pair	u spectroscopic $T = 0$	298°K	u electr. diff.
C—H	0.0750	0.0750	0.0753 ±0.0030
C...H	0.1082	0.1090	0.108 ±0.0030
C—C	0.0510	0.0514	0.0497 ±0.0015
$H_1...H_1'$	0.1180	0.1181	
$H_1...H_2$	0.1758	0.1783	
$H_1...H_2'$	0.1316	0.1320	

The spectroscopic computation is summarized in the following: (For further details of the theory, see *e. g.* Morino *et al.*[2] and Cyvin [3].)

Let Δr_i represent the interatomic displacements for the six types of (bonded and non-bonded) atom pairs ($i = 1, 2, ..., 6$). If the matrix P is formed according to $P_{ij} = \langle \Delta r_i \Delta r_j \rangle$, the mean-square amplitudes of vibration (u^2) will appear on its main diagonal. One has

$$P = K \langle Q^2 \rangle \widetilde{K} \qquad (1)$$

where $\langle Q^2 \rangle$ is a diagonal matrix with the elements $\langle Q^2 \rangle_k = (h/8\pi^2\nu_k) \coth (h\nu_k/2kT)$,[2] and K is the transformation matrix given by $r = KQ$. Here r represents the Δr_i coordinates and Q the vibrational normal coordinates. The K matrix may be computed according to

$$K = VL \qquad (2)$$

The L matrix ($S = LQ$, where S denotes a set of symmetry coordinates) is obtainable by a normal coordinate analysis [4] if the force constants and the equilibrium parameters are known. The V matrix is defined by $r = VS$ and may be obtained from geometrical considerations.

The mean-square amplitude matrix Σ is defined by $\Sigma_{ij} = \langle S_i S_j \rangle$, where S_i and S_j are symmetry coordinates. For this matrix one has

$$\Sigma = L \langle Q^2 \rangle \widetilde{L} \qquad (3)$$

An alternative method of computing the u^2 values may be applied, according to the relation

$$P = V \Sigma \widetilde{V} \qquad (4)$$

from which the u^2 quantities may be expressed in terms of the a matrix elements. The relation (4) is deducible from eqns. (1)–(3).

In the present case a set of force constants for *cyclo*propane has been established [5] by means of vibrational frequencies taken from literature [6] for both C_3H_6 and C_3D_6. For the numerical L matrix elements, see Ref.[5] One of the writers (S. J. Cyvin) intends to give some details of the theory of mean-square amplitude matrices applied to the *cyclo*propane molecule in a coming publication.

A Note on the Crystal Structure of Sodium Dimolybdate

INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

About ten years ago the present author carried out a series of structure determinations of polymolybdates, polytungstates, polyniobates and polytantalates. In most cases the proposed oxygen co-ordination around the heavy atoms was supported by some evidence of vectors in the three-dimensional Patterson functions. There were, however, two exceptional cases with very weak or no evidence at all for the oxygen positions which were assumed from spatial discussions. In one of these cases, $MoO_3 \cdot 2\ H_2O$, the presence of a complicated superstructure has later been shown [1].

The other case is sodium dimolybdate [2]. The molybdenum positions were conclusively derived but the oxygen co-ordination proposed was based on the assumption that the co-ordination around the molybdenum atoms should be either tetrahedral or octahedral. As the resulting structure exhibited an interesting mixed co-ordination an attempt has been made to derive the oxygen positions directly from the three-dimensional Patterson function using the Buerger minimum function [3].

This derivation has confirmed the structural suggestion of the earlier paper. The positions of the oxygen and sodium atoms are, however, shifted to some extent. The old data do not permit a refinement with modern methods and the atomic positions are therefore still very uncertain. The following rough parameters give a R value of 0.17 (the old parameters within brackets):

8 Mo_I	in	8 (*e*)	: $x = 0.25$		
8 Mo_{II}	in	8 (*f*)	: $x = 0.00$		
8 Na_I	in	8 (*d*)	: $x = 0.25$		
8 Na_{II}	in	8 (*f*)	: $x = 0.00$		
16 O_I	in	16 (*g*)	: $x = 0.18$	(0.21)	
16 O_{II}	in	16 (*g*)	: $x = 0.18$	(0.21)	
8 O_{III}	in	8 (*f*)	: $x = 0.00$		
8 O_{IV}	in	8 (*f*)	: $x = 0.00$		
8 O_V	in	8 (*f*)	: $x = 0.00$		

$y = 0.08$		$z = 0.25$	
$y = 0.25$		$z = 0.08$	
$y = 0.00$		$z = 0.00$	
$y = 0.31$	(0.36)	$z = 0.36$	(0.30)
$y = 0.22$	(0.21)	$z = 0.17$	(0.16)
$y = 0.48$	(0.49)	$z = 0.33$	(0.34)
$y = 0.11$	(0.08)	$z = 0.28$	(0.27)
$y = 0.38$	(0.41)	$z = 0.02$	(0.13)
$y = 0.37$	(0.35)	$z = 0.52$	(0.49)

The proposed mixed tetrahedral and octahedral co-ordination around the molybdenum atoms can be considered as strongly supported by this result. The relatively low R value by no means proves, however, that the atomic positions are well determined, as the contributions from the Mo atoms are too dominating. A further discussion of the bond lengths on the basis of these rough parameters therefore cannot be recommended.

from which the u^2 quantities may be expressed in terms of the a matrix elements. The relation (4) is deducible from eqns. (1)–(3).

In the present case a set of force constants for *cyclo*propane has been established [5] by means of vibrational frequencies taken from literature [6] for both C_3H_6 and C_3D_6. For the numerical L matrix elements, see Ref.[5] One of the writers (S. J. Cyvin) intends to give some details of the theory of mean-square amplitude matrices applied to the *cyclo*propane molecule in a coming publication.

A Note on the Crystal Structure of Sodium Dimolybdate

INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

About ten years ago the present author carried out a series of structure determinations of polymolybdates, polytungstates, polyniobates and polytantalates. In most cases the proposed oxygen co-ordination around the heavy atoms was supported by some evidence of vectors in the three-dimensional Patterson functions. There were, however, two exceptional cases with very weak or no evidence at all for the oxygen positions which were assumed from spatial discussions. In one of these cases, $MoO_3 \cdot 2\ H_2O$, the presence of a complicated superstructure has later been shown [1].

The other case is sodium dimolybdate [2]. The molybdenum positions were conclusively derived but the oxygen co-ordination proposed was based on the assumption that the co-ordination around the molybdenum atoms should be either tetrahedral or octahedral. As the resulting structure exhibited an interesting mixed co-ordination an attempt has been made to derive the oxygen positions directly from the three-dimensional Patterson function using the Buerger minimum function [3].

This derivation has confirmed the structural suggestion of the earlier paper. The positions of the oxygen and sodium atoms are, however, shifted to some extent. The old data do not permit a refinement with modern methods and the atomic positions are therefore still very uncertain. The following rough parameters give a R value of 0.17 (the old parameters within brackets):

8 Mo_I	in	8 (*e*)	: $x = 0.25$		
8 Mo_{II}	in	8 (*f*)	: $x = 0.00$		
8 Na_I	in	8 (*d*)	: $x = 0.25$		
8 Na_{II}	in	8 (*f*)	: $x = 0.00$		
16 O_I	in	16 (*g*)	: $x = 0.18$	(0.21)	
16 O_{II}	in	16 (*g*)	: $x = 0.18$	(0.21)	
8 O_{III}	in	8 (*f*)	: $x = 0.00$		
8 O_{IV}	in	8 (*f*)	: $x = 0.00$		
8 O_V	in	8 (*f*)	: $x = 0.00$		

$y = 0.08$		$z = 0.25$	
$y = 0.25$		$z = 0.08$	
$y = 0.00$		$z = 0.00$	
$y = 0.31$	(0.36)	$z = 0.36$	(0.30)
$y = 0.22$	(0.21)	$z = 0.17$	(0.16)
$y = 0.48$	(0.49)	$z = 0.33$	(0.34)
$y = 0.11$	(0.08)	$z = 0.28$	(0.27)
$y = 0.38$	(0.41)	$z = 0.02$	(0.13)
$y = 0.37$	(0.35)	$z = 0.52$	(0.49)

The proposed mixed tetrahedral and octahedral co-ordination around the molybdenum atoms can be considered as strongly supported by this result. The relatively low R value by no means proves, however, that the atomic positions are well determined, as the contributions from the Mo atoms are too dominating. A further discussion of the bond lengths on the basis of these rough parameters therefore cannot be recommended.

Amino Acid Studies. Part III *. Synthesis and Properties of some Isomerides of Albizziine

ANDERS KJÆR AND ELSE VESTERAGER

Organic Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen V, Denmark

In a previous paper of this series [1], syntheses were described of L- and DL-albizziine (2-amino-3-ureidopropionic acid), as well as of L-2-ureido-3-aminopropionic acid (L-*iso*albizziine). It is the purpose of the present communication to report on the preparation and physical data of the isomeric compounds: D-albizziine, D-*iso*albizziine and DL-*iso*albizziine.

D-Asparagine was transformed into N-(*p*-toluenesulphonyl)-D-asparagine (I, Ts = *p*-$CH_3C_6H_4SO_2$) by a modification of the procedure employed in the L-series by Zaoral and Rudinger [2]. Hofmann-degradation of the latter compound, conducted according to Rudinger *et al.*[3], afforded D-2-(*p*-toluenesulphonamido)-3-aminopropionic acid (II) which was further converted into D-2-(*p*-toluenesulphonamido)-3-ureidopropionic acid (III) and thence to D-albizziine (IV) as described for the enantiomeric series by the same authors [3].

Detosylation of (II) afforded optically pure D-2,3-diaminopropionic acid, (V), which was converted into D-*iso*albizziine, (VIII), through the steps (VI) and (VII), according to the procedure utilized in this laboratory for the preparation of L-*iso*albizziine [1]. A similar sequence of reactions, starting from DL-2,3-diaminopropionic acid, yielded racemic *iso*albizziine. Synthetic D-albizziine, (IV), and D-*iso*albizziine, (VIII), as well as all intermediate products, possessed specific rotations similar in magnitude but opposite in sign to those of the L-series. Likewise, the infra-red spectra determined in the solid state coincided for the individual enantiomers throughout the two series, whereas the corresponding racemic modifications showed considerable deviations in their IR-patterns.

Results of some microbiological studies of the synthetic amino acids will be presented elsewhere.

Experimental. N-(p-Toluenesulphonyl)-D-asparagine (I). Several trial runs indicated that the tosylation of asparagine proceeded more satisfactorily than formerly described [2], when the following conditions were employed. In the course of 3 h, a total of 9.5 g of *p*-toluenesulphonyl chloride was added portionwise to a vigorously stirred and ice-cooled suspension of D-asparagine * (5.0 g) and magnesium oxide (5.0 g) in water (100 ml). The suspension was stirred overnight at room temperature, cooled in ice, and then acidified with conc. hydrochloric acid. The precipitate was filtered off and thoroughly extracted with ether. Practically pure N-(*p*-toluenesulphonyl)-D-asparagine (I) remained in a yield of 91 % (8.6 g). The product was recrystallized from methanol (175 ml) to give 6.5 g of pure material, m.p. 182° **, $[\alpha]_D^{22}$ −10.7° (*c* 2, H_2O, containing 1 equiv. of NaOH, pH 6.6) ***.

(Found: C 46.20; H 5.03; N 9.63. Calc. for $C_{11}H_{14}N_2O_5S$: C 46.14; H 4.93; N 9.79.) Reported for the enanti-omeric L-compound: m. p. 175°[4], 191°[2]; $[\alpha]_D^{20}$ +6.8° (K-salt in H_2O)[4]; $[\alpha]_D^{20}$ +9.7° ± 0.5° (*c* 5.4, H_2O + 1 equiv.KOH).

D-2-(p-Toluenesulphonamido)-3-aminopropionic acid (II). The Hofmann-degradation of N-tosyl-D-asparagine was performed essentially as described for the L-enantiomer [3], yet in somewhat smaller yields (*ca.* 50 %) than reported [3] (60 %). A pure specimen of D-2-(*p*-toluenesulphonamido)-3-aminopropionic acid hemihydrate (*cf.* Ref.[3]) was obtained on repeated recrystallizations from water, m. p. 200°, $[\alpha]_D^{22}$ −19.6° (*c* 2.5, 5 N HCl). (Found: C 44.85; H 5.60; N 10.38. Calc. for $C_{10}H_{14}N_2O_4S$, 0.5 H_2O: C 44.93; H 5.66;

* Part II: *Acta Chem. Scand.* **13** (1959) 1565.

* Purchased through *California Corporation for Biochemical Research*, Los Angeles, U.S.A.

** All melting points are uncorrected and determined in capillary tubes in an Anschütz-Hershberg apparatus, with a rate of heating of about 1° per minute near the melting points. For most compounds in the present series these are decomposition temperatures, highly dependent on the rate of heating, as has been pointed out also by other authors [2,3].

*** This rotation is quite dependent on pH-values. Thus, for the L-isomeride we found the following $[\alpha]_D^{25}$- values at *c* = 1.7; + 9.3° to + 9.8° at pH 5.3 to 9.3, + 5.5° at pH 10.3, and −3.2° at pH 11.2.

N 10.48.) A specimen of the corresponding L-isomeride, prepared in this laboratory by exactly the same procedure, had m. p. 200° and $[\alpha]_D^{22}$ +19.9° (*c* 2.5, 5 N HCl). Reported for the L-compound [3]: m. p. 225–226° (capillary, corr.) and 214–216° (decomp. Kofler-block) *, $[\alpha]_D^{22}$ +16.5° ± 0.8° (*c* 2.4, 5 N HCl) (anhydrous specimen).

D-*2-(p-Toluenesulphonamido)-3-ureidopropionic acid* (III). This compound was prepared as described for the L-isomer [3], yet in slightly lower yield. An analytical specimen (from water) had m. p. 169–170°, and $[\alpha]_D^{22}$ −15.8° (*c* 1, 96 % EtOH). (Found: C 43.70; H 5.12; N 13.80. Calc. for $C_{11}H_{15}N_3O_5S$: C 43.84; H 5.02; N 13.95.) Reported value for the enantiomer: m. p. 174–179° (decomp. Kofler-block), (no rotation reported).

D-*Albizziine* (IV). Again, the procedure employed in the L-series for detosylation [3] was followed, except that 6 h in stead of 36 h was found sufficient for complete reaction. A specimen for analysis was obtained by three recrystallizations of the crude product from aqueous ethanol, m. p. 202–205°, the same as that of natural L-albizziine when determined in the same bath. $[\alpha]_D^{24}$ +65.5° (*c* 1.7, H_2O), (Found: C 32.55; H 6.17; N 28.72. Calc. for $C_4H_9N_3O_3$: C 32.65; H 6.17; N 28.56.)

D-*2,3-Diaminopropionic acid* (V). In order to remove the tosyl-grouping from 2-N-tosyl-D-diaminopropionic acid (II), the latter (3.75 g) was heated at 70° for 6 h in a 35 % solution of anhydrous hydrogen bromide in glacial acetic acid (70 ml) containing phenol (4 g), conditions similar to those employed by Poduška *et al.*[5] in the detosylation of glycyl-peptides of diaminopropionic acid. Addition of anhydrous ether to the reaction mixture caused the hydrobromide of (V) (3.5 g) to separate as colourless crystals. The salt was purified by dissolving in water and addition of alcohol, to give a pure product (1.70 g), m. p. *ca.* 240°, $[\alpha]_D^{21}$ −17.3° (*c* 2, 1 N HCl). Reported rotation for D-2,3-diaminopropionic acid hydrochloride: $[\alpha]_D^{25}$ −25.2° (*c* 2, 1 N HCl) [6]. With due corrections for the different anions, this value suggested that partial racemization had occurred during the detosylation reaction, conceivably analogous to the recently demonstrated hydrogen bromide-induced racemization of L-diaminopropionic acid in aqueous solution [1]. That this was not the case, however, was proved by transforming an optically pure sample of L-diaminopropionic acid hydrochloride, $[\alpha]_D^{24}$ +25.0° (*c* 4.7, 1 N HCl or 1 N HBr), by means of an ion exchange column, into the corresponding hydrobromide with the rotation $[\alpha]_D^{21}$ +17.4° (*c* 2, 1 N HCl or 1 N HBr), comparable to that of the antipode described above. Reconversion of the hydrobromide into the hydrochloride afforded material with unchanged rotation (+25.3°).

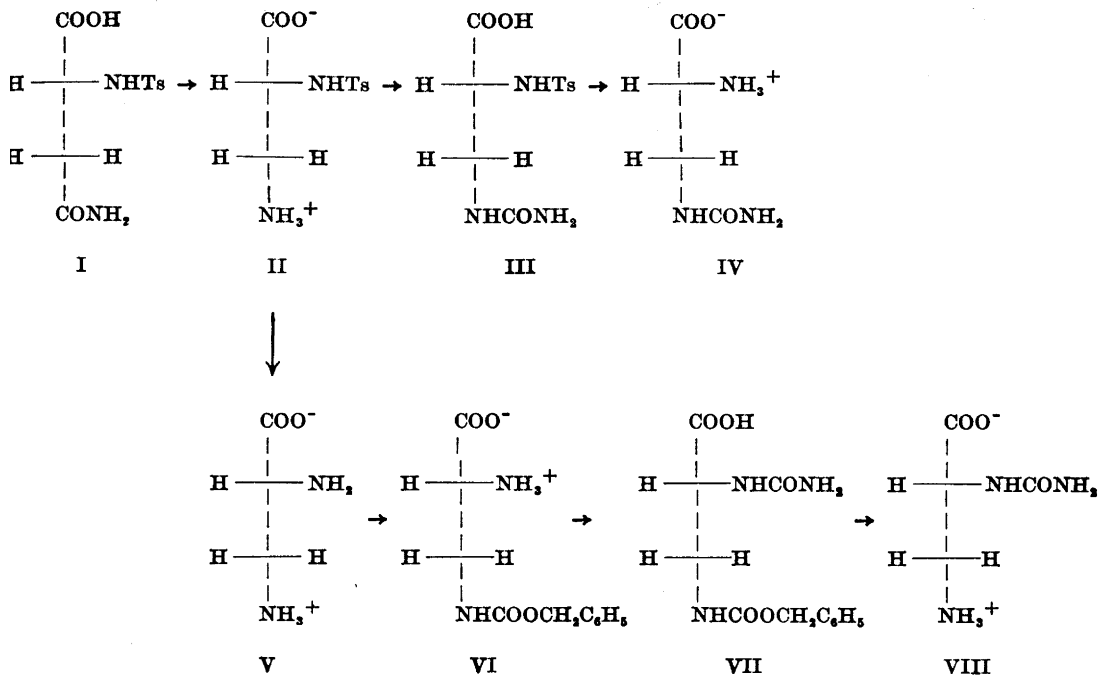
D-*2-Amino-3-benzyloxycarbamidopropionic acid* (VI). D-2,3-Diaminopropionic acid hydrobromide was subjected to carbobenzoxylation in 84 % yield (crude product) as described for the L-acid [1], with the sole modification that four times as much water was used in order to bring the less soluble hydrobromide into solution. A specimen for analysis was produced by two recrystallizations from hot water, m. p. 225°, $[\alpha]_D^{24}$ +15.9° (*c* 1, 1 N HCl). (Found: C 55.65; H 6.00; N 11.82. Calc. for $C_{11}H_{12}N_2O_4$: C 55.45; H 5.92; N 11.76). Reported for the L-enantiomer [1]: m. p. 227–229°, $[\alpha]_D^{21}$ −18.7° (*c* 1, 1 N HCl).

D-*2-Ureido-3-benzyloxycarbamidopropionic acid* (VII). This compound was synthesized according to the directions previously given for the L-isomer [1]. An analytical specimen separated from water in colourless needles, m. p. 190–191°, $[\alpha]_D^{22}$ −4.7° (*c* 1, dimethylformamide). (Found: C 51.10; H 5.34; N 14.79. Calc. for $C_{12}H_{15}N_3O_5$: C 51.24; H 5.38; N 14.94). The formerly described L-isomeride [1], m. p. 188–190°, had the rotation $[\alpha]_D^{22}$ +5.2° (*c* 1, dimethylformamide).

D-*Isoalbizziin* (VIII). Hydrogenolysis of (VII), performed as described in the L-series [1], yielded D-*iso*albizziin, m. p. 204°, $[\alpha]_D^{22}$ +44.6° (*c* 1, 0.1 N HCl). (Found: C 32.30; H 6.09; N 28.48. Calc. for $C_4H_9N_3O_3$: C 32.65; H 6.17; N 28.56.) Reported values for the L-isomeride[1]: m. p. 204–210°, $[\alpha]_D^{25}$ −43° (*c* 1, 1 N HCl.)

DL-*2,3-Diaminopropionic acid.* This racemic amino acid was conveniently synthesized by the method of Hellmann and Haas [7] with a few modifications. Thus, *diethyl benzamidomethyl-acetamidomalonate*, synthesized from

* For a specimen of this hemihydrate, kindly furnished by Dr. Rudinger, we found the m. p. 200°, when determined in the same bath as our D-isomer. The two compounds furthermore had identical IR-spectra.



N,N-dimethylaminomethylbenzamide[7] and ethyl acetamidomalonate[8], (m. p. 149—150°, from toluene). (Found: C 57.85; H 6.13; N 7.84. Calc. for $C_{17}H_{22}N_2O_6$: C 58.27; H 6.33; N 8.00), was used in stead of the dimethyl ester formerly employed[7]. Furthermore, boiling xylene was found preferable to toluene as a solvent for the condensation reaction. Racemic diaminopropionic acid hydrobromide was obtained from the ester upon hydrolysis with hydrogen bromide (83 % yield), m. p. 240° (decomp.).

DL - *2 - Amino - 3 - benzyloxycarbamidopropionic acid.* Upon carbobenzoxylation under the same conditions as employed in the optically active series, DL-2,3-diaminopropionic acid afforded DL-2-amino-3-benzyloxycarbamidopropionic acid in 70 % yield. An analytical sample (from water) had the m. p. 241° (Found: C 55.20; H 5.87; N 11.86).

DL - *2 Ureido - 3 - benzyloxycarbamidopropionic acid.* Again, conversion of the above acid into the ureidoacid was performed as described in the L-series [1] to give a 70 % yield of crude reaction product, which was recrystallized twice from water before analysis, m. p. 186°. (Found: C 51.20; H 5.35; N 14.70).

DL-*Isoalbizziin.* Decarbobenzoxylation of the foregoing acid in the customary way [1] afforded racemic *iso*albizziin which was recrystallized twice from water before analysis, m. p. 201°; the racemate was considerably less soluble in water than the optically active forms. (Found: C 32.25; H 6.05; N 28.32).

The authors are grateful to Dr. Rudinger for advance information on the synthesis of L-albizziine. The technical assistance of Mrs. E. Kläning is acknowledged. Microanalyses were performed by Mr. P. Hansen at the Chemical Laboratory of the University of Copenhagen.

A New Sensitive Reagent for Uranium

1-(2-Thiazolylazo)-*m*-dimethylaminophenol (TAM). Application to the Assay of Rocks and Solutions Low in Uranium

EMIL SØRENSEN

Danish Atomic Energy Commission, Research Establishment, Risø, Denmark

A simple analytical method for uranium is presented. It is based on the extraction of uranyl nitrate with methyl *iso*butyl ketone from a sample solution saturated with aluminium nitrate. An intensely coloured complex is formed *in situ* by addition of the reagent 1-(2-thiazolylazo)-*m*-dimethylaminophenol. The uranium content can be determined spectrophotometrically with a sensitivity of about 0.1 μg.

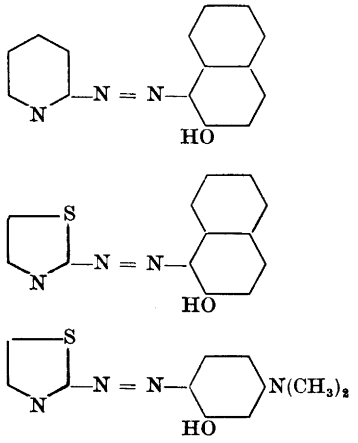
During the investigation of uranium-bearing rocks from southern Greenland the search for easy-handled, sensitive analytical methods was a major point.

A considerable work has been done with a modification of the dibenzoylmethane method by Booman, Maeck, Elliott and Rein [1]. Its principle is that uranyl nitrate is extracted into methyl *iso*butyl ketone (hexone) from a solution saturated with aluminium nitrate. Colour development is made *in situ* by the addition of dibenzoylmethane in pyridine. The lower level of detection is 0.5 μg of uranium. The new method takes its origin in a paper by Spinner and Miller [2]. These authors have determined uranium in thorium process solutions by means of 1-(2-pyridylazo)-2-naphthol (PAN) which forms an intensely coloured uranium complex.

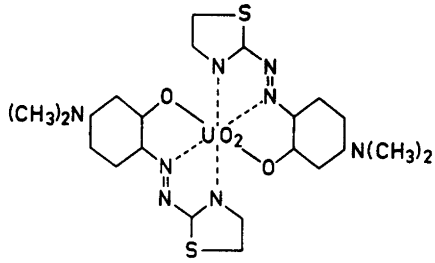
In this laboratory Skytte Jensen has for other purposes prepared a series of dyes on the basis of 2-aminothiazol [3]. Among these the compound 1-(2-thiazolylazo)-2-naphthol (TAN) has been tried as a reagent for uranium and proved useful. However, previous experience suggested that the introduction of a dimethylamino-group in the molecule would intensify the colour. This led to the synthesis of 1-(2-thiazolylazo)-*m*-dimethylaminophenol (TAM). As shown in Fig. 1, the TAM-uranium chelate has an optical density about 100 % higher than that of the corresponding TAN-compound. Therefore TAM was chosen for the further development of this method.

CHELATE FORMATION

The three dyes mentioned have the formulas



The chelate of TAM with the uranyl ion may be written



The dye is slightly soluble in water, the uncharged chelate, however, is nearly insoluble. Both are readily dissolved in a variety of organic solvents, *e.g.* hexone.

The colour depends on the composition of the solvent used. To obtain reproduceable results it is recommended to equilibrate the hexone solution with an aqueous buffer. At low pH the chelate will dissociate, and at high pH the uncomplexed dye assumes a colour much like that of the uranium chelate. Thus a pH optimum must exist for the colorimetric measurement of the chelate against a reagent blank. This optimum has been experimentally obtained by using a buffer containing pyridine — pyridinium chloride in the proportion 7 : 1.

EXPERIMENTAL

Reagents: Ammonium hydroxide 12 M. $Al(NO_3)_3$, $9H_2O$, salting agent. $Al(NO_3)_3$-KIO_3 scrub solution. Methyl *iso*butyl ketone (Shell Chemicals). Dye solution: 0.5×10^{-3} M TAM, 4 M pyridine, 0.5 M HCl in H_2O.

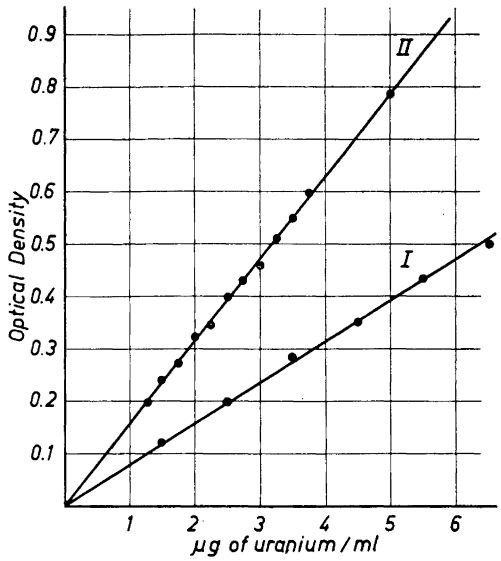


Fig. 1. Standard uranium-optical density curve.

I TAN complex, λ — 585 mμ
II TAM complex, λ — 575 mμ

Aluminium nitrate salting agent: 1 kg of $Al(NO_3)_3$, 9 H_2O (Merck, purum) + 100 ml of H_2O is molten in a beaker and stored in a 1 l two-necked flask. The flask is kept heated on an infrared bath at a temperature just sufficient to prevent crystallization (*ca.* 100°C). One neck is provided with a reflux condenser. The other, allowing for pipetting, is closed with a glass stopper.

$Al(NO_3)_3$-KIO_3-scrub solution. 5.4 g of KIO_3 and 350 g of $Al(NO_3)_3$, $9H_2O$ are dissolved in 250 ml of H_2O. After cooling the specific mass is adjusted to 1.33 g/ml by addition of H_2O or $Al(NO_3)_3$.

Dye solution: 31 mg of TAM are dissolved in 80 ml of pyridine in a 250 ml volumetric flask. About 150 ml of water are added. The mixture is allowed to cool. Then 10.4 ml of conc. HCl are added and the volume is adjusted to the mark with H_2O.

Where not specified, the chemicals used are analytical grade.

Method

Uraniferous rock. In most cases fuming with HF and $HClO_4$ is sufficient to bring the sample in solution. If necessary the fuming may be followed by melting with $NaHSO_4$ without interfering with the extraction procedure. The dissolved sample is oxidized with 2 drops of 6 % H_2O_2 and is neutralized with NH_3 to incipient hydroxide precipitation. Further 0.025 ml of 12 M ammonium hydroxide and 2 ml of salting agent are added per ml of sample solution. After being homogenized by gentle agitation the sample is ready for extraction with hexone of which an amount is taken corresponding to 0.3—1 ml per μg of uranium expected.

It is preferable to carry out the extraction in two stages, proceeding in the following manner: Add exactly half of the hexone to be used, and shake vigorously for 2 min. Centrifuge. Separate in a funnel taking care that the aqueous phase is free from hexone drops. Repeat the operation using the other half of the hexone. Equal volumes from the two extracts are combined and shaken with the scrub solution for 2 min. After complete separation of the phases about 2.5 ml of the organic layer and exactly the same volume of the dye solution are transferred to a small tube with a special pipet arrangement (Fig. 2). They are mixed by gentle agitation for 5 min. (Glass stoppers are used in all

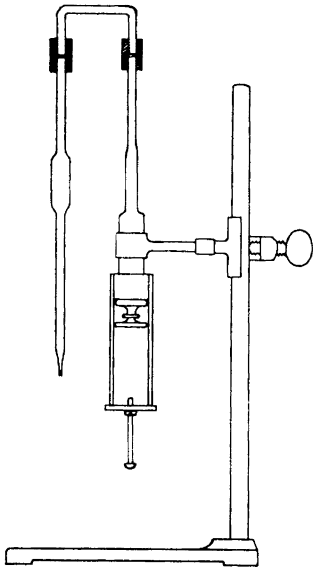

Fig. 2. Syringe with exchangeable pipet.

operations where hexone is involved.) After centrifuging the organic layer is transferred to a 1 cm colorimetric cell and the absorbance is measured at 575 mμ against a reagent blank. The uranium content is read from a standard calibration curve (Fig. 1).

Uranium pregnant liquor. In case of a uranium pregnant liquor the method will be especially applicable for routine work, as the extraction may be carried out in one stage and the scrubbing omitted.

DISCUSSION

The hexone extraction as described here is rather selective for uranium. The most common interfering ions are Ce^{+4}, Fe^{+++} and Th^{+4}. Ce^{+4} is reduced by the H_2O_2-treatment to Ce^{+++}, which is not extracted. Fe^{+++} has a low distribution coefficient but is often present in large concentrations. It is effectively removed by the scrubbing procedure. $Th(NO_3)_4$ is extracted to a considerable extent. However the IO_3^--scrubbing ensures a sufficient low level given by the solubility product of thorium iodate.

Further the two-phase system of chelate formation has an inherent selectivity, as it has been found that only chelates of dipositive metal ions show a definite tendency to be extracted by organic solvents. The calibration curve is a straight line all over the range covered by the spectrophotometer.

The standard deviation of a reading has been estimated to 0.025 μg of uranium per ml.

Outlines of an Optical Method of Measuring Thermal Conductivities of Fluids

OLE LAMM

Institutionen för fysikalisk kemi, Kungl. Tekniska Högskolan, Stockholm 70, Sweden

The relative lack of data on the thermal conductivity of liquids may be ascribed to a certain inconvenience of the methods of measurement in this field. An optical hot wire arrangement is shown to be expedient to an extent, which would hardly have been anticipated. It is necessary to know the change of refractive index with temperature. Many methods, not discussed in this paper, present themselves for this determination.

The analogy between the transport of heat and of matter by diffusion is not limited to the fundamental laws, but also exists in the possibilities of measuring by optical methods. This was very early realized in connection with interference and schlieren observations. Whereas in the field of diffusion and sedimentation [1], electrophoresis [2], and thermodiffusion [3] the practical importance of the optical principles in modern experimental technique is settled, the same cannot, as far as known, be said of thermal conductivity. There is a pronounced need for developments in this latter field, and optical procedures should be investigated besides the electric, thermometric, and calorimetric methods in vogue. The electric arrangement referred to, is especially the "hot wire resistance thermometer" method of Eucken and Englert and of Pfriem [4], which has been the object of a complementary, very careful study in this Institute [5-7]. This is, in part, identical with the Piranie pressure gauge, which is used also for thermal conductivity measurements (von Ubisch[8]). Through all these works, a considerable experience has been won regarding *the state of a liquid or a gas around a vertical hot wire*, characterized by a telescopic symmetry of the convections within certain limits of experimental conditions. In the ideal case, the thermal and optical properties in the horisontal direction around the wire are unaffected by these convections. We will be solely concerned with this "convection free" situation. An elaborate study, among other things of the necessary length of the wire and the permissible output of heat from the wire as a function of viscosity and thermal dilatation, is still lacking.

The curvature of light which propagates in a horisontal plane and passes the region of heat flow around the wire will be the optical basis for the measurement. The phenomenon will be seen from the standpoint of geometrical optics. A refinement according to wave optics can be performed along well known principles. As shown below, the theory and the measurements give a surprisingly simple result. One distinct angle of deflection is observed on each side of the wire. In order to resolve this simple phenomenon in its finer details, if requisite, a wave optical theory will be required; the technically important case of *a hot wall in air* was investigated by optical interferometry well 25 years ago [9,10].

As far as a constant deviation is concerned, there is no need for using methods like the scale or the schlieren arrangements. These methods have been criticized by Gosting; scale method [11], schlieren method [12]. In the *former* case, the criticism is based upon a creditable but incomplete theoretical attempt by Adler and Blanchard, which evidently cannot rival in conclusive evidence with the severe experimental test [13], compare Ref. [14]. (A somewhat modified experimental procedure has been proposed for greater convenience [15].) In the *latter* case, the criticism is limited to the region of maximum deviation of light, in which nobody uses the schlieren method for to some extent exact purposes, owing to the lack of definition of the image which is immediately evident to the experimenter. Hence, the self-warning property [13] is a common characteristic of these methods.

THE THERMAL CONDITIONS

A very thin metal wire is extended in an electrically isolating stationary fluid of thermal conductivity λ and diffusivity $a = \lambda/c\varrho$ (c specific heat at constant pressure, ϱ density). The wire is electrically heated, and represents a linear heat source Q_0 per unit of length and of time (t). Counted from a zero time $t = 0$ ($t < 0$, $Q_0 = 0$), the time derivative of temperature (T) at a radial distance r from the source is [4]

$$\frac{\partial T}{\partial t} = \frac{Q_0}{4\pi\ \lambda t} \exp(-r^2/4at) \tag{1}$$

The heat passing one cm^2 of a coaxial cylindrical surface element at a distance r is, in time dt

$$\mathrm{d}Q = \frac{Q_0}{2\pi r} [\exp(-r^2/4at)]\mathrm{d}t \tag{2}$$

The thermal conductivity is defined according to

$$\mathrm{d}Q = -\ \lambda \frac{\partial T}{\partial r}\ \mathrm{d}t \tag{3}$$

(2) and (3) yield

$$\frac{\partial T}{\partial r} = -\ \frac{Q_0}{2\pi\ \lambda r} \exp\ (-r^2/4at) \tag{4}$$

This gradient corresponds to a refractive index gradient of

$$\frac{\partial n}{\partial r} = -\left(\frac{\partial n}{\partial T}\right)_p \frac{Q_0}{2\pi\ \lambda r} \exp(-\ r^2/4at) \tag{5}$$

In a practical measuring device, the temperature gradient should be as low as possible, and $(\partial n/\partial T)_p$ may be regarded as constant (or nearly constant) and approximated to the value at the temperature of the medium in bulk at the beginning of an experiment (or at the average temperature within the gradient, if needed). This derivative has to be determined in a separate experiment. — For less accurate purposes, it is noted that the equation of Dale and Gladstone, $(n-1)/\varrho$ = const., gives

$$\frac{\mathrm{d}n}{\mathrm{d}T} = -\ (n-1)\gamma \tag{6}$$

and that of Lorenz and Lorentz $(n^2-1)/\varrho\ (n^2 + 2)$ = const.

$$\frac{\mathrm{d}n}{\mathrm{d}T} = -\frac{(n^2-1)(n^2 + 2)}{6n}\ \gamma \tag{7}$$

γ being the coefficient of cubic expansion.

A direct determination of $\partial n/\partial r$, eqn (5), it not easy; it would be measured by the light curvature of rays of incidence *parallel* to the wire. Terminal anomalies make such a procedure seem less advantageous than an incidence transversal to the thread.

THE OPTICAL CONDITIONS

The curvature of light [16] is, according to Snellius' law, always towards regions of higher refractive index. Fig. 1 shows a horizontal section with two cylindrical surfaces S_1 and S_2 of radius $r_1 = r + \mathrm{d}r$ and $r_2 = r$. An incident light ray from the left is deviated at these surfaces in the direction which removes it from the vertical wire at O *. A parallel beam is thus split up in two parts deviated each to its side of the wire. — A ray passing near O is strongly bent in this region; a ray passing at a longer distance from O has a more moderate curvature, but along a greater section of its path. It will appear that this tends to make the resulting deviation independent of the condition of incidence (y_0).

The indices of refraction are, on the two sides of S_1, n and $n' = n + \mathrm{d}n$. By the construction (Fig. 1) is seen that $\mathrm{OA} = r_1 \sin b_1 = r_2 \sin i_2$. Further, by Snellius' law we obtain $n \sin i_1 = n' \sin b_1$. These two relations yield $nr_1 \sin i_1 = n'r_2 \sin i_2$; more generally, C being a constant along the ray,

$$nr \sin i = C \tag{8}$$

We are interested in the differential deviation $\delta = b_1 - i_1$ at the surface S_1. Writing Snellius' law $n \sin i_1 = (n + \mathrm{d}n) \sin (i_1 + \delta)$ and omitting vanishing

* The only ray which would be undeviated is one originally directed towards O. — In practice, the interference phenomenon caused by the wire is considered to be of vanishing intensity.

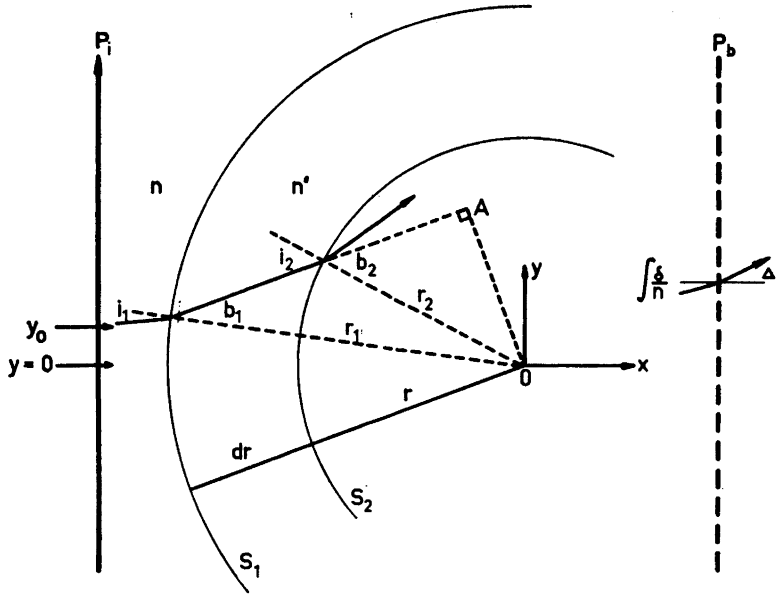

Fig. 1. Horizontal section of the cell, showing the liquid enclosed between P_i and P_b, with the linear source at O, and the direction of light from left to right.

terms, $\sin \delta = -(\mathrm{d}n/n)\ \mathrm{tg}\ i_1$. Approximating $\sin \delta$ by δ, and omitting index 1, yields

$$\delta = -\frac{1}{n}\frac{\partial n}{\partial r}\ \mathrm{tg}\ i\ \mathrm{d}r \tag{9}$$

We introduce i from eqn (8):

$$\delta = -\frac{1}{n}\frac{\partial n}{\partial r}\frac{C\ \mathrm{d}r}{\sqrt{n^2r^2 - C^2}} \tag{10}$$

$\partial n/\partial r$ is given by eqn (5), so we have obtained $\delta = f(r)\mathrm{d}r$ which shall be integrated for different ordinates of incidence y_0 of the cartesian system (x, y of Fig. 1). We will assume

1) a parallel beam of light with an incidence at right angles to the plane P_i and issuing at the plane P_b

2) a temperature gradient which does not reach the planes P_i and P_b, ensuring an integration from $x = -\infty$ to $x = +\infty$

3) refractive indices outside the region between P_i and P_b to be unity

4) that in eqn (8), r and i change significantly along the path of a light ray but neither n nor y. (Owing to $r^2 = x^2 + y^2$, y is of interest in this connection.)

From the approximations 1) and 4) is seen that, along the ray, $y = y_0 = r \sin i$. With this approximation eqn (8) gives $C = ny_0$. Hence, eqn (10) becomes

$$\delta = -\frac{1}{n}\frac{\partial n}{\partial r}\frac{y_0\,\mathrm{d}r}{\sqrt{r^2-y_0^2}} \tag{11}$$

The approximations made, all imply that the total angle of deviation between P_i and P_b, Δ, is supposed to be very small, that is the refractive index gradient is feeble. We will eventually have to demand this from other reasons too, in order to avoid disturbing convections. — It is seen that the argument of eqn (11) becomes infinite at $r = y_0$. This is the point at which the ray passes as near the wire as possible, that is where r is a minimum and $\mathrm{d}r = 0$.

Introducing $\partial n/\partial r$ by eqn (5), and x as independent variable by $r^2 = x^2 + y_0^2$

$$\delta = \frac{1}{n}\left(\frac{\partial n}{\partial T}\right)_p \frac{y_0 Q_0}{2\pi\lambda}\,\frac{\mathrm{d}x}{x^2+y_0^2}\,\exp[-(x^2+y_0^2)/4at] \tag{12}$$

We will integrate this expression in order to obtain the total angle of deviation Δ. The angle in question shall represent the total deviation of the ray, counted from before entering the cell at P_i and after leaving it at P_b, that is in air of refractive index approximately equal to unity. Strictly speaking, all the small angles of Fig. 1 would have to be divided by n (as indicated at the plane P_b), in order to be referred to a specified angle of incidence *in air*. Hence, we obtain Δ directly from eqn (12), as if there were no refraction at P_b

$$\delta = \frac{1}{n}\left(\frac{\partial n}{\partial T}\right)_p \frac{y_0 Q_0}{2\,\pi\lambda}\int_{-\infty}^{+\infty}\frac{\mathrm{d}x}{x^2+y_0^2}\,\exp\,[-(x^2+y_0^2)/4at] \tag{13}$$

The integral reduces to a simple from by assuming $x^2 + y_0^2 = r^2 \ll 4\,at$, an assumption which is strongly supported by the experimental results *. Hence

$$\Delta = \frac{1}{n}\left(\frac{\partial n}{\partial T}\right)_p \frac{y_0 Q_0}{2\pi\lambda}\left|\frac{1}{y_0}\sin^{-1}\frac{x}{\sqrt{x^2+y_0^2}}\right|_{-\infty}^{+\infty}$$

from which

$$2\Delta = -\frac{Q_0}{\lambda n}\left(\frac{\partial n}{\partial T}\right)_p \tag{14}$$

EXPERIMENTAL CONDITIONS

The total angle of deflection, 2Δ may be measured either by photography, see Fig. 5, or with a screw micrometer eyepiece as used in our observations,

* In eqn (5), this approximation leads to a logarithmic decrease of temperature within the region nearest to the wire.

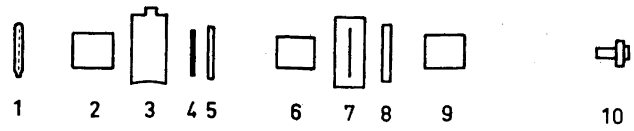

Fig. 2. 1. straight wire lamp, 2. condenser lens, 3. water cell, 4. light filter, 5. fine vertical slit, 6. lens with focal plane at 5, 7. trough with the vertical wire suspended in the liquid to be measured, 8. broad vertical diaphgram, 9. lens, 10. micrometer screw eyepiece adjusted to the slit 5.

see Fig. 2. The arrangement is an Abbe schlieren or Gouy interference device with parallel light passing the cell 7. The eyepiece 10 is adjusted to the focal plane of the lens 9 *.

The diaphragm 8 was 3—4 mm broad. The slit 5 is seen as a central line at the beginning of the experiment, which disappears altogether after in induction time of less than 10 seconds. Instead of this, two distinct lines appear (Fig. 5), the distance of which was read off by the eyepiece micrometer 10 ×. It corresponds to $2\,\Delta$ of eqn (14). The real angle was obtained by comparison with the deviation caused by a glass prism with a *double* deviation angle of 0.01208 radians (red light).

The readings were independent of a diminished breadth of the diaphragm 8. Of course, the lines are finally getting unsharp.

The electric circuit and measurement was the simplest possible, see Fig. 3.

The proportionality of $2\,\Delta$ to Q_0 (eqn 14) has been tested, see Fig. 4. The good linearity observed, and the excellent stability of the eyepiece readings with time is very advantageous for the purpose of determining the coefficient of heat conduction. — An estimation of the systematic error is not possible for the present.

In our experiments, the angle of deviation $2\,\Delta$ varied from 2′ to 10′. — It is interesting to compare $2\,\Delta/Q_0$ of eqn (14) for some substances at 20°C, see Table 1. For the measurement, a high value of $2\,\Delta/Q_0$ is desirable. The step from glycerine to water is, in this respect, greater than that from water to a gas like air. The method might eventually be extended to gases of ordinary or elevated pressures, although the optically useful region around the wire is very narrow in such a case. Hence, the optical requirements become very special, and no test has been made.

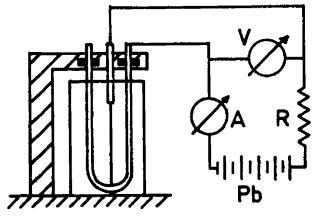

Fig. 3. The vertical wire (0.1 mm Pt) is shown at the left, immersed in the liquid container, a plane parallel glass cuve. The electrical circuit is the simplest possible, by application of a big battery (Pb) of variable voltage, and a high resistance mVVmeter.

* With this adjustment, a screening diaphragm 8 is needed in order to get a clear double line in the eyepiece. However, a re-focusing according to the actual value of Q_0 shows that a double line can be obtained *in absence of the screen.* This gives an insight into the optical properties of the wire surroundings which is not covered by the simple treatment given in this article.

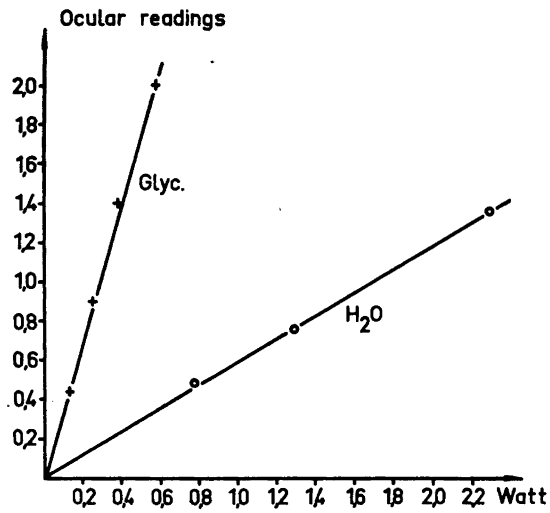

Fig. 4. The proportionality between the ocular readings (line distance in the ocular) and the total energy output from the wire is shown for water and glycerine.

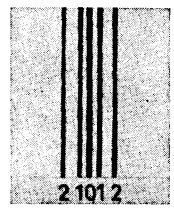

Fig. 5. From photographic exposures of the central line (0) and two double lines (1,1 and 2,2) on an Ilford H.P.S. Plate. Line O: exposure time 7.5 sec., $Q_0 = 0$. Lines 1,1: 15 sec., $Q_0 = 0.00657$ watt/cm. Lines 2,2: 15 sec., $Q_0 = 0.0183$ watt/cm. Voltage of accumulator: 0, 6 and 10, respectively. Substance: colourless liquid paraffin. Light source: straight wire lamp without filter.

A higher energy output Q_0 in the case of water was necessary in order to ensure a sufficient resolving power for this substance, with its exceptionally small $\partial n/\partial T$ and great λ. A refinement of the method of observation is, of course, possible; this would be necessary for an application to water around 4°C (where the risk for convection is specially small), owing to the small value of $\partial n/\partial T$. — The stability in the case of water at 20°C was much better than expected; convections have been observed only when the wire was quite evidently non vertical.

Available experimental data for the calculation of $(dn/dT)_p$ are, even for water, not quite satisfactory. The uncertainty is at least $\pm$ 2 % if estimated without a critical examination of the values of different authors.

Table 2 illuminates further our conditions and presents result on λ as compared with the exact data obtained by Gillam [6].

Additionally, the following data are of interest:

1) The liquid column had the dimensions 4 × 4 × 14 cm, the exact length of the wire was 12.70 cm. The highest effect used for water, 2.28 watt on the whole wire, corresponds to a temperature rise of 10°C/h if no loss of heat occurred to the surroundings.

2) The final reading is normally obtained in 20—30 sec. A high Q_0 and a low λ may increase the induction period considerably. A test of the stability

Table 1.

	$10\lambda^3$ cal/cgs	n		$-10^4\ (dn/dT)_p$ ~D-line	$(-1/\lambda n)(dn/dT)_p = 2\Delta/Q_0$
n-Octanol	0.40	1.429	4.0	(average 18–80°C)	0.70
Glycerine	0.675	1.473	2.79?	(from eqn 7)	0.28
Water	1.44	1.333	0.92	(average from lit.)	0.048
Air (1 at)	0.057	1.00027	0.0100		0.017

Table 2.

21°C	Q_0 watt/cm	$2\Delta/Q_0$ (exp.) cgs/cal	$-10^4\ (1/n)(dn/dT)_p$	$10^3\ \lambda$(opt.) cal/cm sec degree	$10^3\ \lambda$(Gillam [6])
Glycerine	0–0.045	0.269	(1.89)	(0.70)	0.675
Water	0–0.180	0.0460	0.69 ± 2 %	(1.50)	1.44

of the ocular reading over a long period of time was made with glycerine. 0.56 watt was used over the wire, corresponding to the upper limit of Q_0 in Table 2. The line distance was constant over the measured period of 1 ½ h. The lowest value of 5.02 was obtained after 3 and 90 min; the highest value measured was 5.05. The difference is within the accidental errors of the readings. — In the case of mixtures, effects of thermodiffusion may be obtained, and the readings should be made as early as possible.

3) When the current is switched off, the double line disappears and the central line is restored in a time of the order of 5 seconds to several minutes. A new measurement may be started immediately, without stirring of the liquid.

4) With a suitable form of the terminal connections of the wire, a correction for a *low* electrical conductivity of the liquid should be easy to perform.

5) A cylindrical lens may be used in order to decrease the magnification in the direction of the wire, so that an average deviation may be observed in the ocular. However, it is advantageous to use only a narrow middle section of the wire region, where the terminal anomalies are as small as possible.

ELECTROLYTES

Although no experiments on conducting solutions have hitherto been made, there is no doubt as to the possibility of covering the field of most ordinary electrolytes by the use of an electrically isolated wire.

Another possibility is interesting: to use the wire as an electrode and a cylindrical second electrode at a distance around it, and to feed the system with alternating current. It is easily seen that the joule heat evolved per unit of volume of the liquid is inversely proportional to the square of the distance from the wire. This should be compared to the much slower, logarithmic decrease of temperature in the neighbourhood of the heated wire according to our equations. Hence, by electrolytic heating, only the nearest surrounding

of the wire will become appreciably heated directly by the current. — The detailed optical properties of this system, with thermal conduction, has not yet been calculated. However, a simple consideration convinces of that the conductivity even of a thin wire (preferably made of silver) is so much greater than the conductivity of the solution, that hardly any difficulties can arise in obtaining an *even distribution* of the heat effect along the wire. The procedure might be of special interest in cases of very corrosive liquids, molten salts *etc.*, for which an isolating coating of the wire would be difficult to procure. — The optical observations must be made through apertures in the outer electrode.

The arrangement outlined would eventually be another technique for a variety of experiments on the transports of ions and heat.

CONCLUSIONS

In connection with the hot wire arrangement (Schleiermacher and others) an *optical* method has been examined which enables a simple and rapid measuring of coefficients of heat conduction of transparent liquids with considerable exactitude. The experimental test and fundamental theory given, do not allow a final judgement of the attainable accuracy. A separate determination of the change of refractive index with temperature is needed.

The hot wire *resistance thermometer* method, used previously for precision determinations, utilizes the resistance change during the first 20—60 seconds after switching on the current. This valuable method is a typically non stationary procedure. It has many advantages, *e.g.* that of being sufficiently independent of a temperature jump at the wire surface (Eucken). A condition for this seems to be that such a jump does not appreciably depend upon temperature. The optical method described is thermally (quasi-) stationary and *optically stationary*. This greatly simplifies the measuring device. The temperature jump is eliminated, as the method is based on a constant heat source, and not upon the heat flow between surfaces of fixed temperatures. This is especially pronounced in our case, owing to the stationarity mentioned.

The magnitude of the necessary joule heat supply (given the optical arrangement), increases with increasing thermal conductivity and decreasing thermal expansion of the liquid. This did not prevent measurements to be performed with water, using an output of 0.18 watt/cm without disturbances detectable by the method itself. Nevertheless, the procedure may be refined in different directions. Electrolytes can be included.

The method is unsuitable for solids in general. Already the frequent lack of transparency is preventive. By the great simplicity of the method, it may be valuable in improving the evident lack of data in the field of liquids and molten salts, in which essential informations are to be expected.*

* *Note added in proof:* Extended experimental work, and theoretical considerations by O. Bryngdahl, have disclosed fallacies in this work which will become corrected in further publications. Essential for the method is that the stability of the liquid has been established, the disturbances being slower than the restoring by thermal conduction.

The Influence of Temperature on the Protolytic Equilibriums and Reaction-Rate Constants of Basic Triphenylmethane Dyes

RUNE CIGÉN

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The protolytic reaction scheme that was earlier proposed for basic triphenylmethane dyes on the basis of measurements at 20°C in water solutions has now been examined for Methyl Green at 40°C and 60°C. The reaction scheme has proved to be valid at these higher temperatures as well. The dissociation, hydration, and reaction-rate constants have been determined at 20°, 40°, and 60°C. The apparent energies of activation for the slow reactions and the temperature coefficients of the dissociation and hydration constants have been calculated.

The measurements have been carried out spectrophotometrically in water solutions of constant composition and constant ionic strength (0.5 M).

As a continuation of our earlier investigations [1-3] of the protolytic reactions and reaction velocities in water solutions of basic triphenylmethane dyes, we have examined the temperature dependence of the dissociation, hydration, and reaction-rate constants.

The earlier investigations concerning the influence of the temperature on these dyes have only treated the temperature dependence of the reaction rates. They have above all been concerned with the reaction

$$\text{dye ion} + OH^- \rightleftharpoons \text{carbinol}$$

in alkaline solutions. Biddle and Porter [4], it is true, also examined the corresponding reactions in acid solutions, but they did not take into consideration the complicated protolytic scheme and therefore their rate-constants are complex constants for several simultaneous time-reactions. Furthermore, they were not able to take into account the fact that the temperature influences not only the complex rate-constants but the dissociation and hydration constants as well. A determination of all constants in the protolytic scheme was not published until 1956 by Cigén [1].

For Crystal Violet, Langvad [5] made an attempt in 1950 to determine from the Arrhenius equation the energy of activation for the formation of carbinol in alkaline solutions according to the reaction

$$\text{—}\overset{\diagdown}{\underset{\diagup}{}}\text{C}^+ + \text{OH}^- \rightleftharpoons \text{—}\overset{\diagdown}{\underset{\diagup}{}}\text{COH}$$

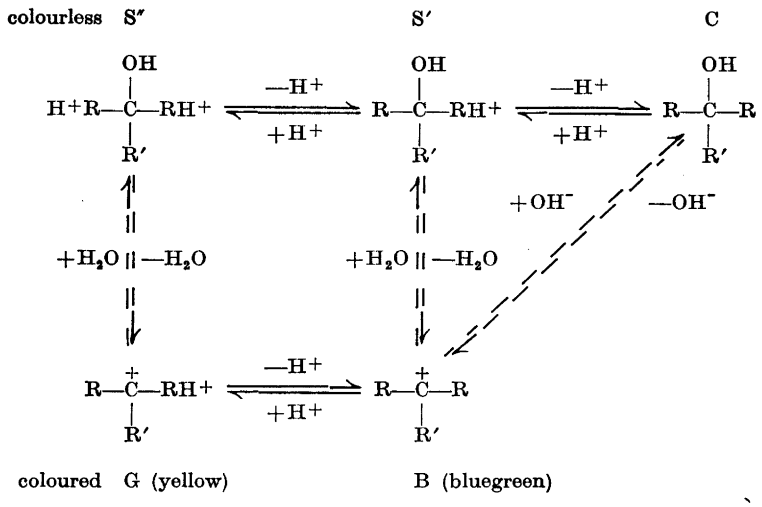
This led Turgeon and LaMer [6] to a careful reinvestigation of the carbinol formation of Crystal Violet as a complement to Hochberg and LaMer's [7] reaction-rate and equilibrium studies of the carbinol formation of triphenylmethane and sulfonphthalein dyes. In order to determine the true energies and entropies of activation Turgeon and LaMer carried out measurements in isocomposition and isodielectric solutions. Unfortunately specific solvent effects turned up in the measurements in isodielectric solutions (mixtures of water — ethanol and water — acetone) which explains why they were not able to verify the relations, deduced by LaMer and Amis [8], between the dielectric constants of solvents and the reaction rates.

A theoretical treatment of the kinetics of solutions necessitates an extrapolation of the measurements to the ionic strength $\mu = 0$ and the dielectric constant $D = \infty$, as has been shown by Brönsted [9], Christiansen [10], Scatchard [11], LaMer [12] and others, if we want to determine the true energies and entropies of activation and the reaction-rate constants. This leads to experimental difficulties even for quite simple reactions, and for complicated reaction systems it seems at present impossible to determine true thermodynamic quantities in detail.

Owing to the above mentioned difficulties the present investigation has been carried out with solutions of constant composition. The ionic strength was kept constant (0.5 M) in order to keep the activity coefficients of the reacting ions and molecules as constant as possible.

Methyl Green $[[(CH_3)_2NC_6H_4]_2\overset{+}{C}C_6H_4\overset{+}{N}(CH_3)_3](ClO_4^-)_2$ was chosen as a representative of the types of dyes investigated. This dye was earlier investigated in detail at 20°C within the pH-range 0—9 [1]. Other investigations of dyes of the same type have led us to feel that Methyl Green could be investigated in detail also at 40° and 60°C even if the pH-range were extended to include the carbinol formation in strong alkaline solutions. If, for the sake of brevity, we write Methyl Green as $\begin{matrix} R \\ R \end{matrix}\!\!\diagdown\!\overset{+}{C}\!\!\diagup\!\!-R'$, where $R = (CH_3)_2NC_6H_4$ and $R' = (CH_3)_3\overset{+}{N}C_6H_4$, we can schematically indicate the reactions that take place when we change the pH of a solution of Methyl Green in the following manner (*cf.* Refs.[1–3]).

Whole arrows indicate that the reactions proceed with a non-measurable velocity — that is, instantaneously — whereas dashed arrows indicate that the reactions take place with a measurable velocity.



The following constants are defined:

$$K_1 = \frac{[G]}{[B][H^+]},\ K_2 = \frac{[S'']_\infty}{[G]_\infty},\ K_3 = \frac{[S'][H^+]}{[S'']},\ K_4 = \frac{[C][H^+]}{[S']},$$

$$K_6 = \frac{[B]_\infty}{[S']_\infty}$$

k_1 = rate constant for the reaction $G + H_2O \rightarrow S''$
k_2 = » » » » » $S'' \rightarrow H_2O + G$
k_3 = » » » » » $B + H_2O \rightarrow S'$
k_4 = » » » » » $S' \rightarrow B + H_2O$
k_5 = » » » » » $B + OH^- \rightarrow C$
k_6 = » » » » » $C \rightarrow B + OH^-$

The investigations were carried out spectrophotometrically and therefore the concentrations of the dye are given in most cases in the form of specific extinctions. The following symbols are used:

ε_B, ε_G = the molar extinction coefficient of B and G.
e_0, e_t, e_∞ = the specific extinction of a solution at the times 0 and t and at equilibrium (thickness of absorbing layer: $d = 1$ cm).
E_0, E_t, E_∞ = the extinctions for $d \neq 1$ cm.
e_B, e_G = the specific extinction of a solution containing only B resp. G.
C_M = the total concentration of dyestuff.

We can derive the following equation for K_1 (*cf.* Refs.[1-2]):

$$K_1 = \frac{e_B - e_0}{(e_0 - e_G)[H^+]} \qquad (1)$$

which can be transformed to

$$\frac{[H^+]}{e_B - e_0} = [H^+] \frac{1}{e_B - e_G} + \frac{1}{K_1(e_B - e_G)} \tag{2}$$

A plot of $[H^+]/(e_B - e_0)$ against $[H^+]$ gives a straight line. The intercept, y, of this line on the Y-axis and its slope, l, give $e_B - e_G = 1/l$ and $K_1 = l/y$, respectively.

At equilibrium we get the extinction

$$e_\infty = \frac{e_B + K_1[H^+] \cdot e_G}{1 + 1/K_6 + K_4/K_6[H^+] + K_1[H^+](1 + K_2)} \tag{3}$$

For acid solutions, pH ≤ 2, (3) gives

$$K_2 = \frac{e_G}{e_\infty} + \frac{e_B - e_\infty(1 + K_1[H^+] + 1/K_6)}{e_\infty \cdot K_1[H^+]} \tag{4}$$

and for weakly alkaline solutions (3) can be written in the approximate form

$$\frac{[H^+]}{e_\infty} = [H^+] \cdot \frac{1 + K_6}{K_6 \cdot e_B} + \frac{K_4}{K_6 \cdot e_B} \tag{5}$$

We get K_4/K_6 from (5) and, under certain circumstances, K_6 as well if we plot $[H^+]/e_\infty$ against $[H^+]$.

We can derive an expression for K_3K_4 in the following way:

$$e_\infty = [B]_\infty \cdot \varepsilon_B + [G]_\infty \cdot \varepsilon_G = [B]_\infty(\varepsilon_B + K_1[H^+] \cdot \varepsilon_G) \tag{6}$$

$$C_M = [B]_\infty + [G]_\infty + [S'']_\infty + [S']_\infty + [C]_\infty$$

$$= [B]_\infty(1 + K_1[H^+] + 1/K_6 + [H^+]/K_3K_6 + K_4/K_6[H^+]) \tag{7}$$

From (6) and (7) we get

$$e_\infty = \frac{e_B + K_1[H^+] \cdot e_G}{1 + 1/K_6 + K_1[H]^+ + [H^+]/K_3K_6 + K_4/K_6[H^+]} \tag{8}$$

since $C_M \cdot \varepsilon_B = e_B$ and $C_M \cdot \varepsilon_G = e_G$. In very weakly acid solutions, pH ~ 5, we can neglect $K_1[H^+]$ in the denominator and $K_1[H^+] \cdot e_G$ in the numerator if we carry out the measurements at a wavelength where $e_G \leq e_B$. After these approximations we differentiate e_∞ with respect to $[H^+]$ and find that e_∞ has a maximum when $[H^+] = \sqrt{K_3K_4}$.

We can deduce the following rate expression for the reactions if we assume that the individual rate constants k_1 to k_4 in the reaction scheme are independent of pH, which was the case for the dyestuffs investigated earlier. Since the total concentrations, C_M, of the dyestuff is very low as compared with the concentrations of the buffer solutions used during the measurements, the reactions are pseudo-unimolecular reactions.

$$k = \frac{1}{t} \ln \frac{e_0 - e_\infty}{e_t - e_\infty} =$$

$$= \frac{k_2[H^+]^2 + k_4K_3[H^+] + k_6K_3K_4}{[H^+]^2 + K_3[H^+] + K_3K_4} + \frac{k_1K_1[H^+] + k_3 + k_5[OH^-]}{K_1[H^+] + 1} \quad (9)$$

where k is the rate constant of the total reactions.

In strong acid solutions, pH $\leq$ 1, it is possible to approximate (9) to

$$k = \frac{1}{t} \ln \frac{e_0 - e_\infty}{e_t - e_\infty} = k_1 \cdot \frac{K_1[H^+]}{1 + K_1(H^+]} + k_2 \quad (10)$$

In strong alkaline solutions we can aproximate (9) to

$$k = k_3 + k_6 + k_5[OH^-] \quad (11)$$

Between these two extreme approximations we can make a smaller approximation of (9) in the pH-range 4—8.

$$k = \frac{k_4K_3[H^+]}{[H^+]^2 + K_3[H^+] + K_3K_4} + k_3 \quad (12)$$

If we differentiate k with respect to $[H^+]$, we find that k has a maximum when $[H^+] = \sqrt{K_1K_4}$ — that is, the same expression as was deduced above.

If we measure the extinctions at the time $t = 0$ and at equilibrium and determine the total rate-constants for the slow reactions of a great number of solutions — obtained by mixing a dye stock solution with appropriate buffer solutions — we can determine the constants in the reaction scheme from the equations given above.

The above aproximations depend, of course, on the relative sizes of the constants; in some cases it may be necessary to carry out successive approximations.

EXPERIMENTAL

Chemicals und solutions. A commercial preparations of *Methyl Green* ("Methylgrün" from Merck) was converted into the corresponding perchlorate, which was recrystallized in water to optical constancy; beautiful green needles with a metallic lustre were obtained. Stock solutions were prepared by weighing and dissolving the perchlorate in distilled water. In the stock solutions C_M was = 4×10^{-5} M. Owing to the fact that the walls of glass vessels strongly adsorb the dyestuff, a stock solution should be stored for a weck before use. The concentration of the dye in the stock solutions then becomes constant for a few months.

Hydrochloric acid, sodium acetate, disodium hydrogen phosphate, potassium dihydrogen phosphate, boric acid, and *sodium hydroxide,* all of analytical grade, were used in the buffer solutions. *Potassium chloride* of analytical grade was added to keep the ionic strength constant (0.5 M).

Apparatus. For the spectrophotometric measurements a modified Beckman DU spectrophotometer was used. It was furnished with double, heatisolated, thermostatic systems. The internal system contained the absorbtion cells and was kept at the experimental temperature by pumping water from a thermostat through its walls. The external system was kept at 30°C in the same way. The solutions for measurement were carried

from flasks in a thermostat to the absorption cells either with pipettes, furnished with double mantles through which water from a thermostat was pumped, or with special syringes. These syringes were furnished with mechanical stoppers, making it possible to regulate and reproduce the volume of the syringes to within 0.1 %. Furthermore the syringes were furnished with diverse, heat-isolating covers and were thermostated in a special air thermostat. Separate experiments were carried out to determine the loss of heat that might occur during the few seconds taken to carry the solutions for measurement from a thermostated flask to a thermostated absorption cell. The loss was compensated for by temperating the syringes used to a temperature somewhat above that of the actual investigation. All solutions were thermostated with an accuracy of ± 0.01°C, and the temperature inside the absorption-cell house was held constant to within 0.05°C.

The determinations of $[H^+]$ were carried out titrimetrically and potentiometrically. For the potentiometric measurements a reference solution (pH = 2) having the composition 0.01 M HCl + 0.49 M KCl was used. In the present paper pH always means $-\log[H^+]$ and not $-\log a_{H^+}$. As electrodes chinhydron and platinum-plate were used for pH < 6 and platinum-black and hydrogen gas for pH > 6. The electrolytically produced hydrogen gas was led through a wash-flask with 0.5 M KCl, which was held at the same temperature as the solutions for measurement.

MEASUREMENTS AND RESULTS

In a water solution of Methyl Green the dye can only be present, for pH > 9, as a single component of those given in the protolytic scheme. At pH > 9 we only need to consider the almost insoluble carbinol. At lower pH-values we get mixtures of three or four components. This gives rise to some complications when we determine the constants as we can not determine ε_B, ε_G or e_B, e_G directly from the measured absorption curves.

We start with a very weakly buffered stock solution (pH ≈ 4.5) of the dyestuff. In such a solution the concentration of the blue form, B, is 80—90 % of the total dye concentration. The remaining constitutents are distributed among S″, S′, and C. We can neglect [G] as compared with [B], [S′], and [S″]. In such a solution we denote the molar extinction coefficient by ε'_B and the specific extinction by e'_B. From $e'_G/e_G = e'_B/e_B$ and eqn. (2) we can determine K_1 by replacing e_B by e'_B and e_G by e'_G.

Determination of K_1. A series of solutions having the composition x M HCl + $(0.5 - x)$ M KCl were quickly mixed with an equivalent volume of a dye stock-solution containing 0.5 M KCl. In most cases the mixing was carried out by injecting the thermostated buffer directly into the thermostated absorption cell in the absorption-cell house. The equilibrium $B + H^+ \rightleftharpoons G$ is reached instantaneously during the mixing, where upon the solution fades owing to the reaction $G + H_2O \rightleftharpoons S''$. By determining the fading rate and extrapolating the extinction to $t = 0$, e_0 was obtained. The measurements were carried out, as in the following, at the wavelength $\lambda = 633$ mμ, where the absorption curve for the blue component, B, has a sharp maximum and where G has very little extinction, $\varepsilon_G \ll \varepsilon_B$.

In Fig. 1 $[H^+]/(e'_B - e_0)$ is plotted against $[H^+]$. A linear relation is indicated, and from the slopes, l, and the intercepts, y, on the y-axis we can calculate K_1 according to eqn. (2). e'_B was determined from measurements on the dye stock-solution. The following results were obtained ($C_M = 1 \times 10^{-5}$ M):

Table 1. Determination of e_0, e_∞, K_2, k, and k_1 at 40° and 60°C in (HCl + KCl) solutions. $\lambda = 633$ mμ.

		Mean	66.6		0.633			32.6		3.11

40°C: $e'_B = 0.650$, $y = 0.1092$ M, $l = 1.576$, $e_G = 0.015$, $K_1 = \mathbf{14.43 \pm 0.15\ M^{-1}}$.
60°C: $e'_B = 0.665$, $y = 0.1273$ M, $l = 1.526$, $e_G = 0.010$, $K_1 = \mathbf{11.99 \pm 0.10\ M^{-1}}$.

Determination of K_2. The dye stock-solution was mixed with suitable HCl + KCl buffers. The solutions were thermostated and the equilibrium extinction, E_∞, was determined in 5 cm absorption cells. From eqn. (4) we can determine K_2 only if we know e_B (ε_B). According to later measurements ε_B was 7.75×10^4 at 40° and 7.80×10^4 at 60° in the stock solutions used. C_M was $= 1 \times 10^{-5}$ M and this gives $e_B = 0.775$ at 40° (in this case C_M was

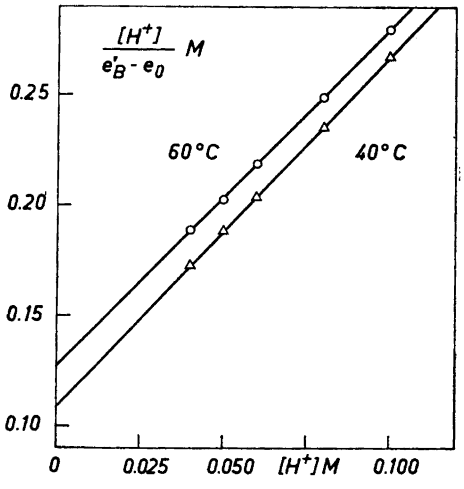

Fig. 1. [H+]/($e'_B - e_0$) as a function of [H+] for the determination of K_1 at 40° (△) and 60° (○). $\lambda = 633$ mμ, $C_M = 1 \times 10^{-5}$ M, $d = 1-2$ cm.

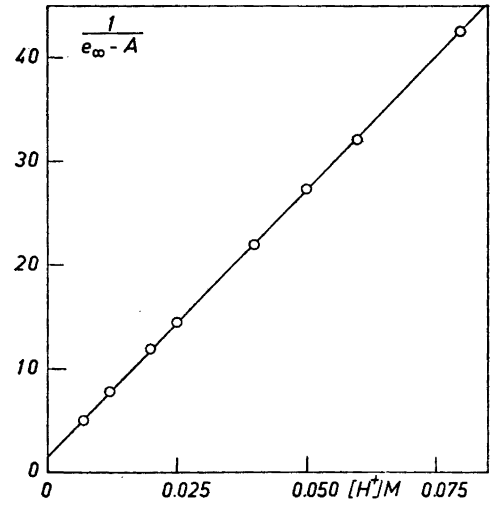

Fig. 2. $1/(e_\infty - A)$ as a function of [H+] for the determination of $K_1 + K_1K_2$ at 60°. $\lambda = 633$ mμ, $C_M = 1 \times 10^{-5}$ M, $d = 2-5$ cm.

$= 0.96 \times 10^{-5}$ M) and $e_B = 0.780$ at 60°. Table 1 gives the e_∞ obtained as well as the calculated K_2-values We get the following mean values: $K_2 = \mathbf{66.6 \pm 0.6}$ at 40° and $K_2 = \mathbf{32.6 \pm 0.3}$ at 60°C.

Because of the high reaction-rates at 60°C the value of K_1 may be uncertain For example, at this temperature the reaction $G + H_2O \rightleftharpoons S''$ has a »half-life period» of 22 seconds when $[H^+] = 0.1$ M. In order to get a further check on K_1 we have proceeded as follows. We can write eqn. (4) as

$$\frac{1}{e_\infty - A} = \frac{1 + 1/K_6}{e_B} + [H^+] \cdot \frac{K_1 + K_1K_2}{e_B} \qquad (13)$$

where $$A = \frac{K_1[H^+] \cdot e_G}{1 + 1/K_6 + [H^+](K_1 + K_1K_2)}$$

In acid solutions with $[H^+] \leq K_1$, A is a correction term which at most reaches one per cent of e_∞. In this correction term we can therefore use the values obtained for K_1 and K_2, even if K_1 is a bit uncertain. In Fig. 2 $1/(e_\infty - A)$ is plotted against $[H^+]$ for $[H^+] = 0.007-0.080$ M. A linear relation is indicated and the slope of the straight line, l, gives us $(K_1 + K_1K_2)/e_B$. From the figure we get $l = 514$ M^{-1} and as $e_B = 0.780$, we get $K_1 + K_1K_2 = 402$ M^{-1}. The above determined K-values ($K_1 = 12.0$, $K_2 = 32.6$) give $K_1 + K_1K_2 = 403$. $K_1 = 12.0$ is therefore correct.

Determination of $K_4/(K_6 + 1)$. A dye stock-solution was mixed with a series of phosphate buffers and the equilibrium extinctions were determined. In Fig. 3 $[H^+]/e_\infty$ is plotted as a function of $[H^+]$. According to eqn. (5)

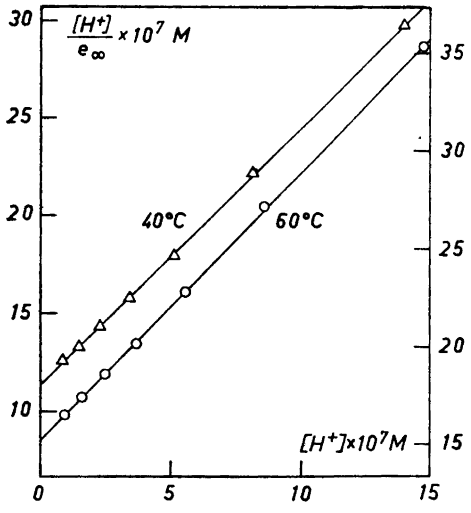

Fig. 3. $[H^+]/e_\infty$ as a function of $[H^+]$ for the determination of $K_4/(1 + K_6)$ at 40° (△, ordinate left) and 60° (○, ordinate right). $\lambda = 633$ mμ, $C_M = 1 \times 10^{-5}$ M, $d = 1$ cm.

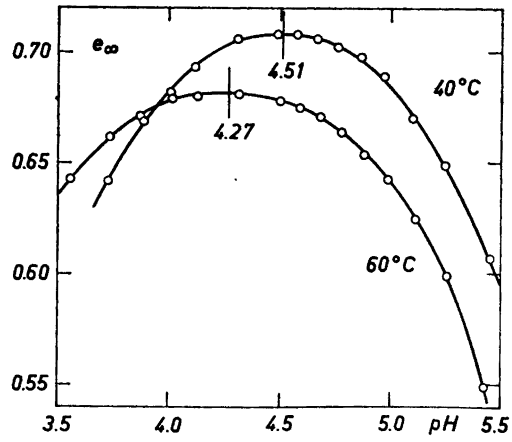

Fig. 4. e_∞ as a function of pH for the determination of K_3K_4 at 40° (upper curve) and 60°. $\lambda = 633$ mμ, $C_M = 1 \times 10^{-5}$ M, $d = 1$ cm.

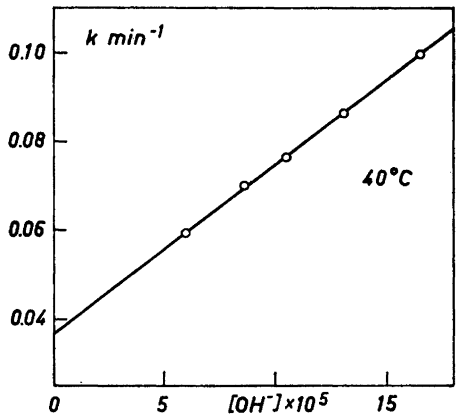

Fig. 5. k as a function of [OH⁻] for the determination of k_5 and $k_3 + k_6$ at 40°. Borate buffers. $\lambda = 633$ mμ, $C_M = 1 \times 10^{-5}$ M, $d = 1$ cm.

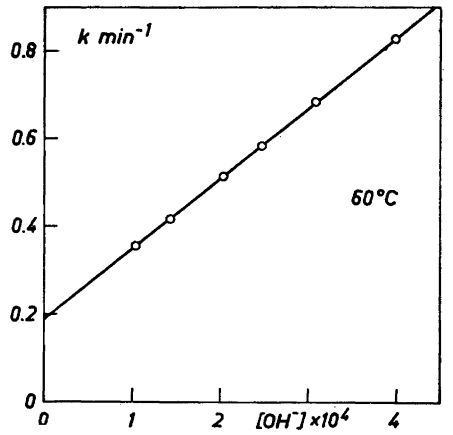

Fig. 6. k as a function of [OH⁻] for the determination of k_5 and $k_3 + k_6$ at 60°. Borate buffers. $\lambda = 633$ mμ. $C_M = 1 \times 10^{-5}$ M, $d = 1$ cm.

we get linear relations; the slopes, l, and intercepts, y, on the y-axis give $K_4/(K_6 + 1) = y/l$ or $K_4/K_6 = y \cdot e_B$. From Fig. 3 we obtain at 40°: $y = 1.130 \times 10^{-6}$ M, $l = 1.314$ and at 60°: $y = 1.517 \times 10^{-6}$ M, $l = 1.367$.

We can determine K_4/K_6 only when we know e_B or K_6. We get $\boldsymbol{K_4/(K_6 + 1) = 8.60 \times 10^{-7}}$ **M** at 40° and $\mathbf{1.110 \times 10^{-6}}$ **M** at 60°C. In these cases the dye sock-solutions used gave, according to later determinations, $e_B = 0.809$ at 40° and $e_B = 0.759$ at 60°C.

Determination of K_3K_4. The equilibrium extinctions were measured for a series of solutions with Methyl Green in acetate buffers. In Fig. 4 e_∞ is plotted as a function of pH. The maxima of the curve in this figure can bee determined (*cf.* p. 982) and we have

$$e_{\infty max} \text{ for } [H^+] = \sqrt{K_3K_4} \qquad (14)$$

From Fig. 4 we obtain $e_{\infty max}$ for pH = 4.51, $\boldsymbol{K_3K_4 = 9.55 \times 10^{-10}}$ **M²** at 40° and pH = 4.27, $\boldsymbol{K_3K_4 = 2.88 \times 10^{-9}}$ **M²** at 60°.

The remaining constants in the protolytic scheme can be determined by means of kinetic measurements and eqn. (9).

Determination of k_3, k_5, *and* k_6. In alkaline solutions eqn. (9) is approximated as $k = k_3 + k_6 + k_5[OH^-]$ (11). The fading rate of Methyl Green in borate buffers was determined for different pH-values and in Figs. 5 and 6 k is plotted against [OH⁻]. We get linear relations that, according to eqn. (11), give at 40°C (Fig. 5): $\boldsymbol{k_5 = 382 \pm 3}$ **min⁻¹ M⁻¹**, $k_3 + k_6 = 0.0367 \pm 0.0003$ min⁻¹ and at 60°C (Fig. 6): $\boldsymbol{k_5 = 1\,500 \pm 10}$ **min⁻¹ M⁻¹**, $k_3 + k_6 = 0.189 \pm 0.002$ min⁻¹. A check on k_5 at 40°C was carried out by kinetic measurement in 0.005

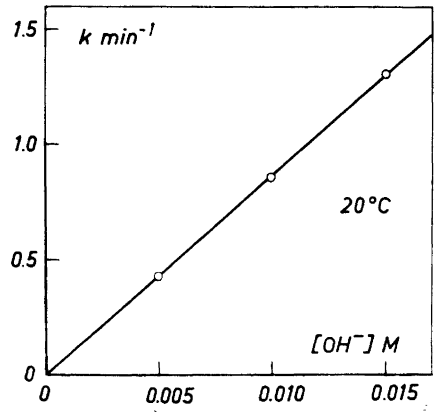

Fig. 7. k as a function of $[OH^-]$ for the determination of k_5 at 20° in NaOH + KCl. λ = 633 mμ, $C_M = 2 \times 10^{-6}$ M, d = 5 cm.

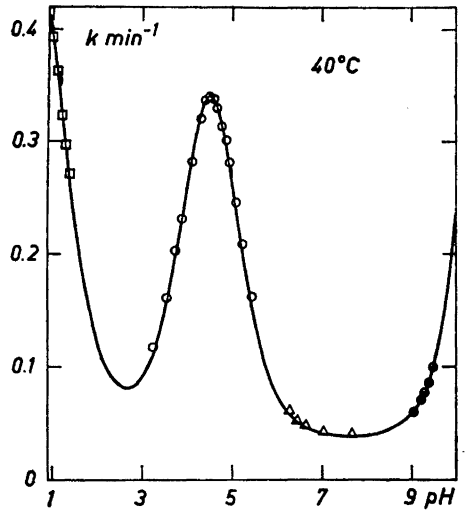

Fig. 8. k as a function of pH at 40°. The solid curve has been calculated from eqn (9). The symbols have been determined experimentally by kinetic measurements in HCl+KCl (□), acetate buffers, (○), phosphate buffers (△), and borate buffers (◒).

M NaOH + 0.495 M KCl. The experimental value for k (1.97 min^{-1}) is in good agreement with the calculated value (1.95 min^{-1}).

In previous investigations on Methyl Green (Ref.[1]) all constants in the protolytic scheme except k_5 and k_6 were determined at 20°C. Those measurements have now been completed with kinetic measurements in NaOH + KCl at 20°C. In Fig. 7, k is plotted against $[OH^-]$ and we get $k_5 = \mathbf{86.8 \pm 0.8\ min^{-1}\ M^{-1}}$ at 20°C. We can not determine $k_3 + k_6$ from the diagram as the straight line passes almost through the origin. However, k_3 has previously been determined to be 0.00621 min^{-1} (in Ref.[1], k_3 = 0.00270 since it was calculated by using ^{10}log). k_6 can be calculated in the following way. At equilibrium we have

$$k_5[OH^-][B]_\infty = k_6[C]_\infty \tag{15}$$

But $[H^+][C]_\infty = K_4[S']_\infty$ and $K_6[S']_\infty = [B]_\infty$ and therefore

$$k_6 = k_5 K_w K_6 / K_4 \tag{16}$$

From Ref.[1] we have $K_w = 1.24 \times 10^{-14}$ M^2 and $K_6/K_4 = 1.43 \times 10^6$ M^{-1} at 20°C and from (16) we get $k_6 = \mathbf{(1.54 \pm 0.06) \times 10^{-6}\ min^{-1}}$. Thus $k_6 \ll k_5$ at 20° and the same is true also at 40° and 60°C. Therefore from Fig. 5 we get $k_3 = \mathbf{0.0367 \pm 0.0003\ min^{-1}}$ at 40° and from Fig. 6, $k_3 = \mathbf{0.189 \pm 0.002\ min^{-1}}$ at 60°C.

Determination of K_3, K_4, K_6 and k_4. These constants can be calculated from eqn. (12), which may be written in the form

$$k = \left(\frac{K_3 K_6 [H^+]}{[H^+]^2 + K_3[H^+] + K_3 K_4} + 1 \right) \cdot k_3 \qquad (17)$$

as $k_3[B]_\infty = k_4[S']_\infty$ and $[B]_\infty = K_6[S']_\infty$, giving $k_4 = k_3 K_6$. We already know $K_3 K_4$, k_3, and $K_4/(K_6 + 1)$. From kinetic measurements in acetate buffers we can determine k for a series of different pH-values.

A stock solution of Methyl Green was almost decoloured by dissolving the dyestuff in 0.01 M HCl + 0.49 M KCl. The greater part of the dye was then transformed into colourless S″ owing to the reactions $B + H^+ + H_2O \rightleftharpoons G + H_2O \rightleftharpoons S''$. This partially decoloured solution was quickly mixed with suitable acetate buffers and the rate, k, was determined. k is the rate at which the blue colour is restored owing to the reactions $S'' \rightleftharpoons S' + H^+ \rightleftharpoons B + H^+ + H_2O$. k was plotted against pH, and then different values of K_6 were tried in eqn. (17).

If we fix K_6 we can determine K_3 and K_4. For every value of K_6 we get a curve from eqn. (17). The value of K_6 was chosen so that the curve calculated from eqn. (17) coincides best with the experimentally found k-values.

In Fig. 8 the k-values, obtained from measurements in acetate buffers at 40°C (circles), are plotted against pH. The solid curve was calculated from eqn. (9). By magnification of the central part of Fig. 8 we find that a curve drawn through the experimental points has a maximum at pH = 4.51, where $[H^+] = \sqrt{K_3 K_4}$. Thus we get the same value of $K_3 K_4$ from the kinetic measurements as from the extinction equilibrium measurements (Fig. 4). The same agreement was also obtained at 60°C. The results were:

at 40°C: $k_{max} = 0.340$ min^{-1} for pH = 4.51, $K_6 = \mathbf{16.0 \pm 0.2}$, $K_3 = \mathbf{(6.54 \pm 0.10) \times 10^{-5}}$ M, $K_4 = \mathbf{(1.46 \pm 0.02) \times 10^{-5}}$ M, $k_4 = \mathbf{0.587 + 0.015}$ min^{-1}.
at 60°C: $k_{max} = 1.118$ min^{-1} for pH = 4.27, $K_6 = \mathbf{27.5 \pm 0.3}$, $K_3 = \mathbf{(9.13 \pm 0.15) \times 10^{-5}}$ M, $K_4 = \mathbf{(3.16 \pm 0.05) \times 10^{-5}}$ M, $k_4 = \mathbf{5.20 \pm 0.10}$ min^{-1}.

Determination of k_6. The ionic product of water, K_w, was determined by measurements with a platinum-hydrogen gas electrode in solutions of the type x M NaOH + $(0.5 - x)$ M KCl, where $x = 0.01$ and 0.02. K_w was found to be 5.21×10^{-14} M^2 at 40° and 1.83×10^{-13} M^2 at 60°C. Then k_6 was obtained from $k_6 = k_5 K_w K_6 / K_4$. $k_6 = \mathbf{(2.18 \pm 0.06) \times 10^{-5}}$ min^{-1} at 40° and $k_6 = \mathbf{(2.39 \pm 0.06) \times 10^{-4}}$ min^{-1} at 60°C.

Determination of k_1 and k_2. The fading rates of the solutions were measured in the experiments giving the K_1-values. In Figs. 9 and 10, $2 + \log(e_t - e_\infty)$ is plotted against the time t. From the intercepts on the ordinate axes the e_0-values were calculated. The e_0-values are tabulated in Table 1, which also contains the complex rate-constants, k, and the k_1-values calculated from eqn. (9). k_2 is obtained from the equations $k_1[G]_\infty = k_2[S'']_\infty$ and $K_2[G]_\infty = [S'']_\infty$, which give $k_2 = k_1/K_2$. The following k-values were obtained: $k_1 = \mathbf{0.633 \pm 0.010}$ min^{-1}, $k_2 = \mathbf{0.00950 \pm 0.00020}$ min^{-1} at 40° and $k_1 = \mathbf{3.11 \pm 0.02}$ min^{-1}, $k_2 = \mathbf{0.0954 \pm 0.0015}$ min^{-1} at 60°C.

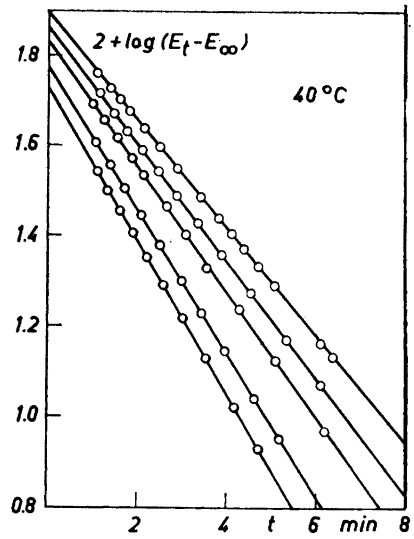

Fig. 9. $2 + \log(E_t - E_\infty)$ as a function of t for the determination of e_0, k_1, and k_2 at 40°. From above [H+] = 0.10, 0.08, 0.06, 0.05, and 0.04 M. λ = 633 mμ, $C_M = 1 \times 10^{-5}$ M, d = 2 cm.

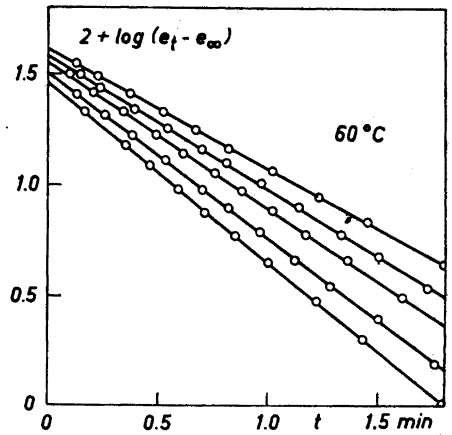

Fig. 10. $2 + \log(e_t - e_\infty)$ as a function of t for the determination of e_0, k_1, and k_2 at 60°. From above [H+] = 0.10, 0.08, 0.06, 0.05, and 0.04 M. λ = 633 mμ. $C_M = 1 \times 10^{-5}$ M, d = 1 cm.

From Fig. 10 we see that it is possible to carry out careful kinetic measurements by means of a manual recording of the extinctions and times even when the "half-life periods" of the reactions are as short as 20 seconds.

In Fig. 8 the experimentally obtained k-values at 40°C are plotted against pH in the pH-interval 1—10. The solid curve was calculated from eqn. (9) by using the values of the constants given above.

Thus all of the constants in the protolytic scheme have been determined. As a check we can use the relation $K_1K_2K_3K_6 = 1$ (by definition). Experimentally we get $K_1K_2K_3K_6 = 0.98$ at 40° and $K_1K_2K_3K_6 = 1.00$ at 60°C. The previous measurements at 20°C gave $K_1K_2K_3K_6 = 1.06$, but the measuring methods and precision have been improved since that time.

At higher temperatures we do not have the same difficulties with the adsorption on the walls of flasks and absorption cells or the precipitation of the almost insoluble carbinol as at 20°C. The most exact measurements were probably carried out at 60°C as the precautions to keep the solutions at the correct temperature in all operations were most rigorous. The reproducibility was very good at 60°C and the greatest uncertainly probably lies in the absolute determination of the temperature inside the absorption-cell house.

A strict, objective error calculation can hardly be performed on such complicated systems as those of the present investigation. The error limits given are therefore based partly on the writer's subjective view gained through many years of work with the same apparatus. The reproducibility of a single

Table 2. The temperature influence on the dissociation and hydration constants. A_K = mean temp.coeff./degree.

Table 3. Reaction-rate constants at 20°, 40°, and 60°C and "apparent" energies of activation.

	20°C	40°C	60°C	ΔE 40°-20° kcal	ΔE 60°-40° kcal
k_1 min^{-1}	0.124	0.633	3.11	14.9	16.5
$k_2 \times 10^3$ min^{-1}	0.943	9.50	95.4	21.1	23.9
$k_3 \times 10^2$ min^{-1}	0.621	3.67	18.9	16.2	17.0
$k_4 \times 10^1$ min^{-1}	0.575	5.87	52.0	21.2	22.6
k_5 M^{-1} min^{-1}	86.8	382	1 500	13.5	14.2
$k_6 \times 10^5$ min^{-1}	0.154	2.18	23.9	24.2	24.8

measurement is in certain cases greater than the absolute accuracy we can obtain through a whole series of measurements.

DISCUSSION

The protolytic scheme that was previously formulated for basic triphenylmethane dyes on the basis of measurements at 20°C thus proves to be valid even if the temperature is raised up to 60°C. Raising the temperature has the effect of displacing the equilibriums towards the coloured, dehydrated forms. Consequently the values of the rate constants k_2, k_4, and k_6 increase with the temperature considerably more than k_1, k_3, and k_5. The dissociation constants increase with the temperature if they are defined as acid constants — that is, as K_3, K_4, and $1/K_1$.

In Tables 2 and 3 are given all of the constants obtained at 20°, 40°, and 60°C. We can not calculate true reaction heats, nor can we say how specific solvent effects influence the different constants. The dielectric constant, viscosity, and association of water change with temperature and influence the activity factors in a way that is difficult to calculate for undiluted solutions. We may note that the effect of the temperature on the acid dissociation constants K_3 and $1/K_1$ is small — that is, on the average, 0.8 % and 1.4 % per degree, respectively, and somewhat greater for K_4, namely 4.0 % per degree, on the average. For the hydration constants K_2 and K_6 the temperature coefficients are, on the average, 3.6 % and 2 % per degree, respectively, in the interval 20°—60°C. The temperature coefficients A in Table 2 are calculated from $K_{60°} = K_{20°} \cdot A^{40}$. The accuracy of the constants determined hardly permits

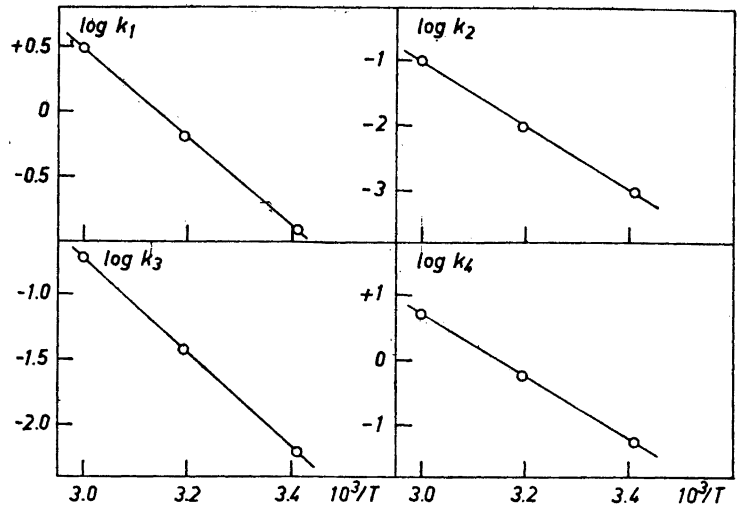

Fig. 11. log k_1, log k_2, log k_3, and log k_6 plotted against $1/T$.

us to decide whether the temperature coefficients are constant or not within the temperature interval investigated.

The rate constants for 20°, 40°, and 60°C are given in Table 3. We can not determine, in the present investigation, the different contributions to the energy of activation and thereby the true energies and entropies of activation. Therefore, the "apparent" energy of activation, ΔE, was only calculated from the Arrhenius equation

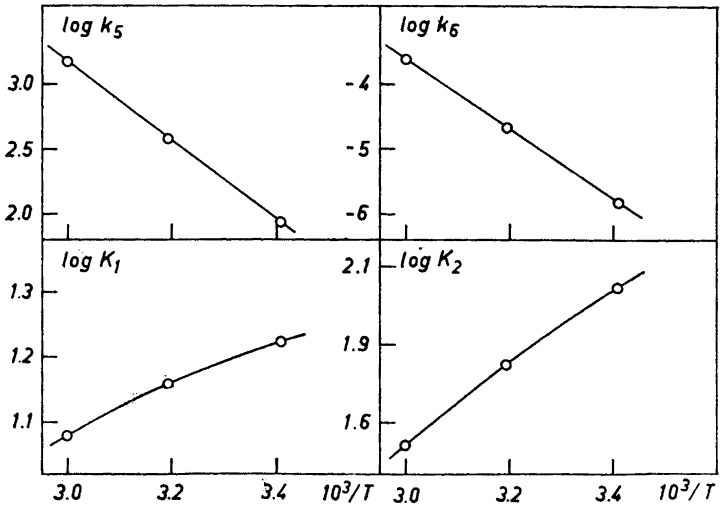

Fig. 12. log k_5, log k_6, log K_1, and log K_2 plotted against $1/T$.

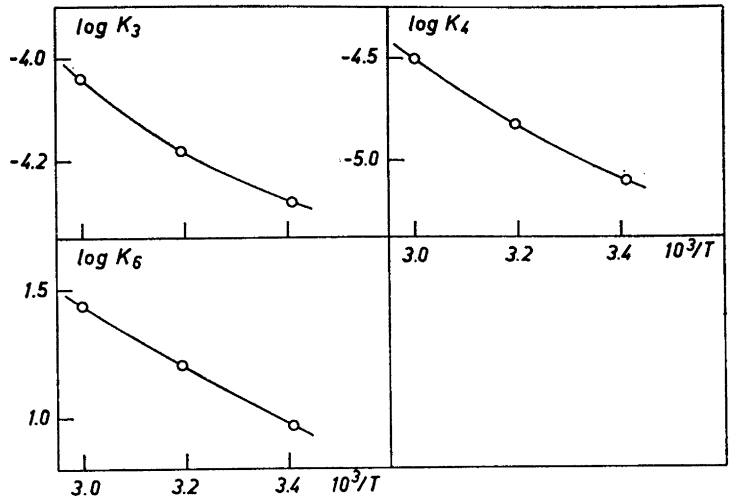

Fig. 13. log K_3, log K_4, and log K_6 plotted against $1/T$.

$$\ln \frac{k_{T''}}{k_{T'}} = \frac{\Delta E}{R} \left(\frac{T'' - T'}{T'T''} \right)$$

ΔE is not constant in the interval 20°—60°C. Table 3 contains the ΔE obtained for the intervals 20°—40°C and 40°—60°C, if it is assumed that ΔE is constant within each of these intervals.

From the table we see that ΔE is 0.7—2.7 kcal higher at 50°C than at 30°C.

In Figs. 11—13 log K; or log k; are plotted against $1/T$. For the rate constants k_1 to k_6 we get almost straight lines, but in each of the small diagrams the middle point lies somewhat below the indicated straight line. This also shows the difference in ΔE at 50° and 30°C. For the remaining constants the small diagrams show curved lines.

A Spectroscopic Study of Some Acceptor-Donor Systems

MARGARETA ZACKRISSON and KARL INGE ALDÉN

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The liquidus curves have been studied for the systems $BiCl_3$—$POCl_3$, $AsCl_3$—$(CH_3)_2CO$ and $SbCl_3$—$(CH_3)_2CO$. One compound has been found in each system: $BiCl_3 \cdot 2POCl_3$, $AsCl_3 \cdot (CH_3)_2CO$ and $SbCl_3 \cdot 2(CH_3)_2CO$.

Infrared and Raman spectra of the three systems have been investigated. The infrared spectra of the following compounds have been studied: $SbCl_3 \cdot (CH_3)_3PO$, $SbCl_3 \cdot 2(CH_3)_3PO$, $SbCl_5 \cdot (CH_3)_3PO$, $5HgCl_2 \cdot 2(CH_3)_3PO$, $HgCl_2 \cdot (CH_3)_3PO$ and $2HgCl_2 \cdot (C_2H_5)_2S$.

The relative acceptor strengths of the acceptor molecules $SbCl_3$, $SbCl_5$ and $HgCl_2$ with $(CH_3)_3PO$ as donor molecule have been measured. The results are briefly discussed.

A preceding paper [1] dealt with a study of molecular interaction with phosphoryl chloride. It was there suggested that the interaction in the systems $AsCl_3$—$POCl_3$ and $SbCl_3$—$POCl_3$ was a dipole-dipole interaction, caused by favourable charge distribution. Phosphoryl chloride is however known to function as a donor molecule [2] and $AsCl_3$ and $SbCl_3$ are possible acceptor molecules.

$SnCl_4$ and $SbCl_5$ were given as examples of acceptor molecules which give adduct formation with $POCl_3$ by acceptor-donor reactions. In those cases the acceptor molecules change their spectra as can be expected from the change in their coordination and symmetry. It was suggested that intermediate cases could possibly also exist.

It was also assumed that the magnitude of the shift of the symmetrical phosphoryl bond vibration frequency could be a rough measure of the acceptor strength if the acceptor molecules compared are under similar conditions.

In order to obtain a better foundation for a discussion of those problems we decided to study some more acceptor-donor systems.

For systems with melting points lower than room temperature it was possible to obtain Raman spectra at every composition. The systems containing compounds with higher melting points have been studied by infrared spectroscopy in the spectral range 2—35 μ. Unfortunately the lower frequencies of the acceptor molecules are not situated in this range.

As it is difficult to avoid moisture during infrared absorption measurements it was preferred to study compounds stable in air.

EXPERIMENTAL

Chemicals. $AsCl_3$, $POCl_3$, $(CH_3)_2CO$ and $(C_2H_5)_2S$ were purified by distillation (B. p. 129°, 105°, 92° and 57°C). $SbCl_5$ was distilled at reduced pressure. $SbCl_3$ was purified by sublimation. $HgCl_2$, Merck *pro analysi*, was not further purified. $(CH_3)_3PO$ and its addition compounds were prepared as described earlier [3]. Anhydrous $BiCl_3$ was prepared from $BiCl_3 \cdot H_2O$, Mallinkrodt analytical reagent, according to Inorganic Syntheses [4]. $2HgCl_2 \cdot (C_2H_5)_2S$ was precipitated from alcoholic solutions of the components.

Spectroscopic measurements. The Raman spectra were obtained photographically as described earlier [1] (in the institute of Physical Chemistry). The infrared spectra were recorded on a Perkin-Elmer Model 21 Spectrophotometer equipped with NaCl and CsBr prisms (in the institute of Biochemistry). The spectra were run with the solutions in thin layers and the solids dispersed in Nujol between NaCl plates in the range 2—15 μ and between TlBr—TlI plates in the range 15—35 μ.

Phase diagrams. The liquidus curves were obtained by the same methods as described earlier [5].

Thermochemical measurements. The method used for measuring relative enthalpy changes has been described very recently [6].

THE SYSTEM $BiCl_3$—$POCl_3$

The liquidus curve (Fig. 1) has a maximum at the composition $BiCl_3 \cdot 2POCl_3$ with the melting point 37°C. The system can not be studied at higher $BiCl_3$ concentrations than 50 mole per cent by this method, because of the distillation of $POCl_3$ at the high temperature required to dissolve $BiCl_3$.

The Raman spectra are given in Fig. 2. The mixture $BiCl_3 \cdot POCl_3$ 1:2 is studied as supercooled liquid. The spectrum of $BiCl_3$ has earlier only been studied in solid state (*cf.* Kohlrausch, *Hand- und Jahrbuch der Chemischen Physik*, 9:IV, Leipzig 1943) and can therefore not be used for comparison. It differs appreciably from the spectrum of $BiCl_3$ dissolved in $POCl_3$.

The shifts of the phosphoryl chloride spectrum are very similar to those caused by $SbCl_3$ except for a splitting of the symmetrical P—Cl bond vibration frequency, 486 cm^{-1}, not observed with $SbCl_3$.

The lowest frequency of $BiCl_3$ shows an obvious continuous shift.

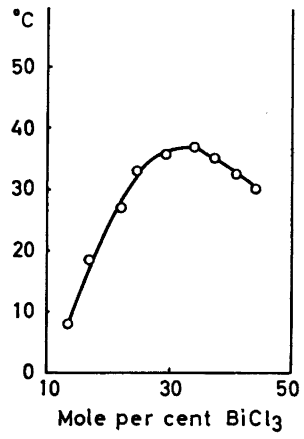

Fig. 1. Liquidus curve for the system $BiCl_3$—$POCl_3$.

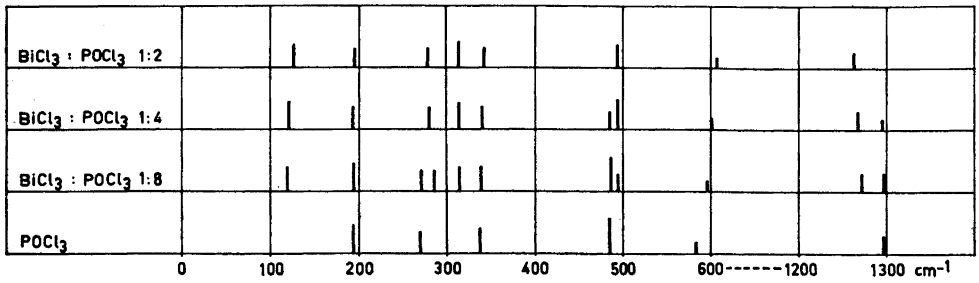

Fig. 2. Raman spectra of the system $BiCl_3-POCl_3$.

THE SYSTEMS $AsCl_3-(CH_3)_2CO$ AND $SbCl_3-(CH_3)_2CO$

The liquidus curves (Figs. 3 a and b) have maxima at the compositions $AsCl_3\cdot(CH_3)_2CO$ and $SbCl_3\cdot 2(CH_3)_2CO$ with melting points $-35°$ and $-24°C$. The tendency of $AsCl_3$ to form 1:1 compounds and of $SbCl_3$ to form 1:2 compounds has been observed before [7]. Studies in the whole range were prevented by supercooling. The reaction vessels were cooled during the measurements. At room temperature a reaction begins in both cases and the liquids darken. (The reaction is probably a condensation of acetone molecules catalysed by the metal halides.)

As the reaction is more rapid in solutions of $AsCl_3$, Raman spectra could not be obtained but the infrared spectra could be recorded.

The solutions of $SbCl_3$ gave a rather dark background in the Raman spectra. The spectrum of the composition 1:1 could not be measured with sufficient accuracy.

The only detectable shifts referred to the spectrum of pure acetone are a decrease of the carbonyl bond stretching frequency and an increase of the antisymmetrical C—C chain vibration frequency. (Only these two frequencies of the acetone spectrum have been listed in Table 1 a.) The same effects were found earlier in addition compounds with acetone as donor and BF_3[8] and $AlBr_3$[9] as acceptors. They are also comparable with the decrease of the phosphoryl band and the increase of the P—Cl bands in the mixtures studied with $POCl_3$.

The infrared spectrum of $AsCl_3$ does not change appreciably.

For comparison the Raman spectra of $SbCl_3$ are tabulated together with the Raman spectra of $SbCl_3$ in $POCl_3$ (Table 1 b).

THE SYSTEM $SbCl_3-(CH_3)_3PO$

The liquidus curve [3] shows maxima at the compositions $SbCl_3\cdot(CH_3)_3PO$ and $SbCl_3\cdot 2(CH_3)_3PO$.

The infrared spectrum of $(CH_3)_3PO$ was investigated by Daasch *et al.*[10] (2—22 μ). We have taken the infrared spectra in the range 2—35 μ and our results are in fairly good agreement with the earlier ones. We have not found

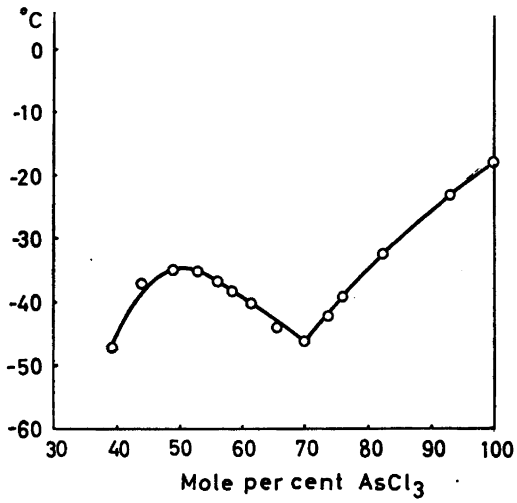

Fig. 3a. Liquidus curve for the system $AsCl_3-(CH_3)_2CO$.

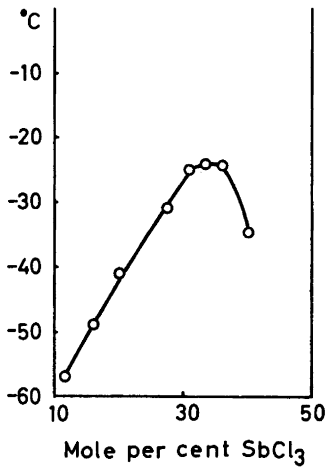

Fig. 3b. Liquidus curve for the system $SbCl_3-(CH_3)_2CO$.

the weak peak at 671 cm^{-1} in the pure substance but it appears in some of the addition compounds. Two new peaks were found in the range 15—35 μ.

(The previous investigators found peaks at 3 410 and 1 672 cm^{-1} and explained the former as arising from reaction with moisture because the substance was very hygroscopic. The latter peak could have the same cause or be a combination frequency. We have also found peaks in those regions but these

disappeared completely after adduct formation. This certainly should be the result if the absorption arose from hydrate formation.)

Antimony trichloride has not been investigated by infrared spectroscopy earlier and an attempt failed because the substance reacted with the TlBr—TlI plates. For comparison, the spectrum of $SbCl_3 \cdot 2POCl_3$ was taken. When the peaks from $POCl_3$ were excluded, two peaks remained.

The results from the infrared study are given in Table 2. The phosphoryl bond vibration frequency 1 158 cm^{-1} is split and shows a larger shift in the 1:1 compound than in the 1:2 compound. (The largest shift is 131 cm^{-1}.) In the range 15—35 μ the two addition compounds show great diversities. The spectra of the components seem not to be very much changed in the 1:2 compound but the 1:1 compound shows new absorption peaks.

THE SYSTEM $SbCl_5$—$(CH_3)_3PO$

Relative enthalpy measurements (carried out in 0.4 M ethylene chloride solutions in mole ratio 1:1) show that $SbCl_5$ is a much stronger acceptor than $SbCl_3$ with $(CH_3)_3PO$ as donor molecule.

The results in Table 2 show that the phosphoryl bond frequency has decreased 126 cm^{-1}. The shift is thus in the same order of magnitude as in the compound $SbCl_3 \cdot (CH_3)_3PO$ in spite of the large difference between enthalpy changes of the two reactions.

The infrared spectrum of $SbCl_5$ has not been investigated, which prevents any comparisons.

THE SYSTEM $HgCl_2-(CH_3)_3PO$

Thermochemical measurements carried out in 0.4 M alcoholic solutions show that $SbCl_3$ gives larger enthalpy change than $HgCl_2$ in reacting with $(CH_3)_3PO$ in the mole ratio 1:1.

Two addition compounds are found in this system: $5HgCl_2 \cdot 2(CH_3)_3PO$ and $HgCl_2 \cdot (CH_3)_3PO$.[3] The symmetrical phosphoryl bond vibration frequency has the largest shift in the 5:2 compound but not as large as in the compounds with $SbCl_3$.

$HgCl_2$ has only one infrared active band in the range studied, the antisymmetrical Hg—Cl bond stretching frequency at 371 cm^{-1}. This frequency decreases at adduct formation (*e.g.* with 1,4-dioxane [11] and $(C_6H_5)_3PO$[3]). One of the two compounds gives a more complicated spectrum in this case too.

THE SYSTEM $HgCl_2-(C_2H_5)_2S$

Two compounds in this system have been described earlier [12]: $2HgCl_2 \cdot (C_2H_5)_2S$ and $HgCl_2 \cdot (C_2H_5)_2S$. The 1:1 compound, however, loses ethyl sulfide on grinding [13] and the infrared spectra could not be taken. The ethyl sulfide has no frequency lower than 640 cm^{-1} but the 1:1 adduct has two low frequencies, 343 and 311 cm^{-1} (*cf.* $HgCl_2$, 371 cm^{-1}).

DISCUSSION

1. The spectra of the systems $BiCl_3-POCl_3$, $AsCl_3-(CH_3)_2CO$ and $SbCl_3-(CH_3)_2CO$ show a similar type of interaction, as found earlier [1] in the systems $AsCl_3-POCl_3$ and $SbCl_3-POCl_3$ but the changes in the spectra of the acceptor molecules are larger.

2. In the systems $SbCl_3-(CH_3)_3PO$ and $HgCl_2-(CH_3)_3PO$, where two compounds have been studied in each system, one of the compounds does not change its spectrum very much but the other shows new peaks in the region where the acceptor molecules absorb.

According to the introduction, the spectra of $SbCl_3 \cdot 2(CH_3)_3PO$ and $HgCl_2 \cdot (CH_3)_3PO$ indicate weak dipole-dipole interaction and $SbCl_3 \cdot (CH_3)_3PO$ and $5HgCl_2 \cdot 2(CH_3)_3PO$ strong interaction caused by acceptor-donor reactions. It is however hard to understand how the acceptor-donor bonds could be of different nature in the same acceptor-donor systems.

The present results do not seem to supply evidence for the suggestion that two different types of interaction exist. They indicate rather that the acceptor-donor bond strengths change continuously from weak to strong interaction.

3. The fact that the spectrum of $2HgCl_2 \cdot (C_2H_5)_2S$ has two low frequencies is in agreement with the structure of this compound, very recently determined by X-ray work at this institute [13]. This structure determination shows that the two $HgCl_2$ molecules are bonded in different ways. One of them has changed its coordination and structure by the adduct formation, the other is rather unchanged.

The new peaks in the spectra of the compounds $5HgCl_2 \cdot 2(CH_3)_3PO$ and $SbCl_3 \cdot (CH_3)_3PO$ may also indicate that the acceptor molecules are bonded in different ways or that the chlorine atoms of the same acceptor molecule are not equivalent after the adduct formation. Such structures have already been found: $3HgBr_2 \cdot 2Bu_3As$[14] and $(TiCl_4 \cdot POCl_3)_2$[15].

4. Sheldon and Tyree [16] have interpreted the shifts obtained in the P—O stretching frequency by adduct formation as due to a weakening of the P—O bond. It must be assumed that the magnitude of these shifts is a measure of the weakening if the donor molecule is the same. It might naturally be supposed that this weakening is closely related to the bond strength between the donor and the acceptor atom.

The two adducts $SbCl_3 \cdot (CH_3)_3PO$ and $SbCl_5 \cdot (CH_3)_3PO$ give about the same shifts of the P—O bond frequency but very large difference between the enthalpy changes of the reactions.

If the above assumptions are correct, these results show that the enthalpy changes at the acceptor-donor reactions are not only dependent on the acceptor-donor bond formation but also very much on the gain or loss of energy involved in the structural changes of the acceptor molecules. The reservation in the earlier paper [1], that the magnitude of the shift as a measure of relative acceptor strengths can only be used "if the acceptor molecules to be compared are under very similar conditions" is thus shown to be well justified.

A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged.

We wish to thank Prof. S. Claesson, Prof. G. Hägg and Prof. A. Tiselius for all the facilities put at our disposal and Dr. I. Lindqvist for suggesting the problem and his stimulating interest during the work.

We also wish to thank Dr. P. O. Kinell for valuable discussions and Mr. S. Johansson for helpful assistance.

The Crystal Structure of Re_3B

B. ARONSSON, (Miss) MAGGIE BÄCKMAN and S. RUNDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structure of Re_3B has been determined by powder and single crystal methods. The dimensions of the orthorhombic unit cell are $a = 2.890$ Å, $b = 9.313$ Å and $c = 7.258$ Å ($\pm$ 0.05 %). There are four formula units in the elementary cell, and the space-group is *Cmcm*. The twelve rhenium atoms are situated in an eightfold position 8 (*f*) ($y = 0.1345$, $z = 0.0620$) and a fourfold position 4 (*c*) ($y = 0.4262$). From space considerations it has been concluded that the boron atoms are also situated in a 4 (*c*) position ($y \simeq 0.744$).

It was reported in an earlier communication [1] that three intermediate phases had been identified in arcmelted rhenium-boron alloys. Two of the phases, Re_7B_3 and ReB_3, were characterized by crystal structure data and the lattice parameters (l.p.) of the third phase, having the approximate composition Re_3B, were also given. As it was possible to obtain single crystals of Re_3B we decided to try to solve its structure with the principal aim of determining interatomic distances with moderate accuracy.

EXPERIMENTAL

Alloys were prepared by arcmelting rhenium (claimed purity *ca.* 99.8 %, obtained from Heraeus, Hanau, Germany) and boron (claimed purity 99.0–99.7 %, kindly donated by Borax Consolidated, London). No chemical analyses were carried out and all reported compositions are nominal.

Powder photographs using Cu$K\alpha$- and Cr$K\alpha_1$-radiation were taken with cameras of the Guinier type (the internal standard was silicon, $a = 5.4306$ Å) and single crystal photographs around the *a*-axis with an ordinary Weissenberg camera using Mo$K\alpha$ radiation. The multiple film technique was employed with thin iron foil between the films. Intensities were estimated by comparison with an intensity scale. Fourier series and structure factor calculations were made on the electronic digital computer BESK with programs (available at BESK) devised by M. Edstrand and Åsbrink *et al.*[2] In the structure factor calculations the atomic scattering factors were approximated to the following expression:

$$f_i = A_i.\exp\left(-\frac{a_i}{\lambda^2}\sin^2\Theta\right) + B_i.\exp\left(-\frac{b_i}{\lambda^2}\sin^2\Theta\right) + C_i.\exp\left(-\frac{c_i}{\lambda^2}\sin^2\Theta\right) + D_i$$

Appel [3] has calculated the following constants on the basis of the scattering factor tables by Tomas and Umeda [4] (rhenium) and Ibers [5] (boron)

	A	B	C	a	b	c
Rhenium	25.854	28.303	19.925	0.170	1.885	15.175
Boron	1.644	0.406	2.878	0.6069	4.5832	33.019

The real part of the dispersion correction, (D_i in the above expression), for rhenium was taken from the table of Dauben and Templeton[6].

RESULTS

The powder photographs of alloys in the composition range $ReB_{0.2}$—$ReB_{0.4}$ indicated the existence of the two-phase regions Re + Re_3B and Re_3B + Re_7B_3. The powder photograph of an alloy with the nominal composition Re_3B is given in Table 1. It may be seen in the table that nearly all lines can be indexed with a centred orthorhombic cell (a = 2.890 Å, b = 9.313 Å, c = 7.258 Å, ± 0.05 %). The origin of the three non-indexed weak lines is unknown. No l.p. variations greater than 0.1 % for Re_3B have been observed indicating that its range of homogeneity is narrow. It is concluded from the unit cell dimensions that there are twelve rhenium atoms in the elementary cell. The calculated X-ray density of Re_3B is 19.4 g/cm³.

Single crystal photographs confirmed that Re_3B is orthorhombic and since *hkl* reflexions only appeared for $h + k = 2n$ and *h0l* reflexions for $l = 2n$, the most probable space groups are *Cmcm*, *C2cm* and $Cmc2_1$. Apart from the normal decrease the distribution of intensities in the 0*kl* and 2*kl* zones was

similar indicating that the rhenium atoms are situated in planes perpendicular to the a-axis with a spacing of $a/2$. With this distribution of atoms the $|F|^2$ values for $0kl$ and $1kl$ reflexions were sufficient for the evaluation of the Patterson section $P(0yz)$. The position and heights of all peaks in $P(0yz)$ could be explained if the rhenium atoms were assumed to occupy one 8(f) and one 4(c) position in the space group *Cmcm*. This space-group was thus chosen and during the refinement of the structure nothing was found to contradict this choice.

The y and z coordinates of the rhenium atoms were refined from successive $\varrho_o(yz)$ and $\varrho_c(yz)$ electron density projections. In the final stages of refinement the F_o values of the four strongest reflexions, which were obviously weakened because of extinction, were replaced by the corresponding F_c values. Using an empirical isotropic temperature factor ($B = 0.07_8$ Å^2) the final R value of 96 observed $0kl$ reflexions (omitting the four strongest reflexions) was 12.4 % *. This relatively high value for the discrepancy index results from no corrections having been made for absorption, and that extinction has been only partly, and extremely crudely, corrected for. It should be noted that because of these errors the uncertainty of the atomic parameters is probably greater than as indicated by the standard deviations calculated from Cruickshank's [7] formula and given below.

From space considerations it is evident that the boron atoms must be located in a 4(c) position with $y \simeq 0.744$. As no boron parameter can be obtained from the experimental data we have chosen it so that the six shortest rhenium-boron atomic distances are equal.

The resulting atomic parameters are:

8 Re_I in 8(f) : $y = 0.1345 \pm 0.0003$, $z = 0.0620 \pm 0.0003$
4 Re_{II} in 4(c) : $y = 0.4262 \pm 0.0003$
4 B in 4(c) : $y = 0.744$

A projection of the structure on the bc-plane is shown in Fig. 1. The structure is very simple and may be described as being built up of triangular prisms of rhenium atoms at the centres of which are boron atoms. The rhenium skeleton is densely packed and the average values of the shortest rhenium-rhenium distances (see Table 2) are only just greater than the shortest rhenium-rhenium distance in elementary rhenium, *i.e.* 2.74 Å. Parallel to {023} the rhenium atoms form slightly corrugated densely packed planes which consist of interconnected triangles and squares.

The boron atoms have the same environment as in a number of other borides [8]: *i.e.* six neighbours at the corners of a triangular prism and three more remote neighbours outside the rectangular faces of the prism. (The two boron neighbours outside the triangular faces of the prism are probably too distant (2.89 Å) for consideration). The average of the six shortest metal-boron distances is 2.23 Å in good agreement with the value of 2.24 Å which is the sum of the normal atomic radius of boron (0.87 Å according to Kiessling [9]) and the atomic radius of rhenium for coordination number 12 (1.37 Å). In Re_3B, as

in the borides of the Th_7Fe_3 and cementite structures [1,9], all the nine neighbours of boron are metal atoms. The coordinations around the metal atoms are also similar in these three closely related structures.

Analysis of Human Bile Lipids by Gas-Liquid Chromatography

ROLF BLOMSTRAND

From the Swedish Medical Research Council, Unit for Biochemical Research Related to Atherosclerosis, University of Lund, Sweden

The lipids of human gall-bladder bile have been fractionated by silicic acid chromatography and the fatty acid composition of the different lipid classes determined with gas-liquid chromatography.

Small amounts of cholesterol ester was found to be present in human bile. Lecithin is the predominating phospholipid.

Palmitic, stearic, oleic and linoleic acid were the major fatty acids in the bile lecithin indicating the presence of several different lecithins in human bile.

An asymmetric or specific positioning of the long chain fatty acids in the bile lecithin is described.

Relatively little is known about the composition of the fatty acids of human bile [1,2]. The major reason for this has been the lack of adequate methods for fatty acid analysis especially on a microscale. From preliminary studies with gas-liquid chromatography (GLC) of the total fatty acids of human bile, it appeared that the fatty acids constituted a complex mixture of several components. The studies were extended with separation of the total bile lipids of human gall-bladder on silicic acid and determination of the fatty acids of the different lipids by GLC.

Furthermore the lecithin of human gall-bladder bile was purified and the fatty acid distribution determined after enzymatic degradation. The results indicate the presence of several different lecithins in the human bile.

METHODS

Bile was collected by aspiration into methanol from the gall-bladder of patients without hepatobiliary disease and also from patients with gall-stones and biliary tract disease (to be published [3]). The bile was extracted with chloroform: methanol 2:1 according to Folch-Lee [4] as modified by Borgström [5]. The total lipids of the bile was subjected to chromatography on silicic acid in order to obtain a neutral fat nonesterified fatty acid fraction and a phospholipid fraction. Then the nonesterified fatty acids were removed from the neutral fat by extraction with alkaline 50 % ethanol. The neutral fat fraction (glycerides, cholesterol and cholesterol esters) were subjected to chromatography on silicic

Table 1. Composition of human gall-bladder bile lipids after separation on silicic acid. The bile was collected from subjects without known biliary disease.

Subject	Total Fat mg/100 ml	Cholesterol mg/100 ml		Fatty acids as percentage of total fatty acids			
		Free	Total	Cholesterol ester FA	Non-esterified FA	Glyceride FA	Phospholipid FA
1	700	110	116	0.7	3.3	4.0	92.0

3	902	125	135	0.9	6.1	7.0	86.0

acid for separation of cholesterol esters and a triglyceride-cholesterol fraction [6]. The phospholipids were fractionated by the procedure described by Hanahan *et al.*[5]

The progress of the chromatographic separation was followed by phosphorus assay and paper chromatography. Lecithin constituted the predominating phospholipid but small amounts of unidentified phospholipids were also found. The lecithins were rechromatographed on aluminium oxide [8]. Enzymatic degradation was performed with phospholipase A *(Crotalus adamanteus* [9]). The hydrolysis products were fractionated on silicic acid in order to separate free fatty acids and unchanged lecithin and lysolecithin. The fatty acids of the lysolecithin were obtained after hydrolysis, acidification and extraction with light petroleum.

GLC was carried out essentially as described by James and Martin [10] using an Argon Pye Chromatograph with an ionization chamber as detector. As stationary phase a polar polyester (LHC–R–296) [11] was used in the ratio Celite: stationary phase 4:1. For identification the samples were also chromatographed at 240°C with silicone oil (Dow Corning High vacuum grease) as stationary phase in the ratio Celite: stationary phase 4:1. The experimental procedures used otherwise have been described earlier [12].

Fatty acids are numbered as suggested by Insull *et al.*[13] The category 20–22? refers to a group of unsaturated fatty acids whose structure has yet to be determined.

RESULTS

The determination of the different lipid components of human gallbladder bile are summarized in Table 1. The phospholipid fatty acids constitute the major components of the total fatty acids of human bile. Small amounts of triglyceride and cholesterol ester fatty acids are also present, as well as small amounts of non-esterified fatty acids. Similar results have been obtained by Nakayama and Johnston [14].

Results of determinations of several components of human biliary fatty acids are summarized in Table 2. Three characteristic fatty acid patterns are found in the phospholipids, triglycerides and cholesterol esters of the human bile. Palmitic, oleic and linoleic acids are the major constituents in all of these lipid classes. Arachidonic acid is also found in significant amounts in the triglycerides, non-esterified fatty acids and the phospholipid fatty acids.

Palmitic acid represents approximately 13 % of the total fatty acids of bile glycerides, 57 % of the cholesterol ester fatty acids and 28 % of the phospholipid total fatty acids. Stearic acid occurs to the extent of 1.8, 9.8 and 3.0 % of the triglyceride, cholesterol ester and phospholipid fatty acids, respectively.

Table 2. The fatty acid composition of the different lipid classes of human gall-bladder bile. The fatty acids were determined with gas-liquid chromatography and the values given are the percentage of the fatty acid methyl esters. The component fatty acids are also designated by a dual symbol giving chain length and number of double bonds. The sum of each column is less than 100 % because of trace amounts of unusual fatty acids detected were omitted from the final tabulation.

Fatty acid		Tri-glyceride FA %	Non-esterified FA %	Cholesterol FA %	Phospho-lipid FA %
Saturated					
Lauric	12:0				1.0
Myristic	14:0	0.9	0.5	0.9	3.2

	20—22 ?	9.5	5.3	0.7	8.0

The results of this study indicate that palmitic acid occurred as a predominating fatty acid component in the lysolecithin formed from bile lecithin by phospholipase A (Table 3). As with palmitic acid stearic acid was also found predominantly in the lysolecithin formed. Small amounts of lauric, myristic, pentadecanoic, palmitoleic, oleic and linoleic acid were also found in the lysolecithin, together with some unidentified fatty acids with 13 carbon atoms. In the fatty acids released by phospholipase A from the bile lecithin the polyunsaturated fatty acid predominated together with oleic acid. Palmitic acid was also present together with trace amounts of myristic and stearic acid. Linoleic acid was the major polyunsaturated fatty acid but linolenic and arachidonic acid were also found in significant amounts. There were two C_{20-22} fatty acids occurring on the gas-chromatogram of this fraction of the lecithin. The exact nature of these fatty acids has not yet been determined.

From the results of this investigation it is evident that there are several lecithins present in the human bile. Recently new evidence has been provided on the position of saturated and unsaturated fatty acid esters in purified egg lecithin [19]. For this reason a brief discussion on the distribution of the fatty acids of the bile lecithin will be given.

It has been known for several years [15] that snake venom phospholipase A liberates mainly unsaturated fatty acids from lecithins containing saturated and unsaturated fatty acids. In recent years it has also been shown that

Table 3. The fatty acid composition of human gall-bladder bile lecithin. The lecithin was purified by silicic acid column chromatography and hydrolysed with phospholipase A. The fatty acids released by the action of phospholipase A and the fatty acids of the lycolecithin were determined by gas-liquid chromatography.

Fatty acid		Percentage of total fatty acids in respective positions of human bile lecithin	
		Fatty acids freed from bile lecithin by phospholipase A	Fatty acids obtained after hydrolysis of lysolecithin
Saturated			
Lauric	12:0		0.9
	13: ?		5.3
Myristic	14:0	0.6	5.3
Pentadecanoic	15:0	0.7	5.4
Palmitic	16:0	17.1	53.8
Heptadecanoic	17:0	0.7	
Stearic	18:0	1.5	6.5
Mono-unsaturated			
Palmitoleic	16:1	6.4	7.9
Oleic	18:1	25.9	6.6
Di-unsaturated			
Linoleic	18:2	32.1	1.7
Poly-unsaturated			
Linolenic	18:3	1.5	
Arachidonic	20:4	5.1	
	20—22 ?	6.0	

both di-saturated and di-unsaturated lecithins are equally well hydrolysed to yield one mole of fatty acid and the corresponding lysolecithin [8]. It was therefore concluded [16] that the action of the enzyme was directed toward one particular ester group C-1 (α) or C-2 (β) in the lecithin molecule. Hanahan [17] using permanganate oxidation procedures, concluded that the snake venom phospholipase A specifically hydrolyzed the ester linkage in the C-1 (α) position. Several investigators [9] have confirmed this finding, but conflicting results [18] have also been obtained, suggesting the lack of specificity of phospholipase A. Tattrie [19] has with a new approach investigated the position of the fatty acids on lecithin. Purified egg lecithin was enzymatically hydrolysed to the corresponding mixture of α-β-diglycerides with lecithinase D. Myristic acid was incorporated into the α position of the diglyceride and the resulting triglycerides were hydrolysed with pancreatic lipase, which specifically cleaves fatty acids from the α and α' positions. Only saturated fatty acids were freed by the pancreatic lipase, proving that the saturated fatty acids occupy the α position of egg lecithin. Since snake venom phospholipase removes only unsaturated fatty acid from egg lecithin the site of hydrolysis must be at the β position of the lecithin according to Tattrie [19]. The specificity of phospholipase A therefore seems well established, although further work is necessary to definitely settle the question about the site of attack of the enzyme.

From the analysis shown in Table 3 it is apparent that there is an asymmetric distribution of the fatty acids in the human bile lecithin. According to the discussion above the predominant ester pattern should be saturated fatty acids in the C-1 (α) ester position and unsaturated fatty acids in the C-2 (β) ester position. However, both C-1 and C-2 position contained saturated and unsaturated fatty acids.

COMMENTS

Bile contains lecithins and small amounts of soaps to which an accessory function in emulsification has been ascribed [20]. The complex picture of the fatty acid composition of the different lipid classes of the bile and especially the complex composition of the fatty acids of the lecithins makes further studies on the metabolism of the biliary fatty acids necessary. There are very little information available on the influence of the dietary fat on the fatty acid pattern of the bile. Furthermore it will be of interest to investigate how the fatty acid pattern of bile might vary in biliary disease.

Recently Borgström [5] has analysed the fatty acid composition of human bile lecithin with the aid of paper chromatography. He found only oleic acid released form the lecithin by phospholipase A and palmitic acid in the lysolecithin. The difference in results has to be found in the different material and methods used for the analyses.

This work is part of investigations supported by the *Swedish Medical Research Council.*

The Crystal Structure of Pd_3Si

B. ARONSSON and (Miss) ANNA NYLUND

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structure of Pd_3Si has been established from single crystal data. The space-group is *Pnma*, and there are four formula units in the elementary cell which has the dimensions $a = 5.735$ Å, $b = 7.555$ Å, and $c = 5.260$ Å. The twelve palladium atoms are situated in 8 (*d*) ($x = 0.1810$, $y = 0.0508$, $z = 0.3217$) and 4 (*c*) ($x = 0.0053$, $z = 0.9036$) positions, and the silicon atoms occupy a 4 (*c*) position ($x = 0.897_6$, $z = 0.469_6$). Pd_3Si, thus, crystallizes in the cementite ($D0_{11}$) structure. The atomic arrangement in Pd_3Si is compared with those in isomorphous phases.

The crystal structures of some platinum metal silicides are being investigated at this Institute principally to elucidate the coordination around the silicon atom. In this paper we present the results of the structure determination of Pd_3Si and also comment on the Pd–Si system. The crystal structures of Ru_2Si and Rh_2Si have been reported in a preliminary note [1] and will be dealt with more comprehensively in a future paper.

EXPERIMENTAL

Palladium powder, (claimed purity 99.9 %, containing traces of Fe, Cu, and Ag), was obtained from Heraeus (Hanau, Germany), and silicon powder (claimed purity 99.9 %) from Pechiney (Paris). Because of the comparatively low melting points of Pd–Si alloys the samples were easily prepared by sintering (or melting) mixtures of the elements in evacuated and sealed silica tubes. No chemical analyses were made.

Powder photographs were taken in cameras of the Guinier type with CaF_2 ($a = 5.4630$ Å) as an internal standard. Two small single crystals ($\sim 0.3 \times 0.04 \times 0.04$ mm) were picked out of an alloy which had the nominal composition $PdSi_{0.3}$ and had been annealed for two days at 900°C. (This temperature is slightly below the reported peritectic temperature [2,3] of 950°C.) Weissenberg photographs were taken around the *b*- and *c*-axes using Mo$K\alpha$ radiation and the multiple film technique with thin iron foil between the films. Fourier projections were calculated with Beevers-Lipson strips and on the digital electronic computer BESK with a program (available at BESK) devised by M. Edstrand. The structure factors were also computed on BESK with a program devised by Åsbrink *et al.*[4] The following expression was used for the scattering factors:

$$f_i = A_i \cdot \exp(-\frac{a_i}{\lambda^2}\sin^2\Theta) + B_i \cdot \exp(-\frac{b_i}{\lambda^2}\sin^2\Theta) + C_i \cdot \exp(-\frac{c_i}{\lambda^2}\sin^2\Theta)$$

Table 1. Crystallographic constants of the well established silicides of palladium.

	Structure type	Lattice parameters (in Å)	References
Pd_3Si	$D0_{11}$	$a = 5.735$, $b = 7.555$, $c = 5.260$	(This work)
Pd_2Si	$C22$	$a = 6.497$, $c = 3.432$ (silicon-poor) *	» »
	(revised)	$a = 6.528$, $c = 3.437$ (silicon-rich) *	» »
PdSi	B 31	$a = 5.599$, $b = 3.381$, $c = 6.133$	10

* These values refer to alloys sintered at 800°C.

Appel [7] has calculated the following constants on the basis of the scattering factor tables by Tomas and Umeda [5] (palladium) and Tomiie and Stam [6] (silicon).

	A	B	C	a	b	c
Pd	15.865	17.354	12.288	0.233	2.565	19.828
Si	2.8315	6.8065	4.3870	0.3235	2.2965	51.770

RESULTS

The Pd—Si system: We confirmed the existence of the earlier reported phases Pd_3Si[2,8], Pd_2Si[9,2,8], and PdSi [10,8]. In alloys containing more than 75 atom per cent palladium and annealed at 600—700°C, two additional intermediate phases were observed. The thermal effects observed by Lebeau and Jolibois [11] around 600°C in palladium alloys may have been caused by the formation of one of these phases, rather than by the supercooling of the peritectic formation of Pd_3Si as suggested in the handbook by Hansen [3]. The phase Pd_9Si_4 reported by Rao and Winterhager [8] could not be detected in our alloys.

The structures and unit cells of Pd_3Si, Pd_2Si and PdSi are given in Table 1. Schubert and Pfisterer [10] found the structure of PdSi to be of the B 31 type. Schubert and Anderko [2] found that Pd_2Si and Fe_2P were isomorphous and, as pointed out by Rundqvist and Jellinek [12], it is very probable that Pd_2Si, similarly to Fe_2P crystallizes in the revised C 22 structure. The lattice parameters (1. p.) of Pd_3Si, (the existence of this phase was first established by Schubert and Anderko[2]), were determined by the present authors. A typical powder photograph of an alloy with the nominal composition $PdSi_{0.3}$ is given in Table 2. We could not detect any significant (*i.e.* > 0.05 %) l.p. variations for Pd_3Si. The l.p's of Pd_2Si, however, were considerably larger in silicon-rich alloys than in silicon-poor — indicating that Pd_2Si has an appreciable range of homogeneity.

The structure of Pd_3Si: The single crystal photographs showed that Pd_3Si is orthorhombic. Since $0kl$ reflexions were only observed for $k + l = 2n$ and $hk0$ reflexions only for $h = 2n$, the possible space-groups are $Pnma$ and $Pn2_1a$. From the unit cell dimensions of Pd_3Si it was thought likely that it had the cementite structure [13-15] (space group $Pnma$). With this assumption the

Table 2. Powder photograph with Cr$K\alpha$ radiation of an alloy with the nominal composition $PdSi_{0.3}$. (The alloy was sintered at 780°C for five days.)

$\varrho(xz)$ and $\varrho(xy)$ projections were found to contain the expected number of maxima on an even background. We concluded that Pd_3Si was isomorphous with cementite ($D0_{11}$-type).

The atomic parameters were refined from successive difference syntheses until the backshift corrections were less than half the estimated standard deviations.

In both projections the observed intensities of the strongest reflexions were weaker than the calculated values, probably mainly due to secondary extinction. In the last stages of refinement the F_o-values of these reflexions, (which are marked with an asterisk in Table 3), were replaced by the corresponding F_c-values. Empirical isotropic temperature factors with $B = 0.55_9$ Å^2 ($h0l$-zone), and $B = 0.44_7$ Å^2 ($hk0$-zone) were applied. No corrections were made for absorption or dispersion.

The final parameters and standard deviations estimated using Cruickshank's formula [16] are as follows (space-group *Pnma*):

8 Pd_I in 8 (d) : $x = 0.1810 \pm 0.0002$, $y = 0.0508 \pm 0.0003$, $z = 0.3217 \pm 0.0002$
4 Pd_{II} in 4 (c) : $x = 0.0053 \pm 0.0005$, $z = 0.9036 \pm 0.0005$
4 Si in 4 (c) : $x = 0.897_6 \pm 0.002_0$, $z = 0.469_6 \pm 0.002_0$

Observed and calculated structure factors are given in Table 3. The final R values are 6.1 % for the 94 observed $h0l$ reflexions, and 8.2 % for the 66

observed *hk*0 reflexions (excluding the reflexions marked with an asterisk in Table 3).

Interatomic distances are given in Table 4. The standard deviations of Pd—Pd distances are less than 0.01 Å, whereas the standard deviations of Pd—Si distances vary between 0.00_8 Å and 0.01_4 Å.

COMPARISON WITH ISOMORPHOUS PHASES

The cementite structure, that has been comprehensively described in earlier papers [14,15,17–19], consists of a rather densely packed framework of the larger atoms, (*A* atoms in the following), which each coordinate 11 or 12 similar atoms. The smaller atoms (*X* atoms) are situated in holes in the *A* atom skeleton; the *X* atoms have nine *A* neighbours, but no contact with atoms of their own kind. As seen from Table 5, the environment of the *X* atom is somewhat different in the four cementite-type phases which have been studied in detail, namely Fe_3C [15], Ni_3B[19], Pd_3Si and $NiAl_3$[17]. In Fe_3C and Ni_3B, six *A* neighbours of the *X* atom are much closer than the other three, and form a triangular prism around the *X* atom. In Pd_3Si two of the *A* neighbours outside the 'prism' are brought nearer to the *X* atom whereas the ninth neighbour is still so remote

Table 5. Interatomic distances between unlike atoms in cementite phases (A_3X).

	Distances between the *X* atom and *A* atoms at the corners of the prism			Distances between the *X* atom and *A* atoms outside the prism		Ref.
	A atoms in 4 (*c*)	*A* atoms in 8 (*d*)	Average	A atoms in 8 (*d*)	*A* atom in 4 (*c*)	
Fe_3C	1.85, 1.89	2.06 (2), 2.15 (2)	2.03	2.31 (2)	3.02	15
Ni_3B	2.02, 2.09	1.99 (2), 2.07 (2)	2.04	2.30 (2)	2.59	19
Pd_3Si	2.35, 2.37	2.35 (2), 2.48 (2)	2.39	2.56 (2)	3.05	this work
$NiAl_3$	2.44, 2.46	2.42 (2), 2.44 (2)	2.44	2.52 (2)	2.72	17

that it probably need not be taken into consideration when discussing the environment of the X atom. The eight shortest Pd—Si distances in Pd_3Si are not very different and the polyhedron of palladium atoms around the silicon atom seems to be best described as distorted archimedian antiprism. Finally, in $NiAl_3$, the nine Ni—Al distances do not differ by more than 12 % and probably all represent bonding contacts.

It is also evident from Table 5 that a contraction of the $A-X$ distances takes place in the series Fe_3C, Ni_3B, Pd_3Si and $NiAl_3$. The difference (in Å) between the average of the six shortest $A-X$ distances and the A radii for coordination number 12, ($r_{Fe} = 1.27$, $r_{Ni} = 1.24$, $r_{Pd} = 1.37$ and $r_{Al} = 1.43$) are 0.76, 0.80, 1.02, and 1.01 in Fe_3C, Ni_3B, Pd_3Si, and $NiAl_3$, respectively. Thus, whereas the figures for Fe_3C and Ni_3B agree well with those found in other carbides and borides, the figure for Pd_3Si is considerably smaller than in previously studied silicides. In $NiAl_3$, as in a number of phases between aluminium and transition metals [18], the distances between unlike atoms are very short.

Acknowledgements. We wish to thank professor G. Hägg for his kind interest and valuable comments on the manuscript. Thanks are also due to Dr. S. Rundqvist for helpful discussions. Financial support from the *Air Force Office of Scientific Research of the Air Research and Development Command, United States Air Force*, through its European Office under Contract No. AF 61(052)-40 and from the *Swedish Technical Science Research Council* is gratefully acknowledged.

Enzymic Hydrolysis of Cysteamine S-Phosphate by Human Erythrocytes

STIG ÅKERFELDT

Biochemistry Section, Eastern Pennsylvania Psychiatric Institute, Philadelphia, Pennsylvania, U.S.A.

Human erythrocytes are shown to contain an enzyme that hydrolyzes cysteamine S-phosphate into cysteamine and *ortho*-phosphate. The enzyme activity, which is absent from serum and practically absent from isolated stromata, is optimal at pH 5.7 (5.5—6.0). Some kinetic data are presented.

In addition to the wellknown biological significance of several compounds containing phosphorylated amino and hydroxyl groups, some recently published reports support the possibility that also compounds containing phosphorylated thiol groups may take part in cellular processes.

The first demonstration of an enzymic S-phosphorylation of a biologically important thiol seems to have been performed by Feuer and Wollemann [1–5] in a study of the formation of "active acetate". Using an enzyme system of brain these authors could show that a phosphate group from adenosine-5'-triphosphate is enzymically transferred to the thiol group of coenzyme A forming coenzyme A S-phosphate *. Smith *et al.* have recently obtained evidence for the formation of this compound in *E. coli* [7,8].

An earlier suggestion by Lynen *et al.*[9,10] and by Lipmann and collaborators [11] that coenzyme A S-phosphate or coenzyme A S-diphosphate should be formed as an intermediary step in the formation of "active acetate" in yeast, was later abandoned [12] (*cf.* Refs. [13–15]).

Reports by other workers indicated that coenzyme A might possibly be S-phosphorylated by enzymes in rabbit liver [16] and spinach [17].

Recent studies by Brahms and Kakol [18] give support to the view that thiol groups of myosin are phosphorylated during the action of this protein on adenosine-5'-triphosphate (*cf.* Ref.[19]).

A study of the properties and possible biological significance of S-phosphorylated thiols of a small molecular size is subject to investigations by the present author. As a part of this program a method was recently developed for

* Regarding the nomenclature applied to these compounds see footnote in Ref.[6]

the preparation of various substances belonging to this category [6,20]. A sodium salt of a compound with some structural relationship to coenzyme A S-phosphate, cysteamine S-phosphoric acid (S-(2-aminoethyl) phosphorothioic acid), was thus prepared [6], and the present paper deals with the enzymic hydrolysis of this compound.

Enzymes capable of hydrolyzing cysteine S-phosphate (prepared from cysteine and $POCl_3$) and the phosphorothioate ion have been demonstrated to be present in rat kidney extracts [21,22]. Forrest *et al.*[23] have desribed a "thionophosphatase", present in *Aspergillus oryzae*, which is capable of hydrolyzing certain aromatic esters of phosphorothioic acid. Feuer and Wollemann [4] have demonstrated the enzymic hydrolysis of coenzyme A S-phosphate by a brain extract.

RESULTS AND DISCUSSION

Preliminary investigations showed that when cysteamine S-phosphate is incubated with RBC * at pH 5—6 it is rapidly converted into *ortho*-phosphate and a nitroprussiate positive substance, which was eventually identified as cysteamine (2-aminoethanethiol).

The factor in RBC responsible for the observed hydrolysis was heat sensitive. Complete inactivation occurred in 5 min at 50°C, pH 5.6, or in 5 min 60°C, pH 6.3. About 50% of the activity remained after exposure to 50°C for 5 min at pH 6.3. (The heating took place in the presence of EDTA (25 mM) and remaining activities were determined at the pH's indicated).

Two obvious possibilities present themselves for a quantitative study of the hydrolysis of cysteamine S-phosphate: a) determination of the thiol released, or b) determination of the *ortho*-phosphate formed. Pilot experiments indicated that the thiol group of cysteamine is rapidly oxidized by RBC (even under nitrogen). The reaction could therefore not be followed quantitatively by the appearence of the thiol without special precautions beeing taken.

On the other hand, the acid lability of the remaining cysteamine S-phosphate (*cf.* Fig. 2) made a determination of liberated *ortho*-phosphate impractical.

It was found, however, that added cysteamine could be quantitatively recovered after incubation with RBC if the incubation took place in the presence of EDTA and the pH was simultaneously kept below *ca.* 8. The enzyme responsible for hydrolysis of cysteamine S-phosphate was not inhibited by EDTA in the concentrations necessary for quantitative recovery of cysteamine. This fact made a determination of the liberated thiol convenient for a quantitative study of the reaction, and this method was therefore adopted.

An investigation of the effect of pH (Fig. 1) showed activity maximum at about pH 5.7 (5.5—6.0). Consequently all subsequent experiments were performed at this pH. It is evident from Fig. 1 that the enzyme is only moderately active at physiological pH. Although recovery of liberated cysteamine is not quite quantitative after incubation at pH's above *ca.* 8, it could be concluded from the experiments performed, that only negligible activity remains between pH 8 and 9.

* Abbreviations used: RBC = human erythrocytes; EDTA = (ethylenedinitrilo)tetraacetic acid.

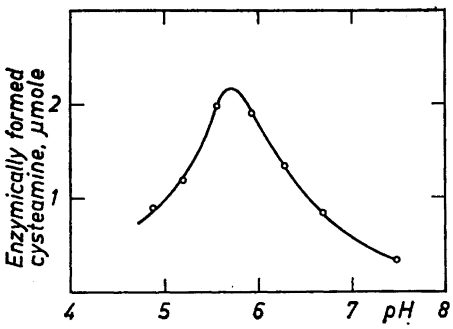

Fig. 1. Effect of pH on the enzymic hydrolysis of cysteamine S-phosphate. Test system (2 ml final volume): cysteamine S-phosphate 9.0 µmole, EDTA 100 µmole, citrate buffer 170 µmole, hemolyzed RBC corresponding to 0.25 ml of packed cells. pH of the complete system as indicated. Blanks contained water instead of RBC. Incubation: 30 min at 37°C. The presented curve constitutes of the average result from 6 different blood samples (individual variations were found to be small).

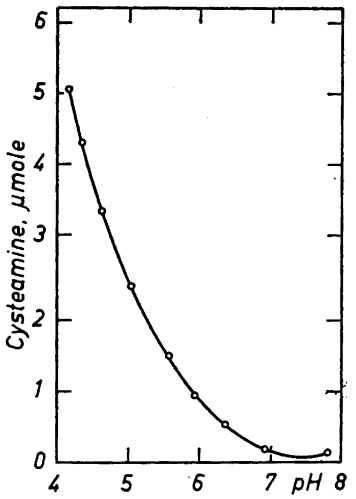

Fig. 2. The spontaneous hydrolysis of cysteamine S-phosphate at 37°C and 30 min as a function of pH. Test system (2 ml final volume): cysteamine S-phosphate 9.0 µmole, EDTA 100 µmole and citrate buffer 170 µmole. pH of the complete system as indicated.

For comparison, the spontaneous hydrolysis of cysteamine S-phosphate in the pH range in question is represented in Fig. 2. As was demonstrated earlier [6] acid hydrolysis of the compound yields the same products as the enzymic hydrolysis. This is in contrast to the behaviour of cysteine S-phosphate as prepared by Binkley [21]. Acid hydrolysis of this compound was reported to give phosphorothioate, ammonia and (presumably) pyruvate. Hydrolysis by rat kidney extract, however, gave cysteine and *ortho*-phosphate. On the other hand, acid hydrolysis of coenzyme A S-phosphate yields coenzyme A and *ortho*-phosphate [4,8].

The enzymic hydrolysis of cysteamine S-phosphate by erythrocytes follows zero order kinetics during the time of the experiments described. The enzyme activity, which seems to be primarily present in the interior of the cells *, is completely absent in serum (Table 1). Substrate saturation of the enzyme is reached at a concentration close to 5 mM (Fig. 3). Higher substrate concentrations are slightly inhibitory.

The effect of enzyme concentration is described in Fig. 4.

* The small activity found in stromata can possibly be attributed to coprecipitation by proteins from the interior of the cells during the preparation of stromata.

Table 1. Enzyme activity of various blood fractions. Test system (2 ml final volume): cysteamine S-phosphate 9.0 μmole, EDTA 100 μmole, citrate buffer 170 μmole. Furthermore the respective solutions contained: hemolyzed RBC corresponding to 0.25 ml of packed cells; stromata corresponding to 0.25 ml of packed cells and serum 0.25 ml. Blanks contained water instead of blood fraction. Final pH 5.6. Incubation: 30 min at 37°C.

Blood fraction	Enzymically formed cysteamine, μmole
Hemolyzed RBC	2.0
Stromata	0.1
Serum	0.0

A phosphomonoesterase having the same optimal pH range as the enzyme described in this paper is known to be present in human erythrocytes (see, *e.g.* Ref.[24]). The previously studied enzyme is only slightly inhibited by fluoride (6—10 % inhibition observed in 10 mM fluoride as determined in RBC hemolysate [25,26]; nor is the purified enzyme markedly inhibited by fluoride [27]), and appears not to be inhibited by small concentrations of EDTA [28].

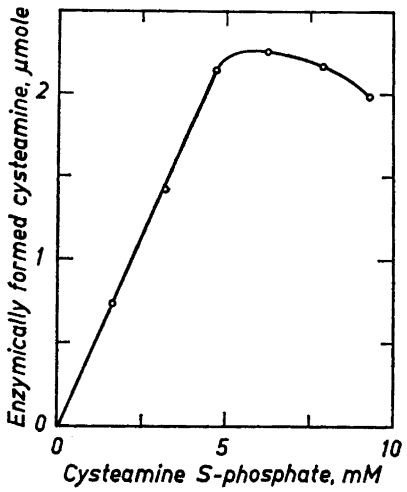

Fig. 3. Effect of cysteamine S-phosphate concentration. Test system (2 ml final volume): EDTA 100 μmole, citrate buffer 170 μmole, cysteamine S-phosphate as indicated and hemolyzed RBC corresponding to 0.25 ml of packed cells. Final pH 5.6. Blanks contained water instead of RBC. Incubation: 30 min at 37°C.

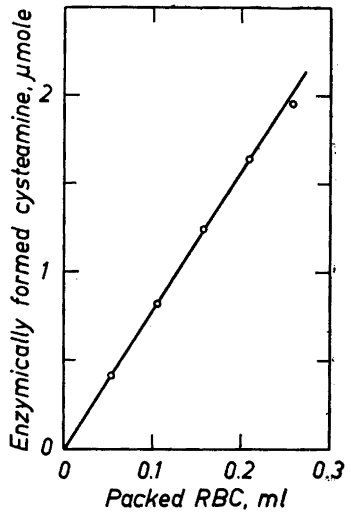

Fig. 4. Effect of enzyme concentration. Test system (2 ml final volume): cysteamine S-phosphate 9.0 μmole, EDTA 100 μmole, citrate buffer 170 μmole and hemolyzed RBC as indicated. Final pH 5.6. Incubation: 30 min at 37°C.

The enzyme hydrolyzing cysteamine S-phosphate shows similar properties, namely: a) the effect of fluoride is small (5 % inhibited by 10 mM NaF and 34 % inhibited by 30 mM NaF); b) it is not inhibited by EDTA (tested up to 75 mM).

Further comparative studies have not been carried out.

EXPERIMENTAL

Materials. Cysteamine S-phosphate was prepared as previously described [6]. RBC were washed several times with 0.9 % NaCl and stored at −20°C. They were used within seven days. The RBC were hemolyzed by thawing and subsequent addition of an equal volume of distilled water immediately before use.

Stromata were prepared at 0°C according to Herbert [29] and were suspended in 0.9 % NaCl before use.

Recovery experiments with cysteamine incubated for 30 min at 37°C with RBC showed that the thiol was quantitatively recovered when the incubation took place in the presence of 50 mM EDTA at pH's between 3 and *ca.* 8 (pH's below 3 were not tested). At pH 3−6 25 mM EDTA was generally sufficient for quantitative recovery, but since the enzyme subject to study, as mentioned, was practically unaffected by the EDTA concentration, 50 mM EDTA was used throughout the experiments.

Determination of cysteamine in the presence of cysteamine S-phosphate. To the incubation tube, containing up to 0.25 ml of hemolyzed RBC in 50 mM EDTA in a total volume of 2.0 ml, was added 1.5 ml of 10 % HPO_3. The mixture was rapidly stirred for 10 sec and 4.0 ml of a 1 M phosphate buffer of pH 7.0 was immediately added. (In order to prevent excessive hydrolysis of cysteamine S-phosphate present, the time allowed for protein precipitation by HPO_3 was kept as short as possible). After stirring the mixture was centrifuged. In the resulting solution of pH *ca.* 6, remaining cysteamine S-phosphate was found to be hydrolyzed at a rate of less than 0.05 % per min at 25°C. The over-all hydrolysis of cysteamine S-phosphate during this procedure was less than 2 %.

Cysteamine was finally determined colorimetrically at 520 mμ with nitroprussiate according to Grunert and Phillips [30], and the results were corrected for the nitroprussiate positive substances already present in the RBC. (The recently developed method [31] employing 2-chloromercuri-6-nitrophenol * as a thiol reagent could not be utilized since this reagent catalyzes the hydrolysis of cysteamine S-phosphate [6].)

Usually the deproteinized solution was slightly colored (owing to the solubilization of some proteins by the change in pH by the addition of the buffer of pH 7.0). Thus a correction was made for the absorption of the test solution at 520 mμ without added nitroprussiate.

In each experiment, where enzyme activity was determined, a correction was made for the spontaneous hydrolysis of cysteamine S-phosphate at the pH in question.

Standardization of the colorimetric method was carried out by the use of: a) commercially available cysteamine hydrochloride, and b) cysteamine solutions obtained by acid hydrolysis of cysteamine S-phosphate. Because of the highly hygroscopic properties of commercial cysteamine and cysteamine hydrochloride, method b) gave more consistent results. However, the two methods agreed within ± 1 %.

Identification of cysteamine as a product of the enzymic hydrolysis of cysteamine S-phosphate. 50 μmole of cysteamine S-phosphate, 1 ml of hemolyzed RBC and 5 ml of 0.15 M citrate buffer, pH 5.6, were incubated at 37°C under nitrogen. A blank sample, carried through the same procedures as the test sample, contained only RBC and buffer. The reaction was stopped after 3 h by the addition of 3.5 ml 10 % trichloroacetic acid. Hydrogen sulfide or ammonia were not detected as products of the hydrolysis. After centrifugation the supernatant solution was divided into two equal parts.

* This numbering follows more closely the system adopted by *Chemical Abstracts*, than the one used previously [31].

One part was treated with iodine in methanol until no more iodine was reduced. Paper chromatography * of the resulting solution was carried out in 1-butanol:acetic acid:water, 4:1:1, and in ethanol:pyridine:water, 2:1:1. Subsequent spraying with ninhydrin and nitroprussiate-cyanide gave, as the only difference between the test and the blank, spots with positions identical with those of cystamine (2,2'-dithiobisethylamine). The spots from the blank sample were faint and did not coincide with the R_F's of cystamine. (Iodine oxidation of the samples was carried out since chromatography of cysteamine in the above solvents gives less satisfactory results than chromatography of cystamine).

The second part of the supernatant solution was made alkaline with KOH and 25 μmole of 2-chloromercuri-6-nitrophenol in 1 ml of 0.1 M NaOH were added. The resulting solution was chromatographed according to Ref.[31] using solvents No. 1 and 3. Only one thiol spot, identical in position with that of MNP-cysteamine [31], was found in this way. (Since EDTA forms a complex with 2-cloromercuri-6-nitrophenol at neutral or alkaline pH's[31], EDTA was omitted from the incubation mixture in this experiment.)

The author is indebted to Mrs. M. Gale for valuable technical assistance.

Potential Chemotherapeutics

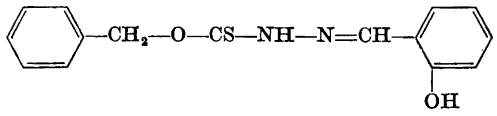
I. Hydrazine Derivatives, Structurally Related to 1-Benzoxythiocarbo-2-salicylidene Hydrazine

KURT SKAGIUS

Research Laboratories, A.B. Pharmacia, Uppsala, Sweden

Structural analogues (fortyone in all), of 1-benzoxythiocarbo-2-salicylidene hydrazine were prepared for antibacterial screening. The substances prepared are aldo- and ketohydrazones of oxycarbo-, oxythiocarbo- and dithiocarbohydrazines and their S- or N-alkylated derivatives.

In 1949 Wangel [1] published a study of some oxythiocarbohydrazides and their hydrazone derivatives. Since these compounds by analogy to the thiosemicarbazones were of interest as potential tuberculostatics, they were subjected to a bacteriologic screening procedure [2]. It was found, in continuation of this work, that the salicylaldehyde hydrazone of benzoxythiocarbohydrazide (I) showed a powerful activity against staphylococci and streptococci *in vitro*. In order to elucidate the structure-activity relation, a series of related substances were synthesized and tested against a number of microorganisms *in vitro*. The results of this investigation will be published elsewhere.



(I)

Firstly, the salicylidene residue of compound (I) was replaced by a number of aromatic aldehyde and ketone residues (Table 1), containing

a) a hydroxyl group in the 2-position of the benzene nucleus and various substituents in other positions
b) a substituted hydroxyl group in the 2-position
c) a hydroxyl group in the 4-position
d) other substituents than hydroxyl in the 2-position.

Since a hydroxyl group in the 2-position of the benzal residue seemed to be essential for the antistaphylococcal action, some benzoxythiocarbo- and benzyldithiocarbohydrazones of aldehydes and ketones, containing an aromatic hydroxyl group, an enolizable carbonyl group or an aliphatic hydroxyl group in the critical position were also prepared (Table 2).

The possible arrangements around the central carbon atom of the oxythiocarbamide group (II) is of special interest, since the action of many antibacterial agents is referred to their ability for chelate or complex formation with metal ions [3]. Substitution of the hydrogen atom in (II) with alkyl groups effectively blocks the possibility of salt formation, which would be the main contribution of the oxythiocarbohydrazide group to a chelate. Also, substitution of the sulfur atom by oxygen and the oxygen atom by sulfur or nitrogen would influence the enolizability of the hydrogen atom and the ability of chelate formation.

The N-methylated derivative of (I) was easily obtained from the sodium salt of benzoxythiocarbothioglycolic acid and salicylaldehyde methylhydrazone hydrochloride according to the method described by Wangel [1]. The S-methyl derivative was obtained by methylation of sodium benzoxythiocarbohydrazide with methyl iodide followed by hydrazone formation with salicylaldehyde. The oxycarbo- and dithiocarbohydrazides were prepared according to general principles [4,5], and the S-benzylthiocarbohydrazone from salicylidene hydrazine and S-benzylthiocarbonyl chloride, prepared from toluenethiol and phosgene.

Finally, some variations of the ester residue of the thiocarbonic acid ester grouping of (I) were carried out. These variations included the esters of 2-

phenylethanol, ethanol, and 4-pyridylmethanol. The hydrazides were prepared from hydrazine hydrate and the potassium xanthates, obtained from potassium hydroxide, carbon disulphide and the alcohol in the usual way.

EXPERIMENTAL *

Hydrazones of the various acylhydrazides were prepared by heating the acylhydrazide and the carbonyl compound in a suitable solvent (ethanol, dioxane, or acetic acid) for a few minutes (if necessary, a few drops of HCl-MeOH were added), and the mixture was left to crystallize. The precipitate formed was recrystallized from dioxane, ethanol or acetic acid. The yields were usually satisfactory (70—90 %). The procedure is illustrated by the following two examples:

3-Hydroxypicolinealdehyde benzoxythiocarbohydrazone. 310 mg (2.5 mmole) of 3-hydroxypicolinealdehyde [6] and 460 mg (2.5 mmole) of benzoxythiocarbohydrazide were dissolved in 5 ml of hot ethanol. After a few minutes crystals appeared. About 15 ml of ethanol was then added and the mixture boiled until the precipitate dissolved. The solution was treated with charcoal, filtered and allowed to cool. The crystals were filtered off and dried. After recrystallization from ethanol, 0.6 g (80 %) of colourless crystals was obtained. The colour changes to yellow-brown in sunlight. The substance begins to melt at 168°C, after which it slowly solidifies and does not melt again below 200°C.

Benzoxythiocarbohydrazone of 3-methyl-3-hydroxybutanone-2. 9.1 g (50 mmole) of benzoxythiocarbohydrazide and 5.1 g (50 mmole) of the ketone were dissolved in about 50 ml of ethanol. The hot solution was treated with charcoal, filtered and the filtrate allowed to cool. After scratching, a slightly cream-coloured precipitate appeared. The crystals were filtered off and dried. After recrystallization from ethanol they melted at 136.5—138°C. Yield 9.8 g (74 %).

Benzylthiocarbonyl chloride. Under external cooling, 50 ml of a 12.5 % solution of phosgene in toluene was stirred in a three-necked flask and a mixture of 5 ml of pyridine and 7.5 ml of toluenethiol in about 50 ml of toluene was added. After one hour the pyridinium chloride was filtered off and the filtrate fractionated *in vacuo*. 8.0 g (70 %) of benzylthiocarbonyl chloride was obtained as an oil, which boiled at 122—123°/10 mm Hg.

1-(S-Benzylthiocarbonyl)-2-salicylidenehydrazine. 5 g (37 mmole) of salicylidenehydrazine were dissolved in dioxane and a solution of 7 g (37 mmole) of benzylthiocarbonyl chloride in ether was added. A colourless precipitate was immediately formed. A solution of 3 ml of pyridine in ether was added and the mixture heated on a steam bath for a few minutes. After cooling, the mixture was poured into water and the ether was allowed to escape. The precipitate was filtered off and dried. 9.2 g (87 %) of a colourless substance was obtained which, after several recrystallizations from ethanol and benzene, melted at 181.5—183°C.

1-Benzoxythiocarbo-1-methyl-2-salicylidenehydrazine. 10 g methylhydrazine sulphate were dissolved in 100 ml of 2 N acetic acid and 40 ml of 5 N sodium hydroxide was added. The solution was heated on a water bath and 11 ml of salicylaldehyde was added with stirring. After half an hour the oily layer was separated and the water layer extracted with ether. The combined organic layers were dried with anhydrous sodium sulphate and methanolic hydrogen chloride was added. Salicylidenemethylhydrazone hydrochloride was obtained as a pale yellow precipitate, which weighed 8.4 g after drying.

5.7 g (30 mmole) of the yellow salt was mixed with 15 ml of 2 N sodium hydroxide and 50 ml of ethanol and a solution of 7.5 g of benzoxythiocarbothioglycolic acid in 15 ml of 2 N sodium hydroxide and 50 ml of water was added. The yellow solution was left at room temperature for three days. The precipitate formed was filtered off and dried. Weight 7.4 g. After repeated recrystallizations from ethanol-dioxane and dioxane-water 4.6 g of 1-benzoxythiocarbo-1-methyl-2-salicylidenehydrazine was obtained. Mp 139—141.5°C.

Potassium 4-pyridylmethylxanthate. 32.7 g (330 mmole) of 4-pyridylmethanol was dissolved in a solution of 22 g of potassium hydroxide in 120 ml of water. 20 ml of carbon

disulphide was added and the mixture was stirred at room temperature for 5 h. During the reaction the potassium salt of 4-pyridyl-methylxanthic acid precipitated. The salt was filtered off and dried. Weight 17 g. The mother liquor was concentrated *in vacuo* to about 1/5 of its original volume and chilled strongly. A further 17 g of the salt was obtained, washed with acetone and dried.

4-Pyridylmethoxythiocarbohydrazide. 17.8 g (80 mmole) of potassium pyridylmethyl-xanthate were dissolved in 30 ml of water and 5 ml of hydrazine hydrate was added. The mixture was left at room temperature for 18 h. The crystalline precipitate was filtered off, washed with water and recrystallized from ethanol. 10 g (67 %) of the hydrazide was obtained as colourless shells, which turned slightly reddish in the air. Mp 142.5—143°C. (Found: C 45.9; H 5.0; N 22.9. Calc. C 45.8; H 5.0; N 23.0.)

A Differential Oxygen Analyser

C. U. LINDERSTRØM-LANG

Danish Atomic Energy Commission, Risø, Denmark

For the determination of very small differences in oxygen content of air samples, a method based on the well known absorption of oxygen by pyrogallol was developed.

Principle: Two vessels, connected through a manometer, are filled with the two samples to be compared; the pressure difference is adjusted to zero. The oxygen is absorbed by the pyrogallol and the pressures are again compared, the pressure difference being proportional to the difference in oxygen content.

Apparatus: Fig. 1 shows a diagram of the apparatus used: The manometer M is connected on each side to a ground joint socket. The vessels carry ground joint cones that fit into the sockets. The vessels have only a 1 cm hole which gives free passage between the vessel and the manometer connection when the vessel is turned to the appropriate position. Opposite the manometer connection another glass tube is fitted to the socket. When the vessels are turned through 180°, the air samples may be introduced through these tubes (B' and B''). The manometer liquid is silicone oil (DC 200/10, d 0.94). The reading is carried out with a cathetometer. In this way pressure differences of up to *ca.* 1 cm silicone oil (—○—1 mm Hg) can be read with an accuracy of 0.01 mm silicone oil (—○— 10^{-3} mm Hg), *i.e.* 10^{-4} % of the total pressure (1 atm.).

The volume of each vessel is approximately 200 ml.

Procedure: Small double walled paper bags are made from lens paper (*ca.* 5 cm long and 0.8 cm diameter); each is filled with 1 g of ground pyrogallol. They are closed at both ends by twisting the paper and attached to a small polyethylene covered magnet (stirrer) by means of a cotton thread.

The cones are greased with Apiezon L. A magnet (stirrer) is placed in the larger section (a) of the vessel. The bag with pyrogallol is placed in the front section (b) of the vessel; ca. 15 ml 50 % (w/w) potassium hydroxide are added through a suitably bent pipette to the a-section of the vessels (see Fig. 1). These are then fitted into the sockets and the whole assembly is lowered into a temperature controlled bath.

The air samples are introduced through the outer tubes B' and B'' after evacuation of the vessels.

The vessels are turned through 180° and connected through the valves A' and A''. In order to remove carbon dioxide and to reach water vapour equilibrium the air in the vessels is stirred now and again during one hour by means of the magnet from section a of the vessel, care being taken that no drops of potassium hydroxide touch the pyrogallol bag.

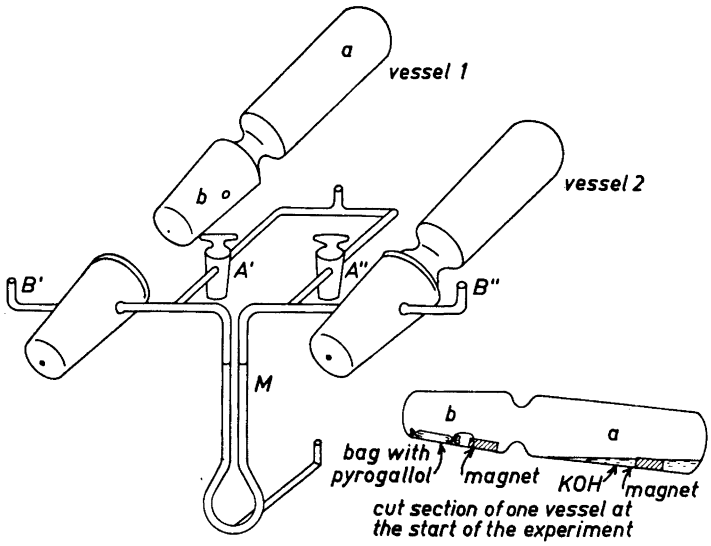

Fig. 1.

A' and A'' are closed and the apparatus is left for at least half an hour during which a small change in manometer reading usually 0—0.05 mm silicone oil may take place.

The vessels are cautiously closed by rotating them until the holes are at the top (tongs are used in order not to heat the samples).

The pyrogallol bags are pulled into the potassium hydroxide solution by the magnet attached; after a couple of minutes of magnetic stirring the bags disintegrate and the pyrogallol dissolves.

Mechanical stirring is effectuated by rocking the apparatus about a horizontal axis until the system approaches equilibrium.

In the meantime the air in the manometer tubes above the silicone oil has been replaced by nitrogen at 0.79 × atmospheric pressure by evacuating and filling through the valves A' and A''. Some time must elapse before the nitrogen is in sufficient equilibrium with the silicone oil in the manometer (after one hour the change may be about 0.01 mm silicone oil per hour). The equilibrium pressure difference is recorded.

The vessels are then opened towards the manometer. Reading and stirring are continued until the manometer is stable, usually after 20 min.

The bulk of each sample is sucked out of the vessel and passed through a carbon monoxide tester under standard conditions. The difference in percentage carbon monoxide is recorded.

Although the principle is very simple, the procedure is never the less a fairly lengthy one. At present only one set of samples can be analysed in a full working day the actual performance of the determination taking 4 h but many improvements can be envisaged which will reduce the labour and shorten the time required to make one determination.

In view of the accuracy obtained this may not compare unfavourably with the best Orsat gas analysis methods.

Calculations: A first approximation: The mole fractions of oxygen in the samples are called $(1-a_1)$ and $(1-a_2)$; total number of gram molecules are n_1° and n_2°. The volumes v_1 and v_2 are assumed to be constant. p_1° and p_2° are the initial pressures, p_1' and p_2' are the final pressures.

According to the gas laws we have at the start of the experiment

$$p_1^\circ v_1 = n_1^\circ RT \qquad \text{and} \qquad p_2^\circ v_2 = n_2^\circ RT$$

At the end

$$p_1' v_1 = a_1 n_1^\circ RT \qquad \text{and} \qquad p_2' v_2 = a_2 n_2^\circ RT$$

or

$$\frac{p_1'}{p_1^\circ} = a_1 \qquad \frac{p_2'}{p_2^\circ} = a_2$$

By subtraction

$$a_1 - a_2 = \frac{p_1'}{p_1^\circ} - \frac{p_2'}{p_2^\circ} = (p_1' - p_2')\frac{1}{p_1^\circ} + (p_2^\circ - p_1^\circ)\frac{p_2'}{p_1^\circ p_2^\circ}$$

$$\frac{}{} \frac{1}{p^\circ}(p_1' - p_2' - \frac{p'}{p^\circ}(p_1^\circ - p_2^\circ)) \quad [(p_1^\circ - p_2^\circ) \text{ is kept as low as possible}];$$

where, when air is tested,

$$p^\circ = 1 \text{ atm and } \frac{p'}{p^\circ} = \frac{4}{5} \text{ (with sufficient accuracy).}$$

For an accurate calculation it is necessary to take the following factors into account:

1. The volumes change when the manometer reading changes.
2. The nitrogen atmosphere that replaces the air in the manometer does not have pressures exactly equal to the pressures inside the vessels after absorption of oxygen.
3. The temperature of the system may change and so may the temperature difference between the vessels.
4. A volume change may take place when potassium hydroxide solution and pyrogallol is mixed.
5. The water vapour pressure will change a) when potassium hydroxide solution and pyrogallol is mixed, b) when the temperature changes.
6. The volumes may change if grease is forced into the vessels from the ground joints.
7. The pyrogallol powder and the bag should have a vapour pressure equivalent to that of the potassium hydroxide solution. In order to obtain this the bags are dried at 80°C and stored in a desiccator over a 50 % potassium hydroxide solution.
8. Deviations from the ideal gas laws may effect the results.
9. Carbon monoxide is produced.

If the conditions listed below are fulfilled then it can be shown by fairly

simple, but rather lengthy, calculations * that the only factors of any importance (*i.e.* factors which give a contribution to the result which approaches the value of the standard deviation) are 1 and 9:

List of conditions:

a. $\frac{\varphi_1}{v_1} - \frac{\varphi_2}{v_2} < 10^{-3}$ and $\frac{\varphi_1}{v_1} \backsimeq \frac{\varphi_2}{v_2} < 10^{-2}$

where φ_1 and φ_2 are the volumes of the manometer tubing above the silicone oil.

b. $p_1 - p_1^* \backsimeq p_2 - p_2^* < 3$ cm silicone oil and $(p_1 - p_2) - p_1^* - p_2^*$ < 0.1 cm silicone oil. p_1^* and p_2^* are the pressures in the manometer after it has been filled with nitrogen but before the vessels are opened (*cf.* p. 1032). p_1 and p_2 are the pressures at the end of the experiment.

c. The one gramme of pyrogallol should be weighed out with an accuracy of a few mg.

d. The 15 ml potassium hydroxide should be measured accurately with a pipette.

e. Variations of bath temperature at any particular point should be less than 0.01°C.

f. The difference between the temperature of vessel 1 and vessel 2 should be less than 0.01°C.

g. The variation of this difference should be less than 0.001°C.

The result of the calculations can be shown to be

$$a_1 - a_2 \backsimeq \frac{1}{p^\circ}\left[(p_1 - p_2) - \frac{4}{5}(p_1^\circ - p_2^\circ) + \left(\frac{p_1}{v_1} + \frac{p_2}{v_2}\right)\frac{A}{2}((p_1-p_2)-(p_1^*-p_2^*))\right] - (co_1 - co_2).$$

Here $p_1^\circ - p_2^\circ$ is the initial pressure difference in cm silicone oil;

$p_1 - p_2$ is the final pressure difference in cm silicone oil;

$p_1^* - p_2^*$ is the pressure difference in cm silicone oil between the manometer tubes after they have been filled with nitrogen but before the vessels are opened;

A is the area (in cm^2) of the cross section of the manometer tubing;

v_1 and v_2 are in cm^3;

co_1 and co_2 are the mole fractions of carbon monoxide in the vessels after the experiment.

A has been found to be 0.048 cm^2. $v_1 \backsimeq v_2 \backsimeq 200$ cm^3,

$$p_1 \backsimeq p_2 \backsimeq \frac{4}{5}p^\circ \backsimeq \frac{4}{5} \times 1.1 \times 10^3 \text{ cm silicone oil,}$$

i.e. $$a_1 - a_2 \backsimeq \frac{1}{p^\circ}((p_1-p_2) - \frac{4}{5}(p_1^\circ - p_2^\circ) + 0.20\,((p_1-p_2) - (p_1^*-p_2^*))) - (co_1 - co_2)$$

* These calculations are available, to anyone interested, by contacting the author.

Carbon monoxide determination: It was found that using the procedure described on p. 1032 for preparing a pyrogallol solution the amount of carbon monoxide liberated is about 0.008 to 0.01 % of total pressure, which agrees well with Kilday's findings [1].

A Carbon Monoxide Gas Detector, Mines Safety Appliances Co., Ltd. (Glasgow) was used for the determination of carbon monoxide. Small differences can be estimated with an accuracy of about 50 % of the difference. Most differences found were about 0.001 ± 0.0005 %.

Difficulties with the grease add to the fairly high standard deviation found in the actual experiment. For instance when the pressure inside the vessel is changed from 1 atm to 0.8 atm the vessels will be pressed against the wall where the hole is and some grease (an uncontrollable amount) may be forced into the vessels. This is an established source of error but its magnitude is difficult to assess. Its importance can of course be diminished by reducing the amount of grease in the ground joint to a minimum.

Results: Two series of experiments have been performed (Table 1): In the first series the samples were known to be identical and in the second there was a constant well defined difference between the two samples. The oxygen content was close to that of normal air (mole fraction 0.209).

In series 2 the results can be divided into two groups:

A. sample I in vessel 2 and sample II in vessel 1 and
B. » I » » 1 » » II » » 2.

Discussion: It is not quite certain why series 2 in general seems better than 1, nor is it known why No. 2 ser. 2 is out. It is in fact a borderline case and could have been left out.

It may seem rather surprising that the zero of the apparatus lies at + 0.01 cm silicone oil and the reason is in fact not known but a fairly plausible explanation seems to be that due to differences in the quality of the ground joints of the vessels the difference between the volumes of grease forced out during the experiment will on an average show a definite value (10^{-2} cm silicone oil is equivalent to 2 μl).

Conclusion: Small differences in the oxygen content ($<$ 0.1 % of total pressure) of air can be determined with a standard deviation of 0.01 cm silicone oil = 10^{-3} % of total pressure (1 atm) or 0.005 % of the oxygen content.

For comparison it should be noted that the very best Orsat gas analysis apparatus may give results reproducible within 0.003 % of total volume or 0.015 % of the oxygen content.

The value of the carbon monoxide correction: It was found impracticable to mix pyrogallol and potassium hydroxide solution in both vessels simultaneously and it turned out that the vessel which is mixed first would always show the highest carbon monoxide value, see Table 2. This finding is in agreement with that of Kilday [1], who states that contact between a fairly high oxygen concentration and pyrogallol with no proper agitation is unfavourable.

The author is indebted to Dr. C. F. Jacobsen, Mr. Th. Rosenberg and Mr. P. Solgaard for helpful discussions.

Cyclizations of Thiocarbohydrazide and its Mono-hydrazones

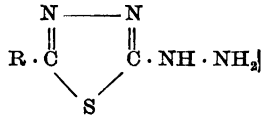
Part I. Reactions with Orthoesters

JAN SANDSTRÖM

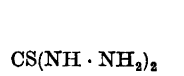
Department of Organic Chemistry, University of Lund, Lund, Sweden

Free thiocarbohydrazide is cyclized by orthoesters to 3-mercapto-4-amino-4,1,2-triazoles, whereas mono-thiocarbohydrazones with the same reagents give the weakly acidic 1,3,4-thiadiazolylhydrazones.

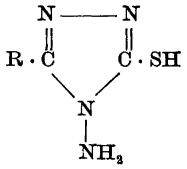
The present investigation was undertaken to find the possibilities of preparing 1,3,4-thiadiazolylhydrazines (I) by cyclization of thiocarbohydrazide (II) with derivatives of carboxylic acids.



I



II



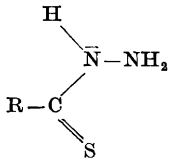
III

However, a direct cyclization of the unsubstituted thiocarbohydrazide was not expected to lead to success, since Stollé and Bowles [1] have shown that this compound reacts with triethyl orthoformate in a closed tube to give 3-mercapto-4-amino-4,1,2-triazole (III, R = H). In the present work, the same compound was obtained when thiocarbohydrazide reacted with formic acid and with formamide. A series of reactions was performed to establish the structure of the triazole, but when the investigation was finished, the author was informed about a more extensive investigation on the same subject by Beyer and Kröger, the results of which were already published [2]. Therefore, the results of the cyclization of the free thiocarbohydrazide are omitted in the present publication.

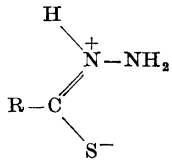
Thiadiazolylhydrazines (I) have previously been prepared by Stollé and Fehrenbach [3], by Fujii *et al.*[4], and by Kanaoka [5,6] by reduction of 2-nitrosamino-thiadiazoles. Fujii has also used hydrazinolysis of 2-alkylsulphonyl-

thiadiazoles, and Kanaoka has used hydrazinolysis of 2-bromo-thiadiazoles. Goerdeler and Galinke [7] have prepared 1,3,4-thiadiazolylhydrazine (isolated as benzaldehyde hydrazone) by reduction of 2-nitramino-thiadiazole.

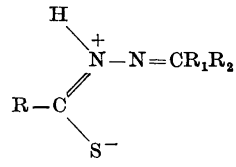
In a previous communication [8], attention has been directed to the property of a benzylidene group of inhibiting cyclization of carboxymethyl 3-benzylidene-dithiocarbazate to benzylidenamino-rhodanine. It was now expected that a similar effect might prevent the 2-nitrogen atom of mono-thiocarbohydrazones from taking part in the cyclization with orthoesters, and thus lead the cyclization to hydrazones of (I), rather than to Schiff bases of the carbonyl compounds and 3-mercapto-4-amino-4,1,2-triazole (III). This expectation has been partly fulfilled, not only with monobenzaldehyde thiocarbohydrazone, but also with monoacetone, mono*cyclo*hexanone, and monoacetophenone thiocarbohydrazone. However, the mechanism proposed in Ref.[8] cannot be responsible for the course of the cyclization of the acetone and *cyclo*hexanone derivatives. Possibly a steric effect is also at work to make the 2-nitrogen atom less available for cyclization than the sulphur atom. However, Hünig [9] has recently found a directing effect, which probably has a bearing on the present problem. He found, that 4-phenylthiosemicarbazide condenses with chloroacetone to give 3-amino-4-methyl-thiazol-2(3)-one phenylimine, whereas acetone 4-phenylthiosemicarbazone with chloroacetone gives acetone 3-phenyl-4-methylthiazol-2(3)-one azine. In the first case the 2-nitrogen atom of the thiosemicarbazide is preferred in the cyclization, whereas in the second case the 4-nitrogen atom seems to be the more available one. Obviously the 1-*iso*-propylidene group has some influence on the availability of the 2-nitrogen atom, and in this case a steric effect seems less likely. Instead, the following proposal is made. Thiohydrazides are resonance hybrids with, among others, the limiting structures (IV a) and (IV b).



IV a



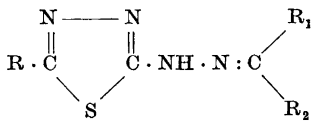
IV b



V

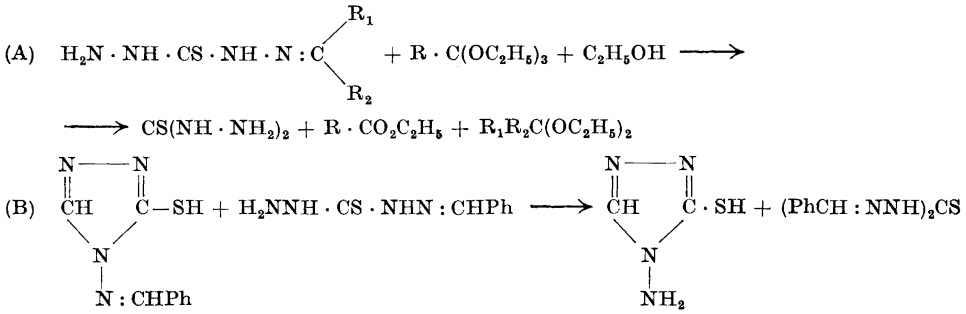
In a thiohydrazone the polar structure, (V), becomes relatively more important, because of the conjugation. Therefore, the 2-nitrogen atom is less basic in thiohydrazones than in thiohydrazides. A similar argumentation can be performed for the amidine structures in Hünig's example. Evidence for the existence of such a conjugation is given by the UV-spectra of the thiohydrazides and thiohydrazones. As an example, methyl dithiocarbazate has its maximum at 2 690 Å, with $\varepsilon = 10\,100$, in absolute ethanol, whereas methyl 3-ethylidene-dithiocarbazate has its maximum at 2 970 Å, with $\varepsilon = 21\,200$ in the same solvent. This bathochromic shift obviously calls for some kind of conjugation between the azomethine group and the thioamide group. The yields have been far from quantitative, and as dibenzaldehyde thiocarbohydrazone and 3-

mercapto-4-benzylidenamino-4,1,2-triazole were found among the products of the reaction between monobenzaldehyde thiocarbohydrazone and triethyl orthoformate, the side reaction (A) may be at least partly responsible.



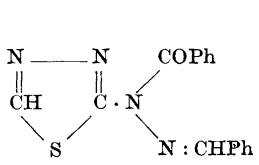
VI

However, a direct formation of 3-mercapto-4-benzylidenamino-4,1,2-triazole cannot be excluded, and the occurrence of dibenzaldehyde thiocarbohydrazone can be explained by the reaction (B), which has been found to occur in boiling toluene.

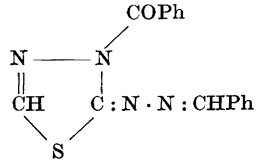


For starting materials, a series of mono-thiocarbohydrazones were prepared by reaction between thiocarbohydrazide and the appropriate carbonyl compound in weakly acidic medium. There is a striking difference between the ease with which the first and the second hydrazine group in thiocarbohydrazide reacts with ketones [10]. The mono-thiocarbohydrazones were refluxed with triethyl orthoformate and triethyl orthoacetate in toluene and without solvent, and the corresponding thiadiazolylhydrazones (VI, R = H and CH_3) were formed in varying yields. Attempts to prepare the free thiadiazolylhydrazines (I) by acid hydrolysis of the acetone hydrazones have failed because the simple thiadiazolylhydrazines are rearranged in acid medium to derivatives of aminotriazole, as will be described in a later publication.

The thiadiazolylhydrazones (VI) are weak acids, and they dissolve readily in aqueous N NaOH but not in N potassium carbonate solution. With benzoyl chloride in pyridine, benzaldehyde thiadiazolylhydrazone (VI, R = R_1 = H, R_2 = Ph) gives two benzoyl derivatives, (VII), and (VIII).



VII



VIII

EXPERIMENTAL

Mono-thiocarbohydrazones

The preparation of monobenzaldehyde thiocarbohydrazone has been described by Stollé and Gaertner [11]. Three new mono-ketone thiocarbohydrazones have been prepared by adding a 50 % excess of the ketone in ethanol to a hot solution of thiocarbohydrazide in N acetic acid. The *monoacetone thiocarbohydrazone* separated as colourless, pointed prisms, m. p. 194—195° (decomp.), in 93 % yield. The product is very slightly soluble in the common organic solvents and in water, and it dissolves with partial decomposition in acidic and alkaline solvents. According to analysis, the crude product is sufficiently pure for all practical purposes. (Found: C 32.9; H 6.99; N 38.2; S 21.9. $C_4H_{10}N_4S$ (146.21) requires C 32.9; H 6.89; N 38.3; S 21.9.)

Monocyclohexanone thiocarbohydrazone was obtained in 83 % yield and crystallized as colourless flakes, m. p. 166—167° (decomp.), from a mixture of absolute ethanol and glacial acetic acid. (Found: C 45.1; H 7.43; N 29.9; S 17.3. $C_7H_{14}N_4S$ (186.27) requires C 45.1; H 7.58; N 30.1; S 17.2.) λ_{max}: 2 500 Å with ε = 12 600.

Monoacetophenone thiocarbohydrazone was obtained in 98 % yield and crystallized from 80 % aqueous ethanol as colourless flakes, m. p. 170—171°. (Found: C 52.1; H 5.95; N 26.9; S 15.3. $C_9H_{12}N_4S$ (208.28) requires C 51.9; H 5.81; N 26.9; S 15.4.) λ_{max}: 3 020 Å with ε = 13 400, λ_{max}: 2 350 Å with ε = 12 000.

1,3,4-Thiadiazolylhydrazones

Acetone thiadiazolylhydrazone (VI, R = H, $R_1 = R_2 = CH_3$). Monoacetone thiocarbohydrazone (9.0 g) and triethyl orthoformate (15 ml) were refluxed for 45 min, and then the volatile material was removed *in vacuo*. The sticky residue was shaken for two days with water (100 ml), and the undissolved material (6.1 g, 63 % yield) crystallized from *n*-butanol as colourless, pointed prisms, m. p. 173—174°. (Found: C 38.6; H 5.26; N 35.8; S 20.6, mol. wt. 160 (Rast). $C_5H_8N_4S$ (156.20) requires C 38.4; H 5.16; N 35.9; S 20.5.) λ_{max}: 2 790 Å with ε = 13 500.

Cyclohexanone thiadiazolylhydrazone (VI, R = H, $R_1R_2 = (CH_2)_5$). Monocyclohexanone thiocarbohydrazone (7.2 g) and triethyl orthoformate (15 ml) were refluxed for 30 min, and then the volatile material was removed *in vacuo*. The sticky residue was dissolved in hot toluene (10 ml), and on cooling, colourless needles separated (1.5 g, 20 % yield), m. p. 168—169° after a further recrystallization from toluene. (Found: C 49.3; H 6.26; N 27.5; S 16.3. $C_8H_{12}N_4S$ (196.27) requires C 49.0; H 6.16; N 28.5; S 16.3.) λ_{max}: 2 790 Å with ε = 14 000.

Benzaldehyde thiadiazolylhydrazone (VI, $R = R_1 = H$, R_2 = Ph). Monobenzaldehyde thiocarbohydrazone (10.0 g) and triethyl orthoformate (10 ml) were refluxed in toluene (100 ml) for one hour. The solution was filtered hot, and on cooling, a colourless crystalline product separated (8.2 g), melting between 165° and 190°. The product was rubbed with a solution of potassium carbonate (10 g) in water (50 ml). The undissolved material was removed by filtration, and the filtrate was acidified with glacial acetic acid. A colourless precipitate was formed (0.9 g, 9 % yield), m. p. 171—172°, identified by mixed m. p. and formation of benzyl derivative [2], as 3-mercapto-4-benzylidenamino-4,1,2-triazole.

The material which did not dissolve in the potassium carbonate solution (6.9 g) was shaken with N NaOH (50 ml) and methanol (50 ml) for 12 h. The undissolved material (1.4 g, 10 % yield) was filtered, and crystallized from glacial acetic acid as colourless needles, m. p. 194—195°, not depressed on admixture with authentic dibenzaldehyde thiocarbohydrazone [1]. (Found: C 63.6; H 4.94. $C_{15}H_{14}N_4S$ (282.37) requires C 63.8; H 5.00.)

Glacial acetic acid (6 ml) was added to the alkaline filtrate, and a pale brown crystalline powder separated (4.8 g, 47 % yield), which crystallized from *n*-butanol as colourless needles of benzaldehyde thiadiazolylhydrazone, m. p. 226—227°. (Found: C 52.9; H 3.94; N 27.5; S 15.7. $C_9H_8N_4S$ (204.24) requires C 52.9; H 3.95; N 27.4; S 15.7.) λ_{max}: 3 210 Å with ε = 24 500, λ_{max}: 2 280 Å with ε = 12 900.

Reaction B: Monobenzaldehyde thiocarbohydrazone (0.5 g) and 3-mercapto-4-benzylidenamino-4,1,2-triazole (0.5 g) were refluxed in toluene for one hour. After cooling, the undissolved material was isolated and extracted with hot water (20 ml). The aqueous

extract was found to be acidic and was neutralized against phenolphthalein with 3.9 ml of 0.1 N NaOH, which corresponds to about 15 % conversion. The aqueous solution was acidified with N HCl (0.5 ml) and a solution of benzaldehyde (0.2 g) in ethanol (10 ml) was added. On the following day the solution had deposited long, colourless needles of 3-mercapto-4-benzylidenamino-4,1,2-triazole (0.09 g), m. p. and mixed m. p. 172—173°.

Benzaldehyde thiadiazolylhydrazone (2.1 g) was dissolved in pyridine (15 ml), and benzoyl chloride (2 ml) was added. On the following day, the brown solution was poured into water (100 ml), and a brownish yellow crystalline product (3.1 g) was precipitated. It was dissolved in 250 ml of boiling ethanol, and on cooling, colourless plates separated (0.5 g, 16 % yield), m. p. 184—186° after recrystallization from toluene. The product was a benzoyl derivative of benzaldehyde thiadiazolylhydrazone. (Found: C 62.5; H 4.00; N 18.0; S 10.3. $C_{16}H_{12}N_4OS$ (308.35) requires C 62.3; H 3.92; N 18.2; S 10.4). λ_{max}: 3 350 Å with ε = 22 000.

An isomer of this compound was obtained by evaporating the mother liquor to one tenth of the original volume. First, unchanged starting material was deposited (0.6 g) and in the filtrate a further amount of crystalline material (0.5 g, 16 % yield) was deposited, m. p. 95—96° after recrystallization from 70 % aqueous ethanol. (Found: C 62.5; H 4.00; N 18.0; S 10.3.) λ_{max}: 2 780 Å with ε = 19 500.

Acetophenone thiadiazolylhydrazone (VI, R = H, R_1 = CH_3, R_2 = Ph). Monoacetophenone thiocarbohydrazone (4.2 g) and triethyl orthoformate (5 ml) were refluxed for 30 min, and then the ethanol and ester were taken off *in vacuo*. The slightly sticky residue was stirred with ethanol (10 ml), and the undissolved material (2.6 g, 60 % yield) crystallized from absolute ethanol as colourless needles, m. p. 198—199°. (Found: C 54.8; H 4.61; N 25.7; S 14.7. $C_{10}H_{10}N_4S$ (218.27) requires C 55.0; H 4.62; N 25.7; S 14.7.) λ_{max}: 3 110 Å with ε = 20 000, λ_{max}: 2 260 Å with ε = 13 000.

5-Methyl-1,3,4-thiadiazol-2-yl-hydrazones (VI, R = CH_3)

By refluxing monoacetone and monobenzaldehyde thiocarbhydrazones with triethyl orthoacetate and working up the solutions as above, low yields of the methyl analogues of the compounds just described were obtained.

Acetone 5-methyl-1,3,4-thiadiazol-2-yl-hydrazone (VI, R = R_1 = R_2 = CH_3) was obtained in 27 % yield and crystallized from absolute ethanol as colourless prisms, m. p. 176—177°. (Found: C 42.4; H 5.92; N 32.9; S 18.8. $C_6H_{10}N_4S$ (170.23) requires C 42.3; H 5.92; N 32.9; S 18.8.) λ_{max}: 2 800 Å with ε = 15 000.

When the mother liquor was made alkaline, and benzyl chloride was added, a 19 % yield of 3-benzylthio-4-amino-5-methyl-4,1,2-triazole [2] was obtained.

Benzaldehyde 5 methyl-1,3,4-thiadiazol-2-yl-hydrazone (VI, R = CH_3, R_1 = H, R_2 = Ph) was obtained in 8 % yield and crystallized from absolute ethanol as colourless needles, m. p. 212—213°. (Found: C 55.2; H 4.71; N 25.6; S 14.6. $C_{10}H_{10}N_4S$ (218.27) requires C 55.0; H 4.62; N 25.7; S 14.7.) λ_{max}: 3 240 Å with ε = 23 800, λ_{max}: 2 300 Å with ε = 12 700.

In the extraction with potassium carbonate solution, a 55 % yield of 3-mercapto-4-benzylidenamino-5-methyl-4,1,2-triazole [12] was obtained.

This investigation has been supported by grants from the *Swedish Natural Science Research Council*, from *Hierta-Retzius Stipendiefond*, and from *Stiftelsen Lars Hiertas Minne*. Experimental assistance from Miss Monica Linders is acknowledged. My thanks are due to Dr. C.-F. Kröger for helpful comments on the manuscript.

Paper Electrophoresis of Carbohydrates in Germanate Buffer

BENGT LINDBERG and BRITA SWAN

Institutionen för träkemi, Kungl. Tekn. Högskolan, Stockholm, Sweden

The paper electrophoretic mobility of some carbohydrates in germanate buffer has been studied. The method seems to be a useful complement to other methods for the separation of these substances. Information of structural significance can be obtained from the mobilities of unknown carbohydrates.

Paper electrophoresis of neutral substances requires the presence of a complexing agent that will give charged complexes with the substances under investigation. Defined spots are obtained either when there is a rapid interconversion between complex and substance or when the equilibrium is displaced strongly towards the complex. The former is preferable as it permits greater differences in mobility between individual substances. Paper electrophoresis of neutral carbohydrates is usually done in borate buffer [1] but hydrogen sulphite [2], arsenite [3], basic lead acetate [3], molybdate [4] and sodium hydroxide [3] have also been used.

Germanate is known to give complexes with polyalcohols, and the reaction has recently been studied by Antikainen [5]. In the present investigation a study has been made of the electrophoretic mobility of some carbohydrates in germanate buffer. After some preliminary experiments the electrophoreses were run in 0.05 M sodium germanate buffer of pH 10.7 at 40° and 1 500 V (25—30 V/cm). The mobilities are given as M_G-values, that is relative to the mobility of glucose. Under these conditions glucose moves about 11 cm in 90 min. The mobilities of the various carbohydrates investigated are given in Tables 1—7. For some substances the M_G-values in borate buffer have also been given. These values are taken from Foster [1] or Frahn and Mills [3] or were determined in separate experiments. The conditions used by Foster [1] and by Frahn and Mills [3] are slighty different, but their M_G-values are very similar and could be compared directly.

As can be seen from Table 1 there are large differences between the mobilities of the monosaccharides in borate and in germanate. In borate, glucose is the fastest sugar and pairs of pentose and hexose sugars with the same configuration, *e. g.* xylose and glucose, have almost the same mobility. In germanate, glucose is the slowest sugar and pentoses move considerably faster than the corresponding hexoses. As discussed below, furanosidic 1,2-*cis*-diols seem

to contribute more to the mobility in germanate than the corresponding pyranosidic groupings, and an M_G-value in this buffer may reflect the conformational stability of the most stable pyranosidic chair form of the sugar. The individual differences between the ketoses is rather small in both buffers, but their mobilities relative to glucose are considerably higher in the germanate buffer.

A study of the mobilities of various partially methylated sugars has enabled some conclusions to be drawn about the structures of the borate complexes [1]. The mobilities in germanate and borate of some sugar derivatives, chiefly methyl ethers, are given in Table 2. Some special effects in germanate buffer can be seen. Firstly, the glucose and xylose derivatives, in which the hydroxyl group at $C_{(2)}$ is replaced by a methoxyl or amino group or by a hydrogen atom, show no mobility at all. This result strongly indicates that germanate complexes with reducing sugars are formed exclusively by 1,2-*cis*-diols in a cyclic form of the sugar. Since sugar alcohols, *e. g.* 2-*O*-methyl-D-glucitol (Table 6), have rather high mobilities, the contributions from complexes with the open chain form of the sugar must be negligible. In the light of these results is seems probable that the same is also true for borate complexes with the sugars. 2-*O*-Methyl-D-galactose, which has a 3,4-*cis*-diol grouping in its pyranose forms, gives a charged complex with germanate.

The high mobilities in germanate of glucose and xylose derivatives in which the $C_{(3)}$-hydroxyl group is etherified or replaced by hydrogen is difficult to understand. A possible explanation may be that, in the parent sugar, this hydroxyl takes part in the formation of an uncharged complex, competing with the charged complex of the α-pyranose or α-furanose form. When the 3-hydroxyl is absent, the uncharged complex cannot be formed and the mobility is therefore higher. The same effect also occurs in the galactose series, where the contribution from the 3,4-*cis*-diol is restricted to the pyranose forms and is probably not very important. In 3-*O*-methyl-D-mannose however the mobility relative to mannose is considerably reduced. In mannose both furanose and pyranose forms can give 2,3-*cis*-diol complexes. The 1,2-complexes are given by the β-forms only and may be less significant than the 2,3-complexes.

Table 1. Monosaccharides.

Substance	M_G in germanate	M_G in borate
D-Glucose	1	1
D-Mannose	1.4	0.72
D-Allose	1.8	0.83
D-Galactose	1.3	0.93
D-Xylose	1.4	1.00
D-Lyxose	1.9	0.71
D-Ribose	2.1	0.77
L-Arabinose	1.5	0.96
L-Rhamnose	1.3	0.52
D-Fructose	2.1	0.90
L-Sorbose	2.0	0.95
D-Tagatose	2.4	0.95

Table 2. Sugar derivatives.

Substance	M_G in germanate	M_G in borate
2-*O*-Methyl-D-glucose	0.0	0.23
2-Deoxy-D-glucose	0.0	0.29
2-Amino-2-deoxy-D-glucose	0.1	—
3-*O*-Methyl-D-glucose	1.4	0.80
3-*O*-Benzyl-D-glucose	1.2	—
3-Deoxy-D-glucose	1.6	0.85
4-*O*-Methyl-D-glucose	0.3	0.24
4-*O*-Benzyl-D-glucose	0.2	0.17
5-*O*-Methyl-D-glucose	1.6	0.65
6-*O*-Methyl-D-glucose	0.96	0.80
2,3-Di-*O*-methyl-D-glucose	0.0	0.12
3-*O*-Methyl-D-mannose	0.8	—

The low mobilities of 4-*O*-methyl-sugars in borate has been attributed to their inability to give a furanose structure [1]. The mobilities of these sugars are also low in germanate, and this explanation is supported by the very high mobility of 5-*O*-methyl-D-glucose, which can only assume this form. The results also show that the greater complex-forming ability of 1,2-*cis*-diols in a furanose ring relative to that of 1,2-*cis*-diols in a pyranose ring is more pronounced in germanate than in borate.

1,6-Anhydro-α-D-galactofuranose	0.0	—

Methylation of glucose or galactose in the 6-position gives a slight reduction in the M_G-value in germanate. This is probably due to the elimination of the interaction with the 5,6-diol in the furanose form. With borate, complexes may also be formed at 4,6-positions in the glucopyranoses.

Of the glycopyranosides and the related 1,5-anhydrides of the glycitols (Table 3), only those with a 1,2-*cis*-diol grouping show significant mobility in germanate. There are rather small differences between the individual substances containing one such grouping. For an anomeric pair of glycosides, the anomer with the aglyconic group in an axial position in the most stable chair form has a somewhat higher mobility. Interactions with the 4,6-position, which contribute to the mobility in borate, *e. g.* in the glucosides, seem to be of no importance in germanate. One of the furanosides, which has a 1,2-*cis*-diol grouping, shows a high mobility in germanate but the others (Table 4), without such a grouping, show low mobilities. The xylofuranoside gives a complex with borate, probably due to interaction with the 3,5-hydroxyls [1], but no complex of this type seems to be formed with germanate. Methyl-α-D-glucofuranoside has a high mobility in borate ($M_G = 0.73$), which can be attributed to a tridentate complex involving the 3,5,6-hydroxyls [1]; 1,4-anhydro-D-glucitol would be expected to have a similar mobility in borate. It is questionable whether a tridentate complex is also formed with germanate and the relatively low mobility can also be due, at least to some extent, to complex formation with the 5,6-hydroxyls.

The M_G-values for a number of oligosaccharides that are given in Table 5 can easily be rationalised in terms of contributions from the reducing and non-reducing monomer residues, based on M_G-values for the analogous sugar ethers and glycosides. The effect of a 3-substituent in the glucose and galactose series is also clearly marked in the disaccharides.

A number of glycitols and glycitol methyl ethers were studied; their M_G-values are listed in Table 6. As these substances have less fixed conformations and a variety of competing complexes may be formed, it is rather difficult to interpret the results. An analysis of the M_G-values obtained show , however, that charged complexes are preferentially formed with 1,2-*trans*-diols (*threo*-configuration) and 1,2-diols in which one of the hydroxyls is primary. 1,2-*cis*-Diols (*erythro*-configuration) and 1,3-diols may also contribute, but to a much lesser extent. The same difference between 1,2-*cis*- and 1,2 *trans*-diols can be observed in borate buffer [1]. It seems to be difficult to draw any conclusions of

structural significance from the electrophoretic mobilities of open chain polyhydroxy compounds in germanate buffer. It does however appear to be a useful method for the separation of for instance the pairs ribitol and arabitol or 2- and 3-*O*-methyl-D-glucitol. Electrophoresis in molybdate [4] seems to be more suitable for the separation of substituted glycitols.

The mobilities of some cyclitols in germanate (Table 7) are rather similar to the corresponding values in borate. It has been demonstrated that tridentate complexes are formed in borate [6] and it is possible that similar complexes are formed with germanate, especially as *scyllo*-inositol shows a definite mobility in this buffer.

DISCUSSION

In a germanate ion with the coordination number six, the distance between two oxygen atoms is 2.64 Å. This is rather close to the distance between the oxygen atoms in tetrahedrally coordinated borate, 2.72 Å (Values for the atomic distances are taken from Pauling [7]). The results described above indicate that germanate gives complexes with 1,2-*cis*-diols in furanosides (O—O = 2.51) and pyranosides (O—O = 2.86) and with open chain 1,2-diols with a *threo*-configuration (the O—O distances are taken from Reeves [8]). The same type of complex is formed with borate but the complexes between germanate and furanosidic 1,2 *cis*-diols seem to be especially strong. The same seems to be true for the complexes with arsenite [3]. Borate also gives complexes with 1,3-diols but this possibility seems to be very limited with germanate. Thus methyl-β-D-glucopyranoside and methyl-β-D-xylofuranoside, although they have low mobilities in germanate (almost nil) show significant mobilities in borate, almost certainly due to the formation of complexes at the 4,6- and 3,5 positions, respectively.

The possibility of the formation of tridentate complexes especially with the cyclitols, can not be excluded, but the mobilities of this substances may also be due to complexes with 1,2-*cis*-diols. *Scyllo*-Inositol, however, has no such groupings but may give an 1,3-*cis*-complex in a boat conformation. With open chain sugars, complexes with 1,3-diols seem to be of lesser importance. As in the case of borate complexes and cyclic acetals, there is little sign of the formation of germanate complexes with 1,2-*trans*-diols in a pyran ring or with open chain 1,2-diols with an *erythro*-configuration.

Germanium has also the coordination number four. For tetrahedrally coordinated germanate the distance between two oxygen atoms is 3.32 Å and any complex formed with this should be uncharged. In furanose rings, the distance between the oxygen atoms in a 1,2-*trans*-diol is 3.45 Å, and such a diol might therefore give uncharged complexe with germanate. There are also other diols, in which the distance between the oxygen atoms can assume values close to 3.32 Å. As mentioned above, derivatives of glucose and xylose, in which the 3-hydroxyl group is replaced by another group, rather unexpectedly have higher mobilities than the parent sugars; this can be explained by the formation of uncharged complexes which will compete with the charged complexes *. It must be admitted, however, that this effect is not perfectly understood.

As can be seen from the Tables, paper electrophoresis in germanate buffer is a useful complement to electrophoresis in borate [1] and other buffers [2-4]. Many separation problems can be dealt with better by electrophoresis in germanate instead of borate and other buffers. For instance, this is probably the only method by which all five mono-*O*-methyl-D-glucoses can be separated in one operation. It should also be possible to obtain information on the structures of unknown carbohydrates from their electrophoretic mobilities in germanate. This is true especially for partially etherified sugars and for reducing oligosaccharides, in which rather few groupings contribute to the mobility and the effect of substitution is often considerable.

Germanate is non-toxic and requires no special precautions. Non-reducing sugars are sometimes difficult to detect on germanate impregnated paper. The same difficulty is observed in borate electrophoresis and may be overcome by increasing the amount of the component or by modifying the method used for localisation. The same spray reagents can be used with both buffer systems.

EXPERIMENTAL

Buffer. An 0.05 M solution of germanate was prepared by adding 50 % aqueous sodium hydroxide to a suspension of germanium dioxide in water until a clear solution of pH 10.7 was obtained. This solution turns milky on keeping but is still quite suitable for use. The milkiness depends on the formation of polygermanates and is accelerated if the solution is heated. After each run, the solutions at the cathode and the anode should be mixed, as the pH increases in the former and decreases in the latter. The pH of the buffer should be checked regularly.

Procedure. The apparatus, of the Kunkel and Tiselius type [9], and the technique were essentially the same as described by Foster [1]. Whatman No. 1 filter paper was used. The electroendosmotic flow is rather high, and the starting line was placed 20 cm from the cathode end of the cooling plate. 2,3,4,6-Tetra-*O*-methyl-D-glucose and D-glucose were run on all papers, the first in order to make a correction for the electroendosmosis, the latter as an internal standard. The electrophoreses were run for 90 min. at 1 500 V, equivalent to 25—30 V/cm. Water at 40° was circulated through the cooling-plate. Under these conditions the migration of D-glucose was about 11 cm.

---

* *Added in proof.* This explanation is probably not valid as we have recently observed that 3-*O*-methyl-D-glucose and 3-*O*-methyl-D-xylose have higher mobilities than their parent sugars also on electrophoresis in sulphonated phenylboronic acid buffers of low pH-values (6—7). In these buffers all complexes must be charged. (P. Garegg and B. Lindberg. *Unpublished results.*)

Localisation of spots. The reducing sugars were localised by spraying with anisidine hydrochloride [10]. Non-reducing sugars were localised either with the silver nitrate — sodium ethoxide reagent [11] or with periodate-benzidine [12], after neutralisation of the paper by spraying with acetic acid. Some spots could not be detected with the former reagent, but the latter, although somewhat more complicated, was more reliable. Distinct, circular spots were usually obtained. The migration distance was measured from the centre of the spots.

Substances. Most of the substances studied were available in this laboratory or at the wood chemistry department of the Swedish Forest Products Research Laboratory. 5-*O*-Methyl-D-glucose and 3-*O*-methyl-D-mannose were kindly supplied by Professor O. Th. Schmidt, Heidelberg, and Dr. G. O. Aspinall, Edinburgh, respectively. The partially methylated glycitols were prepared, in small quantities, by reduction of the corresponding methylated sugars with Raney nickel according to Karabinos and Ballun [13]. These substances, most of which are not described in the literature, were not characterised.

Synthesis of Cellobiouronic Acid

BENGT LINDBERG and LARS SELLEBY

Institutionen för träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

4-*O*-(β-Glucopyranosyluronic acid)-D-glucose or cellobiouronic acid (I) was synthesised starting from 1,6-anhydrocellobiose (IV).

4-*O*-(β-D-Glucopyranosyluronic acid)-D-glucose or cellobiouronic acid has been isolated from hydrolysates of the specific polysaccharides of *Pneumococcus* Types III [1] and VIII [2,3] and its structure has been determined by Hotchkiss and Goebel.[4] The similar serological activity of these and some other bacterial polysaccharides and of oxidised cellulose is apparently related to the presence of cellobiouronic acid residues.

In a recent paper, Marchessault and Rånby [5] have discussed the nature of certain linkages in cellulose, which have an increased sensitivity to acid hydrolysis and have attributed them to the presence of glucuronic acid residues in the cellulose chain. It is known that a biouronic acid linkage, as in cellobiouronic acid (I), is considerably more resistant to acid hydrolysis than an ordinary glycosidic linkage, as in cellobiose (II). Rånby and Marchessault now suggest that the pseudo-biouronic acid linkage, as in pseudo-cellobiouronic acid (III), must be considerably more sensitive to acid hydrolysis than the other linkages.

They also suggest that inductive effects, due to the electrophilic carboxyl groups, are responsible for the known resistance of the biouronic linkage (I) and for the postulated weakness of the pseudo-biouronic linkage (III). A comparison of the rates of acid hydrolysis of the three model substances (I, II and III) is therefore a matter of some interest. The present paper describes the synthesis of cellobiouronic acid (I).

1,6-Anhydro-cellobiose (IV) was prepared by treatment of phenyl-β-cellobioside with alkali.[6] Tritylation and acetylation yielded the pentaacetate trityl ether (V) and detritylation of V gave the pentaacetate (VI), in which all the hydroxyls of cellobiose (II) except the primary hydroxyl in the non-reducing glucose residue are protected. Oxidation of VI with permanganate in acetic acid, as previously used in a similar syntheses of glucuronic acid by Stacey [7], yielded the pentaacetate of 1,6-anhydro-cellobiouronic acid, VIII. This substance was not isolated but was deacetylated and subjected to acid hydrolysis. The 1,6-anhydride linkage was preferentially hydrolysed and the cellobiouronic acid (I) formed was purified from small amounts of contaminating

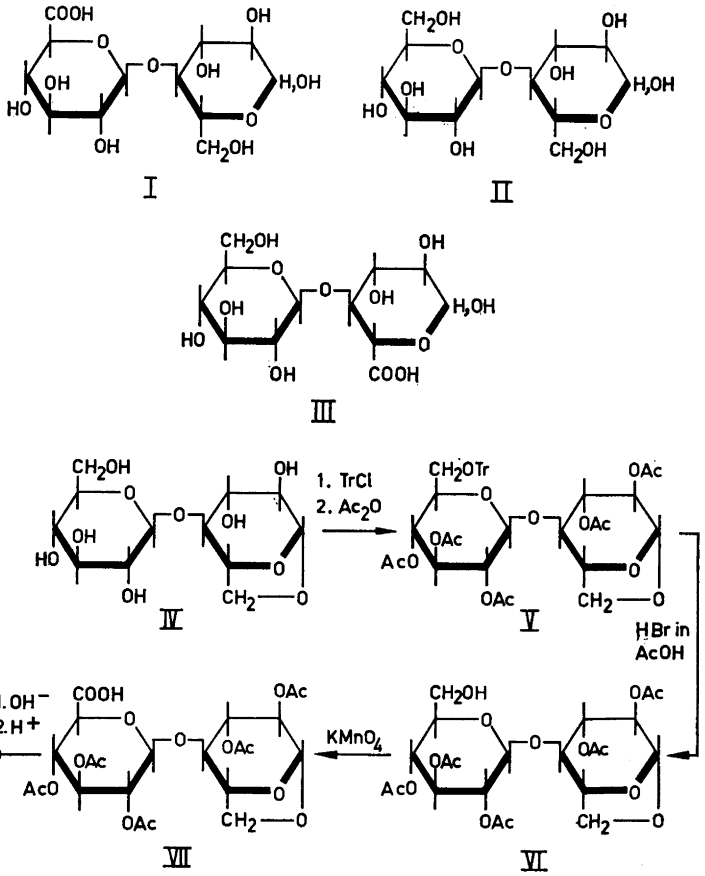
glucose and glucuronic acid by ion exchange chromatography. The amorphous product was chromatographically and electrophoretically pure and gave the α-heptaacetate methyl ester with m.p. 251—252 °, $[\alpha]_D^{20}$ + 44° (in chloroform), in good agreement with previously recorded values for this substance.[2,3] *

EXPERIMENTAL

Melting points are corrected. Concentrations were done under reduced pressure.

1,6-Anhydro-cellobiose (IV) was prepared according to Montgomery *et al.*[6] An attempt to prepare the intermediate phenyl-hepta-*O*-acetyl-β-cellobioside from octa-*O*-acetyl-α-cellobiose, phenol and *p*-toluene-sulphonic acid by the method of Helferich and Schmitz-Hillebrecht [8], failed, probably because of the difficulty of separating the mixture of α- and β-glycosides formed.

2,3,2',3',4'-Penta-O-*acetyl-6'*-O-*trityl-1,6-anhydrocellobiose.* (V) 1,6-Anhydrocellobiose (5 g) was dissolved in anhydrous pyridine (100 ml) and trityl chloride (6.6 g) was added.



* *Added in proof.* In a recent paper [*Chem. Ber.* **95** (1960) 356] Jayme and Werner report the synthesis of cellobiuronic acid by a different route.

The solution was kept overnight, acetic anhydride (20 ml) was then added and after two days the mixture was poured into ice-water (1 000 ml) containing acetic acid (50 ml). The precipitate was collected and crystallised from ethanol, yielding the pure substance (8.0 g), m. p. 119—120°, $[\alpha]_D^{20}$ —50° (chloroform *c*, 1.1). (Found: C 63.3, H 5.71. Calc. for $C_{41}H_{44}O_{15}$: C 63.5; H 5.58.)

*2,3,2',3',4'-Penta-*O*-acetyl-1,6-anhydro-cellobiose* (VI). The trityl derivative (V) (8.0 g) was dissolved in acetic acid (60 ml) and a saturated solution of hydrogen bromide in acetic acid (15 ml) was added. The mixture was shaken for 45 sec. and the trityl bromide was removed by filtration. The solution was immediately poured into ice-water (500 ml) and extracted with chloroform (3 × 100 ml). The chloroform solution was washed with ice-water (5 × 100 ml), dried over calcium chloride and concentrated to a sirup. The sirup crystallised on addition of ether and scratching and was recrystallised from chloroform-ether. The crystals (2.7 g) had m. p. 156—157° and $[\alpha]_D^{20}$ —133°, (chloroform, *c*, 2.0). (Found: 49.4; H 5.75. Calc. for $C_{22}H_{30}O_{15}$: C 49.4; H 5.66.)

*4-*O*-(β-*D*-Glucopyranosyluronic acid)-*D*-glucose (I).* The pentaacetate (VI) (1.0 g) was dissolved in analytically pure, homologue-free acetic acid (10 ml) and finely powdered potassium permanganate (500 mg, 20 % excess) was added. The mixture was stirred at room temperature, and the reaction was followed by chromatography on dimethyl sulphoxide-impregnated paper [9], using benzene as the mobile phase. The starting material and the reaction product had R_F-values of 0.9 and 0.65, resp. The spots were developed with silver nitrate-sodium ethoxide [10].

After two days, when the reaction was complete, the mixture was concentrated to dryness, dissolved in 0.1 N aqueous potassium hydroxide (50 ml) and kept overnight. The precipitate of manganese dioxide was filtered off and the clear, colourless solution obtained was filtered through a column of cation exchange resin, Amberlite IR 120 (H^+).

The solution was concentrated by freeze-drying, dissolved in 0.5 N sulphuric acid and then kept at 100°. The hydrolysis was followed by paper chromatography (ethyl acetate-acetic acid-water, 3:1:1) and paper electrophoresis (0.1 M borate buffer, pH 10). After 12 h the starting material had disappeared. The solution was neutralised with barium carbonate, barium sulphate was removed by filtration and the salts were converted to acids by filtering through a column of Amberlite IR 120 (H^+). The solution which in addition to cellobiouronic acid contained traces of glucose and glucuronic acid (chiefly as glucurone) was added to the top of a column (23 × 2 cm) of anion exchange resin, Dowex 2, in the acetate form. The column was eluted, first with water (3 000 ml) and then with 3 N aqueous acetic acid (500 ml). The latter eluate, which contained chromatographically and electrophoretically pure cellobiouronic acid was concentrated to dryness, dissolved in water and freeze-dried, yielding the compound as a white, amorphous powder (415 mg).

Methyl ester α-heptaacetate of cellobiouronic acid. Cellobiouronic acid (100 mg) was dissolved in methanol (7 ml) and an excess of diazomethane in ether was added. After a few minutes the solution was concentrated to a sirup, and this was then dissolved in acetic anhydride (10 ml) containing zinc chloride (0.5 g) and kept at 60° for 90 min.

The solution was concentrated and the residue was crystallised from ethanol, yielding the methyl ester acetate (60 mg), m. p. 251—252°, $[\alpha]_D^{20}$ +44° (chloroform, *c* 1.2).

Potential Chemotherapeutics

II. 2-(5-Nitro-2-furyl)-5-amino-1,3,4-thiadiazoles *

KURT SKAGIUS

Research Laboratories, A. B. Pharmacia, Uppsala, Sweden

KURT RUBINSTEIN and ELSE IFVERSEN †

Research Division, Aktieselskabet Pharmacia, Copenhagen-Vanlöse, Denmark

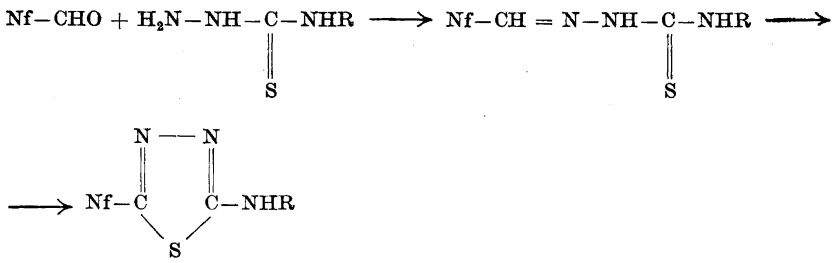
Seventeen 2-(5-nitro-2-furyl)-5-amino-1,3,4-thiadiazoles were prepared by oxidation of the corresponding thiosemicarbazones with ferric salts according to Young and Eyre or electrolytically in the presence of ferric salts.

In 1944 Dodd and Stillman discovered the antibacterial activity of the nitrofurans [1]. Since then a great number of nitrofuryl derivatives have been synthesized and tested. Several of these compounds are hydrazone-type derivatives of 5-nitrofurfural such as nitrofurazone, nitrofurantoin and furazolidone, all possessing a broad antibacterial spectrum [2]. It is also known, that 5-nitrofurfural thiosemicarbazone, in analogy to many other thiosemicarbazones, has a strong tuberculostatic activity [3].

Since the nitrofurans mentioned have a structure, which could be expected to be relatively easily destroyed, for example by acid hydrolysis, it was of interest to synthesize compounds with a more stable structure. This is readily accomplished for example by oxidative ring closure of nitrofurfural thiosemicarbazone to the corresponding aminothiadiazole. As it became clear that this compound had promising antibacterial properties, a series of derivatives were prepared for antibacterial screening.

All substances prepared are 5-(nitrofuryl)-thiadiazoles with an unsubstituted or a monosubstituted amino group in the 2-position of the thiadiazole ring system. They were prepared from nitrofurfural (or its diacetate) and the corresponding 4-substituted thiosemicarbazide as follows (Nf stands for 5-nitro-2-furyl):

* During the preparation of this manuscript the authors were informed that Dr. W. Sherman at Abbott Labs. during the September Meeting of A.C.S. Division of Medicinal Chemistry lectured on nitrofuryl compounds, comprising some of the compounds mentioned in this paper.



The thiosemicarbazides were prepared from the corresponding *iso*thiocyanates and hydrazine hydrate, with the exception of 4-(2-pyridyl)-thiosemicarbazide. When 2-pyridyl-*iso*thiocyanate was allowed to react with hydrazine hydrate in ethanol under various conditions, only 1,6-dipyridyl-2,5-dithiobiurea was obtained. Therefore, 4-pyridylthiosemicarbazide was prepared from the triethylammonium salt of 2-pyridyldithiocarbamic acid.

The oxidation of thiosemicarbazones of aromatic aldehydes is readily performed with ferric chloride [4]. However, when applied to heterocyclic derivatives the method does not always seem to be convenient. Thus, Erlenmeyer *et al.*[5] obtained only a small yield on ferric chloride oxidation of 2-pyridylaldehyde thiosemicarbazone, and Maffii *et al.*[6] obtained 41.6 % yield on oxida-

tion of 2-furfural thiosemicarbazone. In the present work, however, oxidation of 5-nitrofurfural thiosemicarbazone yields about 84 % of the aminothiadiazole. The difference in yield between the furyl and 5-nitrofuryl derivative might be attributed to the inhibitory influence of the nitro group on the acid cleavage of the furyl group.

Attempts were made to use other oxidation agents such as cerium sulphate, lead tetraacetate, chromium trioxide, selenium dioxide, potassium permanganate and hydrogen peroxide. However, either no reaction occurred or unidentified substances were formed (*cf.* Ref.[7]). On the other hand, it was possible to perform an electrolytic oxidation in the presence of small amounts of ferric salts. Probably, the ferrous ions formed by the ring closure were oxidized, thus allowing the reaction to proceed. However, attempts to replace the electric current with potassium permanganate failed, and the yield of aminothiadiazole formed in this case corresponded to the amount of ferric ions originally present in the reaction.

Under alkaline conditions the nitrofuryl group is fairly labile and extensive decomposition may occur. It was found, however, that the oxidation could be performed with potassium ferricyanide in the presence of sodium acetate [8], but the time of reaction was considerably increased.

Compound No. 12 in Table 1 (the 2-phenylethyl derivative) has a very unsharp melting-point in spite of several consecutive recrystallizations. Melting-point depression is obtained when the substance is mixed with the thiosemicarbazone used as starting material. It seems probable, that the broad melting-point interval is due to polymorfism. A similar behaviour is shown by the substance No. 10 (allyl derivative). On recrystallization of the latter compound two kinds of crystals are obtained — brown rods and yellow flakes. At about 150°C the shells turn brown, and a sharp melting point is obtained.

The thiadiazoles prepared are yellow substances with slightly alkaline properties. In contrast to the corresponding thiosemicarbazones, they are readily soluble in cold formic acid, which could be used to separate the substances, when mixtures were obtained. Compound No. 1 (unsubstituted amino group), which is the most promising as a potential chemotherapeutic, is slightly soluble in most common solvents but comparatively soluble in formic acid, dimethyl formamide and dimethyl sulfoxide.

In serial dilution tests *in vitro* Compound No. 1 inhibits growth of a series of strains of *Staphylococcus aureus* in a concentration of 3.2—25 μg/ml, of *Salmonella*, *Shigella* and *Coli* in concentrations of 0.4—6.3 μg/ml and of *Streptococcus* in concentrations of 12.5—200 μg/ml. Further details of the antibacterial screening will be published separately.

EXPERIMENTAL *

5-Nitro-2-furyl thiosemicarbazones. The thiosemicarbazones were prepared by refluxing 5-nitro-furfural diacetate and the corresponding thiosemicarbazide in a mixture of ethanol and dilute sulfuric acid, or by heating 5-nitrofurfural and the thiosemicarbazide in ethanol. The product obtained, usually orange-coloured, was recrystallized from dimethyl formamide, dimethyl sulfoxide, dioxane or ethanol. The products decompose on heating at temperatures given in Table 1.

2-(5-Nitro-2-furyl)-5-amino-1,3,4-thiadiazole. a) 125 g (0.58 mole) of 5-nitro-2-furfural thiosemicarbazone and 1 160 g of a 25 % solution of ferric chloride (490 g of $FeCl_3 \cdot 6\ H_2O$) in water are placed in a 1.5 l beaker, fitted with a stirrer and a thermometer. The mixture is stirred on a water bath at 80°C for 90 min and then chilled to room temperature. The precipitate is filtered off and washed with 800 ml of hot water, followed by 800 ml of cold water, and dried at 60°C. Weight 118 g. The substance is dissolved in 360 g of dimethyl sulfoxide, treated with Norite and filtered. 30 ml of distilled water is added to the hot solution and the mixture is chilled in a refrigerator. The yellow crystals are filtered off, washed with 140 ml of ethanol, 180 ml of water and dried. Yield 108 g (87 %). M. p. 270–271° (decomp.). If the substance is heated slowly it darkens gradually without melting.

b) A porcelain cell with a volume of about 200 ml is placed in a 500 ml vessel, used for electrolysis. A mixture of 21.4 g (0.1 mole) of 5-nitro-2-furfural thiosemicarbazone and 125 ml of 15 % potassium ferrisulfate in water is poured in the cell. The mixture is stirred thoroughly with a perforated platinum anode about 5 × 4 cm^2 in size. A cylinder-shaped copper cathode is placed in the cathode-room outside the cell, which is filled with dilute sulfuric acid.

The electrolysis is performed at about 70°C with about 2 A for 4 h. The solid in the anode-cell is filtered off, washed with hot water and recrystallized from DMF-water as described in method a). Yield 14 g. M. p. 270–272°C.

c) 8.5 g (0.04 mole) of nitrofurfural thiosemicarbazone and a solution of 29 g (0.09 mole) of potassium ferricyanide and 25 g of sodium acetate in 200 ml of water were stirred for 8 h on a water bath. The precipitate obtained on cooling was filtered off, washed and dried. 6.3 g (75 %) of yellow crystals were obtained, which decomposed at 272°C. A reaction time of 2 h and 5 h yielded, respectively, 20–30 % and 50 %.

* Microanalyses by Dr. Wolfgang Kirsten.

The 2-(5-nitro-2-furyl)-5-amino-1,3,4-thiadiazoles, listed in Table 1, were prepared in analogy to method a) above. A few examples further illustrate the procedure:

2-(5-Nitro-2-furyl)-5-allylamino-1,3,4-thiadiazole. 25.4 g (0.1 mole) of 1-(nitrofurfural)-4-allylthiosemicarbazone is stirred on a water bath for 2 h with a solution of 50 ml of 50 % $FeCl_3$ and 70 ml of water. The dark product obtained was dissolved in hot ethanol, carbon added, the hot solution filtered and allowed to crystallize. 12.5 g of yellow-brown needles and 5.8 g of yellow flakes were obtained. The needles melt at 172.5–173.5°C. The flakes rearrange to the brown needles at about 150°C and melt at 172.5–173.5°C.

2-(5-Nitro-2-furyl)-5-carboxymethylamino-1,3,4-thiadiazole. 2.5 g of 1-(nitrofurfural)-4-carbethoxymethylthiosemicarbazone is stirred with 15 ml of 15 % $FeCl_3$ and 20 ml of H_2O on a water-bath for one hour. The dark precipitate was dissolved in ethanol, carbon added, and the hot mixture was filtered. After cooling, 1.95 g of 2-(nitrofuryl)-5-carbethoxymethylaminothiadiazole was obtained as yellow flakes melting at 172.5–174°C.

0.9 g of the ester was heated on a water bath for 3 h with 20 ml of 5 N sulfuric acid. The yellow precipitate was filtered off, and washed with ethanol. 0.8 g of needles were obtained which decomposed at 246–248°C. 0.5 g of the substance was dissolved in 50 ml of ethanol-dioxane 1:1 and filtered. After cooling, 0.4 g of yellow crystals was obtained. M.p. 243.5–244°C (decomp.). Equiv. wt: Found 269. Calc. 270.

The Ion Exchange Properties of Silica Gel

I. The Sorption of Na^+, Ca^{2+}, Ba^{2+}, UO_2^{2+}, Gd^{3+}, Zr(IV) + Nb, U(IV) and Pu(IV)

STEN AHRLAND, INGMAR GRENTHE and BERTIL NORÉN

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

In the present work the metal ion sorption on silica gel has been investigated. The silica gel acts in this respect as an ion exchanger of the weakly acid type and in the case of a monovalent cation the exhange reaction can be written schematically in the following way

$$\begin{array}{c} | \\ -\mathrm{Si}- \\ | \end{array} \mathrm{OH} + \mathrm{Me}^+ \rightleftharpoons \begin{array}{c} | \\ -\mathrm{Si}- \\ | \end{array} \mathrm{OMe} + \mathrm{H}^+$$

For this equilibrium the law of mass action seems to be valid. Moreover an amount of hydrogen ions equivalent to the amount of metal ions sorbed are set free at the sorption on silica gel which has been saturated with hydrogen ions. The amount of metal ion sorbed depends strongly on the pH of the solution. At the sorption of strongly hydrolysed (presumably high molecular) ions the equilibrium is reached slowly, while the sorption of non-hydrolysed (low molecular) ions is quite rapid, the equilibrium usually being reached within five minutes.

Numerous silicon compounds with good sorption properties have long been known. Such compounds are the zeolites, of natural as well as synthetic origin, which are extensively used for the sorption of metal ions from water solutions. Silica gel has also been used previously as a sorbent, particularly for organic compounds and gases.

This investigation was performed in order to investigate more closely the ability of the silica gel to sorb metal ions from water solutions. The aim was especially to find out how this sorption depends on the previous treatment and grain size of the gel as well as on the hydrogen ion concentration of the solution. The sorption to and the affinity for the gel of different metal ions were also studied. Since all the results obtained can be interpreted on the basis of an ion exchange between gel and solution, a short account will first be given of these properties of the gel which makes such an exchange possible.

An ion exchanger consists primarily of an insoluble network containing charged groups. To these groups counter ions are bound in order to preserve the electroneutrality. As these ions do not belong to the structure, they are easily exchangeable. Cation or anion exchangers are obtained depending upon whether the network has a negative or positive charge, respectively. In the organic ion exchangers the network is produced by polymerization of suitable compounds, *e.g.* divinylbenzene and styrene, where the divinylbenzene forms crosslinkages between the chains of polymerized styrene. The charged groups are obtained by substitution in the carbon chain of acid or basic groups.

Hydroxides and hydrous oxides often have a structure where a network is formed by oxygen bridges between the metal atoms. These compounds show ion exchange properties which have recently been extensively investigated by Kraus *et al.*[1]. Depending upon the pH, they act as anion exchangers (at sufficiently low pH) or as cation exchangers (at higher pH).

The anion exchange can take place in two different ways. In acid solution, the basic group $-\overset{|}{\underset{|}{M}}-OH$ takes up hydrogen ions and $-\overset{|}{\underset{|}{M}}-OH_2^+$ is formed. At the same time an equivalent amount of anions are bound as counter ions. For the sake of simplicity, these anions could be assumed to be the monovalent A^- but the reasoning applies as well to the general case A^{n-}. Then the exchange with another anion, B^-, proceeds according to

$$-\overset{|}{\underset{|}{M}}-OH_2A + B^- \rightleftharpoons -\overset{|}{\underset{|}{M}}-OH_2B + A^- \qquad (1)$$

The ion exchange can also take place by direct substitution of the OH-group with B^-

$$-\overset{|}{\underset{|}{M}}-OH + B^- + H^+ \rightleftharpoons -\overset{|}{\underset{|}{M}}-B + H_2O \qquad (2)$$

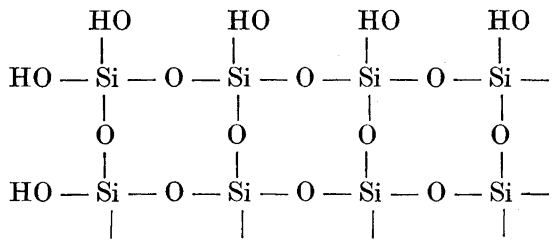
In the latter case a bond is formed between B and M.

At higher pH, where cation exchange takes place, the reaction could for the simple case of a monovalent cation be written according to

$$-\overset{|}{\underset{|}{M}}-OH + Me^+ \rightleftharpoons -\overset{|}{\underset{|}{M}}-OMe + H^+ \qquad (3)$$

The position of these exchange equilibria depends, of course, on the basicity of the group $-\overset{|}{\underset{|}{M}}-O^-$. The stronger the ability of this group to bind H^+, the higher the pH at which the transition from anion to cation exchange takes place. As the hydroxide is not strictly monofunctional, but contains groups of different basicity, it exhibits in a transition region both anion and cation exchange properties.

The structure of silica gel seems to be analogous to the structure of the hydroxides described above. It consists of a network of joined SiO_4-tetrahedrons, where however the oxygen atoms are only partially required to make up the Si-O-Si bridges [2,3]. The rest of the oxygen atoms are free to bind ions from the solution out of which the gel is precipitated. Thus the silica gel consists of structural groups of the following type:



Here the central ion consists of Si^{4+}, which has a rather high electron affinity. This implies that the electron density around an oxygen atom bound to silicon is lower than around one bound to, say, a metal atom. Thus the free electron pairs on the oxygen atoms are comparatively inactive and therefore the basicity relatively low. Hydrogen ions bound to a $-\overset{|}{\underset{|}{Si}}-O^-$ group can therefore be replaced rather easily by other positive ions. The basicity is in fact so low that even if one proton is bound with fair strength (the silica gel is a weak acid), a second proton will not be taken up. Hence cation exchange according to (3) is possible even at comparatively low pH, while anion exchange is not at all possible. So the silica gel will function solely as a weakly acid ion exchanger, for which the exchange reaction can be written schematically as

$$n\ HG + M^{n+} \rightleftharpoons MG_n + nH^+ \qquad (4)$$

In this formula G stands for the unreactive gel framework with its attached functional groups.

The position of this equilibrium depends not only on the basicity of the gel framework but also on its affinity for the metal ion in question. It is reasonable to suppose that those metal ions which have a strong tendency to form complexes with oxygen containing anions can also compete successfully with H^+ in quite acid solutions. This expectation has received full experimental confirmation for such metal ions, *i.e.*, those combining a high charge with a small ionic radius.

EXPERIMENTAL

Chemicals. All chemicals were, if not otherwise stated, of analytical grade and used without further purification.

Two different makes of *silica gel* were used, *viz.* Kebo and Merck 'silica gel for chromatographic use'. The Kebo gel was used in two grain sizes, *viz.* 50—100 mesh and 100—200 mesh. The Merck product had a grain size finer than 300 mesh. Considerable quantities of hydrogen ions were sorbed by all the gels when treated with neutral or acid solutions.

Silica gel, saturated with hydrogen ions, was prepared by repeated washing of these gels with 5 M HNO_3 and/or 5 M HCl at 80–90°C. The gel was then freed from mechanically bound acid by washing with distilled water and dried for 20 h at 100°C. The product sorbed neither hydrogen ions nor water.

Uranyl perchlorate solution was prepared and analysed as described in Ref.[4]

Uranium (IV) perchlorate solution was prepared by electrolytic reduction of uranyl perchlorate solution and analysed according to Ref[5]

Plutonium (A.B. Atomenergi, Stockholm), was obtained as the isotope ^{239}Pu ($T_{1/2}$ = 24 360 years), isolated from neutron irradiated uranium. It was supplied as a nitrate solution of Pu(IV), with $C_{HNO_3} = 0.1$ M and containing about 1 mg Pu/ml ($C_{Pu} \approx 4$ mM). In this solution, however, there exist also appreciable amounts of Pu(III) and Pu(VI). These ions have been formed by the disproportionation of Pu(IV) which can be written as follows, if the nitrate complexes existing in the solution are temporarily neglected

$$3\ Pu^{4+} + 2\ H_2O \rightleftharpoons 2\ Pu^{3+} + PuO_2^{2+} + 4\ H^+$$

If the acidity is increased, the equilibrium is evidently forced strongly to the left, H^+ being present in the fourth power in the equilibrium expression. If nitric acid is used to increase the acidity, a stabilization of Pu(IV) of equal importance will however result from the addition of nitrate ions, as these form complexes preferably with Pu(IV). Thus the equilibrium constant for the plutonium(IV) disproportionation in 1 M perchloric acid [6] is 0.0089 as compared with 4×10^{-7} in 1 M nitric acid [7].

The value of the equilibrium constant also increases rapidly with raising temperature [8]. This is also the case with the tendency of nitric acid to *oxidize* Pu(IV) to Pu(VI)[9,7 p. 270]. It is therefore impossible to convert the plutonium completely into Pu(IV) by heating with only moderately concentrated acid. On the other hand, evaporation with *strong* nitric acid works as a rule (*cf.* Ref.[9]). In those cases where this treatment failed, reduction with hydrogen peroxide has been performed as follows (*cf.* Ref.[10]).

To 5 ml 4 M HNO_3, 0.3 ml of the initial plutonium solution and some drops of 10 % H_2O_2 were added. Then this solution was evaporated nearly to dryness and a new addition of 4 M HNO_3 and 10 % H_2O_2 was made. After 20 h the evaporation was repeated. Then conc. HNO_3 was added and evaporated nearly to dryness. This operation was repeated twice, the solution having a final volume of 0.1 ml of conc. HNO_3. When the evaporation vessel had cooled down to room temperature the content was transferred to a receptable with 10 ml 1 M HNO_3. In this way a stock solution with $C_{Pu(IV)} = 1.2 \times 10^{-4}$ and $C_{HNO_3} \approx 1$ M was obtained, in which Pu(IV) is stable at room temperature.

The amount of plutonium(IV) was determined by investigation of the distribution of the plutonium between 1 M HNO_3 and 0.3 M thenoyltrifluoroacetone in benzene (only plutonium(IV) is extracted into the benzene phase at this acidity) [10,11]. The stock solution contained less than 1 % of the plutonium as Pu(III) + Pu(VI).

All the work with plutonium was carried out either in a glove box or in well-ventilated fumehoods.

Radioactive *zirconium(IV)* solution was prepared by dissolving a known amount of neutron irradiated $ZrO(NO_3)_2 \cdot 2H_2O$ in perchloric acid. The zirconium(IV) concentration of the stock solution was 91.7 mM and its acidity 4 M. By the irradiation (15 g was irradiated for 11 days at a flux of 10^{12} neutrons $\cdot$ cm^{-2} $\cdot$ sec^{-1}) the isotopes ^{93}Zr ($T_{1/2} = 9.5 \times 10^5$ years) and ^{95}Zr ($T_{1/2}$ = 65 days) are preferentially produced. Besides these zirconium isotopes, the preparation also contains two other active nuclides, *viz.* ^{95}Nb ($T_{1/2}$ = 35 days) and to some extent also ^{181}Hf ($T_{1/2}$ = 46 days). ^{95}Nb is an inevitable constituent, as it is the result of the disintegration of ^{95}Zr. Hafnium occurs as a slight impurity in the zirconyl nitrate, but as it has a large thermal neutron cross section relative to zirconium, the formation of the active ^{181}Hf is fairly considerable.

Radioactive *gadolinium (III)* solution was prepared by dissolving neutron irradiated Gd_2O_3 in perchloric acid. The excess of acid was evaporated and the residue dissolved in water. A solution with C_{Gd} = 9.19 mM and pH $\approx$ 3.5 was obtained. The irradiated oxide had been allowed to cool for 3 months and the activity was thus due mainly to ^{153}Gd ($T_{1/2}$ = 236 days).

0.1 M radioactive *sodium chloride* solution was prepared by neutralization of a known amount of neutron irradiated $NaHCO_3$. The CO_2 formed was carefully removed. By

neutron irradiation of $NaHCO_3$ a product was obtained in which the activity comes mainly from ^{24}Na ($T_{1/2}$ = 15 h).

Procedure. The metal ion sorption on the silica gel was established by shaking metal salt solutions of varying pH with a suitable amount of gel. The acidity was adjusted by additions of perchloric acid (for metal ions sorbed at low pH), acetate buffer (for Gd^{3+}), ammonia (for Ba^{2+} and Ca^{2+}) and sodium hydroxide (for Na^+). In principle, the solutions were then shaken until equilibrium was reached. As seen in Tables 3—5 below, this was achieved in quite a short time for ions of charge up to three, while four-valent ions needed several days. In the case of Zr, equilibrium was certainly not reached for $C_H \leq 400$ mM when the experiments were interrupted after three days, and possibly not even completely for values of $C_H \geq 800$ mM which are the ones used for the calculation of D_{Zr} in Fig. 6. The experiments were all performed at 20 ± 0.1°C except one especially mentioned below. The ratio between the volume of solution, v, and the amount of silica gel, m, was as a rule 10^{-2} l/g. The sorbed quantity of metal was obtained by determination of the metal ion concentration in the solution before and after the experiment. For this purpose different analytical methods were used.

The *uranyl* concentration was determined spectrophotometrically by Ahrland's method [13]. Since the solutions contained perchlorate ions, $Na_4Fe(CN)_6$ was used instead of $K_4Fe(CN)_6$ for developing the "uranylhexacyanoferrat colloid". As a suitable wave length 4 900 Å was selected. The acidity and the concentration of cyanoferrate were 0.05 M and 0.2 M respectively. The colloid prepared in this manner has at λ = 4 900 Å a molar extinction coefficient which is only about half as large as that found when the potassium salt is used. Beer's law is however much better fulfilled when the sodium salt is used, especially at the lowest uranyl concentrations measured. In fact concentrations as low as 0.01 mM can be determined in this way with a fair accuracy (≈ 2 %).

Uranium (IV) was determined by cerimetric titration using ferroin (tris-*o*-phenanthroline iron(II) sulfate) as an indicator.

Plutonium was determined radiometrically. Its α-activity was measured with a gas-flow (90 % A, 10 % CH_4) proportional counter (Tracerlab SC-16 P). The samples were measured inside its ionization chamber in a well defined geometry (2 π). Absolute determinations of the concentration of the plutonium solutions were thus feasible. Owing to the short range of the α-particles, dry and very thin samples were prepared, so that the self-absorption of α-particles could be neglected. The α-samples were prepared by evaporation of 0.10 ml of solution to dryness on stainless steel or platinum dishes. The micropipette used for sampling was rinsed once with 1 M HNO_3 and the washing acid was evaporated on the same dish as the main portion of the sample.

Sodium, zirconium and *gadolinium* were also determined radiometrically. The γ-activities of the samples were measured with a scintillation counter (Tracerlab P 20) provided with a thallium activated sodium iodide crystal.

For each radiometrical measurement more than 10 000 counts were registered. Thus the error of counting was always <1 %.

Calcium and *barium* were determined volumetrically with EDTA according to Schwarzenbach [14].

The *hydrogen ion concentrations* of the UO_2^{2+}-solutions were determined by measuring the emf of cells of the type

Au	9.34 mM $HClO_4$ 1 M $NaClO_4$ quinhydrone(s)	1 M $NaClO_4$	C_H mM 1 M $NaClO_4$ quinhydrone(s)	Au

In the rest of the experiments the hydrogen ion concentrations were measured by a glass electrode in connexion with a vacuum-tube potentiometer (Radiometer PHM 3h).

RESULTS

Urunyl sorption isotherms. The description of the sorption properties of the silica gel given here is based upon sorption isotherms obtained for UO_2^{2+}. These were determined at varying pH with three different gels. The results are given

Table 1. The sorption of UO_2^{2+} on silica gel saturated with hydrogen ions. $v/m = 10^{-3}$ l/g. Shaking time 24 h.

in Table 1 and Figs. 1 and 2. C_{MG} (mmoles UO_2^{2+} sorbed per gram silica gel) is plotted against C_{MS} (the concentration of UO_2^{2+} in the water solution expressed in mM) for various C_H (the initial concentration of hydrogen ions).

In the experiments reported in Fig. 1, where silica gels washed only with water have been used the most different behaviour is found for the different gels though the initial concentrations of hydrogen ions were the same. At a given C_H Kebo 50—100 mesh sorbs only about half as much as Kebo 100—200 mesh. The Merck gel, not presented in the figure, sorbs 100 % in the whole range of concentration investigated. It is also evident however, that C_{MG} in-

creases when the hydrogen ion concentration decreases at constant C_{MS}, as could be expected (*cf.* p. 1060).

When the experiments were repeated, using silica gel saturated with hydrogen ions, the results given in Fig. 2 were obtained. At a given pH, the different gels obviously given the same sorption isotherms, within experimental error.

In the series performed with water-washed gels, $[H^+]_S$, the hydrogen ion concentration after the sorption, has dropped considerably below the original hydrogen ion concentration C_H. If the initial concentration of UO_2^{2+} is 0.20 mM and C_H = 1 mM, $[H^+]_S$ is 0.61 mM for the Kebo 50—100 mesh, 0.30 mM for

the Kebo 100—200 mesh and 0.002 mM for the Merck. The decrease in hydrogen ion concentration in the outer solution causes in its turn an increased sorption of UO_2^{2+}.

In the second series on the other hand, $[H^+]_S$ is even somewhat greater than C_H, Table 1. This behaviour is expected, as hydrogen ions must be released from a gel already saturated with these ions, when other cations are sorbed. $[H^+]_S - C_H$ ought to be equivalent to C_{MG}. Bearing in mind the great error inherent in the calculation of $[H^+]_S - C_H$, due to the fact that $[H^+]_S \approx C_H$, it might be considered that this equivalence has been proved, Table 1. A more careful investigation of this point is described later.

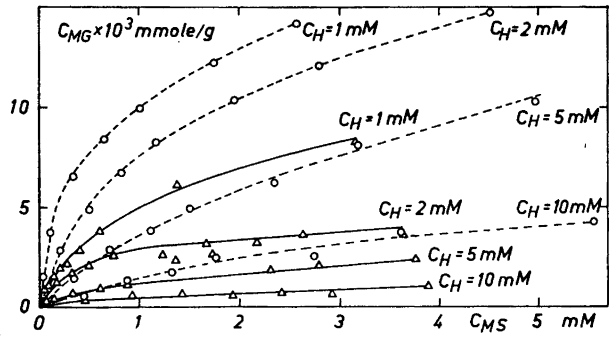

Fig. 1. The sorption of UO_2^{2+} on silica gel washed only with water, $v/m = 10^{-2}$ l/g. Kebo 50—100 mesh △, Kebo 100—200 mesh O.

From the experiments above, it seems reasonable to assume, that the difference between the water-washed gels is due to different counter ions having been sorbed in varying amounts during the preparation of the gel. Hence the more or less pronouced uptake of hydrogen ions from the solution and the lack of reproducibility between different preparations. In order to achieve reproducible conditions only gels saturated with hydrogen ions were used in the subsequent experimental work. These do not alter the pH of the solutions by any irrelevant process.

Alkalimetric titration of H^+-saturated gel. The weakly acid properties of the silica gel are also apparent from an alkalimetric titration of the H^+-saturated gel. The titration was performed by shaking 5 g gel at 20°C with 50 ml sodium hydroxide solution of varying concentration, containing neutral salt to a constant initial concentration of $Na^+ = 100$ mM. The solution and the gel were separated and the pH was determined with a glass electrode or if a substantial part of the base was left by titration. In this case the pH was computed from the relation $pH = 14 - p[OH^-]$. Experiments were performed with Kebo

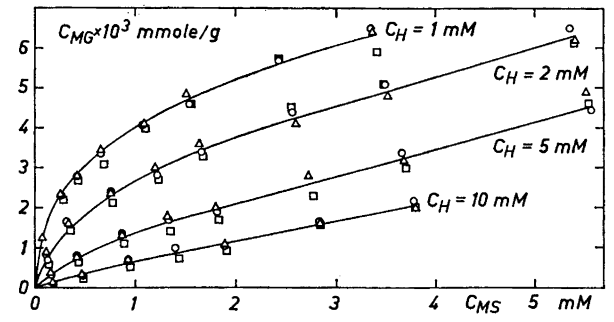

Fig. 2. The sorption of UO_2^{2+} on silica gel washed with acid, $v/m = 10^{-2}$ l/g. Kebo 50—100 mesh △, Kebo 100—200 mesh O, Merck □.

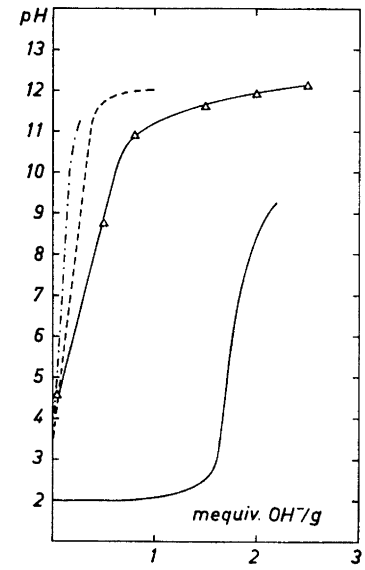

Fig. 3. pH of the outer solution as a function of the total amount of sodium hydroxide added to the solution per g dried ion exchanger. Silica gel △ and ————, sulfonated resin ————, phenolic resin — — — — —, glauconite —.—.—.

50—100 mesh and Kebo 100—200 mesh, both of which gave the same results. Mean values of these are plotted in Fig. 3. Here the titration curves are also drawn for two organic ion exchangers (phenol resin and sulfonated resin) as well as for the ion exchanging mineral glauconite (in greensand) [15]. The titration curve of the silica gel is similar to those of the weakly acid ion exchangers.

Verification of the equivalence between the amount of metal ions sorbed and the amount of hydrogen ions set free. In order to prove more strictly that the silica gel acts as an ion exchanger, a closer investigation than the one previously mentioned has been performed of the relation between the metal ions sorbed and the hydrogen ions set free.

By choosing an ion, *e.g.* Na^+, that is not hydrolysed, it is possible to work with alkaline solutions, thereby obtaining a high sorption. Consequently amounts of H^+ large enough to be accurately determined are set free. This could not be realized for the sorption of UO_2^{2+}.

As in the titration just described the gel was shaken with solution of varying $[OH^-]$, containing a constant initial concentration of $Na^+ = 100$ mM. In this case the neutral salt was however NaCl, labelled wish ^{24}Na. By the determination of the sorbed Na^+ it is necessary to correct for the error caused by the decay of ^{24}Na. This was done by measuring several times during a series the activity of an identical solution with no silica gel added. The amount of H^+ set free was determined by acidimetric titration of the alkali left after the shaking. The results from two series are given in Table 2. In one of the series where as much as 5 g gel was used, it was necessary to correct for the amount of H^+ adhering to the gel on account of incomplete preparatory washing of the gel sample used in these experiments. The correction, which amounted to 0.011 mequiv./g of silica gel, was determined in a special experiment, where silica gel was shaken only with water.

Table 2. The equivalence between the amount of Na^+ sorbed and the amount of H^+ set free. $v = 50$ ml, $m = 0.5$ g and 5 g. Experiments performed with 5 g silica gel are indicated by *. In these cases the amount of H^+ set free is corrected by the amount of acid liberated when the gel is washed only with water (0.011 mequiv./g).

The complete agreement between the amount of sorbed Na^+ and the amount of H^+ set free, fully confirms that the sorption is an ion exchange, as had already appeared probable from the UO_2^{2+}-measurements. This equivalence has also been proved by other workers [16].

The possibility of applying the law of mass action to the exchange reaction (4), was tried on the UO_2^{2+}—H^+ measurements previously mentioned. In this case the reaction could be written as follows

$$2\ HG + UO_2^{2+} \rightleftharpoons UO_2G_2 + 2\ H^+ \qquad (5)$$

Thus from the law of mass action

$$K = \frac{[H^+]^2[UO_2G_2]}{[HG]^2[UO_2^{2+}]} \cdot \frac{\gamma_{H^+}^2 \cdot \gamma_{UO_2G_2}}{\gamma_{HG}^2 \cdot \gamma_{UO_2^{2+}}} \qquad (6)$$

The distribution coefficient D for uranium is defined as the ratio between the concentration of uranium in gel and solution, *viz.* $D = C_{MG}/C_{MS}$ C_{MG} is expressed in mmole/g of silica gel and C_{MS} in mmole/litre. Thus the dimension of D is $l \cdot g^{-1}$. As UO_2^{2+}, under the present conditions, neither forms complexes nor is hydrolysed, the distribution coefficient becomes $= [UO_2G_2]/[UO_2^{2+}]$.

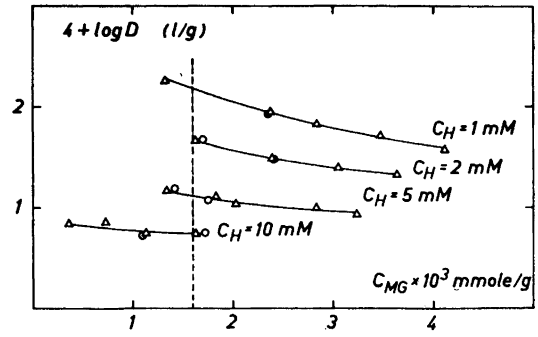

Fig. 4. Log D as a function of C_{MG} for the sorption of UO_2^{2+} on H^+ — saturated silica gel, $v/m = 10^{-2}$ l/g. Kebo 50—100 mesh △, Kebo 100—200 mesh ○.

In Fig. 4, log D is plotted as a function of C_{MG} with C_H as a parameter. The curves are intersected at $C_{MG} = 1.6 \times 10^{-3}$ mmole/g. Thus log D is obtained at a constant and low load. Under these conditions the activity coefficients $\gamma_{UO_2G_2}$ and γ_{HG} as well as [HG] can be considered as fixed.

By taking the logarithms of eqn (6) we obtain

$$\log D = -2 \cdot \log[H^+] \cdot \frac{\gamma_{H^+}}{\sqrt{\gamma_{UO_2^{2+}}}} + \log K \cdot [HG]^2 \frac{\gamma_{HG}^2}{\gamma_{UO_2G_2}} \qquad (7)$$

The last term is a constant and the activity coefficients γ_{H^+} and $\gamma_{UO_2^{2+}}$ could be computed from the equations of Debye-Hückel. $[H^+]$ is obtained by interpolation of the measured $[H^+]_S$ for the points situated on each side of the intersection. If the assumptions made are true, log D plotted as a function of log $[H^+]\,\gamma_{H^+}/\sqrt{\gamma_{UO_2^{2+}}}$ should give a straight line of slope −2.

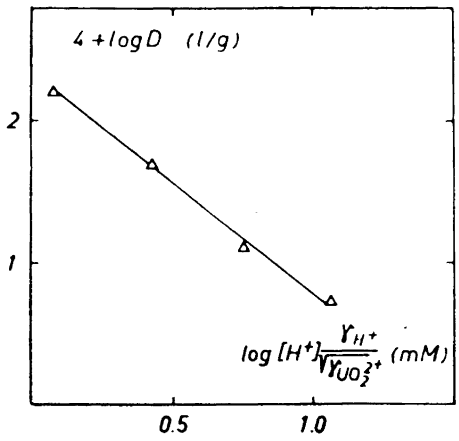

Fig. 5. Log D as a function of log $[H^+]\frac{\gamma_{H^+}}{\sqrt{\gamma_{UO_2^{2+}}}}$ at constant load $C_{MG} = 1.6 \times 10^{-3}$ mmole/g.

From Fig. 5 it is evident that a straight line is obtained, but its slope is only $-(1.6 \pm 0.1)$. This discrepancy can partly be accounted for by the ion invasion into the gel which takes place according to the Donnan equilibrium. The concentration of free hydrogen ions thus established within the gel will strongly influence γ_{HG} which therefore might vary considerably in spite of the load being constant.

Thus, in summing up, the following points are valid for the metal ion sorption on the silica gel:

I. For gel not saturated with hydrogen ions the sorption depends on the manner in which the gel is prepared.

II. If the gel is saturated with hydrogen ions the same sorption isotherms are obtained even with different gel makes.

III. The H^+-saturated gel gives a titration curve similar to those found for weakly acid ion exchangers.

IV. At the sorption of metal ions on a H^+-saturated gel, the amount of hydrogen ions set free is equivalent to the amount of metal ions sorbed.

V. The law of mass action is approximately valid for the exchange reaction.

The affinity of different metal ions to the gel. As previously stated, the sorption of metal ions depends strongly on the pH of the solution. This is true for all of the investigated ions, *viz.* Na^+, Ca^{2+}, Ba^{2+}, UO_2^{2+}, Gd^{3+}, Zr(IV) + Nb, U(IV) and Pu(IV), as is evident from Fig. 6 where log D for the different metal ions is plotted as a function of pH. It is also clear that the log D-curves are displaced to more acid solutions with increasing ratio between the charge and the size of the metal ion. This means that the affinity for the gel follows the

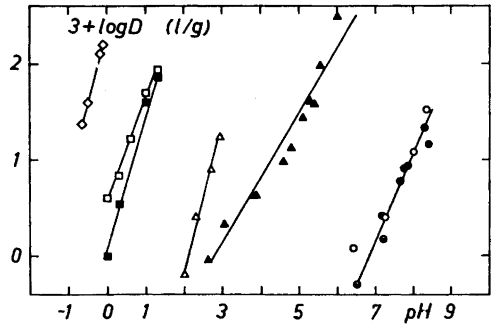

Fig. 6. Log D for some metal ions as a function of pH. Kebo 50—100 mesh, $v/m = 10^{-2}$ l/g.

Element (state)	Zr + Nb	U(IV)	Pu(IV)	U(VI)	Gd	Ca	Ba	Na
Sign	◇	□	■	△	▲	○	◒	●
C_M mM	1.1	2.0	10^{-2}	1.0	0.092	25	25	30

same order which has also been found for the sorption on organic cation exchangers. The position of the UO_2^{2+}-curve about six pH units to the left of the curves of the other ions with charge + 2 is noteworthy. But even though the uranyl ion formally has a charge of only + 2, it often behaves as if its charge is considerably higher [17], *e.g.* on hydrolysis and complex formation.

Obviously the sorption is important only when the pH has passed a definite value. To the left of the log D-curve very little of the metal ion is sorbed, whereas to the right complete sorption occurs. Therefore ions with curves sufficiently apart could, by a suitable choice of pH, be separated from each other.

For practical separations, the sorption capacity, C_{MG}, is of great interest. According to Table 2 the total capacity at saturation is 1.2—1.4 mequiv/g gel. If the total capacity is required the pH must be relatively high at least for ions with a low charge. The sorption capacities for some ions as a function of pH are reported in part II of this work.

The sorption rate is both of theoretical and practical interest. In this respect the different ions can be placed in two groups. Ions like Na^+, Ca^{2+}, Gd^{3+} and UO_2^{2+} are sorbed very fast (in general more than 95 % of the final amount is sorbed within 5 min), whereas ions formed by Zr(IV) + Nb, U(IV) and Pu(IV) are taken up more slowly, see Tables 3, 4 and 5 as well as Fig. 7. The latter group contains those ions which are strongly hydrolysed even in rather acid solution. Moreover large and polynuclear species are formed on the hydrolysis of these ions [18–20].

In order to investigate whether the low reaction rate in the second group is caused by a slow hydrolysis or by a slow sorption, the following experiment was performed.

From the stock solution of Pu(IV), solutions with $C_{Pu} \approx 2 \times 10^{-6}$M and C_{HNO_3} varying between 0.02 and 1 M were prepared. Within the range of $[H^+]$ where the hydrolysis is considerable, *viz.* at $[H^+] \leq 0.5$ M, the sorption rate of both freshly prepared and aged solutions was investigated by analysis of samples taken at different times. When this technique is used the original relations between v and m is admittedly somewhat changed during the experi-

Table 3. The sorption rate of UO_2^{2+}, Gd^{3+}, Ca^{2+} and Na^+. Kebo 50—100 mesh, $v/m = 10^{-2}$ l/g. The initial concentrations and acidities were: $C_U = 0.20$ mM at $C_H = 2$ mM, $C_{Gd} = 0.092$ mM at pH = 5.0, $C_{Ca} = 25.3$ mM at $C_{NH_3} = 140$ mM, $C_{Na} = 100$ mM at $C_{OH} = 50$ mM.

150	89	89	82	27	94	89	84	27	—

ment. In the actual case the change was however slight (≈ 5 %) and could not possibly influence the results very much. The results are given in Table 4.

It is evident, from a comparison between fresh and aged solutions, that both require about the same time to be equilibrated with the gel. A pronounced difference appears, however, in the beginning of the sorption. From the aged solutions with $C_{HNO_3} = 0.02$, 0.05 and 0.1 M, about half the final amount is sorbed in 30 min, whereas the freshly prepared solutions have sorbed as much as 80 % of this amount in this time. A probable explanation of this behaviour is that Pu^{4+} and other low molecular species are preferentially sorbed by the gel. In freshly prepared solutions the polynuclear hydrolysis is not yet finished and therefore the concentration of low molecular easily sorbable species is much higher than in aged ones. Thus the slow sorption of the aged solutions is presumably due to the slow breaking up of the polymerized species dominating there. No difference could be detected at $C_{HNO_3} = 0.5$ M. In this case, as well as for $C_{HNO_3} > 0.5$ M, the equilibrium is also quickly attained. At this acidity Pu(IV) is in fact mainly present (> 95 %) as Pu^{4+} and monomer nitrate complexes [21,22] and the sorption is therefore of the same nature as for Na^+, Ca^{2+}, Gd^{3+} and UO_2^{2+}.

Similar behaviour was found for Zr(IV) + Nb, where only aged solutions were investigated, Table 5. Although the γ-activity used for the analysis

Table 5. The sorption rate of Zr(IV) + Nb at different concentrations of nitric acid. Aged solutions. Kebo 50—100 mesh, $v/m = 10^{-2}$ l/g. $C_{Zr} = 1.1$ mM.

of the solutions partly comes from ^{181}Hf, the results obtained should nevertheless represent the sorption properties of Zr(IV) + Nb, as ^{181}Hf occurs only in tracer concentrations and has such a great chemical resemblance to Zr. This is moreover conclusively proved by the fact that the γ-spectrum of the solution indicates the same ratio Hf to Zr + Nb before and after the sorption. As seen from Table 5, the sorption after 74 h for 0.8 M $\leq C_{HNO_3} \leq$ 4.5 M is increasing with decreasing hydrogen ion concentration as is normally the case. The decrease found for $C_{HNO_3} <$ 0.8 M must be due to the fact that equilibrium had not yet been established for these low acidities, in spite of the long shaking time. As is also seen from Table 5, the time necessary for the sorption to reach half the final value decreases with increasing C_{HNO_3}. This is also true for aged

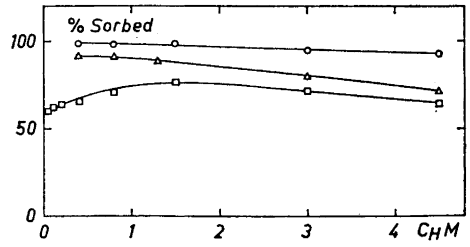

Fig. 8. The sorption rate of Zr + Nb on Kebo 50—100 mesh in hydrochloric (○), perchloric (△) and nitric (□) acid. Shaking time 21 h, $v/m = 10^{-2}$ l/g, $C_{Zr} = 1.1$ mM.

Table 6. The sorption rate of Pu(IV) at 49°C and different concentrations of nitric acid. Freshly prepared solutions. Kebo 50—100 mesh, $v/m = 10^{-3}$ l/g. $C_{Pu} = 2.2 \times 10^{-3}$ mM.

Pu(IV)-solutions (Table 4). A. comparison was also performed of the sorption of Zr(IV) + Nb from nitric, hydrochloric and perchloric acid, Fig. 8. The shaking time was fixed at 21 h. In the figure one notices particularly, that the curves separate widely at small C_H. In perchloric and hydrochloric acid equilibrium is evidently attained faster than in nitric acid, which is rather remarkable.

In order to investigate the influence of the temperature on the sorption rate, a series with Pu(IV) at 49°C was also performed, Table 6. No significant differences in the rate, compared with the series obtained at 20°C, could be observed. The equilibrium sorption, however, was somewhat higher.

These investigations have been performed under a contract with *AB. Atomenergi* (The Swedish Atomic Energy Company), Stockholm. We would like to express our appreciation of this valuable co-operation which has made the present work possible.

Much technical information has also been received from *Försvarets Forskningsanstalt* (The Research Institute of National Defence), *Avd.* 4, Sundbyberg. The γ-spectrometric measurements have been carried out at the Radiophysical Institute, Lund. We are much indebted to the Head of the Institute, Dr Kurt Lidén, for his aid in this respect.

The lanthanide solutions have been put to our disposal by Dr Arthur Sonesson, Lund. We also want to acknowledge a careful linguistic revision of our manuscripts by Dr George Gamlen, Manchester.

Finally, our most sincere thanks are due to Professor Sture Fronœus, Lund, for many fruitful proposals and valuable comments.

The Ion Exchange Properties of Silica Gel

II. Separation of Plutonium and Fission Products from Irradiated Uranium

STEN AHRLAND, INGMAR GRENTHE and BERTIL NORÉN

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

A procedure, based on selective sorption on silica gel, has been worked out for the separation of plutonium and fission products from uranium which has been irradiated with thermal neutrons

In part I of this investigation [1], it has been shown that metal ion sorption on silica gel can be described by an ion exchange mechanism, with silica gel acting as an ion exchanger of the weakly acid type.

The distribution coefficient between gel and solution for the different metal ions accordingly increases strongly with increasing pH. The distribution coefficient is also larger for high-valent ions than for low-valent ones at a given acidity of the solution. A graphical comparison of the metal ions investigated is given in Ref.[1], Fig. 6. It can be seen that the affinity for the ion exchanger is given by the order

$$Zr(IV) > U(IV) \approx Pu(IV) > U(VI) > Gd > Ca \approx Ba \approx Na$$

In the same investigation it was also found that some species are sorbed very fast and other more slowly. UO_2^{2+}, Gd^{3+}, Ca^{2+}, Ba^{2+} and Na^{+} belong to the first group while the second contains Zr(IV), U(IV) and Pu(IV). The ions of the second group are all strongly hydrolysed in the actual solutions and occur mainly as polynuclear aggregates. For Pu(IV) it was found that at higher pH the sorption rate is dependent on the age of the solution.

From these results it is clear that it should be possible to separate Zr(IV), U(VI) and Pu(IV) both from one another and from Gd^{3+}, Ca^{2+}, Ba^{2+} and Na^{+} by suitably varying the pH of the solution.

The aim of this investigation has been to use this selective sorption on silica gel for a separation of uranium, plutonium and fission products from a nitric acid solution of neutron irradiated uranium.

After a cooling period of 100 days rather few elements contribute appreciably to the activity still remaining with the irradiated uranium. Apart from plutonium these are, in order of decreasing activity, zirconium + niobium, yttrium and several lanthanides, ruthenium + rhodium, strontium, barium and cesium (see *e.g.* the compilation of Rydberg[2]). A cooling period shorter than 100 days is not used as a rule because most reprocessing methods presuppose that ^{239}Np, ^{237}U, ^{133}Xe and ^{131}I have decayed before the treatment is started [3].

On the dissolution of uranium metal in nitric acid, uranium is oxidized to U(VI), while most of the plutonium is present as Pu(IV). The standard potentials for the different redox steps between Pu(III), Pu(IV), Pu(V) and Pu(VI) are so close to each other [4] that there is always a certain disproportionation in a solution of the mean oxidation state + 4. There are always finite concentrations of at least Pu(III) and Pu(VI) and at lower acidities also Pu(V). Zirconium is found as Zr(IV) and niobium probably as Nb(V), both more or less hydrolysed. Ruthenium occurs mainly as various nitrosyl-nitrato complexes of Ru(III) [5]. The actual state is highly dependent on the conditions at dissolution [6]. The other fission products have a less complicated chemistry and occur as hydrated metal ion. These of higher charge especially exist to a considerable part as nitrate complexes in the solution.

The ions to be found in a solution of neutron irradiated uranium metal are thus the same or in any case analogous to those ions, the sorption properties of which have been investigated in I. The behaviour of ruthenium, which cannot be anticipated from the experiments already performed, remains obscure. Another serious difficulty is that the separation of uranium and plutonium requires that they are in the oxidation states + 6 and + 4, respectively. Pu(VI), as plutonyl ion, has the same sorption properties as the analogous uranyl ion, while tervalent plutonium as Pu^{3+} shows a close resemblance to the lanthanide group. By a suitable choise of pH and total concentration of plutonium, C_{Pu}, the disproportionation can however be greatly suppressed [7-9]. At low pH, the position of the equilibrium which is independent of C_{Pu} strongly favours Pu(IV). As the pH is raised, a considerable disproportionation will exist in equilibrium, but the rate of the disproportionation reaction is quite slow at low values of C_{Pu}. Thus at pH = 1 in perchlorate medium the rate is less than 1 % an hour for $C_{Pu} < 10^{-4}$ M. The rather strong complex formation between Pu^{4+} and NO_3^- [10,11] also stabilises Pu^{4+} relative to Pu^{3+} and PuO_2^{2+} if a nitrate medium is used.

By treating a disproportionated solution of plutonium with nitrite it is possible to transfer all the plutonium to the oxidation state +4. The reaction is complicated and is certainly not yet fully understood [12].

CHEMICALS USED, ANALYTICAL

The preparations of neodymium, cerium, gadolinium and ytterbium salts were the same as used by Sonesson [13].

Neodymium and ytterbium were analyzed spectrophotometrically using aurinetricarboxylic acid [14]. Cerium(III) was oxidized to Ce(IV) by persulfate and then determined by reduction with Fe(II). The gadolinium solutions contained the isotope ^{153}Gd and were analyzed radiometrically.

The other chemicals were the same as used in I, and were analyzed in the same way as described there.

RESULTS

The investigation consists of the following three parts:

1. Investigation of the sorption properties of separate ions using chromatographic methods.

2. Sorption at continuous passage of solution through the column followed by a determination of the sorption capacity for the metal ions in question.

3. Test separations of solutions of known composition.

Chromatographic experiments. Two different columns have been used, one of 100 cm length and 1.0 cm inner diameter and one of 43 cm length and 1.1 cm diameter. The longer column takes a solution volume of 50 ml, the shorter one a volume of 25 ml. By varying the length of the column and the flow rate, the contact time between solution and gel can be widely varied.

When used, the column is first saturated with nitric acid of desired concentration. Then a given volume of metal ion solution is placed on top of the column. This volume is small compared with the total volume of solution in the column. By means of an acid flow from a vessel on higher level the sample is transported down the column. Fractions of the outflowing solution are collected with a fraction collector and analyzed.

The sorption of *U(VI)* from solutions containing 0.1 and 0.5 M nitric acid was investigated. In both cases, U(VI) passed the column in the solution front. No sorption thus occurred at these acidities, a result consistent with the equilibrium experiments reported in Ref.[1], Fig. 6.

In the *Pu* experiments, the contact time is a variable of about the same importance as the acidity. The following experiments, performed at $C_H = 0.5$ and 0.1 M using different flow rates and column lengths are typical for the influence of each of these variables. For $C_H = 0.5$ M, the results are in Figs. 1 and 2 where C_{Pu} of each fraction, expressed in disintegrations·min^{-1}·ml^{-1}, is given as a function of the volume of solution which has passed down the column. The position of U(VI) for each column, as determined by the experiments mentioned above, is also indicated. Obviously, the plutonium is separated into two peaks. The first of these is found in the same position on the volume axis as U(VI). It contains about 2 % of the total amount of plutonium, *i.e.*

120.3	0	92.2	0.2
133.3	0	103.1	0

just the fraction found by analysis to exist as Pu(III) and Pu(VI). In the second peak the remaining plutonium is found as Pu(IV).

The above conclusions are further strengthened by the fact that the plutonium of the first peak is not extracted at pH = 0 by a 0.1 M solution of thenoyltrifluoroacetone (TTA) in benzene, while the plutonium in the second peak is completely extracted into the organic phase under the same conditions [15].

At the low flow rates a complete separation into two peaks is achieved. If the flowrate is increased, the separation is not so good (as was expected), but the existence of two peaks is nevertheless quite clear.

At $C_H = 0.1$ M, the distribution coefficient for plutonium is much larger than at $C_H = 0.5$ M. An experiment with the long column and a flow rate of 76 ml·hour^{-1}·cm^{-2} is reproduced in Table 1. From this table it can be seen that Pu(IV) is very strongly sorbed and that there is only a small plutonium leakage, less than 1 % of the total amount per fraction of 17 ml, during the continued passage of 0.1 M nitric acid. Pu(III) and Pu(VI) are found as before in the solution front.

By passing 4.5 M nitric acid through the column the plutonium is quantitatively eluted in the strong acid front, as its distribution coefficient at this acidity is very low. In Table 1 another experiment analogous to the previous one is also to be found. The only difference is that in the latter case the plutonium solution has remained for four days on the column before washing

with 0.1 M nitric acid. Pu(III) and Pu(VI) are found as before in the solution front but no Pu(IV) leakage could be detected. On elution with 4.5 M nitric acid, all the Pu(IV) came out as before in the strong acid front.

These column experiments confirm that the plutonium sorption is a fairly slow process. This is also evident from a determination of the *plutonium distribution on the column.* Sorption and subsequent washing with 0.1 M HNO_3 were made in the same way as in earlier experiments. The solution phase was then removed by blowing compressed air through the column. After drying, the silica gel column was removed in sections of fixed length. These were eluted with 4.5 M nitric acid and the amount of plutonium was determined. The resulting distribution curve is reproduced in Fig. 3 and shows that the plutonium penetrates rather deeply into the column before the sorption is complete.

The plutonium(IV) sorption is not entirely reproducible. A large number of experiments have been performed which show a leakage varying between zero and an upper limit given by the first of the experiments reproduced in Table 1. Furthermore the Pu(IV) leakage always decreases with decreasing flow rate.

As is evident from earlier equilibrium experiments [1] the sorption behaviour of *zirconium* is very complicated. The variation in sorption rate with pH is more pronounced than for plutonium(IV). The results from the equilibrium

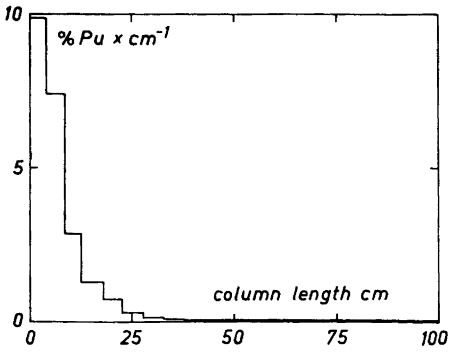

Fig. 3. The distribution of plutonium on the silica gel column when sorbed from 0.1 M nitric acid at a flow rate of 60 ml · h^{-1} · cm^{-2}.

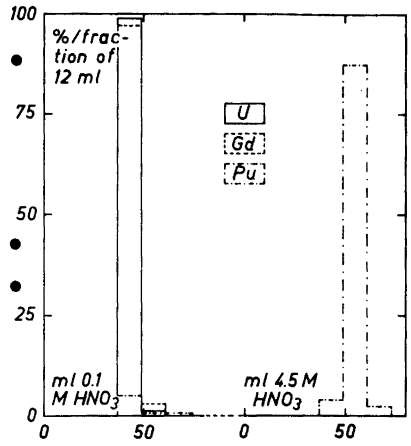

Fig. 4. Separation of Pu(IV) from U(VI), Pu(VI), Pu(III) and Gd(III) by sorption on silica gel from 0.1 M nitric acid, with subsequent elution of Pu(IV) by means of 4.5 M nitric acid. Column length 100 cm, flow rate 60 ml · h^{-1} · cm^{-2}.

measurements have been confirmed qualitatively by column experiments. The long column has been used for all the experiments and the amount of zirconium added has always been 1 ml of 11 mM zirconium(IV) solution.

The results from three runs at C_H = 0.1, 1.5 and 5 M nitric acid and a constant flow rate of about 38 ml·$hour^{-1}$·cm^{-1}, are given in Table 2. The Zr(IV) leakage is very large at the lowest acidity, but rather slight at the higher ones. This behaviour is expected as a result of the very low sorption rate at higher pH-values (*cf.* part I). If the flow rate is increased the leakage also increases rapidly. Thus a doubling of the flow rate at C_H = 1.5 M gives a leakage of the same magnitude as found for C_H = 0.1 M at the lower flow rate.

After a nitric acid wash, the column was eluted with 0.1 M oxalic acid. Because of the high distribution coefficient for Zr(IV) a strong complexing agent is needed for the elution. 1 M sulfuric acid and 0.1 M oxalic acid were both tried, but 0.1 M oxalic acid was the better of the two.

The above is in qualitative accordance with results obtained by Rydberg [2] for sorption of tracer amounts of zirconium on silica gel. According to Rydberg, the leakage is very large even at C_H = 1.5 M. The reason for this difference might be differences in flow rate (not specified in Rydberg's work) or zirconium concentration.

As representatives of yttrium and the lanthanides, neodymium, gadolinium and ytterbium have been studied. The experiments have been performed separately for each ion, using the long column. The result was that no sorption could be proved in 0.1 M nitric acid. Like U(VI), all the lanthanides passed down the column in the solution front.

The results of the chromatographic experiments indicate that Pu(IV) and Zr(IV) might be separated from one another and from U(VI) + lanthanides by a suitable variation of pH. In order to get a good separation the flow rate must not be too high.

The following experiment was performed to confirm this. A solution of U(VI) (0.1 ml 285 mM uranyl perchlorate solution), Pu(IV) (0.1 ml 0.51 mM nitrate solution containing 94.5 % Pu(IV)) and Gd(III) (0.1 ml 4.4 mM perchlorate solution) was chromatographed on the long column at a nitric acid concentration of 0.1 M.

The result, given in Fig. 4 is in complete accord with the previous experiments. U(VI), Gd(III), Pu(III) and Pu(VI) travel down the column in the solution front. Pu(IV) is nearly quantitatively sorbed, the leakage is less than 0.2 % of the total amount of plutonium per fraction of 12 ml. By passing 4.5 M nitric acid, all plutonium sorbed can be quantitatively eluted. The total yield of plutonium is 93.5 %, compared with the initial amount of 94.5 % Pu(IV).

Sorption behaviour on continuous passage of solution. For work with larger amounts of material it is desirable to be able to use a continuous sorption process. In this case it is of interest to know the sorption capacity $S \equiv C_{MG}$ for the column. By applying the law of mass action to the exchange reaction (Ref.[1], eqn. (4)) the following expression is obtained

$$S \equiv [MG_n] = K \frac{[M^{n+}]\ [HG]^n}{[H^+]^n}$$

where K is the concentration constant of the exchange equilibrium. From this expression it can be seen that S increases with increasing $[M^{n+}]$, *i.e.* with increasing C_{MS} and decreasing $[H^+]$. For very high C_{MS}, S will of course finally reach an upper limit when practically all sorption places are occupied by M^{n+} instead of the original H^+. For the sorption of Pu(IV) or fission products where C_{MS} is fairly low as a rule, this saturation value will not, however, be approached in practice.

The sorption capacity, S, has been determined as a function of C_{MS} and pH for a number of metal ions. A solution of fixed metal ion concentration, C_M, and pH is passed down the column and the effluent solution analyzed on the ion in question. The column capacity for a solution of the value of C_M used has been reached when the solutions entering and leaving the column have the same concentration $= C_M$ which is then identical with C_{MS} as defined above. From the break-through curve the sorption capacity is then easily calculated. The value thus obtained was then checked in the following way: The column was rinsed free from mechanically adherent solution by washing with pure solvent of the same pH as was used at the sorption. In order not to disturb the equilibrium in the column appreciably, the volume of the washing liquid was only one to two column volumes. After washing the column was eluted with strong acid and the eluate analyzed. The sorption capacity has been determined in this way as a function of pH for Zr, U(IV), U(VI), Ce(III), Gd, Ca and Ba.

Because of the very low affinity of the ion exchanger for calcium and barium ion experiments with these ions have been done in ammoniacal solution, all the others in nitric acid solution. The results are given in Tables 3—5.

From these tables it can be seen that the sorption capacities for the trivalent lanthanide ions examined are very small within the pH range investigated.

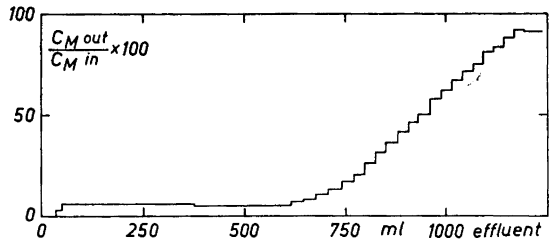

Fig. 5. Break through curve for Zr(IV) on a column filled with 60 g silica gel. Column length 100 cm, corresponding to a solution volume of 50 ml. Flow rate 60 ml · h^{-1} · cm^{-2}. C_M = 0.92 mM, C_H = 5 M.

On the other hand, the capacities for U(VI), U(IV) and Zr(IV) are large even at rather low pH-values. A determination of the sorption capacity for plutonium is not possible because of the small amount of material available. A sorption capacity of the same order of magnitude as for other four-valent ions is a plausible estimate.

Calcium and barium ions are not measurably sorbed at pH-values below 7. At higher pH-values there is a strong increase in sorption, a fact also confirmed by other authors [16-18]. For some reason which is still unknown, saturation capacities much higher than those observed for sodium ions (Ref.[1], Table 2) seem to be reached.

The distribution coefficients $D = C_{MG}/C_{MS}$ which can be calculated from these column experiments as the ratio S/C_M agree fairly well with those obtained in the equilibrium experiments of Ref.[1], even for the four-valent ions.

The slow Zr(IV) sorption gives rise to a leakage of between 5 and 10 % of the total amount Zr on continous passage of solution. A typical break through curve is reproduced in Fig. 5. The rise at about 750 ml is caused by saturation of the column.

Analogous experiments have also been performed on plutonium solutions at concentrations about 10^{-5} M. The flow rate was, however, slower, only 2.3—4.6 ml·$hour^{-1}$·cm^{-2}. The results showed a quantitative sorption of plutonium(IV) and, as before, no retention of plutonium(III) and (VI).

These experiments proved that a selective sorption is possible even with a continuous column process. In the next section some test separations on solutions of known composition are described.

ForU(IV), the found increase of S with C_{MS} is somewhat irregular (*cf.* Table 3) which is certainly due to the fact that solutions of different age were used for the experiments. U(IV) solutions of low C_H alter their properties markedly with time, due to slow hydrolytic reactions [19].

Test separations on solutions of known composition. The first solution had the following composition: C_{Zr} = 9.17 mM, $C_{Pu} = 2.39 \times 10^{-3}$ mM, $C_{U(VI)}$ = 199 mM, C_H = 4 M and a total volume of 100 ml. The γ-activities of the components were measured separately before mixing. For 5 ml samples the U(VI) solution gave 1 525 cpm and the Zr solution 9 663 cpm. The latter

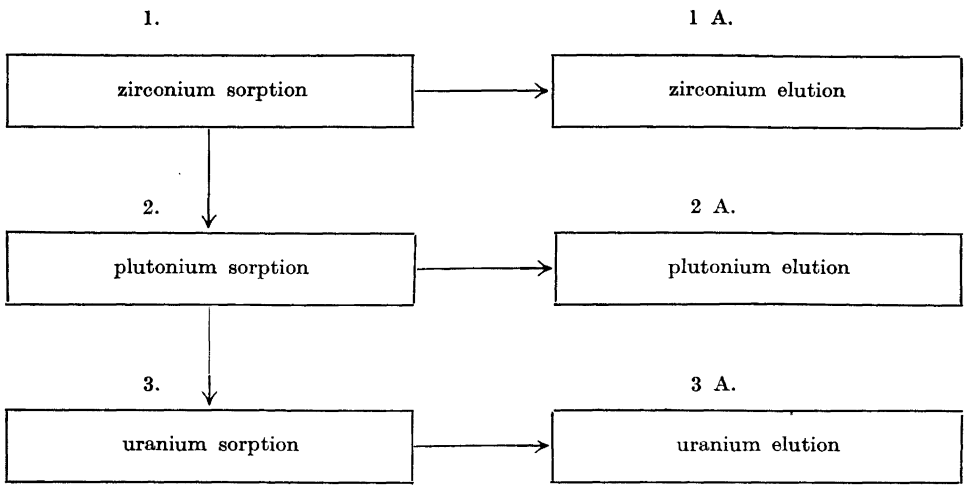

Fig. 6. Block scheme for the separation of uranium, plutonium and zirconium.

solution contained activities from ^{95}Zr, ^{95}Nb and ^{181}Hf, as discussed in Ref.[1] The separation procedure can be illustrated by the block scheme, Fig. 6.

The different steps in the above scheme will now be separately described.

1. The zirconium sorption step is made at $C_H = 4$ M, and a flow rate of about 3.5 ml·hour^{-1}·cm^{-2}.

1 A. After sorption the column is first washed with 4 M nitric acid and then eluted with 0.1 M oxalic acid which quantitatively removes the zirconium.

2. The solution which has passed down the column in step 1 is evaporated to dryness to remove excess nitric acid and is then restored to the initial volume with 100 ml 0.1 M nitric acid. The heating with 4 M nitric acid caused a strong disproportionation and possibly also oxidation of the plutonium. A TTA-extraction proved that only about 12 % of the total amount remained as plutonium (IV). All this amount plus zirconium leakage from step 1 was quantitatively sorbed.

2 A. After washing with 0.1 M HNO_3, plutonium was eluted with 4.5 M HNO_3. Zirconium remained sorbed.

3 and 3 A. After step 2 the solution was partially neutralized with sodium hydroxide, to a pH of about 3. When this solution was passed down the column the uranium was quantitatively sorbed. Sorbed uranium is then removed by a strong acid.

The other solution of known composition which has been separated was a nitric acid solution of neutron irradiated uranium. After irradiation the uranium had cooled for three years. The solution was obtained from A. B. Atomenergi, Stockholm, which gave its composition as: $C_{U(VI)} = 1.075$ M, $C_{Pu} = 1.45 \times 10^{-5}$ M, $C_H = 0.95$ M. The solution also contained long-lived fission products, mainly ^{106}Ru—^{106}Rh, ^{144}Ce—^{144}Pr, ^{90}Sr—^{90}Y and ^{137}Cs—^{137}Ba.

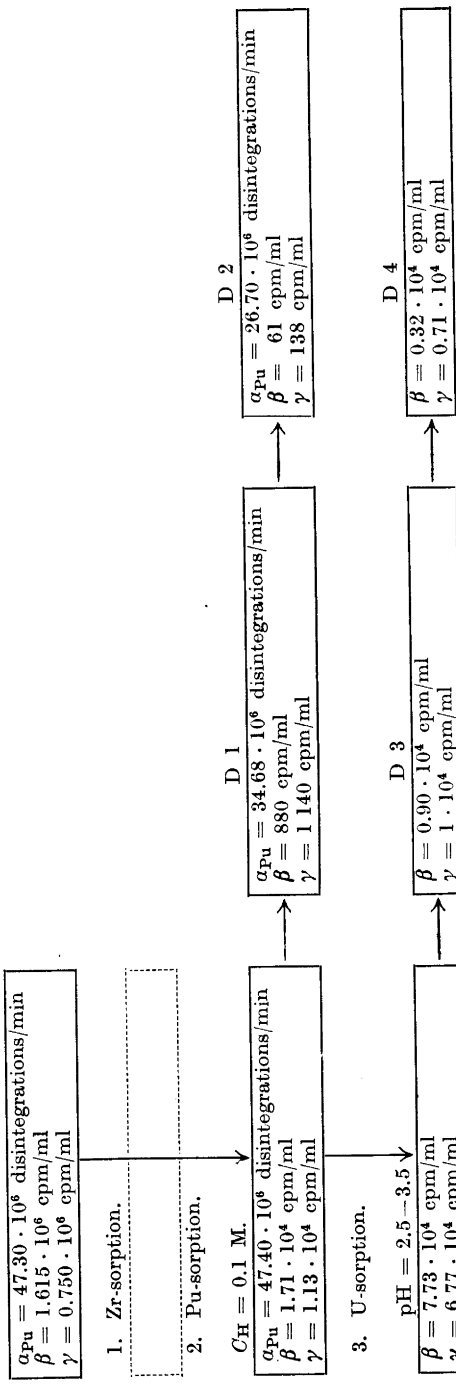

Fig. 7. Block scheme for the separation of the components of a solution of irradiated uranium.

β and γ activities were determined by scintillation counting. The β detector was a Tracerlab P-20 C with a stilbene crystal, the γ detector was the same as used in Ref[1]. The initial activities were $\gamma = 7.500 \times 10^5$ cpm/ml and $\beta = 1.615 \times 10^6$ cpm/ml.

As the amount of plutonium was known (the volume of solution being 100 ml) the total number of plutonium α- decays per minute could be calculated and was $\alpha_{Pu} = 47.30 \times 10^6$. The separation process can be described with the block scheme, Fig. 7, where the different activities at different stages in the separation have also been inserted. The activities are everywhere related to an initial volume of 100 ml and are measured in constant geometry.

1. Because of the short half life ($T_{1/2} = 65$ days) for ^{95}Zr, all $^{95}Zr-^{95}Nb$ has disappeared during the cooling period. The first stage of the process was therefore omitted.

2. The acid excess was removed by evaporationg to dryness and the solid residue dissolved in 100 ml 0.1 M nitric acid. The evaporation also caused in this case a strong plutonium disproportionation but by treating the solution with sodium nitrite the oxidation state was restored to + 4. At a nitrite concentration of 50 mM, this was achieved in a few hours at 80°C. The high concentration of nitrate ions in the rather concentrated uranyl nitrate solution also stabilized the plutonium very much as Pu(IV).

After cooling the solution was passed down the column at a rate of about 3.5 ml·hour^{-1}·cm^{-2}. After washing with 0.1 M nitric acid plutonium was quantitatively eluted with strong nitric acid. The result (Fig. 7) shows that the all plutonium was sorbed and that most of the fission porducts were removed from the plutonium fraction. A further decontamination was obtained by sorbing the plutonium twice more onto the column.

D 1. The eluate from 2 was evaporated to dryness, dissolved in 100 ml 0.1 M nitric acid and treated as before with sodium nitrite. As no uranium was present the nitrate concentration was rather small, 0.1 M compared with 2.3 M at the first reduction. In this solution Pu(IV) disproportionates and in fact only 73.5 % of the plutonium remained fourvalent. On passage down the column a small Pu(IV) leakage, about 0.5 % of the total amount plutonium, was observed. The activity measurements showed a further decontamination from fission products and the plutonium(IV) yield is greater than 99.5 % (Fig. 7).

D 2. The eluate from D 1 is evaporated to dryness and then treated as in the previous decontamination step. About 77 % plutonium was found in the oxidation state + 4. After elution α, β and γ-activities were measured as before (Fig. 7).

The plutonium solution finally obtained was completely separated from uranium and partially decontaminated from fission products. The decontamination factors were for γ-activity 5.4×10^3 and for β-activity 2.65×10^4. On the assumption that plutonium is kept in oxidation state + 4 the separation can be made with a yield larger than 99.5 %. Plutonium missing in D 2 is found as Pu(III) and Pu(VI) leakage from D 1 and D 2. To collect the plutonium in the leakage from D 1, this portion was treated with sodium nitrite. After sorption and elution an amount of plutonium = 9.6×10^6 disintegrations · min^{-1} was recovered.

3. From the solution which hade been passed down the column at 2 the uranium was recovered. By adding sodium hydroxide the pH was increased to between 2.5 and 3.5 and from this solution uranium was sorbed on the column. The column was washed with water and eluted with strong acid. The β and γ activities of this fraction were then measured. After subtracting the activies due to daughter products of uranium (determined separately by measuring a pure uranium solution) the activities of the fission products were obtained.

As seen from Fig. 7 (U-sorption), a small decontamination from fission products was achieved. To get a larger total decontamination the above treatment was repeated twice, decontamination steps D 3 and D 4. The uranium yield was always 100 % and the decontamination factors for the final uranium solution were for β activity 505 and for γ activity 106.

In order to trace the behaviour of the different fission products present, γ-spectra have been recorded for the original solution, the plutonium fraction 2 and the uranium fraction 3. The spectrum of the original solution showed that the γ-activity almost completely came from ^{137}Cs. A small peak from ^{144}Ce, only a few percent of the cesium peak, could also be seen. Spectra from fractions 2 and 3 also showed the presence of ^{137}Cs, while ^{144}Ce had disappeared.

The long cooling period is of course the reason why the γ-activity comes almost exclusively from ^{137}Cs and the uranium decay series and the β-activity from ^{90}Sr and the uranium series.

According to Ref.[1], Fig. 6, Cs^+ and Sr^{2+}, which are very similar to Na^+ and Ca^{2+}, Ba^{2+}, ought not to be sorbed at the pH in question and the decontamination factors are consequently unexpectedly small. For a further study of the pH influence a new decontamination was performed on a part of the original solution. Uranium was sorbed as before but the column was washed with 0.1 mM nitric acid instead of water. After elution and measurements of the activities the decontamination factors were calculated as 75 for γ-activity and 20 for β-activity compared with 8.6 and 6.8 for the corresponding factors in D 3. It is evident that the distribution curve for Cs^+ and Sr^{2+} which ought to be the same as the curves in Ref.[1], Fig. 6, for Na^+ and Ca^{2+}, Ba^{2+} have been shifted towards lower pH-values at the low Cs^+, Sr^{2+} concentrations used here.

The Distribution and Dimerization of Di-*n*-butyl Phosphate (DBP) in Different Solvents

DAVID DYRSSEN and LIEM DJIET HAY

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The distribution of DBP between a number of organic solvents and 0.1 M HNO_3 has been measured at 25°C using ^{32}P-labelled DBP. From the variation of the net distribution ratio, q, with the total concentration of DBP the distribution and the dimerization constants have been determined for the following solvents (log K_d and log K_2 given for each solvent): *n*-hexane (−2.34; +6.87), carbon tetrachloride (−1.44; +6.49), chloroform (+0.24; +4.61), *iso*propyl ether (+0.52; +2.29), tri-*n*-butyl phosphate (+1.97; −0.12), methyl*iso*-butyl carbinol (+2.21, <-1).

An increase in K_d is combined with a decrease in K_2. The explanation given is based on the assumption that complex formation between DBP and the organic solvent molecules competes with the dimerization in the solvent and the solvation of DBP in the aqueous phase. The complex formation constant between DBP (= HA) and TBP (= B), $K_B = [HAB]_{org}\,[HA]_{org}^{-1}\,[B]_{org}^{-1}$, has been determined in carbon tetrachloride as log $K_B = 2.84$.

The results are discussed in relation to some recent work on DBP by Dyrssen [1] and by Hardy and Scargill [2].

It has been shown in previous work by Dyrssen [1] and by Hardy and Scargill [2] that the choice of solvent has great influence on the distribution of DBP (= HA) between an organic solvent and acid aqueous solutions. This is partly due to the fact that the solvent may greatly influence the very pronounced tendency for dialkyl phosphates to dimerize. The purpose of this work was to study the distribution and dimerization of DBP in solvents of different types. The equilibrium constants determined in this work will be used in a study [3] of the extraction of Eu^{3+} and Am^{3+} with DBP in the same set of solvents. A more complete understanding of the reactions between the metal ions and DBP in the organic phase may thus be possible when the concentrations of H_2A_2 (org), HA (org and aq) and A^-(aq) can be calculated. This approach was shown to be fruitful in a study [4] of the extraction of UO_2^{2+} with DBP using chloroform and hexone as solvents.

The same symbols as previously [1] are used in this work except that in accordance with IUPAC K is used instead of k for equilibrium constants.

EXPERIMENTAL

The general procedure has been described earlier [1]. DBP has, however, been purified according to the following new technique (*cf.* Baes [5] *et al.* note 7): 10 ml of DBP was dissolved in 30 ml of petroleum ether (analytical grade). This layer was washed three times with water, and DBP was thereafter extracted with the equivalent amount of 1 M NaOH at 5°C, the cooling being done with ice. The aqueous layer containing the sodium salt of DBP was washed three times with petroleum ether, acidified with HCl and shaken with 30 ml of petroleum ether. The ether phase was washed three times with water and the ether distilled off. The final product, which was pale yellow, was dried at 130°C under reduced pressure (10 mm Hg, N_2 atmosphere) for half an hour. Potentiometric titrations evaluated by the Gran II method [6] for the detection of end-points indicated that the product was free from MBP and at least 99 % pure.

The chloroform (Merck-Darmstadt analytical grade) was washed three times with twice its volume of water to remove the 1 % alcohol. The carbon tetrachloride was of analytical grade (Merck-Darmstadt) and was not further purified. The hexone (methyl *iso*butyl ketone) was washed with $NaHCO_3$ solution, dilute perchloric acid and finally with water. The initial hexone (Kebo) had a boiling range of 114—117°C. The isopropyl ether, boiling range 65—70°C, and *n*-hexane (68—69°C) have a purity of at least 99 % (Kebo). These solvents were not further purified. The hexol (methyl *iso*butyl carbinol), of 99 % purity (Kebo) and boiling range 130—133°C, was treated as hexone. The tri-*n*-

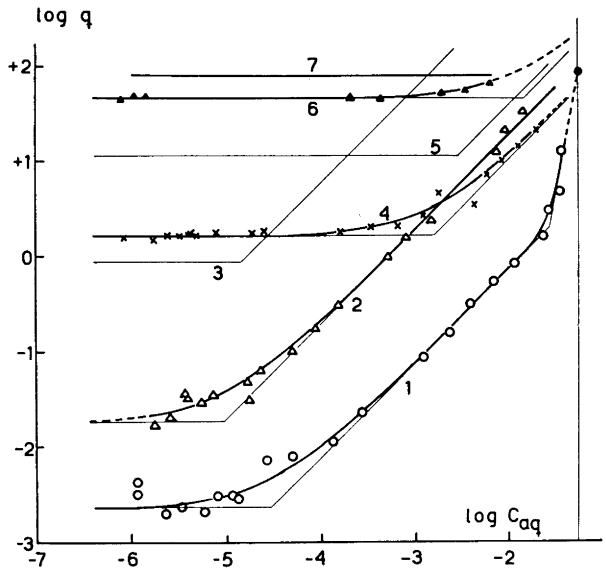

Fig. 1. Distribution of DBP between various solvents and 0.1 M HNO_3 as a function of the total concn. of DBP in the aqueous phase. The maximum value of C_{aq} is determined by the solubility of undiluted DBP in water. Solvents: 1 hexane, 2 carbontetrachloride, 3 chloroform (*cf.* Fig. 2), 4 *iso*propyl ether, 5 hexone (*cf.* Ref.[1]), 6 tributyl phosphate, 7 hexol (*cf.* Table 1). Normalized curve log Y = log $(X + 1)$ is fitted to the data.

butylphosphate (Kebo) was purified by washing it first with an equal volume of 1 M NaOH solution, then with 0.1 M HNO_3 and finally with water.

The radioactive DBP was purchased as previously [1] from Radiochemical Centre, Amersham, England. The aqueous phase was always 0.1 M HNO_3 and the volumes of the two phases were equal.

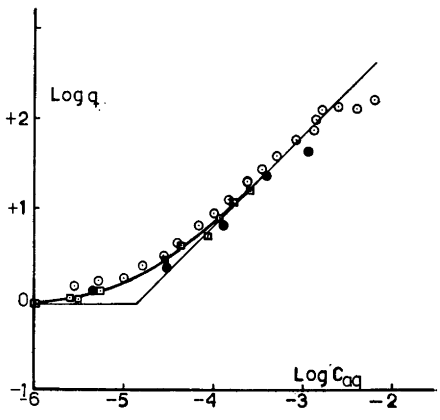

Fig. 2. Distribution of DBP between chloroform and 0.1 M HNO_3 as a function of the total concentration of DBP in the aqueous phase (open squares). Open circles: data from Ref.[1] (aq. phase 0.1 M $HClO_4$). Filled circles: data from Ref.[2] (aq. phase 0.1 M $HClO_4$).

RESULTS

The data are given in Table 1 as log C_A (initial conc. of DBP in the organic layer) and log q (net distribution ratio of DBP). The data, except those for methyl *iso*butyl carbinol where q is independent of C_A, are plotted in Figs. 1 and 2 as log q against log C_{aq} (equilibrium conc. of DBP in the aqueous phase).

C_{aq} was calculated from the following relationship:

$$C_{aq} = C_A(1 + q)^{-1}$$

Assuming that $C_{org} = qC_{aq} = [HA]_{org} + 2[H_2A_2]_{org}$ and

$$C_{aq} = [HA] + [A^-] = [HA] + K_a[HA][H^+]^{-1}$$

the distribution constants, $K_d = [HA]_{org}[HA]^{-1}$, and dimerization constants, $K_2 = [H_2A_2]_{org}[HA]_{org}^{-2}$, were calculated as before [1] by fitting the normalized curve log Y = log $(X + 1)$ to the data $x = \log C_{aq}$, $y = \log q$.

The horizontal asymptote (log $Y = 0$) gives

$$\log K_d\varphi^{-1} = \log Y_0$$

where $\varphi = 1 + K_a[H^+]^{-1} = 2.00$ is kept constant in these experiments and the point of intersection (log X_0, log Y_0) between the two asymptotes gives

$$\log 2\,K_2K_d\varphi^{-1} = -\log X_0;\ \log K_2 = -\log 2\,X_0Y_0$$

The values of K_d and K_2 determined in this manner are collected in Table 2 together with the constants for methyl *iso*butyl ketone (hexone) from earlier work [1] and some constants determined by Hardy and Scargill [2].

The complex formation between DBP and TBP (tri-*n*-butyl phosphate) was determined in a study of the distribution of DBP as a function of the TBP concentration in carbon tetrachloride (= $[B]_{org}$). The aqueous phase was

0.1 M HNO_3.* With $[DBP]_{org} < 10^{-4}$ M and $[TBP]_{org} \gg [DBP]_{org}$ it is possible to neglect $[HA]_{org}$ and $[H_2A_2]_{org}$ (cf. Dyrssen [1], eqns (11) and (13)). The principal reaction studied is then

$$HA\ (aq) + B\ (org) = HAB\ (org)$$

$$q = \frac{[HAB]_{org}}{[HA] + [A^-]} = [HAB]_{org}\,[HA]^{-1}\,\varphi^{-1}$$

or if $K_BK_d = [HAB][B]_{org}^{-1}[HA]$ and $\varphi = 2.00$ is introduced

$$q = 0.50\ K_BK_d[B]_{org}$$

It may be seen from Table 3 that log $q[B]_{org}^{-1}$ is constant not only in dilute solutions of TBP in carbon tetrachloride, but also in highly concentrated solutions and undiluted TBP (3.43 M). This demonstrates the validity of the assumptions which lead to the expression for q above. Further evidence of a molecular interaction of this type is supplied by Baker and Baes [7], who studied the system dioctyl phosphate — trioctyl phosphine oxide, $(RO)_2PO(OH)$ — R_3PO, in octane by means of infrared spectroscopy and isopiestic measurements. The value of K_BK_d calculated from the data in Table 3 is

$$\log K_BK_d = 1.40 \pm 0.06;\ \log K_B = 2.84 \pm 0.08$$

The value is very close to the value of log $K_B = 2.83$ for TBP in kerosene obtained by Hardy and Scargill [2] but considerably higher than the value for TBP in chloroform [1] (log $K_B = 1.60$). This is probably due to association of DBP and TBP [1] with $CHCl_3$.

* It has been pointed out by Hardy and Scargill [2] that the nitric acid concentration in the aqueous phase must be kept low or else one has to consider the complex formation between TBP or DBP and HNO_3 also.

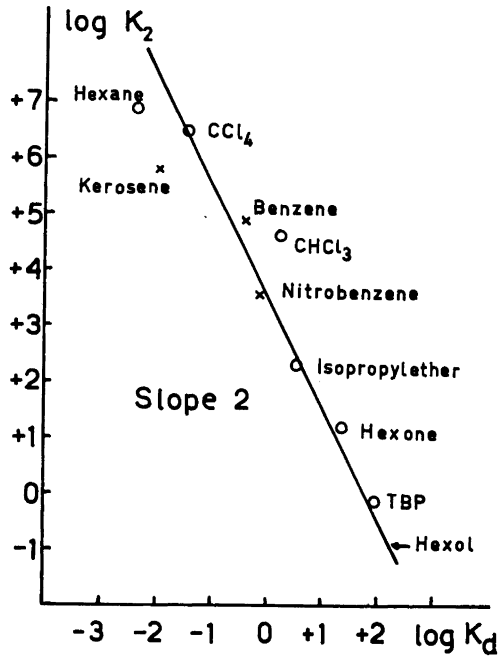

Fig. 3. The dimerization constant, K_2, of DBP in various solvents as function of the distribution constant, K_d. The data are taken from Table 2.

DISCUSSION

It is obvious from Table 2 that an increase in the distribution constant, K_d, is combined with a decrease in the dimerization constant, K_2. If log K_2 is plotted against log K_d as in Fig. 3 the data seem to fall fairly well on a line with a slope of —2. To explain this let us assume a complex formation between the DBP monomer, HA, and the solvent molecule B.

$$\text{HA (org)} + \text{B (org)} = \text{HAB (org)} \qquad \text{(eq. const. } K_B\text{)}$$

The expression for K_d and K_2 may then be written

$$K_d = \frac{[HA]_{org} + [HAB]_{org}}{[HA]} = \frac{[HA]_{org}}{[HA]} (1 + K_B[B]_{org})$$

or $K_d = K_d^\circ(1 + K_B[B]_{org})$

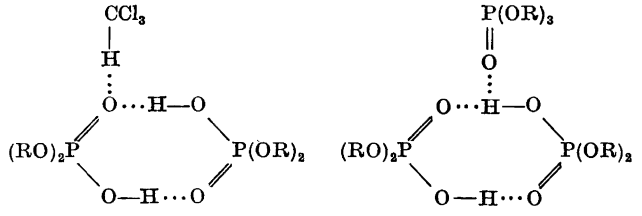
$$K_2 = \frac{[H_2A_2]_{org}}{([HA]_{org} + [HAB]_{org})^2} = K_2^\circ (1 + K_B[B]_{org})^{-2}$$

Combining these equations one obtains

$$K_2 = K_2^\circ K_d^{-2} (K_d^\circ)^2$$

which satisfies the straight line in Fig. 3 (log $K_2^\circ(K_d^\circ)^2 = 3.7$).

The rather good fit of available data to this line means that, apart from the specific interaction due to complex formation between DBP and the solvent, the influence of the solvent on the distribution constant of the dimer ($K_D = [H_2A_2]_{org}[H_2A_2]^{-1}$)is rather independent of organic phase. The solvents have about the same molarity and the picture should therefore not change considerably in going over to mole fraction constants. However, two types of solvents do not fit to the straight line in Fig 3, namely the hydrocarbons, *n*-hexane and kerosene, and chloroform. In the first case it may be explained by assuming that the interaction between the solvent molecule and H_2A_2 is very weak giving a low value of $K_2K_d^2$. In the case of chloroform the reason might be that the interaction between $CHCl_3$ and the dimer is rather much stronger than for the other solvents due to hydrogen bonding with the phosphoryl groups.



$CHCl_3(DBP)_2$ complex TBP$(DBP)_2$ complex

That a 1 : 1 complex is formed between solvents, which may act as acceptors for hydrogen bonds, and DBP, which is a donor of hydrogen, was proved in the case of TBP in CCl_4. Further support of a molecular interaction between DBP and solvents with phosphoryl groups has been supplied by Baker and Baes [7], who studied the system dioctyl phosphate — trioctyl phophine oxide, $(RO)_2PO(OH)$ — R_3PO, in octane by means of infrared spectroscopy and isopiestic measurements. — They also found some evidence of H_2A_2B complex at higher concentrations of HA. — Assuming that no complex formation occurs between CCl_4 and DBP ($K_B = 0$) we calculate approximately

$$\log K_d^\circ = -1.4 \text{ and } \log K_2^\circ = 6.5$$

The acceptor tendency of the solvents for hydrogen bonds may thus be expressed by the value of K_B calculated from

$$\log K_d = -1.4 + \log (1 + K_B[B]_{org})$$

These values are collected in Table 4 together with values of the molarity of the solvent, $[B]_{org}$, and data for the solubility of water in the solvents. It may be seen from Table 4 that there is a close correlation between K_B and the solubility of water in g/l per mole of solvent. In Fig. 4 one may see that the solubility of water in the solvent is also related to K_d. It may thus be said that the acceptor tendency of the solvents for hydrogen bonds governs the solubility of water in the solvents as well. This fact can be used in choosing a suitable solvent for the extraction of metal ions with dialkyl phosphates. It will be shown in the following paper that the choice of the solvent has great

Table 4. Summary of values of $[B]_{org}$, K_B and the solubility of water (L_{H_2O}) for various solvents.

	$[B]_{org}$ [a] M	K_B	L_{H_2O} g/l	$L_{H_2O}\,[B]_{org}^{-1}$

influence on the extraction of Eu^{3+} and Am^{3+} with DBP. This can be explained by complex formation reactions between DBP and the solvent molecules as discussed here.

The results with hexane show a marked increase in log q (Fig. 1) for values of log C_{aq} higher than —1.80 (which corresponds to $C_{org} > 0.05$ M). This very

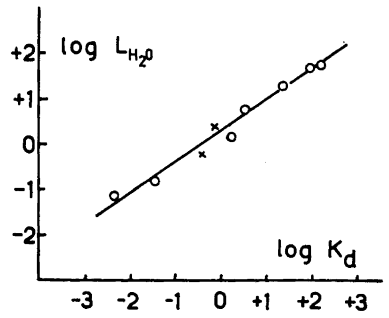

Fig. 4. Correlation between the solubility of water in the organic solvent and the distribution constant, K_d, of DBP between each solvent and 0.1 M HNO_3. The data are summarized in Table 4.

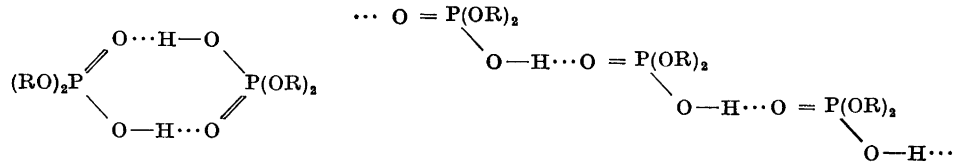
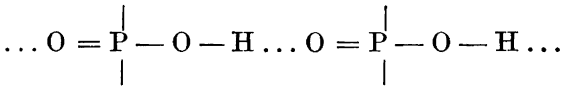
sharp increase of the slope indicates a conversion of the dimer in the form of a eight-membered ring to a polymer possibly in the form of an extended chain:



This proposal for the change in structure is supported by the fact the dibenzyl phosphate crystallizes with a structure [8] which is composed of spirals with the chain



The distance between the two oxygen atoms in the link is very short, 2.494 Å, corresponding to a very strong hydrogen bond.

The transition of DBP in hexane from a dimer to a polymer may also explain the PMR-data and viscosity measurements of solutions of DBP in *n*-hexane. The same type of concentration shift in the proton magnetic resonance and viscosity was also found with carbon tetrachloride as a diluent. This emphasizes the need for great caution in drawing any conclusions about the DBP-species from distribution data where the concentration of DBP in the organic solvent is above 0.05 M. The PMR measurements and viscosity measurements will be extended to the other solvents in the near future and will be published separately.

We wish to thank Professor Lars Gunnar Sillén for his critical examination of our work and Teknologie licentiat Sture Forsén for valuable discussions in connection with his PMR measurements of some of our solutions. The work is part of a program, which is supported by *Statens råd för atomforskning (Swedish Council for Atomic Research)*. The English has been revised by Dr Helen S. Dunsmore.

Solvent Extraction of $^{152, 154}$Eu and ^{241}Am by Di-*n*-butyl Phosphate (DBP) in Different Organic Solvents

DAVID DYRSSEN and LIEM DJIET HAY

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The distribution of ^{241}Am and ^{152,154}Eu between aqueous nitric acid and solutions of di-*n*-butyl phosphate (= HA) has been studied in seven organic solvents. The data indicated that in five systems, M is extracted into the organic phase predominately as $MA_3(HA)_3$. The following values were found for log K for the reaction M^{3+} (aq) + 3 A^-(aq) + 3 HA(aq) $\rightleftharpoons$ $MA_3(HA)_3$(org): in *n*-hexane 13.66 (Eu), 12.38 (Am); in CCl_4 16.80 (Eu), 15.33 (Am); in $CHCl_3$ 19.33 (Eu), 17.98 (Am); in *iso*-propyl ether 14.94 (Eu), 13.72 (Am); in hexone 15.22 (Eu), 14.25 (Am); in hexol 14.15 (Eu), 14.02 (Am). In *n*-hexane, deviations at [HA] $>10^{-1.8}$ M indicate the formation of other complexes, perhaps $MA_3(HA)_6$(org). — In hexol, complexes with less HA appear for [HA] $< 10^{-3}$ M. The data may be accounted for by the additional reaction M^{3+} + 3 A^- $\rightleftharpoons$ MA_3(org), log K = 5.76 (Eu), 5.36 (Am). In tri-*n*-butyl phosphate (TBP), the reaction M^{+3} + $3NO_3^-$ + 3TBP (org) $\rightleftharpoons$ $M(NO_3)_3(TBP)_3$(org) predominates for [HA] $< 10^{-3}$ M; for [HA] $> 10^{-4}$ M, the data indicate M^{3+} + 3 A^- $\rightleftharpoons$ MA_3 (org), log K = 7.49 (Eu), 6.98 (Am).

Parallels are drawn between the effect of the solvent on metal extraction equilibria and on the dimerization and distribution of HA (DBP) itself.

For practical separation of Eu and Am, *n*-hexane, CCl_4 and $CHCl_3$ are the best of the solvents studied; for given concentrations of HA and H^+, *n*-hexane and CCl_4 give the highest distribution ratio.

The use of dialkyl phosphates $(RO)_2P_2OH$ in solvent extraction for trivalent lanthanide and actinide ions has been reported by Peppard *et al.* [1-4], Dyrssen [5], Scadden and Ballou [6].

The aim of the present investigation was to study the influence of various organic solvents on the extraction of Am^{3+} and Eu^{3+} ions from a 0.1 M HNO_3 solution with DBP as complexing agent. The following organic solvents have been used: *n*-hexane, $CH_3(CH_2)_4CH_3$, carbon tetrachloride, CCl_4, chloroform, $CHCl_3$, *iso*propyl ether, $(CH_3)_2CHOCH(CH_3)_2$; methyl *iso*butyl ketone (hexone), $(CH_3)_2CHCH_2COCH_3$, tri-*n*-butyl phosphate, $(n\text{-}C_4H_9O)_3PO$, and methyl *iso*butyl carbinol (hexol), $(CH_3)_4CHCH_2CH(OH)CH_3$.

To explain the results one must take into account the extent of dimerization of DBP in the organic solvents. A separate investigation was carried out to study the distribution behaviour of DBP between the above mentioned organic solvents and an aqueous 0.1 M HNO_3 solution, the results of which are reported in the previous article [7].

EXPERIMENTAL

Reagents: The DBP, $(n\text{-}C_4H_9O)_2PO_2H$, kindly supplied by Albright and Wilson Ltd., London, was purified as described in the previous paper [7].

The β-active nuclide (13 and 16 years) $^{152, 154}$Eu and the α-active 458 years ^{241}Am were obtained from Harwell, England. No carrier was added to the solutions; but the initial concentration of Eu in the 0.1 M HNO_3 solution was about 2×10^{-5} M; the initial concentration of ^{241}Am was calculated as 8×10^{-7} M.

The 0.1 M HNO_3 solution was prepared from analytical grade reagent. The NH_3 solution, used for increasing the pH of the solution in the experiments with hexol, was also of analytical grade.

Distribution measurements: Equal volumes (5 ml) of a solution of DBP in an organic solvent and a 0.1 M HNO_3 solution containing Am and Eu were shaken for 24 h. The two liquid phases were separated by means of centrifugation. All experiments were carried out in a thermostated room at 25.0 ± 0.3°C. From each phase a 0.1 ml volume was pipetted, evaporated to dryness and then heated at 250°C to decompose the remaining organic substances. The activity measurements were carried out in a Tracerlab SC-16 windowless proportional counter. The α-activity was measured at 1 450 V and 10 mV sensitivity and the β-activity at 1 700 V, 1 mV sensitivity and using an Al absorber of 6.2 mg/cm² thickness. Corrections were made for background; in β-activity measurements correction was also made for γ-activity background from Am.

Measurements of the hydrogen ion concentration, when NH_3 was added, were carried out with a Radiometer pHM3i valve potentiometer, equipped with a Radiometer glass electrode G 100 and a calomel electrode K 100. The electrodes were standardized against 0.01 M $HClO_4$ + 0.09 M $NaClO_4$ (-log $[H^+]$ = 2.00). The constants used for the calculations of $[H_2A_2]_{org}$, $[HA]_{org}$, [HA] and $[A^-]$ (ionic medium = 0.1 M HNO_3) are given in the previous article [7].

Symbols and formulas

[ ]	concentrations in the aqueous phase
$[\ ]_{org}$	concentrations in the organic phase
C_A	initial total concentration of DBP in the organic phase
C_{org}; C_{aq}	equilibrium total concentrations of DBP in each phase
HA	di-*n*-butylphosphate (DBP), $(n\text{-}C_4H_9O)_2PO_2H$
K_a (eqn. 3)	stoichiometric acid dissociation constant
K_d (eqn. 1)	distribution constant for HA
K_2 (eqn. 2)	dimerization constant in the organic phase
M	Am or Eu
q_M	net distribution ratio of M (org/aq)

RESULTS AND DISCUSSION

Conclusions about the extractable species

The experimental data obtained with our seven solvents are listed in Tables 1 and 2. The primary data are C_A, the total (analytical) concentration

of HA in the organic phase at the start, and q_M, the distribution ratio of the metal between organic and aqueous phase. From previous work [7], the following equilibrium constants are known:

$$K_d = [HA]_{org}[HA]^{-1}; K_2 = [H_2A_2]_{org}[HA]_{org}^{-2}; K_a = [H^+][A^-][HA]^{-1} \quad (1—3)$$

The total concentration of M is so low that the amount of A bound by M can always be neglected and since the volumes of the aqueous and organic phases are equal, we have

$$C_A = 2[H_2A_2]_{org} + [HA]_{org} + [HA] + [A^-] \quad (4)$$

Inserting $[H^+]$ and the equilibrium constants from the previous paper [7], we may then find the concentrations of the various species for each C_A. At $C_A > 0.06$ M for hexane eqn (4) cannot be used since HA is further polymerized; [HA] and $[A^-]$ can, however, be determined from the distribution curve of DBP [7].

We can now proceed to discuss the formulas of the M-containing species. For the five solvents, *hexane*, *carbon tetrachloride*, *chloroform*, *isopropyl ether* and *hexone*, practically rectilinear plots are obtained if log $q_M [A^-]^{-3}$ is plotted as a function of log [HA] (Figs 1—5). In all cases, the slope is practically equal to 3 (straight lines in Figs 1—5). It thus seems likely that the same reaction predominates in all these solvents. At these low concentrations it seems practically certain that the metal atoms exist as a mononuclear species; it should be noticed that the metal concentration in each phase has been varied by a factor of at least 100 which would be expected to cause deviations from linearity if polynuclear complexes had been important.

Moreover, we may assume that the species in aqueous solution is M^{3+}, *i.e.* Eu^{3+} or Am^{3+}. In the various equilibrium mixtures, the concentration [HA] in the aqueous phase has varied from $10^{-2.0}$ to $10^{-3.6}$, and one would have expected bent curves, if several species had been present in the aqueous phase.

Granted that the metals exist as M^{3+} in the aqueous phase, and that q_M is proportional to $[A^-]^3$ and $[HA]^3$, the following reaction is indicated:

$$M^{3+} + 3A^- + 3\ HA \rightleftharpoons MA_3(HA)_3(org) \quad (5)$$

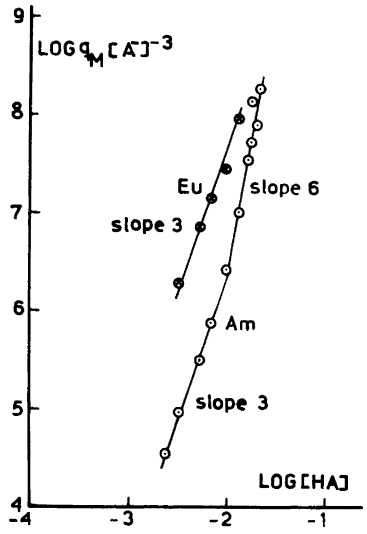

Fig. 1. DBP-hexane: Variation of q_M $[A^-]^{-3}$ with [HA] for the extraction of Eu and Am from 0.1 M HNO_3. The distribution data are given in Table 1. The slope of the straight lines is 3.

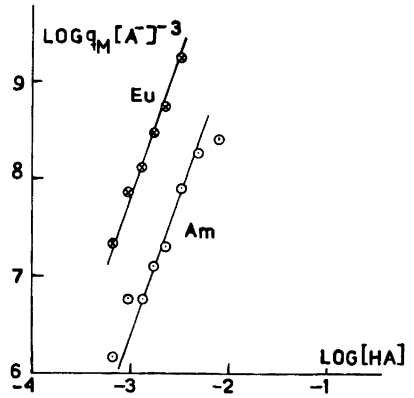

Fig. 2. DBP—CCl_4: Variation of q_M $[A^-]^{-3}$ with [HA] for the extraction of Eu and Am from 0.1 M HNO_3. The distribution data are given in Table 1. The slope of the straight lines is 3.

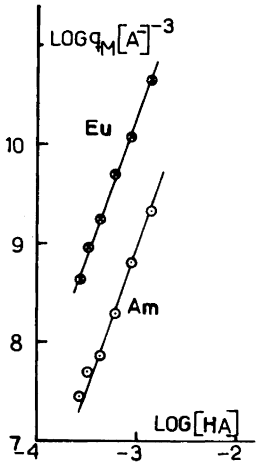

Fig. 3. DBP—$CHCl_3$: Variation of q_M $[A^-]^{-3}$ with [HA] for the extraction of Eu and Am from 0.1 M HNO_3. The distribution data are given in Table 1. The slope of the straight lines is 3.

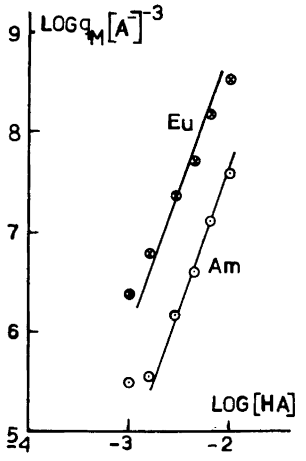

Fig. 4. DBP-*iso*propyl ether: Variation of q_M $[A^-]^{-3}$ with [HA] for the extraction of Eu and Am from 0.1 M HNO_3. The distribution data are given in Table 1. The slope of the straight lines is 3.

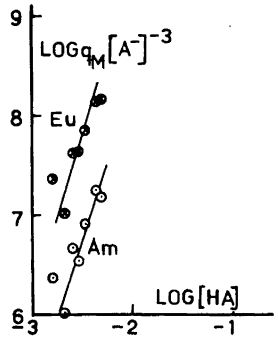

Fig. 5. DBP-hexone: Variation of $q_M\,[A^-]^{-3}$ with [HA] for the extraction of Eu and Am from 0.1 M HNO_3. The distribution data are given in Table 1. The slope of the straight lines is 3.

Since the concentration of HNO_3 is kept constant it is not possible to preclude the possibility that M^{3+} is extracted as a complex also containing HNO_3, *e.g.* $M(NO_3)_3(H_2A_2)_3$. However, since the concentration of HNO_3 is fairly low (0.1 M) it seems probable that nitrate complexes of M may be neglected in the organic phase except when TBP is used as a diluent (see below).

The equilibrium constant for this reaction is easily obtained from the plots:

$$\log K = \log [MA_3(HA)_3]_{org} - \log [M^{3+}] - 3 \log [A^-] - 3 \log [HA] = \\ = \log q_M - 3 \log [A^-] - 3 \log [HA] \qquad (6)$$

The following values for log K were found from Figs 1—5:

In hexane: 13.66 (Eu), 12.38 (Am); in CCl_4: 16.80 (Eu), 15.33 (Am); in $CHCl_3$: 19.33 (Eu), 17.98 (Am); in *iso*propyl ether: 14.94 (Eu), 13.72 (Am); in hexone: 15.22 (Eu), 14.25 (Am).

The large values of K for chloroform suggest that this solvent is more active than the other solvents which might possibly be due to hydrogen bond formation between the H atom in $CHCl_3$ and the PO groups in DBP (*cf.* Ref.[7]).

For *hexane*, the distribution experiments [7] with pure DBP indicated polymers higher than dimers at $C_A > 0.06$ M. It seems as if this polymerization

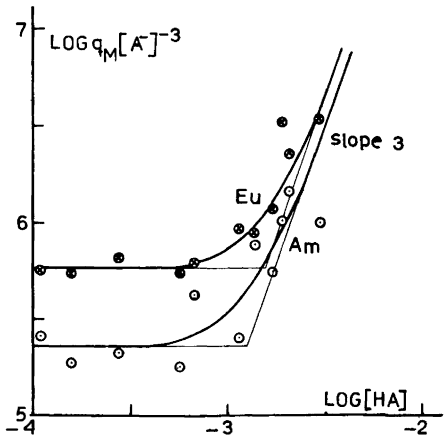

Fig. 6. DBP-hexol: Variation of $q_M\,[A^-]^{-3}$ with [HA] for the extraction of Eu and Am from 0.1 M HNO_3. The distribution data are given in Table 2. The curves are drawn assuming the complexes MA_3 and $MA_3(HA)_3$ in the organic phase (normalized curve: log $(1 + x^3)$ *versus* log x).

affects the distribution of Am; a complex $MA_3(HA)_{\sim 6}$ is indicated in Fig. 1. For Eu, log q is too high to be measured in the region where the corresponding complex could be formed.

For *hexol*, DBP is practically not dimerized in the organic phase. The value of K_d is also fairly large (= 162) and thus $C_A \simeq [HA]_{org}$. The extraction from $[H^+] = 0.1$ was rather low, so experiments were also performed with lower $[H^+]$, see Table 2. Assuming that MA_3 reacts with a certain number of HA's in the organic phase to form an uncharged complex $MA_3(HA)_n$ it is reasonable to plot log $q_M[A^-]^{-3}$ as a function of log [HA] (or log $[HA]_{org}$) as before. The experimental points in Fig. 6 are seen to fall roughly on single curves; there is no indication of a dependence on $[H^+]$ as would be the case if there were complexes other than $MA_3(HA)_n$, *e.g.* $M(NO_3)_3(HA)_3$. The approximate constancy at low C_M indicates that the complex MA_3(org) is formed at low [HA]; one might expect HA to be added stepwise, but the accuracy certainly is insufficient for a detail treatment. Since the slopes tend towards 3, and the species $MA_3(HA)_3$ are indicated by work in other solvents, an attempt was made to describe the data as an approximation, neglecting all reactions except

$M^{3+} + 3\,A^- \rightleftharpoons MA_3$(org) and
$M^{3+} + 3\,A^- + 3\,HA \rightleftharpoons MA_3(HA)_3$(org)

By the usual technique of curve-fitting [8] the equilibrium constants (log K) were found from Fig. 6 to be: for the first reaction + 5.76 (Eu) and + 5.36 (Am); for the second reaction + 14.15 (Eu), + 14.02 (Am).

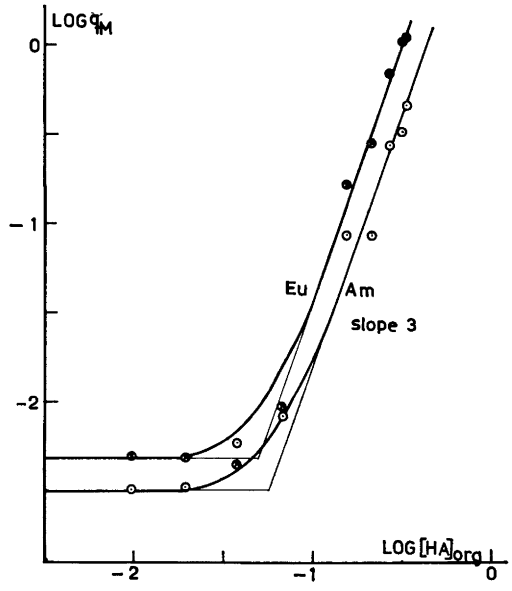

Fig. 7. DBP—TBP: Variation of the net distribution ratio with [HA] org for the extraction of Eu and Am from 0.1 M HNO_3. The distribution data are given in Table 1. The curves are drawn assuming the presence of $M(NO_3)_3$ and MA_3 in the TBP phase (normalized curve: log $(1 + x^3)$ *versus* log x).

Whereas the first values seem to be reliable within $\pm$ 0.1, the second constant is only intended as a very crude approximation, which may be used for approximate calculations but does not satisfactorily describe the real process, which is probably stepwise. A similar curve was previously obtained for the UO_2^{2+}-DBP-hexone system [12].

In *tributyl phosphate* (TBP) also, HA mostly exists as single molecules, HA(org), which are, however, associated with TBP [7]. A plot of log q_M *versus* log $[HA]_{org}$ indicated that q_M approaches a limiting value as $[HA]_{org}$ decreases (Fig. 7). This should correspond to the reaction already studied by McKay *et al.*[9–11]

$$M^{3+} + 3\,NO_3^- + 3\,TBP(org) \rightleftharpoons M(NO_3)_3(TBP)_3(org)$$

The present experiments, where $[TBP]_{org}$ and $[NO]_3^-$ were kept constant, do not give the composition of the complex.

For $[HA]_{org} > 10^{-1.7}$ M, q_M increases with $[HA]_{org}$, which indicates that complexes with A are formed. The limiting slope would correspond to MA_3 (org). The process is probably stepwise but the data suffice only to get approximate values for the total reaction. These were also found by curve-fitting:

$$M^+ + 3\,HA(org) \rightleftharpoons MA_3(org) + 3\,H^+;\ \log K = -1.44\ (Eu),\ -1.81\ (Am)$$

or

$$M^{3+} + 3\,A^- \rightleftharpoons MA_3(org);\ \log K = 7.49\ (Eu),\ 6.98\ (Am)$$

These values are those obtained from the plot of log q_M versus log $[HA]_{org}$. The normalized curves are of the type log $(1 + x^3)$ *versus* log x. The extracted complex may be $MA_3(TBP)_3$, but this can only be proved by variation of the TBP concentration.

Conclusions about the effect of the solvent on the net distribution of Eu and Am

It may be seen from Table 3 and Fig. 8 that for a given total concentration, of DBP ($C_A = 0.1$ M) and acidity ($[H^+] = 0.1$ M) the highest value of q_{Eu} is obtained with *n*-hexane and carbon tetrachloride. The extraction is very poor

Table 3. Summary of the results derived from Tables 1 and 2 for $C_A = 0.1$ M and $[H^+] = 0.1$ M. The net distribution ratio of DBP is derived from data reported in the previous paper [7].

Solvent	log q_{Eu}	log q_{Am}	Δlog q_{Eu-Am}	log q_A
n-Hexane	+2.60	+1.40	1.23	+0.48
CCl_4	+1.81	+0.46	1.30	+1.11
$CHCl_3$	+0.09	−1.27	1.36	+1.87
*Iso*propyl ether	+0.66	−0.44	1.10	+1.02
Hexone	−0.75	−1.81	1.05	+1.42
TBP	−1.78	−2.08	0.46	+1.73
Hexol	−3.34	−3.64	0.33	+1.91

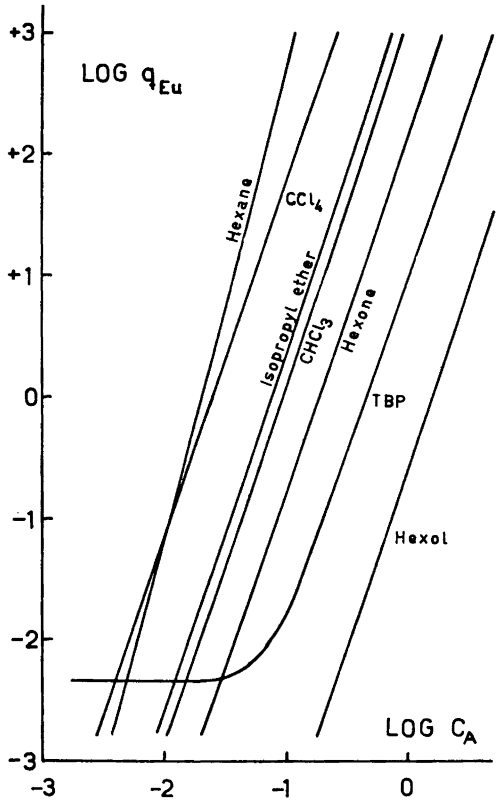

Fig. 8. The distribution of Eu for various organic solvents as a function of the initial concentration of DBP in the organic phase. The aqueous phase was 0.1 M HNO_3 and the volumes of the two phases were equal. Data are given in Tables 1 and 2.

with TBP and hexol. Similar experience has been made with the UO_2^{2+}-dioctyl phosphate and Ca^{2+}-dibutyl phosphate systems (*cf.* Table 4).

In general the order of increasing capacity to extract Eu^{3+} (and Am^{3+}) is that of decreasing value of K_d (*cf.* Table 2 in the previous paper [7]), the distribution constant of DBP monomer, or decreasing solubility of water in the organic solvent (*cf*, Table 4, Ref.[7]). It was pointed out in the previous paper [7] that an increase in K_d was probably due to the formation of a 1 : 1 complex between the DBP monomer, HA, and the solvent molecule. Such a reaction therefore seems to repress the metal extraction. In the case where the metal ion has been extracted from an aqueous phase with DBP in an inert solvent, *e.g.* CCl_4, back extraction into an aqueous layer should then be considerably facilitated by addition of *e.g.*, hexol to the organic layer. This has in fact been utilized by Dyrssen and Ekberg [13] for the preparation of carrier-free ^{90}Y. With the uranyl ion, however, neutral phosphorylated reagents might enter into the coordination sphere, and thus enhance the extraction in spite of any complex formation with the dialkyl phosphate.[17]

Table 4. Influence of the diluent for the UO_2^{2+}-dioctyl phosphate system [14] (initial aq.phase: 0.004 M U(VI) in 0.5 M SO_4^{2-}, pH 1.1) and the Ca^{2+}-dibutyl phosphate system [15] (initial aq.phase: trace quantities of $CaCl_2$ labelled with ^{45}Ca).

Diluent	Distribution ratio	
	UO_2^{2+} — DOP	Ca^{2+} — DBP
Kerosene	135	0.49
Hexane	110	1.13
*Cyclo*hexane	—	1.16
Carbon tetrachloride	20	0.28
*Iso*propyl ether	17	0.121
Benzene	13	0.074
Chloroform	3	0.071
Hexone	—	0.037
*Cyclo*hexanone	—	0.015
*Iso*amyl acetate	—	0.030
2-Ethyl hexanol	0.1	—
Octanol-2	0.08	—
Hexol	—	0.0039

Another factor to consider in choosing a suitable solvent is the distribution of DBP itself. As pointed cut in the previous paper [7], q_A varies considerably with the total concentration of DBP (*cf.* Fig. 1 in Ref.[7]); the values in Table 3 show, however, that for hexane, CCl_4 and *iso*propyl ether considerable amounts of DBP are "lost" in aqueous phase. This could be reduced by using a compound with more carbon atoms, *e.g.* dioctyl phosphate.

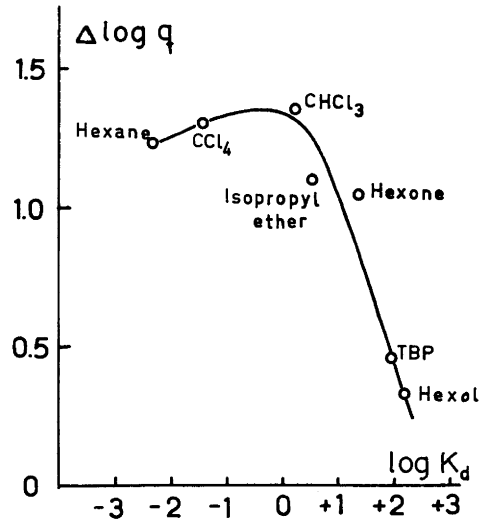

Fig. 9. The difference in distribution ratio q between Eu and Am at $C_A = 0.1$ M for various organic solvents as a function of the distribution constant K_d for the DBP monomer. Aq. phase: 0.1 M HNO_3.

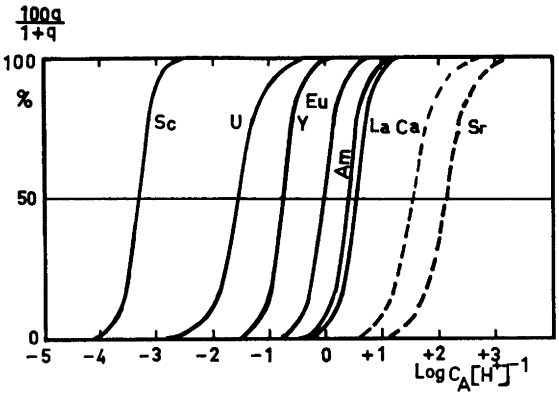

Fig. 10. Curves showing the percentage extraction with DBP—$CHCl_3$ of Sc(III), U(VI), Y(III), Eu(III), Am(III), La(III), Ca(II), and Sr(II) as a function of log $C_A[H^+]^{-1}$. The curves for Ca and Sr are based on very few data.

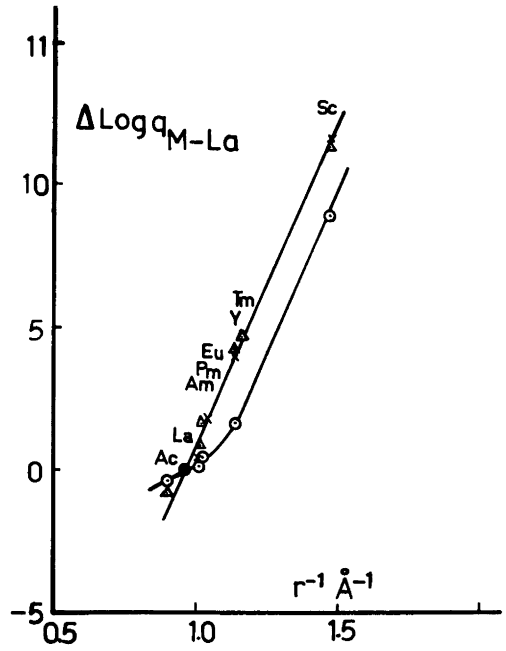

Fig. 11. The difference in distribution ratio, q, between trivalent metal ions and La(III) as a function of the inverted value of the ionic crystal ratio r, according to Zachriasen. Solvent extraction systems: × DBP—$CHCl_3$ reported here, △ Dioctyl phosphate-toluene and O dioctylphenyl phosphate-toluene by Peppard *et al.*[4]

The separation of Eu^{3+} and Am^{3+} may be expressed as $\Delta \log q$. In Table 3 values of $-\log q$ at $C_A = 0.1$ M are given for the various solvents. These data are plotted in Fig. 9 against $\log K_d$. It may be seen that the inert solvents, hexane, CCl_4 and $CHCl_3$ give the best separation.

Throughout our experiments with DBP Eu^{3+} is better extracted than Am^{3+}. This is the order that could be expected from the values of the crystal ionic radii, $r = 0.96$ Å (Eu^{3+}) and $r = 0.99$ Å (Am^{3+}). Fig. 10 summarizes data for other metal ions taken from a FOA-report (not available) by Carlsson, Dyrssen, and Johansson. The order of extraction is generally the same as the order of ionic potential, Nr^{-1}. For three-valent ions there seems to be a straight line relationship between $\Delta \log q_{M-La}$ and $1/r$ (Fig. 11). Similar values of $\Delta \log q$ were found by Peppard *et al.*[4] for dioctyl phosphate in toluene. However, with a dioctylphenyl derivative a different relationship is obtained; it seems as if this rather large complexing agent cannot differentiate very well between the larger tri-valent ions; this might be due to micelle formation. It has been shown by Dyrssen [16] that such a straight line relationship as with DBP and DOP is not obtained with the chelating agent *β-iso*propyl tropolone. Furthermore, with this compound Eu^{3+} is not better extracted than Am^{3+} into chloroform.

The authors wish to thank the head of the institution, Professor Lars Gunnar Sillén, for valuable discussions. The investigation has been supported by *Statens råd för atomforskning (Swedish Council for Atomic Research)*. The English has been revised by Dr. Helen S. Dunsmore.

Oxide Chlorides and Organometalloid Oxides as Donor Molecules

INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

A model of an idealized structure has been suggested, which can be used for the discussion of adducts of oxide chlorides and organometalloid oxides. No safe distinction between single and double bond structures can be made with the experimental data available at present. The results show, however, the importance of inductive effects in donor-acceptor reactions, and some predictions can be made about other adducts than those studied.

In an earlier paper [1] it was pointed out that the semipolar formulation of the donor-acceptor bond is misleading in most addition compounds. In the compounds which in the preceding paper [1] were formally described as addition compounds with oxygen atoms, the formulation is more appropriate, although not at all necessary. The typical example is amine oxide R_3NO, which is written $R_3N^+O^-$ in the semipolar formulation. In this case, the formal charges on the atoms really indicate a strongly increased heteropolar interaction in the N—O bond (while the R—N bond is weakened). There is no possibility of double bond formation in the amine oxides, and the picture of the bond as a covalent bond with strong additional ionic attraction is obvious. In phosphine oxides on the other hand, the possibility of double bond formation cannot be excluded, and the formulation $R_3P{=}O$ has been advanced as more accurate than $R_3P^+O^-$.

In this paper, this question will be discussed together with the inductive effects of donor-acceptor reactions involving the above-mentioned donors. The available structural information will be used, and the compound $SbCl_5$ ($OPCl_3$) will be taken as an example for the discussion.

THE IDEALIZED STRUCTURE

First it is assumed that the single bond structure is correct; the P—O bond is considered as a donor-acceptor bond. The bond picture of the adduct will then be Cl_3P—O—$SbCl_5$ with strong primary inductive effects due to the formation of the donor-acceptor bonds P—O and Sb—O.

Because of the difficulty of making direct comparisons of the measured bond lengths with predicted values, an idealized charge distribution must first be assumed, for which at least some predictions can be made. The deviations of the actual charge distribution from the idealized one are then estimated and the inductive effects on the bond lengths are predicted in a way suggested in the preceding paper [1]. Finally a comparison is made with the experimental results.

The idealized charge distribution selected for this purpose is the following: The *charge distribution in the bond system Cl—P—O* is assumed to be *the same as if the adduct molecule had a perfectly symmetrical distribution around the oxygen atom* (the fictive ion $Cl_3POPCl_3^{2+}$). A similar assumption is made for the O—Sb—Cl bond system (the fictive ion $Cl_5SbOSbCl_5^{2-}$). The bond lengths P—Cl and P—O are then only influenced by the effective electronegativity differences between P and Cl and O, respectively, and the bond lengths Sb—Cl and Sb—O only by the electronegativity differences between Sb and Cl and O.

The difference between the bond lengths to the chlorine and oxygen atoms: $|P—Cl| - |P—O|$ and $|Sb—Cl| - |Sb—O|$ can rather safely be assumed to have almost equal values because the difference in electronegativity between P and Sb is not very large. If the Shomaker-Stevenson formula $r_{AB} = r_A + r_B + 0.09\,|x_A - x_B|$ were valid, the differences should always have a constant value independant of the atoms bonded to Cl and O, but this is probably too far-going a simplification.

The value of this "reference difference" must be larger than the difference between the atomic radii of chlorine and oxygen, 0.25 Å. The Shomaker-Stevenson formula predicts a value of 0.30 Å, but it generally underestimates the bond contraction as shown by comparison with the difference between the recommended [2] C—Cl and C—O bond lengths which is 0.34 Å. The slightly arbitrary assumption is here introduced that the *reference difference* in adduct molecules with symmetrical arrangement around the central atoms (tetrahedron around P and octahedron around Sb in the example) is independent of the nature of the central atoms and has a value of 0.32 ± 0.02 Å.

This is the most arbitrary assumption introduced so far in these discussions and its limitations must be kept in mind.

THE ACTUAL STRUCTURE

The deviations from the idealized charge distribution in the actual molecule can be discussed as a substitution effect. The P—Cl and P—O bonds are influenced by the fictive substitution of $SbCl_5$ for PCl_3^{2+}. As the electronegativity of P is higher than of Sb, and furthermore a positive charge is placed on the PCl_3 group, it can safely be assumed that the effective electronegativity of the PCl_3^{2+} group is larger than that of $SbCl_5$. Electrons are thus released to the bridging oxygen atom at the substitution. This is the primary effect. As the net charge on P in $POCl_3$ is positive and the heteropolarity is P → O the electron addition will lead to an increased P—O bond energy (an electron withdrawal would lead to loss of bond energy according to the discussion in Ref. [1]). The secondary effect is a transfer of electrons from oxygen to phospho-

rus and to a smaller extent to chlorine. As the net charge on chlorine is negative and the heteropolarity is P → Cl, the electron addition will decrease the P—Cl bond energy. The P—Cl bond will thus be longer and the P—O bond shorter than in the idealized structure, and the difference | P—Cl | — | P—O | should have a larger value than 0.32 Å.

The Sb—Cl and Sb—O bonds are in the same way influenced by the fictive substitution of PCl_3^{2+} for $SbCl_5$. This corresponds to a transfer of electrons away from oxygen (compared with in the idealized structure): the Sb—O bond will be weaker and longer. The secondary effect is a withdrawal of electrons from Sb and to some extent from chlorine: the Sb—Cl bond will be stronger and shorter. The difference | Sb—Cl | — | Sb—O | should thus be smaller than 0.32 Å.

Because of the mutual character of the fictive substitutions, the effects on the P—O and Sb—O bonds should be very similar, while the effect on Sb—Cl should be slightly smaller than on P—Cl because the secondary inductive effect is transmitted to five atoms from Sb and to only three from P. (Variations in polarizability might also be of importance.) If the secondary effect is low, the deviations from the reference difference, 0.32 Å, should, however, be very similar in magnitude, the deviation being possibly somewhat larger on the donor side ($POCl_3$). The values found [3] in $SbCl_5$ ($OPCl_3$) are (averaged values):

$$|\text{P—Cl}| - |\text{P—O}| - 0.32 \text{ Å} = 0.18 \text{ Å}$$
$$|\text{Sb—Cl}| - |\text{Sb—O}| - 0.32 \text{ Å} = -0.17 \text{ Å}$$

Considering the uncertainty in the reference difference and the experimental bond lengths, the agreement is striking.

An equal or slightly larger effect would be expected in the compound $TiCl_4(OPCl_3)$ (the electronegativity of Ti is a little lower than that of Sb). This is actually a dimeric molecule [4], but the chlorine bridge formation will influence the Ti—Cl bonds (to nonbridging Cl) and the Ti—O bond to the same extent (*cf.* the discussion of halogen bridges in Ref.[1]) and the relation should still be valid. The averaged values in $[TiCl_4(OPCl_3)]_2$ are:

$$|\text{P—Cl}| - |\text{P—O}| - 0.32 = 0.20 \text{ Å}$$
$$|\text{Ti—Cl}| - |\text{Ti—O}| - 0.32 = -0.20 \text{ Å}$$

The assumption of a single bond structure is thus in complete accordance with the experimental evidence available at present. In the next section the consequences of the assumption of a double bond structure will be discussed.

THE DOUBLE BOND PICTURE

The introduction of a double bond giving the bond system Cl—P=O—Sb—Cl is tantamount to an electron tranfer from the oxygen towards the phosphorus atom compared with in the bond system Cl—P—O—Sb—Cl discussed above.

If the double bond exists, the P=O bond must be stronger than the P—O bond: the new homopolar bond energy must be larger than the loss of heteropolar bond energy (or there would not be any double bond). The P—Cl will be weakened, and the difference | P—Cl | — | P—O | will increase further. Likewise the Sb—O bond energy will decrease and the Sb—Cl bond energy increase. The difference | Sb—Cl | — | Sb—O | will be reduced accordingly.

The effect of a double bond will thus run parallel with the inductive effect of the donor-acceptor reaction, and no distinction can be made between the two bond pictures only from these data.

ADDUCTS OF SELENIUM OXYCHLORIDE

The discussion of $SbCl_5(OPCl_3)$ can easily be extended to adducts of $SeOCl_2$. The only structure known at present is that of $SnCl_4(OSeCl_2)_2$. The experimental data for this compound are [5] (averaged values):

$$|\,Se—Cl\,| - |\,Se—O\,| - 0.32 = 0.09 \text{ Å}$$
$$|\,Sn—Cl\,| - |\,Sn—O\,| - 0.32 = -0.06 \text{ Å}$$

This structure is complicated by weak chloride bridge formation between Se and Sn, and the agreement with the predicted effect must be considered as good.

The smaller effect of the donor-acceptor reaction with $SeOCl_2$ is not only reflected in the smaller value of the deviations from the reference differences but also directly in the Sn—O and Sb—O distances. The Sn—O bond length is actually shorter than the Sb—O bond lengths (in the two compounds discussed earlier) although the radius of antimony should be smaller than that of tin. (In all periods the same trend is found near the inert gas end, that the covalent radius decreases with increasing atomic number.)

The reason why the effect is larger for $POCl_3$ than for $SeOCl_2$ will not be discussed in this paper.

EXTENSION TO OTHER ADDUCTS

If the ideas advanced here are correct, some predictions can be made about the effect in other adducts.

Adducts of phosphine oxides might first be compared with adducts of $POCl_3$. The only difference is that the positive net charge on the PCl_3^{2+} group must be larger than on PR_3^{2+}, and the effective electronegativity accordingly higher. The deviations from the reference differences should therefore be larger in the $POCl_3$ than in the POR_3 adducts. The structure of $SbCl_5[OP(CH_3)_3]$ is at present being investigated in order to test this conclusion.

A comparison between adducts of amine and phosphine oxides would be quite different. It is true that the inductive effect must be largest for the amine oxide if only single bond structures are compared, but two complicating factors must be considered. One is the fact that the heteropolarities of the bonds to carbon are different, N ← C and P → C. The net charge on carbon

is therefore positive in the amine oxide and negative in the phosphine oxide. The secondary effect of the electron addition (compared with in the idealized structure) will thus be a weakening of the P—C bond while the N—C bond energy will be augmented. (Electron addition gives opposite effects to electron withdrawal.) The difference |N—C| — |N—O| is therefore not increased by the effect on the N—C bond and the deviation from the reference difference can be expected to be reduced to some extent. On the other hand there might be a double bond P=O in the phosphine oxides which cannot have a correspondence in the amine oxide. This would increase the deviation from the reference difference for the phosphine oxide adduct.

Both these factors thus work against the larger inductive effect in the single bond structure of the amine oxide adducts and the deviations from the reference difference might very well be larger for the phosphine oxide adducts than for the amine oxide adducts. Part of these difficulties might also be encountered in a comparison of sulfur and selenium compounds such as sulfoxides and selenium oxides. Structure determinations are in progress which probably will give information about these problems.

THE FREE DONOR MOLECULES

The idealized structure can also be used for a discussion of the free donor molecules. The inductive effect of subtracting of PCl_3^{2+} from the idealized structure $Cl_3POPCl_3^{2+}$ must be even larger than at the fictive substitution discussed for donor-acceptor interaction. The difference |P—Cl| — |P—O| — 0.32 Å is actually + 0.23 Å in $POCl_3$, of the order of 0.05 Å larger than in the adducts studied. A corresponding comparison cannot be made for $SeOCl_2$ because its structure is not known, but a study is in progress.

The discussion of the adducts of amine and phosphine oxides in the preceding section can obviously be directly applied to the free donor molecules. The reference differences |N—C| — |N—O| and |P—C| — |P—O| are 0.12 Å (obtained as described earlier). The assumption that the differences should be equal is doubtful in this case with different heteropolarities in the bonds to carbon, but no other reasonable proposal can be made at present.

The values are:

$$|N—C| — |N—O| — 0.12 = 0.06 \text{ Å (alternative value } -0.07 \text{ Å)}$$
$$|P—C| — |P—O| — 0.12 = 0.21 \text{ Å (Ref. [6])}$$

The larger deviation in the phosphine oxide is not unexpected in view of the preceding discussion. The quite different magnitudes of the two deviations indicates, however, that the phosphine oxide probably contains a double bond P=O: the difference between the single bond structures would be expected to be smaller. This is in agreement with the interpretation of the dipole moment measurements [7]. More structural information is necessary, however, before it can be safely stated that the structural evidence can distinguish between the single and double bond pictures. It would be particularly interesting to

know the S—O bond lengths in adducts of sulfones. A number of such adducts have recently been prepared [8] and the crystal structure determinations have shown that only one of the oxygen atoms functions as a donor atom [9].

CONCLUSION

The preceding discussions indicate that the donor action of oxide halides and organometalloid oxides can be explained, or at least rationalized in a rather simple fashion, if the inductive effects are fully considered in the way proposed. The limitations of the approach must be kept in mind until the experimental evidence is more complete. The arbitrariness of the present paper is obviously greater than in the general discussion of inductive effects in the preceding paper [1], but no other approach seems at present to offer similar possibilities to compare bond length differences in a rather exact way. The future experimental results will show how far this is correct and in which respects the treatment must be modified or amended.

This work has been supported by grants from the *Swedish Natural Science Research Council* and from the *Air Force Office of Scientific Research of the Air Research and Development Command, United States Air Force*, through its European Office under Contract No. AF 61 (052)-43. These grants are gratefully acknowledged.

Finally I wish to thank Professor Hägg for his friendly and encouraging interest and my research students for their active collaboration in the development of these ideas.

A New Method of Degrading Glucose to Xylose and Galactose to Arabinose

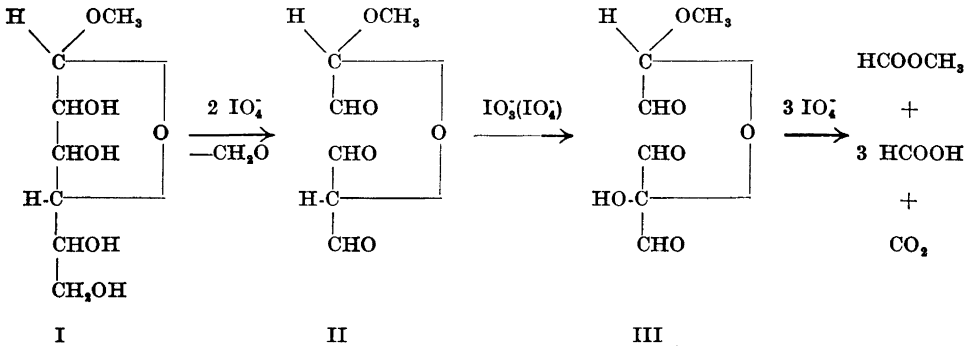
OVE KJØLBERG

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

It has been found that by treatment with periodic acid of such aldohexofuranosides in which the hydroxyl groups at C_2 and C_3 are in *trans*-position, experimental conditions can be established so that the oxidation is restricted to the glycol grouping outside the ring. Formaldehyde is therefore formed, and besides this a monoaldehyde is obtained which by reduction gives an aldopentofuranoside. The method makes it possible to correlate the anomers of the aldohexofuranosides with those of the aldopentofuranosides.

Oxidation of methyl aldohexopyranosides and methyl aldopentofuranosides with periodic acid leads to structurally identical dialdehydes, the optical rotations of which make it possible to correlate the configuration at carbon 1 in the two types of methylosides [1,2]. A marked difference in the oxidation of the two types of methylosides is that the hexopyranosides give formic acid beside the dialdehyde.

On oxidizing a methyl aldohexofuranoside (I) with periodic acid under the same conditions, one would expect the formation of a trialdehyde (II) beside one mole of formaldehyde.

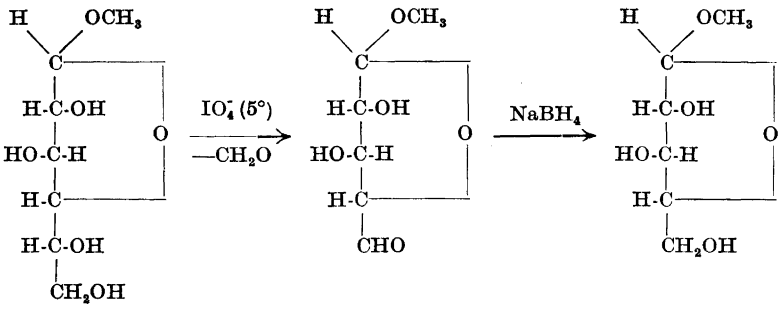


I II III

Experience has, however, shown that the oxidation goes further, and it has been suggested that this is due in the first place to the oxidation of the activated hydrogen atom at C_4 to a hydroxyl group (III). As vicinal hydroxyaldehydes also are easily oxidized by periodic acid [3], the result will be that the whole molecule is disintegrated. Accordingly Hirst *et al.*[4] found that α-methyl-D-mannofuranoside on oxidation gave formaldehyde, formic acid, methyl formate and carbon dioxide. It is therefore not possible to determine the configuration at carbon atom 1 in the aldohexofuranosides in the same way as with the other types of methylosides. On oxidation of α-methyl-D-mannofuranoside and β-ethyl-D-galactofuranoside with lead tetraacetate, Criegee [5] found that in the mannofuranoside the link between C_2 and C_3 was split up first, while in the galactofuranoside the link between C_5 and C_6 was cleaved more easily than that between C_2 and C_3. He meant that the reason for this was that with *cis*-configuration a ring-glycol is attacked more easily by lead tetraacetate than a glycol in which there is free rotation between the carbon atoms, and that the latter glycol is attacked easier than a ring-glycol with *trans*-configuration. Later Price and Knell [6] and Hudson [7] have found that the same is the case on oxidation with periodic acid.

In the present investigation these experiences have been verified. It was further found that starting with galacto- or glucofuranosides in which the configuration at C_2—C_3 is *trans*, the oxidation by lowering the temperature could be localized mainly to the C_5—C_6 position. The oxidation accordingly proceeded as shown in formulae IV—V and VII—VIII. When the temperature during the oxidation was kept at about + 5° each mole of furanoside on consuming one mole of periodic acid gave one mole formaldehyde. After removing iodate and periodate with lead dithionate as described by O'Dea and Gibbons [8], the formaldehyde was determined colorimetrically by means of chromotropic acid according to Eergiwe [9]. During the oxidation the rotation at first changed rapidly, but after one mole periodic acid had been consumed it became practically constant. The oxidation could therefore be followed in a polarimeter. At the appropriate time the oxidation was stopped by addition of barium hydroxide and the C_5-aldehyde isolated as a colourless syrup. Reduction of the aldehyde group would lead to methyl pentofuranoside as shown in the formulae VI and IX. This method therefore represents a degradation of glucose and galactose to xylose and arabinose, respectively.

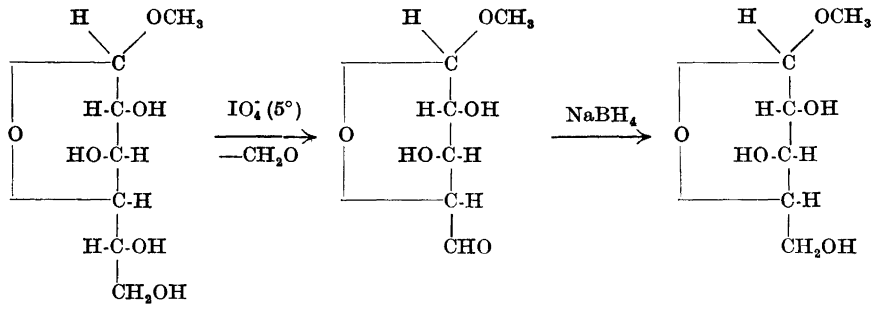
Sodium borohydride was used as a reducing agent. Experimentally it was found that the α- and β-methyl-D-glucofuranosides gave α- and β-methyl-D-xylofuranosides and that the α- and β-methyl-D-galactofuranosides gave β- and α-methyl-L-arabofuranosides, respectively. The four pentofuranosides were identified by means of paper chromatography. Xylose was also identified by preparing the dibenzylidene derivatives of the dimethyl acetal and comparing it with a sample prepared from authentic xylose. As the glucofuranosides used were slightly impure, the specific rotation of the xylofuranosides prepared from them would not give any proof of their identity and they were not subjected to a more detailed investigation. In the case of the galactofuranosides the specific rotation of the arabofuranosides obtained by degradation (Table 1) agree fairly well with those of the pure substances (—125° and + 118°). The β- and α-methyl-L-arabofuranosides were therefore oxidized



IV α-Methyl-D-glucofuranoside

V

VI α-Methyl-D-xylofuranoside



VII α-Methyl-D-galactofuranoside

VIII

IX β-Methyl-L-arabofuranoside

further with periodic acid, giving D'- and L'-methyl-L-hydroxymethyldiglycolaldehyde, respectively. After reduction of these the specific rotation of the enantiomeric diglycols formed were found (Table 1) to be in agreement with the values found before [2,10].

On hydrolyzing the diglycols with mineral acid, methanol, glycerol and glycolaldehyde were obtained. The glycolaldehyde was determined as 2,4-dinitrophenylhydrazone of the *O*-benzoate.

As will be seen this new method of degradation makes it possible to correlate the anomeric aldohexofuranosides to the anomers of the pentofuranosides.

EXPERIMENTAL

β-Methyl-D-galactofuranoside

To a solution of 0.7264 g (3.75 mmole) of the furanoside in water (20 ml) periodic acid (10 ml of 0.430 M solution) was added and the temperature kept at 5°. The optical rotation in a 10 cm tube which was −2.48° after 3 min changed to −2.10° after 25 min and then became constant. The concentration of the monoaldehyde was calculated as 2.00 g in 100 ml and the specific rotation accordingly −105.0°. After 30 min excess of

Table 1. Oxidation of methyl-D-galactofuranosides and methyl-D-glucofuranosides.

β-Meth.-D-glucofur.	−60°	1.11	1.02	−78.5°	−80.3°	—	—	—
α-Meth.-D-glucofur.	+112.5°	1.04	—	+116.2°	+168.2°	—	—	—

periodic acid and the amount of formaldehyde were determined, and after 35 min further oxidation was prevented by adding a hot solution of barium hydroxide until pH 9.5.

Determination of periodic acid: The solution (2 ml) was diluted with water (10 ml) and sodium bicarbonate added until basic reaction. After adding 0.1 g potassium iodide and 5 ml 0.2016 N sodium arsenite the solution was left for 15 min and then titrated with 9.50 ml 0.1015 N KI_3. These data correspond to a consumption of 1.06 mole periodic acid per mole galactoside.

Determination of formaldehyde: The solution (0.3 ml) was neutralized with sodium bicarbonate and diluted with water to 100 ml. To 1 ml of this solution was added 1 ml lead dithionate (2 % in water). After centrifugating, 1 ml of the clear solution was diluted with 9 ml of a solution of 0.25 g chromotropic acid in 250 ml 60 % sulphuric acid. After 30 min the solution was centrifuged and then heated on steam-bath for 40 min. All operations were carried out in darkness. After cooling the absorption at 570 mμ, measured on a Beckmann DU spectrophotometer, was 0.345. As standards of 4.7, 7.1, and 11.8 μg formaldehyde in the same volum showed the absorptions 0.248, 0.413, and 0.680. The absorption 0.345 corresponds to 5.90 μg formaldehyde or 1.05 mole per mole galactofuranoside oxidized.

The isolation of the monoaldehyde was carried out in the same way as described for the dialdehyde by Jackson and Hudson [1]. The monoaldehyde was obtained as a syrup (0.424 g) which was dissolved in water (10 ml) and reduced in the course of one hour by adding 0.1 g sodium borohydride. Excess borohydride was destroyed by bubbling carbon dioxide through the solution until pH 7. After treatment with active carbon α_D in a 10 cm tube was −4.84° and as the concentration of the pentofuranoside was calculated as 4.17 g in 100 ml the specific rotation was −116.1°. In a parallel experiment 0.291 g of β-methyl-D-galactofuranoside gave a monoaldehyde and a pentofuranoside with the specific rotations −107.8° and −119.7°, respectively.

In order to isolate the reduction product, the solution was concentrated at reduced pressure (bath-temperature 35−40°) and the residue dried in a vacuum desiccator above calcium chloride. The residue was shaken with cold anhydrous ethanol (4 times with 10 ml and 3 times with 5 ml) and the ethanolic extract then concentrated *in vacuo*. The resulting syrup was dissolved in water (200 ml) and the solution passed successively through 100 g of Amberlite IR-45 (weak anion exchange type) and 100 g of Amberlite IR-120 (strong cation exchange type). On concentrating the eluate under reduced pressure a pale yellow syrup was obtained which was chromatographed on Whatman paper No. 1 using methyl ethyl ketone as moving phase and *m*-phenylenediamine hydrochloride

(0.6 g in 100 ml 70 % ethanol) as developer. The dominating spot had the same R_F-value as α-methyl-L-arabofuranoside while a smaller spot had the same R_F-value as arabinose.

Oxidation of the pentofuranoside: A solution of the syrupy pentofuranoside in water (10 ml) after treatment with active carbon had $\alpha_D^{20} = -3.34°$ in a 10 cm tube showing that it contained 0.270 g (1.65 mmole) α-methyl-L-arabofuranoside. The solution was mixed with 5 ml 0.430 M periodic acid (2.15 mmole). After 3 h at room temperature α_D^{20} became constant at $-2.12°$ and $[\alpha]_D^{20}$ accordingly $-116.9°$ ($c = 1.77$). In a second experiment was found $-118.3°$. An analysis carried out as described above showed that each mole furanoside had consumed 0.98 mole periodic acid. The dialdehyde was isolated as described for the monoaldehyde and was obtained as a slightly impure syrup (0.140 g) which after dissolving in water (10 ml) was reduced with 0.1 g sodium borohydride. The optical rotation in a 10 cm tube was now found to be $+0.15°$ and as the concentration of the diglycol was calculated as 1.41 g/100 ml the optical rotation was $+10.6°$.

The diglycol was benzoylated and after hydrolyzing the acetal group, the 2,4-dinitrophenylhydrazone of glycolaldehyde-*O*-benzoate was prepared. Recrystallized three times from chloroform-light petroleum, m. p. 187—188°; no depression on mixing with authentic sample. (Found: C 52.24; H 3.68; N 16.41. Calc. for $C_{15}H_{12}O_6N_4$: C 52.38; H 3.55; N 16.20.)

α-Methyl-D-galactofuranoside

The oxidation of this furanoside was performed in the same way as described for β-methyl-D-galactofuranoside. The optical rotation became practically constant in 30 min when $[\alpha]_D$ was $+102.3°$. Analysis showed that each mole furanoside consumed 1.08 mole periodic acid and led to the formation of 0.99 mole formaldehyde. Starting with 0.3188 g of α-methyl-D-galactofuranoside 0.143 g monoaldehyde was obtained which after dissolving in water was reduced by adding 50 mg sodium borohydride. Excess of borohydride was quenched with carbon dioxide and the solution treated with active carbon when it was found that the specific rotation of the pentofuranoside was $+114.6°$. The furanoside was isolated as described above. On a paper chromatogram the main spot had the same R_F-value as β-methyl-L-arabofuranoside. Also in this case a smaller spot with the same R_F-value as arabinose showed that some hydrolysis of the furanoside had taken place.

As a further control the furanoside (0.106 g) was oxidized with periodic acid. Per mole it consumed 1.05 mole periodic acid and the specific rotation of the dialdehyde formed was found to be $+148.8°$. Reduction of the dialdehyde with sodium borohydride led to a diglycol with the specific rotation $-11.1°$.

β-Methyl-D-glucofuranoside

To a solution of 0.3901 g (2.01 mmole) of the slightly impure furanoside (syrup) 10 ml 0.272 M periodic acid was added and the temperature kept at 5°. In 15 min the rotation became practically constant and the specific rotation of the monoaldehyde found to be $-78.5°$. Analysis showed that each mole of the glucofuranoside had consumed 1.11 mole of periodic acid and formed 1.03 mole formaldehyde.

The monoaldehyde (0.195 g) isolated in the usual way was reduced with 0.15 g sodium borohydride and the specific rotation of the reduction product determined to be $-80.3°$. The pentofuranoside was isolated as described for the arabofuranoside, but with the exception that in this case the solution was treated first with the cation exchanger and thereafter with the anion exchanger (Amberlite IR-4B). The result was that more of the furanoside was hydrolyzed and the paper chromatogram showed two spots of nearly equal strength, one with the same R_F-value as β-methyl-D-xylofuranoside and the other with that of xylose. A mixture of ethyl acetate-propanol-water (5:3:2) was used as moving phase.

The presence of xylose was verified in the following way. The pentofuranoside was hydrolyzed in 1 N hydrochloric acid by heating to 100° for 2 h. After removing the acid

by treatment with an ion exchange resin (IR-4B) the solution was concentrated *in vacuo* and the last trace of water removed in a vacuum desiccator above calcium chloride. The residue was dissolved in 4 ml anhydrous methanol containing 0.5 N hydrogen chloride, and 1 ml freshly distilled benzaldehyde was added. After 8 days the dibenzylidene derivative formed was filtered and washed thoroughly first with water and then with cold methanol. Recrystallized from ethyl acetate, m. p. 213.5—214°; no depression on mixing with the dibenzylidene dimethylacetal prepared from D-xylose. (Found: C 67.84; H 6.45; MeO 16.38. Calc. for $C_{21}H_{24}O_6$: C 67.73; H 6.50; MeO 16.65.)

α-Methyl-D-glucofuranoside

The crystalline furanoside, m. p. 61—62° (0.1576 g = 0.81 mmole) dissolved in water (5 ml) was oxidized by adding 3.5 ml 0.272 M periodic acid (0.95 mmole). At 5° the rotation became approximately constant in 20 min when the specific rotation of the monoaldehyde was found to be +116.2°. Analysis showed that each mole furanoside had consumed 1.04 mole periodic acid.

The monoaldehyde (87 mg isolated as above) was reduced with 50 mg sodium borohydride and the specific rotation of the reduction product was found to be +168.2°. Isolated in the usual way the reduction product gave on a paper chromatogram one main spot with the same R_F-value as α-methyl-D-xylofuranoside and a smaller spot showing the presence of xylose.

The author wishes to express his gratitude to Professor Dr. Endre Berner for his kind interest in the work and for many valuable discussions.

The Solubility of Methane in Hydrocarbons, Alcohols, Water and Other Solvents

AXEL LANNUNG* and J. CHR. GJALDBÆK

The Royal Danish School of Pharmacy, Chem. Laboratory A, Copenhagen, Denmark

The solubility of methane in a series of solvents has been determined. For each solvent used, the values found for the Bunsen absorption coefficients at 18°, 25° and 37°C are, respectively, as follows: *n*-hexane 0.885, 0.869, 0.816; *cyclo*hexane 0.701, 0.675, 0.643; acetone 0.594, 0.564, 0.547; benzene 0.535, 0.523, 0.510; ethanol 0.512, 0.489, 0.455; methanol 0.500, 0.479, 0.446; water 0.0352, 0.0313, 0.0260 and *cyclo*hexanol 0.266 at 25°C and 0.252 at 37°C.

The experimental values obtained are in agreement with values calculated from equations derived on a semiempirical basis, and are compared with values found by other authors.

The experiments presented in this paper have previously been carried out by the first author in the *Chemical Laboratory of the Royal Veterinary and Agricultural College*, Copenhagen.

MATERIALS AND PROCEDURE

Methane was generated from magnesium methyl iodide in a gasometer with airfree water and ethyl ether as blocking liquid; the methane was led slowly through a trap cooled with solid carbon dioxide, dried over concentrated sulphuric acid and phosphorus pentoxide, and condensed in a container cooled with liquid air. The methane was freed from atmospheric air by repeated distillations at a pressure of about 35 mm Hg, the air being pumped out after each distillation. It was finally purified by fractional distillation. The fraction used in the experiments showed by determination of the specific gravity an apparent molecular weight of 16.08 (22.40 l 0°C) in accordance with the corresponding value of the literature.

The solvents used were of the same origin and purity as described in a previous paper [1]. *Normal hexane* was fractionated by distillation of "*n*-Hexan aus Petroleum, Kahlbaum"; the fractions used in the experiments showed boiling point 68.85°C (760 mm) and vapour pressure 154 mm Hg at 25°C. The solubility determinations were carried out as previously described [1].

* Present address: Gentofte Apotek, Copenhagen.

RESULTS

The results of the solubility determinations are shown in Table 1; the calculated mean is considered to be reliable to within 1 %.

Table 2 shows that most of the present solubility determinations are higher than found by other authors; exceptions are the solubility determinations in acetone and benzene. In these solvents the present results are in strict accordance with Horiuti's results.

CORRELATION WITH THEORY

In a previous paper, [2,p.54] it was shown that eqn (1) can account for the solubility of methane in non-polar solvents.

$$\log x_2 = \log x_2^i - \frac{\overline{V}_2}{2.303\ RT}(\delta_1 - \delta_2)^2 - \left[\log \frac{\overline{V}_2}{V_1} + 0.4343\left(1 - \frac{\overline{V}_2}{V_1}\right)\right] \quad (1)$$

In this equation x_2 denotes the solubility in mole fraction, x_2^i the "ideal" solubility, $\overline{V}_2$ the partial molal volume of the gas in the saturated solution, V_1 the molal volume of the solvent, δ_1 the "solubility parameter" of the solvent defined as the square root of the energy of vaporization (ΔE_1) per ml, *i.e.*

$$\delta_1 = \sqrt{\frac{\Delta E_1}{V_1}}$$

δ_2 the "solubility parameter" of the gas (see below) and T the absolute temperature. With regard to the derivation of eqn (1) reference should be made to Hildebrand and Scott [3].

The ideal solubility at 25°C was calculated by means of the equation

$$\log x_2^i = \frac{\Delta H}{2.303\ R}\left(\frac{1}{T} - \frac{1}{T_b}\right)$$

where ΔH is the heat of vaporization of methane (1 955 cal/mole) at the boiling point T_b = 112°K. The value for the ideal solubility was calculated to be 39.8×10^{-4}.

When a gas is dissolved in a liquid the volume of the solution is always greater than the volume of the solvent. From this expansion — which is only to a slight degree dependent on the solvent — one can calculate the partial molal volume of the gas in the solvent. Using the measurements of Horiuti [4] we get the value 52 ml for methane in benzene. The solubility parameter for methane, δ_2, was calculated from eqn (1) to be 6.20, using Horiuti's values for the solubility of methane in benzene and in carbon tetrachloride.

In Table 3 the experimental values of the solubility have been compared with values calculated by means of eqn (1).

In Table 3 we have included the calculated values for the solubility of methane in some polar solvents, listed in the order of their increasing dielectric constant. It can be seen that the experimental values are higher than the values calculated from eqn (1). It should be emphasized that this equation is derived on the assumption that the molecules are non-polar and that chemical reactions are absent. Deviations of the same order of magnitude have previously been found for the calculated solubility of carbon dioxide, oxygen, carbon monoxide and nitrogen in polar solvents [5].

In a recent paper [6] it is shown that eqn (1) can account for the solubility at 25°C of nitrogen, argon and ethane in alcohols, if δ_1 is substituted by δ_1^* calculated from

$$\delta_1^* = \delta_1 - (\varepsilon - 1)(0.165 - 0.00143\alpha \times 10^{25}) \quad (2)$$

In this equation, δ_1 is calculated from

$$\delta_1 = \sqrt{\frac{\Delta E_1}{V_1}} = \sqrt{\frac{\Delta H_1 - RT}{V_1}}$$

where ΔH_1 is the heat of vaporization of the solvent at the absolute temperature T and V_1 the molal volume of the solvent. In eqn (2) ε is the dielectric constant of the solvent and α the polarizability of the gas.

Table 4 shows that the solubilities of methane in ethanol, methanol and in *cyclo*hexanol can also be calculated by the same procedure. For methane we have used $\alpha \times 10^{25} = 26.0$. Included in Table 4 is a calculation of the solubility of methane in water; such a calculation gives only a rough estimate [6], and the fair agreement with the experimental value for this solvent is regarded to be casual.

If we use the δ_1^* values in the calculation of the solubility in the solvents mentioned in Table 3, we get no improvement. The deviations between calculated and experimental values turn out to be nearly the same. For acetone on the contrary we get a much greater deviation; using for this solvent a value

Table 3. Solubilities of methane at 25°C expressed in mole fractions x_2. Comparison of experimental and calculated values.

Solvent	V_1	δ_1	$x_2 \times 10^4$ exptl.	calc.	per cent deviation
n-Hexane	132	7.27	50.8	49.7	+ 2.2
*Cyclo*hexane	109	8.20	32.7	34.8	− 6.4
Carbon tetrachloride	97.1	8.60	28.6	28.2	+ 1.4
Benzene	89.3	9.15	20.9	21.0	− 0.5
Dioxane	86.1	10.0	12.9 g)	12.6	+ 0.2

g) Guerry, D., see Ref. in Table 2.
f) Horiuti, J., see Ref.[4]

Table 4. Solubilities of methane at 25°C in some alcohols and in water. Comparison of experimental and calculated values.

Solvent	V_1	δ_1	ε	$x_2 \times 10^4$ exptl.	calc.	per cent deviation
Ethanol	58.7	12.8	24.3	12.8	12.7	+ 0.8
*Cyclo*hexanol	106	11.7	15.0	12.6	14.5	−13
Methanol	40.7	14.35	32.8	8.71	9.31	− 6
Water	18.1	23.4	78.0	0.253	0.292	−13

for the dielectric constant of 20.9, we obtain $x_2 = 39 \times 10,^{-4}$ a value much higher than the experimental one, $x_2 = 18.6 \times 10.^{-4}$ It should be mentioned that eqn (2) has been evaluated for alcohols all having nearly equal dipole moments.

On the Alkylation Type Substitution and Ester Condensation at the α-Position of N,N-disubstituted Amides of Arylacetic Acids

O. MÄRTENSSON and E. NILSSON

Pharmacia, Research Laboratories, Uppsala, Sweden

A simple method for substitution of alkylation type at the α-carbon atom of N,N-disubstituted arylacetic acid amides is described and discussed. Sodamide has been used as basic agent and toluene or benzene as reaction medium. Many compounds have been prepared according to the method and the result can be surveyed in tabular form. The aryl groups used in the investigation are phenyl, 1-naphthyl and 3-phenanthryl. No remarkable changes in reactivity as to sodium salt formation could be observed by these alternations of the aryl group, nor do variations in the substituents on the amide nitrogen change the activation of the α-hydrogen appreciably. The groups introduced are mainly of alkyl type but some heteroaromatic halogenides react in the same way. Condensations of esters (Claisen condensations) with the N,N-disubstituted amides have also been carried out with sodium methoxide or sodium ethoxide as condensing agents in the presence of an inert solvent (toluene or xylene), but this method seems to be less general than the substitution procedure, and somewhat unpredictable as to the results. However, cases including condensation under ring closure seem to form a subgroup in which the method is general.

In contrast to ester and nitrile groups, the activation by an amide group of the hydrogen at the adjacent carbon atom (the α-hydrogen) has been given comparatively little attention. The alkylation of esters and nitriles and ester (Claisen) condensation belong to the basic synthetic methods and have recently been reviewed [1,2]. As to the amides, unless the amide group is disubstituted, reactions generally occur under replacement of amide hydrogen. The main interest has therefore been connected to such reactions and not so much to the secondary effects caused by the amide group as a whole on the adjacent atoms and α-hydrogen in particular. (Since the reactions in the α-position can be studied mainly on N,N-disubstituted amides, for brevity, we omit this epithet unless otherwise stated.) It is also well known that an aryl group (*e.g.* phenyl) definitely activates the hydrogen at an adjacent carbon atom, an effect which

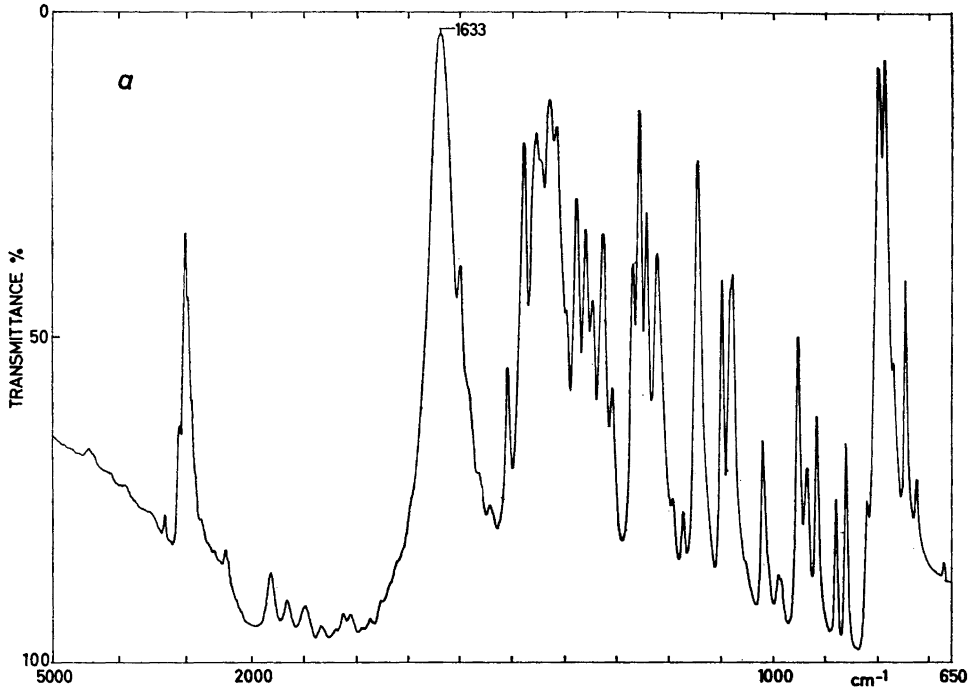

Fig. 1. Infrared spectrum of the parent amide 1-naphthylacetic acid N,N-diethylamide (a) and of its α-(2′-dimethylaminoethyl) derivative (b), showing that the frequency and intensity of the C=O bond of the amide group remain almost unchanged after substitu-

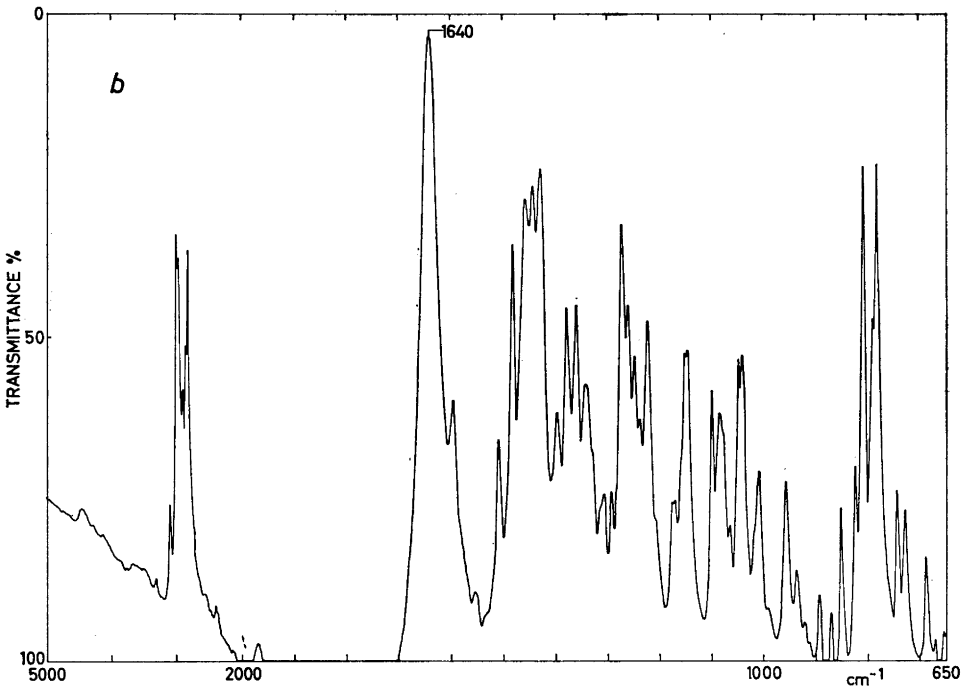
may be exemplified by the increasing mobility of α-hydrogen in the series toluene, diphenylmethane and triphenylmethane. The combined activation of α-hydrogen by an aryl group and nitrile and/or ester groups occurs in well known compounds such as phenylacetonitrile, phenylmalonic esters and phenylcyanoacetic esters. As to arylacetic acid amides, the mobility of the α-hydrogen of the amides of phenylacetic acid was expected to be between that of phenylacetonitrile and that of alkyl phenylacetate. The former compound easily forms a salt with sodamide in toluene in contrast to ethyl phenylacetate, which cannot be alkylated in the presence of sodamide in boiling toluene. It should be pointed out that the ability of salt formation and of alkylation depends very much on the basic agent used and the reaction conditions. The situation is quite different when such a strong agent as phenylsodium is used or when the salt formation is carried out with liquid ammonia as solvent. Thus, ethyl phenylacetate has recently been phenylated, too, in a yield of 63 % by bromobenzene in liquid ammonia and excess of sodamide [3]. In this paper we therefore intend merely to collect our experience and the results of a fairly extensive investigation in this laboratory [4,5] of introducing groups in the α-position of arylacetic acid amides. For completeness some



tion. The frequency of ten another compounds investigated proved to be within the range 1 633—1 648 cm^{-1}. — All spectra are drawn with KBr pellet technique on a Unicam SP 100 IR instrument. The experimental error is ± 2 cm^{-1}.

comments have also been given to a patent by Cusic [6] which turned up some years ago. He reports ten basically substituted cyclic amides of phenylacetic acids (they are included in Table 1). With the exception of one case in which sodamide has been used, lithium amide has been preferred as basic agent. The conventional method applied by us consists in substituting the amides in the presence of sodamide in an inert solvent, generally toluene. The reaction, which will be commented on below as to some practical details, can be written:

$$ArCH_2COY + RX \xrightarrow[\text{solvent}]{NaNH_2} \underset{\displaystyle R}{\overset{\displaystyle |}{ArCHCOY}} + NaX$$

Ar = phenyl, substit. phenyl, 1-naphthyl or 3-phenanthryl,
Y = secondary amido group of various types
R = alkyl (mainly tertiary aminoalkyl), *cyclo*alkyl, aralkyl and heteroaromatic radicals,
X = halogen

It is obvious that the reaction leads to substitution at the α-carbon atom and not to O-substitution. Thus the reaction product expected to be 2-phenyl-

(1,4)-butanedioic acid 1-(N,N-diethylamide)-4-(N-methylanilide) is converted by acid hydrolysis to phenylsuccinic acid in a yield of 90 %. Reduction of the amides with lithium aluminium hydride gives tertiary amines in very good yields (Table 2). Moreover, infrared spectra indicate that the carbonyl frequency remains almost unaltered after introduction of R (Fig. 1).

In the case of diphenylacetic acid amides the activation of the α-hydrogen is increased more by the second phenyl group and they form sodium salts more easily than when only one phenyl group is present. Indeed, substitution at the α-carbon atom by conventional methods has been applied [7,9] or probably applied [10] for synthetic purposes several times during the last years. In connection with the diphenylacetic acid amides it may also be pointed out that xanthene-9-carboxylic acid amides can be substituted at the 9-position by almost the same procedure ($LiNH_2$ or NaH in boiling toluene) as Cusic [11] has shown. However, this is easily expected since the corresponding esters can already be substituted at this position under fairly simple conditions: the salt has been formed by boiling the ester solution in toluene with potassium [12]. Further, it may be noted that phenyl-2-pyridyl-acetic acid amides have been alkylated by the conventional method in this laboratory [4].

In addition to this substitution method, which may be interpreted as an alkylation in *sensu lati*, we have also tried to carry out ester (Claisen) condensations with some of the parent acid amides. This reaction which leads to β-ketoamides under liberation of alcohol from the ester with which the amide is condensed, seems to be much more limited as to its application. We now intend to treat these two cases separately in somewhat greater detail.

A. SUBSTITUTION OF ALKYLATION TYPE

According to our standard method for substitution (several examples are given in the experimental part) the amide is dissolved in benzene or toluene (generally 0.1 mole amide per 100 ml solvent), a slight excess of the theoretical amount of sodamide (commercial ground quality has been used) is added, and the mixture warmed to reflux under stirring. A strong evolution of ammonia generally begins before the mixture boils — at least when toluene is used as solvent. After refluxing during 1—2 h the strong evolution of ammonia ceases. (The strength of the ammonia evolution is easily followed by putting dry strips of indicator paper at the mouth of the reflux condensor.) At this time the sodium salt of the amide has formed a precipitate in the flask in most cases. The mixture is then cooled somewhat before the compound RX is added — the extent of cooling, of course, and the rate of adding the alkylating compound must be adapted to the reactivity of the latter. When the agent is added, the salt of the amide generally disappears, the temperature increases, and a second strong evolution of ammonia starts. This second "ammonia peak" probably originates from sodamide which has been enclosed in the sodium salt formed and now can react. When the salt of the amide (*e.g.* N-benzyl-N-propylamide of phenylacetic acid) is soluble the salt formation is more complete and the second "ammonia peak" less pronounced. The reaction is never violent. After the second ammonia evolution has decreased further boiling for 1—2 h is

generally enough to ensure a complete or almost complete reaction. Of course, to be certain, one ought to prolongate the reaction time when, for example, chlorides are used, as they are known to react slowly. In this case the sodium salt formed disappears slowly and the second "ammonia peak" is not pronoucend.

As to the salt formation in toluene or benzene, in no case has this proved to occur at room temperature. Warming to above 50°C is necessary. Heating up to the boiling point of the reaction mixture is to be preferred in most cases. Thus phenylacetonitrile is much more reactive under the same conditions. On the whole the power of forming salts under our conditions varies very little with the substituents at the amide nitrogen. Heavy groups seem merely to increase the solubility of the sodium salt.

On the whole it is of fairly little importance how the substitution reaction is carried out. The procedure described above is of particular interest when the alkylating agent may react with the sodamide itself and one can hardly demand a higher yield than that corresponding to the sodium salt formed during the first reflux. Otherwise, at least on a small laboratory scale, one only has to mix the reacting compounds and the solvent and boil the mixture. Alternatively, one may add the sodamide in portions to the boiling mixture. Since the reaction time is fairly short, a loose cotton plug at the top of the reflux condensor is sufficient for exclusion of moisture. It may be removed during the periods of strong evolution of ammonia. The conditions are not rigorous. However, as in all cases when sodamide is used, its quality is very important for the success of the reaction. Too large an excess of sodamide should be avoided, since some of the alkylation products may be unstable under prolonged reflux with sodamide as has been proved by our attempts to carry out a second alkylation of these monoalkylated compounds.

We have chosen the easily available sodamide as basic agent with benzene or toluene as reaction media. In all the listed examples except one, Cusic [6] has used lithium amide. Since no yields are given, it is difficult to say whether it is to be preferred to the less expensive sodamide. However, the yields obtained by using sodamide are generally so good, that there seems to be no reason to use other alkali amides.

Sodium hydride reacts very slowly in forming salts in benzene or toluene and we have not been able to use it with success. Phenylsodium in toluene has also been used as an agent in forming salts, but it is generally not necessary to use such a reactive compound. As far as we have tried it, it gives no advantages.

A single trial with phenylacetic acid pyrrolidide and di-*iso*butylacetal suggests that the alkylation method of esters and nitriles by Weizmann *et al.* [13] which uses potassium hydroxide in solvents of acetal type, is not applicable with success to our amides.

Other polar solvents such as diglyme (ethylene glycol dimethyl ether) and dioxane have also been tried. With sodium hydride and diglyme the reaction is very slow and the yield almost none. Dioxane and sodium hydride give somewhat better yields. When sodamide has been tried in combination with these solvents, we have not been able to isolate any substitution product from the reaction mixture. On the whole these attempts to replace toluene and

benzene with other "polar" solvents and/or to replace the sodamide with sodium hydride have not been encouraging enough to justify further work in order to improve these modifications.

The compounds RX used for the introduction of R are halogenides. Chlorides and bromides have mainly been used. Alkyl *p*-toluenesulfonates have been tried in a few cases without appreciable success. They seem to react too easily with the sodamide to be recommended. Epoxides (ethylene oxide has been used in a very few trials) do not seem to give unique reaction products. There are reasons to believe that some polymerisation occurs on the hydroxyl groups formed. When R contains one or more ester groups one must expect low yields, since competition reactions occur. However, R containing a N,N-disubstituted amide group (*e.g.* RX = chloroacetyl-N-methylaniline) behave better in this respect. Of course, R is not allowed to bear groups containing a hydrogen atom more active than that in the α-position of the amide, nor groups which may rearrange so that such structures are formed.

As mentioned in the introduction the aryl groups used are phenyl, 1-naphthyl and 3-phenanthryl. No appreciable differences in reactivity as to salt formation have been observed in this series during the synthetic work. Only in the phenyl case syntheses have been carried out with substituents in the aryl group, and then only when the substituent is a halogen atom. Even in this case we have not been able to establish definite differences in reactivity between the *o*-, *m*- and *p*-compounds and the unsubstituted amides which are of interest for the application of the general method used by us. The case where the phenyl group bears one lower alkyl group has also been reported [4,6]. The method is limited as to the substituents of the aryl group and does not allow substituents which contain a hydrogen atom more mobile than that in α-position, such as hydroxy or acetamino groups, nor groups which can rearrange to give such a hydrogen.

A disadvantage of the method is that compounds with small substituents (R) often may be difficult to separate from the parent compound. If R bears a basic group, or is a heavy one, the separation from the parent amide is easy. On the other hand disubstitution seems to be of little importance. On the whole, side reactions are rare. The introduction of a second group in the α-position by this method is generally not so easy as that of the first one. Longer reaction time and sometimes also a stronger salt-forming agent than sodamide are necessary. In some cases proximity effects may also make the introduction of a second group difficult.

Most of the compounds with aryl equal to phenyl or substituted phenyl are viscous, colourless or faintly yellowish oils. When solid, their melting points are generally lower than that of the parent amides. They are very soluble in most organic solvents — often also in petroleum ether — and are difficult to recrystallize in good yields. The group consisting of the α-pyridyl derivatives is an exception to these characteristics.

As to the practical use of the compounds prepared according to this substitution method, those with a tertiary amino group (*e.g.* R = dialkylaminoalkyl) have pronounced and interesting pharmacological properties. Some of the α-substituted amides are also valuable as intermediates for further synthetic work. At least for some compounds a further substitution in the α-position

can be carried out. That this is the case for the phenyl-(2-pyridyl)-acetic acid amides has been shown in this laboratory. Moreover, as far as we have tried, the amide group has been easily reduced to a tertiary amino group by the conventional lithium aluminium hydride method [14] in excellent yield. We have included some amines (see Table 2) prepared according to this method and which do not seem to have been reported previously. Since a necessary condition for success in using this method in the reduction of N,N-disubstituted amides seems to be that there remains at least one hydrogen atom at the α-carbon, and this condition is fulfilled within the series, the reduction method can be expected to be generally applicable.

Finally, it may be noted that we have tried to apply the method to some thiocarbonamides without success. Thus, gentle heating of a mixture of sodamide, phenylthioacetylmorpholine and 2-morpholinoethylchloride in toluene in addition to ammonia causes evolution of hydrogen sulphide. No compound corresponding to a substitution product could be isolated from the refluxed mixture. Some phenylthioacetylmorpholine could be recovered.

B. ESTER (CLAISEN) CONDENSATION

As mentioned above, in contrast to the substitution of alkylation type in the α-position, the condensation of amides with esters need more care, and special conditions in each case, to insure the success of our method (sodium methoxide or sodium ethoxide as condensing agent with an inert solvent, generally toluene or xylene, as reaction medium). Several cases which lead to ring closure, under formation of 1-substituted 3-phenylpyrrolidine-2,4-diones and 1-substituted 3-phenylpiperidine-2,4-diones, have been investigated and they give fairly good to excellent yields, indicating that the method can be expected to be general in these cases. The success is more unpredictable when the condensation does not involve ring closure. At least some of the condensation products (*e.g.* α-methoxalyl-phenylacetic acid dimethylamide) seem to be very sensitive to alkali, thereby undergoing acid cleavage since fairly large amounts of acid corresponding to the ester (from oxalic acid diesters we obtain the monoesters) used can be isolated from the reaction mixture. This sensitivity to alkali is also characteristic for the purified condensation product. The reaction product must therefore be poured into a mixture of ice and dilute acid when worked up. In some cases we have been able to distil off only half the stoichiometric amount of alcohol. From these reaction mixtures we have not yet been able to isolate any condensation product but only the acid and the parent amide. The temperature sensitivity is also pronounced. When too high temperature is used during the reaction — for example when the alcohol formed is distilled off — no desired reaction product can be isolated, but a waxy or highly viscous, yellowish brown product remains after the solvent is removed. At this time we therefore report only those cases in which we have been successful.*

* Stronger condensing agents, such as phenylsodium have not yet been tried.

otes: In order to make this table complete we have included also about ten compounds for which detailed data are not available. Most of these derivatives are taken from the patent by Cusic mentioned in the text, and they differ from the other compounds listed in so much as generally lithium amide has been used in their syntheses. The yields are the total ones and refer to the parent amide, unless the compounds listed are ammonium salts, in which case the figures refer to the corresponding tertiary base. When more than one yield figure is given, the compound in question has been further purified by redistillation or recrystallization. Melting points and boiling points are uncorrected. The former have been read from short normal thermometers covering intervals of 50°. Unless otherwise stated, X in the compound RX is chlorine. With a few exceptions the substitutions have been carried out with 0.05—0.4 mole of parent amide.

EXPERIMENTAL

The amides used as starting materials have generally been prepared from the appropriate secondary amines and acid chlorides with benzene as solvent. In fairly few cases the Schotten-Baumann reaction has been applied. The yields are generally excellent or at least good. Several of these amides have been prepared earlier but some do not seem to have been reported previously. Since we find it practical, we have collected the boiling points and/or melting points of all amides used by us (however, the boiling points of the amide esters used in cyclic condensation have been listed in Table 3):

Phenylacetic acid: dimethylamide, b. p. 125—29°/0.7 mm, m. p. 40°; diethylamide, b. p. 111—13°/0.3 mm; di*iso*propylamide, m. p. 50—53°; di-*n*-butylamide, b. p. 122—24°/0.1 mm; di*iso*butylamide, b. p. 113—16°/0.1 mm; di*cyclo*hexylamide, m. p. 83—85°; *cyclo*hexyl-*n*-butylamide, b. p. 148—50°/0.2 mm; benzyl-*n*-propylamide, b. p. 176—78°/0.8 mm; dibenzylamide, m. p. 60.5—62.5°; diphenylamide, m. p. 74—75°; pyrrolidide, m. p. 47—48.5°; piperidide, b. p. 174—79°/8 mm; morpholide, m. p. 65.5—67°.

o-Chlorophenylacetic acid: dimethylamide, m. p. 54—54.5°.

m-Chlorophenylacetic acid: dimethylamide, b. p. 124—25°/0.2 mm.

p-Chlorophenylacetic acid: dimethylamide, b. p. 144—45°/0.4 mm; diethylamide, b. p. 120—25°/0.2 mm; morpholide, m. p. 103—05°.

α-Naphthylacetic acid: diethylamide, m. p. 77.5—79°; di*iso*propylamide, m. p. 84—85°.

Phenanthrene-3-acetic acid: diethylamide, m. p. 94—95°.

A. Examples of substitution of alkylation type

α-(p-Chlorobenzyl)-phenylacetic acid pyrrolidide. In a three-necked 500 ml flask, equipped with a reflux condensor, a mechanical stirrer and a dropping funnel, a mixture of 37.9 g (0.2 mole) phenylacetic acid pyrrolidide (m. p. 47—48.5°), 8.2 g (0.21 mole) commercial, ground sodamide and 200 ml of dry toluene is warmed. At about 80° a strong evolution of ammonia begins. After boiling for about 2 h the strong evolution of ammonia has ceased, and a white precipitate of the sodium salt of the pyrrolidide has been formed. The mixture is now cooled to room temperature. A solution of 33.6 g (0.21 mole) *p*-chlorobenzylchloride in 50 ml of dry toluene is added during a period of about 15 min. by means of the dropping funnel. The temperature in the flask increases to about 60° and the salt disappears. The solution becomes rose-coloured but this colour soon becomes pale as the sodium chloride is formed. The flask is warmed again to reflux. At this point a further strong evolution of ammonia begins but decreases after a boiling time of about 30 min. After further reflux for 2 h the evolution of ammonia has ceased almost completely. The mixture is now cooled to room temperature and cold water added carefully. After one further washing with water the toluene layer is dried with fused magnesium sulphate. The toluene is distilled off under diminished pressure. The remaining oil is distilled and the fraction 205—210°/0.8 mm is collected. Yield 48 g (76.5 %). The oil crystallizes almost immediately, m. p. 92—95°. Recrystallization from 100 ml *cyclo*hexane gives 43.5 g (70.5 %) of white crystals, m. p. 96—97°. For analysis see Table 4.

α-Cyclohexyl-phenylacetic acid diisopropylamide. 109.7 g (0.5 mole) of phenylacetic acid di*iso*propylamide are dissolved in 400 ml of dry toluene, 21 g of sodium amide are added and the mixture refluxed for about 2 h or until the rapid evolution of ammonia has decreased and a large precipitate is obtained in the flask. 65 g (theoret. 59.3 g) of *cyclo*hexylchloride are added gradually to the boiling mixture. During this procedure the salt reacts and disappears and evolution of ammonia takes place. The refluxing is then continued for about 5 h. After cooling to room temperature and twice shaking the reaction mixture with water, the toluene layer is dried with anhydrous sodium sulphate and the solvent distilled off. The main part of the remaining oil distils at 128—132°C/0.1 mm Hg. It solidifies to a mass of crystals. Yield 85 g (57 %). 5.0 g recrystallized from petroleum ether gives 3.5 g (total yield 40 %) of *α-cyclo*hexyl-phenylacetic acid di*iso*propylamide, m. p. 81—82.5° and 88.5—89°C. For analytical data see Table 1.

α-(2-Diethylaminoethyl)-phenylacetic acid diisopropylamide. 109.7 g (0.5 mole) of phenylacetic acid di*iso*propylamide, dissolved in 450 ml of dry toluene is boiled while stirring with 21 g of sodium amide for about 2 h. After that time the strong evolution of ammonia has ceased and a yellow precipitate has been formed in the flask. After cooling to about 50°C, a dried solution of 2-(diethylamino)-ethylchloride (liberated from 98 g of the hydrochloride) in ca. 200 ml of toluene is added. The reaction mixture is gently warmed until the reaction begins, *i. e*, the sodium salt dissolves and evolution of ammonia increases. The reaction mixture is then refluxed for about 3 h. The mixture is cooled to room temperature and water is added carefully. The toluene layer is then washed two times with water and then extracted two times with dilute hydrochloric acid. The base is liberated from the acid solution with dilute sodium hydroxide. The precipitated oil is dissolved in ether and the water phase extracted once more with ether. The united ether solutions are dried with anhydrous sodium sulphate and the ether evaporated. The main part of the remaining oil distils at 115—20°C/0.1 mm and consists of the α-diethylaminoethyl compound. Yield 128 g (81 %).

The hydrochloride precipitates as an oil when ethanolic hydrochloric acid is added to an ether solution of the base. When the acid containing ether is decanted and, to secure basic reactions ether with further base is added the hydrochloride solidifies, m.p. 142—4°C.

To 9.6 g (0.02 mole) of the α-(2-diethylaminoethyl)-phenylacetic acid di*iso*propylamide, dissolved in 100 ml of dry ether, is added 5.5 g of methyl iodide, dissolved in 50 ml of dry ether. After two days 8.4 g of methylammonium compound is filtered off. After recrystallization from a mixture of ethanol and ether 7.7 g (57 %) is collected, m. p. 144—6°C. For analytical data see Table 1.

α-(2-Dimethylaminoethyl)-α-(α'-naphthyl)-acetic acid diethylamide. To 48.3 g (0.2 mole) of α-naphthylacetic acid diethylamide dissolved in 200 ml of dry toluene are added 8.2 g of sodium amide and the mixture is boiled for about 2 h while stirring until the rapid evolution of ammonia has ceased and a yellowish precipitate has been formed. After cooling down to about 50°C, an amount of 2-(dimethylamino)-ethyl chloride, prepared from 35 g of the hydrochloride, dissolved in about 150 ml toluene is added. The mixture is slowly heated, whereby the precipitate is dissolved and ammonia is evolved. The mixture is then refluxed for about 4 h. After cooling, the mixture is shaken two times with water and then extracted two times with dilute hydrochloric acid. The base is liberated from the acid solution by means of dilute sodium hydroxide and dissolved in benzene. The benzene layer is separated and the water phase extracted one time with benzene. The benzene solutions are united and the benzene is driven off. A solidifying oil is obtained. After recrystallization from petroleum ether (cooling with dry ice and ethanol) the α-(2-dimethylaminoethyl) compound is obtained in a yield of 76 % (47 g), m. p. 62—63°C. For analytical data see Table 1.

α-(3-Diethylaminopropyl)-phenylacetic acid morpholide. A mixture of 82.1 g (0.4 mole) of phenylacetic acid morpholide, 350 ml of dry toluene and 16.4 g of sodium amide is refluxed for about 3 h until the strong evolution of ammonia has ceased. The mixture is cooled to about 70°C and 63 g (theoret. 60.0 g) of 3-(diethylamino)-propyl chloride is added gradually. Thereafter the mixture is warmed and refluxed for about 3 h. After cooling to room temperature the reaction mixture is worked up as described in the previous example. After a fore-run of about 20 g the substituted morpholide distils at 156—158°C/0.1 mm. Yield 88 g (69 %). The remainder in the distilling flask is insignificant. For analysis see Table 1.

B. Examples of ester (Claisen) condensation

α-Methoxalyl- and *α-ethoxalyl-phenylacetic acid dimethylamide.* Sodium ethoxide is prepared from 4.8 g (0.21 mole) of sodium and 15 ml of absolute ethanol in 100 ml of dry xylene and the excess of alcohol is distilled off. At room temperature a solution consisting of 32.6 g (0.2 mole) of phenylacetic acid dimethylamide, 30 g (29.2 g = 0.2 mole) of diethyl oxalate and 50 ml of xylene is added to this mixture. The reaction mixture is warmed gently to 85° and kept at this temperature for about 45 min. The reaction mixture is cooled to room temperature and put into a mixture of 75 ml 5 N HCl and ice. Crystals begin to separate from the xylene layer and further precipitate is formed when 200 ml

of petroleum ether is added. The crude product is filtered off, yielding 27 g of the ethoxalyl compound. From the mother liquor another 7.5 g can be obtained with approximately the same melting point, 97—100°. Total yield 65.5 %. Recrystallization from a mixture of benzene and petroleum ether gives 23.5 g (total yield 45 %) with melting point 98—100°. For analytical data see Table 3.

When dimethyl oxalate and sodium methoxide are used, almost the theoretical amount of methanol can be distilled off. The crude yield is 32 g (62 %). After two recrystallizations from a mixture of benzene and petroleum ether the yield is 20 g (40 %). See also Table 3.

α-Nicotinoyl-phenylacetic acid diethylamide. Sodium ethoxide is prepared from 4.8 g of sodium and 15 ml of absolute ethanol, in 100 ml of dry xylene and the excess of ethanol is distilled off. At room temperature a mixture of 38.2 g (0.2 mole) of N,N-diethylphenylacetamide, 30.2 g (0.2 mole) of ethylnicotinate and 100 ml dry xylene is added to the sodium ethoxide suspension during stirring. The mixture is now warmed gently, and in the course of about 2.5 h about the theoretical amount of ethanol (ca. 27 ml) is distilled off. The mixture is then cooled to room temperature and cold water is added. The sodium salt dissolves. The xylene phase is separated and the water phase washed with ether. To the water phase is now added 5 N hydrochloric acid until pH is about 4. The precipitate is collected on a funnel and washed with water. The dried, slightly yellow crude product (47.5 g, 80 %) melts at 129—133°. Recrystallization from a mixture of benzene (100 ml) and petroleum ether (100 ml) raises the m. p. to 136—138°. A further recrystallization from a mixture of benzene and *cyclo*hexane gives 40.5 g (68.5 %), m. p. 136—138°. For analytical data see Table 3.

1-Methyl-3-phenyl-quinoline-2,4-(1H,3H)-dione. 28.2 g (0.1 mole) methyl N-methyl-N-phenacetylanthranilate, dissolved in 50 ml dry toluene is added to sodium methoxide (from 2.7 g sodium) in ca. 50 ml dry toluene at room temperature while stirring. A precipitate is formed. The mixture is warmed and the theoretical amount of methyl alcohol is distilled off. After cooling to room temperature the precipitate is dissolved by adding cold water, and the separated water solution washed with ether. The solution is acidified with 5 N hydrochloric acid, and the precipitate filtered off and washed with water. Yield 24.8 g (99 %), m. p. 220—224°. Recrystallization from 700 ml of ethanol gives 21.5 g (86 %), m. p. 222—226°. For analytical data see Table 3.

The authors are indebted to Mr. W. Kirsten and his assistants for elementary analyses and to Dr. B. Nygård for infrared analyses.

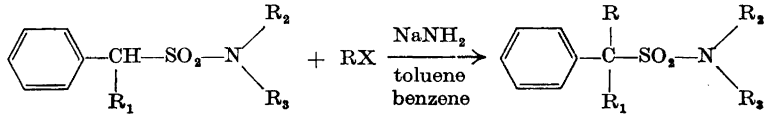
On the Alkylation at the α-Position of Some N,N-disubstituted Toluene(α)sulphonamides and Diphenylmethane-(α)sulphonamides

O. MÄRTENSSON and E. NILSSON

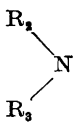
Research Laboratories, A.B. Pharmacia, Uppsala, Sweden

Some N,N-disubstituted toluene(α)sulphonamides and diphenylmethane(α)sulphonamides have been alkylated at the α-position by using sodamide as basic agent and benzene or toluene as solvents. It is shown, that this method is less general and requires more selected reaction conditions than when applied to the corresponding N,N-disubstituted carbonamides. The yields of α-substitution products often are lower. Some of the sulphonamides react very slowly with sodamide. In most of these cases the difficulties can be overcome by using a stronger basic agent, phenylsodium. A survey of the results is given in tabular form.

In a previous paper [1] we have given an account of alkylation at the α-position of N,N-disubstituted arylacetic acid amides. In this context we found it to be of interest to investigate to what extent an exchange of the carbonamide group against a sulphonamide group altered the situation. As expected the activation of the α-hydrogen in many cases proved to be great enough to allow an alkylation by the method applied by us earlier in the carbonamide case, *i.e.* using sodamide as basic agent and benzene or toluene as inert solvent. The reaction can be written



R_1 = H or phenyl,



= dialkylamino, benzyl-*n*-propylamino, dibenzylamino, N-methylanilino, pyrrolidino, piperidino and morpholino groups.

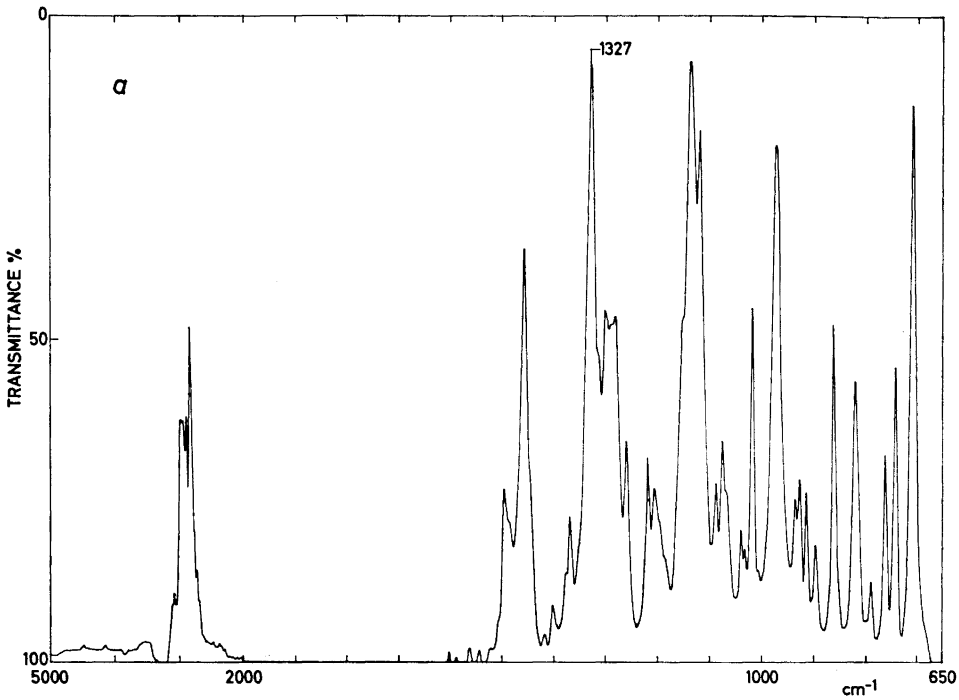


Fig. 1. Infrared spectrum of (a) α-(2-morpholinoethyl)-toluene(α)sulphonic acid N,N-dimethylamide and (b) α-(2-morpholinoethyl)-diphenylmethane(α)sulphonic acid N,N-diethylamide. The significant frequency (at 1 327 cm^{-1} and 1 316 cm^{-1}, respectively)

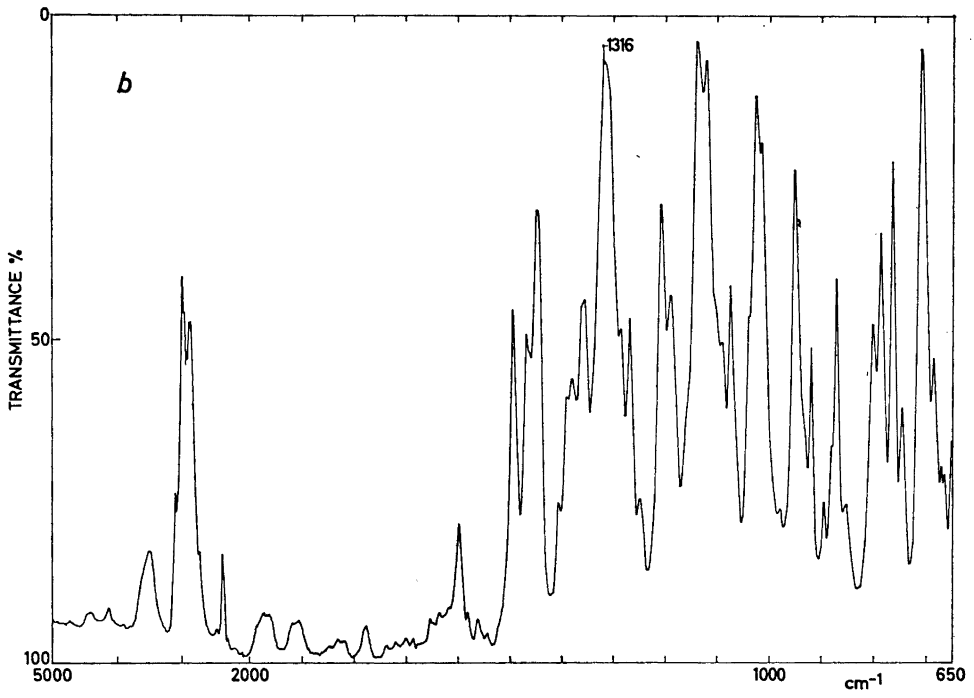
In most cases we have used 2-morpholinoethyl chloride as RX in order to get substitution products which are easily isolated from the reaction mixture, but some further examples are given in Table 1 in which the results have been compiled.

It is true, that most of the parent toluene(α)sulphonamides and at least some of their α-substituted derivatives can be distilled in vacuum at a pressure of some tenths of a mm Hg. However, this procedure provides that the reaction mixture to be worked up is fairly free from by-products which are still more temperature sensitive, hence would disintegrate and make it difficult to keep the pressure low enough. That is not always the case.

In contrast to the N,N-disubstituted arylacetamides, the N,N-disubstituted toluene(α)sulphonamides and diphenylmethane(α)sulphonamides behave very different as to a variation of the substituents of the amide group when treated with sodamide in an inert solvent such as benzene or toluene. Thus, toluene (α)sulphonylmorpholine reacts fairly slowly with sodamide in boiling toluene under salt formation, while the corresponding dimethylamine compound is rapidly destroyed by sodamide in boiling benzene. From the reaction mixture of this last reaction which proceeds under evolution of sulphur dioxide and



has been indicated by its numerical value. — All spectra are drawn with KBr pellet technique on a Unicam SP 100 IR instrument. The experimental error is 2 cm^{-1}.

dimethylamine, stilbene has been isolated. Tentatively, we suggest the reaction can be explained as including a first benzylation step whereafter the benzylated compound disintegrates according to formula (6) given by Hauser and Harris [2]. However, the dimethylamide can be alkylated in fairly good yield with morpholinoethyl chloride at a temperature of about 70° when the chloride is added to the reaction mixture before warming. The difference between the various N,N-disubstituted sulphonamides is sometimes so pronounced that the sodamide procedure seems to be of limited practical importance for the substitution of some of the sulphonamides. In these cases we have tried phenylsodium as basic agent, and generally with success. N,N-Dibenzyl-toluene(α)sulphonamide, for example, reacts very slowly in boiling toluene. After boiling for about 6 h, 60 % of the parent sulphonamide could be recovered, but no substitution product could be isolated from the reaction mixture. When phenylsodium was used, the yield of recrystallized α-(2-morpholinoethyl) compound was about 70 %.

The optimal reaction conditions are not always easy to find. In some cases of slowly reacting sulphonamides an increase in reaction time and/or reaction temperature does not increase the yield appreciably. To what extent

this result depends on a competitive destruction of the parent sulphonamide and/or the final substitution product, is difficult to say.

The limitation of the alkylation methods applied here are presumably the same as those of the carbonamide case. Some of the sulphonamides are also definitely less soluble in toluene and benzene than the corresponding carbonamides and therefore require more solvent. It should also be pointed out that several of the parent sulphonamides are not easily prepared by conventional methods. Thus, according to our experience to-date, the diphenylmethane(α) sulphonamides can be prepared only *via* diphenyldiazomethane (see also under Experimental). Some of the toluene(α)sulphonamides which otherwise are easily synthetized from toluene(α)sulphonyl chloride and the appropriate secondary amine, may be difficult to prepare or cannot be obtained by this route. Thus, toluene(α)sulphonyl chloride in benzene reacts with di-*iso*propylamine under formation of considerable amounts of a compound with high melting point (240—241.5°C after recrystallization from chloroform), almost insoluble in benzene and most other conventional solvents, including water. Judging from the composition and the fact that not the entire expected amount of amine is consumed during the reaction, we presume this compound to be α-[(toluene(α')sulphonyl)]-toluene(α)sulphonyldi*iso*propylamine, $C_6H_5CH(SO_2CH_2C_6H_5)SO_2N(C_3H_7)_2$.

The results are collected in Table 1. From the above it follows that the alkylations have been carried out by applying three procedures. The first one (1:b) includes more or less incomplete salt formation by boiling the parent sulphonamide with sodamide in toluene for some hours, followed by adding the alkyl halide and further refluxing. It is this procedure which was applied by us as standard method for alkylation of N,N-disubstituted arylacetic acid amides. When it has failed or has not given satisfactory results for the sulphonamides, we have tried a procedure (I:a) which is a slightly modified version of the preceding one. All the reaction components have been mixed together in toluene, and the mixture gently heated until a distinct evolution of ammonia begins and is kept at this temperature until the ammonia evolution has definitely decreased. The third procedure (II) includes the use of phenylsodium as basic agent and has been applied in some cases where the sodamide procedures have not given the desired results. For practical examples of the three procedures see under Experimental.

In order to show that the substituted compounds actually contain the sulphonamide group after alkylation, we have checked the infrared spectra of four of the compounds with reference to the SO_2 frequencies of the sulphonamide group. In Fig. 1 the most significant frequency of the sulphonamide group in the 1 320 cm^{-1} range has been indicated on the curves for two of the compounds investigated.

Some tentative efforts have also been made to condense esters with N,N-disubstituted sulphonamides in the presence of sodium methoxide as condensing agent and with xylene as medium, but these trials have not been encouraging. From a mixture of dimethyl oxalate and N,N-dimethyltoluene(α)sulphonamide only approximately half the theoretical amount of methanol could be distilled off when the temperature was raised to 90°C, and 75 % of the parent sulphonamide could be isolated from the reaction mixture. In order to try

whether a condensation including ring closure would be more easy to carry out or not, we applied the same method to methyl N-(*p*-chlorotoluene(*a*) sulphonyl)-N-*iso*propyl-2- aminopropionate. In this case not less than 87.5 % of N-*iso*propyl-p-chlorotoluene(*a*)sulphonamide (m.p. 137—139°C) could be isolated from the acrylate smelling reaction mixture, indicating that a fission of the amide bond had taken place.

EXPERIMENTAL

As mentioned above the N,N-disubstituted toluene(*a*)sulphonamides have been prepared from toluene(*a*)sulphonyl chloride and the appropriate secondary amines according to known methods and generally with benzene as solvent. Rather few compounds of this type have been reported previously [3,4]. Of course the sulphonamides have considerably higher melting point and boiling point than the corresponding carbonamides and are less soluble than these. That is also the case with the *a*-substitution products. As to the N,N-disubstituted diphenylmethane(*a*)sulphonamides, only the piperidide seems to have been reported earlier [5]. With some minor modifications, which to some extent have been inspired by a recent short communication by Miller [6], we have used the method given by these authors. We have therefore merely collected the melting and/or boiling points of the N,N-disubstituted sulphonamides mentioned in this paper or otherwise known.

Toluene(*a*)sulphonic acid: dimethylamide m. p. 100—101°; diethylamide m. p. ca 30°, b.p. 135—140°/0.3 mm; di-*n*-butylamide b.p. 136—138°/0.1 mm; N-methylanilide m. p. 102—104°; N-ethylanilide m. p. 118—119°; *n*-propyl-benzylamide b.p. 183—188°/0.3 mm; pyrrolidide m. p. 93—94°; piperidide m. p. 136—138°; morpholide m. p. 174—176°.

p-Chlorotoluene(*a*)sulphonic acid: piperidide m. p. 160—162°C; *iso*propyl(*β*-carbomethoxyethyl)-amide m. p. 64.5—66°.

Diphenylmethane(*a*)sulphonic acid: diethylamide m. p. 135—136°; pyrrolidide 175—177°; piperidide m. p. 167—168°.

N,N-Dimethyl-a-(2-morpholinoethyl)-toluene(a)sulphonamide (Method I:a). In a 250 ml flask, equipped with a reflux condenser, stirrer and thermometer, 19.9 g (0.1 mole) of N,N-dimethyltoluene(*a*)sulphonamide, 150 ml of dry toluene, 15.5 g (14.9 g = 0.1 mole) of 2-morpholinoethyl chloride and 4.2 g of commercial, ground sodamide are mixed together. The mixture is warmed gently while stirring. At a temperature of 60—65° a strong evolution of ammonia begins. The reaction mixture is now kept at a temperature of ca 70° for 6 h (a reaction time which perhaps may be shortened). The contents of the flask are cooled to room temperature, water is added and the toluene layer washed with water. The toluene layer is extracted with dilute hydrochloric acid. The united acid solutions are washed with ether, and the base is liberated by adding 5 N sodium hydroxide. When the stirred mixture is inoculated, the oil crystallizes fairly rapidly. The precipitate is filtered off and washed with water and petroleum ether. Yield 22.0 g (70.5 %) m. p. 75.5—77°. After two recrystallizations, the last one including treatment with active carbon, the yield is 17.1 g (55 %) m. p. 76—77°. For analytical data see Table 1.

The hydrochloride can be precipitated in excellent yield from an ether solution of the base by means of alcoholic hydrochloric acid. After recrystallization from methanol and ether the melting point is 203—205°. Yield 83 % (from 5.0 g of the base).

a-(2-Morpholinoethyl)-diphenylmethane(a)sulphonylpyrrolidine (Method I:b). A mixture of 15.1 g (0.05 mole) of diphenylmethane(*a*)sulphonylpyrrolidine, 2.1 g of commercial, ground sodamide and 100 ml of dry toluene is refluxed while stirring for one hour. During this time ammonia is evolved and some precipitate is formed in the flask. The mixture is cooled to about 60° and 8.5 g (theoret. 7.5 g) of 2-morpholinoethyl chloride is added. The mixture is heated again and refluxed for 5 h. After cooling to room temperature, water is added and the mixture washed with water. When excess of 2 N hydrochloric acid is added to the toluene layer under continuous stirring a viscous oil separates, form-

Notes: It should be observed that one of the parent sulphonamides, *p*-chlorotoluene(*a*)sulphonylpiperidine (and the corresponding substitution product) has a chlorine atom in *para* position (see note h) which is not indicated in the general formula in the heading. — With the exception of 2-bromopyridine, chlorides have been used as alkylating agents. — For methods I:a, I:b and II see the introductory text and under Experimental. — When the substitution products are tertiary amines, B indicates base and S hydrochloride. — The yields are the total ones and refer to the parent sulphonamide. When more than one yield figure is given under a certain method, the compound prepared according to this method has been further purified by recrystall-

ing a third phase. It crystallizes on scratching. The precipitate is filtered off, washed with water and ether. The yield of this almost pure hydrochloride of the substitution compound is 12.0 g (53.5 %) m. p. 163.5—165°. For analytical data see Table 1.

The base can be precipitated from a dilute aqueous solution of the hydrochloride by dilute sodium hydroxide. After recrystallization from *cyclo*hexane the m. p. is 110—112°.

N,N-Dibenzyl-α-(2-morpholinoethyl)-toluene(α)sulphonamide (Method II). 50 ml of sodium dispersion (prepared from 12.5 g of sodium, 250 ml of dry toluene and 0.3 ml of oleic acid under nitrogen, by means of an "Ultra-Turrax" dispergator and cooled to room temperature) is pipetted into a 0.5 l flask equipped with reflux condensor, thermometer, stirrer and a dropping funnel. A slow flux of nitrogen is allowed to pass through this

equipment About 10 ml of a solution of 5.7 g (about 0.05 mole) of chlorobenzene in 25 ml of dry toluene is added to the dispersion *via* the dropping funnel in order to start the formation of phenylsodium. When the reaction has started, the remaining chlorobenzene solution is added to the sodium dispersion, while stirring, at such a rate that under intermittent cooling with a dry ice-alcohol bath the reaction temperature is kept at about 25°. When all the chlorobenzene solution has been added, the cooling bath is removed and the black reaction mixture is allowed to stand while stirring for about 15 min. If the temperature increases again during this period, the mixture should be cooled again. A solution of 17.5 g (0.05 mole) of N,N-dibenzyl-toluene (*a*)sulphonamide in about 120 ml of warm, dry toluene (this sulphonamide like some others, *e. g.* the morpholino compound, is only slightly soluble in cold toluene) is added *via* the funnel while stirring, and the flask is warmed to 55° for about 10 min. During this procedure the black colour of phenylsodium disappears and the contents of the flask become grayish. The flask contents are cooled to about 40° and a solution of 8.0 g (7.5 g = 0.05 mole) of 2-morpholinoethyl chloride in 25 ml of dry toluene is added while stirring *via* the funnel. The reaction mixture is now heated. At about 90° the grayish precipitate disappears and the reaction mixture becomes almost clear. The temperature is kept at about 110° for one hour. The flask contents are now cooled to room temperature and water is added carefully. The toluene layer is washed with water. When 2 N hydrochloric acid is added to the toluene phase the hydrochloride of the morpholinoethyl derivative precipitates as a third oily phase, which crystallizes on scratching. The precipitate is filtered off and washed with water and ether. Yield 18.3 g (78.5 %) m. p. about 140°. Recrystallization from a mixture of toluene and acetone gives 14.2 g with m. p. 168—170°. From the mother liquor another 1.5 g can be obtained with the same m. p. Total yield 69 %.

The base was liberated from 5.0 g of the hydrochloride and taken up in ether. When the ether is evaporated, 4.6 g of the base is obtained. After recrystallization from 50 ml of *cyclo*hexane, the yield is 4.3 g (91 %). For analytical data see Table 1.

The authors are indebted to Mr. W. Kirsten and his assistants for elementary analyses and to Dr. B. Nygård for infrared analyses.

The Crystal Structure of Ti_5O_9

STEN ANDERSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The crystal structure of Ti_5O_9, the second member of the homologous series Ti_nO_{2n-1}, has been determined. It is triclinic, spacegroup $P\bar{1}$, with a cell content of 2 Ti_5O_9 and with unit cell dimensions $a = 5.569$ Å, $b = 7.120$ Å, $c = 8.865$ Å, $\alpha = 97.55°$, $\beta = 112.34°$ and $\gamma = 108.50°$. It may be described in terms of TiO_6-octahedra, which are joined by sharing edges and corners to form slabs of rutile structure, extending infinitely in two dimensions and possessing a finite width corresponding to five TiO_6 octahedra. The slabs are mutually connected by octahedra sharing faces.

The Ti_5O_9 structure provides the clue to the problem of finding the crystal structure of any member of the homologous series Ti_nO_{2n-1}, $Ti_{n-2}Cr_2O_{2n-1}$ and V_nO_{2n-1}.

The existence of a considerable number of discrete phases in the composition region $MO_{1.75-1.90}$ has been demonstrated for the titaniumoxygen system[1-3], for the titanium-chromium-oxygen system[4] and for the vanadium-oxygen systems[5]. The related and regularly changing appearance of the powder patterns of all these phases, the compositions of which are in close agreement with the general formula M_nO_{2n-1} (n integer), suggested that the various structures are all based on a common structural principle, in analogy with the case[6-8] for the molybdenum and the molybdenum wolfram oxides of the homologous series $(Mo,W)_nO_{3n-1}$.

It was thus thought possible to derive the structure of any member of the series M_nO_{2n-1} provided that the detailed structure of one homologue were known. This article gives an account of the structure determination of the phase Ti_5O_9. General structural data for the series will be given elsewhere[9].

EXPERIMENTAL

Details about the preparation and some other data concerning the $TiO_{1.80}$ sample have been given in previous communications[1,2]. Crystals of Ti_5O_9 were obtained by heating this sample at 1 150°C for three days in evacuated silica tubes. The crystals formed minute rods always found to be twinned. A fragment obtained by crushing a crystal was, however, found to have only a relatively small twin parasite, and was thus suitable for single-crystal studies.

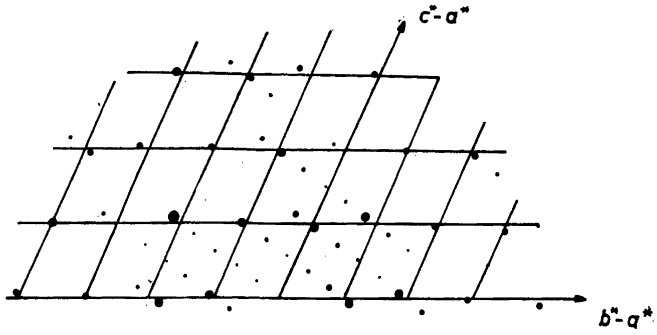

Fig. 1. The reciprocal lattice plane $h0l$ of Ti_5O_9. The networks represent the reciprocal lattice of the subcell (rutile).

Weissenberg photographs of the layer lines $(0-3, k, l)$ and $(h, 0-4, l)$ were registered with CuK radiation using multiple film techniques. The intensities of the reflexions were estimated visually.

A remarkable feature of the photographs was the extremely low number of reflexions hkl with k odd. Thus, the $(h1l)$ layer line contained only three strong, one medium and two weak reflexions.

Accurate unit cell dimensions were obtained from photographs taken in a Guinier focusing camera using strictly monochromatized Cu$K\alpha_1$ radiation and applying a procedure described in a previous communication from this Institute [10].

DERIVATION OF THE STRUCTURE

The single crystal data showed the structure to be triclinic, *i.e.* the symmetry should be $P1$ (No. 1) or $P\bar{1}$ (No. 2).

The Guinier powder photograph gave the following unit cell dimensions, referred to the lattice parameter of potassium chloride $a = 6.2919$ Å at 20 C:

$$a = 5.569 \text{ Å}, \quad b = 7.120 \text{ Å}, \quad c = 8.865 \text{ Å},$$
$$\alpha = 97.55°, \quad \beta = 112.34°, \quad \gamma = 108.50°.$$

The observed density of 4.29 indicated that the unit cell contains 2 formula units of Ti_5O_9, the calculated density being 4.31. The powder pattern has been published in a previous report [11].

The reciprocal lattice plane $h0l$, which is illustrated in Fig. 1, shows the presence of a pronounced substructure in real space. By considering the three-dimensional data, it was found that the substructure unit coincides with the structure of the rutile type, as was already suggested by the appearance of the powder pattern [1-3]. The [010]-direction of Ti_5O_9 was found to correspond to [111] of rutile. The structure determination could thus be started along the lines developed by Magnéli [7,8,12,13] when studying several molybdenum and wolfram oxides and especially $W_{20}O_{58}$.

The substructure character in this case implies that the strong reflexions of Ti_5O_9 occur close to the reciprocal lattice points of rutile. Assuming the structure to possess a centre of symmetry, the various strong reflexions were

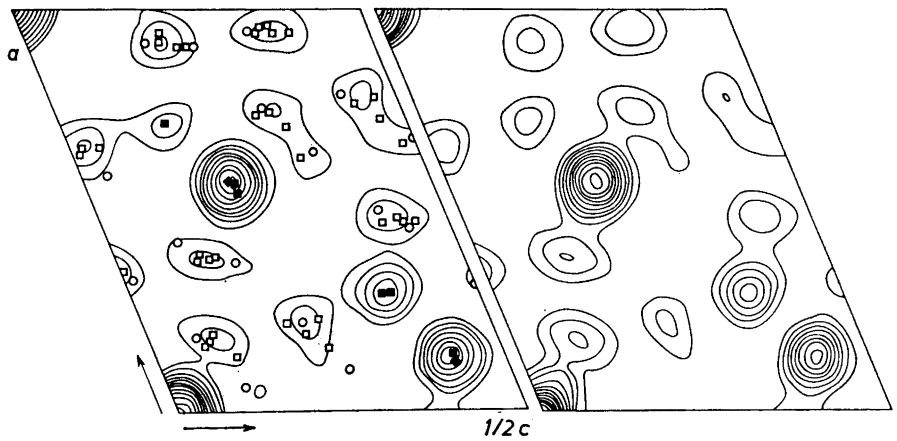

Fig. 2. Patterson projections along [010]. 1) Calculated from $|F|^2_{obs}$. 2) Calculated from $|F|^2_{calc}$. ◆ : Ti-Ti vectors (Multiplicity 8); ■ : Ti-Ti vectors (Multiplicity 4); □ : Ti-O vectors (Multiplicity 4); O : Ti-O vectors (Multiplicity 2).

assigned the signs of the corresponding rutile reflexions. This was done for two alternatives, *viz.* with a metal atom in or not in the origin position.

The two-dimensional Fourier sum* calculated over the strong reflexions *h0l*, which should correspond to a projection parallel to [010] of the "electron density function" for both alternatives, showed heavy maxima which could be attributed to titanium atoms and also minor ones which might be interpreted as due to oxygen atoms. Both alternatives were in fair agreement with the Patterson projection along [010] illustrated in Fig. 2 : 1. By including more reflexions in the Fourier sum, it was found possible to arrive at an index of agreement

$$\frac{\sum || F(h0l_{obs}| - |F(h0l)_{calc} ||}{\sum |F(h0l)_{obs}|}$$

as low as 0.20. It was thus thought that this structure proposal should not be very different from the actual structure, which, however, might lack the centre of symmetry.

In order to find the *y* coordinates corresponding to the approximate structure, the [100] projection of the Patterson function was studied (*cf.* Fig. 3 : 1). In this way it was possible to find the metal atom coordinates. However, when calculating the *F(hkl)* values, it was observed that the agreement was rather poor for the weak layer lines with *k* odd.

* During the later stages of the investigation the computational work was highly facilitated by the employment of the electronic digital computer BESK of the Swedish Board of Computing Machinery. Programmes for automatic Patterson and electron density syntheses and for automatic calculation of structure factors have been prepared by members of this research group [14,15].

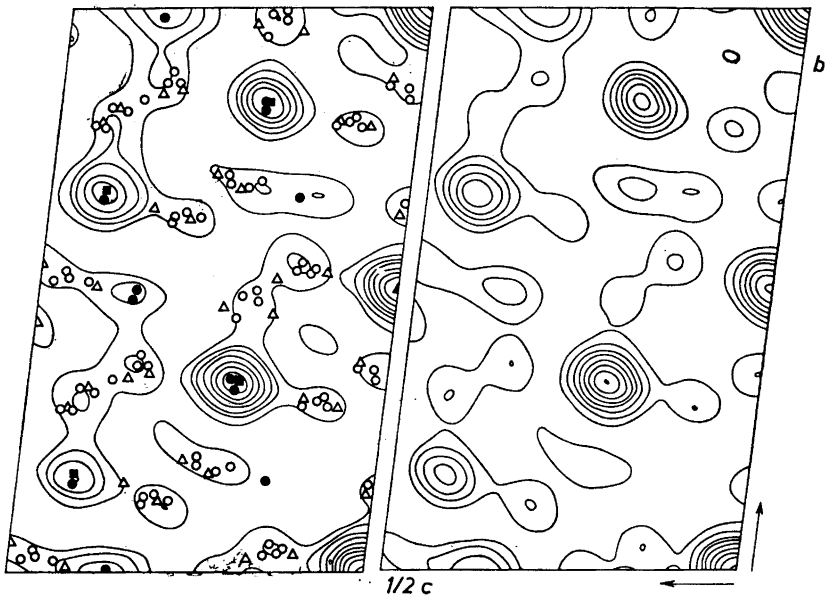

Fig. 3. Patterson projections along [100]. 1) Calculated from $|F|^2_{obs}$. 2) Calculated from $|F|^2_{calc}$. ▲ : Ti-Ti vectors (Multiplicity 10); ■ : Ti-Ti vectors (Multiplicity 4]; ● : Ti-Ti vectors (Multiplicity 2); O: Ti-O vectors (Multiplicity 2); △: Ti-O vectors (Multiplicity 1).

Starting from the approximate centrosymmetric structure thus derived, the metal atom positions were modified to improve the agreement with the Patterson function. The changes of the coordinates were considerable only for one of the ten titanium atoms and implies that the symmetry of the structure was lowered to $P1$. The electron density projections parallel to [010] and [100] calculated on the basis of the modified structure showed maxima interpretable as due to all the titanium and oxygen atoms of the unit cell.

The agreement between the Patterson functions calculated from the observed and the corresponding calculated $|F|^2$ values and the interatomic vector sets required by the structure is demonstrated in Figs. 2 and 3 and Table 1.

In Fig. 3 : 1 it can be seen that there is no maximum in the Patterson projection corresponding to the titanium-titanium vector of the lowest multiplicity required by the structure. Such a phenomenon has been demonstrated by Magnéli [13] to be due to the large number of non-observed reflexions. Thus the Patterson projection calculated from $|F|^2_{calc}$ omitting all reflexions below "the limit of visibility" (Fig. 3 : 2) does not show a maximum corresponding to this titanium-titanium vector. The two weak maxima in Fig. 3 : 1, which are not required by the metal atom structure correspond to the oxygen-oxygen vectors of highest multiplicity.

The index of agreement, R, for the two projections [010] and [100] was found to be 0.13 and 0.15, respectively. For all the 272 registered reflexions, the R-value is 0.18. The 19 observed reflexions hkl with k odd, which are due only to the oxygen atom contributions have $R = 0.10$, which indicates that the oxygen atom positions should be fairly accurate. Table 2 gives the observed and calculated F values for reflexions $h0l$, $0kl$ and hll.

DESCRIPTION OF THE STRUCTURE

The structure is built up of TiO_6 octahedra which are joined by sharing corners, edges and faces. All the interatomic distances are of reasonable lengths, *viz.* 2.81—3.19 Å for the Ti-Ti distances, 1.75—2.35 Å for the Ti-O and 2.4—3.15 Å for the O—O distances. The shortest Ti-Ti distance connects the metal atoms of TiO_6 octahedra with a face in common.

The oxygen atom packing is roughly a deformed hexagonal close packing and similar to that of rutile. The structure may be described as being built up of rutile-type elements, with a complicated arrangement of the metal atoms in the interstitial positions of the lattice formed by the anion packing.

The metal atom positions in the projections along [010] and [100] are shown in Figs. 4 and 5. The dotted lines refer to an alternative origin, which apparently is a centre of symmetry for the metal atom arrangement. However, this is not true since it has a significant deviation from centrosymmetry. The origin chosen was preferred because it emphasizes the true centrosymmetry found to be present in the arrangement of the oxygen atoms.

In both projections the metal atoms form chains of five TiO_6-octahedra (if these chains were of infinite length, the structure would be rutile). The chains are connected to form rutile-type slabs possessing an infinite extension in two dimensions and a characteristic finite width (five TiO_6-octahedra) *i.e.* the length of the chain in a third direction, indicated by arrows in Fig. 5. The mutual connection of the slabs takes place by means of TiO_6-octahedra sharing faces.

Table 2. Observed and calculated structure factors *h0l*, *0kl* and *h1l* for Ti_5O_9. The values of the phase angle, α are expressed as fractions of one cycle.

In the rutile structure there are channels of empty interstitial positions along the *c* axis ($\frac{1}{2}00$ or $\frac{1}{2}0\frac{1}{2}$). In the Ti_5O_9 structure the end atoms of the chains (*cf.* Figs. 4 and 5) occupy such positions of the neighbouring rutile slabs. The latter are thus mutually "out of phase" by $\frac{1}{2}(b_r + c_r)$ (*cf.* Fig. 6), which gives rise to a so called" shear structure". A term introduced by Wadsley [17].

The structure of the shear plane (the border region of the two "out of phase" rutile-type blocks) is closely related to the corundum-structure type. Thus, parallel to the *b* axis of Ti_5O_9, infinite chains of double-octahedra are found, the doublets being formed by two single TiO_6-octahedra sharing a face. The double octahedra are coupled together within the chains by having edges in common (*cf.* Fig. 7 : 1). These chains are included in the rutile-typs slabs, the connection taking place by octahedra sharing edges and corners (Fig. 7 : 2).

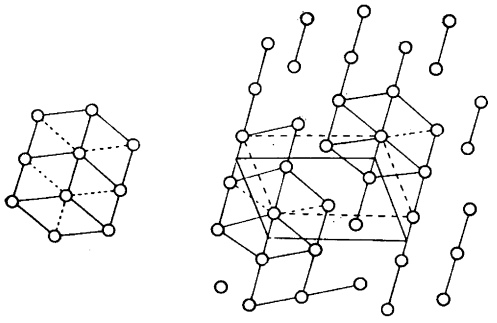

Fig. 4. The metal atom arrangement of Ti_5O_9 viewed along [010] and of rutile parallel to [111].

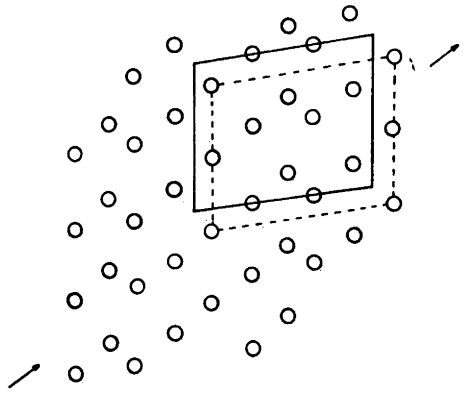

Fig. 5. The metal atom arrangement of Ti_5O_9 viewed along [100]. The arrows show the direction of the finite extension of the rutile slabs.

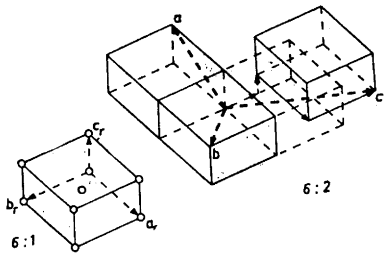

Fig. 6. 1) Unit cell of rutile with positions of metal atoms indicated. 2) Interrelation of basic rutile-type structure of adjacent slabs of Ti_5O_9. Unit cell axes of the latter indicated by dashed heavily-drawn arrows.

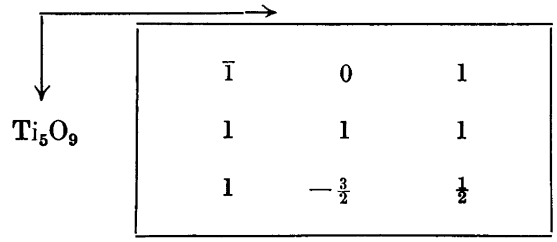
The metal-metal distance over the common face is 2.81 Å, while the distance between metal atoms over the common edge is 3.19 Å. The corresponding distance [16] for Ti_2O_3 are 2.56 and 2.99 Å.

The shearing mechanism can be described by means of a translation matrix. Fig. 6 demonstrates the interrelation of the basic rutile-type structure of adjacent slabs of Ti_5O_9. If the axes of the rutile-type subunit cell $\boldsymbol{a}_r$, $\boldsymbol{b}_r$ and $\boldsymbol{c}_r$ are used to define the coordinate system, then the axes of the ideal Ti_5O_9 unit cell will be:

$$\begin{aligned} \boldsymbol{a} &= \boldsymbol{c}_r - \boldsymbol{a}_r \\ \boldsymbol{b} &= \boldsymbol{a}_r + \boldsymbol{b}_r + \boldsymbol{c}_r \\ \boldsymbol{c} &= \boldsymbol{a}_r - \tfrac{3}{2}\,\boldsymbol{b}_r - \tfrac{1}{2}\,\boldsymbol{c}_r \end{aligned}$$

The matrix



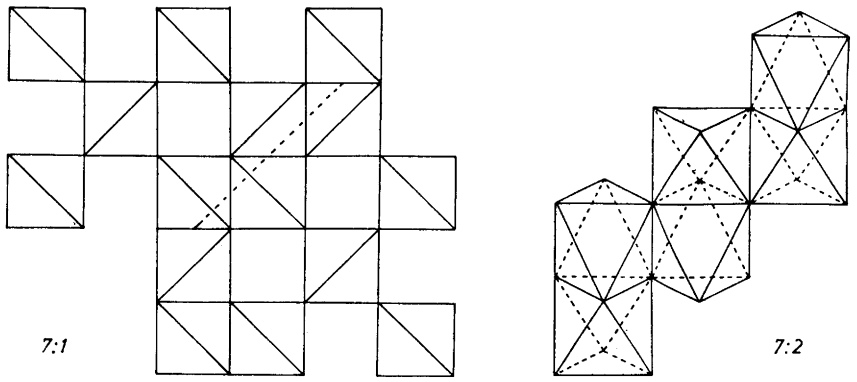


Fig. 7. 1) Projection of part of the Ti_5O_9 structure along the subcell c-axis showing the shear mechanism. The dotted line is parallel to the b-axis and the shear chain of the corundum structure. 2) The shear chain of the corundum structure.

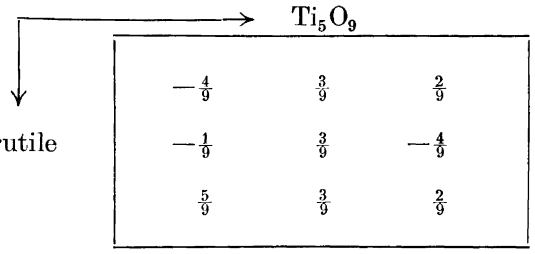
thus makes it possible to obtain the relation between the indices of Ti_5O_9 and rutile.

If the vectorial equations given above are solved for a_r, b_r and c_r, the following expressions are obtained:

$$a_r = \tfrac{1}{9}(-4a + 3b + 2c)$$
$$b_r = \tfrac{1}{9}(-a + 3b - 4c)$$
$$c_r = \tfrac{1}{9}(5a + 3b + 2c)$$

The matrix



thus interrelates the atomic positions x, y, and z of Ti_5O_9 with those in the coordinate system difined by the rutile-type subcell ($x_r y_r$ and z_r).

By means of the latter matrix it has thus been possible to calculate the "ideal" atomic positions of the structure of Ti_5O_9 (Table 3). The deviation for some atoms from the coordinates of the actual structure should be due to the repulsion between the close metal atoms of octahedra sharing faces.

DISCUSSION OF THE STRUCTURE

It is of considerable interest to compare the structures of Ti_5O_9 and the homologues Ti_nO_{2n-1} with the structures previously found by Magnéli [6] for the series M_nO_{3n-1} and M_nO_{3n-2}. There are, of course, no obvious geometrical rela-

tions, because the subcells of rutile and of ReO_3-type are quite different. However, the principles for deriving the geometrical relations in each series are exactly the same. For example, in Mo_8O_{23} the major structural elements of the ReO_3-type structure are characterized by a finite width of 8 MoO_6 octahedra. In Mo_9O_{26}, the width of the slabs is extended to comprise one more MoO_6 octahedron. In any member of the series M_nO_{3n-1} there are two constant axes, a and b, parallel to the shear plane, while the c axis is determined by the thickness of the ReO_3-blocks and thus increases with n.

In the series Ti_nO_{2n-1}, V_nO_{2n-1} and $Ti_{n-2}Cr_2O_{2n-1}$ the same characteristics have been observed. The a and b axes and the angle γ all remain constant irrespective of the value of n, while the length and direction of the c axis are determined by the finite width of the rutile-type slabs and are thus functions of n. General structural data for the three series M_nO_{2n-1} have been derived from the matrices given above and will be reported elsewhere.

Acknowledgements. The author wishes to express his sincere gratitude to Professor A. Ölander for his kind interest and to the principal investigator of this research programme, Dr. Arne Magnéli, for having suggested this investigation, for his never-failing interest and for many valuable discussions. I also want to thank Miss Lena Jahnberg for her valuable assistance in the calculations.

The investigation has been sponsored in part by the *Office, Chief of Research and Development, U.S. Department of Army,* through its European Research Office and in part by the *Swedish Natural Science Research Council.*

Studies on the Folic Acid, Pyrimidine and Purine Requirements of Four Lactobacilli

ARNE E. BOLINDER and WOLFGANG G. KURZ

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The specificity of the folic acid *, pyrimidine and purine requirements of four lactobacilli obtained from Moore and Rainbow [1] and isolated from the contaminant flora of English top fermentation brewer's yeast was investigated. The previous findings of these authors that the four strains designated L3, L4, L5, and L6 required pteroylmonoglutamic acid (PGA) **, a pyrimidine and purine(s) were confirmed. Further studies revealed that each of these requirements was non-specific and could be met using a range of related substances. The results obtained can be summarized as follows:

1. PGA could be replaced by N^5-formyltetrahydro-PGA, N^{10}-formyl-PGA, thymidine and TMP.
2. PABA was not essential in the presence of PGA or any compound replacing PGA.
3. The pyrimidine requirement of all four strains could be met using either uracil, uridine, 2′(3′)-UMP, deoxyuridine, cytosine, cytidine, 2′(3′)-CMP, deoxycytidine or deoxy-CMP.
4. The purine requirement of strain L4 could be met using either adenine, adenosine, 2′(3′)-AMP, deoxyadenosine, deoxy-AMP, hypoxanthine, inosine or deoxyinosine.
5. Strains L3, L5, and L6 could utilize as a sole purine source all the purine compounds active for strain L4 as well as guanine, guanosine, 2′(3′)-GMP, deoxyguanosine, deoxy-GMP, xanthine or xanthosine which were all inactive for strain L4.
6. Extracts of barley, kilned malt (without rootlets) and kilned malt rootlets, wort and beer were found to be active for replacing the folic acid, pyrimidine and purine requirements of all four lactobacilli.

Certain lactic acid bacteria have long been known to occur in association with brewery materials, *e.g.* malt, beer and yeast, but few studies have been carried out on their nutritional requirements. Recently, Russel, Bhandari and Walker

* "Folic acid" (factors) refers generally to the group of compounds chemically related to PGA which are capable of stimulating the growth of *Streptococcus faecalis* ATCC 8043 and *Lactobacillus casei* ATCC 7469; individual compounds will be specifically named.

** The following abbreviations are used in this paper: PGA for pteroylmonoglutamic acid; PABA for p-aminobenzoic acid; deoxy-CMP, TMP, deoxy-AMP, and deoxy-GMP for the 5′-monophosphates of deoxycytidine, thymidine, deoxyadenosine and deoxyguanosine; 2′(3′)-UMP, 2′(3′)-CMP, 2′(3′)-AMP and 2′(3′)-GMP for mixtures of the 2′- and 3′-monophosphates of uridine, cytidine, adenosine and guanosine, respectively.

studied the vitamin [2] and amino acid [3] requirements, and the interrelationships affecting the need for purines, PGA, and PABA [4] of 34 lactic acid bacteria isolated from the contaminant flora of English top fermentation beers and yeasts [5]. Moore and Rainbow [1] have studied the nutritional requirements of four strains of lactobacilli isolated from the contaminant flora of English top fermentation brewer's yeasts with respect to growth factors of the vitamin B-complex, purines, pyrimidines, amino acids and major sources of energy, and some biochemical activities. The strains were designated L3, L4, L5, and L6. Strains L3 and L4 were tentatively identified as strains of *Lactobacillus brevis*. According to Moore and Rainbow, all the strains required PGA, uracil and purines. [1] Through the courtesy of Dr. C. Rainbow, Department of Applied Biochemistry, University of Birmingham, we obtained cultures of the strains L3, L4, L5, and L6 for investigations on the replaceability of each of these growth requirements by a range of related substances. [6] In the present investigation, further studies of these and related problems have been made.

EXPERIMENTAL

Organisms. Since receiving the strains L3, L4, L5, and L6 from Dr. Rainbow in January 1956, stab cultures of these lactobacilli were maintained on Bacto micro assay culture agar (Difco) * and transferred at least once every two months. The cultures after incubation overnight at 30°C were stored in the refrigerator. Good growth also occurred in stab cultures on Bacto malt agar (Difco) but Bacto micro assay culture agar was superior.

Strain L6 was the slowest growing organism of the four brewery lactobacilli. The complete semisynthetic medium (see below) used in the tube tests did not give a good early growth with strain L6 and maximum growth did not occur until after 72 h of incubation at 28°C. Only 48 h or an even shorter time of incubation was required by strains L3, L4, and L5 in the tube tests. Sometimes broth subcultures of sufficient growth density were difficult to obtain with strain L6 and, in some tube test series, L6 unexpectedly failed to grow. These difficulties were also encountered to a certain degree with strain L4 whereas strains L3 and L5 were easy to work with.

Inocula. The inoculum medium consisted of equal volumes of single strength complete basal medium (see below) and Micro inoculum broth (Difco). Centrifuge tubes were filled with 5 ml portions of inoculum medium and a glass bead and were sterilized for 15 min at 120°C. Broth subcultures were incubated at 30°C for 18—24 h. For the preparation of inocula the subcultures were centrifuged, washed three times with 5 ml portions of sterile 0.9 % sodium chloride solution, resuspended and diluted in sterile sodium chloride solution to a turbidity of 65 % light transmittance read at 6 400 Å with a Coleman Model 11 Universal spectrophotometer. One ml of this suspension, corresponding to about 0.05 mg dry weight of cell material, was mixed with 50 ml sterile sodium chloride solution and, after thorough shaking, two drops of this dilute suspension was used to inoculate each tube.

Media. The complete medium used in these investigations was that of Moore and Rainbow [1] in a slightly modified form, having the following composition per 500 ml double strength medium: Bacto vitamin-free casamino acids (Difco), 10 g; L-cystine and L-cysteine hydrochloride, 100 mg each; DL-tryptophan, 200 mg; glucose and L-arabinose, 10 g each; sodium acetate (3 H_2O), 20 g; K_2HPO_4, $(NH_4)_2SO_4$, and NaCl, 1 g each; $MgSO_4 . 7H_2O$, 100 mg; $MnSO_4 . 4H_2O$, 30 mg; $FeSO_4 . 7H_2O$, 10 mg; adenine sulfate, guanine hydrochloride, and uracil, 10 mg each; thiamine hydrochloride, riboflavin, nicotinic acid, calcium pantothenate, and pyridoxine, 1 mg each; biotin, 10 μg; PABA, 500 μg; and PGA, 100 μg. The pH was adjusted to 6.5.

* Difco Laboratories, Inc., Detroit, Michigan, U.S.A.

As well as the complete medium, incomplete media lacking one or several essential factors were also used, *e. g.* purine deficient medium, (see below). All media were made up from stock solutions of each constituent as desired and the pH was adjusted to 6.5. The unsterilized double strength media were stored at −20°C. Media stored for 3−4 months have been successfully used.

Tube tests. Tube tests using a final volume of 10 ml were made in optically calibrated tubes (19 × 180 mm). A 5 ml amount of the factors or extracts to be tested was added to the test tubes, followed by 5 ml of double strength medium and a glass bead and the tubes were covered with aluminium caps. The tubes were sterilized by autoclaving at 120°C for 5 min. After cooling to room temperature in running tap water and inoculating (see above), the tubes were incubated at 28°C in a thermostated water bath. After 48, 72 and 96 h of incubation, growth was measured turbidimetrically as % light transmittance against uninoculated blanks set at 100 % light transmittance at 6 400 Å with a Coleman Model 11 Universal spectrophotometer. Since in most cases very little further growth occurred after 72 h of incubation, only the readings after 48 and 72 h of incubation are given in the tables. Each value in the tables is the mean of at least two separate tube tests. In each tube test two duplicate tubes were employed. The readings of identical tube tests made on separate occasions usually agreed very well. When there was poor agreement the tube test was repeated until consistent results were obtained.

Biochemicals. PGA (Folvite), N^5-formyltetrahydro-PGA (synthetic folinic acid, leucovorin), pteroic acid and N^{10}-formylpteroic acid (rhizopterin) were gifts from Lederle Laboratories; N^{10}-formyl-PGA (rhizopterin glutamate) was a gift from Hoffman-La Roche. The pyrimidine and purine derivatives were obtained from the California Corporation for Biochemical Research, Los Angeles, California. The deoxyribonucleotides are the 5′-phosphate esters while the ribonucleotides are mixtures of the 2′- and 3′-phosphate esters. Adenine and cytidine were supplied as hemisulfates, guanine and deoxycytidine as hydrochlorides, deoxy-AMP and deoxy-GMP as the monoammonium salts, TMP as dihydrate of the calciumsalt, 2′(3′)-GMP as dihydrate of the trisodium salt, 2′(3′)-AMP and 2′(3′)-UMP as the dihydrates, and uridine as the monohydrate; all other nucleic acid derivatives were supplied as pure compounds without water of crystallisation etc.

Purity of deoxyuridine, deoxycytidine, thymidine, and TMP. The purity of these deoxyribose compounds was checked by bioautography of paper chromatograms. Two solvent systems were used: (I) *sec.* butanol-water-conc. ammonia (80:20:3 v/v) and (II) *sec.* butanol-water-conc. acetic acid (75:25:3 v/v). The following R_F values were found in solvent system (I): folinic acid factors * and deoxyribonucleotides 0, deoxycytidine and deoxyuridine 0.35, thymidine 0.56; and in solvent system (II): deoxyribonucleotides 0.04−0.10, deoxycytidine 0.38, deoxyuridine 0.53, thymidine 0.65 and folinic acid factors 0.20−0.55. For bioautography, agar plates inoculated with either *Pediococcus cerevisiae (Leuconostoc citrovorum)* ATCC 8081 or *Lactobacillus leichmannii* 313 ATCC 7830 were used. The plates were made according to the procedure reported earlier for the plate assay of folinic acid factors with *P. cerevisiae* [7]. For both test organisms, the *P. cerevisiae* agar medium was used but the amounts of glucose and sodium acetate were doubled. After incubation overnight at 37°C, the plates were read. *P. cerevisiae* responds to thymidine and folinic acid factors whereas *Lb. leichmannii* responds to vitamin B_{12} (and factors), deoxyribonucleosides and deoxyribonucleotides.

Bioautography of moderate amounts (about 10 μg) of deoxyuridine revealed that it was contaminated by a small amount of thymidine. Quantitative work (quantitative paper chromatography combined with microbiological tube assays with *P. cerevisiae* and/or *Lb. leichmannii*) showed that deoxyuridine was contaminated by 0.15 % of thymidine (the mean value obtained from three separate determinations). On the other hand, thymidine was found to be contaminated by 1.5 % of deoxyuridine (only one determination was made). Furthermore, bioautography of large amounts (about 40 μg) of deoxycytidine and TMP revealed that these compounds were contaminated by faint traces (less than 0.02 %) of deoxyuridine and traces (about 0.05 %) of thymidine, respectively. According to the suppliers, these four deoxyribose compounds were guaranteed to have a purity of 100 ± 2 % as tested spectrophotometrically.

---

* "Folinic acid factors" designates those folic acid factors that are closely related to N^5-formyltetrahydro-PGA and are capable of stimulating the growth of *P. cerevisiae*.

Extracts of brewery products. The same brewery products were used as previously investigated [6]. Water extracts of kilned malt (without rootlets) and kilned malt rootlets were made by mixing 5 g of the finely ground (Wiley mill) material with 40 ml 0.1 M phosphate buffer at pH 6.5. After heating at 100°C for 10 min, the volumes were made up to 100 ml with distilled water and centrifuged. Water extracts of barley were made by mixing 5 g of barley with 40 ml 0.1 M phosphate buffer at pH 5.8. The mixture was first homogenized (MSE-homogenizer) and then heated at 100°C for 10 min. After cooling, the starchy mixture was liquefied by treatment for 4 h at 37°C with a bacterial amylase preparation (50 mg of Rapidase). The enzyme action was terminated by steaming for 10 min. The pH was then adjusted to 6.5 and the volume made up to 100 ml with distilled water and centrifuged. Samples of wort (12.5 % extract) and beer (made from this wort) from a top yeast fermentation were treated as follows: to 80 ml of sample were added 5 ml 1 M phosphate buffer, the pH adjusted to 6.5 and the volume made up to 100 ml. After heating at 100°C for 10 min and then cooling, the mixtures were filtered if necessary.

RESULTS AND DISCUSSION

Folic acid requirement. Moore and Rainbow [1] showed that all four strains required PGA but did not investigate the specificity of this requirement. We found that the PGA requirement of all four strains was quite nonspecific and could be met by any one of N^5-formyltetrahydro-PGA, N^{10}-formyl-PGA, thymidine, TMP or extracts of brewery materials. The growth promoting effects of these compounds and extracts after 48 and 72 h of incubation in a PGA deficient medium are given in Table 1. Omission of PABA from the PGA deficient medium gave the same growth for all compounds and extracts tested in Table 1. PABA was therefore not essential in the presence of PGA or any of the compounds and extracts that were able to replace PGA in the nutrition of these four lactobacilli.

Of the folic acid factors tested, PGA, N^5-formyltetrahydro-PGA, and N^{10}-formyl-PGA were about equally active for all four strains whereas pteroic acid and N^{10}-formylpteroic acid were inactive (see below). Strains L3 and L5 had the smallest folic acid requirement and the complete medium contained over a 100-fold excess of the amount of PGA required for optimum growth for these two strains. Strain L4 and particularly strain L6 had a much higher folic acid requirement than strains L3 and L5. Thymidine and TMP, which also promoted growth for all four strains in a PGA deficient medium, were required in much larger amounts than PGA for obtaining similar growth levels. These two compounds were about equally active on a molar basis.

The following compounds were unable to promote growth in a PGA deficient medium (containing PABA) for all four lactobacilli after 96 h of incubation when tested in the amount per tube given in brackets: pteroic acid (10 μg), N^{10}-formylpteroic acid (1 and 10 μg), thymine (100 and 1 000 μg), uridine (100 and 1 000 μg), 2′(3′)-UMP (100 and 1 000 μg), cytosine (100 and 1 000 μg), cytidine (100 μg), 2′(3′)-CMP (100 μg), deoxycytidine (100 and 500 μg), deoxy-CMP (100 μg), orotic acid (500 μg), deoxyadenosine (100 μg), deoxyguanosine (100 μg), Tween 80 (5 mg) and vitamin B_{12} (0.1 μg).

Somewhat irregular results were obtained when testing the growth promoting effect of deoxyuridine (not tabulated). We reported earlier that 100 μg of deoxyuridine per tube was inactive for all four lactobacilli in PGA deficient medium [6]. Repeated tube tests showed that strain L5 occasionally responded to 100 μg of deoxyuridine and that all four strains responded to 500 μg of deoxyuridine. However, the turbidity readings of repeated experiments were not sufficiently uniform to merit inclusion in Table 1. In all these cases, the growth promoting effect of deoxyuridine was too high to account for the low trace contamination by 0.15 % thymidine. A possible explanation of the irregular growth promoting effect of large amounts of deoxyuridine could be that an uneven carry-over of PGA occurred when inoculating the tubes and that this resulted in a varying degree of formation of thymidine (or TMP) from deoxyuridine. Separate experiments showed that resting cells of strain L5 were able to convert about 1 % of added deoxyuridine to thymidine (mean value of four resting cell experiments) when incubated in buffered glucose-arabinose solution at 28°C for 4 h.

Growth experiments were also made with strain L5 in an attempt to demonstrate the presence of trans-N-deoxyribosylase [8,9] but these tests were negative. No growth of strain L5 after 72 h of incubation was found in a PGA deficient medium with thymine (1 000 μg) + deoxyuridine (100 μg) or thymine (1 000 μg) + deoxycytidine (100 μg).

All the extracts of brewery materials tested were found to be active in replacing the folic requirement for all four lactobacilli. This finding was expected since earlier investigations from this laboratory had shown that these brewery materials contained folic acid factors and thymidine [6,10]. In particular, kilned malt rootlets were found to be rich in both folic acid factors and thymidine. As seen from Table 1, the extract of kilned malt rootlets was more active on a dry weight basis than the extract of kilned malt (without rootlets) and the extract of barley for strains L3, L4, and L5. The reverse order of activity of these extracts was, however, found for strain L6. Wort and beer were very active and both had almost the same growth promoting effect in a PGA deficient medium for all four lactobacilli.

The specificity of the folic acid requirement of lactobacilli varies from organism to organism. The folic acid requirement of these four brewery lactobacilli resembled that of *Lactobacillus casei* ATCC 7469 in many respects [11,12]. Thus, *Lb. casei* as well as the four brewery lactobacilli require the complete folic acid molecule with the glutamic acid group for growth; pteroic acid and N^{10}-formylpteroic acid are completely or almost completely inactive. Thymine is inactive for the four brewery lactobacilli but is active in replacing PGA for *Lb. casei* [11,13]. Thymidine, on the other hand, promotes growth in a PGA deficient medium for all five of these organisms [11,13]. However, none of the thirty-four brewery lactobacilli investigated by Russell *et al.* [2] had any requirement for PGA but one organism required PABA. The method used by Russel *et al.* [2] for determining the vitamin requirements of lactobacilli, which depended upon the evidence of a single transfer into the deficient media, has been critisized by Ford *et al.* [14] who recommend at least two or three transfers when assessing the vitamin requirements of bacteria, particularly when requirements for vitamin B_6, folic acid and biotin are being studied.

Pyrimidine requirement. Moore and Rainbow [1] showed that the pyrimidine requirement of all four lactobacilli could be met by uracil or cytosine but not by thymine. Strains L3, L5, and L6 could utilize orotic acid for growth in a pyrimidine deficient medium. These findings were confirmed. We further found that the pyrimidine requirement of all four strains could be met by any one of uridine, 2′(3′)-UMP, deoxyuridine, cytidine, 2′(3′)-CMP, deoxycytidine, deoxy-CMP or extracts of brewery materials. The growth promoting effects of these compounds and extracts after 48 and 72 h of incubation are given in Table 2. Uracil and cytosine were the most active of these compounds, whereas the ribonucleotides had the lowest activity. Orotic acid had the same growth promoting activity as uracil or cytosine for strains L3, L5, and L6 whereas strain L4 could not utilize orotic acid.

The following compounds were unable to promote growth in a pyrimidine deficient medium for all four lactobacilli after 96 h of incubation when tested in the amounts per tube given in brackets: N^5-formyltetrahydro-PGA (10 μg), N^{10}-formyl-PGA (10 μg) thymine (100 and 1 000 μg), thymidine (100 μg),

TMP (100 and 500 μg), Tween 80 (5 mg), and vitamin B_{12} (0.1 μg). When testing 1 000 μg of thymidine per tube, a growth response was obtained for all four strains. However, the contamination of thymidine by 1.5 % of deoxyuridine could completely account for this growth promoting effect of thymidine in the pyrimidine deficient medium.

All the extracts of brewery materials tested were found to be active in replacing the pyrimidine requirement for the four lactobacilli. Extract of kilned malt rootlets was found to be more active on dry weight basis than either of kilned malt (without rootlets) or barley for all four strains. Wort and beer each had the same activity for all four strains. We have shown earlier [6,10] that kilned malt rootlets, wort and beer contained a growth factor for *Lb. leichmannii* 313 ATCC 7830 and *Lb. acidophilus* R-26 ATCC 11506 with the same R_F-value as deoxyuridine in several chromatographic solvent systems.

Russell *et al.* [4] investigated the uracil requirement of thirty-four brewery lactobacilli and found that uracil was essential for seventeen organisms and

stimulatory to four others. The specificity of the uracil requirement of these brewery lactobacilli was not investigated. For pyrimidine requiring lactobacilli the specificity of the requirement for pyrimidine varies greatly from organism to organism. In several instances, it has been shown that lactobacilli can meet their pyrimidine requirement by means of several closely related pyrimidines or pyrimidine derivatives. [15-18]

Purine requirement. Moore and Rainbow [1] showed that the purine requirement of strains L3, L5, and L6 could be met by adenine, guanine, xanthine or hypoxanthine. Strain L4 required hypoxanthine alone or adenine together with either guanine or xanthine [1]. However, the purine requirement of strain L4 has changed somewhat with time. This strain will now also grow on adenine alone (private communication from Dr. Rainbow). We confirmed these findings. Further investigations revealed that the purine requirement of all four lactobacilli could also be met by any one of several purine derivatives or extracts of brewery materials. The growth promoting effects of these compounds and extracts after 48 and 72 h of incubation are given in Table 3.

As seen from Table 3, strains L3, L5, and L6 could utilize any one of the purine derivatives tested as a sole purine source. Strain L4, on the other hand, could only utilize adenine, adenosine, 2′(3′)-AMP, deoxyadenosine, deoxy-AMP, hypoxanthine, inosine or deoxyinosine as a sole purine source. Extracts of brewery materials were active for all four strains.

For all four strains, the highest growth levels (2—10 % light transmittance) were obtained with adenine + guanine (100 μg of each) or deoxyadenosine + deoxyguanosine (100 μg of each) after 72 h of incubation. Strains L3 and L5 were similar in the utilization of individual purine compounds. For both strains, the highest growth levels were also obtained with 100 μg of any one of the purines or adenosine whereas the remaining purine nucleosides had the highest growth levels for strain L3 and good growth (10—20 % light transmittance) for strain L5. The purine nucleotides were less active on a molar basis for both strains.

For strain L4, no single purine compound could duplicate the high growth promoting effect of adenine + guanine or deoxyadenosine + deoxyguanosine. The compounds most active in promoting the growth of strain L4 in a purine deficient medium were adenosine, hypoxanthine, inosine and deoxyinosine followed by deoxyadenosine and deoxy-AMP. Considerably less active for strain L4 on a molar basis were adenine and 2′(3′)-AMP whereas guanine, xanthine and their derivatives were completely inactive. Although guanine alone was inactive, it greatly enhanced the growth promoting effect of adenine. Deoxyguanosine, which was also inactive alone, enhanced the growth promoting effect of deoxyadenosine.

For strain L6, the highest growth levels (after 72 h of incubation) were also obtained with hypoxanthine, inosine or deoxyinosine. Of the remaining purine bases, only guanine gave good growth whereas adenine and xanthine had low growth promoting effects. However, adenine had a synergistic growth effect together with guanine. For all four strains, purine nucleosides were more active growth promotors than purine nucleotides.

The following compounds were unable to promote growth in a purine deficient medium for all four strains after 96 h of incubation when tested in the

amounts per tube given in brackets: thymidine (1 000 μg), deoxyuridine (500 μg) and vitamin B_{12} (0.1 μg).

All extracts of brewery materials tested were found to be active in replacing the purine requirement for all four strains. Extract of kilned malt rootlets was

found to be more active on dry weight basis than either of kilned malt (without rootlets) or barley, just as was the case when these extracts replaced the pyrimidine requirement for all four strains. Wort and beer each had the same activity. Extracts of brewery materials are known to contain purines and purine derivatives. We have shown earlier [6,10] that kilned malt rootlets, wort, and beer contain an acid labile growth factor for *Lb. leichmannii* 313 and *Lb. acidophilus* R-26 with the same R_F-value as deoxyguanosine in several solvent systems. Harris and Parsons [19,20] investigated the purine derivatives present in wort and found that the greater part of these compounds consists of adenosine and guanosine. Deoxyadenosine and deoxyguanosine as well as the free purines adenine and guanine were also identified.

The specificity of the purine requirement of lactobacilli varies greatly from organism to organism and is intimately related to their pyrimidine, folic acid, and vitamin B_{12} requirements [16,21,22]. It should be pointed out that the four strains of brewery lactobacilli investigated here had absolute requirements for folic acid, a pyrimidine and a purine. In no instance, could these requirements be met using vitamin B_{12}.

Russell *et al.*[4] investigated the purine requirements of several brewery lactobacilli by omitting in turn each of the purines, adenine, guanine and xanthine, from the complete medium which contained PGA, PABA, and uracil. Of the thirty-four organisms investigated, twenty-six were unaffected by the omissions of any one of the purines. Adenine was found to be essential to seven organisms. Guanine was essential to one organism and stimulatory to two whereas xanthine was not required by any strain and stimulated the growth of only one strain. The interrelationships in the requirements for purines, PGA, PABA, and uracil were investigated for some of the strains. However, the specificity of the purine requirement of these lactobacilli, found in the presence of PGA, PABA, and uracil, was not investigated.

Combined folic acid, pyrimidine, and purine requirements. The four strains of lactobacilli under investigation had absolute requirements for folic acid, a pyrimidine and a purine. As shown above, each of these requirements could be met by an appropriate deoxyribonucleoside. It was therefore considered of interest to measure the growth promoting effects of various combinations of deoxyribonucleosides in a medium deficient in PGA, PABA, pyrimidines and purines. Extracts of brewery materials were also tested. The turbidity readings after 48 and 72 h of incubation are given in Table 4.

The combination of the four deoxyribonucleosides, deoxyadenosine + deoxyguanosine + deoxyuridine + thymidine (100 μg of each), gave nearly optimum growth for all four strains. Only certain combinations of two or three deoxyribonucleosides gave good growth for some of the strains: for strain L5, the combination of deoxyguanosine + deoxyuridine (100 μg + 500 μg) and, for strains L3 and L5, the two combinations of deoxyadenosine + deoxyuridine + thymidine (100 μg of each) and deoxyguanosine + deoxyuridine + thymidine (100 μg of each). The response of strain L4 to the various combinations of deoxyribonucleosides was in accordance with the previous finding that deoxyguanosine alone could not meet the purine requirement of this strain. As seen from Table 4, the combination of deoxyadenosine + deoxyguanosine + deoxyuridine (100 μg of each) was inactive or almost

inactive for all four strains. This showed that PGA or a compound active in replacing PGA was still required when the purine and pyrimidine requirements were met using suitable deoxyribonucleosides.

Extract of kilned malt rootlets (50 mg), wort (1.2 ml), and beer (1.2 ml) gave optimum growth for all four strains. For strain L6, the turbidity readings after 48 h of incubation with these extracts exceeded those obtained with the complete semisynthetic medium. This difference was more pronounced when the turbidities were compared at shorter incubation times than 48 h. This showed that these extracts contained factors that promoted the early growth of strain L6. For all four strains, extract of barley (100 mg) gave poor growth whereas extract of kilned malt (100 mg) gave good or quite good growth. This indicates that to a certain extent there was a formation of important growth factors for these four lactobacilli during the malting process. A comparison of the growth promoting effects of extract of kilned malt (50 and 100 mg) and of wort (0.1 and 1.2 ml) reveals that, during the mashing process, there was a much greater formation of these growth factors than during the malting process [6] (0.1 and 1.2 ml of wort correspond to about 17 and 200 mg of malt, respectively, since in the brewing process about 6 ml of wort is obtained per gram of malt).

Acknowledgements. The authors are very grateful to Professor H. Lundin, Head of the Division, for his encouraging interest in this work. They are also grateful to Dr. C. Rainbow, Dept. of Applied Biochemistry, University of Birmingham, for providing cultures of the brewery lactobacilli, to Lederle Laboratories Division, American Cyanamide Co., Pearl River, New York, for samples of the different folic acid factors, and to A. B. Stockholms Bryggerier for samples of the brewery materials.

On Osmotic Pressure of Macromolecules

J. A. CHRISTIANSEN

Sundvænget 9, Hellerup, Denmark

Elementary considerations show that the osmotic pressure of a solution containing non permeating molecules in a solvent consisting of permeating molecules can be calculated *as if* the former constituted a gas at the same temperature and concentration, *provided* that the form and magnitude of and the forces between them be maintained. The abridged van der Waals equation $p(V-B) = RT$ is derived by introducing in the equation $V\,\mathrm{d}p = n\,\mathrm{d}\mu$ (J. W. Gibbs, 1897) local concentrations and local activity-coefficients.

It is shown anew that if $2b$ be the unavailable volume for a pair of congruent hard molecules and N be the number of molecules in the volume V, the available volume is $V-Nb$ as shown by van der Waals 1899. A short history of this statement is given. It is emphasized that two different definitions of the unavailable volume $2b$ of the pair exist. In the case of hard, spherical molecules they yield the same result, $2b = 8v_m$, where v_m is the volume of one sphere. In all other cases they yield different results. The two definitions are:

I. $2b$ is the volume inside which the centre of one molecule must be if it be required that the one has points in common with the other one, supposed fixed.

II. $2b$ is the volume inside which the center of one molecule can not come without expenditure of work by the surroundings, the other molecule supposed fixed.

Def. I is used by B. H. Zimm and A. Isihara. Def. II is a consequence of the present author's derivation of the abridged van der Waals equation.

It is shown that for long rods Def. II agrees with experiments on long chain-molecules. The condition for this agreement is $b\varrho \geq 8$, where b is in cm^3/g and ϱ is the density in $\mathrm{g/cm}^3$ of the solid solute or is the reciprocal of its partial specific volume in the solution.

The discussion of experimental values yields suggestions regarding the constitution of some chainlike macromolecules. The suggestions seem to be confirmed by knowledge from other sources.

Two corrections mentioned in a paper by the author and the late Dr. C. E. Jensen are withdrawn. The first one relates to the difference in density between the inner and the outer liquid, the other one to the difference in surface-tension between the same two liquids.

Both corrections relate to measurements with the "inverted osmometer". A third correction, subtraction of one third of the diameter of the capillary from the height measured, is introduced.

PART I. THEORY

In the following we shall understand by the osmotic pressure (O.P.) of a solution of macromolecules that measured by means of a membrane which is impermeable and only impermeable to macromolecules, say molecules of molecular weights from some ten thousand and upwards.

It seems to be desirable to survey the basic ideas underlying our present knowledge of O.P. because in the rapidly expanding literature more or less controversial interpretations of the same phenomena have turned up so that the reader sometimes finds himself caught in a maze. The following is an attempt to illustrate different aspects of O.P. Not all of the author's views agree with views expressed by recent authors and his sincere hope is that this presentation should induce readers to meditate themselves on the problems involved.

The thermodynamic definition of osmotic pressure and its realisation by experiments

Fortunately, there are no controversies regarding the thermodynamic definition of O.P. It may be expressed as follows: The osmotic pressure is that excess pressure which must be exerted on the inner liquid, the solution, in an osmometer to prevent flow of the outer liquid, containing only permeating solvent molecules, through the membrane. This is the same as to say, that at equilibrium the chemical potentials of the permeating components of the inner liquid must be equal on both sides of the membrane.

The aim of all direct methods of determination of the O.P. is to realize this definition by experiment. As one example the reader may be referred to the method described by Christiansen and Jensen [1] in which the buoyancy of an air column in a vertical capillary produces the excess pressure on the inner liquid. If that pressure does not equal the O.P. there will be a flow of liquid through the membrane. The rate of flow (positive outwards, negative inwards) is measured by means of a horizontal microscope provided with an ocular micrometer scale. Experiment shows, that it depends linearly on the height of the air column, the resistance of the membrane against flow of the permeating liquid thus being independent of the direction of movement.

In exceptional cases the resistance proved to be greater for outward motions than for inward ones. Such experiments were discarded. In most cases the effect could be eliminated by removal and rinsing of the membrane. It is therefore probable that this valve effect is due to a layer of macromolecules, partly blocking the outward, but not the inward flow.

By means of a graph it is easy to find by interpolation the length of the column which corresponds to zero flow and from this by calculation the O.P.

Even at the largest rates of flow the linear velocity of the permeating liquid through the membrane (a collodion membrane) is extremely small, so small that, if the outer liquid be a mixture, diffusion-equilibrium is extremely nearly maintained in the displaced elements of the permeating liquid.

This follows from the following rough estimate: An exceptionally high rate of movement of the meniscus in the capillary is 20 divisions in the ocular micrometer in 10 min, which corresponds to 0.4 mm^3/10 min. The surface of the membrane is about 200 mm^2 and consequently the linear velocity across the membrane is about 0.002 mm/10 min. As now diffusion coefficients in gels like the water containing collodion membranes used are known not to be much smaller than those in water, we arrive at the result mentioned.

The permeation is therefore very nearly reversible. From this follows, that the liquid which permeates the membrane from the outside must have very nearly the same composition as that which permeates from the inside. In other words, the solvent, the permeating part, of the inner liquid is (very nearly) identical in composition with that of the outer liquid, or we may say that the outer liquid is the solvent of the inner liquid even if the former is a mixture.

Calculation of the osmotic pressure

The thermodynamic definition does not tell us whether or how the O.P. may be calculated from the concentration of the (non permeating) solute. Let us therefore consider the equilibrium situation more closely. It is a fact that at equilibrium there is a pressure-difference between the inner and the outer liquid. It is also a fact, that at equilibrium there is no flow of solvent through the membrane. Furthermore the (permeating) solvent can only contribute to the pressure difference by flowing through the membrane. Consequently its contribution to the pressure difference must be zero at equilibrium. Therefore we should get the same pressure difference if we removed the solvent from both sides of the membrane, *provided* that we maintain not only the temperature and the concentration of the solute molecules, but also their form and magnitude and the forces between them. In other words we may calculate the excess pressure at equilibrium, the osmotic pressure, as if it were the pressure of a gas with the prescribed properties.

From this follows immediately, that the limiting law of van't Hoff must tend to be valid at such dilutions where the effects of the finite volume of the solute molecules and of the forces between them have vanished. Whether we may say, that the pressure difference at equilibrium be "due to" the bombardment of the (non permeating) solute molecules against the semipermeable membrane remains a matter of taste, the essential thing being that it can be calculated as described.

To treat the problem in more detail we shall use a method proposed by Gibbs [2]:

At constant temperature we have generally for a solution containing k + 1 components

$$V\mathrm{d}p = n\mathrm{d}\mu + \sum n_i d\,\mu_i \;(i = 1, 2, ...k) \qquad (1)$$

where V is the volume, and n and μ are, respectively, the number of moles and the chemical potential per mole of the non permeating solute and n_i and μ_i the corresponding quantities for the k permeating molecules. If now this solution is contained in an osmometer surrounded by the semipermeable

membrane and is in equilibrium with an outer liquid containing only the solvent substances at constant temperature, pressure and composition all $d\mu_i$'s are zero and we get

$$Vdp = nd\mu \tag{2}$$

exactly the same equation which is valid for a one component system. It is eqn (2) which we owe to Gibbs. The responsibility for the following must remain with the present author.

Let us now assume as usual that

$$d\mu = RT \, d\ln (cf) \tag{3}$$

where c is the concentration of the solute and f its activity coefficient. Now, if c means the overall concentration it is evident that

$$dn/n = dc/c \tag{4}$$

But (4) is also true if c means a local concentration, which may be different in different volume elements. This follows from the consideration that a small relative increase in the number of molecules of solute in the volume V cannot alter their distribution on the different volume elements.

It should be added that if we let c mean the local concentration it must be understood as the number of centers of gravity of solute molecules in a certain volume-element divided by the volume of that element.

Let us now assume that the solution is so dilute that f equals the same constant everywhere in the solution. Without loss of generality we may put this constant equal to one. Combining (2), (3) and (4) we then get by integration

$$Vp = RTn \tag{5}$$

because V at the small pressures in question is certainly independent of p. We thus arrive at van't Hoff's limiting law, or the gas-law. But evidently this is no proof of that law, because (3) has been chosen so as to lead in the limit to (5). The real proof of (5) rests of course on the validity of Maxwell's law of equipartition.

Let us now proceed one step further. Using again (3) and (4) we get by integration of (2)

$$Vp = RTn + RT\int n d\ln f \tag{6}$$

f is assumed to be defined by

$$f = \exp(g/RT) \tag{7}$$

where g is a molar potential energy depending on the space coordinates of the center of gravity of a solute molecule. In accordance with the Boltzmann principle we shall assume that the activity a of the solute is constant everywhere inside the osmometer, *i.e.*

$$a = cf \qquad (a \text{ constant}) \tag{8}$$

We shall only treat the case in which the solute molecules at a distance do not exert forces on each other, but that to force them nearer to each other, when they are already in contact, requires expenditure by the surroundings of an amount of work (per mole) which is several times as large as RT even for very small displacements. In other words, we consider the molecules to be hard bodies having well defined finite volumes. In that case g is either zero (when the molecules are out of contact) or g/RT is so large that f to all intents and purposes can be considered as infinitely large, the interval between these two cases being so small that it can be neglected. Therefore we have everywhere inside the osmometer

$$c \ln f = a \ln f/f = 0 \tag{9}$$

because if one factor is different from zero the other one is zero. Therefore

$$c \, \mathrm{d}\ln f + \ln f \, \mathrm{d}c = \mathrm{d}(c \ln f) = 0 \tag{10}$$

We have seen before that $\mathrm{d}c/c = \mathrm{d}n/n$ so that (10) can also be written

$$n \, \mathrm{d}\ln f + \ln f \, \mathrm{d}n = 0 \tag{11}$$

As now $n = \int c \mathrm{d}V$, (6) can be rewritten

$$\int (p/RT - c(1 - \ln f))\mathrm{d}V = 0 \tag{12}$$

If in (8) f equals one we have $a = c'$, where c' is the concentration in volume elements where the solute molecules are "free". Therefore

$$\int (p/RT - c'(1 - \ln f)/f)\mathrm{d}V = 0 \tag{13}$$

Now for those parts of the volume, where $\ln f$ is different from zero we get

$$c' \int ((1 - \ln f)/f)\mathrm{d}V = 0 \tag{14}$$

For those parts of the volume, where the centers of the solute molecules are "free", *i.e.* where f equals one

$$\int (p/RT - c')\mathrm{d}V = 0 \tag{15}$$

which means that $p/RT = c'$.
Now

$$n = \int c \, \mathrm{d}V = c' \int \mathrm{d}V/f \tag{16}$$

The contributions to the latter integral evidently comes only from those volume-elements in which f equals one. Denoting that part of the volume, where f is different from one (the unavailable volume) by B, we evidently get

$$c' = n/(V - B) \tag{17}$$

or

$$p(V—B) = nRT \tag{18}$$

That this equation agrees exactly in form with van der Waals's equation for the case where intermolecular forces are absent is no wonder as it has been derived from exactly the same assumptions as the latter.

The unavailable volume

As emphasized by all authors on the subject there are two kinds of unavailable volumes. The first kind is due to the fact, that the centers of the solute molecules cannot approach the inner surfaces of the osmometer beyond a certain distance. The second kind arises from the circumstance that the centers of two solute molecules cannot approach each other beyond a certain distance. A rough estimate shows at once, that if the osmometer be not microscopically small we may completely neglect the first kind. We shall now try to survey the situation concerning the unavailable volume of the second kind.

Statistics. Let us consider at first one pair of molecules identical in magnitude and shape, and let it be assumed that we have somehow succeeded in determining the unavailable volume $2b$ for the pair. Let us further assume that the volume V contains N single molecules of the solute. If we number these and take out, *e.g.*, number one it is evident that we may combine this with the $N—1$ others to $N—1$ pairs with the total unavailable volume $2b(N—1)$. However, as all the $N—1$ pairs contain molecule number one, only half of this volume belongs to the $N—1$ second partners, those with the numbers 2,3.....N. Consequently we must ascribe to each of these partners the part b of the unavailable volume. If furthermore we ascribe the same part b to molecule number one, this paired with any one of the other molecules will form a pair with the unavailable volume $2b$ as it should. It follows from this argument that the space available to the center of molecule number one or to any other of the N molecules is $V—(N—1)b—b = V—Nb$. Thus Nb equals B, the unavailable volume introduced before. B evidently means the same whether we let b mean the unavailable volume for one molecule and N the number of molecules or we let b mean the unavailable volume for one mole and replace N by n, meaning the number of moles. Using the latter convention (18) can be rewritten in the form

$$1—bc = RTc/p \tag{19}$$

where $c = n/V$ is the overall molar concentration of solute molecules. We may also let c mean the concentration in g/litre in which case (19) becomes

$$M(1—bc)/RT = c/p \tag{20}$$

where M is the molecular weight of the solute. In that case b becomes the unavailable volume of the solute in litre/g.

The expression $V—Nb$ for the available volume has a rather complicated history. J. D. van der Waals has it in the second edition of his book: *Die Continuität des Gasförmigen und Flüssigen Zustandes* (1899) **I**, p. 45. His argument, in which he corrects an error committed by R. Clausius, is different from that given above.

L. Boltzmann in his: *Vorlesungen über Gastheorie*, 1st Ed. 1898, reprinted 1912, part II, p. 7, has (our notation) $V-2(N-1)\,b$ for the same quantity. In his argument, which is similar to ours, he counts, however, the contribution to the unavailable volume from what we have denoted as molecule number one $N-1$ times in stead of only once. Then in his last work (with J. Nabl) in *Encyclopädie der Mathematischen Wissenschaften* V (1907) p. 551, Boltzmann quotes, without remarks, from the above mentioned book of van der Waals the latter's value $V-Nb$. It seems evident, therefore, that Bolzmann accepted this value before he died.

Finally, in his *Dynamical Theory of Gases*, 2nd Ed. (1916) p. 138, J. H. Jeans quotes Boltzmann's value from 1898, $V-2(N-1)b$ without mentioning the error.

We shall therefore stick to the value for the unavailable volume $B = Nb$ and not use $B = 2(N-1)b$. It must be added that the expression "an unavailable volume of the second kind" has only a meaning if N is at least two.

Geometry. The magnitude of the unavailable volume, depends on the geometrical form of the solute molecules. Van der Waals and his first successors calculated $2b$, the unavailable volume for a pair of molecules, only for the case of hard spherical bodies which is by far the easiest one to treat. It is easy to see that the volume around a sphere A inside which the centre of another sphere B cannot come without the expenditure of work is a sphere whose radius is d, where d is the diameter of one of the spheres. In other words, the unavailable volume $2b$ for the pair is eight times v_m where v_m is the volume of one of the molecules forming the pair if they are both spherical. For the following it is of interest to note that in this case and only in this case two different definitions of the unavailable volume $2b$ lead to the same result, *viz.*

Def. I: $2b$ is the volume inside which the centre of molecule B must be if molecule A be fixed and it be required, that they shall have points in common.

Def. II: $2b$ is the volume inside which the centre of one molecule cannot come if the other one be fixed, unless work is performed by the surroundings.

For non spherical molecules definitions I and II lead to different results, the more so the more the form of the molecules deviate from a sphere. Def. II evidently is the one required by our derivation of the abridged van der Waals equation.

As examples of approximately spherical molecules certain globular macromolecules, *e.g.* certain proteins might be mentioned, but we shall focus our attention on a quite different type, molecules of the pearl-string type. Most or at least many of them are not at all stiff. If they were they might reasonably be considered as cylindrical rods, a case which seems next to the sphere in simplicity. However they must often be expected to perform not only intermolecular Brownian motions but also intramolecular motions of a similar irregular kind, resulting in incessant changes in "curliness" and end to end length. To take this accurately into account in an attempt to calculate the unavailable volume for a pair of such molecules seems nearly hopeless. The only problem one may reasonably expect to be able to solve is the tremendously simplified problem of determining $2b$ for a pair of stiff circular cylinders with given height and length. Isihara [3] has suggested that for the solution of the corresponding problem for flexible molecules one might use information concerning average dimensions of such molecules obtained by means of light-scattering experiments. To the present author this seems doubtful because it seems to him that the lengths measured by optical methods may be quite

different from those which are decisive for the magnitude of the unavailable volumes. Actually, just because of the flexibility of the pearl-string model one would expect the decisive length for this to be the length of the string, while the average lengths measured by optical methods may be much shorter. Anyhow, we may not commit gross errors by replacing the pearl string by the same in its stretched form and then replace this by a cylinder of the appropriate dimensions, diameter d and height h.

The unavailable volume for a pair of solid cylinders

B. H. Zimm [4] and A. Isihara [5,6] have solved, the former approximately, the latter exactly, the following problem: Given two congruent cylinders, A and B, A being fixed in space and B movable. Find the volume inside which B must move if it be required that the common volume of A and B does not vanish. Zimm and Isihara consider the volume so defined to be the unavailable volume $2b$ for a pair of cylinders, in other words they use Def. I. Isihara's result [3,6] is

$$2b/v_m = \pi + 3 + \pi d/2h + 2h/d \qquad (21)$$

Now b can be determined by measurements of the osmotic pressure p at several concentrations c. We then plot c/p against c. According to (20) the graph obtained should be a straight line and seems to be so when only reliable experiments are taken into account. For details of the experiments and evaluation of the sources of error in osmotic experiments the reader is referred to Part II of this paper. From the intercept of the line with the axis of ordinates we may calculate the molecular weight and from its slope we get b in cm^3/g if c is in g/cm^3. Furthermore v_m might be taken as the partial specific volume in cm^3/g in the solvent in question or failing that, as the reciprocal density (ϱ) of the solid substance. However, measured in this way v_m may very probably be low because evidently the solute molecule may be covered with a sheath of solvent or it may be wound up in a "helix" whose effective volume at collisions may be several times larger than that of the densely packed molecules. Values of $b\varrho$ therefore represent an upper limit to the value of b/v_m. The former values usually lie in the range from about ten to less than one hundred. On the other hand the number of "pearls" on the "string" can be estimated from our knowledge of the chemical composition of the substance in question and its molecular weight. This number cannot be very different from the ratio h/d. A low estimate of this ratio is 100. From (21) it is seen that for this value of h/d, b/v_m becomes 100, and by actual calculations in the particular examples it is found to be much greater. This disagreement between values of $b\varrho$ determined experimentally and b/v_m predicted by the calculation of Isihara [5,6] is so large, that serious doubt arises whether the definition (I) of the unavailable volume be the right one. What can be said at the present stage is that it is certainly different from Def. II adopted by the present author. This definition may be repeated here as follows: Let cylinder A be fixed and B be movable. The volume unavailable to B is then that volume inside which the center of B cannot be brought unless work is performed on the system.

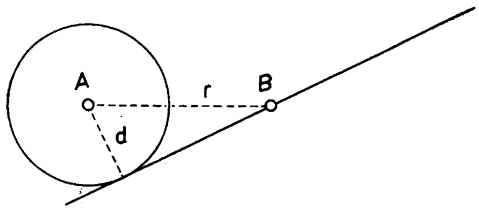

Fig. 1.

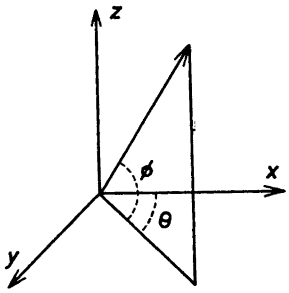

Fig. 2.

To illustrate the difference between the two definitions let us proceed in the following manner: We replace cylinder A by one of the same height but with diameter $2d$ and replace simultaneously B by its axis of lenght h. Furthermore we consider the particular case that the axes of A and B are perpendicular to each other. The projection on a plane perpendicular to the axis of A is shown in Fig. 1. In this plane we may evidently speak of an unavailable area instead of an unavailable volume. Now according to Def. I the middle point of B certainly belongs to the unavailable area if the situation is as illustrated. According to Def. II, however, the same point does not belong to the unavailable area because we may shorten the radius vector r from the center of A to the middle point of B without performing work. Of course the line B will then slide or roll on the circle A but this does not require work as no forces resists a motion of that kind. But the radius vector cannot be decreased to a value less than d, the radius of the circle, unless work is performed on the system. Therefore, according to Def. II, the area unavailable to the centre of B is the area of circle A, which is certainly less than the unavailable area defined according to Def. I.

In this argument we have neglected the fact that both A and B are endowed with kinetic energy, translatory and rotatory. Strictly speaking we should therefore consider the probability of finding the two centers in between distances r and $r + dr$ from each other. This probability depends partly on the kinetic and partly on the potential energy, both corresponding to the distance r. We know, however, from general theory that the average kinetic energy at a given temperature does not depend on r. Consequently our result must remain the same as that obtained under the assumption that the two cylinders are at rest. It seems therefore that both experimental results and theoretical considerations indicate that Def. II and not Def. I. must be the right one.

Calculation of the unavailable volume for a pair of cylindrical molecules.

The unavailable volume evidently depends on the orientation in space of the axes of the cylinders. Let the axis of A be parallel to the x-axis in a system of rectangular space coordinates as in Fig. 2 and let its centre be placed in the

origin. We want now to determine the volume which is unavailable to the centre of B. On account of the cylindrical shape of A and B the unavailable area is for all orientations of the axis of B equal to $\pi\, d^2$. The unavailable length however depends on the orientation of the B-axis. If this be parallel to the x-axis the length is evidently $2h$, beginning at $x = -h$ and ending at $x = +h$. The vectors indicating the possible directions of the B-axis must always be positive and must therefore lie inside the corner limited by the three positive half-axes of coordinates. Denoting geographical longitude by Θ and geographical latitude by φ, the surface element on a sphere with radius unity is $\mathrm{d}S = (\cos\varphi\ \mathrm{d}\Theta)\ (\mathrm{d}\varphi)$. As we shall assume that all orientations (inside the octant) are equally probable the element of probability $\mathrm{d}w$ is $A\mathrm{d}S$. As the vector in question ($\mathrm{d}w$) must have its endpoint somewhere inside the equilateral spherical triangle whose sides are $\pi/2$ we have

$$\int \mathrm{d}w = 1 = A\int \mathrm{d}S = A\ 4\pi/8 \tag{22}$$

Consequently

$$\mathrm{d}w = 2\cos\varphi\ \mathrm{d}\varphi\ \mathrm{d}\Theta/\pi \tag{23}$$

The components of the unavailable length multiplied by the element of probability thus becomes for the axes indicated

$$\begin{aligned} &(x)\colon\ 4h\cos^2\varphi\ \mathrm{d}\varphi\ \cos\Theta\ \mathrm{d}\Theta/\pi \\ &(y)\colon\ 2h\cos^2\varphi\ \mathrm{d}\varphi\ \sin\Theta\ \mathrm{d}\Theta/\pi \\ &(z)\colon\ 2h\sin\varphi\ \cos\varphi\ \mathrm{d}\varphi\ \mathrm{d}\Theta/\pi \end{aligned} \tag{24}$$

where it be remembered that when the B-axis is parallel to either the y or to the z-axis the unavailable length is h, the end correction being already included in the contribution from the (x) position.
Performing now all the integrations from zero to $\pi/2$ we get as contributions to the average length unavailable to the center of B

$$(x)\colon\ h;\ (y)\colon\ h/2;\ (z)\colon\ h/2.$$

Thus the volume unavailable to the center of B, when A is fixed becomes $2h \cdot \pi d^2$. To get the volume unavailable to the center of A when B is fixed we must fix the axis of B perpendicularly to the x-axis. It is immaterial whether we choose the y- or the z-axis. Let us choose the latter and let furthermore the fixed B-axis extend from the origin along the two branches of the z-axis. The calculation need not be repeated as we evidently get the same result as before. We cannot, however, simply add the two results to get $2b$. Each of the two volumes $2\pi hd^2$ represents the volume of a cylinder with height $2h$ and radius d, but their axes intersect at right angles and divide each other in the ratio one to one. In the case of cylindrical bodies this ratio is of course immaterial so long as the two cylinders intersect but if the bodies were *e.g.*, prolate ellipsoids this would not be so. Now the total volume of two cylinders intersecting each other as described is equal to $2b$ and we get

$$2b = 4\pi hd^2(1 - 4d/3\pi h) \text{ if } d \leq h \tag{25}$$

For $d>h$, that is if the molecules are coin-shaped, $2b$ is represented by two "coins" each of radius d and thickness $2h$ intersecting each other symmetrically at right angles. The volume of such a body is

$$2b = 4\pi hd^2 - 16(d^3 - (d^2 - h^2)^{3/2})/3 \quad (26)$$

For small values of h/d this converges against

$$2b = 4\pi hd^2 - 8dh^2 = 4\pi hd^2(1-2h/\pi d) \quad (27)$$

Thus for very long "rods" and for very thin "coins" we get

$$2b = 16v_m \quad (28)$$

while for spherical molecules

$$2b = 8v_m \quad (29)$$

PART II. COMPARISON WITH EXPERIMENTS

In the last two or three decades an immense number of determinations of O.P. particularly such of the filament or the rod type have been carried out. It would take too much time and space to review them all and the following examples are therefore chosen more or less at random. Peculiarly enough many of the results quoted were obtained by the time-consuming and not always quite reliable static method, although the principle of the dynamic method had been known for many years. Even when the present author at the Carlsberg Laboratory constructed an osmometer [7] according to the latter, the principle had been used more than twenty years before. [8,9]

The apparatus constructed by Fuoss and Mead [10] (1943) has since been used by several authors in U.S.A. It works according to the static principle, but with the important improvement, that the osmotic equlibrium is reached in a relatively short time and from both sides.

Some years ago the late Dr. Jensen and the present author [1] constructed, as mentioned before, a new type of a dynamic osmometer, an inverted osmometer, so called because the membrane is at the upper end of the observation capillary. This has since been used by different persons for different purposes and on a number of different solutes, but hitherto only with water or aqueous solutions as solvents. It is believed to have several advantages as compared to older models, particularly also to the Carlsberg model described by Sørensen [7] in 1917. First of all its volume is only about 400 mm^3, its active surface being about 200 mm^2. The Carlsberg model contained about 15 cm^3, including about 4 cm^3 dead space, and had an active surface of about 30 cm^2. The diameters of the cylindrical parts were, respectively, about 7 and about 14 mm. In the new model therefore in which there is practically no dead space the time necessary to reach diffusion equilibrium has been reduced by a factor of about four. Also the mechanical properties have been improved: On changing the hydrostatic pressure on the inner liquid the strain in the membrane is changed. This would be harmless if there were no elastic aftereffects in the collodion membranes used. Sørensen [7] showed that actually such effects seem to be present, but he showed also that the errors they produce were insignificant.

It can be estimated from experiments quoted in detail by Sørensen [7], that his results are reliable to within one in about three hundred. In the new model the small membranes are about as thick as those in the Carlsberg model which are much larger and the resulting strains are therefore smaller. Accordingly elastic after-effects were not observed in experiments with the new model. To avoid these effects some recent osmometers [10] have a plane membrane supported by one or two perforated discs. This, however, has the drawback that the active surface becomes much reduced, or the volume strongly increased, because evidently, even if the whole surface of the disc were active it would be, for the same overall dimensions of the apparatus, less by a factor about two than the test tube shaped membrane.

Experience with the new apparatus has shown that osmotic pressure may be determined with an accuracy better than 0.1 mm water pressure for pressures below 5 mm, the range of the ocular micrometer. Above 5 mm the accuracy is limited to 0.1 mm, the heights being measured by means of a millimeter scale with Vernier on the vertical stem of the microscope. In any case the accuracy obtained can be read from the graph connecting the rate of movement of the air column with its height.

In most other, particularly older apparatuses, including those of both types, static and dynamic, the accuracy seems not to be much better than 1 mm, and sometimes to be worse. Furthermore, at some measurements performed according to the static method and with one-sided approach to equilibrium, complete equilibrium may not always be reached. For these reasons many measurements of O.P. lower than about 10^{-3} atm, reported in the literature, may be off by 10 % or more.

Some earlier authors have used the abridged van der Waals equation to represent their results, *i.e.* they have plotted c/p against c, where c usually is the concentration in g/litre and p the pressure in some arbitrary unit. When points relating to the lowest pressures (less than 10^{-3} atm) are neglected reasonably straight lines are usually obtained. More recent authors often calculate and plot p/c against c, thereby obtaining curves with an upward bend. Some such experiments have been recalculated by the present author who, again omitting low and therefore doubtful pressures, got nearly straight lines.

Fortunately earlier authors gave their numerical results in tables. More recent authors seem to have abandoned this useful habit and give their results in graphs, from which it is difficult to read their numerical results accurately enough for recalculations. In all the following examples the present author has performed a recalculation and redrawn the corresponding graphs, thereby obtaining the values indicated for the molecular weight, M, and the values of b in cm^3/g.

According to theory $b = 8v_m$ if the molecules are (nearly) cylindrical. If v_m were the specific volume of the substance in question we should expect to get $b\varrho = 8$ if ϱ be the density in g/cm^3 of the substance in question. In stead of that one finds in most cases that $b\varrho$ is two to five or even ten times as large as that. The explanation is evident: v_m is the volume of a cylinder, which cannot penetrate a similar one. If now the principal chain in the molecule has many short branches, or if it be wound up in a helix, two such molecules can only penetrate each other to a distance which may be two or three times

that calculated from the densest possible packing of the constituents, as in the corresponding solid. This means that the factor in question may easily be four or even nine. It should of course be more correct to use the partial specific volume of the solute in the solvent in question instead of the reciprocal density of the solid substance, but even the volume measured that way may easily be less than v_m because the small solvent molecules can accomodate themselves in the structure of the solute macromolecules while other solute molecules can not. Therefore, the only thing we can state with some certainty is that the product $b\varrho$ must be equal to or greater than eight, provided that attractions between the rod-molecules can be neglected.

Example 1

Experiments by Kroepelin and Brumshagen [11]. Recalculated by J. A. Chr.
Solute: Caoutchouk. Solvent: Benzene.

Temp.	M	ϱ	b	$b\varrho$
11°C	210 000	0.91 g/cm³	about 40 cm³/g	about 36
40°C	210 000	0.91 »	about 70 »	about 62

Remarks: As mentioned by the authors themselves, the b values are rather inaccurate, but it seems certain that b at 40°C is essentially larger than b at 11°C.

As an explanation it may be suggested that different rubber-molecules be curled into helixes of different diameters, those with the larger diameters having the greater energy-contents.

Example 2

Experiments by Schultz [12]. Recalculated by J. A. Chr.
Solute: Cellulose-nitrate. Solvent: Acetone.
Temp. 27°C. Density, ϱ : 1.35 g/cm³

Specimen	M	b	$b\varrho$
N66	about 54 700	about 25 cm³/g	about 34
N65	about 36 700	about 21 »	about 28

Remarks: Polysaccharide chains are probably straight, but the nitro-groups substituted for hydrogen in the hydroxy-groups may act as short side-chains.

Example 3

Experiments by Schultz [12]. Recalculated by J. A. Chr.
Solute: Polystyrene. Solvent: Toluene.
Temp. 27°C. Density, ϱ : 1.06 g/cm³

Specimen	M	b	$b\varrho$
P.S. 20°	about 141 000	about 30 cm³/g	about 32
P.S. 135°	» 160 000	» 29 »	» 31
P.S. 200°	» 57 500	» 23 »	» 24

Remark: The aromatic side-chains must increase the effective diameter of the principal chain but may prevent its curling up.

Example 4

Experiments by Schultz [12]. Recalculated by J. A. Chr.
Solute: Polyethylene oxide. Solvent: Water.
Temp. 27°C. Density, ϱ : 1.12 g/cm³.

Specimen	M	b	$b\varrho$
II	about 64 400	about 54 cm³/g	about 60
III	» 26 600	» 26 »	» 29
IV	» 17 700	» 26 »	» 29

Remark: In the book by H. Staudinger, *Die hochpolymeren organischen Verbindungen* (1932) p. 293, one author, H. Lohmann, gives arguments for zigzag formulae of the polyethylene oxides illustrated in a plane. This illustration may very naturally be taken as the projection formula of a helix.

Example 5

Experiments by Jensen and Marcker [13]. Recalculated by J. A. Chr.
Solute: Dextrane, fractionated. Solvent: 0.2 M KCl in Water.
Temp. 20°C. Density taken to be 1.588 g/cm³ (sucrose), (starch about 1.5)

Specimen	M	b	$b\varrho$
Dextrane	about 140 000	4.93 cm³/g	7.84

Remarks: Unfortunately no determinations of the density of the solid or of its specific volume in the solution were performed. Assuming that different polysaccharides have the same specific weights the value of ϱ for sucrose has been taken. The value for starch, 1.5, is probably low, because it refers to granules of native starch which may include some air.

It is said in the paper [13] that the (commercial) specimen was very polydisperse and had to be freed from the low molecular fraction by dissolution and reprecipitation, but even so it became certainly not monodisperse. As, by experience, unavailable volumes are usually independent of the molecular weights for rod-molecules derived from the same structural unit, the degree of polymerisation is probably irrelevant for the value of $b\varrho$.

The deviation of $b\varrho$ from 8 is certainly less than the probable error. The result therefore suggests that the polysaccharide chain be not coiled up. Because of the cyclic constitution of the units this seems intrinsically probable.

Addendum to Example 5, and amendments to a paper on the inverted osmometer

In Table 2 in the paper by Jensen and Marcker [13] there is one misprint (19.40 for 10.94) and one line is missing. The complete table shall therefore be reprinted below. Furthermore, the heights of the air-column had not been

corrected for curvature at its ends. This has now been done by subtracting one third of the diameter of the capillary (0.07 cm) from the heights (p) in the table. The corrected values of c/p are under the heading (c/p). Values of c/p have been calculated from the formula $c/p = A—Abc$ with $A = 5.68$, $Ab = 0.0280$. They are under the heading $(c/p)_{calc}$. Finally, values of the difference $(c/p)—(c/p)_{calc}$ are in the last column.

Table 2 by Jensen and Marcker [13], revised and enlarged by J. A. Chr.

c mg/ml	p cm	c/p	(c/p)	$(c/p)_{calc}$	
0				5.68	
5.19	1.05	4.94	5.05	5.54	−0.49
10.94	2.07	5.31	5.37	5.37	0.00
19.40	3.90	4.98	5.01	5.14	−0.13
31.51	6.45	4.89	4.91	4.83	+0.08
40.00	8.80	4.55	4.56	4.56	0.00

The deviations in the last column are such that if caused by errors in the determination of p three of them would correspond to errors of about 1 mm. Such errors are, however, nearly impossible and it is therefore much more probable that they have arisen from lack of homogeneity in the fraction investigated. It should be recalled in this connection, that it was certainly not monodisperse. If this be the cause of the deviations it is quite natural that it is the determination in which the smallest amount of substance (5 mg) was weighed in, which shows the largest deviation.

Amendments to the paper by Christiansen and Jensen[1]

On p. 1252 the authors mention three corrections which should be applied:

1. A correction for the finite density of air (saturated with water vapour at 20°C). This correction varies with the varying total pressure in the apparatus, but it is so small that its value at one atmosphere, 0.0011 g/cm^3, can safely be used in all cases. Therefore the significant figures in the value of q on p. 1254, 246.8, should be replaced by 247.1.

2. A correction for the difference in density between the outer and the inner liquids. This correction is at any rate very small, and if complete equilibrium in the gravity-field has been established, not only across the membrane but also in the column of inner liquid extending from the upper end of the capillary to the upper end of the air-column, only the density of the outer liquid is relevant. This item be therefore withdrawn.

3. A correction for the difference in surface-tension between the solution at the upper end of the air-column and the solvent at the lower end. This be also withdrawn for the following reason: Water adheres strongly to glass. We must therefore assume that the cylindrical part of the air-column is surrounded by a liquid film, which, as known from the works of M. Vollmer, most probably is easily movable along the glass wall. The capillary forces at the ends of this cylindrical film must tend to drag it in opposite directions, and at osmotic equilibrium the forces must counterbalance each other exactly.

Example 6

Experiments by Jensen and Marcker [13]. Recalculated by J. A. Chr.
Solute: Potassium hyaluronate. Solvent: 0.2 M KCl in water.
Temp. 20°C. Density, : 1.16 g/cm³ (spec. vol. det. by Jensen)

Specimen	M	b	$b\varrho$
Prep. I	122 000	35.8 cm³/g	41.6
Prep. II	144 000	35.8 »	41.6
Prep. III	144 000	35.8 »	41.6
Prep. IV	1 066 000	43.0 »	50.0

Remarks: At a former occasion Jensen [14] determined the specific volume of another specimen of potassium hyaluronate by pycnometric determinations in 0.2 M KCl in water. Result: 0.86 cm³/g. It is evident from the table that b depends only slightly on the molecular weight of the preparation. It is also evident that the product $b\varrho$ is 5—6 times larger for the hyaluronate than for dextran, although the former is a derivative of a polysaccharide and the latter is a polysaccharide. This may partly be due to the circumstance that the former contains carboxyl-groups as side-chains, but the effect of this may be masked by the property of its being a polyelectrolyte. In a forthcoming paper, Graae and Marcker point out that the large unavailable volume of the hyaluronate may be due to electrical forces from the ionic atmosphere surrounding the negatively charged "backbone" of the polyion. The effective diameter of the cylinder may be expected to be not very different from the Debyelength $1/\varkappa$ and b should therefore increase with decreasing ionic strength of the solvent. Graae and Marcker have found experimental evidence in the literature that this be true for another chain-like polyelectrolyte.

Addendum to Example 6

The values for c/p in Table 3 of the paper in question have not been corrected for curvature at the ends of the air column. Table 3 has therefore been recalculated by the present author (see below) and the values for M and b in the table above are the results of this recalculation. It should be noted that in the columns marked p in the original table 3 the number of significant figures should have been increased by one in some cases. The figures in the column marked c/p, however, have in all cases been calculated from the orginal data and have sufficient numbers of significant figures. The recalculation, therefore, is based on the figures in that column. One misprint in the original p-column, 1.00 in stead of 1.06, has been found. As in the addendum to Example 5 c/p is the original value, (c/p) the corrected one and $(c/p)_{calc}$ that calculated according to the formula $p/c = A—Abc$. The differences (exp) — (calc) are in the last column.

Table 3 by Jensen and Marcker [13], revised and enlarged by J. A. Chr.

Prep. I. $A = 4.92$; $b = 0.0358$ litre/g.

c mg/ml	p cm	c/p	(c/p)	$(c/p)_{calc}$	
0				4.92	
16.00	7.89	2.03	2.03	2.10	−0.07
13.00	4.91	2.65	2.66	2.63	+0.03
11.00	3.70	2.97	2.99	2.98	+0.01
7.00	1.85	3.78	3 83	3.69	+0.14
5.00	1.292	3.87	3.94	4.04	−0.10

Prep. II. $A = 5.85$; $b = 0.0358$ litre/g.

0				5.85	
16.00	6.50	2.46	2.47	2.50	−0.03
13.00	4.19	3.10	3.12	3.13	−0.01
11.18	3.21	3.49	3.52	3.51	+0.01
5.00	1.059	4.72	4.83	4.80	+0.03

Prep. III. $A = 5.85$; $b = 0.0358$ litre/g.

0				5.85	
7.51	1.85	4.06	4.12	4.27	−0.15
5.10	1.10	4.64	4.74	4.78	−0.04
3.53	0.710	4.97	5.14	5.11	+0.03
2.56	0.490	5.22	5.49	5.31	+0.18

Prep. IV. $A = 43.0$; $b = 0.0432$ litre/g.

0				43.0	
19.99	3.49	5.72	5.76	5.80	−0.04
16.00	1.20	13.33	13.59	13.22	+0.37
13.78	0.85	16.21	16.68	17.38	−0.70
10.21	0.450	22.69	23.90	23.98	−0.08
7.48	0.280	26.71	29.15	29.10	+0.05

It should be noted how surprisingly accurately the van der Waals abridged formula holds, even in cases where the available volume is less than half of the total volume, in the case of Prep. IV even less than one seventh.

It should be added, that in recalculating the tables for Prepns. I—III the present author has taken advantage of the fact found by Jensen and Marcker that the b-values are, inside the experimental errors, the same for these preparations.

It is seen that in all the examples quoted bQ is equal to or greater than eight. On the other hand it is less than one hundred. Now according to the formula of Zimm [4] and Isihara [3,6] the lower limit for the product should be, for long molecules, the height of the cylinder divided by its diameter. The lowest value of this ratio occurring among the examples is probably the one in Example 4, specimen IV, and even here it can hardly be below 150. In the other examples rough estimates yields much larger values for the same ratio. This confirms the suggestion that Def. II and not Def. I be the right one to use.

The authors sincere thanks are due to Dr. Thor A. Bak for his drawing the authors attention to A. Isihara's calculations and to professor Dr. W. Fenchel for his highly instructive explanations and discussions of the same.

Finally the author should like to express his sincere gratitude to his former coworkers, the late Dr. C. E. Jensen, J. Graae and K. Marcker for their careful and intelligent work with the problems of osmotic pressure and its measurement, without which the present paper had had to remain unwritten. Particularly, thanks are due to Mr. Marcker for information regarding technical and other details from his work in cooperation with C. E. Jensen.

Dehydrogenation of Phenols

I. Dehydrogenation of 2,6-Dimethylphenol with Silver Oxide

BENGT O. LINDGREN

Wood Chemistry Department, Swedish Forest Products Research Laboratory, Stockholm, Sweden

The dimeric and polymeric products obtained by oxidation of 2,6-dimethylphenol with silver oxide were investigated. The results show that the phenoxyl radicals probably formed as intermediates mainly react to give diphenyl ether groups (Path A in Scheme 1).

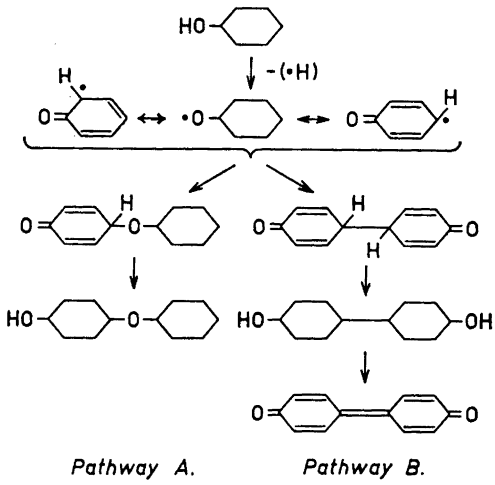
One electron oxidation of phenols (reviews [1,2]) affords phenoxyl radicals. Due to their different mesomeric forms they can pair to form stable products in various ways. They may react to form ether linkages (Path A in Scheme 1) or they may form carbon-carbon bonds (Path B). In the first case, quinol ethers and diphenyl ethers are obtained, in the second, bis-(*cyclo*hexadienone) derivatives, diphenyls and diphenoquinones.

Several examples of both types of oxidation products are known. The commonest types of dimers actually obtained are the diphenyls and diphenoquinones. The yields of these products are usually however rather low, the main products often being polymeric materials. It is therefore also necessary to study these polymers before deciding whether A or B represents the preferred reaction path.

These oxidation polymers have been studied only in the case of *o*-cresol. Pummerer [3] has briefly mentioned, without giving experimental details, that potassium ferricyanide oxidation gives a polymer with ether-linked phenolic units. According to Goldschmidt [4] *o*-cresol reacts with lead dioxide in acidified ether to give a trimer of the same type. His arguments are, however, not conclusive.

In some cases, high yields of diphenyls and diphenoquinones have been obtained by oxidation of phenols. For example, both benzoyl peroxide [5] and chromium trioxide in acetic acid [6] convert 2,6-dimethylphenol in high yield into the corresponding diphenoquinone. It is probable, however, that these reactions do not involve one electron mechanisms [7,8] but pass through cationic intermediates, as in the reactions of periodate [9] and lead tetracetate [10] with phenols.

On the other hand, reduction of ferric chloride and potassium ferricyanide involves only one electron and it seems likely therefore that their reactions with phenols involve



Scheme 1. The reaction pathways at dehydrogenation of phenols.

phenoxyl radicals. These reagents have also been used to prepare relatively stable phenoxyl radicals from sterically hindered phenols. It is of interest that in their reaction with 2,6-dimethylphenol the yields of the diphenyl and the diphenoquinone are much smaller than in the above mentioned cases [6].

Recently Ley, Müller and co-workers [11] have shown that labile quinol ethers are the initial products formed when phenols react with 2,4,6-tri-*tert.* butylphenoxyl-(1) and similar stable radicals. These may then split into radicals, which slowly form bis-(*cyclo*hexadienone) derivatives and diphenyls.

In the present investigation a study has been made of the oxidation of 2,6-dimethylphenol with silver oxide. The polymeric materials formed were examined as well as the dimeric products. This oxidation must be of the one electron type because the reduction of silver oxide, like that of ferric chloride and potassium ferricyanide, involves only one electron. Silver oxide was actually used by Pummerer [12] in some of his pioneer works to prepare stable phenoxyl radicals.

The oxidation was carried out by shaking a benzene solution of the phenol with silver oxide at room temperature. In some experiments sufficient silver oxide was added to abstract one hydrogen atom from each phenol molecule, in others, enough was used to abstract two hydrogen atoms (mole ratio silver oxide/phenol = 0.5 and 1, respectively).

In the first case a compound (I), the composition of which corresponded to $C_{16}H_{18}O_2$, was isolated in a yield of 15 %. The other substances obtained were 3,3′,5,5′-tetramethyl-4,4′-diphenoquinone (yield 11 %) and small amounts of 3,3′,5,5′-tetramethyl-4,4′-dihydroxy-diphenyl. The greater part of the residue was unreacted 2,6-dimethylphenol (yield 31 %) and undistillable, polymeric material.

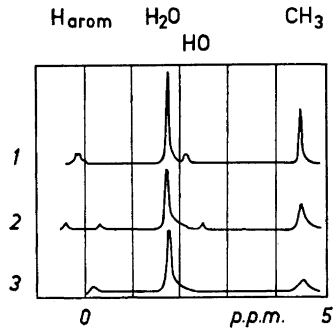


Fig. 1. NMR spectra of 1) 2,6-dimethylphenol, 2) compound (I), and 3) the solid polymer. Carbon tetrachloride solution. External standard: water.

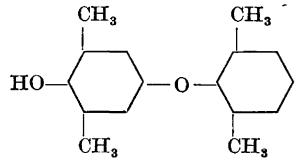
The UV spectrum indicated that substance (I) was aromatic (λ_{max} 288 mμ, ε 7 400 in methanol). Acetylation showed that it contained one hydroxyl group which was found to be phenolic by the bathochromic shift [13] of the 288 mμ maximum in alkaline solution (λ_{max} 310 mμ, ε 9 000 in N methanolic KOH). The IR spectrum of the compound indicated the presence of both 1,2,3-trisubstituted (maxima at 715 and 780 cm^{-1}) [14] and 1,2,3,5-tetrasubstituted (maximum at 850 cm^{-1}) [15] benzene nuclei. (2,6-Dimethylphenol as a trisubstituted benzene derivative has peaks at 722 and 755 cm^{-1}). No carbonyl band was present. From this it was probable that the compound was 3,5,2′,6′-tetramethyl-4-hydroxydiphenyl ether (formula I), which can be obtained from the phenol by Pathway A, Scheme 1.

The NMR spectrum showed a single strong resonance peak at a chemical shift of 4.45 p.p.m. relative to benzene hydrogen (Fig. 1). This must be due to methyl groups in α-position to a benzene nucleus (reported values for methyl substituted benzenes about 4.7 p.p.m.) [16]. 2,6-Dimethylphenol has a strong peak at the same point. The 2.40 p.p.m. peak is probably caused by hydroxylic hydrogen (2.15 for 2,6-dimethylphenol) as it shifted to 2.20 p.p.m. on addition of dimethyl sulphoxide, which would form hydrogen bonds with the hydroxyl groups.

Two single resonance bands were obtained for aromatic hydrogen, one on each side of the peak for benzene hydrogen (—0.40 and 0.24 p.p.m., respectively). They may correspond to the coupled magnetic resonance for the hydrogen atoms in the phenolic benzene nucleus (—0.40 p.p.m.) and in the non-phenolic nucleus (0.24 p.p.m.).

The NMR showed the absence of aliphatic (except CH_3) and olefinic hydrogen. It is thus in agreement with the formula (I):



I

Structure (I) was confirmed by periodate degradation which gave 2,6-dimethyl-*p*-quinone. This reaction is analogous to the formation of phenol and *p*-quinone by periodate oxidation of *p*-hydroxy-diphenyl ether [9]. That 2,6-dimethyl-phenol was not obtained from (I) may be due to the fact that it reacts rapidly with periodate [17]. Unsubstituted phenol, on the other hand reacts very slowly with periodate [9].

When 2,6-dimethylphenol was treated with sufficient silver oxide to abstract two hydrogen atoms the diphenyl ether (I) was obtained in very low yield. A white amorphous material was isolated which had the elemental composition $C_8H_{8.12}O_{0.94}$ and must therefore have been formed from dimethyl-phenol by elimination of two hydrogen atoms.

Determination of the molecular weight of this material from the melting point depression of benzene solutions gave values of 1 300 and 1 900 (two samples), corresponding to 10—16 dimethylphenol units, respectively.

Heating with acetic anhydride and pyridine did not introduce any acetyl groups into the product and it therefore contained few or no hydroxyl groups. In agreement its IR spectrum (Fig. 2) showed only weak absorption in the vicinity of 3 500 cm^{-1}. There were two peaks in the carbonyl range, at 1 700 and 1 740 cm^{-1}. The extinction coefficients of these carbonyl peaks were, however, rather low and the occurrence of carbonyl groups was therefore regarded as small in the polymer. These groups have not been further examined.

The product did not oxidise potassium iodide and therefore did not contain any peroxide groups. Thus, the bulk of the oxygen atoms in the polymer must be present in ether groups.

The UV spectrum of the polymer (Fig. 3) showed that it was made up largely of aromatic units. (Maxima at 238 mμ, ε 9 150; 278 mμ, ε 1 670; and 285 mμ, ε 1 640. Dioxan solution; ε-values calculated on a C_8-basis.) Its NMR spectrum (Fig. 1) supported this as it did not contain any resonance peak for aliphatic (except the CH_3 peak at 4.45 p.p.m.) or olefinic hydrogen. The aromatic hydrogen peak (0.22 p.p.m.) was above the benzene hydrogen peak.

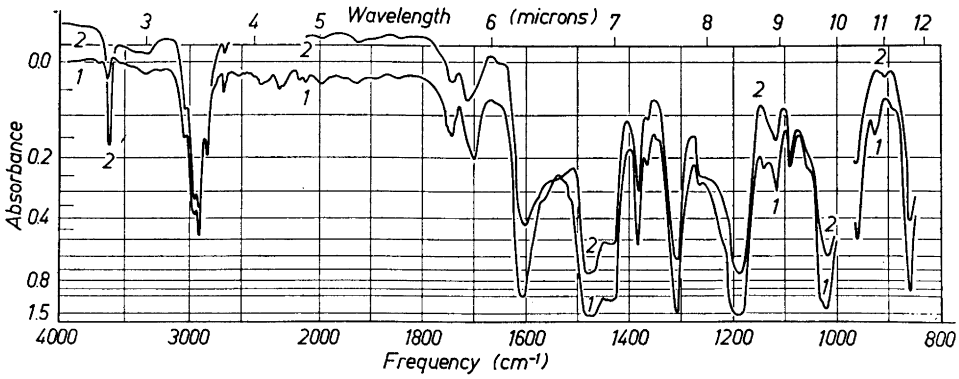


Fig. 2. IR spectra of 1) the solid polymer, and 2) the sirupy material from the mother liqour. Curve 2 displaced to lower absorbance for its separating from curve 1. Carbon tetrachloride solution.

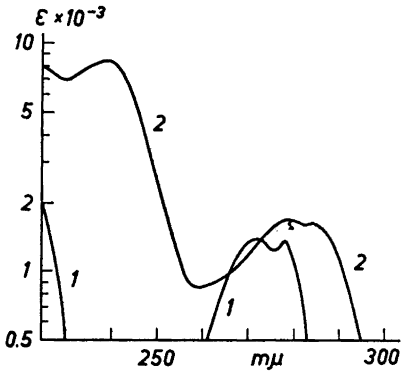

Fig. 3. UV spectra of 1) 2,6-dimethylphenol, and 2) the solid polymer. Methanol solution.

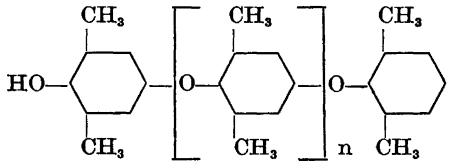
The IR spectrum gave an indication of the substitution in the benzene nucleus since it had a maximum at 850 cm^{-1} characteristic for 1,2,3,5-tetra-substituted benzene derivatives.

No trace of a maximum was present in the UV curve at 250—270 mμ, where diphenyl derivatives show strong absorption. (3,3′,5,5′-Tetramethyl-4,4′-dihydroxy-diphenyl: λ_{max} 267 mμ, ε 17 500 in methanol.)

These findings strongly indicated that the polymer is built up mainly according to formula (II). It also contained other structural features including a small percentage of carbonyl groups.

The polymeric material was obtained in a yield of about 40 %. From the mother liquor a semi-solid material was obtained, which gave essentially the same IR spectrum as the solid polymeric material (Fig. 2) but with the significant difference that the semi-solid material had a strong hydroxyl absorption peak. Its molecular weight was about 390, corresponding to 3.2 dimethylphenol units. These findings indicated that the material was of the same



II

type as the solid polymer, but had a lower molecular weight. Distillation of the syrup gave a small amount of the diphenyl ether (I).

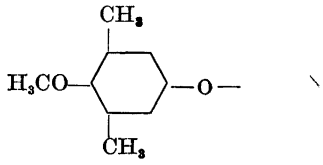
The yield of the syrup was about the same as the yield of the solid material (about 40 %). These experiments show therefore that on silver oxide oxidation in benzene the intermediate phenoxyl radicals mostly react according to Path A forming diphenyl ether groups.

The diphenyl ether (I) was obtained only in relatively low yield in these oxidations. Even when a theoretical amount of silver oxide was used the main products isolated were the starting material and the polymer. It is therefore

probable that the dimer (I) is oxidised more easily than the dimethylphenol. This may be due to activation of the phenolic hydroxyl group of (I) by the phenoxy group in the *para*position.

When the oxidation was carried out in the more polar solvent dimethylformamide, the polymeric material was again obtained together with tetramethyl-diphenoquinone. The yield of the polymer was, however, low, at least in part due to difficulties in isolating the material. The similarity of the polymeric materials was shown by the IR spectra.

Kuhn [18] has recently elaborated a new methylation technique for carbohydrates. The sugar, dissolved in dimethylformamide, is treated with silver oxide and methyl iodide. When 2,6-dimethylphenol is methylated in a corresponding way there is competition between the oxidation and the methylation reactions. From the reaction mixture a polymeric material was isolated the IR spectrum of which was identical with those of the above mentioned polymers. Analysis gave the empirical formula $C_8H_{8.03}O_{0.97}(OCH_3)_{0.065}$. The product thus contained one methoxyl group to 15 dimethylphenol units. Cryoscopic molecular weight determination gave a value corresponding to 14 units in the molecule. Probably the methoxyl groups were present as end groups (III) in the polymer.



III

EXPERIMENTAL

Oxidation of 2,6-dimethylphenol in benzene solution, mole ratio silver oxide/phenol = 0.5. Silver oxide (25 g) was added in portions to a solution of 2,6-dimethylphenol (25 g) in benzene (500 ml). The mixture was then shaken for 17 h at about 20° in the dark. Undissolved material was collected and extracted with boiling acetic acid. On cooling, red crystals (2.7 g) m.p. 208–210° (undepressed by admixture with 3,3′,5,5′-tetramethyl-4,4′-diphenoquinone) were obtained.

The benzene filtrate was evaporated and the residue was dissolved in a small amount of benzene. Undissolved dark green crystals (0.2 g) were removed. These had m.p. 186–187°, undepressed on admixture with the quinhydrone from 3,3′,5,5′-tetramethyl-4,4′-dihydroxy-diphenyl and 3,3′,5,5′-tetramethyl-4,4′-diphenoquinone. The benzene solution was again evaporated and the residue was distilled. The following fractions were collected: 1) b.p. 60–70° 0.3 mm Hg, 7.7 g of 2,6-dimethylphenol, m.p. 41.5–42°. 2) b.p. 140–150° 0.4 mm Hg, 3.9 g of substance (I), m.p. 101–105°.

The m.p. of substance (I) was raised to 105–108° by repeated recrystallisation from methanol – water. A small amount of crystalline material m.p. 223–225° (undepressed by admixture with 3,3′,5,5′-tetramethyl-4,4′-dihydroxy-diphenyl) was obtained from the mother liquor.

Compound (I). Found: C 78.9; H 7.3; O 14.0; OH 6.3. Calc. for $C_{16}H_{18}O_2$ (242): C 79.3; H 7.4; O 13.2; OH 7.0.

Oxidation with periodate. Sodium *para*periodate (3 g) dissolved in acetic acid – water (1:2 v/v, 100 ml) was added to a solution of substance (I) (0.6 g) in acetic acid (10 ml). The solution turned yellow. It was allowed to stand at room temperature for half an hour. The solution was then extracted with benzene, and the benzene solution was shaken with 5 % sodium hydroxide solution, dried (sodium sulphate) and evaporated. The residue (0.2 g) was sublimed at about 80° (bath temperature) and a pressure of 15 mm Hg to give yellow needles (0.11 g, yield 33 %) m.p. 55–58°. Recrystallisation from light petroleum increased the m.p. to 67–67.5°, undepressed by admixture with 2,6-dimethyl-*p*-quinone.

No 2,6-dimethylphenol was isolated from the sodium hydroxide solution. Similarly, no phenol was obtained when one mole of periodate was added to one mole of substance (I).

Oxidation of 2,6-dimethylphenol in benzene solution, mole ratio silver oxide/phenol = 1. Silver oxide (23 g) was added in portions to a solution of 2,6-dimethylphenol (12 g) in benzene (250 ml). The mixture was then shaken overnight at about 20°. Undissolved material was collected and extracted several times with boiling acetic acid. On cooling, 3,3′,5,5′-tetramethyl-4,4′-diphenoquinone (1.0 g) crystallised from the acetic acid.

The benzene filtrate was extracted with 5 % sodium hydroxide solution (from which 0.17 g of 2,6-dimethylphenol could be recovered) and dried (sodium sulphate). The addition of light petroleum (b.p. 60—70°) to the benzene solution precipitated a white, amorphous material which was collected by centrifuging and washed with light petroleum. Weight after drying in a vacuum at room temperature, 2.1 g. Preparation A. (Found: C 80.4; H 6.7; O 12.6; mol. wt. 1 300). The IR and UV spectra are shown in Fig. 1 and Fig. 2, respectively.

The filtrate from material A was evaporated to dryness and the residue was dissolved in *iso*propyl ether. Ethanol was added to this solution and the white precipitate obtained was collected and washed with light petroleum. Weight 2.6 g. Preparation B. The IR and UV spectra were very similar to those of preparation A. (Found: C 80.5; H 6.8; O 12.5; mol. wt. 1 900).

The *iso*propyl ether — ethanol solution was evaporated to dryness, giving a semi-solid residue (4.7 g). Preparation C. Mol. wt. 390. IR spectrum in Fig. 2.

Acetylation of preparations A and B. Samples of A and B (300 mg each) were heated with pyridine (3 ml) and acetic anhydride (3 ml) for 1 h at 100°. Water was added and the mixture was then extracted with benzene. The benzene solution was shaken with sodium bicarbonate solution and dried. Dissolved material was precipitated by adding methanol, filtered and washed with methanol. Both products gave 0 % acetyl.

Oxidation of 2,6-dimethylphenol in dimethyl formamide solution, mole ratio phenol/silver oxide = 1. Silver oxide (4 g) was added in portions to a solution of 2,6-dimethylphenol (2 g) dissolved in dimethylformamide (40 ml). The mixture was shaken overnight at room temperature. The solid material was then filtered off and extracted with boiling acetic acid. From the acetic acid solution 3,3′,4,4′-tetramethyl-4,4′-diphenoquinone (0.15 g) crystallised during cooling.

Chloroform and water were added to the dimethylformamide filtrate to give two phases. The upper layer was extracted several times with chloroform. The chloroform solutions were combined, shaken with water 6 times, dried and evaporated to dryness. The residue (0.67 g) was dissolved in benzene, and methanol added to the solution. The white precipitate obtained was collected (72 mg). The IR spectrum of this material agreed with those of preparations A and B above.

Oxidation of 2,6-dimethylphenol in dimethylformamide — methyl iodide solution. Silver oxide (7.5 g) was added in portions to a solution of 2,6-dimethylphenol (3 g) in dimethylformamide (15 ml) and methyl iodide (9 ml), and the mixture shaken overnight at room temperature. Undissolved material was removed and the filtrate was shaken with sodium thiosulphate solution and then with water. After drying, the solution was evaporated and the residue (1.35 g) was dissolved in *iso*propyl ether. Crystals of undissolved 3,3′,4,4′-tetramethyl-4,4′-diphenoquinone were removed (a few mg), the solution was poured into ethanol and the white precipitate (0.35 g) obtained was collected by centrifuging. (Found: C 79.5; H 6.8; O 13.6; OCH_3 1.66). The UV and IR spectra were identical with those of preparations A and B.

Acknowledgement. The author wishes to thank Miss Marit Goliath and Mr Sigurd Söderberg for valuable experimental assistance. The IR spectra were recorded at the department of Organic Chemistry, Royal Institute of Technology by Miss Gurli Hammarberg, and the NMR spectra were determined in the department of Physical Chemistry of the Royal Institute of Technology by Dr. Sture Forsén and Mr Jan-Christer Eriksson. I am greatly indebted to them for their co-operation.

Short Communications

The Occurrence of Cephalin, Sphingomyelin, and Lysolecithin in Bile

FUMIO NAKAYAMA and
ROLF BLOMSTRAND

The Swedish Medical Research Council, Unit for Biochemical Research related to Atherosclerosis, University of Lund, Sweden

Since Thudichum studied the phospholipids in bile as early as 1862[1], lecithin has been believed to be the only phospholipid present in bile [2,3]. However, in 1958 Nakayama and Johnston [4] fractionated biliary phospholipids with silicic acid column chromatography and presented data showing the constant presence of several phospholipid peaks other than that corresponding to lecithin. Furthermore, the complicated pattern of fatty acids of biliary phospholipids obtained by gas chromatography suggests the complexity of phospholipids composition in bile [5]. These findings prompted us to identify the phospholipid components in bile.

The bile from rat and rabbit given ^{32}P-orthophosphate intraperitoneally was extracted with chloroform-methanol 2:1 mixture followed by partition with physiological saline solution essentially based on the technique of Folch *et al* [6]. The labelled biliary phospholipids were purified by silicic acid column chromatography [7]. The methanol fraction containing the phospholipids was concentrated and subjected to paper chromatography together with ^{32}P-labelled liver phospholipids using the solvent system of di*iso*butylketone, acetic acid, and water (40:25:5) [8] followed by autoradiography (Fig. 1). The autoradiogram of rat liver phospholipids (Ia) indicated the presence of six phospholipid components which were earlier identified by Marinetti *et al.*[9] as A-unidentified phospholipid, B-lysolecithin, C-sphingomyelin, D-lecithin, E-cephalin, F-unidentified phospholipid, as shown in Fig. 1. The autoradiogram of biliary phospholipids from rabbit (IIa) and from rat revealed the presence of lysolecithin, sphingomyelin, lecithin and cephalin in bile of the two species studied.

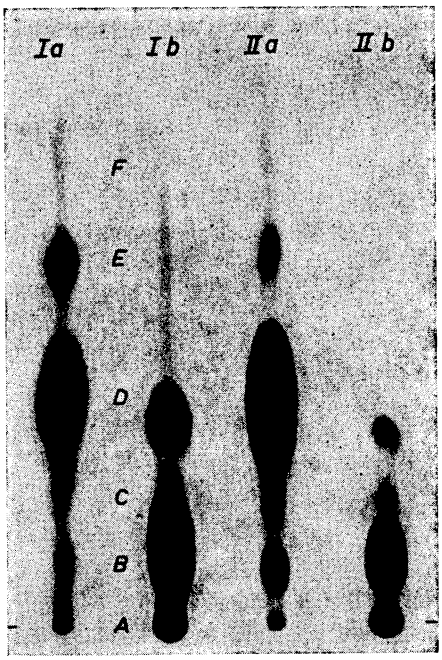

Fig. 1. Autoradiogram of ^{32}P-labelled rabbit liver and bile phospholipids. Ia-liver phospholipids, Ib-liver lecithin hydrolysate with snake venom *(Crotalus adamanteus)*, IIa-bile phospholipids, IIb-its hydrolysate with snake venom. Silicic acid impregnated Whatman No. 3 paper, ascending, solvent system-di*iso*-butylketone: acetic acid:water 40:25:5. A-unidentified phospholipid, B-lysolecithin, C-sphingomyelin, D-lecithin, E-cephalin, and F-unidentified phospholipid.

The further evidence for the presence of lysolecithin in bile was provided using the combination of snake venom and autoradiography. A part of the labelled phospholipids was hydrolyzed with snake venom *(Crotalus adamanteus)* [10] and subjected to paper chromatography together with the original phospholipids. After hydrolysis with snake venom of the pure liver lecithin obtained by preparative paper chromatography, the lecithin spot was diminished greatly and transformed into a lysolecithin spot (Ib). The lecithin spot of biliary phospholipids (IIa) was diminished greatly after similar hydrolysis and transformed into a lysolecithin spot, thus confirming the presence of lysolecithin in bile (IIb).

Separation of Nucleic Acids and Protein by Electrophoresis Combined with Counter Flow

R. ELIASSON, E. HAMMARSTEN and H. PALMSTIERNA

Department of Bacteriology Karolinska Institutet, Stockholm 60, Sweden

A good separation of proteins and nucleic acids from cell extracts could be achieved by electrophoresis in long columns stabilised with ethanolised cellulose [1]. The length of the path needed to affect such a separation was 300—320 cm. The diameters of the columns was 3.5 cm, and in a few cases 8.0 cm (unpublished). It became apparent that some material contained in the protein fractions was lost in the large amounts of cellulose (*e. g.* the neurotoxin from *Bordetella pertussis*).

The experiments to be described aim at a separation of the nucleic acids from the proteins in small columns as a preliminary to a further separation of these compound groups by means of chromatography. It was also desirable to let the proteins be in contact with as little cellulose as possible. Very small columns are also desirable for the separation of the components in biologically active nucleoproteins.

From these considerations we have tried to replace the length of the migration path by a steady flow of buffer against the direction of the electrophoretically migrating compounds. For this purpose we have used jacketed and cooled columns, with a length and diameter of 45 and 3.5 cm, respectively. We have also been working with 35 × 1 cm columns, about which will be reported later on. The packing, cooling, continuous buffer exchange and the buffer composition were exactly the same as described before [1]. The end of the side tube was, as usual, closed by a tightly fitting, thick dialysis membrane. Micropumps were constructed with capacities suitable for pumping the buffer in the direction opposite to the electrophoretic migration of the polyelectrolytes to be separated.

In the present paper we report experiments (*cf.* Table 1) where suction was simply applied to the buffer above the stabilised part of the column, with the purpose of finding the rate of flow that would permit the nucleic acid to migrate towards the anode at reduced speed, and drive the

Separation of Nucleic Acids and Protein by Electrophoresis Combined with Counter Flow

R. ELIASSON, E. HAMMARSTEN and H. PALMSTIERNA

Department of Bacteriology Karolinska Institutet, Stockholm 60, Sweden

A good separation of proteins and nucleic acids from cell extracts could be achieved by electrophoresis in long columns stabilised with ethanolised cellulose [1]. The length of the path needed to affect such a separation was 300—320 cm. The diameters of the columns was 3.5 cm, and in a few cases 8.0 cm (unpublished). It became apparent that some material contained in the protein fractions was lost in the large amounts of cellulose (*e. g.* the neurotoxin from *Bordetella pertussis*).

The experiments to be described aim at a separation of the nucleic acids from the proteins in small columns as a preliminary to a further separation of these compound groups by means of chromatography. It was also desirable to let the proteins be in contact with as little cellulose as possible. Very small columns are also desirable for the separation of the components in biologically active nucleoproteins.

From these considerations we have tried to replace the length of the migration path by a steady flow of buffer against the direction of the electrophoretically migrating compounds. For this purpose we have used jacketed and cooled columns, with a length and diameter of 45 and 3.5 cm, respectively. We have also been working with 35 × 1 cm columns, about which will be reported later on. The packing, cooling, continuous buffer exchange and the buffer composition were exactly the same as described before [1]. The end of the side tube was, as usual, closed by a tightly fitting, thick dialysis membrane. Micropumps were constructed with capacities suitable for pumping the buffer in the direction opposite to the electrophoretic migration of the polyelectrolytes to be separated.

In the present paper we report experiments (*cf.* Table 1) where suction was simply applied to the buffer above the stabilised part of the column, with the purpose of finding the rate of flow that would permit the nucleic acid to migrate towards the anode at reduced speed, and drive the

Table 1.

a) DNA prepared from calf thymus.
b) DNA prepared from *B. pertussis*.
c) Protein: Serum albumin containing praealbumun and some globulin.
d) Protein: Unknown amount of cell proteins from *B. pertussis*.
e) Not corrected for the path passed during the application of the sample before the electro phoresis was started.
f) The protein was driven out of the column by the counter flow. Measured by the photometer mentioned in the text.
g) The migration is measured from the front of the substances, when appearing after elution. The effective volume of the stabilised part of the column was measured by using phenol red.

proteins the opposite way or reduce their mobility to zero. In experiments to be published later suction has been applied with the view of isolating all protein. In Table 1 the mobilities are expressed as the position of the fronts of nucleic acids and proteins, as found after elution of the column following the electrophoresis either they have been performed with or without counter flow of the buffer solution. In cases were the proteins were driven against their electrophoretic mobility by the counter flow, the elution of the proteins was followed during the electrophoresis by a LKB Uvicord continuous photometer at 254 mμ (Svensson [2]). The nucleic acids recovered by elution after electrophoresis contained no protein as judged by the ninhydrin reaction (Moore and Stein [3]) after acid hydrolysis of solutions with 0.2 mg NA/100 ml and sublimation of the ammonium chloride *in vacuo*. Some dilution of the nucleic acid and protein fractions occurred, but the volumes could easily be reduced by a recently developed ultrafiltration method [4].

The authors are grateful to engineer E. Meyer for skilful technical assistance and the construction of the micropumps.

Synthesis of Some 1,4-Benzoxazine Derivatives and their Antimicrobial Activity

ERKKI HONKANEN and
ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

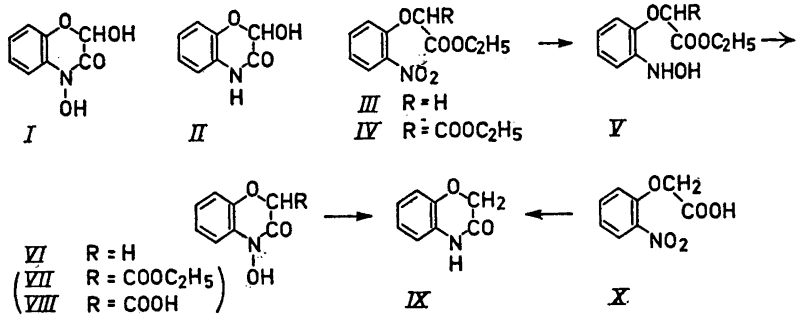
After the natural aglucone was isolated from crushed plants, and it was found to possess antimicrobial properties, the activity of different derivatives of this compound arose attention. In an earlier paper the synthesis of 2,4-dihydroxy-1,4-benzoxazin-3-one (I) and 2-hydroxy-1,4-benzoxazin-3-one (II) are described [1]. Another method for preparing 4-hydroxy-1,4-benzoxazine derivatives is also developed. When the reduction of *o*-nitrophenoxy acetic (or *o*-nitrophenoxy malonic) acid ester (III or IV) is performed in neutral medium with zinc dust, the hydroxylamino group in the first formed intermediate product (V) immediately reacts with the carboethoxy group, and ring closure to compounds VI and VII occurs. The compound VII can be readily hydrolyzed to the corresponding acid (VIII) with dilute sodium hydroxide solution.

4 - Hydroxy - 1,4 - benzoxazine - 2,3 - dione (XIII) was prepared by a similar method as 2,4-dihydroxy-1,4-benzoxazin-3-one [1]. The starting material was also now *o*-methoxymethoxyphenyl hydroxylamine (XI). By allowing this compound to react with oxalic acid ethyl ester chloride and hydrolyzing the intermediate product (XII) with methanolic hydrochloric acid, 4 - hydroxy - 1,4 - benzoxazine - 2,3 - dione (XIII) is formed. The rearrangement of 2,4 - dihydroxy - 1,4-benzoxazin - 3-one to benzoxazolinone [3] is obtained also by 4-hydroxy-1,4-benzoxazine-2,3-dione. Benzoxazolinone (XIV) could be detected in the water solution of XIII after heating for half an hour at 100°C.

The syntheses of 1,4-benzoxazine-2,3-dione [8] (XV) and 3,4-dihydro-2H-1,4-benzoxazine [9] (XVI) are described earlier in the literature.

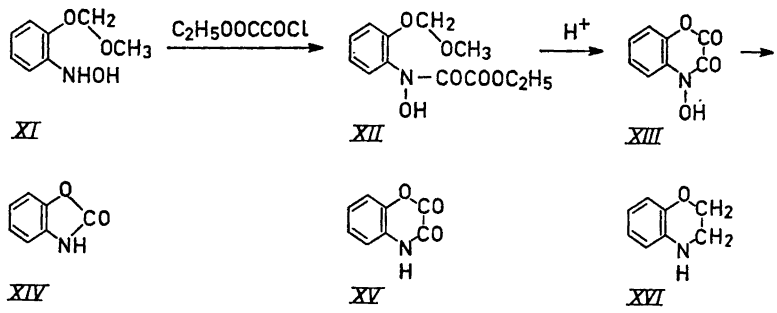
The growth-inhibiting effect of these compounds (I, II, VI, VIII, IX, XIII, and XVI) on *Fusarium nivale* was investigated. The results are given in Fig. 1. The antibacterial activity of the 4-hydroxy-1,4-benzoxazine derivatives (I, VI, VIII, and XIII) was determined with *St. aureus*, *Ps. fluorescens*, and *E. coli*. The results are shown in Fig. 2.

It can be seen in Fig. 1 that the strongest antifungal effect of the 1,4-benzoxazine derivatives was exerted by compound XVI in which the heterocyclic ring is completely hydrogenated. The difference in



If the reduction of *o*-nitrophenoxy acetic acid (X) is carried out with sodium hydrogen sulphite the lactam, 2H-1,4-benzoxazin-3(4H)-one, is obtained [2]. This compound (IX) is also formed when 4-hydroxy-1,4-benzoxazin-3-one (VI) is reduced with zinc dust in boiling acetic acid.

effectivity between compounds VI and IX on the one hand and XIII and XV on the other shows that the compounds with the NOH group are about twice as effective as the corresponding compounds with the NH group. On this basis the NOH compound corresponding to com-



XI XII XIII XIV XV XVI

pound XVI would be the most effective one of the substances in this group. The compound has not, however, been synthesized. The oxidation of 2 as well as 3 carbon atoms lowers the effectivity. The effect of 4-hydroxy-1,4-benzoxazine on bacteria is almost the same as its effect on *Fusarium*. In a concentration of 1 mg/ml compound VI inhibited the growth of *St. aureus*, *Ps. fluorescens*, and *E. coli* (Fig. 2).

All melting points are corrected.

o-*Nitrophenoxy acetic acid ethyl ester* was prepared according to the method of Duparc [4].

4-Hydroxy-1,4-benzoxazin-3-one. A mixture of 225 mg of o-nitrophenoxy acetic acid ethyl ester, 200 mg of ammonium chloride and 200 mg of zinc dust in 10 ml of 60 % ethanol was shaken for 2 h at room temperature. The solution was filtered, and the filter washed first quickly with 2 % acetic acid (to decompose the sparingly soluble zinc salt of the formed hydroxamic acid) and then with alcohol. Water was added to the filtrate, and the solution was extracted with ether. The ether solution was washed with dilute sodium hydroxide. Upon neutralisation of the aqueous layer with hydrochloric acid, the hydroxamic acid was extracted with ether. After drying with sodium sulphate the solvent was evaporated and the residue crystallized from water. Yield 100 mg (60 %); m. p. 168–169°C. (Found: N 8.28. Calc. for $C_8H_7NO_3$: N 8.48.) The compound gave an intensely blue-violet colour with aqueous ferric chloride. UV-Spectrum (in ethanol): max. 258 mμ, ε = 6 300; max. 286

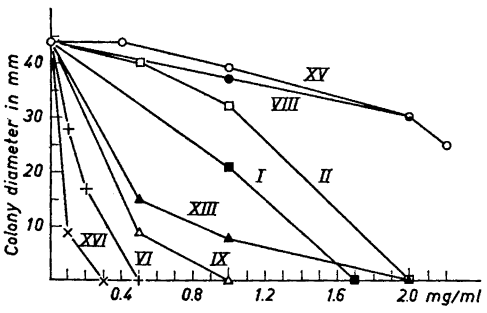


Fig. 1. Growth-inhibiting effect of 1,4-benzoxazine derivatives on *Fusarium nivale*. Oat-glycerol-agar nutrient solution, pH 6.4.

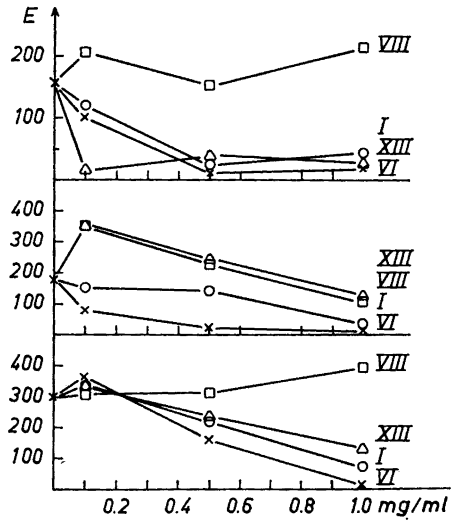

Fig. 2. Growth-inhibiting effect of 4-hydroxy-1,4-benzoxazine derivatives on *St. aureus* (topmost), *Ps. fluorescens* (middlemost), and *E. coli* (undermost). Broth nutrient solution, pH 6.5. Extinction (E) read at 622 mμ.

mμ, ε = 5 100. R_F-Value (Whatman No. 4 paper, solvent *i*-PrOH:NH_4OH:H_2O, 8:1:1) 0.39 (desc.).

Reduction of 4-hydroxy-1,4-benzoxazin-3-one. The reduction was carried out with zinc dust by a similar procedure as in the case of 2,4-dihydroxy-1,4-benzoxazin-3-one [1]. The reduction product melts at 171—172°C, mixed m.p. 171—172°C with 2H-1,4-benzoxazin-3(4H)-one [2].

o-*Nitrophenoxy malonic acid diethyl ester* has been prepared previously from the potassium salt of *o*-nitrophenol and bromomalonic acid diethyl ester by Bischoff [5] who obtained this compound as a crystalline solid (m. p. 116—118°C). When this procedure was repeated, a small amount of crystals were obtained which melted at 115—118°C. On the basis of the molecular weight determination and analysis, this compound should be the bis-(*o*-nitrophenoxy)-malonic acid diethyl ester, for which Bischoff [6] reports the m. p. 119°C. To obtain the *o*-nitrophenoxy malonic acid the uncrystallized part of the reaction mixture was hydrolyzed with aqueous sodium hydroxide at room temperature. Hydrochloric acid was then added to pH 6, and the unreacted *o*-nitrophenol was extracted with ether. The water solution was then made strongly acid and extracted several times with ether. The ether solution was dried, and the solvent evaporated. The residue was dissolved in a few ml of conc. ammonium hydroxide solution, and ethanol was added until separation of crystals occurred. The ammonium salt was filtered off and washed with cold ethanol. After recrystallization from aqueous alcohol the crystals were dissolved in water. The solution was made acid by hydrochloric acid and extracted with ether. After drying the solvent was evaporated, and the residue crystallized from a mixture of ether-benzene. M. p. 128—130°C. (Found: N 5.87. Calc. for $C_9H_7NO_7$: N 5.81.)

The *o*-nitrophenoxy malonic acid was then esterified by refluxing for 4 h with 1 % hydrogen chloride in absolute ethanol. The solvent was evaporated, and the residue dissolved in ether and washed with sodium hydrogen carbonate solution. After drying the ether was evaporated and the residue distilled *in vacuo*. The *o*-nitrophenoxy malonic acid diethyl ester was obtained as a pale yellow oil, which did not crystallize on standing for several weeks at room temperature or in a refrigerator. B. p. 145—150°/0.05 mm. (Found: N 4.77. Calc. for $C_{13}H_{15}NO_7$: N 4.71.)

4-Hydroxy-2-carbethoxy-1,4-benzoxazin-3-one. A mixture of 297 mg of *o*-nitrophenoxy malonic acid diethyl ester, 200 mg of ammonium chloride, and 200 mg of zinc dust in 10 ml of 60 % alcohol was shaken for 2 h at room temperature. The solution was filtered, and water was added to the filtrate. After extraction with ether and drying, the solvent was evaporated, and the residue crystallized from benzene. Yield 120 mg (50 %); m. p. 133—134°C. (Found: N 5.98. Calc. for $C_{11}H_{11}NO_5$: N 5.90.) Violet colour reaction with ferric chloride in alcohol. UV-Spectrum (in ethanol) max. 266 mμ, ε = 5 100; max. 288 mμ, ε = 5 100.

4-Hydroxy-2-carboxy-1,4-benzoxazin - 3 - one. 24 mg of 4-hydroxy-2-carbethoxy-1,4-benzoxazin-3-one were dissolved in 1 ml of 1 N sodium hydroxide solution and allowed to stand overnight. The solution was made slightly acid by hydrochloric acid and extracted several times with ether. After drying the solvent was evaporated and the residue crystallized from an ether-benzene mixture. Yield 15 mg (71 %); m. p. 144—146°C. (Found: N 6.70. Calc. for $C_9H_7NO_5$: N 6.65.) Blue colour reaction with ferric chloride. UV-Spectrum (in ethanol) max. 265 mμ, ε = 5 350; max. 289 mμ, ε = 5 300. R_F-Value (Whatman No. 4 paper, solvent *i*-PrOH:NH_4OH:H_2O, 8:1:1) 0.11 (desc.).

4-Hydroxy-1,4-benzoxazine-2,3-dione. 1.5 g of oxalic acid ethyl ester chloride [7] in 20 ml of ether were gradually added to a solution of 3.3 g of crude *o*-(methoxymethoxy)phenyl hydroxylamine [1] in 50 ml of dry ether under cooling (0°C). The ether solution was decanted from the dark brown oil and evaporated to dryness. The residue was dissolved in 20 ml of methanol and 2 ml of 2 N hydrochloric acid and refluxed for 15 min. The solvent was evaporated under reduced pressure. Water was added, and the mixture was extracted several times with ether. The solvent was evaporated after drying, and the residue crystallized from a mixture of alcohol-benzene. Yield 380 mg (21 %); m. p. 230—233°C (decomp.). (Found: N 7.98. Calc. for $C_8H_5NO_4$: N 7.82.) Red-violet colour reaction with ferric chloride. UV-Spectrum in ethanol max. 303 mμ, ε = 5 900; in water max. 280 mμ, ε = 2 900. R_F-Value (Whatman No. 4 paper, solvent *i*-PrOH:NH_4OH:H_2O, 8:1:1) 0.08 (desc.).

Conversion of 4-hydroxy-1,4-benzoxazine-2,3-dione to benzoxazolinone. A dilute water solution (20 μg/ml) of 4-hydroxy-1,4-benzoxazine-2,3-dione was heated for half an hour on a water bath. The UV-spectrum was then measured. The maximum by 280 mμ was shifted to 270 mμ (ε = 4 200) which is characteristic for benzoxazolinone (max. 270 mμ, ε = 4 200).

1,4-Benzoxazine-2,3-dione was prepared according to the method of Puxeddu and Sanna [8]. UV-Spectrum (in ethanol) max. 303 mμ, ε = 5 800.

3,4-Dihydro-2H-1,4-benzoxazine was prepared from 2H-1,4-benzoxazin-3(4H)-one by reduction with lithium aluminium hydride [2]. UV-Spectrum (in ethanol) max. 274 mμ, $\varepsilon = 5\,350$, max. 296, $\varepsilon = 3\,150$.

This investigation belongs to a research project under U.S. Public Law No. 480, 83rd Congress.

Amino Acid Composition of Seal Myoglobin I

NEVENKA M. RUMEN*

Medicinska Nobelinstitutet, Biokemiska Avdelningen, Stockholm, Sweden

The isolation and purification of seal myoglobin I has been described recently [1]. The quantitative composition of amino acids has been determined by the method of Moore and Stein [3] using Amberlite IR-120 columns. For each analysis, 20 mg of salt-free myoglobin I was dissolved in 6 N HCl, the solution was cooled in an ice bath and the tubes were evacuated with a water pump and sealed. The hydrolyses were conducted in pairs in an oven at 110°C for 20 and 70 h. The cooled tubes were opened and the contents centrifuged and evaporated to dryness over NaOH pellets in a vacuum desiccator at room temperature. The dry material was dissolved in a small amount of water and dried. Each, nearly colorless, residue was dissolved in 0.2 N sodium citrate buffer, pH 3.25 just before putting it on the column. A sample containing 0.0949 μmole of amino acids, calculated on the basis of protein, was used in each run.

The calculations are based on Moore and Stein's [3] values for color yields, and residues/mole are based on a molecular weight of 18 600 deduced from the iron content [1]. It has been possible to detect small peaks for methionine sulfoxide in 20 and 70 h hydrolysates. Table 1 shows the values obtained.

The amide ammonia values are not included in the summation of amino acid residues.

In order to provide a check on the amide NH_3 values calculated from the chromatographic results, the amide nitrogen was determined by two different methods, micro Kjeldahl and Nessler. For the Nessler nitrogen a solution of 3 mg of protein in 2 ml N H_2SO_4 was heated for 4, 6 and 8 h in a sealed tube at 105°C[4]. An ammonium sulfate solution was used as a standard. In the micro-Kjeldahl technique 22 mg of protein was heated with 0.9 ml of 6 N HCl for 20 h in a sealed tube at 110°C. The resulting ammonia was titrated with 0.5 N H_2SO_4 using an "Agla" micrometer

syringe. The Nessler results after 8 h hydrolyses were the same as the 20 h micro-Kjeldahl.

As Kendrew [5] has mentioned in *Structure and function in myoglobins and other proteins*, "myoglobins from different species have amino acid compositions which are broadly similar, but differ in detail". We may only confirm his statement by comparing the compositions of the purified myoglobins which are presently available, namely sperm whale [6], seal and horse [7] myoglobin. The results show that these myoglobins differ only in details.

The amino acid analysis of Mb II, Mb III, Mb IV and Mb V are in progress using the procedure of Moore and Stein.

I wish to thank Professor Hugo Theorell for his advice and Miss Ann-Marie Fridén for her able technical assistance.

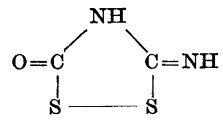
Structure of Rhodan Hydrate

ASBJÖRN HORDVIK

Chemical Institute, University of Bergen, Bergen, Norway

So far X-ray structure determinations of two unsaturated five-membered cyclic disulphides have been reported [1,2]. Observed bond lengths in the thiuret ion [1] and in 4 - methyl - 1,2 - dithia - 4 - *cyclo*pentene - 3 - thione [2] indicate that the five-membered ring has some aromatic character. This seems to explain the relatively high stability of unsaturated five-membered cyclic disulphides as contrasted with saturated ones. It is hoped that a determination of the molecular structure of rhodan hydrate will give further information that can be used to test this idea. The rhodan hydrate molecule has, according to Söderbäck [3], the following structure:



The preparation of rhodan hydrate has been described by Söderbäck [3,4], and the unit cell and space group have been reported by Foss [5]. The crystals are monoclinic, $a = 12.50$ Å, $b = 5.24$ Å, $c = 14.67$ Å,

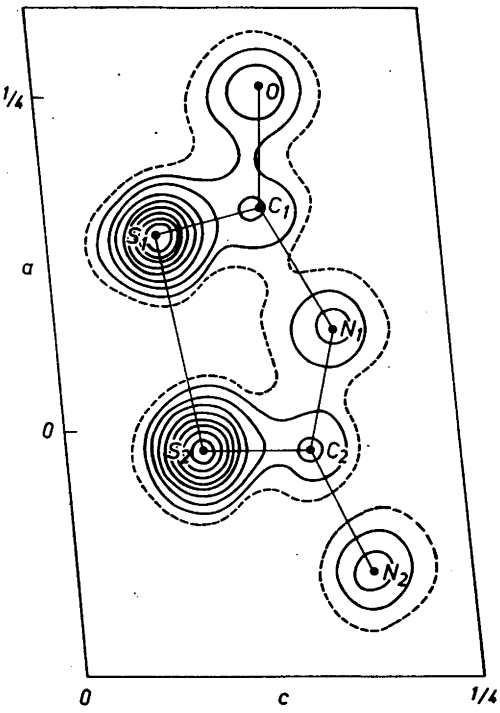


Fig. 1. Electron density projection of rhodan hydrate along the *b*-axis showing one asymmetric unit. Plane group *p*2 and origin in center of symmetry in the projection. Contours at arbitrary but equal intervals.

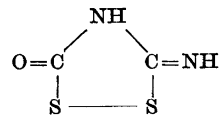
Structure of Rhodan Hydrate

ASBJÖRN HORDVIK

Chemical Institute, University of Bergen, Bergen, Norway

So far X-ray structure determinations of two unsaturated five-membered cyclic disulphides have been reported [1,2]. Observed bond lengths in the thiuret ion [1] and in 4 - methyl - 1,2 - dithia - 4 - *cyclo*pentene - 3 - thione [2] indicate that the five-membered ring has some aromatic character. This seems to explain the relatively high stability of unsaturated five-membered cyclic disulphides as contrasted with saturated ones. It is hoped that a determination of the molecular structure of rhodan hydrate will give further information that can be used to test this idea. The rhodan hydrate molecule has, according to Söderbäck [3], the following structure:



The preparation of rhodan hydrate has been described by Söderbäck [3,4], and the unit cell and space group have been reported by Foss [5]. The crystals are monoclinic, $a = 12.50$ Å, $b = 5.24$ Å, $c = 14.67$ Å,

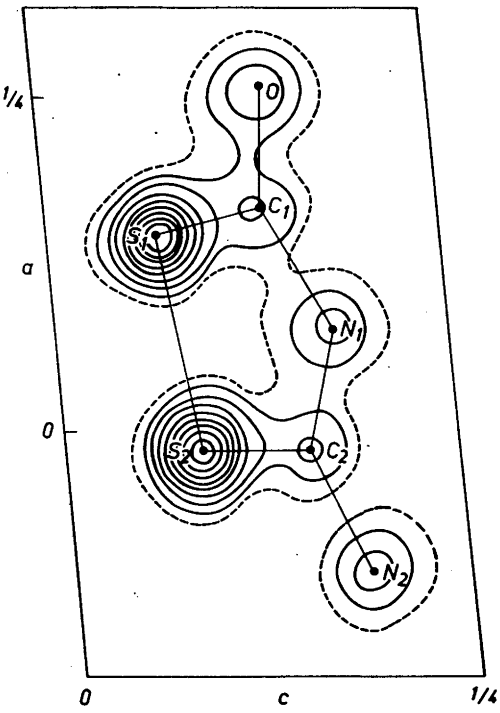


Fig. 1. Electron density projection of rhodan hydrate along the *b*-axis showing one asymmetric unit. Plane group *p*2 and origin in center of symmetry in the projection. Contours at arbitrary but equal intervals.

Table 1. Atomic coordinates, in fractions of corresponding cell edges.

	x	z
S_1	0.1470	0.0695
S_2	−0.0150	0.0865
C_1	0.1635	0.1365
C_2	−0.0135	0.1550
N_1	0.0760	0.1750
N_2	−0.1060	0.1885
O	0.2585	0.1450

$\beta = 95\ 1/2°$. Preliminary results of a complete crystal structure determination of rhodan hydrate are given here.

The space group of rhodan hydrate was found to be either $C2/c$ or C/c. The morphology of the crystals indicates [5] the presence of a twofold axis and thus the correctness of the centrosymmetric space group. The "average test" and "zero moment test" [6] also indicated centrosymmetry.

Attempts to solve the structure from Patterson projections did not succeed, and the solution was then sought by means of Harker Kasper inequalities and the "multiplication rule" [7]. This led to three possible sets of signs for the 35 strongest reflections in the b-axis projection. The molecule was recognised in one of the corresponding Fourier maps, and after three Fourier-refinements the reliability factor R was 0.115. The electron density map is reproduced in Fig. 1. The map shows that the cyclic form of rhodan hydrate, anticipated by Söderbäck [3], is correct. Further refinement will be carried out by means of $(F_o - F_c)$-technique.

The σ-Phase Ta_2Al

LARS-ERIK EDSHAMMAR and BO HOLMBERG

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

In the course of a study of the tantalum-aluminium system recently started at this Institute, the existens of a σ-type phase has been observed in samples of the approximate composition Ta_2Al prepared by arc-melting in an argon atmosphere.

The dimensions of the tetragonal unit cell obtained from a Guinier powder pattern were found to be:

$a = 9.828$ Å $\qquad c = 5.232$ Å

The axial ratio $c/a = 0.532$ is similar to that found for other σ-phases such as the one occurring in the nickel-vanadium system studied by Kasper and Waterstrat [1] using neutron diffraction techniques. Since the ratios of the atomic radii r_{Ta}/r_{Al} and r_V/r_{Ni} are comparable, the atomic distribution reported for the nickel-vanadinium phase was tentatively adopted for Ta_2Al:

Space-group: $D_{4h}^{14}-P4/mnm$.

Unit cell content: 10 Ta_2Al.

Table 1. The Guinier powder pattern of Ta_2Al ($CuK\alpha_1$ radiation).

$\beta = 95\ 1/2°$. Preliminary results of a complete crystal structure determination of rhodan hydrate are given here.

The space group of rhodan hydrate was found to be either $C2/c$ or C/c. The morphology of the crystals indicates [5] the presence of a twofold axis and thus the correctness of the centrosymmetric space group. The "average test" and "zero moment test" [6] also indicated centrosymmetry.

Attempts to solve the structure from Patterson projections did not succeed, and the solution was then sought by means of Harker Kasper inequalities and the "multiplication rule" [7]. This led to three possible sets of signs for the 35 strongest reflections in the b-axis projection. The molecule was recognised in one of the corresponding Fourier maps, and after three Fourier-refinements the reliability factor R was 0.115. The electron density map is reproduced in Fig. 1. The map shows that the cyclic form of rhodan hydrate, anticipated by Söderbäck [3], is correct. Further refinement will be carried out by means of $(F_o - F_c)$-technique.

* Line overlaps line of neighbouring phase.

(I) 2 Al in 2(*b*).
(II) 4 Ta in 4(*f*) with $x=0.103$.
(III) 8 Ta in 8(*i*) with $x=0.371$, $y=0.037$.
(IV) 8 Al in 8(*i*) with $x=0.566$, $y=0.240$.
(V) 8 Ta in 8(*j*) with $x=0.316$, $z=0.250$.

The powder diffraction pattern required by this atomic arrangement was found to be in satisfactory agreement with the observed data (*cf.* Table 1) which evidently shows that the $\sigma(Ta_2Al)$ phase is essentially ordered.

The existence of a σ-phase in the niobium-aluminium system was recently reported by McKinsey and Faulring [2]. The composition (Nb_2Al) and powder diffraction data suggest that this phase is analogous in structure to Ta_2Al.

Further studies on the tantalum-aluminium system are in progress.

The authors wish to express their sincere gratitude to Dr. Arne Magnéli for his never-failing interest and many valuable discussions. Thanks are due to Mr. A. Eriksson for his skilful experimental assistance.

The Crystal Structures of Hf_3Al_2 and of $Hf_5Al_3O_x$

LARS-ERIK EDSHAMMAR

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The existence of the phases Hf_3Al_2, $HfAl_2$, and $HfAl_3$ in the hafnium-aluminium system was reported in a previous note [1] which also gave the structure types of the two latter phases. Further studies on this system carried out on specimens obtained by arc-melting in an argon atmosphere followed by quenching to room temperature has revealed the existence of two further phases having the compositions Hf_3Al_2 and HfAl.

It was also observed that samples of compositions $HfAl_{0.5-0.7}$ gave a few very weak extra lines which could not be attributed to any of the phases mentioned above but were found to be greatly reminiscent of the strong reflexions [1] given by the oxygen-stabilized phase $Zr_5Al_3O_x$. The isomorphism thus suggested between the hafnium and the zirconium alloy phases was confirmed by gradually adding oxygen (as HfO_2) to the samples. Attempts to prepare a hafnium analogue of the oxygen-free phase Zr_5Al_3 of $D8_m$ type were unsuccessful.

The unit cell of Hf_3Al_2 was found to be tetragonal with the following dimensions:

$a = 7.535$ Å $\qquad c = 6.906$ Å

The powder pattern of the phase demonstrates clearly that it is isomorphous with the corresponding phase in the zirconium-aluminium system. The space group is $D_{4h}^{14}-P4_2/mnm$ and the atomic positions are the same as given by Wilson [2] for Zr_3Al_2:

8 Al in 8(*j*) with $x=\frac{1}{8}$, $z=0.21$.
4 Hf in 4(*f*) with $x=0.34$.
4 Hf in 4(*g*) with $x=0.20$.
4 Hf in 4(*d*).

The agreement between observed and calculated powder patterns is satisfactory.

The powder pattern of $Hf_5Al_3O_x$ could be indexed assuming a hexagonal unit cell with the dimensions:

$a = 8.066$ Å $\qquad c = 5.678$ Å

The following structure of $Hf_5Al_3O_x$ was derived from the powder data:

Cell content: 2 $Hf_5Al_3O_x$.

Space-group: $D_{6h}^3-P6_3/mcm$.

4 Hf in 4(*d*).
6 Hf in 6(*g*) with $x=0.23$.
6 Al in 6(*g*) with $x=0.59$.

The oxygen atoms have been neglected and no attempt was made to estimate the oxygen contents. It seems likely, however, that the oxygen atoms are located in interstitial positions 000 or $00\frac{1}{2}$ as suggested by Aronsson [3] for various $D8_8$ phases stabilized by small non-metal atoms.

The author wishes to express his gratitude to Dr. A. Magnéli for his kind encouragement and many helpful discussions.

Infrared Spectrophotometry: A Semi-Micro Die for Oblong KBr-pellets

FREDRIK MÖHL

Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden; Institute of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

A macro-die for oblong pellets has been described by Kirkland [1]. His pellet was pressed in a rather complicated tool, which was afterwards inserted in the spectrophotometer.

We needed a similar device, but as we wanted to store the samples afterwards and also wanted a smaller pellet (we had earlier made a beam-condensing microscope for our Perkin-Elmer model 21) [2], Kirkland's die was not suitable for our purpose. We therefore constructed a die to press 2.5 × 0.3 mm² pellets in simple plate disks. Semi-micro and micro dies pressing pellets in plate disks have been described [3] and are also commercially available, but these make cylindrical pellets, which obviously means either a waste of substance or a pellet much too small to fill the image of the monochromator's entrance slit. Manufacturing difficulties seem to have prevented the constructions of semi-micro dies for oblong pellets.

Fig. 1 shows our die. The plunger slides in a guide made in two parts forming a cylinder, with the plane of intersection longitudinal but slightly off axis. Into the plane intersection surface of the larger part is milled a space for the plunger and pusher.

Straight through the guide an evacuating hole is bored (across the plunger-space), terminating at each end in a circular groove around the guide. The heavy-duty contact-surface between plunger and pusher is cylindrical. This is to avoid any tilting moment on the plunger.

The power is transmitted to the pusher by a cylindrical piston. Two O-rings ensure tightness, and their compressibility allows a sufficient stroke for the piston.

The disk is punched from an 0.3 mm stainless steel plate. It is kept in position in the die by 3 pins protruding from the guide. One of the pins is slimmer than the others and does not fit in its hole in the disk, it serves only to prevent the disk being turned wrongly. A jig is used when the pin-holes are bored in the disk.

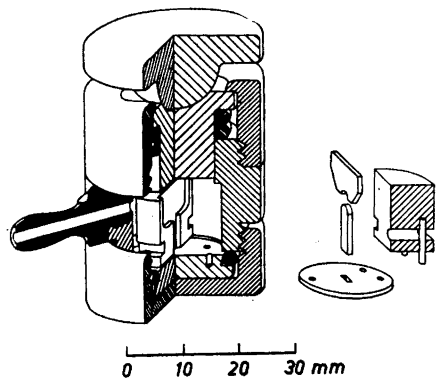

Fig. 1. Die in section. Disk, plunger, pusher and one of the guide halves (in section) lifted out and shown beside the die.

Beneath the disk is a polished bottom-plate kept firmly in position by a screw cap and sealed by an O-ring.

The guide should be made of stainless steel and the plunger, pusher and bottom-plate of hardened alloyed steel.

It proved difficult to make the oblong pellet-hole in the right place in the disk. We finally solved the problem by using the die as a punching tool. Before the punching, the plunger is exchanged for a punch and the bottom-plate for a bolster made in two halves in the same way as the guide.

To make a pellet one turns the die upside down, removes the cap and bottom-plate and pushes down the plunger with a clean plate-strip. Then a mixture of about 35 μg of substance and 1 mg of KBr is filled into the plunger-space. (The operator should wear a mask while handling the tiny amount of powder, to protect it against his breath). The disk, bottom-plate and cap are placed in position (cap tightened firmly) and the pellet can be pressed in the usual way. The force on the piston should be 820 newtons.

The best results are obtained with 30—40 μg of substance, but even less will do (if some loss of detail may be tolerated), as shown in Fig. 2.

To make the pellet 20 μg of 2DL-methyltetracosanoic acid and 1 mg of KBr were

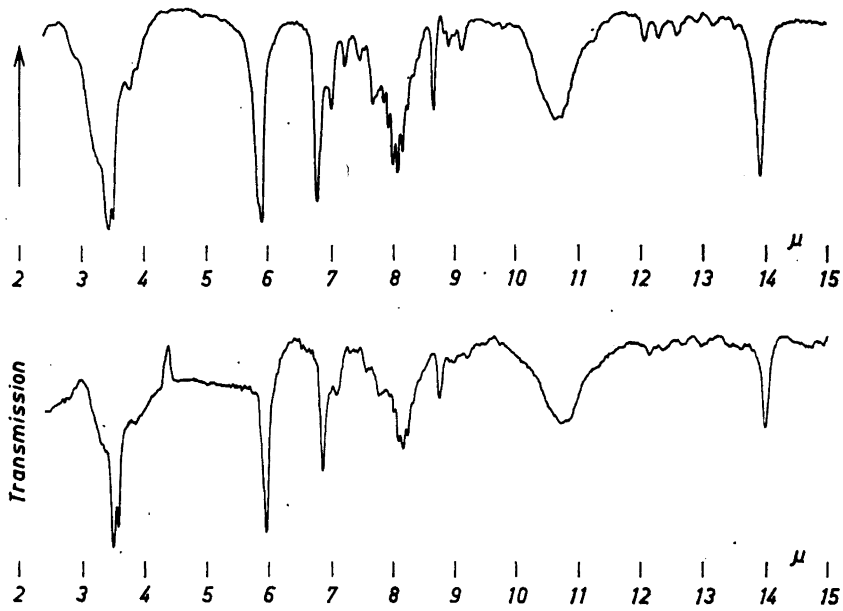

Fig. 2. Spectra of 2 DL-methyltetracosanoic acid. The macro spectrum (top) was made from a circular pellet measuring 13 mm in diameter and containing 3 mg of substance in 300 mg of KBr. The semi-micro spectrum (bottom) was made from a 2.5 × 0.3 mm^2 pellet containing 20 μg of substance in 1 mg of KBr. Spectra scanned at 4 and 6 min/micron, respectively. Slit program was 927 for both.

weighed out and mixed thoroughly with a small spatula (not ground in a mortar, as this would entail considerable loss of material). The slow scanning (6 min/micron) is due not so much to the sample as to the microscope, which transmits only a fraction of the available energy, most of it being masked off by the Schwarzschild condenser. (The construction with elliptic mirrors developed simultaneously by Perkin-Elmer is much better in this respect. But unfortunately it is not a twin device and cannot be used for the comparison of two samples.)

The oblong pellet transmits as much energy as a circular pellet of 6.5 times its area. This of course applies also to a macro pellet, provided it can be brought sufficiently close to focus. The construction described here seems also to be well suited for macro dies.

In a future version of the die we are planning to make the guide conical instead of cylindrical, so that it can be easily lifted out and taken apart for cleaning.

Acknowledgements. The author wants to thank Mr Per Olsson, Uppsala, for making the die, and Mr Donald Burton, Stockholm, for idiomatic corrections of the English text.

A Simple Device for Automatic Equilibration of Paper Chromatograms

LENNART KRABISCH and JAN SJÖVALL

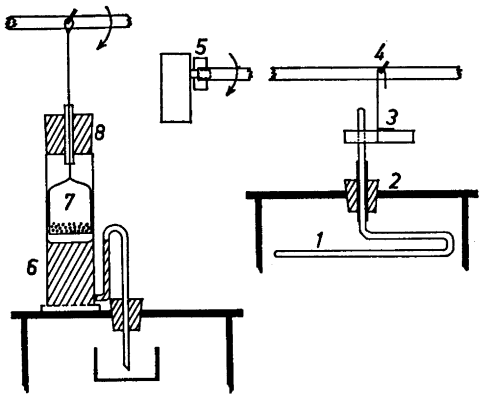
Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

In paper chromatography, it is often necessary to equilibrate the papers with the vapours of the solvents in the chromatographic chamber before they are brought into contact with the mobile phase. Much time would be saved if this contact could be achieved automatically so that the chromatography could start at any time during the night. Delivery of mobile phase from reservoirs by the automatic turning of a stopcock has been described [1-3]. For the chromatography of bile acids [4] we have used a simple and inexpensive device which can be applied to ascending as well as descending chromatography and which can be adapted to suit most sizes of chromatographic vessels.

Since the completion of this work an automatic solvent addition funnel based on a siphon principle has been described [5].

Description of the apparatus. The figures refer to the diagram.

Ascending chromatography. The papers are suspended in the vessel from a bent glass rod (1) inserted into and emerging from a piece of glass tubing which is fixed in a cork (2) placed in a hole in the covering glass plate. The diameter of the glass tubing should be just large enough to permit free vertical movement of the glass rod. With the aid of a clothespin the glass rod is attached to the timer unit with a piece of bent brass wire (3) so that the lower ends of the chromatograms are about one cm above the mobile phase on the bottom of the chromatographic chamber. The timer unit consists of a brass tubing fitted with small spin (4) on which the glass rods with the papers are hung. One end of the brass tubing is connected with the winding screw for the alarm (5) of an alarm clock, the other end is loosely supported in a bearing. The connection between the brass tubing and the clock should be made so that it is easy to take the pieces apart. The clock is adjusted to a predetermined time and when the alarm rings the papers are lowered into the solvent. By a proper adjustment of the clothespin their fall is stopped when they have descended into the mobile phase.



Descending chromatography. The same timer unit is used as for the ascending technique. A siphon made of a measuring cylinder (6) is placed on the glass cover of the tank. The glass tubing is introduced through a cork in a hole in the covering plate, the tip being in position just above the chromatograms in the trough. The desired amount of mobile phase is introduced into the cylinder (maximum just below the bend of the siphon) and a cylindrical glass bulb containing leadshot (7) is cautiously introduced and suspended above the solvent surface in the cylinder. The bulb has a diameter about 3 mm less than the inner diameter of the cylinder. It is attached to the timer unit with a thin silver wire hung on one of the pins of the brass tubing. The measuring cylinder is stoppered with a cork and the silver wire passes through a capillary tube in the cork (8). When the alarm rings the glass bulb hanging above the solvent surface falls and the mobile phase is emptied into the trough. The larger the volume of the bulb, the smaller is the minimum volume that can be drained from the cylinder.

The device described has been in constant use in our laboratory for a year. As judged from the chromatograms, the entrance hole for the glass rod in ascending chromatography and the hole for the silver wire in descending chromatography do not cause changes in the vapour equilibration with our phase systems. The timer unit has the advantage that it can be used for several chromatographies at the same time,

irrespectively of whether the ascending or the descending technique is used. The use of an ordinary alarm clock makes the apparatus inexpensive but if the equilibration time must exceed eleven hours another type of timer is required.

A Note on the Action of Firefly-Extracts on ATP

B. O. HANSEN* and JOHN GRAAE

Institute of Biological Chemistry, University of Copenhagen, Denmark

Use of the enzyme system from *Photinus pyralis* for the determination of minor amounts of ATP has been suggested and further a method implying it has been described by Strehler and Totter [1]. In order to study the extent of the postulated linear dependence of light intensity on ATP concentration experiments were carried out with different amounts of firefly-extracts and of ATP.

The experiments were carried out in small test tubes closed with a rubber stopper. ATP solution, enzyme extract and either arsenate buffer or water was mixed by rapid shaking. Light intensity was then determined by a photometer. If we suppose that light intensity is a direct measure of the reaction velocity and accept that the phototube (type RCA 1-P-21) is linear in the spectral area in question [2], then the photometer readings directly express reaction velocity in arbitrary units. It is known that oxygen is required for the reaction but this is supposed to be present in a concentration that is sufficient for the reaction, for two reasons: First it

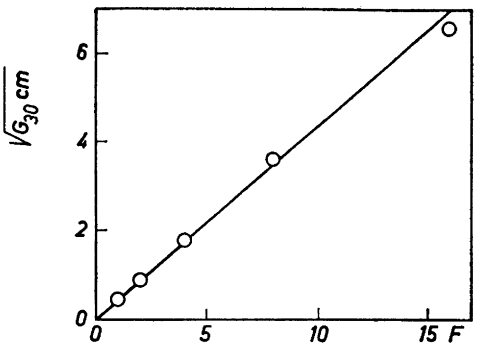

Fig. 1. Abscissa: Concentration of firefly-extract in arbitrary units. Ordinate: Square root of galvanometer deflection measured 30 sec. after start of experiment. Each experiment was made with a mixture of 500 μl water, 100 μl ATP solution (34 μg/100 μl) and 200 μl firefly-extract. t = 25.1°C.

is demonstrated by Hastings *et al.*[3] that only decreasing oxygen pressure to a very minute fraction of the normal has any influence on the reaction and secondly, we have demonstrated that bubbling of atmospheric air through the test tubes did not restore activity when the light intensity had fallen to approximately zero. Yet activity could be restored by the addition of either ATP or firefly extract de-

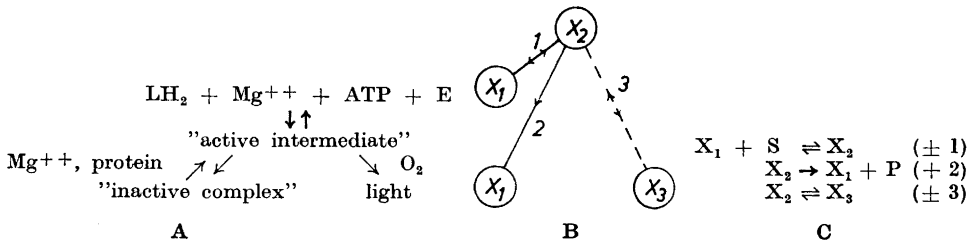

Fig. 3. A. Reaction scheme suggested by McElroy *et al.*[5] for the luciferase reaction. (E = enzyme;LH_2 = reduced luciferin). *B.* Reaction scheme suggested by Christiansen [6] to be the general scheme for a reaction following the Henri-Michaelis chronometric integral. (X_1, X_2 and X_3 are different forms of the enzyme or combinations of enzyme and substrate.) *C.* The same as *B*, written as ordinary equations. (S = substrate and P = products.)

pending on the initial ratio between these two components.

The effect of varying the amount of firefly extract is shown in Fig. 1. It is seen that light intensity measured 30 sec. after mixing the reagents is proportional to the square of the concentration of firefly extract. This is in good agreement with the commonly accepted fact that the extract contains two components that are important for the reaction, the enzyme luciferase and another component, luciferin [3,4].

The dependence of reaction velocity on ATP concentration was studied too. It is seen from Fig. 2 that the reaction kinetics is in accordance with the Henri-Michaelis scheme, when initial velocity is measured 30 sec. after mixing. Frequent readings during initial few minutes do, however, not show reaction kinetics in accordance with a normal Henri-Michaelis reaction, as the extremely rapid initial fall in light intensity is not caused by a decrease in the concentrations of the reactants [3]. To explain this it has been suggested by McElroy *et al.*[5] that part of the luciferase in one way or another is reversibly inactivated (Fig. 3). The scheme suggested for this particular reaction is then identical with the one proposed by Christiansen to be the general scheme for the simplest enzymatic reaction. It is reasonable to suggest that the luciferase reaction differs from the simple enzymatic reactions by approaching steady state with respect to reaction ± 3 (Fig. 3) after a few minutes instead of immediately.

A similar reaction mechanism is described by Andersen [7] in the case with arylsulphatase A, only in this case steady state with respect to the inactivating reaction was reached about 60 min. after the initiation.

*iso*Thiocyanates XXXVIII *. Glucocapangulin, a Novel *iso*Thiocyanate-Producing Glucoside

ANDERS KJÆR, HELENE THOMSEN and (in part) S. E. HANSEN

Organic Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark

Capparis angulata Ruiz et Pav. *(Capparidaceae)* is a shrubby xerophyte indigenous to the coastal regions of Northern Peru. A seed specimen of this plant, made available to us **, possessed a pungent taste, suggestive of the presence of *iso*thiocyanate-producing glycosides. In fact, paper chromatography of an aqueous-methanolic extract of the seed embryos revealed the presence of a single glycoside with an R_B-value [1] of 1.05 in *n*-butanol: acetic acid:water (4:1:5). Enzymic fission with myrosinase produced an ether-soluble *iso*thiocyanate, convertible by methanolic ammonia into a thiourea derivative which on paper chromatography in water-saturated chloroform, migrated at a rate corresponding to an R_{ph}-value [2] of 1.04.

When a crude glycoside fraction, prepared in the usual way from defatted seed embryos (30 g) by extraction with 70 % methanol and subsequent purification on acid-washed alumina [3], was subjected to acetylation [4,5], a water-soluble, crystalline glycoside acetate monohydrate (3 g) was obtained in form of the potassium salt. A pure specimen (from 96 % ethanol), m. p. 168–169° (3°/min.)***, $[\alpha]_D^{22}$ −16.5° (*c* 0.85, CH_3OH), −19.0° (*c* 1.2, H_2O), gave analytical data concordant with the composition $C_{23}H_{32}O_{14}NS_2K,H_2O$. (Found: C 40.46; H 5.27; N 2.10; S 10.08; K 5.99; H_2O 3.0 (Karl Fischer). Calc.: C 40.30; H 5.23; N 2.13; S 9.78; K 5.96; H_2O 2.8), differing from that of all heretofore isolated *iso*thiocyanate glucosides [6]. Upon hydrolysis with conc. HCl at room temperature, the glycoside acetate afforded *hydroxylamine*, identified by paper chromatography [7]. Treatment of the acetate with methanolic ammonia resulted in formation of the free glucoside as a colourless, glassy product. Enzymic fission of the latter in phosphate buffer at pH 6.7 with a sulphate-free myrosinase preparation resulted in liberation of *sulphate* and formation of an ether-extractable mustard oil. In the aqueous phase, enzymically liberated *glucose* could be identified by paper chromatography in several solvent systems. Hence, the new glycoside is of the usual type [7] and accordingly has been named *glucocapangulin*.

On the likely assumption that acetylated glucocapangulin is a tetraacetate, its composition allows for a side-chain of $C_7H_{13}O$. The clue to its identification was found in a conspicuous band at 1 705 cm^{-1} (KBr) in the otherwise orthodox IR-spectrum of acetyl-glucocapangulin, indicative of a carbonyl function in its side-chain. This suspicion was confirmed by a positive qualitative test with 2,4-dinitrophenylhydrazine. Aldehyde or methyl ketone structures were ruled out by standard tests. Since the enzymic hydrolysis of glucocapangulin did not proceed entirely satisfactory, recourse was taken to hydrolytic degradation of the crystalline acetate with 20 % HCl at 50° for 2.5 h. As expected from acid formation in analogous cases [7], a colourless crystalline keto-acid, m. p. 32° (from hexane), was isolated in about 50 % yield. The partial structure, $C_6H_{13}(CO)(COOH)$, was established for this acid by analysis of its *S-benzylthiuronium salt*, m. p. 132°. (Found: C 58.90; H 7.58; N 8.54; S 10.07. Calc. for $C_{16}H_{24}O_3N_2S$: C 59.26; H 7.46; N 8.64; S 9.88), *p-bromophenacyl ester*, m. p. 89°, (Found: C 54.21; H 5.48; Br 22.36. Calc. for $C_{16}H_{19}O_4Br$: C 54.11; H 5.39; Br 22.51), and *semicarbazone*, m. p. 186°. (Found: C 50.22; H 7.97; N 19.52. Calc. for $C_9H_{17}O_3N_3$: C 50.22; H 7.96; N 19.52).

Wolff-Kishner reduction [8] of the keto-acid (88 mg) afforded a reduced acid, characterized as its S-benzylthiuronium salt (40 mg), m. p. 147°, and identical with *octanoic acid*, as apparent from undepressed mixed melting point and coinciding infrared spectra and X-ray diffraction patterns

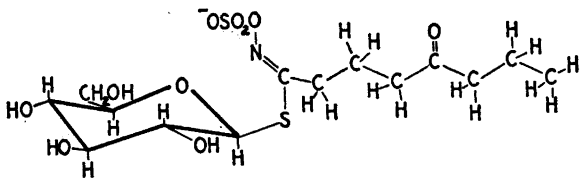
*** All melting points are determined in capillary tubes on immersed thermometers in an Anschütz-Hershberg apparatus. When not otherwise indicated, the rate of heating near the melting points has been less than 1°/min.



II

of the above salt and one prepared from authentic octanoic acid.

Assignment of the keto-grouping to the 5-position of the unbranched C_8-acid was indirectly rendered possible on basis of the following data. 2-Oxooctanoic acid was ruled out when its S-benzylthiuronium salt was prepared and found to melt at 156°. (Found: C 59.32; H 7.43; N 8.62), the 3-oxo-isomeride is incompatible with the stability properties of the present acid, 4-oxooctanoic acid semicarbazone melts at 153° [9], 6-oxooctanoic acid has the m. p. 52° [10] and, furthermore, is disqualified by the fact that the IR-spectrum of the 'natural' acid is devoid of the skeletal vibration at 720 – 750 cm^{-1} diagnostic of the $(CH_2)_4$-grouping. Finally, negative haloform reaction of the naturally derived acid excludes 7-oxooctanoic acid as a possibility.

$$CH_3CH_2CH_2COCH_2CH_2CH_2COOH$$

I

Confirmation of structure (I) for the acid hydrolysis product of acetylated glucocapangulin was eventually obtained by synthesis of authentic 5-oxooctanoic acid (m. p. 32.8°) according to Yoho and Levine [11]. Comparison of the S-benzylthiuronium salts, *p*-bromophenacyl esters and semicarbazones of the naturally derived and synthetic keto-acid by means of mixed melting points and infra-red spectra left no doubt as to their identity.

From the above experimental data, it follows that the glucocapangulin ion most likely possesses the traditional structure (II) and thus represents the first example of a glucoside of this type containing a carbonyl function. Biogenetically, it may arise from intermediates formed in the fatty acid cycle.

A full account of the present work will be presented in a forthcoming communication in this journal.

The assistance of Miss E. Vesterager in the synthetic work is acknowledged. The authors are thankful to Dr. E. Krogh Andersen for the X-ray diffraction patterns. Microanalyses have been performed by Messrs. G. Cornali and W. Egger. The Crystal Structure of Iron(II) Sulphate Pentahydrate Glycine

INGVAR LINDQVIST and ROBERT ROSENSTEIN

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The bonding between iron and glycine in this compound has never been elucidated, and because of the clinical interest of the compound, AB Pharmacia, Uppsala, has suggested to us to determine the crystal structure so far that the coordination in the compound could be considered as definitely established.

Experimental. Crystals were prepared from a hot concentrated solution of the salt plus an excess of sulphuric acid. The crystallization is best done in an inert atmosphere to prevent oxidation. The carefully dried crystals, which have a pale greenish-blue colour are, however, stable in air.

Roughly prismatic crystals with a cross-section of about 0.02 × 0.02 mm² were used for the X-ray work. Weissenberg photographs were taken of three such crystals around the three almost perpendicular triclinic axes. Lattice parameters were obtained from high-order reflections in the equatorial zones. $a = 6.86$ Å, $b = 13.6$ Å, $c = 6.07$ Å, $\alpha = 96.1°$ $\beta = 96.8°$, $\gamma = 92.5°$. Probable space-group is $P\bar{1}$. Assuming two formula units per cell, the calculated density is 1.92 gcm^{-3}, obs. 1.87 gcm^{-3}, measured by a pycnometric method.

Cu-K radiation could be employed, in spite of the iron content. The intensities were estimated visually by comparison with a standard scale.

Crystal structure. The Patterson projections $P(xy)$ and $P(yz)$ were calculated and the Fe and S positions were derived from these projections. The positions of the light atoms were determined by successive electron density and difference maps. The approximate parameters determined in this way are:

O_1	(0.178, 0.055, 0.708)
O_2	(0.104, 0.133, 0.205)
O_3	(0.759, 0.085, 0.958)
O_4	(0.488, 0.123, 0.287)
O_5	(0.770, 0.140, 0.560)
O_6	(0.655, 0.285, 0.403)
O_7	(0.460, 0.205, 0.670)
O_8	(0.169, 0.383, 0.535)
O_9	(0.633, 0.463, 0.681)
O_{10}	(0.169, 0.343, 0.067)
O_{11}	(0.663, 0.472, 0.869)
C_1	(0.023, 0.322, 0.858)
C_2	(0.149, 0.398, 0.737)
N	(0.003, 0.345, 0.100)
S	(0.588, 0.1885, 0.487)
Fe_1	(0,0,0)
Fe_2	($\frac{1}{2}$,$\frac{1}{2}$,0)

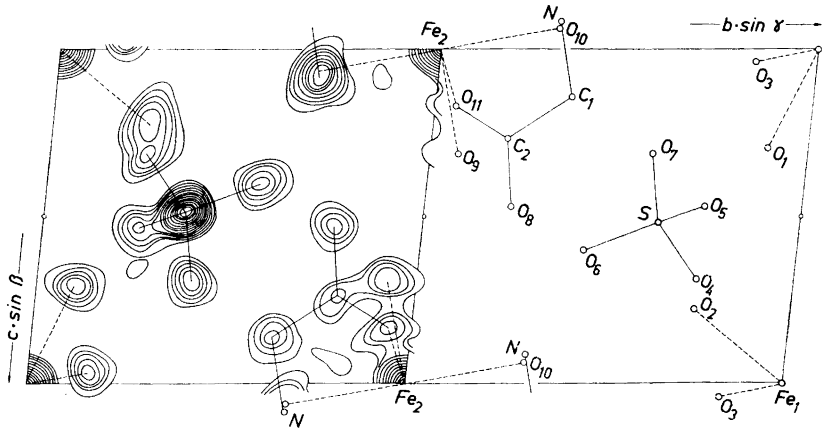

Fig. 1a. Iron (II) sulfate pentahydrate glycine: a axis projection, showing the complete unit cell. Electron density contours are drawn for the unique portion to the left and the corresponding atomic positions are indicated to the right across the center of symmetry.

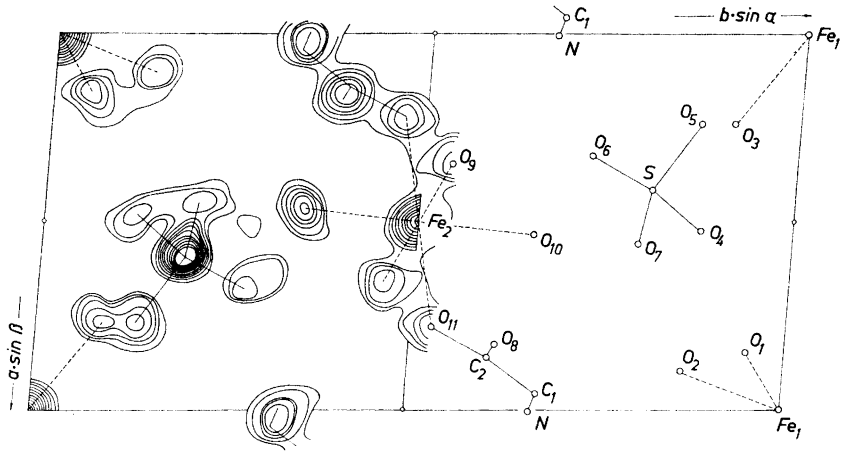

Fig. 1b Iron (II) sulfate pentahydrate glycine: *c* axis projection, showing the complete unit cell. Electron density contours are drawn for the unique portion to the left and the corresponding atomic positions are indicated to the right across the center of symmetry.

Average temperature factors for the two projections, (B *hk*0) : oxygen 3.0, carbon 3.8, nitrogen 3.4, sulfur 1.51, iron 1.62 Å², B (0*kl*): oxygen 2.5, carbon 3.3, nitrogen 2.9, sulfur 0.89, iron 1.00 Å². The residual error indices are R (*kh*0) = 0.14, R (0*kl*) = 0.18.

The structure is shown together with two electron density maps in Fig. 1*a* and *b*. It is built up of two different kinds of complex cations: $Fe(H_2O)_6^{2+}$ and $Fe(H_2O)_4(^-OOCCH_2NH_3^+)_2^{2+}$. In the latter ion one of the oxygen atoms of the carboxyl group in the glycine »Zwitterion» is bonded to the central Fe^{2+} ion. The two glycine molecules are in trans positions. These complex cations obviously can build up a structure, together with the sulphate ions, with more favorable lattice energy than one containing only one type of cation $Fe(H_2O)_5(^-OOCCH_2NH_3^+)^{2+}$. The accuracy of the structure determination does not permit a detailed discussion of the bond lengths but it is quite clear that a complicated hydrogen bridge system joins the different parts of the structure. The aim with this structure determination has, however, only been to establish the co-ordination around the Fe^{2+} ions and this problem has been definitely solved. Every suggestion about chelate bonding with the amino group can thus be rejected.

This work has been supported by a grant from *AB Pharmacia* which is gratefully acknowledged.

Finally we wish to thank Professor Hägg for all facilities put at our disposal.

A Note on the Structure of Barium Tetraborate

J. KROGH-MOE

Svenska Silikatforskningsinstitutet, Göteborg, Sweden

Crystalline barium tetraborate, $BaO \cdot 4B_2O_3$, was obtained by Levin and McMurdie as a congruently melting phase in the system barium oxide — boron oxide[1]. Single crystals of this phase were prepared during the present study by fusing barium carbonate with the calculated amount of boric acid in a platinum

crucible at 1 000°C, and crystallizing the melt at 800°C. Weissenberg and oscillation X-ray photographs, taken about three axes of these crystals, showed an orthorhombic symmetry with the following unit cell dimensions:

$$a = 8.56 \text{ Å}$$
$$b = 2 \times 8.69 \text{ Å}$$
$$c = 13.20 \text{ Å}$$

A very weak doubling along the b axes was observed and is indicated in the above figures by writing 2×8.69 Å instead of 17.38 Å. The calculated density is 2.91 g/cm³ with 8 formula units of $BaO \cdot 4B_2O_3$ in the cell.

The Weissenberg diagrams disclose a pronounced pseudo tetragonal symmetry of barium tetraborate. This agrees with the optical properties of the compound. Thus Levin and McMurdie were unable to decide whether the crystals were uniaxial or biaxial negative [1]. The same authors also noted that the crystals exhibit polysynthetic twinning. Some of the present X-ray diagrams show twinning, in which the twins have paralell c-axes with the 010 plane facing the 100 plane.

Approximate barium positions can be determined by inspecting the X-ray diagrams. From the rotation diagram around the c-axes it is seen that the general hkl reflections are on average considerably stronger for even values of l than for odd. Therefore, as a first approximation, a reduced cell with halved b and c axes may be considered for the heavy barium atoms. This pseudo cell contains two barium atoms. Further information is obtained from equatorial and non-equatorial Weissenberg photograms. It is found that reflections are often weak or missing whenever $h + k' + l' = 2n + 1$. Here the indices k' and l' ($= l/2$) refer to the pseudo cell with halved b and c axes. This partially fulfilled condition of systematic extinctions suggests an approximately body-centered arrangement of the barium atoms in the pseudo cell, where the barium atoms thus can be given the preliminary parameter values 0,0,0 and $\frac{1}{2},\frac{1}{2},\frac{1}{2}$. The shortest distance between two barium atoms is 6.94 Å with these parameter values.

The correct space group of barium tetraborate is difficult to decide because of the pseudo symmetries. The final space group determination will therefore have to await further work.

The Bacteriostatic Action of Benzoic and Salicylic Acids

III. The Effect on Pyruvate and Acetate Oxidation by Different Organisms

INGMAR BOSUND

State Dairy Research Station, Alnarp, Sweden

The influence of benzoic and salicylic acids on pyruvate and acetate oxidation by resting cells of different organisms was investigated.

Both inhibitors blocked pyruvate oxidation at the acetate level in experiments with washed cells of *Proteus vulgaris* and *Escherichia coli* harvested from a medium containing amino acids and additional carbon sources. A similar but less marked effect was observed with cells pre-grown without added amino acids, but not in experiments with cells cultivated in a medium with acetate as the sole carbon source.

Benzoic and salicylic acids did not produce a corresponding effect on pyruvate oxidation by *Pseudomonas fluorescens* or baker's yeast in a similar investigation with these organisms. In the presence of benzoic acid washed cells of *Ps. fluorescens* oxidized acetate completely to CO_2 and H_2O, if the cells were pre-grown in a medium with acetate as the sole carbon source.

The experiments with baker's yeast were performed at three different pH-values and included an investigation of the influence of benzoic and salicylic acids on growth and on endogenous respiration. It was shown that all effects could be ascribed solely to the undissociated molecules of the acids. With both inhibitors there was close correspondence between inhibition of acetate oxidation and inhibition of growth at all pH-values.

Previously in this investigation [1,2] the influence of benzoic and salicylic acids on the oxidation of glucose, pyruvate and acetate by washed cells of *Proteus vulgaris* was studied. It was observed that both inhibitors specifically blocked glucose and pyruvate oxidation at the acetate level in experiments with cells grown in a medium containing glucose and amino acids. When the cells were grown with acetate as the sole carbon source no such inhibition was noticed — on the contrary, in such experiments, both benzoic and salicylic acids caused an increase in the total CO_2-output, especially from pyruvate.

These results clearly indicate that the influence of benzoic and salicylic acids on the metabolism of resting cells is largely determined by the prehistory of the cells. It seemed important to investigate this relationship somewhat further and at the same time include other organisms in the study. For this purpose *Escherichia coli*, *Pseudomonas fluorescens* and baker's yeast were selected.

It was suggested previously in this work that the results obtained with *P. vulgaris* might be associated with the presence of a special type of pyruvate oxidase in this organism. This enzyme, which transforms pyruvate directly into acetate without intermediate formation of any metabolically active C_2-compound (Moyed and O'Kane[3]), has also been shown to occur in *E. coli* (Razzell and Gunsalus [4]). It was therefore considered of interest to compare the effects of benzoic and salicylic acids on pyruvate oxidation by these organisms.

Ps. fluorescens and baker's yeast were selected as test organisms for essentially two reasons. Firstly, it was considered of importance to study the effects of the inhibitors under investigation on organisms essentially different from *P. vulgaris* and *E. coli*. Secondly, it was desirable to choose organisms capable of growing with acetate as the sole carbon source and with fairly known pyruvate metabolism.

EXPERIMENTAL

Organisms. The strain of *P. vulgaris* used in this investigation was the same as before. *E. coli* (NCTC 8196) and *Ps. fluorescens* (NCTC 950) were obtained from the National Collection of Type Cultures, London. Baker's yeast was supplied by Svenska Jästfabriks AB.

Media and growth conditions. The liquid media employed for cultivation of *P. vulgaris* and *E. coli* in this investigation were essentially the same as those previously [2] described (medium A containing glucose and casein hydrolysate and medium B with acetate as the sole source of carbon). In some experiments, however, medium A was modified by replacing glucose by sodium pyruvate and sodium succinate (final concentration, 0.5 g per liter of each), and in others casein hydrolysate was omitted.

In all experiments using liquid culture media, the inoculations were made with heavy amounts of washed cells (generally grown in the same media), and the cultures were adequately aerated during growth. The cells were harvested early in the logarithmic growth phase (generally 3—4 h after inoculation), which was ascertained by turbidity measurements. This procedure made it unnecessary to sterilize the growth medium.

Ps. fluorescens was grown for 24—48 h on Petri dishes containing substrates with the same composition as above (nicotinamide omitted) and solidified by addition of 1.5 % agar. In experiments where *Ps. fluorescens* was inoculated in liquid media, aerated or non-aerated, the growth rate was generally low, and the total amount of cell mass obtained was small.

Preparation of cell suspensions. *P. vulgaris* and *E. coli* were harvested from the liquid media by centrifugation, washed and suspended in phosphate buffer at appropriate pH as described previously [1].

Ps. fluorescens was harvested by washing off the colonies from the agar surface with 1/15 M phosphate buffer. The resulting cell suspension was centrifuged, and the cells were washed twice in 1/15 M phosphate buffer. In the work with baker's yeast, the yeast cells were suspended in buffer and aerated for 1 h prior to the experiments in order to reduce endogenous respiration. Some of the studies were performed at pH-values, where phosphate was unsuitable as buffer substance. In these cases 1/15 M potassium biphthalate or a mixture of 1/15 M potassium biphthalate and 1/15 M potassium phosphate was used. It was ascertained by experiments that the biphthalate ion had no influence on the rates of oxygen consumption recorded in the respiration studies.

Respiration studies. The procedure followed was essentially the same as that previously described[1]. The values recorded in figures and tables are, as before, in appropriate cases corrected for endogenous respiration.

RESULTS

Experiments with Proteus vulgaris. Respiration studies described in the first two parts of this series show, that the influence of benzoic and salicylic acids on the metabolism of resting cells varies considerably with conditions prevailing during cultivation of the cells. Especially the composition of the growth medium seems to be of importance. This is demonstrated by the fact that these inhibitors block glucose and pyruvate oxidation by resting cells of *P. vulgaris* at the acetate level, if the cells are pre-grown in glucose-casein hydrolysate medium, but not if the cells are grown in acetate medium. In this work some additional experiments were performed in order to emphasize the validity of these results.

The glucose-casein hydrolysate medium previously employed (medium A) was modified by exchanging glucose for pyruvate and succinate. This supplied the growth medium with an excess of two easily utilizable carbon sources, which as well could give rise to large amounts of starting material for the operation of the TCA cycle. The medium was inoculated with a large amount of cells, which were harvested as soon as the logarithmic growth phase was established. This procedure, besides insuring reproducible conditions of growth, was thought to give rise to cells with a high ability to oxidize acetate. It is evident from Fig. 1 A, however, that benzoic acid, even with such cells, completely inhibited pyruvate oxidation at the acetate level (similar results were obtained with salicylic acid). This inhibition was not affected by simultaneous oxidation of succinate added together with the pyruvate. Previously in this work [2] small amounts of succinate were shown markedly to reduce inhibition of acetate oxidation by benzoic acid.

Fig. 1 B illustrates an experiment with washed cells pre-grown in medium A with omission of casein hydrolysate leaving NH_4^+ ions as the sole source of nitrogen. The presence of benzoic acid during pyruvate oxidation by such cells neither inhibits the oxygen consumption at the acetate level nor increases the total amount of oxygen consumed per mole of pyruvate (as in experiments with cells grown with acetate as the sole carbon source) but seems to produce some intermediary form of effect.

Experiments with E. coli. Figs. 2 A and 2 B illustrate the influence of benzoic acid on pyruvate oxidation by washed *E. coli* cells. The cells were pre-grown in medium A with pyruvate and succinate instead of glucose (Fig 2 A) or in medium B (Fig 2 B) and harvested in the logarithmic growth phase. It is evident, that the results are very similar to those obtained with *P. vulgaris*. Even with *E. coli* pyruvate oxidation is blocked at the acetate level by benzoic acid, when the cells have been cultivated in a fairly rich medium, whereas no such inhibition is observed in studies with cells grown in the simple acetate medium. Corresponding experiments with salicylic acid gave essentially the same results (not shown here). Benzoic and salicylic acids were required at concentrations of about 7 and 1.5 mM, respectively, in order completely to

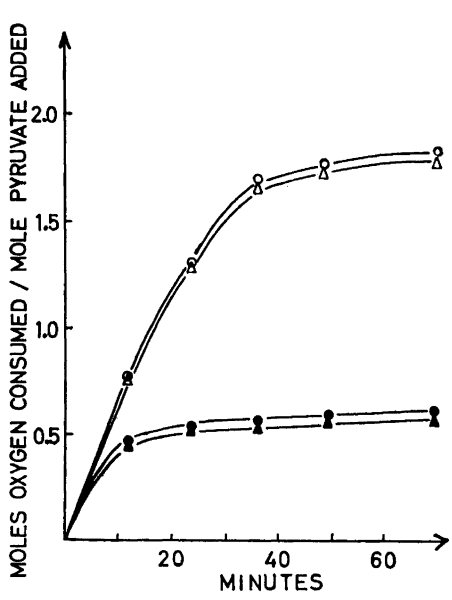

Fig. 1 A. Effect of benzoic acid on pyruvate oxidation by washed *P. vulgaris* cells. The cells were previously grown with aeration in a medium containing pyruvate, succinate and casein hydrolysate and harvested in the logarithmic growth phase. The vessels contained besides 4.5 mg dry wt. of cells, 133 μmoles of potassium phosphate and 7 μmoles of sodium pyruvate: △ no further additions; ○ 0.2 μmoles of sodium succinate; ▲ 8.3 mM benzoic acid; ● 0.2 μmoles of sodium succinate and 8.3 mM benzoic acid. Final volume, 2.4 ml. Experimental conditions: gas phase, air; pH 6.0; temp. 37°C.

The cells were previously grown with aeration in a medium containing glucose and ammonium chloride as carbon and nitrogen sources and harvested in logarithmic growth phase. The vessels contained besides 2.0 mg dry wt. of cells and 133 μmoles of potassium phosphate: ○ 7 μmoles of sodium pyruvate; ● 7 μmoles of sodium pyruvate and 9.7 mM benzoic acid. Final volume, 2.4 ml. Experimental conditions: gas phase, air; pH 6.0; temp. 37°C.

inhibit pyruvate oxidation at the acetate level. In the experiment with acetate grown cells shown in Fig. 2 B benzoic acid did not increase the total amount of oxygen consumed per mole of substrate in contrast to what was observed in corresponding experiments with *P. vulgaris*. Such an increase was, however, occasionally obtained even in respiration studies with *E. coli* in the presence of slightly lower concentrations of benzoic acid.

Experiments with Pseudomonas fluorescens. In another series of experiments the effect of benzoic and salicylic acids on the pyruvate and acetate oxidation by washed *Ps. fluorescens* cells was investigated. The cells were grown on agar plates, as described in the experimental part. The solid media were either pyruvate-succinate-casein hydrolysate agar or acetate agar. In a few experiments the cells were grown on succinate agar (acetate agar with acetate

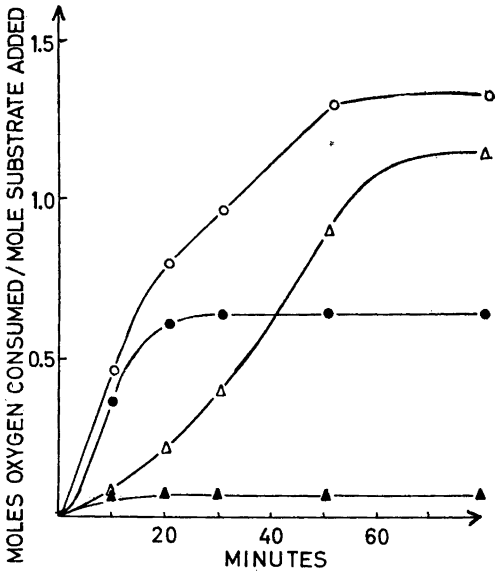

Fig. 2 A. Effect of benzoic acid on pyruvate and acetate oxidation by washed *E. coli* cells. The cells were previously grown with aeration in a medium containing pyruvate, succinate and casein hydrolysate and harvested in the logarithmic growth phase. The vessels contained besides 4.0 mg dry wt. of cells and 133 μmoles of potassium phosphate: O 7 μmoles of sodium pyruvate; ● 7 μmoles of sodium pyruvate and 7.5 mM benzoic acid; △ 7 μmoles of sodium acetate; ▲ 7 μmoles of sodium acetate and 7.5 mM benzoic acid. Final volume, 2.4 ml. Experimental conditions: gas phase, air; pH, 6.0; temp., 37°C.

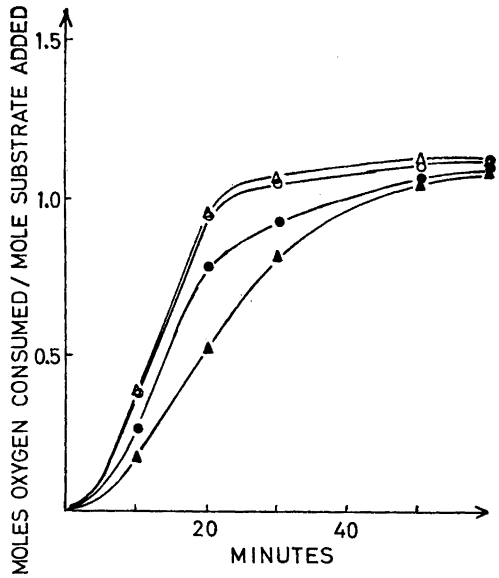

Fig. 2 B. Effect of benzoic acid on pyruvate and acetate oxidation by washed *E. coli* cells. The cells were previously grown with aeration in a medium containing acetate as the sole carbon source and harvested in the logarithmic growth phase. The vessels contained besides 2.5 mg dry wt. of cells and 133 μmoles of potassium phosphate: O 7 μmoles of sodium pyruvate; ● 7 μmoles of sodium pyruvate and 7.5 mM benzoic acid; △ 7 μmoles of sodium acetate; ▲ 7 μmoles of sodium acetate and 7.5 mM benzoic acid. Final volume, 2.4 ml. Experimental conditions: gas phase, air; pH 6.0; temp. 37°C.

replaced with an equal amount of succinate). The results of these studies can be summarized as follows:

1. The rate of oxygen consumption during oxidation of acetate was greatest with cells pre-grown on acetate agar, intermediate with cells pre-grown on succinate agar and smallest with cells pre-grown on pyruvate-succinate-casein hydrolysate agar. The Q_{O_2}-values recorded with such differently grown cells were roughly the same as those obtained in experiments with *P. vulgaris* and *E. coli* pre-grown in liquid media of analogous composition.

2. The inhibiting effect of benzoic acid on the rate of acetate oxidation was strongest in experiments with cells oxidizing acetate at a low rate. Accordingly inhibition was greatest in experiments with cells pre-grown on pyruvate-

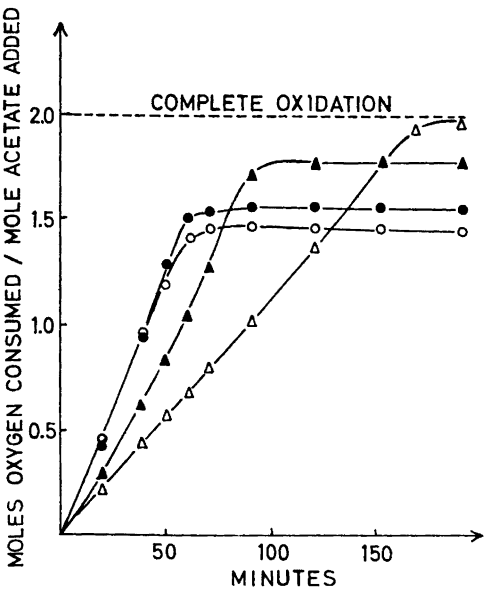

Fig. 3. Effect of benzoic acid on acetate oxidation by washed *Ps. fluorescens* cells. The cells were previously grown on acetate agar. The vessels contained besides 1.2 mg dry wt. of cells, 133 μmoles of potassium phosphate and 7 μmoles of sodium acetate: ○ no further additions; ● 2 mM benzoic acid; ▲ 4 mM benzoic acid; △ 6 mM benzoic acid. Final volume, 2.2 ml. Experimental conditions: gas phase, air; pH 6.0; temp. 25°C.

succinate-casein hydrolysate agar (50 % inhibition at about 2 mM benzoic acid) and smallest in experiments with cells pre-grown on acetate agar and harvested in the logarithmic growth phase (50 % inhibition at about 15 mM benzoic acid). These results are analogous to those previously obtained with *P. vulgaris.*

3. No sign of a specific inhibiting effect on pyruvate oxidation at the oxidation level of acetate in presence of benzoic or salicylic acid was observed in any experiment with washed cells regardless of the composition of the medium on which the cells had been grown. In this respect there exists a clear difference between *Ps. fluorescens* on one hand and *P. vulgaris* and *E. coli* on the other.

4. As with *P. vulgaris,* benzoic acid increased the total amount of oxygen consumed per mole of acetate in experiments with cells previously grown with acetate as the sole carbon source. This increase was most significant if the cells had passed the logarithmic growth phase at the time of harvesting. In respiration studies with such cells the acetate oxidation — in presence of 4—6 mM benzoic acid — proceeded, until the theoretical amount of oxygen required for complete oxidation of the acetate to CO_2 and H_2O had been consumed. At these concentrations the rate of oxygen consumption was inhibited to about 50 % by benzoic acid (Fig. 3). If the cells were grown on succinate agar, a similar but smaller increase was observed in presence of benzoic acid. A corresponding increase in oxygen consumption was recorded in respiration studies with pyruvate as substrate.

Some remarks concerning these experiments may be added to the above summary. Washed cells of *Ps. fluorescens* prepared from cultures grown on yeast extract agar can be adapted to oxidize benzoic acid by incubating them in the

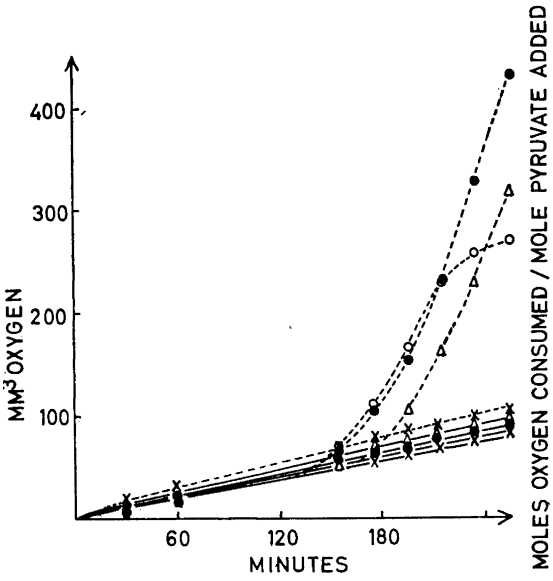

Fig. 4. Adaptation by washed *Ps. fluorescens* cells to oxidation of benzoic acid. The cells were previously grown on yeast extract agar. The vessels contained besides 1.0 mg dry wt. of cells and 33 μmoles of potassium phosphate: × no further additions; O 1.75 μmoles of sodium benzoate; ● 2.50 μmoles of sodium benzoate; △ 4.78 μmoles of sodium benzoate. Dashed lines, pH 7.0; solid lines, pH 6.0; gas phase, air; temp. 25°C.

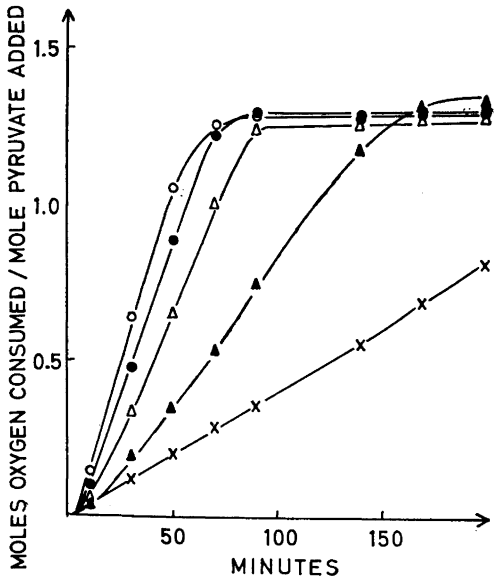

Fig. 5. Effect of benzoic acid on pyruvate oxidation by baker's yeast. The vessels contained 40 mg wet wt. of yeast, 7 μmoles of sodium pyruvate and benzoic acid at the following concentrations: O no benzoic acid; ● 1.4 mM; △ 2.8 mM; ▲ 4.2 mM; × 8.4 mM. Final volume, 2.4 ml. Experimental conditions: gas phase, air; pH 6.0; temp. 25°C.

presence of this substance, as shown by Stanier [5]. It may be argued that some of the oxygen consumed in experiments where benzoic acid is added can be ascribed to such oxidation. This possibility can, however, be ruled out in the present investigation by the following facts: a) in all experiments an aliquot of the cells was incubated with benzoic acid as the sole substrate in a separate vessel, and in no case was any increase of the oxygen consumption observed in these vessels during the experimental time; b) the exponential increase of the rate of oxygen consumption during the adaptation process (Fig. 4) should be clearly revealed, even during simultaneous acetate oxidation, if it actually occurred. The adaptation experiment shown in Fig. 4 was made at pH 7.0 with washed cells grown on yeast extract agar as described by Stanier. It is noteworthy that no adaptation occurred at pH 6.0 — the pH value maintained in the actual experiments in this study; c) the uptake in presence of benzoic acid of almost exactly the amount of oxygen required for complete oxidation of the acetate to CO_2 and H_2O was obtained irrespectively of the amount of acetate added or the length of the experiment.

Table 1. Effect of benzoic acid on pyruvate oxidation by baker's yeast. Each vessel contained 40 mg wet wt. of yeast in 1/15 M biphthalate-phosphate buffer and 7 μmoles of sodium pyruvate. Final volume 2.2 ml. Experimental conditions: gas phase, air; temp. 30°C; pH 5.0.

* In this calculation $10^{-4.20}$ was used as dissociation constant for benzoic acid and $10^{-3.00}$ for salicylic acid.

In studies on cell respiration, where the amount of oxygen consumed per mole of exogenous substrate (substrate added to the medium) is determined, it is of importance that the simultaneous endogenous respiration (oxygen consumption due to oxidation of cell material) is low, since it is a matter of controversy whether this latter oxygen consumption is suppressed during oxidation of exogenous substrate or not. If it is suppressed, it is clearly not correct to substract the value of the endogenous respiration from the experi-

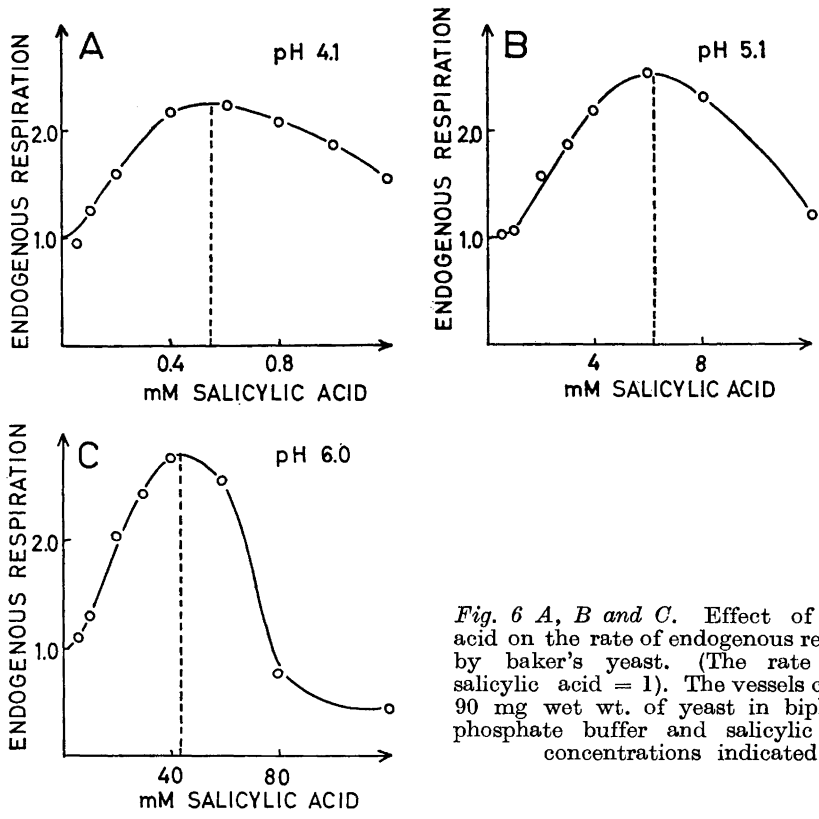

Fig. 6 A, B and C. Effect of salicylic acid on the rate of endogenous respiration by baker's yeast. (The rate without salicylic acid = 1). The vessels contained 90 mg wet wt. of yeast in biphthalate-phosphate buffer and salicylic acid at concentrations indicated.

mentally determined oxygen consumption when calculating the oxygen uptake per mole of exogenous substrate. In the present investigation this problem was of minor importance, since endogenous respiration in *Ps. fluorescens* cells, grown and washed as described, is practically zero.

Experiments with baker's yeast. In this study the effect of benzoic and salicylic acids on pyruvate and acetate oxidation and on endogenous respiration was investigated at three different pH-values. In addition the growth inhibiting effect in glucose-casein hydrolysate medium was determined at the same pH-values. Fig. 5 shows the influence of various concentrations of benzoic acid on pyruvate oxidation by baker's yeast at pH 6.0. It is evident, that there is no sign of a specific inhibiting effect in the presence of benzoic acid at the oxidation level of acetate. This is also apparent from Table 1, which shows the *R.Q.*-values during oxidation of pyruvate in the presence and absence of benzoic acid. Similar results were obtained with salicylic acid. In no case there was any significant increase found in the amount of oxygen consumed per mole of pyruvate or acetate in presence of the inhibitors studied. The results of respiration studies at pH 4.1, 5.1 and 6.0 are shown in Table 2,

which gives the concentrations of benzoic and salicylic acids required for 50 % inhibition of the rates of pyruvate and acetate oxidation. The results can be summarized in the following way:

1. Irrespective of the experimental pH-values, the same concentration of undissociated inhibitor is required for a certain effect.

2. The oxidation of pyruvate and glucose (not shown here for the latter substance) is more sensitive, especially to benzoic acid, than the oxidation of acetate. This is contrary to the results obtained in experiments with *P. vulgaris* and *E. coli* previously reported.

3. There is good agreement between inhibition of acetate oxidation and growth with both benzoic and salicylic acids. The concentrations necessary for complete suppression of acetate oxidation is approximately twice those required for 50 % inhibition and thus closely corresponding to those preventing growth at pH 6.0 and 5.1. At pH 4.1 no growth occurred, not even in the absence of inhibitor.

During this investigation it was noticed that salicylic acid significantly stimulated the endogenous respiration of the yeast cells. The appearance of such an effect generally indicates that the stimulating substance affects the energy conservation process in the cells. Since interference with this process and inhibition of acetate oxidation previously in this work have been placed in relation to each other, the increase in endogenous respiration in the presence of salicylic acid was determined at pH 4.1, 5.1, and 6.0. The result of this study is shown in Fig. 6 A, B, and C. Maximal increase in the rate of endogenous oxygen consumption occurred at 0.55, 6.1 and 43 mM salicylic acid at the three pH-values investigated. These figures correspond to a constant value of undissociated salicylic acid in the three experiments, as calculated in Table 2.

No similar stimulation of endogenous respiration was caused by benzoic acid.

DISCUSSION

The role of pyruvate as a key intermediate in the metabolism of microorganisms has been recognized and studied for a long time. Special attention has been paid to the mechanism by which it is converted to acetyl-CoA, a metabolically active compound, which can be used by the cell as a building stone in the synthesis of cell material or as an energy source. The latter function is fulfilled by its oxidation to CO_2 and H_2O through the TCA cycle. This cycle is now accepted as the chief pathway of terminal respiration in most aerobic organisms. The oxidative decarboxylation of pyruvate may, however, occur by other pathways without the intermediate formation of acetyl-CoA, *e.g.* the direct formation of free acetate from pyruvate by the pyruvate oxidase system in *P. vulgaris*.

The presence of benzoic and salicylic acids during pyruvate oxidation by resting cells of *P. vulgaris* leads to an accumulation of large amounts of acetate in the medium as previously [1] reported. These results were tentatively explained by assuming that some step in the pathway leading from pyruvate to acetyl-CoA was inhibited, while the acetate producing pyruvate oxidase system

was insensitive to the inhibitors investigated. This interpretation was supported by further experiments [2] with *P. vulgaris* grown under different conditions.

The results reported in this work are principally concerned with the effect of benzoic and salicylic acids on pyruvate and acetate metabolism in *Escherichia coli*, *Pseudomonas fluorescens* and baker's yeast. The similarity of the pyruvate metabolism in *P. vulgaris* and *E. coli* was pointed out by Razzell and Gunsalus [4]. They reported that extracts from *E. coli* yield one particulate and one soluble fraction, which combine to generate acetate from pyruvate with oxygen consumption. The two fractions are mutually replaceable with analogous fractions obtained from *P. vulgaris*. Likewise, *P. vulgaris* was shown to possess an acetyl-CoA generating system apparently identical with that in *E. coli*. It is consistent with these findings that benzoic and salicylic acids affect pyruvate oxidation by these two organisms in the same way.

The terminal respiration of *Ps. fluorescens* and baker's yeast has been studied extensively, and no oxidase system analogous to that present in *P. vulgaris* and *E. coli* producing acetate directly from pyruvate has been reported. This may explain the absence of a specific inhibiting effect of benzoic and salicylic acids on the acetate level during pyruvate oxidation by *Ps. fluorescens* and baker's yeast (Fig. 5).

Irrespective of the inhibition pattern, however, the terminal respiration of all the organisms investigated is inhibited by benzoic and salicylic acids at concentrations which suppress the growth rate in a medium containing glucose and amino acids. The close correspondence between these effects is especially apparent in the experiments with baker's yeast (Table 2).

Previously in this work results have been reported indicating that under certain conditions benzoic and salicylic acids may increase both the rate and the extent of substrate breakdown. In particular it was shown in experiments with acetate grown cells of *P. vulgaris* that the assimilation of acetate was more sensitive to benzoic acid than its oxidation. This finding is confirmed by the respiration studies with acetate grown cells of *Ps. fluorescens* reported in this paper (Fig. 3). It is evident that benzoic acid may cause a complete oxidation of acetate to CO_2 and H_2O and thereby prevent utilization of this substance in synthesis of cell material. The effect of benzoic acid in these experiments is quite analogous to that obtained by Clifton [6] in his early investigation of the prevention of acetate assimilation in *Pseudomonas calcoacetica* by 2,4-dinitrophenol, sodium azide and iodoacetate. The two first mentioned substances are now well known as specific inhibitors of oxidative phosphorylation.

It is evident that benzoic and salicylic acids may inhibit both respiration and assimilation at concentrations affecting growth. Inhibition of terminal respiration may well be the primary cause of the growth inhibiting effect in a medium containing large amounts of readily utilized substrates such as glucose and amino acids. Both inhibitors are, however, more effective in a poor medium and it is possible that interference with the synthesis of cell material is a more important factor in this case. This question is now under investigation.

This work is part of an investigation supported by the *Swedish Natural Science Research Council* and the *Swedish Technical Research Council*.

The Bacteriostatic Action of Benzoic and Salicylic Acids

IV. The Effect on Oxidation of TCA Cycle Intermediates, Lactate and Gluconate

INGMAR BOSUND

State Dairy Research Station, Alnarp, Sweden

Resting cells of *Proteus vulgaris* oxidize succinate, fumarate, malate and oxalacetate at similar rates, whereas α-ketoglutarate is attacked more slowly. Exogenous citrate is not metabolized at pH 6.0 by resting cells.

The rate of oxidation of the dicarboxylic acids involved in the TCA cycle is inhibited to a varying extent by benzoic and salicylic acids according to the conditions prevailing during growth of the cells. The total amount of oxygen consumed per mole of substrate is mostly somewhat increased by the inhibitors studied.

The oxidation of lactate (in contrast to the oxidation of pyruvate) is not blocked at the acetate level by benzoic and salicylic acids.

Streptomycin, at concentrations arresting growth, does not affect the oxidation of pyruvate by resting cells of *P. vulgaris*.

Most of the experiments reported in this series have been concerned with the influence of benzoic and salicylic acids on the oxidation of glucose, pyruvate and acetate. Interest has been focused primarily on the effect of these inhibitors on the metabolism of the acetyl group, especially its entrance into the TCA cycle.

Conclusive proof of the occurrence of the TCA cycle in *Proteus vulgaris* has as yet not been produced, in contrast to what has been shown for the other organisms used in this work (*Escherichia coli*, *Pseudomonas fluorescens* and baker's yeast). From a general point of view, however, this metabolic cycle most likely occurs also in *P. vulgaris*. This is indicated by the fact that this organism can be adapted to growth on acetate as the sole carbon source and can oxidize acetate at least almost completely to CO_2 and H_2O.

The present investigation is concerned with the ability of resting cells of *P. vulgaris* to oxidize members of the TCA cycle and the effect of benzoic and salicylic acids on these oxidations. In addition, the effects of benzoic acid on pyruvate and lactate oxidation were compared in respiration studies with labelled substrates. Some experiments with streptomycin were included in these studies owing to certain similarities between the influence of this inhibitor and that of benzoic acid on resting cell metabolism.

EXPERIMENTAL

Organism. The same strain of *Proteus vulgaris* was used as before. The ability of this strain to grow in simple media, especially with acetate as the sole source of carbon, seems to have diminished somewhat in the course of this investigation. No change affecting the results obtained with the inhibitors studied has, however, occurred.

Medium and growth conditions. The cells were cultured at 35 – 37°C with aeration either with glucose as carbon source or with pyruvate and succinate. In the former case the cells were harvested in the stationary phase, in the latter case early in the logarithmic phase. The growth conditions have been described in detail previously [1].

Methods. The procedure adapted in the preparation of cell suspensions and in respiration measurements was essentially the same as previously outlined. In the studies with labelled substrates the respiratory CO_2, absorbed in KOH during the experiment, was precipitated as $BaCO_3$ after dilution with a known amount of K_2CO_3. The precipitate was washed and dried and the radioactivity determined in a Geiger-Müller counter after plating the carbonate on aluminium dishes. The total amount of radioactivity supplied to the cells was determined in the same way after conversion of an aliquot of the substrate into CO_2 by the wet decomposition method of van Slyke and Folch [2].

Reagents. All reagents used were commercial preparations. The pyruvic acid was redistilled before use. Samples of sodium pyruvate-2-^{14}C and sodium DL-lactate-2-^{14}C were supplied by The Radiochemical Centre, Amersham, England. Streptomycin was obtained as the sulfate from AB Kabi, Stockholm, Sweden.

RESULTS

The effect of benzoic and salicylic acids on the oxidation of TCA cycle intermediates. The capacity of washed *Proteus vulgaris* cells to oxidize citrate and the dicarboxylic acids of the TCA cycle is shown in Table 1. Somewhat lower Q_{O_2}-values were generally observed in experiments with cells pre-grown without aeration. In no case was citrate metabolized at the pH in question (6.0). The dicarboxylic acids were oxidized at nearly identical rates with the exception of α-ketoglutaric acid.

Table 1. Rate of oxygen consumption during oxidation of TCA cycle intermediates by washed cells of *P. vulgaris*.

Substrate	A *	B *
	μl oxygen consumed per mg dry wt. and hour	μl oxygen consumed per mg dry wt. and hour
Citrate	0	0
α-Ketoglutarate	20	20
Succinate	60	100
Fumarate	60	100
Malate	50	100
Oxalacetate	50	80

* A. Cells pre-grown in glucose-casein hydrolysate medium, aerated during growth and harvested in the stationary growth phase.
B. Cells pre-grown in pyruvate-succinate-casein hydrolysate medium, aerated during growth and harvested in the logarithmic growth phase.

Benzoic acid at concentrations lower than 8 mM did not appreciably suppress the oxidation of succinate, fumarate, malate or oxalacetate in experiments with resting cells grown as in B, Table 1. The degree of inhibition increased rapidly with increasing concentration of inhibitor and was total at 12—15 mM of benzoic acid. When the cells were cultured as in A, benzoic acid was somewhat more effective as an inhibitor. With both types of cells α-ketoglutarate oxidation was the most sensitive.

The dicarboxylic acids of the TCA cycle can easily be converted to pyruvate in most cells *via* oxidation to oxalacetate followed by decarboxylation of this substance. Such a transformation is, in fact, necessary if these acids are to be oxidized by way of the TCA cycle. Since the oxidation of pyruvate is blocked at the acetate level by benzoic and salicylic acids, these inhibitors might be expected to affect the oxidation of the TCA cycle intermediates in a corresponding way. This would imply that benzoic and salicylic acids would block the oxidation of succinate, fumarate, malate and oxalacetate at the acetate level, *e.g.* after consumption of 1.5, 1.0, 1.0 and 0.5 moles of oxygen per mole of substrate, respectively (Fig. 4). It was thus of considerable interest to investigate the effect of these inhibitors on the total amount of oxygen consumed per mole of acid. Fig. 1 shows an experiment with succinate, fumarate, malate and pyruvate. It is evident that benzoic acid did not affect the oxidation of the dicarboxylic acids in the predicted way. On the contrary, the amount of oxygen consumed was increased in the presence of benzoic acid. Similar results were obtained in experiments with cells pre-grown in glucose-casein hydrolysate medium and in studies with salicylic acid.

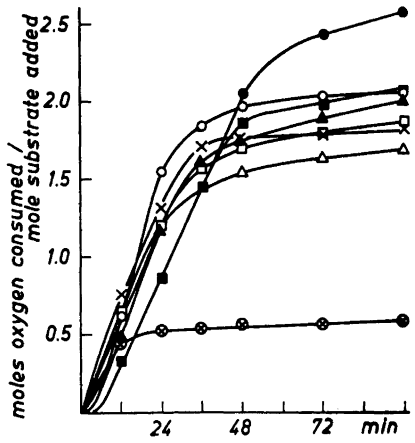

Fig. 1. Effect of benzoic acid on oxidation of succinate, fumarate, malate and pyruvate by washed *P. vulgaris* cells grown as in B, Table 1. Each vessel contained 4.5 mg dry wt. of cells and 133 μmoles of potassium phosphate. ×——× 5 μmoles of sodium pyruvate, ⊗——⊗ 5 μmoles of sodium pyruvate and 8 mM benzoic acid, O——O 5 μmoles of sodium succinate, ●——● 5 μmoles of sodium succinate and 8 mM benzoic acid, □——□ 5 μmoles of sodium fumarate, ■——■ 5 μmoles of sodium fumarate and 8 mM benzoic acid, △——△ 5 μmoles of sodium malate, ▲——▲ 5 μmoles of sodium malate and 8 mM benzoic acid. Temp. 37°C; pH 6.0; final volume 2.4 ml.

Table 2. Effect of benzoic acid on the total amount of oxygen consumed during oxidation of pyruvate and fumarate. The oxidation was carried out with washed cells of *P. vulgaris* pre-grown in glucose-casein hydrolysate medium, aerated during growth and harvested in the stationary phase. Each vessel contained 1/15 M phosphate buffer at pH 6.0 and substrate and inhibitor as shown. Gas phase air; temp. 30°C.

Substrate	Total amount of oxygen consumed, µl	
	without inhibitor	with 10 mM benzoic acid
5 µmoles of pyruvate	210	70
5 µmoles of fumarate	275	285
5 µmoles of pyruvate 5 µmoles of fumarate	455	365

These results seem to indicate that pyruvate formed within the cell during oxidation of TCA cycle intermediates is not freely interchangeable with pyruvate entering the cell from the external medium. Table 2 shows another experiment illustrating the same point. The figures recorded in this table show that the effect of benzoic acid on the total amount of oxygen consumed during oxidation of exogenous pyruvate persists even when an equal amount of fumarate is oxidized simultaneously. The amount of oxygen consumed per mole of fumarate was not influenced by benzoic acid in this experiment.

The influence of benzoic acid and streptomycin on the oxidation of pyruvate and lactate. In another series of experiments the effect of benzoic acid on pyruvate oxidation was compared with its effect on lactate oxidation. It is difficult to imagine any other way of oxidizing lactate in a living cell than *via* pyruvate; consequently, one would expect the lactate oxidation to be strongly inhibited by benzoic acid after consumption of 1.0 mole of oxygen per mole of lactate. But as shown in Fig. 2, no such blocking of the lactate oxidation at the acetate level seemed to occur. This result is supported by the experiments with pyruvate-2-^{14}C and lactate-2-^{14}C summarized in Tables 3 and 4. According to Table 3, benzoic acid almost completely inhibits the occurrence of the keto carbon atom of pyruvate in the respiratory CO_2. Table 4 indicates that the extent of oxidation of the corresponding atom in the lactate molecule to CO_2 is only slightly affected. It may be noted that the rate of lactate oxidation in the latter experiment was strongly inhibited by benzoic acid and that in the presence of 8 mM of the inhibitor the oxidation was stopped before the rate of oxygen consumption had decreased to the value of the endogenous respiration.

Some years ago Umbreit *et al.*[3,4] studied the influence of streptomycin on the oxidative metabolism of resting cells of *Escherichia coli* and observed effects somewhat resembling those obtained with benzoic acid in this work. They reported that under certain conditions streptomycin prevented pyruvate from entering the terminal respiration system and suggested that the inhibited reaction might be a "direct condensation" of oxalacetate and

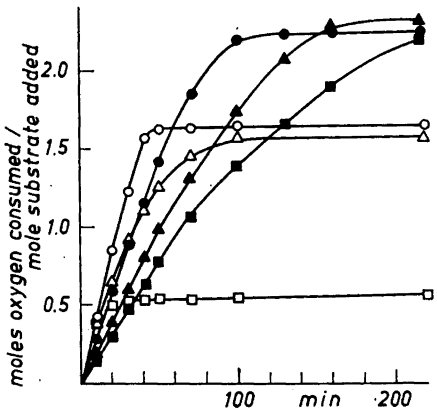

Fig. 2. Effect of benzoic acid on pyruvate and lactate oxidation by washed *P. vulgaris* cells grown as in B, Table 1. Each vessel contained 5.2 mg dry wt. of cells and 133 μmoles of potassium phosphate. O———O 7 μmoles of sodium pyruvate, △———△ 7 μmoles of sodium pyruvate and 4 mM benzoic acid, □———□ 7 μmoles of sodium pyruvate and 8 mM benzoic acid, ●———● 7 μmoles of sodium lactate, ▲———▲ 7 μmoles of sodium lactate and 4 mM benzoic acid, ■———■ 7 μmoles of sodium lactate and 8 mM benzoic acid. Temp. 37°C; pH 6.0; final volume 2.4 ml.

pyruvate to a 7-carbon intermediate. They did not exclude the possibility of formation of a transitory 2-carbon intermediate from pyruvate before the condensation with oxalacetate, but showed later [5] that formation of citrate was not influenced by streptomycin. Since the reaction

$$\text{pyruvate} + 0.5\ O_2 \rightarrow \text{free acetate}$$

Table 3. Effect of streptomycin and benzoic acid on the amount of $^{14}CO_2$ produced during oxidation of $CH_3{}^{14}COCOOH$. The oxidation was carried out with washed cells of *P. vulgaris* pre-grown in pyruvate-succinate-casein hydrolysate medium, aerated during growth and harvested in the logarithmic growth phase. Each vessel contained 1/15 M phosphate buffer, 7 μmoles of sodium pyruvate-2-^{14}C (with a total activity of 11 600 cpm.), 5.5 mg dry wt. of cells, and inhibitor as indicated. Gas phase air; pH 6.0; temp. 30°C.

Inhibitor	Mole O_2 / mole pyruvate	Mole CO_2 / mole pyruvate	*R.Q.*	Fraction of the amount of radioactivity supplied recovered in respiratory CO_2	Fraction of the amount of substrate carbon recovered in respiratory CO_2
—	1.37	1.70	1.24	0.41	0.57
Streptomycin 8 mg/ml	1.36	1.84	1.35	0.40	0.61
Benzoate, 8 mM	0.56	1.02	1.82	0.08	0.34

Table 4. Effect of benzoic acid on the amount of $^{14}CO_2$ produced during oxidation of $CH_3{}^{14}CHOHCOOH$. The oxidation was carried out with washed cells of *P. vulgaris* pre-grown in pyruvate-succinate-casein hydrolysate medium, aerated during growth and harvested in the logarithmic growth phase. Each vessel contained 1/15 M phosphate buffer, 7 μmoles of sodium DL-lactate-2-^{14}C (with a total activity of 12 100 cpm.), 5.5 mg dry wt. of cells, and inhibitor as indicated. Gas phase air; pH 6.0; temp. 30°C.

Inhibitor	$\frac{\text{Mole } O_2}{\text{mole lactate}}$	$\frac{\text{Mole } CO_2}{\text{mole lactate}}$	*R.Q.*	Fraction of the amount of radio-activity supplied recovered in res-piratory CO_2	Fraction of the amount of substrate carbon recovered in respiratory CO_2
—	2.05	2.04	0.99	0.66	0.68
Benzoate, 5 mM	1.83	1.80	0.99	0.56	0.60
Benzoate, 8 mM	1.45	1.40	0.97	0.39	0.47

as well as the subsequent oxidation of acetate seemed to be completely insensitive to streptomycin, the effect of this inhibitor was demonstrable only on cells with a very low capacity to oxidize acetate. In the work of Umbreit *et al.* such cells were obtained by growing the culture in a rich medium without aeration and keeping the washed cells at refrigerator temperatures for some days before the experiments.

According to this study, the effect of streptomycin on the pyruvate oxidation by *P. vulgaris* cells pre-grown with heavy aeration, as in this investigation, should be very small, if any, since the first rapid step in the pyruvate oxidation by such cells is apparently the formation of free acetate from pyruvate. Nevertheless it was of interest to compare the effects of benzoic acid and streptomycin on cells aerated during growth. The data from such an experiment are given in Table 3. It is evident that streptomycin had no influence on the oxidation of pyruvate even in a final concentration of 8 000 μg/ml. The effect was not enhanced by incubation of the cells with streptomycin for one hour before addition of pyruvate. Oxidation of lactate was equally insensitive to streptomycin as was pyruvate oxidation by resting cells grown with acetate as the sole carbon source (resting cells pre-grown in this way apparently [6] have very little tendency to form free acetate during pyruvate oxidation). It may be argued that the experimental pH (6.0) was too low to produce a pronounced streptomycin effect, but growth experiments showed that the strain of *P. vulgaris* used was sensitive to streptomycin at a concentration of 25 μg/ml at this pH.

The effect of benzoic and salicylic acids on the oxidation of gluconate. In recent years it has become increasingly evident that many microorganisms in addition to dissimilating glucose *via* the classical scheme of Embden-Meyerhof may utilize another enzymatic mechanism. This pathway, usually called the hexosemonophosphate pathway, starts with glucose-6-phosphate, which *via* 6-phospho-gluconate is transformed to pentose phosphate in two oxidative

steps (the second accompanied by decarboxylation). From this intermediate glucose-6-phosphate can be regenerated through a series of anaerobic reactions. Consequently glucose can be oxidized completely to CO_2 and H_2O by this pathway without the participation of the TCA cycle.

Since benzoic and salicylic acids block glucose oxidation at the acetate level by inhibiting the function of the TCA cycle, it was considered of interest to investigate the effect of these inhibitors on the oxidation of some intermediate in the hexosemonophosphate pathway. As phosphorylated substances do not readily penetrate the cell membrane of intact cells, these experiments were performed with gluconate. Preliminary studies showed that washed cells of *P. vulgaris* pre-grown in glucose-casein hydrolysate medium and harvested in the logarithmic growth phase oxidized glucose and gluconate at approximately the same rate but in the case of gluconate only after an initial lag phase. The total amount of oxygen consumed per mole of gluconate was generally about 3.5 moles. As is shown in Fig. 3, salicylate inhibited the rate of gluconate oxidation rather strongly, whereas the rate of glucose oxidation was as usual considerably increased at these salicylate concentrations. No clear effect was observed on the oxygen consumption per mole of gluconate. Corresponding results were obtained with benzoic acid.

DISCUSSION

As mentioned above, there is no reason to question the occurrence of the TCA cycle in cells of *Proteus vulgaris* even if, as shown here, citrate (and presumably also the other tricarboxylic acids of the cycle) is oxidized at a

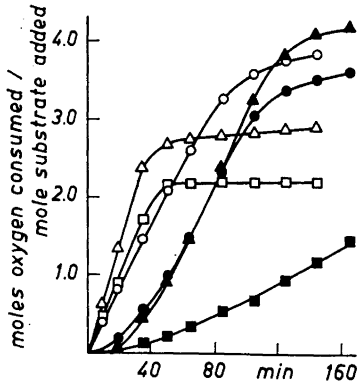

Fig. 3. Effect of salicylic acid on oxidation of glucose and gluconate by washed *P. vulgaris* cells grown in glucose-casein hydrolysate medium, aerated during growth and harvested in the logarithmic growth phase. Temp. 37°C; pH 6.0; final volume 2.4 ml.

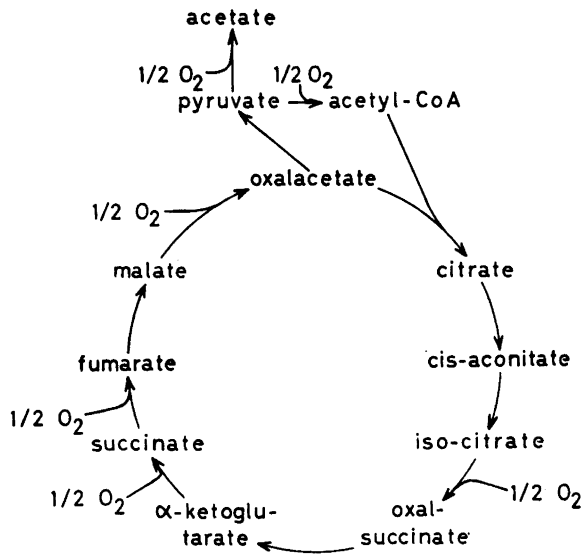

Fig. 4. Oxidative steps in the TCA cycle.

very low rate or not at all when added to suspensions of intact cells. This failure to attack intermediates of the cycle is certainly, as in analogous cases, due to impermeability of the cell membrane.

It was also pointed out that in order to oxidize TCA cycle intermediates beyond the oxalacetate stage, the cell must decarboxylate the oxalacetate to pyruvate (Fig. 4). The further metabolism of this pyruvate is, however, obviously not blocked at the acetate level by benzoic or salicylic acid, since the amount of oxygen consumed during oxidation of TCA cycle intermediates is increased by these inhibitors (Fig. 1). The reason may be that pyruvate formed from oxalacetate does not come into contact with the acetate producing pyruvate oxidase occurring in *P. vulgaris*. Anyhow, the results given in Fig. 1, Fig. 3 and Table 2 suggest that pyruvate originating from TCA cycle intermediates is not freely interchangeable with exogenous pyruvate or pyruvate formed from glucose. Such an interpretation is supported by the general conception that the TCA cycle enzymes, functioning more or less as a unit, are held together by some rigid structure, while the soluble glycolytic enzymes are spread throughout the cell protoplasm. It is a matter of controversy what the rigid structure might be like in a bacterial cell, which can obviously not contain anything as complex as the mitochondria of an animal cell. Evidence seems, however, to be accumulating [7,8] that the function of the TCA cycle in bacteria is closely associated with the cell membrane.

The difference in the action of benzoic acid on pyruvate and lactate oxidation (Fig. 2) is more difficult to interpret. It is possible, however, that better knowledge of the localisation in the cell of the enzymes involved might result

in the same line of reasoning as that set forth above. It may be significant that Mitchell and Moyle [8] reported that 80—95 % of the lactic dehydrogenase in *Staphylococcus aureus* is associated with the cell membrane. Similar results were obtained by Storck and Wachsman [9] in experiments with *Bacillus megaterium*. They showed after carefully controlled disintegration of the cells that the enzymes responsible for lactate oxidation were associated with the cell membrane fraction, while the enzymes responsible for pyruvate and glucose oxidation were localized in the supernatant.

Whatever hypothesis is put forward to account for the experimental data, it is evident that the oxidation of acetate is inhibited more than the oxidation of TCA cycle intermediates by benzoic and salicylic acids. This points to the activation of the acetate molecule as the primary site of action. Among the dicarboxylic acids of the TCA cycle the oxidation of α-ketoglutarate seems to be most sensitive to benzoic acid which agrees with results obtained by Kaplan, Kennedy and Davis [10] in experiments with rat tissue homogenates. It may be significant that the first step of this oxidation is CoA-dependent and the same type of reaction as the transformation of pyruvate to acetyl-CoA. The possibility that benzoic acid (and various other carboxylic acids) affects fatty acid metabolism in liver cells by interfering with the function of CoA has been suggested and investigated by Avigan, Quastel and Scholefield [11]. Their results show that various reactions of acetyl-CoA are specifically inhibited by acyl-CoA compounds such as benzoyl-CoA. The effects were not due to simple removal of free CoA. It is possible but still doubtful whether a similar interference occurs in bacterial cells.

The experiment illustrated in Table 3 shows that streptomycin, at concentrations far exceeding those necessary for inhibition of growth, has no influence on pyruvate oxidation by resting cells of *P. vulgaris* grown in the way described. In this respect, the effects of streptomycin and benzoic acid are clearly different. It is nevertheless true that under certain conditions both inhibitors prevent pyruvate from entering the terminal respiration system and that this effect may be closely associated with the inhibition of growth. As a matter of fact there seems to be other similarities in the action of streptomycin and benzoic and salicylic acids. In 1951 Bernheim and DeTurk [12] reported that streptomycin, benzoic acid and several members of the hydroxy benzoic acid series specifically inhibit the assimilation of ammonia during succinate oxidation by *Pseudomonas aeruginosa*. Fitzgerald and Bernheim [13] have presented data showing that streptomycin inhibits the formation of adaptive enzymes. Results indicating a similar effect by benzoic and salicylic acids have been obtained in this work and will be presented in a future paper. These effects may, of course, be secondary and due to an interference with the formation of high energy compounds, which is very probable in the case of salicylic acid. It may also be mentioned that both salicylic acid [14] and streptomycin [15] have been reported specifically to inhibit the synthesis of pantothenate.

The real significance of these apparent similarities can be made evident only by further research, and it is certainly true that, especially in the case of streptomycin, many facts not mentioned here have to be considered.

Pyridine-N-Oxide-Aldoximes

Their Synthesis, and Chemical and Biochemical Properties

KLAS-BERTIL AUGUSTINSSON, HANS HASSELQUIST and LENNART LARSSON

Institute of Organic Chemistry and Biochemistry, University of Stockholm and Research Institute of National Defence, Department 1, Sundbyberg 4, Sweden

The three isomers of pyridine-N-oxide-aldoximes were synthesised and their properties described, including infrared spectra and dissociation constants. The new aldoximes were incapable of reactivating cholinesterases inhibited by tetraethyl pyrophosphate both *in vitro* and *in vivo*.

Successful treatment by certain oximes of poisoning caused by organophosphorus compounds has recently been reported; especially active are pyridine-2-aldoxime-N-methyl iodide (PAM) and its methane sulphonate analogue (P2S)[1]. The present report describes the synthesis and some chemical and biochemical properties of the corresponding pyridine-N-oxide-2-aldoxime and its two isomers (3- and 4-aldoxime).

EXPERIMENTAL

The N-oxides of pyridine-aldoximes were prepared by a general method described previously by Ochiai[2]. Hydrogen peroxide (30 %) is allowed to act upon the pyridine derivative (Schuchardt, Germany) in glacial acetic acid solution at 70—80°C.

Pyridine-N-oxide-2-aldoxime (*POA 2*). To 2 g (16.4 mmole) of pyridine-2-aldoxime, dissolved in 10 ml of glacial acetic acid, was added 2 ml of hydrogen peroxide (30 %). The mixture was heated for 3 h at 80°C. After cooling 40 ml of ethyl acetate was added to the reaction mixture, resulting in the precipitation of the reaction product. The product was collected by filtration after one hour in the refrigerator, and washed with ethyl acetate. Crude product, 0.5 g. A further 0.4 g of crystallized product was obtained from the filtrate after keeping for 48 h in the refrigerator.

The two fractions of crystals were combined and dissolved in a small amount of boiling water, active charcoal was added, and the mixture filtered while still boiling. The pyridine-N-oxide-2-aldoxime crystallized upon cooling. Recrystallization from water gave 0.78 g (34 % yield) of the pure compound as colourless needles; m.p. 221—222°C with slow decomposition and brown-red colourization. Analysis, see Table 1. This aldoxime was synthesised recently by Jerchel and Heider[3] using another method.

The ethyl acetate solution from which the N-oxide aldoxime was isolated was evaporated to dryness under vacuum, leaving a dark-yellow oil, which dissolved on heating in 10 ml of water to give a clear solution. Upon cooling, a colourless substance crystallized out, which was identified as the original pyridine-2-aldoxime (m.p. 111—113°C). Solid sodium carbonate was added to the filtrate to pH 6.5. After 24 h in the refrigerator another portion of pyridine-2-aldoxime was obtained. Altogether 0.85 g of unreacted aldoxime was isolated in this way.

When a longer reaction period or a greater amount of hydrogen peroxide, was employed, approximately the same amount of N-oxide aldoxime was obtained. The remaining solution contained, however, approximately 1 g of picolinic acid (m.p. 138—139°C with rapid decomposition). The latter procedure was therefore not to be preferred because of difficulties in separating the acid from the oxime.

Pyridine-N-oxide-3-aldoxime (*POA 3*). Pyridine-3-aldoxime, 2 g (16.4 mmole), was dissolved in 20 ml of glacial acetic acid, 6 ml of 30 % hydrogen peroxide was added, and the mixture incubated at 35°C for 48 h.; the same yield was obtained on keeping the mixture for ten days at room temperature. Evaporation under vacuum gave a sticky crystalline product, which was dissolved in 10 ml of absolute ethanol with heating. After cooling at room temperature long, light yellow rods crystallized out; m.p. 212—213°C with decomposition. Recrystallization twice from absolute ethanol gave pure pyridine-N-oxide-3-aldoxime; m.p. 217—218°C. Yield, 1.06 g (46 %).

The ethanol filtrate, from which the reaction product was isolated, was evaporated under vacuum to approximately 3 ml. The remaining yellow oil was stirred, and acetone added until no further precipitation occurred. The collected precipitate was washed with acetone and dried, treated with 25 ml of hot *iso*propanol, and the solution filtered hot; the undissolved matter was then washed afterwards with boiling *iso*propanol. The crystallized product was recrystallized twice from small amounts of water; m.p. 256—257°C. Yield, 0.4 g. The product was identified as nicotinic acid-N-oxide with the same m.p.[4]

Pyridine-N-oxide-4-aldoxime (*POA 4*). Pyridine-4-aldoxime, 2 g (16.4 mmole), dissolved in 10 ml of glacial acetic acid, was treated with 2 ml of hydrogen peroxide (30 %) for 48 h at 35°C. The reaction solution was diluted with 10 ml of water and evaporated under vacuum until crystallization began. The crystalline product was dissolved in 10 ml of methanol by gentle heating, and was then left for crystallization. The yellow prisms were recrystallized twice from methanol. The pyridine-N-oxide-4-aldoxime was obtained as colourless prisms, m.p. 228—229°C; yield 720 mg.

The filtrate was evaporated under vacuum to a yellow oil, which was not possible to crystallize from methanol. The oil, probably consisting of the acetate of the reaction product, was dissolved in 5 ml of water and treated with solid sodium carbonate to pH 6.5, when crystals, a mixture of starting material and the N-oxide were formed. The whole mixture was shaken three times with ethyl acetate. The aqueous phase was left for 24 h at room temperature, the precipitated crystals were collected, washed with a small amount of water and recrystallized from methanol. The product was identified as pyridine-N-oxide-4-aldoxime; yield 400 mg. The total yield was 1.12 g (50 %).

From the ethyl acetate filtrate, 0.35 g of unreacted pyridine-4-aldoxime (m.p. 132—133°C) was isolated. No formation of carboxylic acid was observed.

Infra-red spectrophotometric measurements. The infra-red spectra were recorded on a Perkin-Elmer spectrophotometer, Model 21, equipped with a rock-salt prism, and the following settings were used: resolution 927; response 2:1 170; gain 5.9; suppressions 3; speed about 1 μ/min; scale 5 cm/μ. The potassium bromide technique was employed, and 1 mg of sample was ground mechanically with 300 mg of this salt.

Determination of dissociation constants. The dissociation constants of the three aldoximes were determined at 25°C with an automatic recording titrator as described previously by Larsson and Hansen[5]. The compounds were dissolved in 0.100 M potassium chloride solution and the concentration of the compounds was approximately 5.0 mM. Titration was performed with 0.0991 M sodium hydroxide. The pH-meter was standardized against 0.05 M potassium hydrogen *o*-phthalate (pH = 4.01) and 0.01 M borax (pH = 9.18).

Cholinesterase determinations were performed by the Warburg technique at 25°C with acetylcholine chloride (20 mM) as substrate[6]. Purified cholinesterase preparations from human plasma (butyrocholinesterase, BuChE) and *Torpedo* electric organ (acetyl-

cholinesterase, AChE) were employed, and esterase activity was expressed in b_{30}, *i.e.* μl CO_2 evolved in 30 min from a bicarbonate-CO_2 buffer solution (pH 7.4), corrections being made for spontaneous hydrolysis of acetylcholine.

Reactivation experiments. Tetraethyl pyrophosphate (TEPP) was used as »irreversible» cholinesterase inhibitor and appropriate aqueous solutions of it were prepared immediately before use. The enzyme solutions (in bicarbonate buffer, unless otherwise stated) were incubated with the inhibitor for 45 min in the main compartment of the flask; total volume of the incubation mixture, 1.2 ml. The aldoxime (0.4 ml of an aqueous solution) was then added from one of the ampoules, and after various reaction periods (15 to 60 min) the substrate (0.4 ml of a bicarbonate solution) was added to the mixture from the second ampoule. When other techniques were used, this is stated in the legend to the tables.

Pyridine-2-aldoxime-N-methyl methane sulphonate (P2S), known to be a good reactivator of cholinesterases [1], was used as a reference compound.

RESULTS AND DISCUSSION

Properties of the aldoximes. The 2- and 3-aldoximes were readily soluble in water; the 4-aldoxime was less so, but upon heating it dissolved rapidly. All three compounds dissolved readily in boiling methanol, and were sparingly soluble in benzene, acetone and ethyl acetate. Positive oxime reaction according to Feigl and Demant [7] was given by all three aldoximes. The analytical data for the compounds synthesised are listed in Table 1.

Infra-red spectra. The following group frequency assignements can be made from the infra-red spectra (Fig. 1):

The 3 000 cm^{-1} region. The three absorption bands at 3 175—2 958 cm^{-1} can be assigned to CH stretchning frequencies [8], and the unresolved bands at 2 874—2 597 cm^{-1} can probably be ascribed to associated OH stretching frequencies.

The 1 650—1 400 cm^{-1} region. The C=N stretching of the oxime group is expected to occur at about 1 650 cm^{-1}, and the weak absorption band at 1 650—1 639 mc^{-1} has thus been attributed to this group [9]. The remaining five bands in this region may be ascribed to vibrations of the pyridine nucleus [8,10,11]. The origin of the absorption band at 1 508—1 504 cm^{-1} is, however, ambiguous.

The 1 325—1 290 cm^{-1} region. The two absorption bands appearing in this region may be possibly be assigned to the OH bending frequencies [9].

Table 1. Analytical data and thermodynamic dissociation constants of pyridine-N-oxide-X-aldoximes ($C_6H_6N_2O_2$; M = 138.1) and dissociation constants of the corresponding N-methyl-derivatives [13].

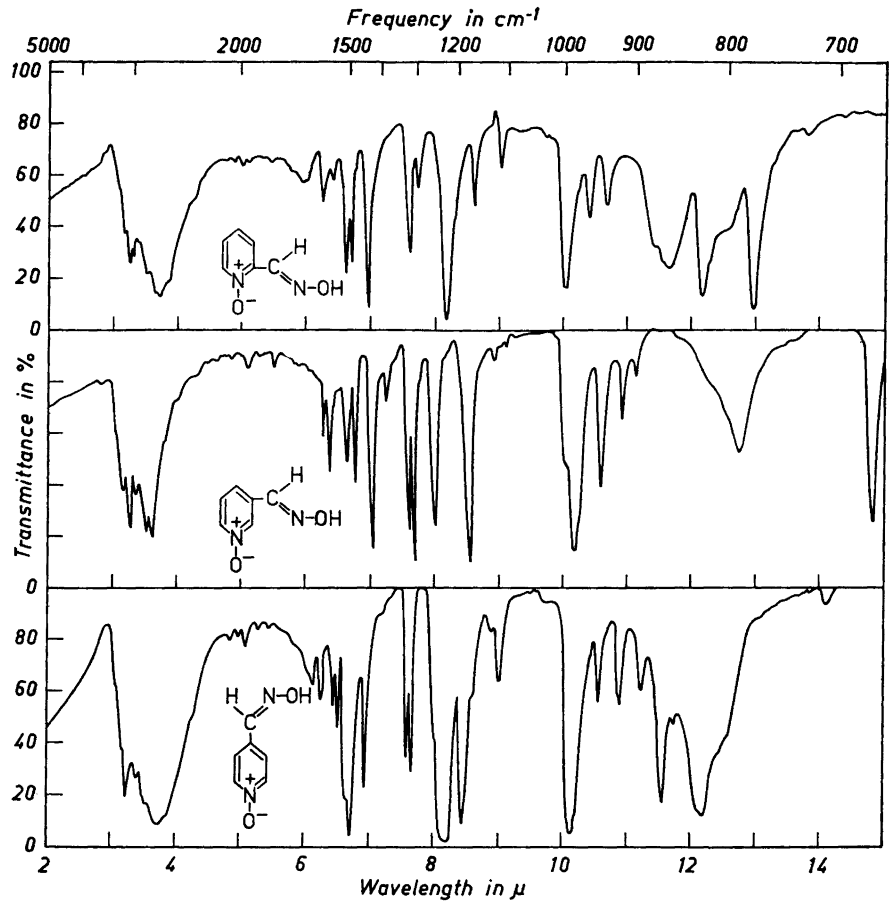

Fig. 1. The infra-red spectra of pyridine-N-oxide-aldoximes.

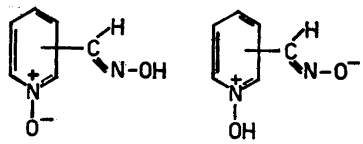
The 1 255—1 220 cm^{-1} region. The very strong absorption band occurring in this region has been attributed to the $N^+—O^-$ stretching frequency [10,11].

The 1 185—975 cm^{-1} region. The two absorption bands at 1 185—1 159 cm^{-1} and 1 119—1 105 cm^{-1} have been interpreted as CH deformation bands [10,11]. The strong and broad absorption at 996—978 cm^{-1} has been given the same assignment [10,11], but it is probably overlapped by a band caused by stretching of the N-OH linkage [9,12].

The infra-red data obtained are thus in agreement with structures proposed from the synthesis of the compounds, and they indicate that the compounds exist as N-oxides (I) and not in the tautomeric form (II).

An impurity which can be expected to be present in the samples is the carboxylic acid corresponding to the oxime. Owing to the weak overtone

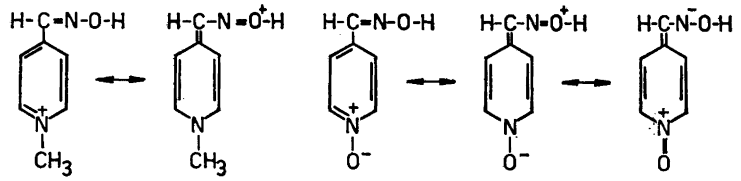


I II

bands of the pyridine nucleus occurring in the region of the carbonyl absorption band (1 700 cm^{-1}) it is, however, not possible to decide from the spectra obtained whether traces of carboxylic acid may be present or not.

From the titration curves of the N-oxide of the pyridine aldoximes it was found that the deviation between the amount of titrand added to the equivalence point, and the amount calculated from the quantity weighed out in no case exceeded 1.1 %.

The thermodynamic dissociation constants of the compounds are given in Table 1, where the constants of the N-methyl pyridine-aldoximes [13] have also been included. A comparison between the constants of the two series shows that the substitution of an oxide group for a methyl group at the nitrogen atom causes an increase in the pK_a-value. Primarily, this increase may be ascribed to the reduction of the strong inductive effect of the positively charged nitrogen atom when the substituent is changed from methyl to oxygen. This increase is expected to be greatest in the 2-aldoxime and least in the 4-aldoxime. As appears from Table 1, the increase is especially pronounced in the 2- and 4-aldoximes which probably depends upon a mesomeric effect. The pyridine-4-aldoxime-N-methyl can be described as a resonance hybrid of structures III and IV, and the N-oxide as a hybrid of the analogous structures V and VI and moreover structure VII [14]. The large difference between the pK_a-value of the N-methyl-derivative and of the oxide indicates that the contribution of structure VII may more or less balance structure VI. This will thus serve as a partial explanation of the lower acidity, *i.e.* higher pK_a-value, of the pyridine-N-oxide-4-aldoxime. Analogous structures and arguments are valid for the 2-aldoxime but not for the 3-aldoxime.



III IV V VI VII

On the presumption that the aldoxime group in the pyridine-N-oxide-2-aldoxime exists in the anti-form, the formation of a weak intramolecular hydrogen bond is conceivable, and such a bond would furthermore increase its pK_a-value. It is, however, not possible to decide from an infra-red spectrum

Table 2. Reactivation of cholinesterases inhibited by tetraethylpyrophosphate (TEPP). The solutions of esterase preparations (E) were incubated with the inhibitor (I) for 45 min before the addition of aldoxime (R). After various periods of time (»reactivation») the substrate (S) was added to the reaction mixture. BuChE, human serum butyrocholinesterase; AChE, electric organ acetylcholinesterase, P2S, pyridine-2-aldoxime-N-methyl methane sulphonate, 0.125 mM; POA 2, POA 3 and POA 4, pyridine-N-oxide-X-aldoximes, 1.25 mM (concentration values for the aldoximes are those during reactivation).

recorded on a solid sample whether there is an intra- or intermolecular hydrogen bond.

Cholinesterase inhibition. None of the three pyridine-N-oxide-aldoximes in 10^{-3}M concentration inhibited acetyl- and butyrocholinesterase. Pyridine-2-aldoxime-N-methyl methane sulphonate, used in the same concentration, inhibited these esterases 12 and 17 % respectively.

Reactivation of cholinesterases inhibited by an organophosphorus compound. In 1.25×10^{-3}M concentration the three pyridine-N-oxide aldoximes were incapable of reactivating both butyro- and acetylcholinesterase inhibited by tetraethyl pyrophosphate (TEPP) (Table 2). For comparison, pyridine-2-aldoxime-N-methyl methane sulphonate used in ten times lower concentration (1.25×10^{-4} M) was tested in the same series of experiments. The results confirmed previous observations [1] that this derivative could reactivate phosphorylated cholinesterases, particularly acetylcholinesterase. It was observed that during incubation of the inhibited acetylcholinesterase with the pyridine-N-oxide-aldoximes, the activity of the partly inhibited esterase was reduced progressively with time. It was concluded that the phosphorylated aldoximes, formed during the incubation with the reaction mixture, containing phosphorylated esterase and unreacted TEPP, are more active esterase inhibitors than TEPP. This further decrease in enzyme activity was not due to TEPP alone, as could be demonstrated in control experiments.

Table 3. Reactivation of inhibited butyrocholinesterase by pyridine-N-oxide-2-aldoxime. Details as in Table 2, except for the concentration of the aldoxime which was seven times higher (8.75 mM). Reactivation period, 60 min.

It is reasonable to assume that in the reactivation of the phosphorylated enzyme the oximes react in their anionic forms [15]. Owing to the higher pK_a-values of the pyridine-N-oxide-aldoximes it might be expected that they are more nucleophilic and thus better reactivators than the N-methylderivatives, but the higher nucleophility is counteracted by the comparably lower concentration of the anions of the N-oxides at a fixed pH-value. One probable reason of the low reactivation power of the N-oxides may thus be that their pK_a-values are too high to give maximum reactivation at the pH-value in question [16]. According to these hypotheses, the N-oxide-aldoximes are expected to give better reactivation when the pH is increased. Preliminary experiments with pyridine-N-oxide-2-aldoxime used in higher concentration (8.75×10^{-3}M) and in a buffer solution of higher pH (8.0) revealed that butyrocholinesterase inhibited by TEPP could be partly reactivated under such experimental conditions (Table 3). A more decisive reason for the low reactivation power of the N-oxides compared with the N-methyl-derivatives is that the orientating effect of the positively charged nitrogen atom is cancelled by the adjacent, negatively charged oxygen atom [17,18].

Effect in vivo. The pyridine-N-oxide-aldoximes were less toxic ($LD_{50} >$ 200 mg/kg body weight, white mice, i.p.) than P2S. Mice injected intraperitoneally with 200 mg per kg body weight showed no toxic symptoms. Preliminary experiments *in vivo,* revealed that the new aldoximes were inactive in protecting mice from fatal intoxication with ω-dimethylaminoethylthio-*iso*propoxy-methyl-phosphine oxide [19].

Our thanks are due to Prof. Gustaf Ljunggren, Director of Research Institute of National Defence, Department 1, for the kind interest he has shown in this work, to Dr. Anders Sundwall for the toxicological tests, and to Mrs. Gunnel Jonsson for skilled technical assistance.

Periodate Oxidation of Phenols

V *. 2,4-Dimethylphenol

ERICH ADLER, LENNART JUNGHAHN, ULF LINDBERG, BRITT BERGGREN and GERTRUD WESTIN

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The action of sodium periodate on 2,4-dimethylphenol produces 2,4-dimethyl-*p*-quinol (II), 2,4-dimethyl-*o*-quinol (III) and 3,5-dimethyl-*o*-quinone (XII). However, of these products, only the *p*-quinol (II) remains unchanged and can be separated from the reaction mixture. The *o*-quinol (III) rapidly dimerises by a Diels-Alder addition to give a 1,4-ethenonaphthalene derivative (IV), and as well gives the yellow *o*-quinol-*o*-quinone adduct (XIII) by diene addition to the *o*-quinone (XII). This adduct can also be obtained as the colourless enol XIV.

Although sodium periodate reacts very slowly with unsubstituted phenol [1], it is rapidly consumed by a variety of alkyl-substituted phenols. In several cases, well-defined reaction products can be isolated **. The present paper deals with the action of periodate on 2,4-dimethylphenol (I).

Phenol I when treated in aqueous solution with excess periodate at room temperature consumed slightly more than 1 mole of the oxidant almost instantly; further oxidation after this proceeded very slowly. A methylene chloride extract obtained from the light-red reaction mixture after an oxidation period of a few minutes yielded a crude crystalline product (40 %), from which three substances (A, B, C) were separated.

Substance A, m.p. 73—74°, was obtained in a yield of about 2 %, based on phenol I, by briefly extracting the crude product with ether. It proved to be identical with 2,4-dimethyl-*p*-quinol (II), which has been described by Bamberger and Brady [2].

After removing II, the crude product was treated with dilute aqueous sodium hydroxide giving an alkali-insoluble, white residue (substance B) and a deep-yellow solution, which gave a third solid (substance C) on acidifica-

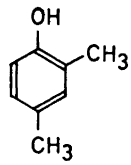
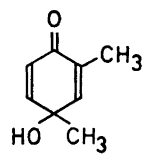
** Preliminary communication, see Ref. [16]



I



II

tion. These two products were both obtained in about 20 % yield based on phenol I.

Substance B. Analysis and the molecular weight of the alkali-insoluble substance, m.p. 237—238°, indicated the composition $C_{16}H_{20}O_4$, corresponding to a dimeric oxidation product of I with one extra atom of oxygen per molecule of I. The ultraviolet absorption of B (Fig. 1) showed that the aromatic structure of the starting material (I) had been lost. A strong absorption with a shoulder at 225 mμ (log ε, 3.88) ("K-band") and a weaker band at 307 mμ (log ε, 2.48) ("R-band") suggested the presence of an α,β-unsaturated carbonyl grouping. The position of the K-band indicated that the ethylenic bond of this chromophore carried only one substituent (Woodward rules [3], *cf.* also Fieser and Fieser [4]); in the present case this substituent would obviously be the ring carbon atom attached to the β-position of the enone grouping. The presence of the latter grouping was also shown by the infrared absorption spectrum (Fig. 2) which had a strong band at 1 680 cm^{-1} (conjugated CO) as well as a weaker absorption at 1 620 cm^{-1} (C = C conjugated with CO). A strong band at 1 720 cm^{-1} indicated the presence of an isolated carbonyl group, and the occurrence of strong absorption in the hydroxyl band region (3 400 cm^{-1}) and the presence of 2 active hydrogen atoms showed that the substance contained

..... Diacetate (IV, OAc instead of OH).

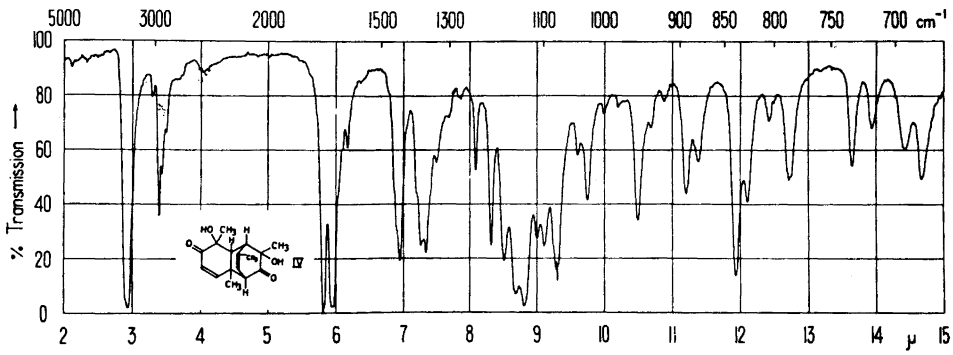

Fig. 2. Infrared spectrum of dimeric 2,4-dimethyl-*o*-quinol (IV) (= Substance B).

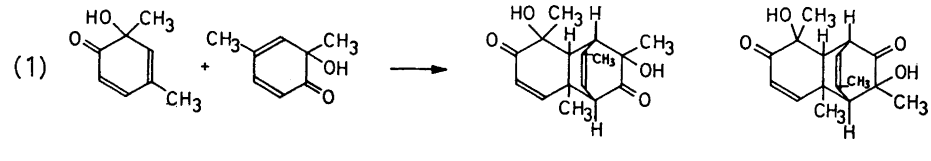
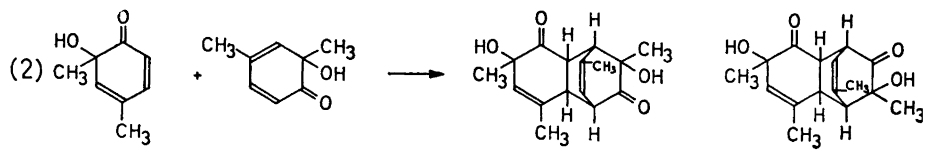
two (alcoholic) hydroxyl groups. Although remaining unchanged on refluxing with acetic anhydride-pyridine, substance B gave a diacetate, m.p. 182—184°, in moderate yield when heated with acetic anhydride and sodium acetate, and in good yield when perchloric acid was used as a catalyst. The ultraviolet absorption spectrum of the diacetate (Fig. 1) clearly exhibited the features of an α,β-unsaturated ketone (K-band, λ_{max} 226 mμ, log ε_{max} 3.95). Alkaline hydrolysis of the diacetate regenerated substance B.

The data reported above suggested that substance B was formed by oxidation of phenol I to a quinol, $C_8H_{10}O_2$, followed by dimerisation. Since the *p*-quinol II is stable in the monomeric form, the intermediate quinol undergoing dimerisation should be the 2,4-dimethyl-*o*-quinol III.

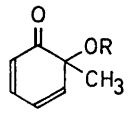
Several *o*-quinones have been found [5–10] to undergo dimerisation by diene addition. A similar diene reaction between two molecules of 2,4-dimethyl-*o*-quinol (III) could give rise to four isomeric dimers (IVa-c). Isomer IV would



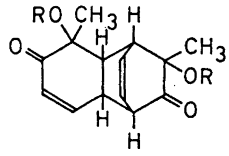


be formed as shown by Scheme (1), the molecule of III acting as a philodiene utilising the γ,δ-double bond of its conjugated carbonyl system. Isomer IVa could be formed in a similar way. The two remaining isomers, IVb and IVc, would be formed by addition of the α,β-ethylenic bond of the philodiene component to the diene system of the second molecule, as shown by Scheme (2). Structures IVb and IVc, however, can be excluded since they do not contain the α,β-unsaturated ketone grouping shown by the ultraviolet and infrared spectra of the substance. Consequently, the neutral dimer, m.p. 237—238° (substance B), could have structures IV or IVa, both of which are in harmony with the experimental data reported above.

No decision between structures IV and IVa has as yet been made, but some evidence in favour of IV is given by a comparison with similar dimeric dienones. Dimerisation by diene addition has recently been found by Metlesics and Wessely [11] in the case of 2-methyl-*o*-quinol acetate (V), obtained by oxidation of *o*-cresol with lead tetraacetate. Unlike 2,4-dimethyl-*o*-quinol (III), the *o*-quinol acetate V was stable in the monomeric state at room temperature; it dimerised, however, on heating to 120° [11]. Hot acid hydrolysis of the result-



V : R = Ac
VI : R = H



VII : R = Ac
VIII : R = H

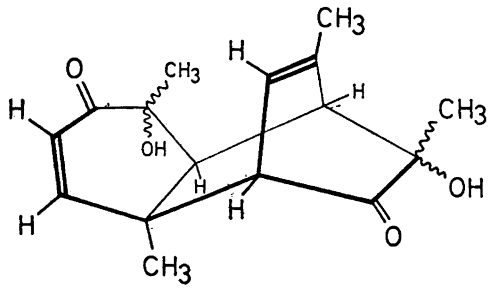
ing dimeric *o*-quinol acetate (VII) gave the dimeric *o*-quinol VIII, which was also obtained on similar hydrolysis of V followed by spontaneous dimerisation of the expected monomeric *o*-quinol VI [11]. Metlesics and Wessely [11] have provided unambiguous proof of structure VIII by degrading the dimer to 1,7-dimethylnaphthalene. On the basis of these results, structure IV, which is analogous to VIII, would seem more probable than structure IV a.

Structure IV rather than the isomeric structure IVa would also be analogous to the structure for dimeric 2,6,6-trimethyl-2,4-*cyclo*hexadienone put forward by Brown, Curtin and Fraser [12]. The dimerisation of the latter dienone (and of some other cyclic 2,4-dienones reported in literature [13]) is a diene addition quite similar to that occurring with *o*-quinones and *o*-quinols and is subject to similar possibilities of isomerism. In the following, substance B will be assumed to have structure IV although structure IVa cannot be excluded.

The exclusive formation of only one of four possible dimers of the hypothetical *o*-quinol III is a further example of the frequently encountered selectivity of the Diels-Alder reaction. Reaction at the γ,δ-double bond rather than at the α,β-double bond of an $\alpha,\beta,\gamma,\delta$-unsaturated carbonyl system acting as a philodiene has been previously observed [14,15].

Assuming that the diene reaction of the *o*-quinol III follows the "*endo* rule", dimer IV could be given the following steric representation, which is analogous to those proposed by Brown, Curtin and Frazer [12] for dimeric 2,6,6-trimethyl*cyclo*hexadienone and by Metle-

sics and Wessely [11] for the dimeric *o*-quinol acetate VII; the configuration at the *tert.* carbinol groups is still unknown.



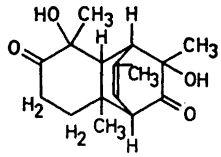
Examination of a Stuart-Briegleb model of IV indicated that the bi*cyclo*octene system present is fairly strained. This may possibly explain the occurrence of the absorption band at 210 mμ (log ε, 3.93) (see Fig. 1), which might be ascribed to the strained ethylenic bridge.

The formation of dimeric *o*-quinols similar to IV has been observed in this laboratory as a result of the periodate oxidation of other alkylated phenols, including 2,5- and 2,6-dimethylphenol, 2,4,6-trimethylphenol (mesitol) and thymol (preliminary communication, see Ref. [16]). In neither case could the expected monomeric *o*-quinol be isolated, since rapid dimerisation took place in the oxidation mixture. Wessely and co-workers [17,18] obtained 2,3-dimethyl-*o*-quinol and 2,3,5-trimethyl-*o*-quinol as monomers. Recently, periodate oxidation of 2,3,5-trimethylphenol was also found [19] to yield monomeric 2,3,5-trimethyl-*o*-quinol, which does not undergo dimerisation at room temperature. Several monomeric and dimeric *o*-benzoquinols carrying an acetonyl residue instead of an alkyl group at the carbinol C-atom of the quinol ring have been obtained in this laboratory by Magnusson [20].

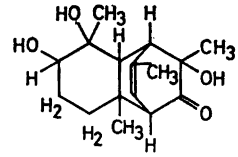
The results of some hydrogenation experiments which were carried out with substance B were in harmony with the proposed structure (IV). Hydrogenation, in ethanolic solution, with a Pd-catalyst gave a dihydro derivative, m.p. 194—5°. It contained two isolated carbonyl groups (infrared absorption bands at 1 723 and 1 710 cm^{-1}), which indicated that the ethylenic double bond of the conjugated enone system had been hydrogenated. Treatment of IV with hydrogen and platinum oxide in 93 % acetic acid resulted in rapid consumption of 1 mole of H_2, followed by slow consumption of a second mole. The tetrahydro derivative thus obtained had m.p. 219—20° and showed only one carbonyl function in its infrared spectrum. The position of this carbonyl absorption band (1 720 cm^{-1}) was similar to that of the unconjugated CO group in the starting material, indicating that, in addition to the ethylenic bond, probably the keto group of the unbridged six-membered ring of IV had been reduced. As a result of the reduction of one of the two keto groups of IV, the infrared spectrum of the tetrahydro compound showed two hydroxyl bands (3 500 and 3 260 cm^{-1}) as well as a band at 1 280 cm^{-1} which can be ascribed to a secondary hydroxyl group. Catalytic hydrogenation of substance B in acetic acid solution over platinum oxide at a pressure of 3.5 atm. produced

a hexahydro derivative, m.p. 201—2°, the infrared spectrum of which was devoid of carbonyl bands but showed strong absorption at 1 280 cm^{-1} (*sec.* OH).

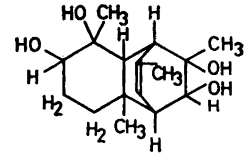
On the basis of these results, structures IX, X and XI are proposed for the dihydro, tetrahydro and hexahydro derivatives of IV.



IX



X



XI

Evidently, hydrogenation of the ethylenic bond of the bridge of the bi*cyclo*octene system did not occur under the experimental conditions used. Another case has recently been reported [21] in which catalytic hydrogenation of a methyl substituted ethylene bridge, similar to that present in IV, was hindered.

An attempt was made to convert the hexahydro derivative (XI), by heating with selenium, into a naphthalene derivative, which would necessarily involve the elimination of the methyl-substituted ethylene bridge as well as migration or loss of the angular methyl group. However, only small amounts of impure oils could be obtained. The oily products formed on Wolff-Kishner or sodium borohydride reduction of IV also failed to give pure reaction products on distillation at atmospheric pressure or on selenium dehydrogenation.

It is striking that when 2,4-dimethylphenol is treated with excess periodate the dimeric *o*-quinol IV is obtained although the postulated monomeric intermediate (*o*-quinol III) as well as the dimer (IV) contain α-ketol groupings which would be expected to be susceptible to periodate cleavage. However, the isolated dimer IV was found to be practically stable even on several hours' treatment with periodate. It was then expected that the α-glycol groupings present in the hydrogenation products X and XI reported above would be more easily oxidised. In fact, the tetrahydro derivative X consumed 1 mole of periodate in 1 h, further oxidation proceeding extremely slowly, and the hexahydro compound XI consumed 2 moles of periodate in 15 min. These results provide further support of structure IV for substance B and of the structures for its hydrogenation products that are given above. They also exclude the possibility that substance B might be a diene adduct of a mol. of *o*-quinol III, acting as a diene, and a mol. of *p*-quinol II, acting as a philodiene, rather than the dimeric *o*-quinol (IV). Neither of the isomers which could possibly arise by *o*-quinol-*p*-quinol addition would be able to give a hexahydro derivative consuming 2 moles of periodate.

Substance C. When the yellow alkaline extract obtained from the crude periodate oxidation product (*cf.* p. 1261) was poured into excess acetic acid, a colourless substance (C), m.p. 192—193°, precipitated. It had the composition $C_{16}H_{18}O_4$ with two hydrogen atoms less than the neutral product B (IV). The acidic character of C is due to the presence of an enolic hydroxyl group; this was indicated by the intense (dark violet-brown) colour reaction with ferric chloride. Absorption at 1 634 and 1 715 cm^{-1} in the infrared spectrum

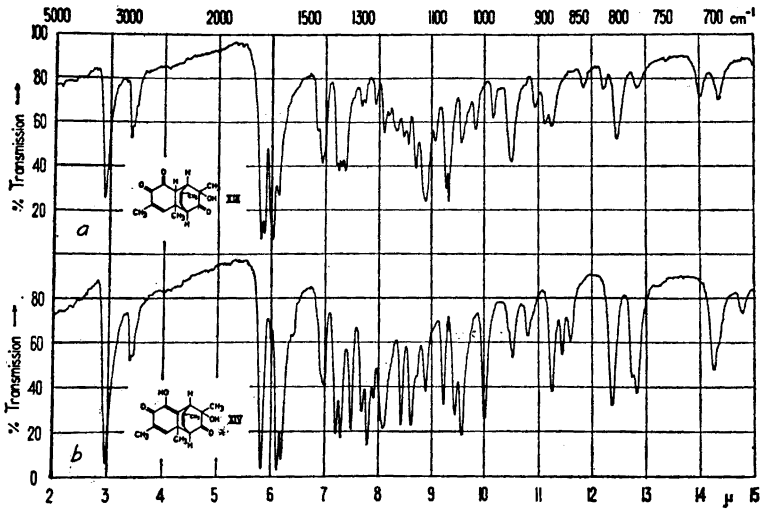


Fig. 3. Infrared spectra of addition product of 2,4-dimethyl-*o*-quinol and 3,5-dimethyl-*o*-quinone (= Substance C); *a*, keto form (XIII) and *b*, enol form (XIV).

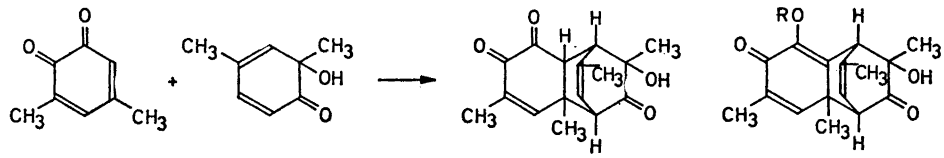
of C (Fig. 3b) revealed the presence of one conjugated (and chelated) and one unconjugated carbonyl function. A band at 1 612 cm^{-1} can be ascribed to the ethylenic bond conjugated with the first-mentioned carbonyl group. This data suggested that C might have been formed by Diels-Alder addition of one mol. of *o*-quinol III (diene) and one mol. of 3,5-dimethyl-*o*-quinone (XII) (philodiene), the latter probably also arising on periodate oxidation of the starting phenol I. This *o*-quinol-*o*-quinone addition could give rise to an adduct of structure XIII and enolisation of the latter would yield XIV. (The isomeric structure which would arise if the diene III were inverted, *cf.* the corresponding dimer IVa, p. 1263, cannot be excluded.)



Strong evidence for the correctness of structure XIV for the enol C is provided by the fact that the ultraviolet absorption of the substance (Fig. 4) is very similar to that reported by Horner and Sturm [5] for the dimer of 4,5-dimethyl-*o*-quinone. The latter has been shown [5] to be the enol XVI, containing a 2-hydroxy-2,5-*cyclo*hexadienone chromophore similar to that present

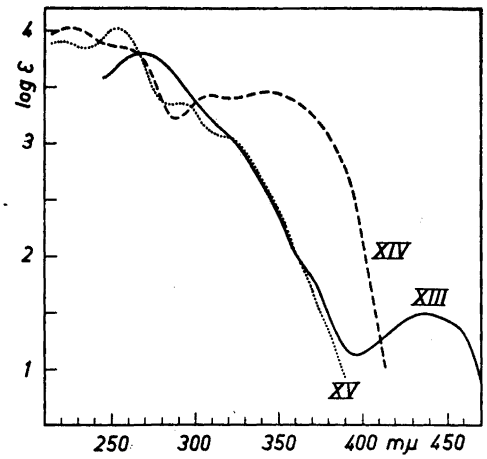


Fig. 4. Ultraviolet absorption spectra. Adduct of 2,4-dimethyl-*o*-quinol and 3,5-dimethyl-*o*-quinone (= Substance C),
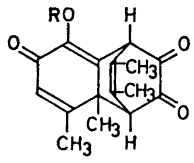
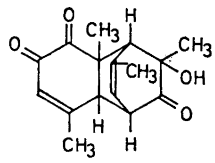
———— keto form (XIII); solvent, chloroform
– – – – – enol form (XIV); solvent, 95 % ethanol
..... monoacetate of enol form (XV); solvent, 95 % ethanol.

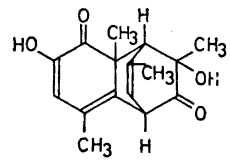
in the postulated structure XIV. Furthermore, substance C when treated with acetic anhydride-pyridine gave a monoacetate (XV), m.p. 213—214°, the ultraviolet absorption of which (Fig. 4) again was very similar to that of the monoacetate (XVII) of the enol XVI of Horner and Sturm.



XVI : R = H
XVII : R = Ac



XVIII

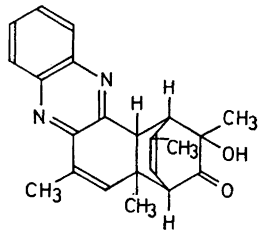


XIX

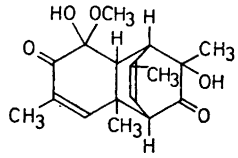
Since the *o*-quinone XII is unsymmetrically substituted, and either of its two C=C double bonds might be expected to have philodienic properties, a Diels-Alder addition of XII and III could alternatively yield the adduct XVIII, isomeric with XIII. The enol form of XVIII, *i. e.* XIX, however would have a 2-hydroxy-2,4-dienone chromophore rather than the "crossed conjugated" 2-hydroxy-2,5-dienone system present in Horner and Sturm's enol (XVI) and therefore almost certainly would have an ultraviolet absorption markedly different from that of the latter enol. This seems to exclude structure XIX for the enol C.

As mentioned above, the colourless enol XIV is precipitated from its yellow solution in aqueous alkali by pouring the solution into an excess of acetic acid. Slow neutralisation of the alkaline solution with acetic acid, however, produced

a yellow crystalline product, which after recrystallisation from ethyl acetate had a melting point (193—194°) only a few degrees above that of enol XIV; unlike the colourless enol, the yellow product gave no colour reaction with ferric chloride. The infrared spectrum of the yellow substance (Fig. 3a) showed three carbonyl bands (1 724, 1 704 and 1 662 cm^{-1}) instead of the two carbonyl bands for enol XIV; a further band at 1 630 cm^{-1} can be ascribed to an ethylenic bond conjugated with a CO group. The ultraviolet spectrum (Fig. 4) has a maximum at 269 mμ (log ε, 3.80) and in addition, a weak absorption band with a maximum at 437 mμ (log ε, 1.48) which indicates the presence of a 1,2-diketone grouping and is responsible for the yellow colour of the substance. The formation of a quinoxaline derivative (XX), m.p. 161—162°, on treatment with *o*-phenylenediamine confirms the occurrence of a 1,2-diketo grouping. Like enol XIV, the yellow substance dissolves in aqueous alkali yielding an intensely yellow solution (enolate of XIV) from which either the colourless enol XIV or the yellow substance (or mixtures of both) can be recovered depending on the manner, in which neutralisation is carried out (see above). Treatment of the yellow product with acetic anhydride-pyridine gave the enol acetate XV. From these results it is evident that the yellow product is the keto form XIII of substance C, and that the enol form XIV and keto form XIII are interconvertible.



XX



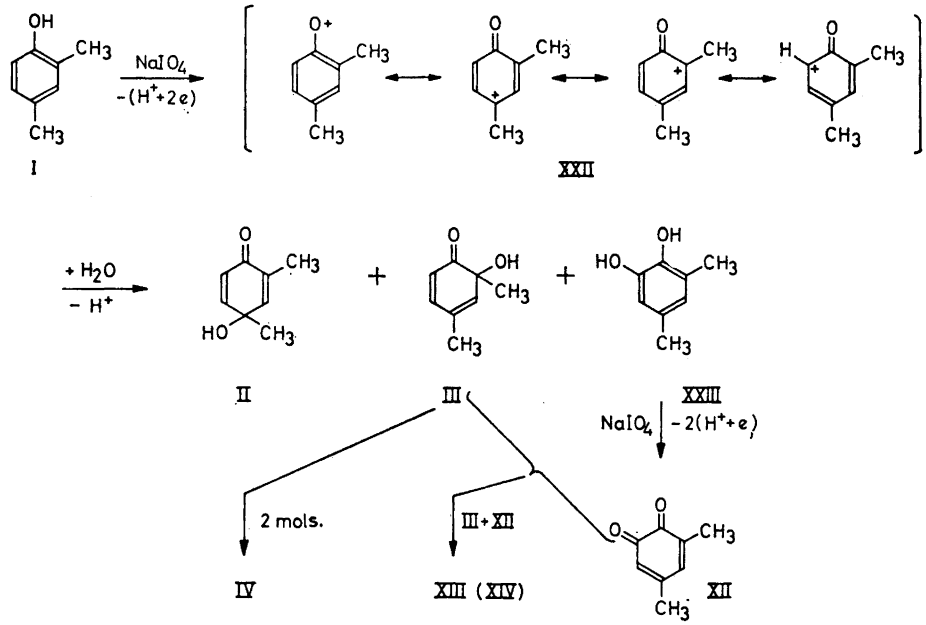
XXI

Recrystallisation of ketone XIII from methanol gave a colourless substance, the m.p. (191—192°) of which was approximately the same as that of XIII and XIV; it gave no colour reaction with ferric chloride. Analysis indicated an addition product of equimolar amounts of XIII and methanol. According to its infrared absorption, the methanol adduct contained a non-conjugated and a conjugated carbonyl group (1 720 and 1 670 cm^{-1}). Structure XXI is therefore ascribed to this compound. A colourless solution of XXI in dioxan when acidified with dilute sulphuric acid turned yellow and deposited yellow crystals of XIII. This behaviour is in harmony with the hemiketal structure XXI.

The fact that the melting points of the enol form XIV, the keto form XIII and also of the hemiketal of the latter (XXI) fall within a very narrow range (190 – 194°) seems to be due to conversion of the enol and the hemiketal into the yellow keto form XIII on heating to temperatures a few degrees below the melting point.

To summarise, the course of the reaction between 2,4-dimethylphenol (I) and periodate, in aqueous solution, can be represented as follows.

Periodate attacks the phenol at the hydroxyl group, producing, possibly by a one-step two-electron transfer [1], the mesomeric aroxyl cation XXII. Addition of water, and loss of a proton, converts XXII competitively into the *p*-quinol II, which is formed in minor amounts, the *o*-quinol III (main



reaction), and the catechol XXIII, the latter being immediately oxidised further to the *o*-quinone XII. While the *p*-quinol (II) is stable, the *o*-quinol III rapidly dimerises by Diels-Alder addition to yield the dimeric *o*-quinol IV, m.p. 237—238°, and simultaneously *o*-quinol III also adds to the *o*-quinone XII with the formation of the *o*-quinol-*o*-quinone adduct XIII, m.p. 193—194°, or its enol form, XIV.

Although *o*-quinones, in dimerisation by a Diels-Alder reaction, act both as diene and as philodiene [5–10], they were found to act as dienes in adding to another 1,3-diene such as butadiene or *cyclo*pentadiene [22,5], while the latter behaved as philodienes. The formation of addition product XIII seems to be the first certain case of an *o*-quinone behaving as a philodiene towards a diene component other than a second molecule of the same *o*-quinone. In the present case, the diene component, *i.e.*, the *o*-quinol III, evidently has more pronounced "diene" properties than the *o*-quinone XII, the latter therefore becoming a philodiene in the addition III + XII. Diene activity of *o*-quinol acetates towards typical dienophilic substances as well as towards 1,3-butadiene and *cyclo*pentadiene has been demonstrated by Wessely and co-workers [23,21]. The formation both of the dimeric *o*-quinol (IV) and of the *o*-quinol-*o*-quinone

adduct XIII seems to proceed much more rapidly than the hitherto unknown self-dimerisation of 3,5-dimethyl-*o*-quinone (XII) which also might have been expected to take place in the periodate reaction mixture. Preliminary experiments showed that the latter *o*-quinone is comparatively stable in aqueous solution and will therefore be available for addition to the highly active diene, *o*-quinol III, present in the periodate oxidation mixture.

The primary steps in the oxidation of 2,4-dimethylphenol with periodate as presented in the scheme above are closely analogous to those observed by Wessely and Sinwel [24] in the oxidation of the same phenol with lead tetraacetate. The latter reaction yielded the acetate of *o*-quinol III and the diacetate of *o*-quinone XII; the acetate of *p*-quinol II was probably formed also. The differences in the final results of the lead tetraacetate and the periodate reactions, respectively, are due to the greater stability of the monomeric *o*-quinol acetates as compared with the marked tendency of free *o*-quinols to undergo diene addition, as demonstrated in the present paper and in unpublished work [16].

EXPERIMENTAL

Ultraviolet and visible absorption spectra were recorded with a Perkin-Elmer Spectracord 4000-A, infrared spectra with a Perkin-Elmer model 21 instrument (KBr-discs). Analyses by A. Bernhardt, Mülheim (Ruhr), Germany. The determinations of active hydrogen have been carried out by Tekn.lic. R. Magnusson.

Oxidation of 2,4-dimethylphenol with periodate. A stirred solution of 2,4-dimethylphenol (20 g) in water (3.5 l) was mixed with 1.2 l of an aqueous solution of sodium metaperiodate (70 g, molar ratio phenol/periodate = 1/2). After 5 min, ethylene glycol (20 g) was added in order to reduce excess periodate. A light-brown amorphous precipitate (0.8 g) was removed by filtration and the orange-red solution was repeatedly extracted with methylene chloride. The combined extracts were dried over anhydrous calcium sulphate and evaporated leaving a reddish-brown, partly crystalline product.

*2,4-Dimethyl-*p*-benzoquinol (II) (= Substance A).* The crude reaction product was treated with ether, in which a minor part of the product dissolved. Concentration of the red ether extract gave a light-red crystalline solid, which was recrystallised several times from benzene-hexane; colourless needles and flat prisms, m. p. 72—73°, identified by infrared absorption (OH, 3 470 cm^{-1}; conjugated CO, 1 670 cm^{-1}) and mixed m. p. with 2,4-dimethyl-*p*-benzoquinol, m. p. 73—73.5° [2]. Yield, about 2 %. Recrystallisation from water gave the hydrate, m. p. 53—54°, reported by Bamberger and Bradey [2].

Dimeric 2,4-dimethyl-o-benzoquinol (IV) (1,2,3,4,4a,7,8,8a-Octahydro-2,8-dihydroxy-2,4a,8,9-tetramethyl-3,7-dioxo-1,4-ethenonaphthalene) (= Substance B). The residue obtained by ether extraction of the crude reaction product was treated with 0.5 N aqueous sodium hydroxide (10 ml per g of the solids). The nearly white insoluble residue was filtered off and washed with water. Recrystallisation from benzene gave colourless prisms, m. p. 237—238°. (Found: C 69.54; H 7.36; active H 0.70; mol. wt. (Rast) 279. Calc. for $C_{16}H_{20}O_4$: C 69.54; H 7.30; active H 0.72; mol. wt. 276.32). UV spectrum, Fig. 1; IR spectrum, Fig. 2.

Diacetate (IV, OAc instead of OH). a) A mixture of IV (0.58 g), acetic anhydride (7 ml) and anhydrous sodium acetate (0.7 g) was refluxed for 2.5 h. The solvent was removed under reduced pressure and the dark-brown oily residue dissolved in ethanol. Addition of water gave colourless prisms (yield, about 25 %), m. p. 183—184° after recrystallisation from ethanol.

b) A 2 M solution of acetic anhydride in ethyl acetate containing 1.15 % of perchloric acid [25] (12 ml) was added to IV (800 mg), which rapidly dissolved. After 10 min at room temperature, water was added, the ethyl acetate layer repeatedly washed with water and dried over anhydrous Na_2SO_4. The solvent was removed under reduced pressure and the residue recrystallised from ethanol, yielding prisms (76 %), identical by m. p. and

mixed m. p. with the product obtained according to a). (Found: C 66.80; H 6.74; CH_3CO 23.04. Calc. for $C_{20}H_{24}O_6$: C 66.65; H 6.71; CH_3CO 23.89.) UV spectrum, Fig. 1.

Treatment of the diacetate with 10 % ethanolic potassium hydroxide for 20 h at room temperature regenerated substance IV, identified by m. p. and mixed m. p. and IR spectrum. Yield, 91 %.

Dihydro derivative of IV (IX) (Decahydro-2,8-dihydroxy-2,4a,8,9-tetramethyl-3,7-dioxo-1,4-ethenonaphthalene). A palladium chloride-barium sulphate catalyst (176 mg), containing 9 % $PdCl_2$, was hydrogenated in abs. ethanol (10 ml). A solution of IV (152 mg) in abs. ethanol (30 ml) was added and shaking in a hydrogen atmosphere was continued. After 10 min. 1 mole of H_2 per mole of IV had been consumed and hydrogen uptake ceased. (In 93 % acetic acid instead of ethanol, similar hydrogenation took place but the time required was 30 min.) Evaporation of the filtered ethanol solution gave a colourless crystalline product, needles from ethyl acetate-hexane, m. p. 194—195°. (Found: C 68.73; H 7.85. Calc. for $C_{16}H_{22}O_4$: C 69.04; H 7.97.) IR maxima (cm^{-1}): 3 410 (OH); 1 723 and 1 710 (CO).

Tetrahydro derivative of IV (X) (Decahydro-2,7(or 3?)8-trihydroxy-2,4a,8,9-tetramethyl-3(or 7?)oxo-1,4-ethenonaphthalene). Platinum oxide (80 mg) was hydrogenated in 93 % aqueous acetic acid (10 ml), and 500 mg IV, dissolved in 10 ml of the same solvent, was added. After 4 min, 1 mole of H_2, and after a further 150 min, a total of 2 moles of H_2, had been consumed. Evaporation and recrystallisation from ethyl acetate-hexane gave needles, m. p. 219—220°. (Found: C 68.68; H 8.56. Calc. for $C_{16}H_{24}O_4$: C 68.54; H 8.63.) IR maxima (cm^{-1}): 3 480 and 3 240 (OH), 1 720 (CO), 1 280 (*sec.* alcohol).

Hexahydro derivative of IV (XI) (Decahydro-2,3,7,8-tetrahydroxy-2,4a,8,9-tetramethyl-1,4-ethenonaphthalene). A solution of IV (1.4 g) in acetic acid (60 ml) was shaken for 24 h, in the presence of 0.17 g PtO_2, with hydrogen at 3.5 atm. pressure. Evaporation of the filtered solution gave a crystalline residue, which was recrystallised from ethyl acetate-hexane. Prisms, m. p. 201—202°. (Found: C 68.07; H 9.07. Calc. for $C_{16}H_{26}O_4$: C 68.05; H 9.28.) IR maximum at 3 330 cm^{-1} (broad), no carbonyl bands.

Adduct of 2,4-dimethyl-o-quinol and 3,5-dimethyl-o-quinone, enol form (XIV) (1,2,3,4,4a,7 - Hexahydro - 2,8 - dihydroxy - 2,4a,6,9 - tetramethyl - 3,7 - dioxo - 1,4 - ethenonaphthalene) (= Substance C). The orange-yellow alkaline solution obtained after filtering off substance B (see above) was allowed to run fairly rapidly into an excess of glacial acetic acid. The almost white precipitate formed was recovered and recrystallised from glacial acetic acid. Colourless prisms, m. p. 191—192°. (Found: C 69.83; H 6.58; active H 0.92. Calc. for $C_{16}H_{18}O_4$: C 70.05; H 6.61; active H 0.73.) IR spectrum, Fig. 3b; UV spectrum, Fig. 4. An alcoholic solution of the substance gave a dark violet-brown colour reaction with alcoholic ferric chloride.

Enol acetate (XV). Acetylation of enol XIV with acetic anhydride in pyridine at room temperature and recrystallisation of the product from ethyl acetate gave the acetate, colourless needles, m.p. 213—214°. No colour reaction with ferric chloride. (Found: C 68.62; H 6.53. Calc. for $C_{18}H_{20}O_5$: C 68.34; H 6.37.) UV spectrum, Fig. 4. IR maxima (cm^{-1}): 3 400 (OH), 1 765 (vinyl ester CO), 1 722 (CO), 1 658 (conj. CO), 1 626 (C=C).

Adduct of 2,4-dimethyl-o-quinol and 3,5-dimethyl-o-quinone, keto form (XIII) (1,2,3,4,4a,7,8,8a-Octahydro-2-hydroxy-2,4a,6,9-tetramethyl-3,7,8-trioxo-1,4 - ethenonaphthalene). A solution of enol XIV (1 g) in 0.5 N aqueous sodium hydroxide (10 ml) was neutralised by dropwise addition of acetic acid. The yellow crystals deposited after cooling were repeatedly recrystallised from ethyl acetate to give yellow prisms, m. p. 194—195°, which gave no colour reaction with alcoholic ferric chloride. (Found: C 70.18; H 6.64; mol. wt. (Rast) 297. Calc. for $C_{16}H_{18}O_4$: C 70.05; H 6.61; mol. wt. 274.30.) UV spectrum, Fig. 4; IR spectrum, Fig. 3a.

Acetylation of XIII with acetic anhydride-pyridine at room temperature gave the enol acetate XV, identical with that obtained from enol XIV. A solution of XIII in acetic anhydride (in the absence of pyridine) was refluxed for 1 h, and the resulting dark-brown solution was poured into water; a dark, amorphous precipitate formed, which was removed by filtration. From the filtrate, unchanged XIII crystallised on cooling.

Quinoxaline derivative from XIII (XX). A solution of XIII (200 mg) and *o*-phenylenediamine (79 mg) in chloroform (50 ml) was kept over anhydrous Na_2SO_4 at room temperature for two weeks. The brown solution was extracted with 0.25 N NaOH, 1 N H_2SO_4 and aqueous $NaHCO_3$, and evaporated. The solid residue (190 mg) was recrystallised

from methanol to give slightly yellow prisms, m. p. 161–162°. (Found: C 75.99; H 6.18; N 8.36. Calc. for $C_{22}H_{22}O_2N_2$: C 76.27; H 6.41; N 8.09.)

Methanol addition product of substance XIII (XXI). A hot methanolic solution of the yellow ketone XIII on cooling deposited colourless needles, m. p. 191–192°, which gave no colour reaction with ferric chloride. IR maxima (cm^{-1}): 3 330–3 280 (OH), 1 720 (CO), 1 670 (conj. CO), 1 635 (C=C). (Found: C 66.65; H 7.61; OCH_3 10.20. Calc. for $C_{17}H_{22}O_5$: C 66.65; H 7.24; OCH_3 10.13.)

A sample of XXI was dissolved in cold dioxane. On addition of a drop of dilute aqueous sulphuric acid the colourless solution became yellow, and, on dilution with water, deposited yellow crystals of XIII.

Complex Dibenzofurans

I. Dehydration of Polyhydroxy-*p*-terphenyls

NILS E. STJERNSTRÖM

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The synthesis of a series of polymethoxy-*p*-terphenyls, all containing methoxyl groups in the 2,2′,5′,2″-positions, is described. The series was suitable for a study of the structural requirements for facile acid catalysed dehydration of 2,2′-dihydroxydiphenyl derivatives with formation of dibenzofurans. A brief discussion of the dehydration experiments is presented.

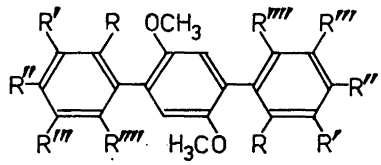
During the course of our studies on the acid catalysed polymerisation of quinones crystalline dioxidoterphenyls of still incompletely known structure were obtained in addition to large amounts of amorphous products [1,2], which presumably also contain dibenzofuran units. The mechanism of the formation of the trimeric and polymeric reaction products is not known, but the simplest assumption is that they are formed by dehydration of polyphenolic intermediates.

Several examples of acid catalysed dehydration of hydroxydiphenyls are known. The conversion of *o,o′*-dihydroxydiphenyl to dibenzofuran does not proceed smoothly and heating with zinc chloride is needed [3]. Some substituted *o,o′*-dihydroxylated diphenyls are, however, more easily dehydrated. This dehydration is frequently a source of complication when di- or polyphenol methyl ethers are demethylated with hydrobromic or hydriodic acid. Thus 2,4,2′,4′-tetramethoxydiphenyl [4] easily yields the corresponding dibenzofuran derivative and analogous reactions are reported for 2,4,2′,6′-tetramethoxydiphenyl [5], 4-methyl-2,6,2′,4′-tetramethoxydiphenyl [6], 2,2′-dimethyl-4,6,4′,6′-tetramethoxydiphenyl [7], diphloroglucinol hexamethyl ether [8], 2,4,5,2′,4′,5′-hexamethoxydiphenyl [9] and 2,5,2′,5′-tetrahydroxy-4,4′-dimethoxydiphenyl [10].

Dehydrations, effected under relatively mild conditions, are of obvious interest in relation to the formation of dibenzofuran derivatives in the acid polymerisation of *p*-benzoquinones. Apart from the above mentioned diresorcinol derivatives comparatively little (*cf.* Refs.[2,11] dealing with hydroquinones) is known about the ease with which *o,o′*-hydroxylated di- or polyphenols undergo transformation into dibenzofurans and as a consequence this investigation was undertaken.

An ideal series of compounds for a study of the dehydration reaction would be substituted anisols, containing in the *ortho* position a 2-methoxy-, a 2,3-dimethoxy- or a 2,4-dimethoxyphenyl group, *etc.* Some unsymmetrical polymethoxydiphenyls of this type have been prepared, but they are not easily synthesised.

Our earlier experience in the transformation of trihydroquinone hexamethyl ether (III) to the dioxido-*p*-terphenyl VIIa [2] made the series of 2,5-disubstituted hydroquinone dimethyl ethers I—V attractive for a comparative study, especially because terphenyl derivatives are formed during the polymerisation of *p*-benzoquinones. Compounds of this type are easily prepared by the mixed Ullmann coupling of suitable mono- and diiodophenyl derivatives. The reaction products are readily separated by fractional distillation *in vacuo* followed by recrystallisation.



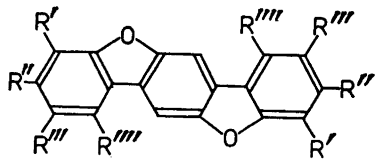
I $R=R'=OCH_3$; $R''=R'''=R''''=H$

II $R=R''=OCH_3$; $R'=R'''=R''''=H$

III $R=R'''=OCH_3$; $R'=R''=R''''=H$

IV $R=R''''=OCH_3$; $R'=R''=R'''=H$

V $R=R'=R''=OCH_3$; $R'''=R''''=H$



VI $R''=OCH_3$ (VIa: OH instead of OCH_3); $R'=R'''=R''''=H$

VII $R'''=OCH_3$ (VIIa: OH instead of OCH_3); $R'=R''=R''''=H$

VIII $R''''=OCH_3$ (VIIIa: OH instead of OCH_3); $R'=R''=R'''=H$

IX $R'=R''=R'''=R''''=H$

Coupling of 2,5-diiodohydroquinone dimethyl ether with 3-iodoveratrol yielded a mixture containing mainly 2,3,2',3'-tetramethoxydiphenyl and 2,3,2',5',2'',3''-hexamethoxy-*p*-terphenyl (I). Similarly 2,4,2',5',2'',4''-hexamethoxy-*p*-terphenyl (II), 2,6,2',5',2'',6''-hexamethoxy-*p*-terphenyl (IV) and 2,3,4,2',5',2'',3'',4''-octamethoxy-*p*-terphenyl (V) were synthesised employing 4-iodoresorcinol dimethyl ether, 2-iodoresorcinol dimethyl ether and 4-iodopyrogallol trimethyl ether, respectively. A ratio 1:8 of diiodohydroquinone dimethyl ether and monoiodocompound was generally used and the yields were about 40 % based on the diiodocompound. Some dehalogenation of the monoiodocompound with formation of the corresponding phenol ethers always occurred, but this is a common observation in Ullmann reactions.

With one exception the starting materials were prepared according to standard procedures as indicated in the experimental part. Kauffmann and Kieser [12] obtained 4-iodoresorcinol dimethyl ether in a rather poor yield by iodination of resorcinol dimethyl ether in alcoholic solution with iodine and mercuric oxide. Omission of the solvent raised the yield substantially (*cf.* the synthesis of 4-iodopyrogallol trimethyl ether [10]).

Pummerer *et al.*[13] reported the synthesis of the diresorcyl- and dipyrogallylhydroquinones corresponding to II and V by condensing *p*-benzoquinone

with resorcinol and pyrogallol under acid conditions. The present author was, however, unable to confirm the results of Pummerer *et al.* On attempting to synthesise the diresorcyl derivative 2,4,2′,5′,2″,4″-hexahydroxy-*p*-terphenyl (demethylated II), according to Pummerer *et al.* an amorphous product, was obtained. Similar results were reported by Erdtman [1] who after methylation of this amorphous material succeeded in isolating a crystalline substance. This product was assumed to be 2,4,2′,5′,2″,4″-hexamethoxy-*p*-terphenyl (II), but it was not identical with compound II, obtained by the Ullmann reaction. It might perhaps be a diphenyl derivative; this problem, however, requires further investigation.

The formation of 2,4,2′,5′-tetrahydroxydiphenyl by simply heating resorcinol with *p*-benzoquinone has been claimed by Pummerer *et al* [13]. This reaction could not be reproduced either and in an attempt to repeat the synthesis of the dipyrogallylhydroquinone octaacetate (2,3,4,2′,5′,2″,3″,4″-octaacetoxy-*p*-terphenyl, corresponding to V), the present author obtained pyrogallol triacetate as the sole crystalline product. The m.p. of Pummerer's »octaacetate» was surprisingly low (158°). Pyrogallol triacetate melts at 165° and the slightly impure pyrogallol triacetate obtained from the reaction melted at about 160°. These results suggest that Pummerer's »octaacetate» was pyrogallol triacetate.

The dehydrations were studied in the following way. The methoxylated terphenyl was refluxed with an excess of constant boiling hydrobromic acid for three days. The phenol obtained was collected and methylated directly. The methylation product was either identical with the starting material or a substance of dioxidoterphenyl type with a high melting point and exhibiting strong fluorescence in ultra violet light.

In our earlier experiments [2] the trihydroquinone derivative III was converted into the corresponding dioxidoterphenyl VIIa (characterised as the dimethyl ether VII). It has now been found that the diresorcylhydroquinone hexamethyl ethers II and IV are dehydrated to the dihydroxydioxido-*p*-terphenyls VIa and VIIIa (characterised as VI and VIII). The terphenyls I and V, containing veratrol- and pyrogallol trimethyl ether groupings, however, did not undergo ring closure.

The first step in these reactions is of course demethylation and it is interesting to note that the terphenyls II and IV, which show a pronounced aptitude for ring closure, are derivatives of *m*-dihydroxybenzene as are the diresorcinols. The latter also undergo facile dehydration as previously mentioned in this paper. Another interesting feature of these reactions is that a hydroxyl group in the 3 and 3″-positions does not facilitate the dehydration. Other cases of the same type are represented by, *e.g.*, 2,3,4,2′,3′,4′-hexahydroxydiphenyl [14] and a tetrapyrogallol (with the diphenyl linkages in the *o*-positions to hydroxyl groups; Erdtman, unpublished results), both easily prepared by demethylation of the corresponding methyl ethers with hydrogen bromide. This problem will be the subject of a future communication.

Ullmann [15] reported normal demethylation of 2,5,2′,5′-tetramethoxydiphenyl, dihydroquinone dimethyl ether, with hydrobromic acid. According to our experience with trihydroquinone the 2,5,2′,5′-tetrahydroxydiphenyl should undergo dehydration with formation of 2,8-dihydroxydibenzofuran.

A reinvestigation showed that dihydroquinone tetramethyl ether on prolonged refluxing with constant boiling hydrobromic acid gave 2,8-dihydroxydibenzofuran in good yield. This is also in accordance with the early findings of Nietzki *et al.*[11] on the dehydration of a dimethyldihydroquinone dimethyl ether, the structure of which was elucidated by Posternak *et al.*[16], with concentrated hydrochloric acid.

Zinc dust distillation of the dioxido-*p*-terphenyl derivative VIa gave 2,2′,5′,2″-dioxido-*p*-terphenyl (IX) identical with the dioxido-*p*-terphenyl described by Schimmelschmidt [17] (*cf.* Ref.[2]).

EXPERIMENTAL

All melting points are uncorrected

4-Iodoresorcinol dimethyl ether. Finely divided iodine (300 g) followed by freshly precipitated mercuric oxide (240 g) were added in small portions to resorcinol dimethyl ether (150 g) with vigorous stirring. Complete decolouration of the reaction mixture was awaited before each new addition of iodine. The exothermic reaction required about an hour. The hot reaction mixture was filtered with suction and the inorganic material thoroughly washed with ether. The ether was evaporated and the residue, a yellow oil, crystallised on scratching. The crude product (265 g, 92 % yield) was recrystallised from methanol. Yield 215 g, 81 %, m.p. 40—41° (lit.[12] m.p. 40°).

Ullmann reaction. General procedure. 2,5-Diiodohydroquinone dimethylether [18] (3.9 g), copper bronze (35 g) and the monoiodocompound (3-iodoveratrol [19], 4-iodoresorcinol dimethyl ether, 2-iodoresorcinol dimethyl ether [20], 21 g, or 4-iodopyrogallol trimethyl ether [10], 25 g) were thoroughly mixed in a 300 ml flask and heated on a salt bath to 220—240°, when a vigorous reaction started which raised the temperature to about 300°. After some minutes the reaction mixture was allowed to cool and the organic products extracted with chloroform. The solvent was evaporated and the residue subjected to distillation *in vacuo*.

2,3,2′,5′,2″,3″-Hexamethoxy-p-terphenyl (I). The combined extracts from three runs yielded veratrol (3 g), 2,3,2′,3′-tetra methoxydiphenyl (28 g) and a light brown thick syrup (7 g, b.p. about 300°, 0.4 mm), which crystallised on scratching with a few drops of methanol. The substance was recrystallised from *n*-butanol. M.p. 177—179°. (Found: C 69.9; H 6.5. Calc. for $C_{24}H_{26}O_6$: C 70.2; H 6.4.)

2,4,2′,5′,2″,4″-Hexamethoxy-p-terphenyl (II). The distillation *in vacuo* yielded a very small amount of resorcinol dimethyl ether, 2,4,2′,4′-tetramethoxydiphenyl (8.5 g) and an oil (2.5 g, b.p. 215—265°, 1 mm), which crystallised on scratching with a few drops of methanol. The product was recrystallised from acetic anhydride and sublimed *in vacuo*. M.p. 207—209°. (Found: C 69.8; H 6.7. Calc. for $C_{24}H_{26}O_6$: C 70.2; H 6.4.)

2,6,2′,5′,2″,6″-Hexamethoxy-p-terphenyl (IV). The combined products from three runs yielded resorcinol dimethyl ether (5 g), 2,6,2′,6′-tetramethoxydiphenyl (21 g) and a highboiling yellow oil (5,3 g, b.p. 240—300°, 1 mm), which crystallised on cooling. The terphenyl was recrystallised from a mixture of ligroin and benzene and was finally purified by sublimation *in vacuo*. M.p. 227—228°. (Found: C 70.0; H 6.5. Calc. for $C_{24}H_{26}O_6$: C 70.2; H 6.4.)

2,3,4,2′,5′,2″,3″,4″-Octamethoxy-p-terphenyl (V). The combined products from three runs yielded pyrogallol trimethyl ether (5 g), 2,3,4,2′,3′,4′-hexamethoxydiphenyl (31 g) and a dark yellow crystalline material (7 g, b.p. *ca.* 300°, 1 mm), which was recrystallised from ligroin. Colourless crystals, m.p. 171—172°. (Found: C 66.4; H 6.4. Calc. for $C_{26}H_{30}O_8$: C 66.4; H 6.4.)

Demethylation and dehydration. General procedure. The polymethoxy-*p*-terphenyl (*ca.* 500 mg) was refluxed with hydrobromic acid (48 %, 25 ml) in an atmosphere of carbon dioxide or nitrogen for three days. The reaction mixture was allowed to cool, diluted with water (100 ml) and filtered. The crude phenol was directly methylated in methanol suspension with an excess of dimethyl sulphate and sodium hydroxide.

4,4'-Dimethoxy-2,2',5',2''-dioxido-p-terphenyl (VI). 2,4,2',5',2'',4''-Hexamethoxy-*p*-terphenyl (II, 590 mg) yielded a crude blue phenolic precipitate (VIa, 400 mg, m.p. *ca.* 345°, decomp.) which was methylated. The yield of dimethyl ether VI was almost quantitative. It was recrystallised from acetic anhydride. M.p. 290—292°. (Found: C 75.4; H 4.5. Calc. for $C_{20}H_{14}O_4$: C 75.5; H 4.4.)

6,6''-Dimethoxy-2,2',5',2''-dioxido-p-terphenyl (VIII). 2,6,2',5',2'',6''-Hexamethoxy-*p*-terphenyl (IV, 560 mg) yielded a crude brown phenolic precipitate (VIIIa, 330 mg, m.p. *ca.* 330°, decomp.), which was converted into compound VIII in an almost quantitative yield. It was purified by recrystallisation from acetic acid and sublimation *in vacuo*. M.p. 287—289°. (Found: C 75.5; H 4.7. Calc. for $C_{20}H_{14}O_4$: C 75.5; H 4.4.)

Demethylation of 2,3,2',5',2'',3''-hexamethoxy-p-terphenyl (I). This compound (570 mg) yielded a crude blue phenolic precipitate (400 mg, m.p. *ca.* 280°, decomp.) which was quantitatively converted to the starting material by methylation.

Demethylation of 2,3,4,2',5',2'',3'',4''-octamethoxy-p-terphenyl (V). The octamethyl ether (450 mg) yielded a crude blue phenol (350 mg, m.p. *ca.* 260°, decomp.), which on methylation was almost quantitatively converted to the starting material.

Demethylation and dehydration of 2,5,2',5'-tetramethoxydiphenyl. 2,5,2',5'-Tetramethoxydiphenyl [15] (900 mg) was refluxed with constant boiling hydrobromic acid (30 ml) in an atmosphere of carbon dioxide for 80 h. The reaction mixture was then diluted with water (100 ml) and the slightly bluish 2,8-dihydroxydibenzofuran (400 mg) collected. M.p. 233—235°. The phenol was converted to 2,8-dimethoxydibenzofuran, m.p. 89—90°, and 2,8-diacetoxydibenzofuran, m.p. 152—154°, using standard procedures. Swislowsky [21] reports the following melting points for these substances: 242—243°, 88—89° and 150—151°, respectively.

2,2',5',2''-Dioxido-p-terphenyl (IX). 4,4''-Dihydroxy-2,2',5',2''-dioxido-*p*-terphenyl (VIa, 200 mg) was thoroughly mixed with zinc dust (2 g) and heated in a test tube to red heat when a partially phenolic mixture (*ca.* 20 mg) of substances sublimed on the cool walls of the tube. The mixture was treated with dilute sodium hydroxide and the insoluble material sublimed *in vacuo* and recrystallised from chlorobenzene. M.p. 264—266°. Mixed melting point with an authentic sample [2,17], 265—266°.

The author is grateful to Dr. I. Wellings for checking the manuscript.

Optical Phenomena in Turbidimetric Analysis Applied to Sulfate Determination in Phosphoric Acid

SVEN-ERIC DAHLGREN

Research and Development Dept., AB Förenade Superfosfatfabriker, Landskrona, Sweden

A theory for optimum measuring wavelength at turbidimetric analysis is presented. As the validity of Lambert-Beer's law is limited at short wavelengths the theory has not been satisfactorily verified when applied to barium sulfate dispersions in gelatine solution. The optical properties of such dispersions have been studied and recommendations for measurements are given. A standard deviation of 1.5 % was obtained.

For a rapid and accurate determination of the sulfate content in technical phosphoric acid by wet processes, gravimetric methods are not convenient. Gravimetric methods are time consuming and considerable errors may thereby be introduced. Coprecipitation by cations can be eliminated by an ion-exchange technique, but the fact remains that the phosphate ion is among those anions giving the heaviest coprecipitation with barium sulfate.

A titrimetric method using the sodium salt of rhodizonic acid as an external indicator is rapid and simple but not very accurate, and may in some cases completely fail. Neither is the volumetric estimation of a centrifuged barium sulfate precipitate very accurate.

The two requirements mentioned seem to be most easily obtained by physical methods, primarily by turbidimetric and nephelometric determination of a barium sulfate dispersion. Precipitation in an ethyl alcohol-dipropylene glycol solution [1,2] was considered to be too cumbersome, and a gelatine solution was preferred. A turbidimetric method using gelatine has been presented by Gassner and Friedel [3]. The preparation of the test dispersion described by G. and F. was found to have some disadvantages, which have been eliminated. Further, there was a need for further study of the optical properties of the dispersion based on present knowledge of light-scattering by small particles.

THEORY – OPTIMUM MEASURING CONDITIONS FOR TURBIDIMETRIC ANALYSIS

Light-scattering phenomena by small particles are of a most complicated nature. The light is scattered in different directions and the space distribution of light intensity and polarization is a function of particle size, particle shape, light wavelength and the refractive index of the particles relative to the surrounding medium. In addition to this, the design of the optical geometry of the measuring equipment influences the data obtained. At a turbidimetric measurement part of the scattered light radiation reaches the photoreceiver of the instrument, as it takes a finite space angle. In the following, some fundamentals have been taken from the excellent monograph by van de Hulst [4] and applied to the present problem.

Let the total energy scattered in all directions by a particle be equal to the energy of the incident wave falling on the area C_{sca}, the cross section for scattering. The efficiency factor for scattering, Q_{sca}, is defined by

$$Q_{sca} = \frac{C_{sca}}{G} \tag{1}$$

where G = geometrical cross section of the particle.

Assume a spherical particle and introduce the parameter ϱ

$$\varrho = \frac{4\,\pi\,r \cdot |m - 1|}{\lambda} \tag{2}$$

where r = particle radius

m = relative refractive index, that is the ratio between the refractive index relative to vacuum of the particle, and that of the dispersing medium

λ = light wave length in the medium, that is the the ratio of light wave length in vacuum and the refractive index of the dispersing medium relative to vacuum.

The physical meaning of ϱ is the phase lag suffered by the central ray that passes through the sphere along a full diameter. For non-absorbing spheres m is a real number and for absorbing ones a complex number.

In the case light absorbing particles

$$Q_{ext} = Q_{sca} + Q_{abs} \tag{3}$$

where Q_{ext} = efficiency factor for extinction, Q_{abs} = efficiency factor for absorption.

The efficiency factors for extinction and absorption are analogous to that for scattering. Thus for non-absorbing particles the efficiency factors for scattering and extinction are equal. For the present problem absorption need not to be taken into consideration.

In Fig. 1, the efficiency factor for extinction of non-absorbing spheres is shown as a function of ϱ for different values of the relative refractive index. The wave form of the extinction curves depends on interference between light transmitted through the particles and diffracted light. The "ripple"

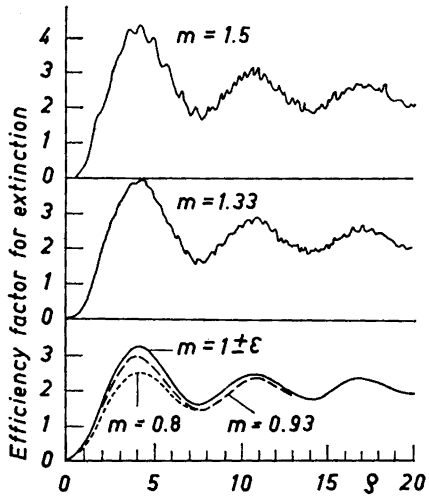

Fig. 1. Extinction curves at different relative refractive indices. After van de Hulst.

which becomes more pronounced when m increases, has no simple explanation. It is of special interest to note that the "ripple" is almost negligible for low values of m and ϱ.

In practice, dispersions of particles of uniform size are seldom found. For mixtures of particles of various sizes we define the effective radius r_{eff} as

$$r_{\text{eff}} = \tfrac{3}{4} \cdot \frac{\text{total particle volume}}{\text{total geometrical cross section}} \tag{4}$$

The corresponding phase lag is denoted by ϱ_{eff} and the effective efficiency factor for extinction by $\overline{Q}$. In Fig. 2 are shown extinction curves for various distributions of radii of dispersed particles when m is close to 1.

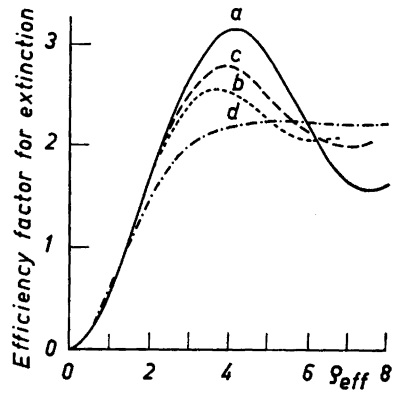

Fig. 2. Extinction curves for mixtures of particles of various sizes, all with m close to 1.

Curve a: uniform size with radius r_1
Curve b: $f(u) = u^{-1}$ for $0 < u \leqslant 1$ $r_{eff} = \frac{2}{3} r_1$
Curve c: $f(u) = 1$ for $0 < u \leqslant 1$ $r_{eff} = \frac{3}{4} r_1$
Curve d: $f(u) = e^{-u}$ for $0 < u < \infty$ $r_{eff} = 3 r_1$
where $u = r/r_1$ and $f(u) =$ the number distribution function.

The curves show how the typical features are washed out if particles of a range of sizes are present. Of interest is that for not too high values of ϱ_{eff} the curves nearly coincide. The transmission T of a dispersion is given by

$$T = \exp(-\overline{Q}\,\pi\, r_{eff}^2 \cdot nl) \tag{5}$$

where $n =$ the number of particles per unit volume of dispersion with size reduced to r_{eff}
$l =$ the path length

On indexing the reference sample with "o" and the test sample with "t" the following expression of the extinction E is obtained

$$E = \log \frac{T_o}{T_t} = \frac{\overline{Q}\,\pi\, r_{eff}^2 \cdot l}{\ln 10} (n_t - n_o) \tag{6}$$

Assume $n_o = 0$, the concentration of the disperged material to be c, and its solubility in the dispersing medium to be s. Thus eqn. 6 changes into

$$E = \frac{k\,\overline{Q}\,l}{r_{eff}} (c - s) \tag{7}$$

where $k =$ a proportionality constant.

Eqn. 7 holds within the region of Lambert-Beer's law. From this equation it is clear that for analytical applications, such a wave length should be chosen that a variation of the effective radius in the preparation is almost completely eliminated by a corresponding change in the effective efficiency factor for extinction. The most favourable wave length can indirectly be obtained from Fig. 2 by determining the tangent point between a straight line through the origin and the extinction curve before the first maximum. Depending on the size distribution, there are different extinction curves and a more or less flat optimum. If the measured extinction of a polydisperse dispersion is plotted against the reciprocal wave length, the curve obtained is equiform to the effective efficiency factor for extinction against ϱ_{eff}. The origin in this case is the point of infinite long wave length. From experimental data the most favourable wave length is thus directly obtained.

A consequence of the above is that the dispersion, if possible, should be prepared under such conditions that in addition to good reproducibility an effective radius is obtained, corresponding to a most favourable wave length within the measuring region of the available equipment.

It is often pointed out that the main drawback of turbidimetric methods of analysis is a lack of reproducibility in preparation of the dispersion. The presented theory shows that the effect of moderate variations in the size distribution can be eliminated. Great care in the preparation work must, however, be maintained.

Investigations by Lewis and Lothian [5] on barium sulfate dispersion with particle radius 4.6 μ gave a refractive index of 1.52 compared with 1.64 on crystalline barium sulfate. This indicates a water content of 60 % by volume of the particles, which is in accordance with specific gravity determination by sedimentation. This is explained by formation of particles through condensation of sub-microscopic units. In a medium with an refractive index close to that of water the relative refractive index will be 1.14. Since this is close to 1 the ripple on the extinction curve may be neglected for not too high values of ϱ.

EXPERIMENTAL

Solutions

Sulfate-free water. The regular distilled water was found to give a weak opalescence on addition of barium chloride. Therefore deionized distilled water has been used. Deionizing was made by Crystalab Deeminizer Model CL-5.

Gelatine solution. For preparing the gelatine solution, sulfate-free gelatine quality 1/241 Special from Deutsche Gelatinfabriken, Göttingen-Würtenberg, is used. Per liter of solution 5 g gelatine and 0.5 g thymol as a preservative are taken. After swelling for 15—30 min in deionized distilled water the mixture is heated under agitation until all gelatine has dissolved and the solution becomes clear. It is then cooled to room temperature. After a day, an increase in viscosity and weak opalescence are apparent. This depends on a transition from sol to gel state, the latter being the stable state at room temperature. On heating to 40—45°C for a few minutes and cooling to room temperature the solution again becomes clear and light-fluid. This should be repeated every day before usage. There is no apparent change in the sol state for several hours after heating. The solution may be used for at least 2 weeks.

Barium chloride — gelatine solution. Except for about 10 ml fill a 1-litre volumetric flask with above described gelatine solution. Add 20 g $BaCl_2 \cdot 2\ H_2O$ and dissolve it completely. The flask is then filled to the mark with gelatine solution.

Standard solution. 0.2718 g K_2SO_4 A R ad 500 ml with deionized distilled water. 1 ml equivalent to 0.1 mg S.

Alternatively: 0.2721 g K_2SO_4 A R ad 500 ml. 1 ml equivalent to 0.3 mg SO_4.

Alternatively: 0.2665 g K_2SO_4 A R ad 500 ml. 1 ml equivalent to 0.3 mg H_2SO_4.

Phosphoric acid solution. 200 g conc. phosphoric acid ad 1 000 ml with deionized distilled water.

Preparation of barium sulfate dispersion with known sulfate content. For work with dispersions with up to 0.35 mg S per 50 ml the standard solution is diluted with deionized distilled water 1:10. From a burette, different amounts of the diluted solution are charged into a series of dry 100 ml Erlenmeyer-flasks. The amount is preferably a multiple of 2.5 or 5 ml, but not greater than 35 ml. To each flask is added 5.0 ml of phosphoric acid solution and deionized distilled water to bring the total volume to 40.0 ml. Then 5.0 ml of gelatine solution is pipetted, and finally 5.0 ml of barium chloride-gelatine solution added drop-wise from a burette under shaking to each flask. After 10 min, extinction measurements can be carried out.

The pH of the solution should be 1—2.5, found by Gassner and Friedel [3] to be optimum.

If some other maximum sulfate content is to be investigated the dilution of the standard solution should be appropriately changed so that no more than 35 ml of the diluted solution need to be taken.

Preparation of the reference sample. In a dry 100 ml Erlenmeyer-flask 35.0 ml of deionized distilled water, 5.0 ml of phosphoric acid solution, 5.0 ml of gelatine solution and 5.0 ml of barium chloride-gelatine solution are taken and the mixture shaken.

Measuring equipment

All measurements in glass cells were made with a Beckman B spectrophotometer and all measurements in quartz cells were made with a Beckman DU spectrophotometer.

RESULTS

Behaviour at very low sulfate concentrations. When measuring at successively decreasing sulfate concentrations, a linear relationship was obtained between extinction and concentration down to a limit where a discontinuous change took place and the extinction was zero (Fig. 3). The reason is that a certain critical supersaturation, a threshold value, must be surpassed to initiate nucleation. From the figure it is clear that there is lower limit for turbidimetric determination in gelatine solution at about 0.05 mg S per 50 ml of final solution, that is about 1 ppm.

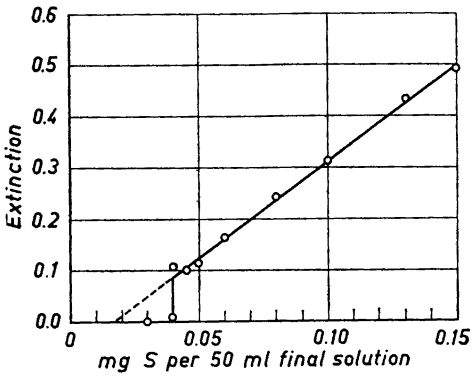

Fig. 3. Behaviour at very low sulfate concentrations. Wave length 420 mμ and 50 mm glass cells.

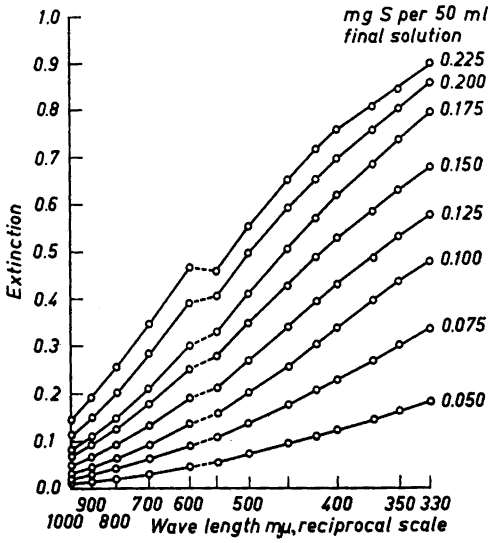

Fig. 4. Influence of light wave length on the extinction at different sulfate concentrations. 50 mm glass cells.

In an ethyl alcohol-dipropylene glycol solution the solubility of barium sulfate is completly different. It is possible in such a solution to determine nephelometrically sulfate concentrations down to 0.01 ppm.[2]

Extinction measurements in glass cells at varying sulfate concentration and light wave length. In a first series of measurements the extinction was determined over the whole wave length range of Backman B for sulfate concentrations from 0.050 to 0.225 mg S per 50 ml final solution at 0.025 intervals in 50 mm glass cells. In Fig. 4 the results are plotted with the sulfate concentration as parameter. When changing over from blue sensitive to red sensitive phototube a kink was obtained on the extinction curves, which was not the case with colorimetric determinations. Since the measurement of scattered light is sensitive to geometrical variations of the optical system in quite another degree than that of directed light, a geometrical dissimilarity between the two tubes may be responsible for the phenomenon. Since there is a reciprocal wave length scale in Fig. 4 a direct comparison with Fig. 1 is possible. This shows that the investigated range must be prior to the first maximum. At still shorter wave lengths an extinction maximum is to be expected.

In Fig. 5 the results are plotted with the wave length as parameter. The curves for 330 and 350 mμ are clearly bent and the points not so well positioned along the curve as for the other wave lengths. At 400 mμ there is a linearity up to 0.15 mg S per 50 ml which is further extended at 420 and 450 mμ. A weak tendency for the 500 and 550 mμ curves to bend in the opposite direction from the other curves is observed.

A similar series of measurements was carried out with 20 mm glass cells within the concentration range 0.05 to 0.30 mg S per 50 ml final solution at 0.05 intervals. The extinction scale in Fig. 6 is enlarged 2.5 times relative to that in Fig. 5 in order to compensate for the difference in light path of the cells. If Lambert-Beer's law is valid, the curves in the two figures should

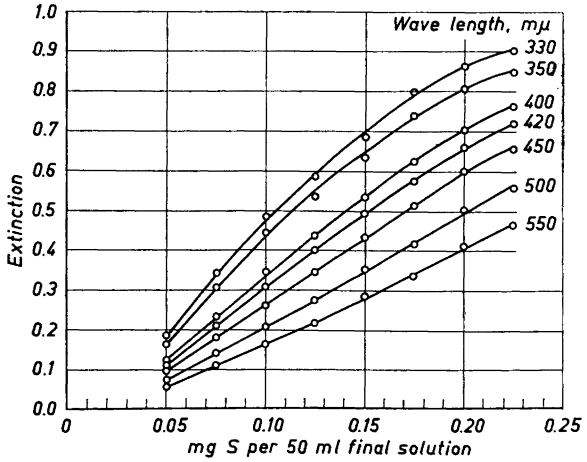

Fig. 5. Influence of sulfate concentration on the extinction at different light wave lengths using 50 mm glass cells.

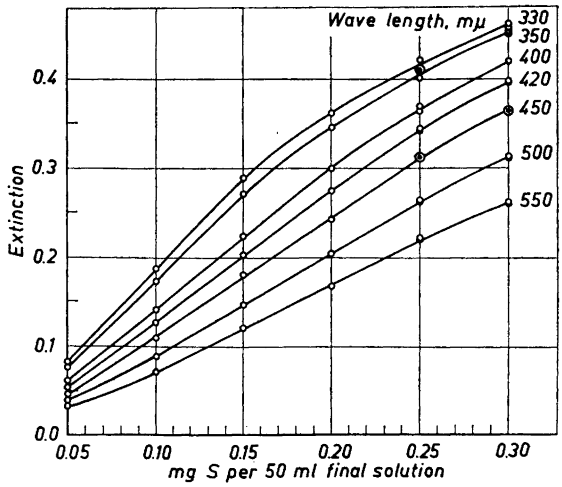

Fig. 6. Influence of sulfate concentration on the extinction at different light wave lengths using 20 mm glass cells.

coincide. After a minute parallel shift it is found that the curves for 330 and 350 mμ do not coincide, but intersect at two points. At 400 mμ they coincide up to 0.15 mg, at 420 mμ up to 0.175 mg, at 450 mμ up to 0.20 mg and at 500 and 550 mμ within the whole range.

The validity limit of Lambert-Beer's law thus varies with the wave length. A series of 11 solutions containing 0.150 mg S per 50 ml final solution were measured in 20 mm glass cells at different wave lengths and standard deviation calculated.

Wave length mμ	Standard deviation %
330	2.2
350	2.3
370	2.6
400	2.6
420	2.5
450	2.9
500	3.5
550	3.6

The relative standard deviation thus increases at increasing wave length in accordance with the theory presented.

Double determinations for the same conditions and lengths were made with a gelatine solution of varying age. When the trial was stopped after 1 month no change had been observed.

Extinction measurements in quartz cells at varying sulfate concentration and light wave length. Since an extinction maximum was expected at a wave length below the Beckman B range, further measurements were made with a Beckman

DU using 10 and 20 mm quartz cells. Owing to light absorption in the suspending medium itself, measurements below 240 mμ were impossible and in fact it has an absorption peak already at 270—280 mμ. This resulted in a marked peak on the extinction curves obtained with 20 mm cells but not on those obtained with 10 mm cells.

At decreasing wave length the linear range of extinction *versus* sulfate concentration diminished considerably, and was too small for practical purposes. Thus since Lambert-Beer's law was not valid here, the theory of optimum measuring wave length could not be satisfactorily verified.

CONCLUSIONS

Some results have been obtained which are in accordance with the presented theory of optimum measuring wave length; however, it could not be satisfactorily verified when applied to barium sulfate dispersions in a gelatine solution. The standard deviation is almost the same in the 330—420 mμ region but increases at longer wave lengths. The sensitivity increases with decreasing wave length. At the same time, however, the validity region of Lambert-Beer's law is decreased. An adequate compromise therefore seems to be a wave length of about 420 mμ, where determinations may be carried out within the range 0.05—0.20 mg S per 50 ml of final solution. Preferably, concentration and cell size is selected so that an extinction of 0.3 to 0.5 is obtained. For that reason a 50 mm cell is well suited. With these specifications 12 equally prepared solutions showed a standard deviation of 1.5 %.

Acknowledgement. Sincere thanks are due to Mr Kornél Horváth, who with great care and interest carried out all the measurements.

The Chemistry of the Natural Order Cupressales XXVIII * Constituents of *Juniperus virginiana* L.

JARL RUNEBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Commercial cedarwood oil contains cuparene, cedrol, widdrol, α-cedrene and thujopsene. Evidence was obtained for the presence of a dextrorotatory curcumene containing a vinylidene group and gas chromatography indicated the presence of several other unidentified sesquiterpenes.

Investigations on the heartwood constituents of *Juniperus chinensis* L.[1] and *J. utahensis* Lemm.[2] have been described in two previous papers. Among the compounds identified in these juniper woods were the sesquiterpene hydrocarbons cuparene [3] and thujopsene [4] and the sesquiterpene alcohol widdrol [5]. The structures of the two latter compounds are at present under investigation in this laboratory. Experience gained in the examination of these juniper woods has now been applied to cedarwood oil [6,7]. Commercially this is the most important of the juniper wood oils.

Cedarwood oil is produced by steam distillation of saw mill waste of the American red cedar, *Juniperus virginiana*. The highest yield of oil, about 3.5 % of the wood, is obtained from older trees containing a greater proportion of heartwood. The crude oil is discoloured and the commercial product is obtained by redistillation of the crude material. The boiling point range of cedarwood oil has been given as 264—280° at atmospheric pressure. Several hundred thousand pounds of the oil are produced a year in the United States for use in perfumery and in scenting soaps.

Among the compounds previously reported in cedarwood oil is α-cedrene but although this has been shown to be present it has probably never been isolated in a pure state from the natural oil. Natural cedrene has a lower negative specific rotation (usually about —55°) than the synthetic product (—91°) obtained by dehydration of cedrol [8]. The natural material is considered to be a mixture of α-cedrene and the corresponding exocyclic isomer β-cedrene, but it has not been proved that the exocyclic compound present

* Part XXVII. *Acta Chem. Scand.* **14** (1960) 797.

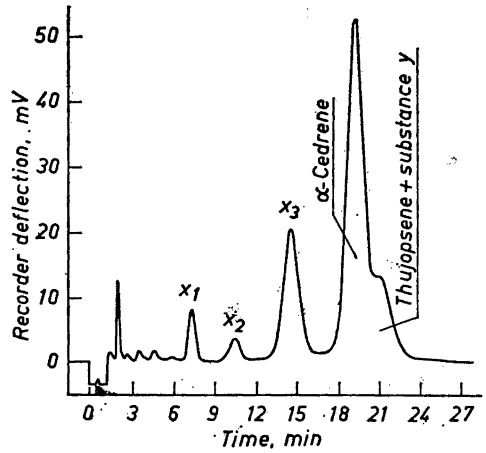

Fig. 1. Gas chromatogram of fraction IIa (Table 2). Argon flow rate 25 ml/min.

actually has the cedrene skeleton. Cedrol has frequently been isolated from *J. virginiana* and cedrenol [9] (*of.* Ref. [10]) and pseudocedrol [11] have also been reported to occur in the wood.

The commercial sample of cedarwood oil used in this investigation was subjected to a preliminary distillation followed by redistillation of some of the fractions obtained. Traces of monoterpenes or compounds with similar boiling points were detected in the lowest boiling fractions by gas chromatography (see Fig. 1, peaks with retention times up to about 11 min.). Only minute amounts of compounds containing hydroxyl groups were present in these fractions. Infrared spectra and gas chromatographic analysis showed that α-cedrene was the main component of the oil. The second largest constituent was thujopsene which has not previously been demonstrated in cedarwood oil. One of the main fractions was oxidised with selenium dioxide to a mixture of aldehydes, and then with silver oxide to yield the corresponding carboxylic acids. Chromatography of this mixture gave α-cedrenic acid [12] and hinokiic acid (thujopsenic acid [4]).

Thujopsene was almost completely separated from α-cedrene by fractional distillation but gas chromatographic analysis showed that both fractions still contained other compounds.

The specific rotations of the distillation fractions listed in Table 2 indicate that in addition to α-cedrene (—91°) and thujopsene (—112°) there are at least two further compounds present, probably with positive rotations. One is concentrated in the first fractions of Table 2 and gives a separate peak on gas chromatography, the other is concentrated in the last fractions and is apparently covered by the thujopsene peak.

Two of the fractions of Table 2 were dehydrogenated and then treated with ozone at low temperature. The material unattacked by ozone was optically inactive and it was identical with a synthetic sample of dihydro-*ar*-curcumene [13]. Neither α-cedrene nor thujopsene gave dihydro-*ar*-curcumene when treated in the same way. *d*-γ-Curcumene [14], which gives dihydro-*ar*-

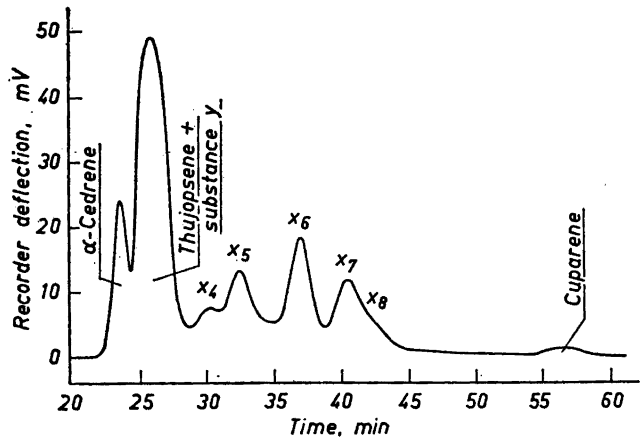

Fig. 2. Gas chromatogram of fraction IIIc (Table 3). Argon flow rate 17 ml/min.

curcumene on selenium dehydrogenation [15] was at first considered a possible precursor of this substance. Since, however, the ultraviolet spectra of the two fractions, before dehydrogenation, show maxima only at 205 and 207 mμ, respectively, they cannot contain any major amounts of *d*-γ-curcumene. However, the infrared spectra of both fractions show comparatively strong bands at 1 645 and 883 cm^{-1} indicating the presence of a compound containing a vinylidene group. It therefore appears likely that the dihydro-*ar*-curcumene precursor (substance *y*, Figs. 1 and 2) is an isomer of curcumene containing a vinylidene group.

An attempt was made to purify the above sesquiterpenes by chromatography on basic alumina. The first fractions eluted by light petroleum were reasonably pure α-cedrene but thujopsene could not be separated from the other components of the mixtures.

Naves has previously reported the presence of dextrorotatory bicyclic sesquiterpenes in *J. virginiana* [16], and one of these has now been identified. The material boiling slightly higher than the main α-cedrene-thujopsene fraction was redistilled and a fraction showing strong aromatic absorption in the infrared and ultraviolet was ozonised at low temperature. The material unattacked by ozone was identified as cuparene [3].

Gas chromatographic analysis of the cuparene containing fractions showed the presence of at least 7 unidentified compounds. The separation of these compounds on a larger scale offers considerable difficulties but could probably be achieved by preparative gas chromatography. No isomerisation of these compounds on the stationary phase used was observed.

The highest boiling part of cedarwood oil was a mixture of sesquiterpene alcohols. The first fractions containing alcohols (fraction IIIh (Table 3) and fractions IVa—IVc (Table 4)) crystallised on standing and were separated into cedrol and widdrol by chromatography on alumina. The highest boiling

alcohol fractions remained liquid and appeared, according to their infrared spectra to consist of a complex mixture of alcohols and carbonyl compounds.

The compounds isolated are listed below with very approximate estimates of the amounts present (as a percentage of dried cedarwood oil): α-Cedrene 35, thujopsene 30, cuparene 2, cedrol 4 and widdrol 2.

EXPERIMENTAL

Rotations were measured in chloroform; melting points, taken on a hot stage, are corrected; boiling points are uncorrected. Light petroleum refers to the fraction b.p. 40–60°.

The cedarwood oil (Ia, Florida, redistilled) used was obtained from the Dragoco Co, Holzminden, Weser, Germany. The oil was dried over sodium sulphate and a sample (2010 g) was then subjected to a preliminary distillation through a 40 cm, packed column. The fractions obtained are listed in Table 1.

Table 1. Distillation of cedarwood oil. Total distillate 1 729 g or 86 %

Fraction	Weight (g)	B.p. (°C)	Pressure (mm Hg)	Rotation ($[\alpha]_D$)	Refractive index ($n_D^{25.0}$)
Ia	181	74–114	11	−57	1.4999
Ib	250	114–118	11	−60	1.5018
Ic	399	82–83	1	−66	1.5007
Id	343	83–84	1	−58	1.5011
Ie	325	84–89	1	−47	1.5024
If	231	89–111	1	+ 4	1.5077
Ig (residue)	271				

Fractions Ia (65 g) and Ib (237 g) were combined and distilled through a 1 m, vacuum jacketed, packed column giving the fractions listed in Table 2.

Dehydrogenations. (a) Dihydro-*ar*-curcumene was obtained from fraction IIb (5 g) by heating with finely powdered selenium (5.0 g) to 200° in a carbon dioxide atmosphere; the temperature was gradually raised to 280° and held there for 48 h. The reaction product was filtered and distilled (b.p. 122–129°/10 mm) and the oil obtained (4.3 g) was ozonised in methylene chloride (20 ml) at −70°C until an excess of ozone was indicated by the appearance of a blue colour. When the reaction mixture had reached room temperature, zinc dust (4.7 g) activated with glacial acetic acid (1 ml) was added with stirring and the mixture was left over-night and filtered. Hydrogen peroxide (30 %, 10 ml) in potassium hydroxide (10 %, 5 ml) was added dropwise to the filtrate and the mixture was refluxed for 5 min. The aqueous phase was separated and the organic phase was extracted with sodium hydroxide (2 N), washed with water, dried and evaporated giving

a viscous oil (3.4 g). This was chromatographed on basic alumina (40 g). The first 100 ml of light petroleum eluted a hydrocarbon fraction which on distillation under reduced pressure gave an oil (0.95 g), b.p. 126°/9 mm, $[\alpha]_D$ 0°, $d_{22.0}$ 0.8767, $n_D^{25.0}$ 1.4862, which was identified as dihydro-*ar*-curcumene [15,17]. The infrared spectra of the dehydrogenation product and of a synthetic sample [18] were superimposable. On treatment with aqueous nitric acid (30 %) in a sealed tube at 170° followed by methylation with diazomethane in ether, the dehydrogenation product gave dimethyl terephthalate, m.p. and mixed m.p. 140.0–140.5°.

(b) Fraction IIh (5.0 g) was dehydrogenated and ozonised in the same way as IIb. The material unattacked by ozone (1.57 g) was identified as dihydro-*ar*-curcumene.

α-Cedrene and thujopsene. Fraction Id (30 g) was dissolved in ethanol (95 %, 500 ml), selenium dioxide (18.0 g) was added and the mixture was refluxed for 5 h. After filtering, the solution was evaporated and the oil obtained was distilled, b.p. 95–115°/1.0 mm (21.8 g). This oil (17.5 g) was added to a suspension of silver oxide (sodium hydroxide 12.9 g, silver nitrate 28.8 g) in water (600 ml). The mixture was refluxed with vigorous stirring for 24 h. Solid material was filtered off and the filtrate was extracted with ether, acidified and again extracted with ether. This second extract, on evaporation gave a crystalline residue (A, 6.4 g).

Silica gel (30 g) suspended in a solution of dimethyl sulphoxide in chloroform (5 %, 100 ml) was poured into a chromatographic column and then washed successively with *iso*propyl ether and light petroleum. The crude acids A (916 mg) were chromatographed on this pretreated silica gel using an *iso*propyl ether-light petroleum mixture (1:2) as mobile phase. The first 250 ml of solvent eluted a crystalline substance (149 mg) which was sublimed three times in a vacuum giving *α*-cedrenic acid [12], m.p. 123.5–125.0°, $[\alpha]_D$ −69° (*c*, 2.0) (identified by mixed m.p. and IR). The next 150 ml of solvent eluted a second compound (240 mg) which was recrystallised from light petroleum, m.p. 166.5–167.5°, $[\alpha]_D$ −85° (*c*, 2.4), identified as hinokiic acid [4] (mixed m.p., IR). The rest of the chromatographed sample appeared to be polymeric material.

Cuparene. Cuparene was concentrated by redistillation of the highest boiling fraction in Table 1 (I f, 210 g).

Table 3. Redistillation of fraction If. Total distillate 192 g or 91 %.

Fraction	Weight (g)	B.p./14 mm Hg (°C)	Rotation ($[\alpha]_D$)	Refractive index ($n_D^{25.0}$)
IIIa	18.4	124–126	−77	1.5000

IIIh	34.8	147–153	+31	–

Fraction IIIf (5.0 g) was ozonised and treated in the same way as the dehydrogenation product of fraction IIb. The material unaffected by ozone (810 mg), b.p. 117°/7 mm, $[\alpha]_D$ +65°, $n_D^{25.0}$ 1.5206, was identified as cuparene [3] by comparing its physical constants and infrared spectrum with those of an authentic sample.

Cedrol and widdrol. A sample of the crystalline fraction IIIh (2.5 g) was chromatographed on basic alumina (40 g). Light petroleum eluted an oil (0.17 g) which was not further investigated, 2 % ether in benzene gave cedrol (1.45 g) which was recrystallised from 95 % ethanol, m.p. 85.0–85.5°, $[\alpha]_D$ +11° (identified by mixed m.p. and IR). Elution with benzene-ether (1:1) gave widdrol [5] (0.56 g) which was recrystallised from acetonitrile, m.p. 95.0–96.0°, $[\alpha]_D$ +105° (identified by mixed m.p. and IR).

Main sesquiterpene alcohol fraction. The residue (Ig, 271 g) from the preliminary distillation described in Table 1 was distilled in a 1 m, vacuum-jacketed, packed column, giving the fractions listed in Table 4.

Table 4. Distillation of the main sesquiterpene alcohol fraction. Total distillate 214 g or 79 %.

The Beginning Solubilization of 20-Methylcholanthrene in Aqueous Solutions of Conjugated and Unconjugated Bile Acid Salts

Bile Acids and Steroids 79

ARNE NORMAN*

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The first stage of association in aqueous bile salt solutions was studied by measuring the amounts of solubilized 20-methylcholanthrene. It was observed to begin in sodium deoxycholate, chenodeoxycholate and cholate solutions when the concentrations of bile salts rose to approximately 0.005 M, 0.006 M and 0.012 M, respectively. The glycine and taurine conjugates of these bile acid salts were found to undergo initial association in approximately the same concentration ranges as the respective unconjugated bile salts. The sodium and potassium salts of lithocholic and cholanic acids and their taurine and glycine conjugates were found to be only sparingly soluble in water. Even saturated solutions of these compounds were unable to solubilize 20-methylcholanthrene.

Studies carried out using various colloid-chemical methods have shown clearly that association to micelles takes place in aqueous solutions of the sodium salts of conjugated and unconjugated bile acids. The previous work in this field has been reviewed by Ekwall *et al.* [1,2].

The ability to solubilize lipoid substances is a characteristic property of association colloids and the establishment of a beginning solubilization can be taken to indicate the occurrence of association. Ekwall [3] introduced the use of fluorescent polycyclic hydrocarbons in the study of the solubilizing power of association colloids and in the determination of the colloid concentration where solubilization begins. The solubilities of these hydrocarbons can be readily determined by measuring the fluorescence or ultraviolet absorption of their solutions.

* Present address: Department of Chemistry, Karolinska Institutet, Stockholm 60, Sweden.

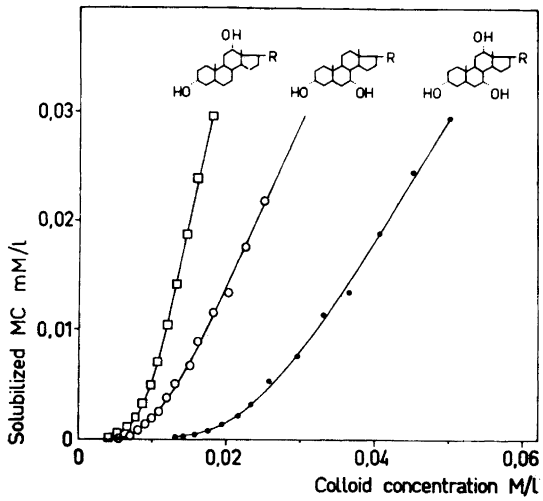

Fig. 1. Solubilization of 20-methylcholanthrene in aqueous solutions of sodium deoxycholate (□—□), sodium chenodeoxycholate (○—○), and sodium cholate (●—●).

The aim of the present study was to compare the first stages of association in solutions of bile acid salts and their taurine and glycine conjugates. The present paper reports the results of fluorometric determinations of the beginning solubilization of 20-methylcholanthrene in solutions of sodium cholate, deoxycholate, chenodeoxycholate, lithocholate and cholanate and their taurine and glycine conjugates.

MATERIALS AND METHODS

20-Methylcholanthrene (MC) was a product of Eastman-Kodak Co., Rochester, N.Y. The synthesis and physical properties of the conjugated and unconjugated bile acid salts were reported in a previous paper of the author [4].

Methylcholanthrene was added in excess to ampoules containing the bile salt solutions. After they had been closed by fusion, the ampoules were shaken at 40°C for 48 h. After this period the undissolved methylcholanthrene was removed from the solutions by filtration and the amounts of methylcholanthrene solubilized by the solutions were determined by measuring the intensity of fluorescence (according to Ekwall *et al.* [5]) or the ultraviolet absorption (according to Klevens [6]). The fluorescence intensities were measured with a Beckman Model DU Quartz Spectrophotometer provided with the fluorescence accessory

Potassium glycolithocholate	0.0004	0.0007
Potassium glycocholanate		0.001
Potassium taurocholanate	0.0006	0.001

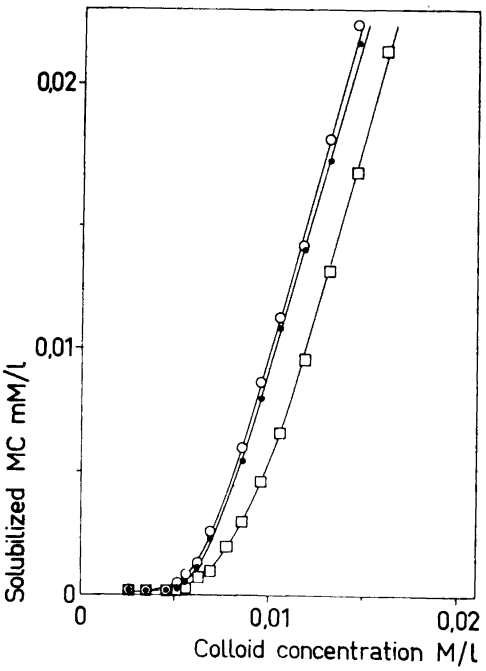

Fig. 2. Solubilization of 20-methylcholanthrene in aqueous solutions of sodium deoxycholate, (□—□) sodium taurodeoxycholate (O—O), and sodium glycodeoxycholate (●—●).

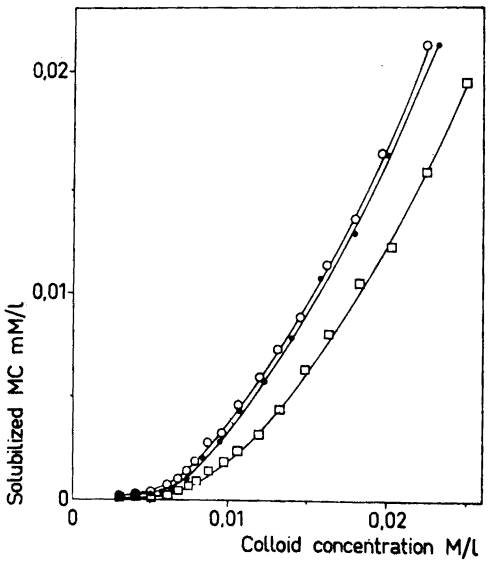

Fig. 3. Solubilization of 20-methylcholanthrene in aqueous solutions of sodium chenodeoxycholate (□—□), sodium taurochenodeoxycholate (O—O), and sodium glycochenodeoxycholate (●—●).

set. The measurements were all made at room temperature. No precipitation was found to occur when the temperature decreased from 40° to 20°C, which is in accordance with the observation of Sjöblom [7] that the solubilizing power of bile acid salts does not diminish with decreasing temperature.

Reference solutions containing different amounts of methylcholanthrene in the same bile salt solution were prepared as follows. A known volume of a standard solution of methylcholanthrene in benzene was added from an Agla micrometer burette to an ampoule and the benzene was evaporated from the ampoule *in vacuo* at room temperature. A measured volume of the bile salt solution was introduced into the ampoule which, after it was closed by fusion, was shaken in a thermostat at 40° for 48 h.

RESULTS

The time necessary to attain maximal solubility of methylcholanthrene in the solutions was studied by determining the amounts of methylcholanthrene solubilized after the ampoules were shaken for different lenghts of time at 40°C. The results obtained with 0.04 M cholate and 0.015 M deoxycholate solutions revealed that equilibrium was attained after 24 h.

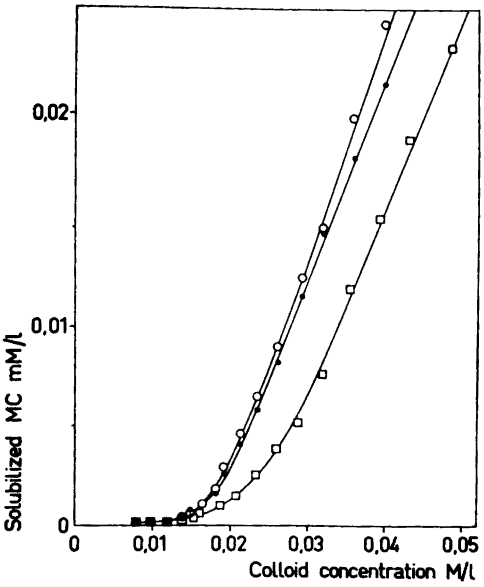

Fig. 4. Solubilization of 20-methylcholanthrene in aqueous solutions of sodium cholate (□—□), sodium taurocholate (○—○), and sodiumglycocholate (●—●).

In a number of cases the amounts of solubilized methylcholanthrene were determined by both fluorescence and ultraviolet absorption methods. Conforming results were obtained by both methods. However, the fluorescence method is appreciably more sensitive and is hence more suitable for the determination of the low solubility when a low degree of association prevails in the colloid solution.

Figs. 1—4 show the results of solubilization determinations by the fluorescence method on solutions of the sodium salts of deoxycholic, chenodeoxycholic and cholic acids and their taurine and glycine conjugates. All these compounds are very soluble in water and the beginning solubilization becomes clearly evident within a narrow concentration range in their solutions. Similar experiments were carried out on solutions of the sodium and potassium salts of lithocholic and cholanic acids and their taurine and glycine conjugates but no solubilization of methylcholanthrene was observed to take place even in their saturated solutions. These compounds are, however, only sparingly soluble in water as shown by the solubilities of the potassium salts of the conjugated acids at 20° and 40° (Table 1). The solubilities of the sodium and potassium salts are approximately equal and the salts of lithocholic and cholanic acids are less soluble than the corresponding salts of the conjugated acids.

DISCUSSION

By determining the solubilities of *p*-xylene, cholic acid, cholesterol and 20-methylcholanthrene in cholate solutions, Ekwall and his collaborators [1,2] found that a beginning solubilization occurs when the cholate concentration

rises to about 0.015 M. The activity of the cholate anion in cholate solutions saturated with cholic acid also changes at the same concentration owing to the beginning association. The corresponding data for sodium deoxycholate show that the first signs of association are observed at a concentration of about 0.005 M. These experiments reveal that the number of hydroxyl groups and their location in the molecule influence the association process. The curves in Fig. 1 show that the solubilizing powers of chenodeoxycholate solutions are weaker than those of deoxycholate solutions. In addition, solubilization begins at a somewhat higher concentration in chenodeoxycholate solutions than in deoxycholate solutions. Hydroxyl groups at carbon atoms 3 and 12 (deoxycholic acid) favour micellar association more than hydroxyl groups at carbon atoms 3 and 7 (chenodeoxycholic acid).

The configurations of the side chains in bile salts apparently have a lesser influence on the association process and the properties of the micelles than the structure of the ring skeleton. Figs. 2, 3 and 4 show that the concentration where beginning association occurs do not differ essentially for the conjugated and unconjugated bile salts with the possible exception that the solubilization begins at a slightly lower concentration in the case of the conjugated salts. The solubilizing powers of the taurine and glycine conjugates are practically equal and slightly greater than those of the corresponding unconjugated bile salts. The solubilizing powers increase more rapidly and become linear, *i.e.*, the ratio of the amount of hydrocarbon solubilized and the concentration of the association colloid becomes constant, at lower concentrations of the conjugated salts.

Acknowledgement. This investigation was begun at the Institute of Physical Chemistry, Åbo Akademi. I wish to express my gratitude to Professor Per Ekwall, the Head of the Institute, for his guidance.

The Conductance of Conjugated and Unconjugated Bile Acid Salts in Aqueous Solutions

Bile Acids and Steroids 80

ARNE NORMAN*

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The equivalent conductances of aqueous solutions of the sodium salts of cholic, taurocholic, glycocholic, deoxycholic, taurodeoxycholic, glycodeoxycholic and dehydrocholic acids in the concentration range from 0.002 to 0.5 M were measured at 40°C. All these bile salts were found to differ from a normal uni-univalent electrolyte in their conductance behaviour. The beginning association leads to a greater than normal increase in the conductance in cholate and deoxycholate solutions. The advancement of the association in more concentrated solutions causes the slope of the curve plotting equivalent conductance against root concentration to decrease. With deoxycholate this results in a maximum which is followed by a minimum, while with cholate only a change in the slope of the curve occurs. The variations in the courses of the conductance curves are less pronounced for bile salts than for paraffin chain salts and therefore an evaluation of the critical concentration from the conductance data is not possible for bile acid salts. The conductance curves for the conjugated bile acid salts do not differ essentially from those for the unconjugated bile acid salts, which may be taken to indicate that the progress of association is similar.

Numerous studies have shown that salts of bile acids are association colloids. From the values of the osmotic coefficients of bile acid solutions Roepke and Mason [2] concluded that an association takes place in solutions of both conjugated and unconjugated bile acid salts. McBain *et al.* [3] studied the solubilization of water-insoluble lipophilic dyes by cholate and deoxycholate solutions and deduced that the hydrotropic properties of bile acid salt solutions are due to the formation of micelles. Micelle formation is not so clearly revealed by conductance data because of the weak influence of association on conductance in bile salt solutions [2]. Mellander and Stenhagen's [4] measurements showed

* Present address: Department of Chemistry, Karolinska Institutet, Stockholm.

that the conductance of sodium taurocholate solutions was normal below 0.01 M but above this concentration the conductance curve suddenly changed its slope. Ekwall and Fontell [5] studied the conductances of sodium cholate solutions over a wide concentration range (0.005 M to 0.4 M) and found that the curve plotting the equivalent conductance against the square root of the concentration resembled the curves obtained for soaps, but was less affected by the association.

Extensive studies of the association in sodium cholate and deoxycholate solutions have been carried out by Ekwall and coworkers [6,7]. A stepwise association was found to take place and three different concentration limits (limits 1, 2 and 3) were shown to exist in the solutions of the bile acid salts studied. Below the first limit, there is no association. Between the limits 1 and 2 the association is of limited scope and leads to the formation of very small aggregates, but already above the limit 2 all the added substance associates to form somewhat larger aggregates. Above the limit 3, the degree of association increases further. Aggregates of colloidal dimensions could be demonstrated to exist down to the limit 3. The concentration limits in deoxycholate solutions were 0.004—0.006 M (limit 1), 0.009—0.010 M (limit 2) and 0.04—0.05 M (limit 3), while those in cholate solutions were 0.013—

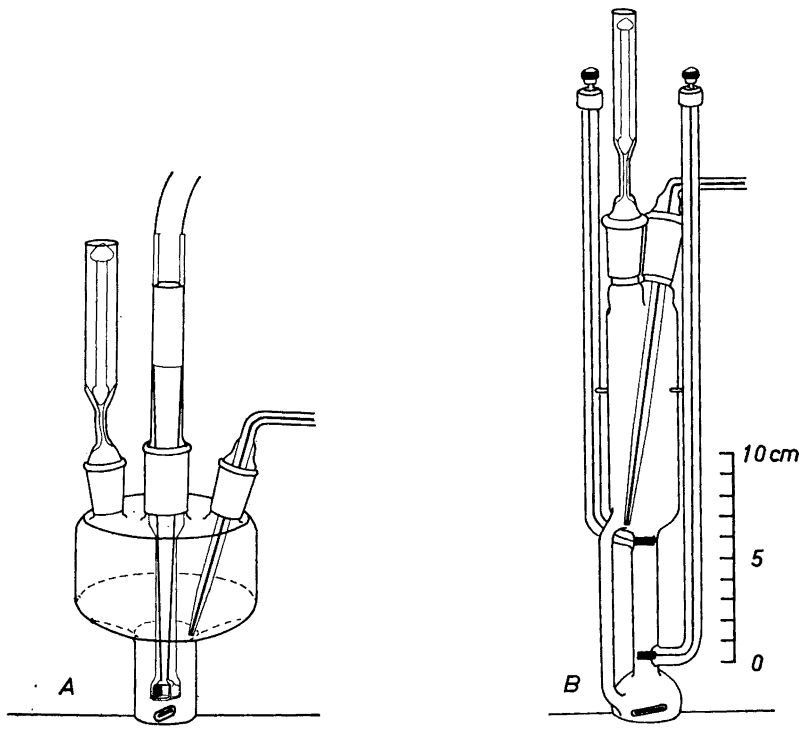

Fig. 1. Conductance cells.

0.015 M, 0.045—0.050 M and 0.09—0.11 M. If one wishes to define the critical concentration for micelle formation in these solutions of bile acids salts, it lies according to Ekwall at the concentration limit 2 where the association is almost complete.

The aim of the present investigation was to study the influence of association on the conductance of aqueous solutions of sodium cholate, deoxycholate and dehydrocholate. The conductances of aqueous solutions of the glycine and taurine conjugates of cholate and deoxycholate were also measured to permit a comparison of the processes of association in solutions of conjugated and unconjugated bile salts. Automatic recording of resistance according to Andersson, Stenhagen and Mellander [1] was used to determine the resistances of bile acid salt solutions on progressive dilution.

EXPERIMENTAL

Materials. The sodium salts of the conjugated bile acids were synthesized as described previously [8]. All the salts were dried *in vacuo* at 100° for 12 h before use. The water employed had been distilled twice and had a specific conductance not greater than 0.5 $\times 10^{-6}$ ohm^{-1} cm^{-1} at 25°C.

Table 1.

Cell type	Cell constant	Minimum volume (ml)	Total volume (ml)
A	0.87	22	210
B	5.78	29	80
C	0.57	40	120

Conductance cell. The conductance cells were of the types shown is Figs. 1 and 2. It was found that the solutions in these cells could be very effectively mixed with rotating magnetic bars. The cells A and C were made of Pyrex glass and the double electrodes used in them of Jena glass. Cell B was made of Jena glass. Each cell was equipped with a valve that allowed air to escape when liquid was added to the cell. The conductance of the solution determined which cell could be used. The electric field between the electrodes varies with the level of the surface of the solution above the electrodes and the effect of this level on the resistance of the cell was studied. The resistances of the cells were measured after the cells had been filled with 0.01 N potassium chloride so that the electrodes were just covered and then continually as more potassium chloride solution was added. Fig. 3 shows the variation of the cell constant with the height of the electrolyte within the cells. It will be seen that the value of the cell constant no longer changes after a certain level has been exceeded. Characteristic values for the three cells are collected in Table 1. The values of the cell constants were checked from time to time using fresh potassium chloride standard solutions.

Thermostat. To avoid condensation of solvent, the whole conductance cell (A) and the spiral tube (B) through which water was introduced into the cell were immersed in the water of the thermostat to the level indicated in Fig. 2. The thermostat (C) was made of transparent Lucophlex, 4 mm thick, and was fastened to a stand. The heat source was a 250 W infrared lamp which was focussed on the wall of the thermostat. With the lamp connected to the electric mains through an electronic relay operated by a contact thermometer (D), the temperature of the water within the thermostat could be kept constant at 40° ± 0.005°C.

Introduction of solution into the conductance cell. The apparatus employed to effect progressive dilution of the electrolyte solution with water is shown in Fig. 2. An all-glass syringe (K) with a spherical ground surface is fastened to a drive mechanism (L) which moves the plunger at a constant velocity. The syringe is connected by a two-way stopcock and capillary tubes to the inlet tube (B) of the conductance cell and to a storage vessel (H). In this way access of carbon dioxide from the air to the water being introduced into the cell is avoided during an experiment. The rate of flow of water was varied between 1 and 2 ml/min. This rate was determined by the time required for the water to warm up to a constant temperature within the spiral tube.

Procedure. Suitable weights of the bile acid salts were dissolved and the solutions diluted to volume in volumetric flasks at 40°C with water free from carbon dioxide. An amount of each solution was then weighed into the conductance cell. The cell together with the spiral tube was immersed in the thermostat and fastened by a clamp to the stand. The spiral tube was connected to the unit for introducing water into the cell.

The continuous recording of the electrolytic resistance was carried out with an apparatus described by Andersson, Stenhagen and Mellander [1]. A condition that must be fulfilled when this method is employed is that no greater capacitive unbalance develops during the recording. For a discussion of errors in measurement and for a description of a circuit that permits simultaneous compensation and registration of the capacitance, a paper by Andersson, Möhl and Stenhagen may be consulted [9]. On diluting a 0.1 M taurocholate solution to a 0.02 M solution in cell A, the capacitance of the cell increased by only 20 pF while the resistance increased by 335.2 Ω. The null position was re-established eight times by balancing the resistive and capacitive components of the bridge separately while the resistance was being recorded in this experiment. It is thus obvious that the capacitive unbalance developed did not materially affect the recorded resistance values.

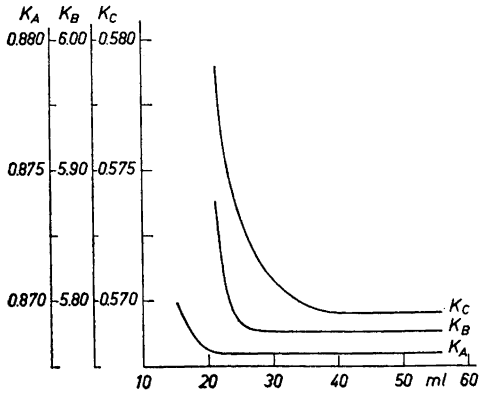

Fig. 3. Variation of cell constants for cells A, B and C as a function of the added volume of 0.01 M potassium chloride solution. Temperature: 40°C. Continuous recording of electrolytic resistance.

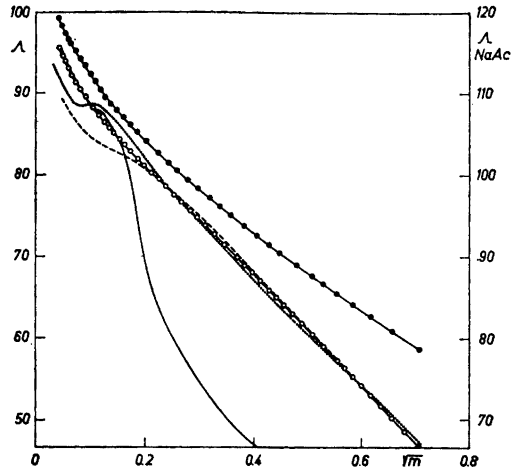

Fig. 4. Equivalent conductance at 40°C. as a function of the square root of the molar concentration for sodium dehydrocholate (O—O), sodium deoxycholate (.....), sodium cholate (— — — —), and sodium acetate (●—●). The values for sodium laurate (———) at 40°C are those reported by Ekwall [14].

RESULTS

The method employed to record the resistance continuously can be applied only to relatively dilute (under 0.05 M) solutions of bile acid salts in which the equilibration of the solution during the addition of water can be effected practically instantaneously. The results of the measurements are plotted in Figs. 5, 7 and 8. When more concentrated solutions are employed, the time that is required before the resistance becomes constant after the addition of a certain quantity of water is so long that a satisfactory accuracy cannot be attained in the measurement of resistance by the continuous recording technique. For example, solutions of the bile salts studied that are between 0.5 and 0.3 M require 10 to 15 min before the value of the resistance becomes constant. Figs. 4, 9 and 10 give the results of the determinations of electrolytic resistance for individual dilution series. Several series of dilutions extending over the same concentration range were prepared from each bile acid salt. Separately recorded curves plotting the equivalent conductance as a function of concentration exhibited satisfactory agreement.

DISCUSSION

The variation of equivalent conductance against root concentration is shown for sodium cholate, deoxycholate, dehydrocholate, acetate and laurate in Fig. 4. The courses of the curves for these compounds in the concentration range 0.002—0.05 M are seen in Fig. 5.

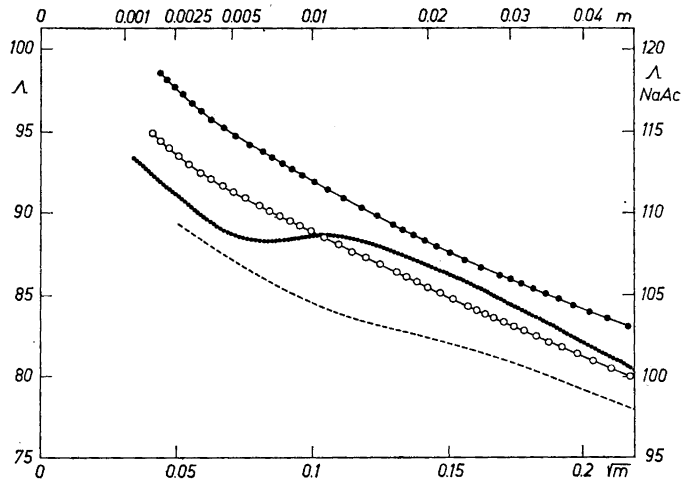

Fig. 5. Equivalent conductance at 40°C as a function of the square root of the molar concentration for sodium dehydrocholate (O—O), sodium deoxycholate (.....), sodium cholate (— — — — —) and sodium acetate (● — ●).

In the concentration range below 0.05 M, the curve for dehydrocholate is similar in form to the curve for a normal uni-univalent electrolyte, *e.g.* sodium acetate. According to McBain [3] the osmotic coefficients of dehydrocholate solutions do not deviate significantly from the values for a normal electrolyte and Ekwall and coworkers [10] were unable to detect any association in dilute solutions of this bile acid salt by solubilization studies. The latter authors found that a low degree of association occurs when the concentration of the salt exceeds 0.15—0.2 M (limit 1) and a higher degree of association at concentrations above 0.7 M (limit 2). Accordingly, no deviation from the normal variation of the conductance was to be expected below 0.15 M.

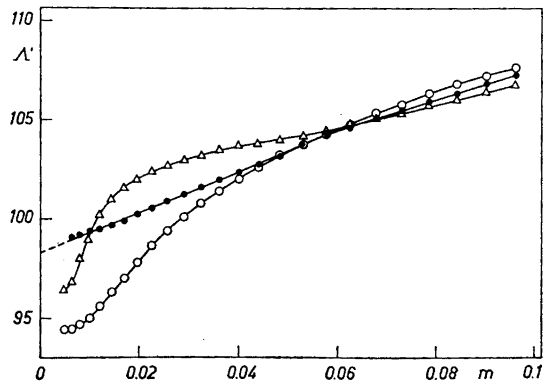

Fig. 6. Plot of Λ' *versus* molar concentration for sodium cholate (O—O), sodium deoxycholate (△—△), and sodium dehydrocholate (● — ●). 40°C.

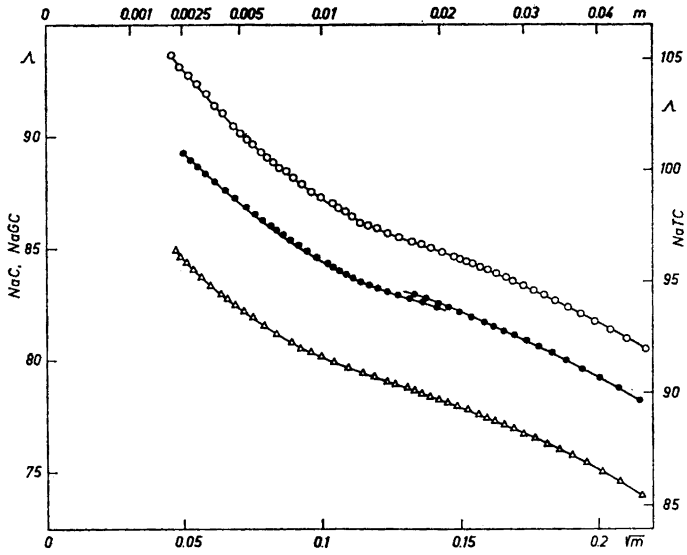

Fig. 7. Equivalent conductance at 40°C as a function of the square root of the molar concentration for sodium cholate (●—●), sodium taurocholate (O—O), and sodium glycocholate (△—△).

Both sodium cholate and sodium deoxycholate exhibit a behaviour that deviates clearly from that of a normal uni-univalent electrolyte. The equivalent conductance of sodium cholate begins to decrease at a slower rate than in the case of a normal electrolyte when the concentration exceeds 0.01 M but when the concentration exceeds 0.04 M the conductance decreases more rapidly. The curve for sodium deoxycholate passes through a minimum at a concentration of 0.005 M and a maximum at a concentration of 0.01 M, while above the latter concentration the equivalent conductance decreases relatively rapidly. The first deviations from the behaviour of a normal electrolyte thus occur with both cholate and deoxycholate at the same concentrations where Ekwall and coworkers [6] detected the first signs of beginning association (limit 1) The second deviations occured at concentrations (limit 2) where the association is, according to Ekwall, of such degree that all the added bile salt anions undergo association.

The deviations from the normal behaviour become more clearly evident when the limiting equivalent conductance Λ_∞ is determined by extrapolating the plot of the function $\Lambda' = \dfrac{\Lambda + A\sqrt{c}}{1 - B\sqrt{c}}$ (where A and B are the constants of the Onsager equation) *versus* concentration (Fig. 6) [11]. The corresponding points for dehydrocholate lie close to a straight line as is the case for a normal electrolyte. The deviations seen at the lowest concentrations are evidently due to hydrolysis and the presence of impurities in the water. The value of the equivalent conductance of sodium dehydrocholate at infinite dilution is

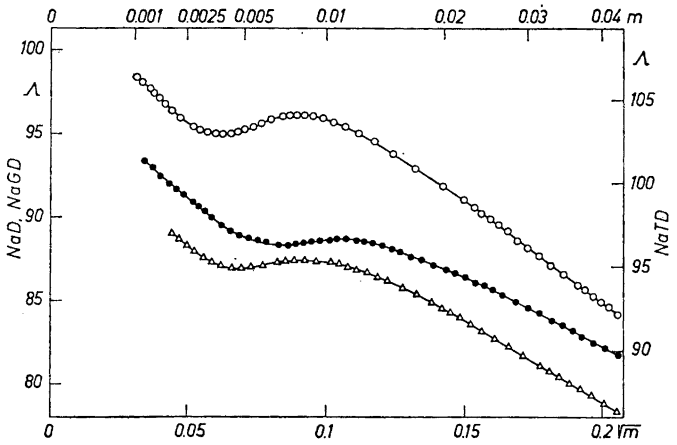

Fig. 8. Equivalent conductance at 40°C as a function of the square root of the molar concentration for sodium deoxycholate (● — ●), sodium taurodeoxycholate (O — O) and sodium glycodeoxycholate (△ — △).

found by extrapolation to be 98.0. The curves plotting Λ' are so abnormal for cholate and, especially, deoxycholate that no value can be obtained for the limiting equivalent conductance by extrapolation.

The equivalent conductance of cholate and deoxycholate solutions between the concentration limits 1 and 2 is higher than the value calculated assuming the existence of single ions only. The increased conductance is possibly due to a higher mobility of the aggregates in accordance with Stokes' law. After the first increase noted in cholate and deoxycholate solutions when association sets in, the conductance decreases more than would be expected for a normal univalent electrolyte as the bile salt concentration increases over the limit 2 (Figs. 4 and 5). The behaviour is similar to that observed in solutions of the sodium salts of higher fatty acids in which a marked decrease in the equivalent conductance occurs above the critical concentration. The decrease in the latter solutions has been mainly ascribed to the binding of gegenions by the micelles. Also the lowering of the conductance with increasing concentration in cholate and deoxycholate solutions above concentration limit 2 may presumably be ascribed to the same factor. Micelle formation in bile salt solutions has only a slight effect on the conductance and hence it is difficult to evaluate the critical micelle concentration of bile salts as in the case of the sodium salts of higher fatty acids.

The curves plotting equivalent conductance against root concentration for solutions of the taurine and glycine conjugates of cholate and deoxycholate (Figs. 7 — 10) all deviate from the corresponding curve for a normal uni--univalent electrolyte but do not differ in this respect essentially from the curves for the unconjugated bile salts. The first deviation from the normal behaviour does, however, occur at a lower concentration (0.003 M) with tauro- and glycodeoxycholate than with unconjugated deoxycholate (0.005 M).

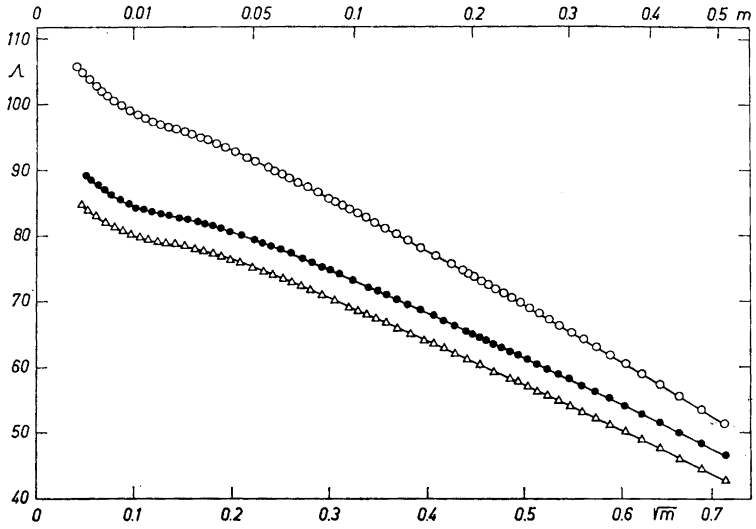

Fig. 9. Equivalent conductance at 40°C as a function of the square root of the molar concentration for sodium cholate (●—●), sodium taurocholate (O—O), and sodium glycocholate (△—△).

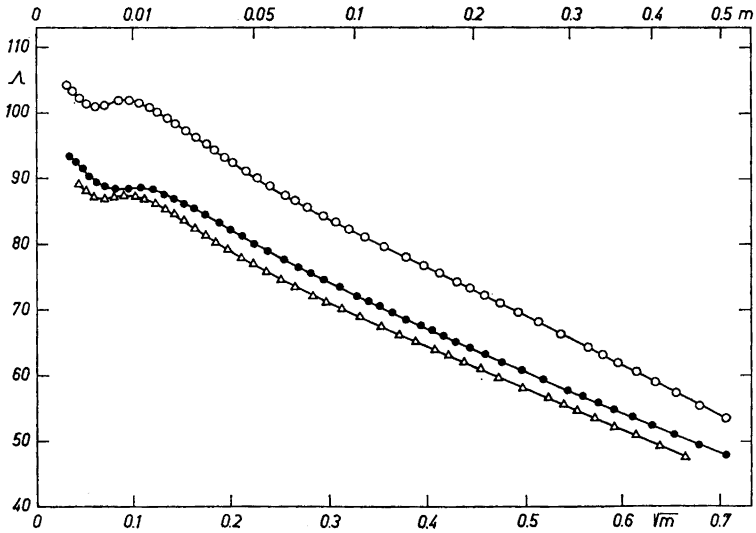

Fig. 10. Equivalent conductance at 40°C as a function of the square root of the molar concentration for sodium deoxycholate (●—●), sodium taurodeoxycholate (O—O), and sodium glycodeoxycholate (△—△).

Judging from the variation of the equivalent conductance with concentration, it seems improbable that there is any greater difference in the nature of the association process between the conjugated and unconjugated compounds. This conclusion is in accord with the results of previous studies of the ability of the taurine and glycine conjugates of cholate and deoxycholate to solubilize xylene [6,12] and 20-methylcholanthrene [13]. These observations suggest that the various phases of the association process, the beginning association and its stepwise development, and the saturation capacities of the aggregates formed are with only minor variations similar for both conjugated and unconjugated bile acid salts.

Acknowledgement. The author wishes to express his gratitude to Professor Einar Stenhagen and Dr. Carl-Ove Andersson for valuable help with construction of the apparatus for conductivity measurements, and to Professor Per Ekwall for helpful discussions. The skilful technical assistance of Mrs. Margret Månsson is gratefully acknowledged. A Brownian Motion Theory of Chemical Reactions

THOR A. BAK and IGOR W. PLESNER

Institute for Physical Chemistry, University of Copenhagen, Denmark

A theory for the dissociation of a diatomic molecule in weak interaction with a thermostat is proposed. Exact solutions are given for a harmonic oscillator.

In the classical collision theory of chemical reactions in gases it was generally assumed that dissociation of a molecule occurs by direct transitions from low vibrational states to the dissociated state. In recent years [6] it has however become clear that the energy transfer to the vibrational degrees of freedom during a molecular collision generally is small compared with the dissociation energy. Under these circumstances it is necessary to consider the dissociating molecule as performing a random walk or Brownian motion in "energy space" on its way to the dissociation energy. The small random changes in energy are caused by the collisions between the reacting molecule and the other molecules which act as a thermostat. Although large amounts of translational energy may be transferred during such collisions, only a small part of the collision energy goes into the vibrational degrees of freedom, and we can therefore speak of the reacting molecule as being weakly coupled to a thermostat. For the case of a diatomic molecule imbedded in a crystal lattice it is of course even more so that the molecular oscillator is only loosely coupled to the crystal lattice.

The first one to investigate such an approach to chemical kinetics was Kramers [5] who in 1940 developed a theory of Brownian motion in a field of force and thus was able to make a diffusion model of chemical reactions as suggested many years before by Christiansen [4]. In this theory one visualizes the chemical reaction as the escape of a particle from a potential minimum due to the shuttling action of the thermostat. If $\Phi(E,t)$ denotes the probability that the particle has the energy E at time t, one finds for the case of weak interaction between the particle and the thermostat ("small viscosity" in the language of Kramers)

$$\frac{\partial \Phi}{\partial t} = \eta \frac{\partial}{\partial J} J\left(1 + kT \frac{\partial}{\partial E}\right)\Phi \qquad (1)$$

where $J(E) = \int p dq$ is the action variable, η is the parameter which measures the interaction with the heat bath. In the special case of a parabolic potential minimum this equation reads

$$\frac{\partial \Phi}{\partial t} = \eta \frac{\partial}{\partial x} x \left(1 + \frac{\partial}{\partial x}\right)\Phi \tag{2}$$

where $x = E/kT$.

The coupling parameter (friction coefficient) η is defined by the Langevin equation

$$\dot{p} = -\eta p + K(q) + A(t) \tag{3}$$

in which p is the linear momentum of the particle, $K(q)$ the force whose potential is the potential energy along the reaction coordinate, and $A(t)$ the "random force" which represents the action of the thermostat. It is usually assumed that the friction coefficient is constant (that is, independent of p) but Kramers mentions the possibility that it might be replaced by an arbitrary (even) function of p, although he does not investigate this case further. As we shall see below for the case of Brownian motion in crystals the assumption that η is independent of p is identical with an assumption by Peierls about the interaction between normal modes in a crystal, which can be shown to be valid to the same accuracy as for instance the Debye approximation in the theory of specific heat. It is therefore not inconceivable that one might find physical systems which for their proper description would require a theory in which η is not assumed to be constant.

A quantum mechanical analogue of Kramers' theory was given by Montroll and Shuler [7] for the case of a particle in a parabolic potential minimum, *i.e.* an harmonic oscillator. Let the classical frequency of the oscillator be ω so that the energy levels are $(n + \frac{1}{2})\hbar\omega$ and let Θ denote $\hbar\omega/kT$. Montroll and Shuler then obtain in their random walk model the following equation

$$\frac{dx_n}{dt} = \varkappa \{n e^{-\Theta} x_{n-1} - [n + (n+1) e^{-\Theta}] x_n + (n+1) x_{n+1}\} \tag{4}$$

where x_n is the probability that the oscillator is in a state with energy $n\hbar\omega$ over the zeropoint energy, and $\varkappa$ is a parameter which measures the interaction with the heat bath. A similar equation has been proposed by Nikitin [8].

It is not immediately obvious that an equation of this type is a quantum mechanical analogue of the Kramers equation, but assuming $\Theta << 1$ so that $e^{-\Theta}$ can be replaced by $1-\Theta$ we can write the equation as

$$\frac{dx_n}{dt} = \Theta \varkappa \left\{ n\Theta \frac{x_{n+1} - 2x_n + x_{n-1}}{\Theta^2} + \frac{x_{n+1} - x_n}{\Theta} + n\Theta \frac{x_n - x_{n-1}}{\Theta} + x_n \right\} \tag{5}$$

When we replace $n\Theta$ by x and x_n by Φ and furthermore let $\hbar \to 0$, we get

$$\frac{\partial \Phi}{\partial t} = \eta [x\Phi'' + (1+x)\Phi' + \Phi] = \eta \frac{\partial}{\partial x} x \left(1 + \frac{\partial}{\partial x}\right)\Phi$$

where η is the limit of $\Theta\varkappa$ as $\hbar \to 0$.

In this way we see that the two approaches lead to corresponding equations and that the equation of Montroll and Shuler therefore is the proper generalization of the Kramers equation.

In both theories one uses transition probabilities or random forces, and this gives rise to the parameter η $(= \Theta\varkappa)$ which essentially is a non calculable quantity. It is true that, as stated by Montroll and Shuler, η is in principle calculable from the quantum mechanical theory of collisions, but if one tries to do so eqn. (4) will require additional justification, since there is as yet no simple way of getting such a "master equation" directly from quantum mechanics or classical mechanics. If one can justify the use of the master equation, *i.e.*, essentially explain how irreversibility arises in a mechanical system, then within this framework the calculation of η will be immediate, but within the conceptually much simpler framework of the Kramers theory or Montroll and Shuler theory the coupling constant is, to our minds, best considered as an empirical parameter.

To get a theory for chemical reactions one now assumes that the particle under consideration performs a Brownian motion in the potential hole as long as its energy is smaller than E_{act}, and that it is annihilated when its energy exceeds E_{act}. This is evidently a crude model of a particle passing a potential barrier, and since it is possible to solve eqn. (2) exactly for the boundary condition $\Phi(x^*,t) = 0$ (all t), it is possible in this way to estimate how much the distribution in energy space $\Phi(x,t)$ differs from the equilibrium distribution and how much this influences the rate constant.

BROWNIAN MOTION OF A DIATOMIC MOLECULE

Using the explicit assumption that the oscillating molecule is in weak interaction with the thermostat we can write the energy of the system consisting of a molecule plus the thermostat as

$$\mathcal{H} = H_T + H_M + \lambda V$$

where λ is a small dimensionless parameter.

The energy of the thermostat can be considered as a sum of energies of a large number of subsystems without interaction, that is,

$$H_T = \sum_k H_T^{(k)}$$

and we now introduce angle-action variables for the subsystems of the thermostat and for the molecule and make a Fourier expansion of the interaction potential V on the angle variables. For the special case of a harmonic oscillator imbedded in a lattice, which we have considered previously [1,2,11] we have

$$\mathcal{H} = \sum_{f=1}^{N} \omega_f J_f + \omega J + \lambda \sum_\nu \sum_f \{V_{\nu f}^{+} \, e^{i(a_f + \nu\alpha)} + V_{\nu f}^{-} \, e^{i(-a_f + \nu\alpha)}\}$$

Here f is the wavenumber for the normal modes of the lattice, α and J denote angle-action variables, and $V_{\nu f}{}^{+} = V_f q_f^{\circ}{}_{+} J_\nu(fr_0)$, where $q_f^{\circ}{}_{+}$ is the amplitude of the f'th normal mode, r_0 the amplitude of the molecular oscillator and $J_\nu(fr_0)$ denotes the Bessel function of order ν. V_f is assumed to be independent of the energy of the oscillator. For a derivation of this expression for $\mathcal{H}$ see Ref. [1] or Ref. [2]

Using this Hamiltonian the Liouville equation is set up and solved by the perturbation technique used by Brout and Prigogine [3]. In the limit $\lambda \to 0$, $t \to \infty$, $\lambda^2 t$ finite, $N \to \infty$ this leads to eqn. (2) after an integration over the frequency spectrum of the lattice, provided the so-called Peierls assumption [9]

$$\frac{|V_f|^2}{\omega_f{}^2} = \text{constant}$$

is valid. Since in this derivation of eqn. (2) η is proportional to $|V_f|^2/\omega_f{}^2$ we see that the assumption that this quantity is independent of f and of the energy of the oscillator is tantamount to the assumption of Kramers, that η is independent of the momentum of the particle. The range of validity of the Peierls approximation has been investigated by Plesner [10] who has shown that in a one-dimensional lattice with nearest neighbour interaction it has the same range of validity as the Debye approximation for the frequency spectrum of the lattice. Since the assumption of a Debye spectrum is necessary anyway in integrating over the frequency spectrum of the crystal, the Peierls approximation is a reasonable assumption in this case, but it is quite possible that when considering a system where the thermostat is not a crystal one can get an energy dependent friction coefficient.

CHEMICAL REACTION AS ANNIHILATION OF PARTICLES

To use the equation for Φ in a model of chemical reactions we must have an intramolecular potential which allows a dissociation of the molecule, *i. e.*, a potential for which the particle has one or more "bound states" and a "free state" into which it goes or through which it passes from one bound state to another.

So far we have not been able to treat a potential of this type, and we have therefore used the following model of a chemical reaction. A particle which is weakly coupled to a thermostat moves in potential $V = V(q)$ as long as its energy is smaller that E^*, but when its energy reaches E^*, it ceases to exist. For the special case of a harmonic oscillator eqn. (2) will then apply for $x < x^* = E^*/kT$, but for $x > x^*$ we have $\Phi(x,t) = 0$. The solution of this boundary value problem in the range $0 < x < x^*$ is

$$\Phi = \sum_a c_a e^{-a\eta t} e^{-x} {}_1F_1(-a,1,x)$$

where the summation over a goes over the roots of

$${}_1F_1(-a,1,x^*) = 0$$

∞	0	1	2	3	4

* α_k (k = 1, 2, 3, 4, 5) are the zeros of the function ${}_1F_1(-a, 1, x^*)$ considered as a function of a. The numbers in brackets are the powers of ten by which the values given for α_k should be multiplied.

considered as an equation in a. The first five roots of this equation are tabulated in Table 1 for different values of x^*.

It is seen that when $x^* \sim 10$, α_2 (and *a fortiori* α_3, α_4, ...) will be more than a thousand times larger than α_1, so that to an excellent approximation we can set

$$\Phi = c_1 e^{-\alpha_1 \eta t} e^{-x} {}_1F_1(-\alpha_1, 1, x)$$

where α_1 is the smallest root in the equation ${}_1F_1(-\alpha_1, 1, x^*) = 0$.

Table 2. The table shows the ratio between the "true" rate constant $k = \eta a_1 (x^*)$ and the equilibrium rate constant $k_{eq} = \eta x^* e^{-x^*}$ as function of x^*.

k/k_{eq}	1.21730	0.83407	0.82245	0.85582	0.88576
x^*	2	4	6	8	10
k/k_{eq}	0.90670	0.92180	0.93257	0.94060	0.94661
x^*	12	14	16	18	20

From this we get immediately that the rate constant for escape from the potential minimum is $\alpha_1\eta$ and furthermore we see that while the reaction is going on the change in Φ is so that the relative change in Φ is independent of x. In other words, the distribution function in energy space has a quasi-stationary character.

It is easily verified that as $x^* \to \infty$, α_1 becomes asymptotically equal to $x^* e^{-x^*}$. Since in this limit Φ approaches the equilibrium distribution e^{-x}, we shall denote $k_{eq} = \eta x^* e^{-x^*}$ the equilibrium rate constant. It is well to bear in mind, though, that in deriving this expression we have nowhere used the assumption about equilibrium as is done, for instance, in the transition state method. Table 2 shows how the exact value of $\alpha_1(x^*)$ compares with the "equilibrium value" of α_1, and it is seen that for $x^* > 10$ the error is less than 12 %. It is true, therefore, that for reasonable values of the activation energy the equilibrium hypothesis is a good approximation, but only when the equilibrium result is taken to be the limit of the non-equilibrium result, as the barrier height is increased to infinity. To introduce the equilibrium assumption at an earlier stage would not only lead to a quite different result, but it would also lead to a non-consistent theory.

CONCLUSION

Above we have compared the different Brownian motion approaches to chemical kinetics and shown how they lead to the same result in the case of a dissociating harmonic oscillator. In comparison with earlier derivations of the equation for this case our method which is based on the method of Brout and Prigogine may seem unduly complicated. This is due to the fact that we have not made any assumptions about "random interactions", but only used that the thermostat is large (infinitely many degrees of freedom) and that the interaction is weak ($\lambda \to 0$). Therefore, to our mind, our derivation of the Kramers equation in the weak interaction limit does present some advantage over previous derivations.

Hydrogenation as an Aid in the Identification of Unsaturated Hydrocarbons by Gas Chromatography

BENGT SMITH and RAGNAR OHLSON

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

Methods are described for the hydrogenation of unsaturated hydrocarbon fractions obtained by condensation from analytical gas chromatographs. These hydrogenation methods make possible the identification of various unsaturated hydrocarbons on the basis of the retention times of their hydrogenation products.

The identification of unsaturated hydrocarbons by gas chromatography is mainly based on the determination of retention times using various columns (*cf.* Ref[1].). This method is generally successful when applied to alkenes boiling in the range below 100° in which case retention times for the majority of the compounds on a number of columns are well known [1]. However, in the case of higher boiling alkenes and for other types of unsaturated hydrocarbons, *e.g.* alkadienes and alkynes, the situation is less favourable since our knowledge about the retention times of these compounds is not so detailed. To complement the existing identification methods for unsaturated hydrocarbons, we have worked out some micro hydrogenation procedures which are applicable to the hydrogenation of such fractions as are obtained by condensation from analytical gas chromatographs using packed columns. The general principle of the method is to freeze out a compound or a mixture of compounds coming from the gas chromatograph and then hydrogenate the product partly or fully and, finally, re-run the hydrogenated product on a suitable column. From the chromatogram obtained, conclusions may be drawn concerning the nature of the compounds present in the original mixture. The advantage of the method is that compounds, the retention times of which are unknown, can be converted to compounds with known retention times, *e.g.* alkenes to alkanes, alkadienes to alkenes and alkanes, and alkynes to alkenes and alkanes. In addition compounds which cannot be separated on existing stationary phases may be converted by hydrogenation to separable products.

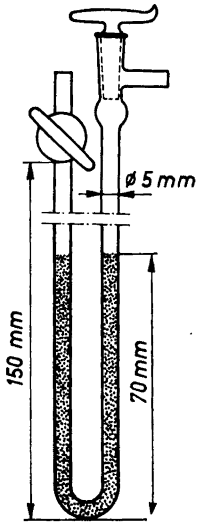

Fig. 1. U-Tube used in the hydrogenation experiments.

HYDROGENATION PROCEDURES

The procedures used in the full and stepwise hydrogenations of unsaturated hydrocarbons will be described in the following.

Procedure for the full hydrogenation of unsaturated hydrocarbons. A mixture of platinum dioxide (Adams catalyst [2]) and iron filings contaning about 1 wt. % of the oxide was used as hydrogenation catalyst. The iron filings acted as carriers for the platinum dioxide but they were also used because of their good heat conduction properties which facilitated the condensation of hydrocarbons from the gas stream coming from the chromatograph*. The iron filings-platinum dioxide mixture was filled into a U-tube (see Fig. 1) and the tube was immersed in a dry ice-acetone cooling bath and connected to the outlet of the chromatograph. In this way, the fraction of interest was condensed in the U-tube.

The tube was disconnected from the chromatograph and removed from the cooling bath. One side of the tube was closed and the other connected to a hydrogen container. Hydrogen was blown into the tube at such a rate that the pressure was raised to 3 kg/cm^2 during about 1 min. The tap on the tube was closed and the tube was removed from the hydrogen container and immersed in hot water (80—90°C) for 10 min. It was then connected to the gas inlet of the chromatograph (Perkin-Elmer Vapor Fractometer Model 154) and the hydrogenated products transferred to the chromatograph. Helium was generally used as the carrier gas. In the case of low boling hydrocarbons, however, it was sometimes necessary to use hydrogen instead since the large peak produced by the hydrogen in the U-tube, using helium as the carrier gas, tended to obscure compounds with short retention times. The same U-tube could be used without repacking for a considerable number of times **.

Procedure for the stepwise hydrogenation of alkadienes. The hydrogenation catalyst and equipment was the same as before but the conditions were changed. Thus, after the condensation of the hydrocarbon fraction in the U-tube, the latter was not removed

* Certain samples of iron filings were found to promote hydrogenation also in the absence of platinum dioxide.

** Care should be exercised in the hydrogenation procedure because of the ignition hazards connected with dry Adam's catalyst. Air must not be allowed to enter the hydrogenation tube.

from the cooling bath but allowed to remain there during the filling of the tube with hydrogen.

The tube was removed from the cooling bath and shaken for a few seconds in order to mix the hydrocarbon fraction with the catalyst and then replaced in the bath. The tube was then connected to the gas inlet of the chromatograph, the cooling bath was exchanged for a beaker containing hot water (80—90°C) and, after 5—10 sec, the contents in the U-tube were blown into the chromatograph. The hydrogenation takes place almost entirely during the short time in the heating bath. It was namely found that, if the hydrogen in the U-tube was exchanged for helium before the heating, almost no hydrogenated products were formed.

Procedures for the stepwise hydrogenation of alkynes. Method 1. This method was identical to that described for the full hydrogenation of unsaturated hydrocarbons with the exception that the hydrogenation was performed at room temperature for 1 min.

Table 1. Hydrogenation of dienes.

Compound	Unchanged (wt %*)	Hydrogenation products (wt %*)	
		Partly hydrogenated	Fully hydrogenated
1,3-Butadiene	82	1-Butene (6) *cis*-2-Butene (1) *trans*-2-Butene (2)	*n*-Butane (9)
1,4-Pentadiene	75	1-Pentene (9)	*n*-Pentane (16)
1, *cis*-3-Pentadiene	21	1-Pentene (4) *cis*-2-Pentene (10) *trans*-2-Pentene (7)	*n*-Pentane (58)
1,*trans*-3-Pentadiene	9	1-Pentene (4) *cis*-2-Pentene (3) *trans*-2-Pentene (6)	*n*-Pentane (78)
1,2-Pentadiene	98	1-Pentene (0.3) *cis*-2-Pentene (0.6) *trans*-2-Pentene (0.1)	*n*-Pentane (1)
1,5-Hexadiene	68	1-Hexene (11)	*n*-Hexane (21)
cis-2,*trans*-4-Hexadiene	22	*cis*-2-Hexene (8) *trans*-2-Hexene (14) *cis*-3-Hexene (3) *trans*-3-Hexene (6)	*n*-Hexane (47)
trans-2, *trans*-4-Hexadiene	15	*cis*-2-Hexene (2) *trans*-2-Hexene (14) *cis*-3-Hexene (3) *trans*-3-Hexene (6)	*n*-Hexane (60)
1,*trans*-3-Hexadiene	70	*cis*-2-Hexene (2) *trans*-2-Hexene (5) *trans*-3-Hexene (3)	*n*-Hexane (20)
1,3-*Cyclo*pentadiene	79	*Cyclo*pentene (8)	*Cyclo*pentane (13)

* These values are only approximate since they were obtained by the internal normalization method putting percentage area equal to the weight per cent.

Method 2 utilized metallic sodium covered by a layer of sodium amide [3,4] as catalyst and source of hydrogen*. A thread of sodium was pressed and transferred to the U-tube in a nitrogen atmosphere. Gaseous ammonia was then passed through the tube in order to form a layer of sodium amide on the surface of the sodium thread. After the condensation of the sample the tube was closed and left for 2 min at room temperature.

Material. The unsaturated hydrocarbons collected in Tables 1 and 2 were prepared in this laboratory. The synthesis of certain of these compounds as well as their retention values on various columns will be published elsewhere.

RESULTS and DISCUSSION

Full hydrogenation of unsaturated hydrocarbons. The hydrogenation procedure previously described was applied to a considerable number of straight chain and cyclic unsaturated hydrocarbons containing double and triple bonds. In all cases, a nearly 100 % conversion to the corresponding saturated hydrocarbons was obtained. No partly hydrogenated products, *e.g.* alkenes from alkadienes and alkynes, were formed. Among the saturated cyclic hydrocarbons, only *cyclo*propanes reacted, yielding paraffins. Aromatic hydrocarbons were converted to *cyclo*hexanes with a yield generally exceeding 90 %.

Stepwise hydrogenation of alkadienes. It turned out to be a difficult task to stop the hydrogenation of an alkadiene at the alkene stage. Several attempts at room temperature, using poisoned platinum dioxide and other less active catalysts, failed. The technique described in the experimental part, however, made possible the conversion of a sufficient amount of a diene to the corresponding monounsaturated hydrocarbons. Some typical results of the hydrogenation of a number of straight chain and cyclic dienes are given in Table 1.

In most instances, the expected hydrogenation products were formed. Thus, there was obtained 1-butene from 1,3-butadiene as the results of 1,2-addition, and *cis*- and *trans*-2-butene as the result of 1,4-addition. Naturally, the fully hydrogenated product, *n*-butane, was also formed. There was a marked difference in reactivity between various dienes, 1, *trans*-3-pentadiene being especially reactive. In this case, it was necessary to shorten the hydrogenation time in order to get enough of the alkenes. The two 1,3-pentadienes gave the same hydrogenation products. It was, however, still possible to distinguish between the two isomers on the basis of the proportions between *cis*- and *trans*-2-pentene. In the case of 1,*cis*-3-pentadiene, more *cis*-2-pentene than *trans*-2-pentene was formed. The *cis* isomer can be formed by 1,2- as well as 1,4-addition but the *trans* isomer only by 1,4-addition**. For 1, *trans*-3-pentadiene, the reverse is true and more *trans*-2-pentene than *cis*-2-pentene was obtained. Although the further hydrogenation to *n*-pentane might change the original proportions between *cis*- and *trans*-2-pentene, the results have in numerous experiments always turned out to be in accordance with the theory.

1,2-Pentadiene was the only diene of allene type investigated here. It was found to be considerably more resistent to hydrogenation than dienes with

---

* Concerning the use of sodium alone as catalyst, *cf.* p. 1322.

** Concerning the possibilities of a *cis-trans* isomerization during the hydrogenation, *cf.* below.

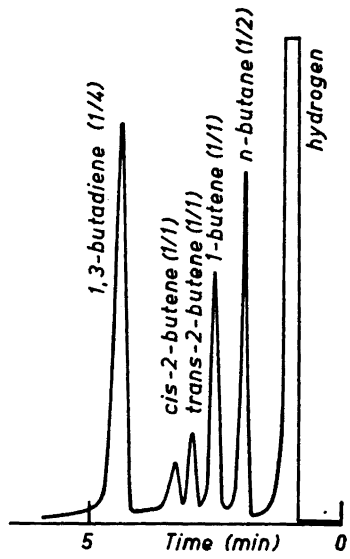

Fig. 2. Hydrogenation of 1,3-butadiene. Column, dimethylsulpholane (20 %) on Chromosorb 30—60 mesh, 3 m. Temperature 25°C. Flow of He 25 ml/min. Recorder attenuation as denoted.

conjugated and isolated double bonds. Thus, only 2 % of it was converted. This difference in reactivity makes it easy to distinguish between 1,2-pentadiene and the two 1,3-pentadienes by partial hydrogenation although the same hydrogenation products are formed.

The results of the hydrogenation of the two 2,4-hexadienes are noteworthy. From *cis*-2,*trans*-4-hexadiene, the expected hydrogenation products were formed. The same hydrogenation products, however, were obtained in the case of *trans*-2,*trans*-4-hexadiene, the formation of *cis*-2-hexene being unexpected. Since we believe that the experimental conditions excluded any contamination from other compounds, we are forced to assume that an isomerization takes place during the hydrogenation. Neither in this case nor in several other cases investigated did any isomerization occur in the absence of hydrogen. Attempts to convert *trans*-2-hexene and *trans*-3-hexene to their *cis* isomers using the method for the partial hydrogenation of alkadienes also failed. Thus, it must be concluded that a *cis-trans* isomerization can take place in certain instances under the experimental conditions used but the phenomenon does not seem to be a general one.

We are not aware of any previous reports on catalytic *cis-trans* conversions of ethylenic hydrocarbons although the corresponding thermal reaction has been studied [5]. Catalytic isomerization of dimethyl maleate on hydrogenation catalysts, however, has been observed [6].

One proposed mechanism [7] for the hydrogenation of ethylenic double bonds on metal catalysts involves a reaction between a chemisorbed alkene molecule and hydrogen to form a chemisorbed alkyl radical which is then further hydrogenated to an alkane during the second step. Since the first step is reversible, the possibility of a *cis-trans* isomerization obviously exists.

Table 2. Hydrogenation of alkynes.

Compound	Catalyst	Unchanged (wt %*)	Hydrogenation products (wt %*)	
			Partly hydrogenated	Fully hydrogenated

	Na (method 2)	37	1-Hexene (63)	0

* *Cf.* note under Table 1.
** The method used for the partial hydrogenation of alkadienes was applied.

It is known that migration of a double bond may occur in the presence of hydrogenation catalysts [8–11]. There are, however, no indications in our experimental material that such a migration takes place under the conditions used for the partial hydrogenation of dienes.

The chromatogram obtained after the hydrogenation of 1,3-butadiene is shown in Fig. 2.

Stepwise hydrogenation of alkynes. Some results from the stepwise hydrogenation of alkynes are given in Table 2. Hydrogenation over platinum dioxide mainly produced alkanes and *cis* alkenes in those instances where two stereoisomeric forms of the alkene were present. This result is in accordance with previous experience [12]. There are no signs of a double bond migration taking place during the hydrogenation (*cf.* above). Hydrogenation in the presence of sodium amide was quite stereospecific, the *trans* alkene being formed only. A possible mechanism for this reaction has been proposed by Raphael [13]. In the hydrogenation of 1-hexyne using method 2, it was found that sodium alone was as effective a catalyst as sodium covered with a layer of sodium amide. In this case hydrogen is furnished in the reaction between 1-hexyne and sodium. No hydrogenation took place when 3-hexyne was treated in the same way, since no hydrogen is formed. It seems possible to identify a triple bond in 1-position by this method.

Sodium amide is said not to promote the hydrogenation of an alkene to the corresponding alkane. We have, however, repeatedly obtained small amounts of *n*-hexane in the hydrogenation of 2-hexyne. It may be that small amounts of impurities in the sodium, *e.g.* traces of metal from the sodium press, are responsible for this conversion.

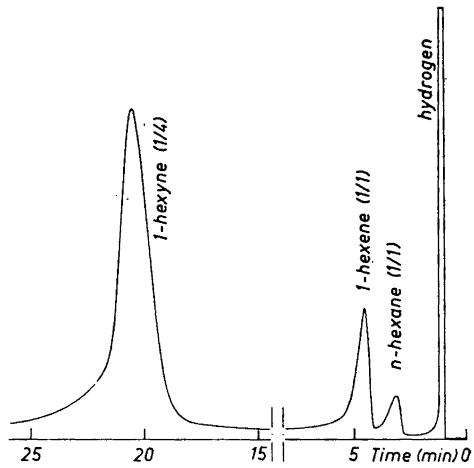

Fig. 3. Hydrogenation of 1-hexyne. Column, β,β'-oxydipropionitrile (20 %) on Chromosorb 30—60 mesh, 2 m. Temperature 25°C. Flow of He 50 ml/min. Recorder attenuation as denoted.

The results of the hydrogenation of 1-hexyne using the method for the partial hydrogenation of alkadienes illustrate the small conversion of an alkyne under these conditions (*cf.* 1,5-hexadiene in Table 1).

It is not possible to hydrogenate dienes to alkenes by any of the methods used for the hydrogenation of alkynes. The first method only produces saturated hydrocarbons and, with the last two, the dienes remain unchanged apart from the possible formation of traces of monounsaturated and saturated products. The chromatogram obtained after the hydrogenation of 1-hexyne over platinum dioxide is shown in Fig. 3.

Use of the hydrogenation methods. The examples given above demonstrate the application of the hydrogenation methods to the identification of unsaturated hydrocarbons. The methods are especially useful in the case of dienes and alkynes and, in many instances, permit a simple and straightforward identification of these hydrocarbons. They are also valuable for deciding whether a band on the chromatogram contains unsaturated hydrocarbons or not and for the conversion of unseparable, unsaturated hydrocarbons to separable, saturated ones. Thus, in the qualitative and quantitative analysis of mixtures of 3- and 4-methyl-1-pentene which until recently[14] could not be separated on any stationary phase known, we hydrogenated the mixture to 2- and 3-methylpentane which could easily be separated on, for example, squalane.

The Crystal Structure of Hydrogen Peroxide Dihydrate *

IVAR OLOVSSON** and DAVID H. TEMPLETON

Lawrence Radiation Laboratory and Department of Chemistry, University of California, Berkeley, California, U.S.A.

The crystal structure of hydrogen peroxide dihydrate, $H_2O_2 \cdot 2H_2O$, has been determined from single crystal X-ray data. Exposures at −70° and −190°C indicate the same structure. The crystals are monoclinic (space group $C2/c$) with four molecules in a unit cell of dimensions: $a = 9.400$, $b = 9.479$, $c = 4.51$ Å and $\beta = 121.33°$ at −190°C. The structure contains planar chains of water molecules connected by hydrogen bonds of 2.74 Å. The chains are crosslinked by the hydrogen peroxide molecules into a three-dimensional network by hydrogen bonds of 2.76 and 2.69 Å. Peaks in a difference synthesis suggest the positions of the hydrogen atoms in these bonds, and indicate slight displacements from the lines joining the oxygen atoms. These positions correspond to a dihedral angle of about 130°, in the hydrogen peroxide molecule, between the planes defined by the peroxide link and the hydrogen atoms.

The melting point diagram of the system hydrogen peroxide-water indicates only one intermediary compound, $H_2O_2 \cdot 2H_2O$. The existence of a crystalline phase of this composition has also been confirmed by X-ray powder diffraction data (Natta and Rigamonti [1]). They concluded that the lattice had a low symmetry but were unable to index the photographs. The melting point of the dihydrate has been reported as: —51°C (Maass and Herzberg [2]), —52.10° (Foley and Giguère [3]), —50.2° (Mironov [4]). These investigations also indicate that solid solutions are absent.

The present work involves the determination of the crystal structure of $H_2O_2 \cdot 2H_2O$ from single crystal X-ray diffraction data obtained at —190°C. X-ray photographs taken at —70°C indicate the same structure.

EXPERIMENTAL

The crystals were grown from solutions of hydrogen peroxide and water sealed in glass capillaries (diameter 0.1—0.2 mm. and wall thickness 0.01—0.02 mm.). The hydrogen peroxide (Becco's hydrogen peroxide of 90 %) was distilled in a vacuum system

* This work was performed for the U.S. Atomic Energy Commission.

** Permanent address: Institute of Chemistry, University of Uppsala, Uppsala, Sweden.

and the middle fraction taken out and mixed with distilled water to the desired composition. The analysis was made by titration with permanganate. The sample used had a composition of 48.8 wt. % H_2O_2, corresponding to 1.98 moles per mole of hydrogen peroxide.

The single crystals were grown in the ordinary way in a modified Weissenberg camera (Olovsson and Templeton [5]). As the crystal was grown it was apparent that the melting point was in reasonable agreement with the earlier-published data cited above. It was very difficult to get crystals that were not twinned. The crystal chosen was composed of two twins related by reflexion in the *bc* plane or rotation about *c*, but it was quite easy to get each reflection uniquely indexed. Equi-inclination Weissenberg photographs, layers 0 to 3, were taken with rotation around the *c* axis using Cu-*K* radiation. The results below refer to the data from −190°C but the photographs from −70°C indicate the same structure. The relative intensities were estimated visually by using multiple-film technique (four films) and comparing with an intensity scale. The data were corrected for the Lorentz and polarization effects.

UNIT CELL AND SPACE GROUP

The data showed the diffraction symmetry $2/m$. The systematic absences require an *I*-centered monoclinic cell with almost orthogonal axes ($a' = 8.038$ Å, $b' = 9.479$ Å, $c' = 4.51$ Å, $\beta' = 92.70°$) or a *C*-centered cell with $\beta \sim 120°$. The *C*-centered cell was chosen in order to be in agreement with the International Tables [6]. The unit cell parameters are then*:

$a = 9.400 \pm 0.002$ Å, $b = 9.479 \pm 0.002$ Å,

$c = 4.51 \pm 0.01$ Å, $\beta = 121.33° \pm 0.03°$. ($t = -190°$C)

a, *b* and *c* were determined from rotation and quartz-calibrated zero-layer Weissenberg photographs ($a = 4.913$ Å for *a* -quartz; $\lambda_{\text{Cu-}K\alpha_1} = 1.54051$ Å, $\lambda_{\text{Cu-}K\alpha_2} = 1.54433$ Å), β was obtained by the method of angular lag [7].

Giguère, Knop and Falk [8] report a preliminary value of 1.20 for the density at the melting point. With four molecules per unit cell, the calculated density at −190°C is 1.36. Systematic absences were, in addition to the extinctions due to the *C*-centering: $(h0l)$ for l odd. These data suggest the space groups Cc or $C2/c$, assuming that the absences are space group extinctions. As shown below, the structure is well described in $C2/c$ (C_{2h}^6) with the atoms in the general 8-fold positions: (0,0,0 and $\frac{1}{2},\frac{1}{2},0$) + (x,y,z); $(\bar{x},\bar{y},\bar{z})$; $(\bar{x},y,\frac{1}{2}-z)$; $(x,\bar{y},\frac{1}{2}+z)$.

DETERMINATION OF THE ATOMIC COORDINATES

A comparison of the unit cell dimensions for ice ($a = 4.51$ Å, $c = 7.34$ Å; Megaw [9]), ammonia monohydrate ($a = 4.51$ Å, $b = 5.587$ Å, $c = 9.700$ Å; Olovsson and Templeton [5]), and hydrogen peroxide dihydrate ($a = 9.400$ Å, $b = 9.479$ Å, $c = 4.51$ Å) shows that they all have one axis in common, 4.51 Å. In the first two compounds this corresponds to the unit length of a planar zig-zag chain of tetrahedrally hydrogen bonded water molecules (distance O—H———O = 2.76 Å). This immediately suggests that the present structure also contains such chains, oriented along the *c* axis. The atoms in the chain then must be related to each other by the *c* glide, and the *y* coordinate

* A different choice of *C*-centered cell, gives $a = 9.030$ Å and $\beta = 117.23°$.

of a water oxygen can be estimated to 0.084. The subsequent interpretation of the three-dimensional Patterson maps was based on the four-fold positions in space group *Cc*. In the structure obtained, the oxygen atoms in a H_2O_2 molecule were not symmetry-related to each other and the same refers to the oxygen atoms in the two water molecules. The coordinates of this structure were subjected to about 6 cycles of Fourier and least-squares refinement. After suitable choice of the origin (the x and z coordinates for one atom are arbitrary), these partly refined oxygen coordinates were for H_2O_2: O (1), (−0.009, 0.184, 0.089); O (2), (0.008, −0.181, −0.061) and for H_2O: O (3), (0.299, 0.084, 0.271); O (4), (−0.298, −0.081, −0.299). If the space group were *C*2/*c*, the atoms O (1) and O (2) as well as O (3) and O (4) would be related by the centre of symmetry at (0,0,0), and this is obviously very nearly the case here. The centrosymmetric space group *C*2/*c* was therefore chosen for the further work, which means only two independent oxygen atoms per asymmetric unit. In this structure, according to the interpretation given below, the dihedral angle H-O-O-H of the hydrogen peroxide molecule is about 130°. This seemed somewhat disturbing and other structural solutions were then looked for. However, in a systematic study of the Patterson maps, using both *Cc* and *C*2/*c*, no other structure could be found than the one already obtained.

The coordinates and isotropic temperature factors for oxygen and an over-all scale factor were refined by least-squares methods on the IBM 650 computer (the interlayer scale factor was then based on the relative exposure time). R_3 (see below) was the quantity actually minimized. The weighting factor w in this expression and some other details of the program are described elsewhere (Olovsson and Templeton [5]). For reflections too weak to be observed, the quantity $F_o - F_c$ was set equal to zero in the sums when $F_c < F_{min}$ and equal to $F_{min} - F_c$ when $F_c > F_{min}$. In the »LS II» program, modified for the space group *C*2/*c*, the only crossterms used were those between the x and z coordinates of the same atom. The scattering factors used for oxygen (uncharged) are those published by Berghuis *et al.*[10] The shifts in the coordinates in the final cycles were less than 0.0001. The results, together with the standard deviations, after about 20 cycles of refinements are given in Table 1. The »unreliability factors» at this point were:

$$R_1 = \Sigma \, | \, |F_o| - |F_c| \, | \, / \Sigma \, |F_o| = 0.091$$
$$R_2 = [\Sigma (|F_o| - |F_c|)^2 / \Sigma \, |F_o|^2]^{\frac{1}{2}} = 0.086$$
$$R_3 = \Sigma [w(|F_o| - |F_c|)^2 / \Sigma w \, |F_o|^2]^{\frac{1}{2}} = 0.092$$

The observed and calculated structure factors are compared in Table 2. Hydrogen atoms are omitted from these calculations.

DISCUSSION OF THE STRUCTURE AND HYDROGEN POSITIONS

The structure is shown in Fig. 1. The bond distances and angles with their standard deviations are given in Table 3 and Fig. 2. The correlations between symmetry-related atoms and the uncertainty of the unit cell dimensions were considered in the calculations of these standard deviations.

The water molecules are hydrogen-bonded to each other into planar chains oriented along the c axis and in the planes $x = 0.20$, 0.30, 0.70 or 0.80, respectively. The chains are cross-linked by the hydrogen peroxide molecules into a three-dimensional network. It appears that the hydrogen peroxide molecules are not bonded to each other; the two-fold axis passes through the centre of the O-O bond. The oxygen-oxygen distance in the water chain (2.741 Å with a standard deviation $\sigma = 0.005$ Å) is slightly different from the corresponding distances in ammonia monohydrate (2.759 Å, $\sigma = 0.005$ Å; Olovsson and Templeton [5]) and ice (2.755 Å, $\sigma = 0.008$ Å; Tables of interatomic distances [11]). One of the oxygen-oxygen distances between water and hydrogen peroxide is 2.761 Å ($\sigma = 0.004$ Å), while the other is significantly shorter, 2.685 Å ($\sigma = 0.004$ Å). When refining the structure, the atomic coordinates were repeatedly changed by hand in trials to make both of these distances equal, but the subsequent least-squares treatment invariably shifted them back again. The O-O distance in hydrogen peroxide, 1.481 Å ($\sigma = 0.009$ Å), is in agreement with the value 1.48 ± 0.01 Å given in Tables of interatomic distances [11].

The bond angle in the water chain is close to the tetrahedral value but the deviations of other angles from their normal values when these water chains and the hydrogen peroxide molecules are linked together (Fig. 2)

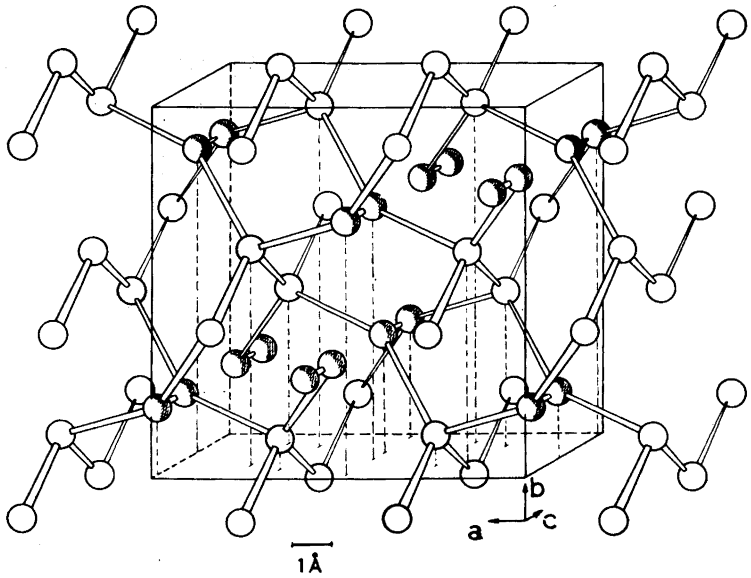

Fig. 1. The crystal structure of hydrogen peroxide dihydrate. The peroxide groups are shaded.

indicate some strain in the structure. The low melting point is another indication of low stability. The following arguments about the locations of the hydrogen atoms are similar to those presented in the case of ammonia monohydrate (Olovsson and Templeton [5]). One of the hydrogen atoms in water

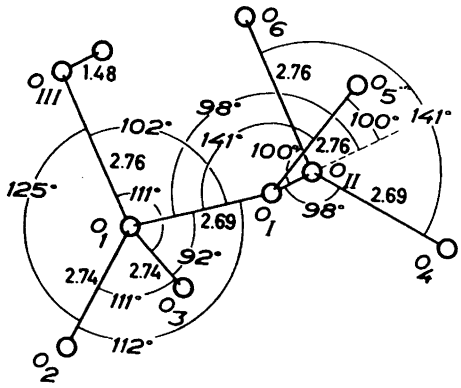

Fig. 2. Bond distances and angles to the neighbors of a water molecule and a hydrogen peroxide molecule (the orientation is the same as in Fig. 1.).

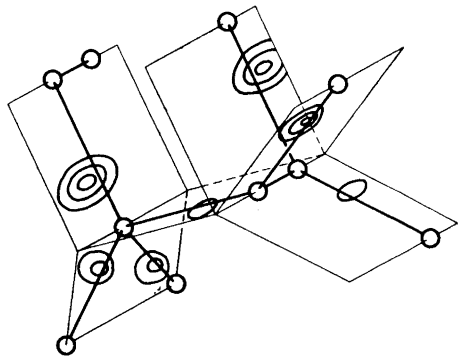

Fig. 3. Schematic representation of the difference synthesis in various sections. The contours are drawn at 0.70, 0.85 and 1.00 e · Å^{-3}. The atoms are the same as in Fig. 2.

Table 3. Bond distances and angles with their standard deviations (*cf.* Fig. 2).

Around O_I:

Bond	Distance (Å)
$O_I - O_{II}$	1.481 ± 0.009
$O_I - O_1$	2.685 ± 0.004
$O_I - O_5$	2.761 ± 0.004

Bonds	Angle (deg.)
$O_{II} - O_I - O_1$	97.7 ± 0.2
$O_{II} - O_I - O_5$	100.4 ± 0.2
$O_1 - O_I - O_5$	140.5 ± 0.2

Around O_1:

Bond	Distance (Å)
$O_1 - O_2$	2.741 ± 0.005
$O_1 - O_3$	2.741 ± 0.005
$O_1 - O_I$	2.685 ± 0.004
$O_1 - O_{III}$	2.761 ± 0.004

Bonds	Angle (deg.)
$O_I - O_1 - O_2$	111.7 ± 0.1
$O_I - O_1 - O_3$	91.5 ± 0.1
$O_I - O_1 - O_{III}$	101.8 ± 0.1
$O_2 - O_1 - O_3$	110.7 ± 0.2
$O_2 - O_1 - O_{III}$	125.0 ± 0.2
$O_3 - O_1 - O_{III}$	110.6 ± 0.2

is obviously involved in the hydrogen bonds of the water chain. The question is then to which one of the two oxygen atoms the hydrogen atom should be pointed. The two directions are not equivalent when regard is paid to the distribution of the other nearest neighbors (in contrast to the situation in ammonia monohydrate). But it is not entirely obvious from a structural point of view which orientation should be preferred. The three-dimensional $F_o - F_c$ synthesis (based on the oxygen coordinates only) seemed to give a definitive answer, as a well resolved »hydrogen peak» appeared in one direction but not in the other. The difference synthesis * is shown schematically in Fig. 3, where all the other hydrogen atoms also seem to be visible. All »hydrogen peaks» in the difference maps are close to the lines connecting the heavier atoms; the approximate coordinates are (0.305, 0.040, 0.105) and (0.385, 0.155, 0.345) for the »hydrogen atoms» bonded to O_1 and (0.105, 0.135, 0.120) for the »hydrogen atom» bonded to O_I. These peaks correspond to O-H

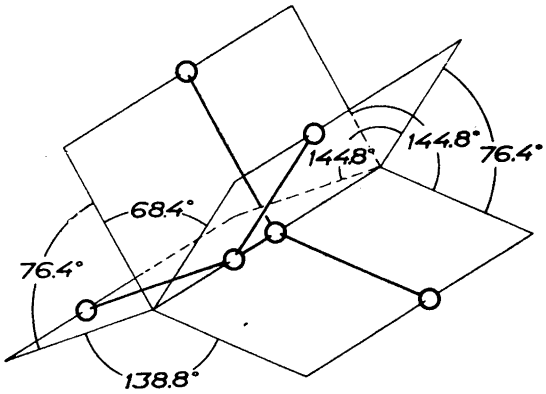

Fig. 4. Dihedral angles with the peroxide group and the nearest oxygen neighbors.

* The Fourier calculations were made on the IBM 701 computer at University of California Computer Center.

bond distances of about 1.0 Å, as expected. The apparent deviations from the connecting lines are such that they make the angles H-O-H in water and O-O-H in hydrogen peroxide closer to the values in the pure compounds ($\wedge$ O-O-H is according to a neutron diffraction investigation by Busing and Levy [12] close to 102°). The dihedral angles between planes defined by the peroxide group and the nearest oxygen neighbors are shown in Fig. 4. If the two-fold symmetry applies to the hydrogen atoms there are obviously only two values possible for the dihedral angle H-O-O-H, namely about 139° or 68° (if hydrogen is on the connecting lines) and the former was definitely indicated by the difference synthesis. The same dihedral angle is about 10° less with the experimental hydrogen positions. The same angle in solid hydrogen peroxide itself is about 90° (Busing and Levy [12]). For the urea-hydrogen peroxide addition compound $CO(NH_2)_2 \cdot H_2O_2$ Lu, Hughes and Giguère [13] report this angle to be 106° (assuming that the hydrogen atoms are on the connecting lines). Spectroscopic evidence indicates that the restoring force for twisting about the O-O bond is rather small (Giguère and Harvey [14]). And infra-red investigation of the crystalline dihydrate at low temperature actually indicates that the peroxide molecule is somewhat distorted in this compound [8].

Spectroscopic Studies on Enols

II.* Proton Magnetic Resonance and Infrared Spectra of Diacetoacetic and Cinnamoylacetoacetic Esters

STURE FORSÉN and MARTIN NILSSON

Research Group for Nuclear Magnetic Resonance, Division of Physical Chemistry, and Division of Organic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Proton magnetic resonance (PMR) data and infrared spectra of methyl and ethyl diacetoacetate confirm the complete enolisation of these compounds and also show that the intramolecular hydrogen bonds are stronger than in the enol of triacetylmethane. The spectra of ethyl cinnamoylacetoacetate and 3-cinnamoylpentane-2,4-dione are also discussed. The PMR spectrum of the latter compound shows the presence of two different chelate enols.

In the first part of these studies the extremely low infrared chelate carbonyl frequency and enol proton resonance field of a complex natural product, ceroptene [1], successively led to the investigation of simple β-triketones. It was found that even the first member of this series, triacetylmethane, was completely enolised in solution. The PMR and IR spectra indicated that the intramolecular hydrogen bond in the enol was very strong.

As β-triketones constitute a special case of α-substituted β-diketones it seemed desirable to investigate the influence of α-substituents other than acyl groups on the properties of the conjugated chelate system.

The esters of diacetoacetic acid are easily prepared and are almost completely enolised, as indicated by bromine titration experiments [2]. Methyl and ethyl diacetoacetate were chosen for comparison with triacetylmethane and cinnamoylacetoacetic ester and 3-cinnamoylpentane-2,4-dione for comparison with the cinnamoyl derivatives investigated in Part I.

---

* Part I. Forsén, S. and Nilsson, M., Proton Magnetic Resonance Studies of Enolised β-Triketones, *Acta Chem. Scand.* **13** (1959) 1383.

EXPERIMENTAL

Methods. The PMR measurements were made on dilute carbon tetrachloride solutions at 40 Mc/s and 22 ± 1°C. The resonance shifts are given in *p.p.m.* against an external water standard and are indicated by δ_{aq}*; a positive sign denotes a shift towards higher field. The infrared spectra were recorded for *ca.* 0.1 M solutions in carbon tetrachloride. For further details the reader is referred to Part I.

Materials. Methyl and ethyl diacetoacetate were prepared according to a standard procedure [3] and were purified *via* the copper salts and distilled through a short Vigreux column. Methyl diacetoacetate,b.p. 84.5–85.0°/12 mm (Lit. b.p. 101–102°/20 mm.[3]) Ethyl diacetoacetate, b.p. 93.0–93.5°/11 mm (Lit. b.p. 95–97°/11 mm [4]).

Ethyl cinnamoylacetoacetate was prepared from sodioacetoacetic ester and cinnamoyl chloride in ether and was recrystallised from methanol and sublimed, m.p. 53–54° (Lit. m.p. 44° [5]). (Found: C 69.0; H 6.4. Calc. for $C_{15}H_{16}O_4$: C 69.2; H 6.2.)

3-Cinnamoylpentane-2,4-dione: Acetylacetone (0.1 mole) in dry ether (100 ml) was treated with powdered sodium or sodium hydride (0.1 mole) at 0° to give the sodium salt. Cinnamoyl chloride (0.1 mole) in ether solution was added with stirring at 0° during 1 h. The colour of the mixture at first became deep yellow but turned to pale yellow towards the end of the addition. The mixture was stirred at room temperature for another hour and water was then added. The ether solution was washed with water and with sodium hydrogen carbonate solution and was then extracted with sodium carbonate (10 %). The extract was acidified and the product recovered by ether extraction. The crude product was recrystallised from *cyclo*hexane to afford 3-cinnamoylpentane-2,4-dione in a 40 % yield. The melting point was, however, unsharp and varied somewhat. The freshly collected material had m.p. 58–62°, but on aging the m.p. range broadened. This as well as the general appearance of the crystals seemed to indicate the presence of two interconvertible forms. A sample was dried at room temperature over paraffin and phosphorus(V)oxide and analysed, m.p. 54–59°. (Found: C 73.2; H 6.1. Calc. for $C_{14}H_{14}O_3$: C 73.0; H 6.1.) 3-Cinnamoylpentane-2,4-dione gave a strong red colour with iron(III)chloride and a green colour with copper(II)acetate.

RESULTS

The PMR spectrum of ethyl diacetoacetate in carbon tetrachloride solution and the chemical shifts are given in Fig. 1. The assignments are obvious. The enol proton signal (1) occurs at δ_{aq}—13.35, markedly lower than for triacetylmethane (δ_{aq}—12.60). The signals from the protons of the acetyl groups (3) coalesce and the ethoxyl group shows up clearly (signal groups 2 and 4). The spectrum of the pure liquid was practically the same as that of the solution and no signals due to the presence of the non-enolised ester were detected.

In methyl diacetoacetate (spectrum not shown) the enol proton gives a signal at even lower field, δ_{aq}—13.43, the acetyl protons absorb at δ_{aq} 2.53 and the methoxyl protons at δ_{aq} 1.07.

The carbonyl region of the infrared spectrum of the ethyl ester is shown in Fig. 2. The peak at 1 710 cm^{-1} was assigned to the ester carbonyl group and the broad band at 1 560 cm^{-1} to the chelate carbonyl group. In the *O-H* region there is a very broad and weak absorption between 3 000 and 2 000 cm^{-1}. The relevant absorptions of the methyl ester are identical with those of the ethyl ester.

---

* For conversion to τ-values [Tiers, G. V. D. *J. Phys. Chem.* **62** (1958) 1151] the following relation is valid at 22°C: $\tau = \delta_{aq} + 5.19$.

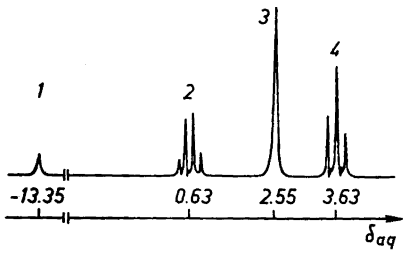

Fig. 1. PMR spectrum of ethyl diacetoacetate (carbon tetrachloride solution, mole fraction, $x = 0.08$).

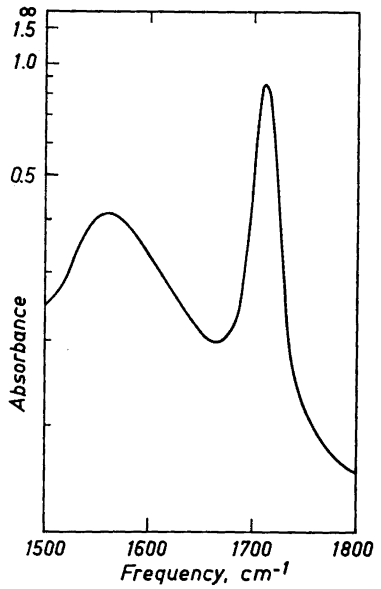

Fig. 2. The carbonyl region of the infrared spectrum of ethyl diacetoacetate (0.1 M solution in carbon tetrachloride, 0.1 mm cell, the absorption of the solvent is compensated)

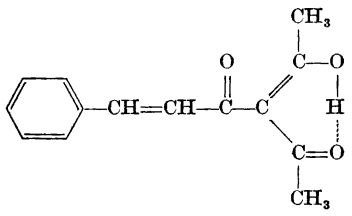
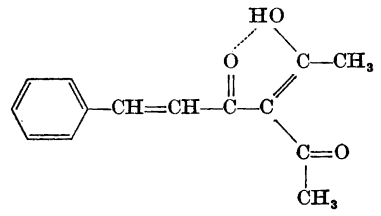
The PMR spectrum of ethyl cinnamoylacetoacetate, presented in Fig. 3, is more complicated but still easy to interpret. Signal 1 is due to the enol proton and signal group 2 is made up by contributions from the protons of the benzene ring and from the protons at the *trans* ethylenic double bond (conventional coupling constant, $J = 15$ c/s). Signal groups 4 and 6 are due to the ethoxyl protons and signal 5 to the acetyl protons. Signal 3 may be due to the presence of a small amount (less than 5 %) of non-enolised material.

The IR spectrum contains bands due to the ester carbonyl group (1 710 cm^{-1}), to the ethylenic double bond (1 630 cm^{-1}) and to the conjugated benzene ring (1 580 cm^{-1}). A broad band at 1 530 cm^{-1} is tentatively assigned to the chelated carbonyl group.



I a



I b

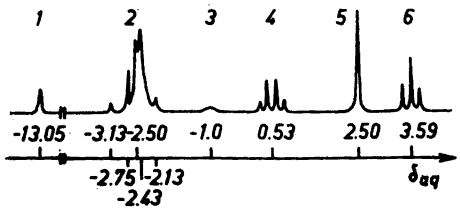


Fig. 3. PMR spectrum of ethyl cinnamoylacetoacetate (carbon tetrachloride solution, $x = 0.08$).

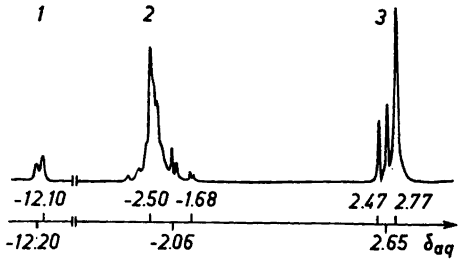

Fig. 4. PMR spectrum of 3-cinnamoylpentane-2,4-dione (carbon tetrachloride solution, $x = 0.08$).

The PMR spectrum of 3-cinnamoylpentane-2,4-dione can be interpreted in terms of the two enol forms I *a* and I *b*.

The spectrum of the enol I *a* should contain a single peak for the acetyl protons, whereas form I *b* should give two different acetyl peaks.

In the PMR spectrum, shown in Fig. 4, there are three peaks in signal group 3, which judged from the chemical shift should be due to acetyl protons. The relative intensities are 4:1:1. Signal group 1 must be due to the enol protons; the intensity ratio is 2:1. Signal group 2 consists of signals from the benzene ring protons and from the protons of the ethylenic double bond. The splitting of the latter indicates *trans* configuration ($J = 15$ c/s) as well as an effect similar to that found in signal groups 1 and 3 (internal intensity ratio 2:1). The spectrum is thus apparently made up by contributions from forms I *a* and I *b* in the proportion 2:1.

In benzene solution the splitting persists approximately unchanged, while the intensity ratio is somewhat lowered (1.8:1).

The infrared spectrum of the solution as well as of the solid compound (recorded on a potassium bromide disc) showed bands at 1 675 cm^{-1} (conjugated carbonyl group), 1 635 cm^{-1} (ethylenic double bond), 1 605 and 1 580 cm^{-1} (benzene ring) and also a broad band with the centre near 1 550 cm^{-1} due to the chelate carbonyl group.

DISCUSSION

The PMR data for the diacetoacetic esters indicate that the protons of the acetyl groups are equivalent. This is analogous to the findings for acetylacetone [6] and triacetylmethane and indicates a rapid transfer of the proton in the hydrogen bond. The equivalence of the acetyl protons and the "normal" infrared absorption of the ester carbonyl group indicates that the ester carbonyl, as expected, is not directly engaged in hydrogen bonding.

The data for the diacetoacetic esters fit well into the correlation of enol proton shifts and chelate carbonyl absorption frequencies for β-triketones in Part I and also indicate that the hydrogen bonds in these esters are stronger

than in the enol of triacetylmethane and similar to that in acetyldimedone (δ_{aq}—13.30).

The carbalkoxy group thus has a larger effect than the acetyl group in increasing the strength of the hydrogen bond and stabilising the conjugated chelate system. As steric factors can be regarded as fairly constant the effect could be described in terms of the greater "inductive, electron-withdrawing power" of the carbalkoxy group.

The data for the cinnamoyl derivatives, however, deviate from this pattern. The comparison of cinnamoylacetoacetic ester and cinnamoylpentanedione indicates that the hydrogen bond is strongest in the former and thus confirms the larger effect of the carbethoxy group on the conjugated chelate system.

The infrared chelate carbonyl absorptions indicate that the hydrogen bond is more marked in the cinnamoyl derivatives than in the simple diacetoacetic esters and unconjugated β-triketones. The PMR enol proton shifts on the other hand indicate the opposite to be the case. For acyl-dimedones both PMR and IR data indicated the hydrogen bonds to be stronger in the conjugated compounds (Part I). The splitting of the enol proton signal from cinnamoylpentanedione also presents the unexpected fact that the isomer, which occurs in the least amount, has the largest negative enol proton shift.

The enol protons of the two forms of cinnamoylpentanedione are situated at different distances from the benzene ring as well as from the ethylenic double bond. Magnetic anisotropy effects from these sources [7,8] may therefore contribute to the observed splitting of the enol proton signal.

When judging the enol proton resonance frequency in cinnamoylacetoacetic ester and cinnamoylpentanedione it is to be noted that the olefinic protons of these compounds absorb around δ_{aq}—2.4, a significantly higher field than that for the corresponding resonance of ceroptene and cinnamoyldimedone (δ_{aq} *ca.*—3.1). For the present no attempt has been made to explain these phenomena, which probably are related to the larger flexibility of the molecules now investigated.

Acknowledgements. We wish to thank Professor H. Erdtman and Dr. E. Forslind for their kind encouragement and interest, Miss Gurli Hammarberg for the infrared measurements, Mr. E. Pettersson for technical assistance and Dr. B. R. Thomas and Dr. I. Wellings for improving the language of the manuscript.

Demethylation and Degradation of Sugars in Acid Hydrolysis

INGEMAR CROON, GUNNEL HERRSTRÖM, GÖRAN KULL and BENGT LINDBERG

Institutionen för träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

The magnitude of demethylation and degradation of some methylated sugars during conditions of acid hydrolysis has been studied. The conditions were typical for various procedures used for the hydrolysis of methylated polysaccharides. The investigation thus throws some light upon possible sources of error when the structure of a polysaccharide is studied by the methylation technique.

The methylation technique involving the complete methylation of a carbohydrate, hydrolysis and identification and quantitative determination of the methylated sugar obtained is an important method in structural carbohydrate chemistry. A prerequisite for the correct interpretation of the results especially for polysaccharides, which may give mixtures of several methylated sugars, is that the methylation is complete and that the methylated sugars are not degraded or demethylated during the acid hydrolysis of the methylated polysaccharide. Although some polysaccharides are difficult to methylate completely it is usually possible to obtain a product with a methoxyl content rather close to the theoretical value. No systematic studies of the demethylation and degradation of methylated sugars under the conditions used in acid hydrolysis seem to have been made, but some observations have been recorded in the literature.

Freudenberg and Boppel [1] studied the demethylation of 2,3,6-tri-*O*-methyl-D-glucose on treatment with 36 % aqueous hydrochloric acid at +5°, the conditions used for the hydrolysis of methylated starch, and found that 2 % or more of di-*O*-methyl-D-glucoses was formed. They believed that one of these, presumably the 2,6- and definitely not the 2,3-derivative, was formed preferentially. Chanda *et al.*[2] studied the demethylation of 2,3-di-*O*-methyl-D-xylose and 2,3,4-tri-*O*-methyl-D-xylose on treatment with 1 % methanolic hydrogen chloride and found 0.2 and 2 % demethylation, respectively. Croon and Lindberg [3] observed that the treatment of seven partially methylated glucoses, first with 72 % sulphuric acid at 0° and then with 12 % sulphuric acid at 100° did not produce any apparent demethylation but that the sugars showed between 3 and 6 % degradation. In a recent publication, Goldstein

Table 1. Acid hydrolysis conditions.

Conditions	Acid	Temp.	Time
1	2 % HCl in water	100°	13 h
2	a) 2 % HCl in methanol	100°	13 h
	b) 0.5 N HCl in water	100°	8 h
3	a) 72 % sulphuric acid	Room temp.	0.5 h
	b) 12.4 % sulphuric acid	100°	4 h
4	a) 98 % formic acid	100°	6 h
	b) 0.5 N sulphuric acid	100°	14 h

Table 2. Degradation of methylated sugars under hydrolytic conditions.

Conditions used	2,3-Di-*O*-Me-xylose	2,3-Di-*O*-Me-glucose	2,3,6-Tri-*O*-Me-glucose
1	6– 7 %	8 %	7 %
2	1– 3 %	–	7 %

2,3,6–G	2	0.9

a) 2,3-X = 2,3-Di-*O*-methyl-D-xylose, 2,3-G = 2,3-Di-*O*-methyl-D-glucose and so on.
b) The methanolic HCl was heated for 13 h under reflux and not in a sealed tube.

et al.[4] report that 1,4-di-*O*-methylerythritol was demethylated to 1.3 % when refluxed with 3 % methanolic hydrogen chloride for 18 h.

The present paper is a report of studies on the degradation and demethylation of 2,3-di-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-glucose and 2,3,6-tri-*O*-methyl-D-glucose under different conditions. The conditions used are listed in Table 1; they were selected as representative of those various procedures used in the hydrolysis of methylated polysaccharides.

The extent of degradation was determined by measuring the decrease in optical rotation after the hydrolytic treatment. This method is subject to serious limitations as some reversion might occur and small mechanical losses

are not excluded. The observed effects were generally rather small and the values in Table 2 should be regarded as highly approximate. They do, however, allow a comparison of the different methods of hydrolysis.

Formolysis in 98 % formic acid involves severe degradation, and the reaction solutions become very dark. The use of 90 % formic acid is often reported and is probably less harmful; Isbell *et al.*[5] report good results with this mixture. In the other treatments the degradation is less, usually of the same order of magnitude as that observed for the free sugars during the total hydrolysis of polysaccharide material.

In order to study the demethylation the products obtained after hydrolytic treatment were fractionated by carbon column chromatography and the lower ethers isolated were characterised by paper chromatography and paper electrophoresis. The percentages of lower methylated products obtained after different treatments are given in Table 3. These values also are probably not very accurate, but they give the correct order of magnitude. Comparable amounts of 2- and 3-*O*-methyl-D-xylose were formed during the demethylation of 2,3-di-*O*-methyl-D-xylose. Similarly, comparable amounts of 2- and 3-*O*-methyl-D-glucose and of 2,3-, 2,6- and 3,6-di-*O*-methyl-D-glucose were formed from 2,3-di-*O*-methyl-D-glucose and 2,3,6-tri-*O*-methyl-D-glucose, respectively.

Methylated polysaccharides are generally insoluble in hot aqueous solutions, and for that reason methanolysis, formolysis or treatment with 72 % sulphuric acid is performed before hydrolysis with dilute, aqueous acid. It is evident from the present investigation that hydrogen chloride, either in water or methanol, causes a significant amount of demethylation and that the use of sulphuric acid is therefore preferable. Formolysis in 98 % formic acid causes almost no demethylation but is accompanied by considerable degradation. Of the methods investigated, the pretreatment with 72 % sulphuric acid followed by hydrolysis with 12 % sulphuric acid offers the best compromise. It is possible, however, that equally good or better results may be obtained by formolysis in 90 % formic acid, followed by acid hydrolysis. Aspinall *et al.*[6] have hydrolysed a methylated polysaccharide that was soluble in cold water, by carrying out the reaction in dilute sulphuric acid and raising the temperature only slowly, so as to keep the material in solution. This method seems to have definite advantages.

The substances studied in the present investigation did not show any selective demethylation and the methoxyl groups in different positions seem to show comparable reactivities. This was to be expected; smaller differences in reactivity are reasonable but a highly selective demethylation seems most improbable.

EXPERIMENTAL

Paper chromatography and *paper electrophoresis* were carried out on Whatman No. 1 filter paper.

Solvent systems: Ethyl acetate-acetic acid-water, 3:1:3.
Butanone, saturated with water.
Buffer: 0.1 M borate buffer at pH 10.

Starting materials. 2,3-Di-*O*-methyl-D-glucose and 2,3,6-tri-*O*-methyl-D-glucose were prepared by conventional methods. 2,3-Di-*O*-methyl-D-xylose was prepared by methylation, detritylation and hydrolysis of methyl-5-*O*-trityl-D-xylofuranosides (α- and β-mixture) analogously to the synthesis by Robertson and Gall [7], of the same substance from methyl-5-*O*-benzoyl-D-xylofuranosides. The substance was purified by carbon column chromatography and distillation under reduced pressure. It did not crystallise but was chromatographically and electrophoretically pure and indistinguishable from 2,3-di-*O*-methyl-D-xylose, obtained as the main product of hydrolysis of fully methylated xylans.

Estimation of the extent of degradation

The optical rotation of an aqueous solution of the methylated sugar (*c* 2.0) was determined, 5.00 ml of this solution was concentrated to dryness in a rotating laboratory evaporator and the residue was treated according to one of the four different alternatives described below.

1. It was dissolved in 2 % aqueous hydrochloric acid (4 ml), refluxed for 13 h, diluted to 5.00 ml and the optical rotation was determined (2 dm tube).
2. It was dissolved in 2 % methanolic hydrogen chloride (5 ml) and heated in a sealed tube to 100° for 13 h. The methanol was replaced with water by distillation under reduced pressure, the volume was adjusted to 4.5 ml and the solution was refluxed for 8 h. The volume was then adjusted to 5.00 ml and the optical rotation was determined.
3. It was dissolved in 72 % sulphuric acid (0.44 ml) and kept at room temperature for 30 min. Water was added (3.52 ml) and the solution was heated to 100° for 4 h, diluted with water to 5.00 ml and the optical rotation was determined.
4. It was dissolved in 98 % formic acid (6 ml) and heated to 100° for 6 h, then concentrated to a syrup under reduced pressure, dissolved in 0.5 N sulphuric acid (4.5 ml) and heated to 100° for 14 h. It was then diluted to 5.00 ml and the optical rotation was determined.

For treatments 1, 2 and 3 the decrease in optical rotation was only between 0.02° and 0.05°, duplicate experiments showing a fairly good agreement. The concentrations during the acid treatments were somewhat too high, and some reversion probably occurred.

The formolysis gave a larger decrease in rotation, about 0.2.°

Estimation of the demethylation

A sample of the methylated sugar (about 1.0 g) was subjected to hydrolytic treatment as described above. The acid was removed by filtration through a column of Amberlite IR 4 B and the aqueous solution was concentrated to a small volume and added to the top of a carbon-Celite column (4 × 40 cm). The sugars were eluted with aqueous ethanol, using gradient elution. For the dimethyl ethers, elution with 5 000 ml, 0 → 25 % ethanol was sufficient. The products from the hydrolytic treatment of 2,3,6-tri-*O*-methyl-D-glucose were eluted with 8 000 ml, 0 → 50 % ethanol. Pure starting material was recovered together with smaller amounts of partially demethylated sugars. The fractionation of the latter was incomplete and they were therefore combined and the total amount present was determined by weighing, hypoiodite titration and determination of the optical rotation. The components of these fractions were characterised by paper chromatography and paper electrophoresis and their proportions were estimated from the intensities of the spots. In the experiments with 2,3-di-*O*-methyl-D-xylose, very small amounts of xylose were observed in the hydrolysate in addition to the mono-*O*-methyl-D-xyloses and starting material.

Kinetics of the Hydrolysis of Acetic Anhydride in Acetone-Water and Dioxane-Water Mixtures

JOUKO KOSKIKALLIO

Department of Chemistry, University of Oulu, Oulu, Finland

From the values obtained for the rate constants and activation entropies and energies of the acid hydrolysis of acetic anhydride in acetone-water and dioxane-water mixtures, it is concluded that the hydrolysis occurs simultaneously by two mechanisms, A-1 and A-2. When the composition of the solvent mixture is altered, one mechanism is favoured over the other. A-2 dominates in mixtures containing approximately 50 % acetone while A-1 dominates in mixtures containing only small amounts of water. An other important factor affecting the rate in solvent mixtures is the variation of the proton availability with solvent composition.

The acid-catalysed solvolysis of acetic anhydride involves, as do many other acid solvolyses, a fast proton transfer pre-equilibrium

$$Ac_2O + SH^+ = Ac_2OH^+ + S \qquad (1)$$

followed by a slow reaction which may be either bimolecular, A-2,

$$Ac_2OH^+ + H_2O \xrightarrow{\text{slow}} AcOH + AcOH_2^+ \qquad (2)$$

or unimolecular, A-1,

$$Ac_2OH^+ \xrightarrow{\text{slow}} AcO^+ + AcOH \qquad (3)$$

The reactions following the step (2) or (3) that lead to the final products are all fast. The equilibrium of reaction (1) is far on the left and therefore the experimental rate constant

$$k_{exp.} = Kk \qquad (4)$$

is equal to the product of the equilibrium constant K of the proton transfer reaction (1) and the rate constant k of the slow reaction, either (2) or (3).

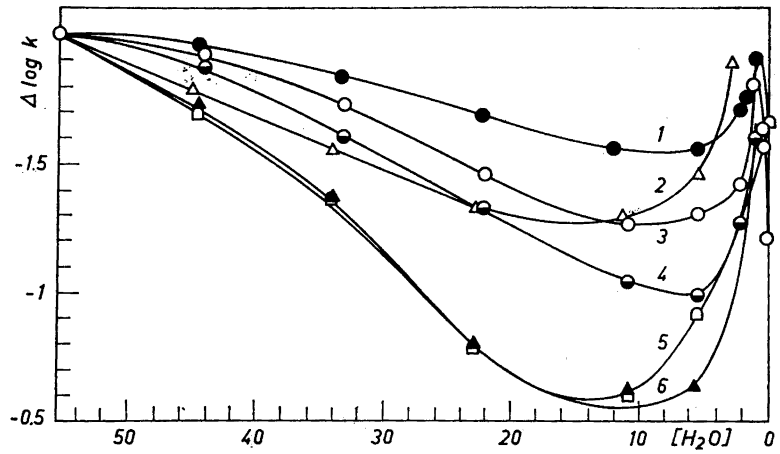

Fig. 1. Plot of log$k$ (solvent mixture) — log$k$ (water) and acidity function H_0 against [H_2O] for the hydrolysis of acetic anhydride in acetone-water and dioxane-water mixtures. 1. ethyl acetate, acetone-water. 2. diethoxymethane, dioxane-water. 3. acetic anhydride, dioxane-water. 4. acetic anhydride, acetone-water. 5. H_0, dioxane-water. 6. H_0, acetone-water.

It was found in a previous study [1] of the acid hydrolysis of acetic anhydride that the rate constant k varies only slightly over the whole range of methanol — water mixtures, whereas K, and therefore also $k_{exp.}$, changes considerably when the composition of the solvent mixture is altered. The change of K could be quantitatively explained by variations in the proton transfer equilibrium between water and methanol. The present investigation was undertaken in order to find out whether similar proton transfer equilibria are important in dioxane — water or acetone — water mixtures.

EXPERIMENTAL

Acetic anhydride (E. Merck AG, pro analysi), aniline (E. Merck AG, pro analysi) and acetone (E. Merck AG, pro analysi) were used as such. The water content of the acetone, 0.21 mole/litre, was determined by the Karl Fischer method. Dioxane (Fluka AG, purified by the method of Hess and Frahm) contained about 0.053 mole/litre of water. In order to remove any remaining hydroxylic compounds the dioxane was purified again by the method of Hess and Frahm [2]. After this treatment the dioxane contained less than 0.002 mole/litre of water. A stock solution of 1 N hydrochloric acid was prepared from a Titrisol ampoule (E. Merck AG). Solutions of hydrochloric acid in dioxane were prepared immediately before use by passing hydrogen chloride produced from sodium chloride and concentrated sulphuric acid into the dioxane. The acetone-water and dioxane-water mixtures were prepared by weighing in volumetric flasks.

Methods previously described [3] were used to determine the rate constants of the hydrolysis of acetic anhydride in the mixtures. The catalytic rate constant was obtained by subtracting the rate constant of the spontaneous reaction in the pure solvent mixture from the rate constant obtained in the same solvent mixture containing added hydrochloric acid. The second-order formula was used to calculate the rate constants when the concentration of water in the solvent mixture was less than 0.5 mole/litre, and the first-

order formula when the other solvent mixtures were employed. A good constancy of the rate constant was obtained in all cases except at the lowest water concentrations of 0.1 – 0.15 mole/litre. In these latter mixtures the second-order rate constant increases about 20 % when the reaction proceeds from 10 to 60 % change. The mean values of the rate constants are given in Tables 1 and 2.

DISCUSSION

In Fig. 1 are shown plots of log$k$ (solvent mixture) — log$k$ (water) against the water concentration of the solvent mixture for the acid hydrolysis of acetic anhydride, diethoxymethane [4], and ethyl acetate [5], and curves plotting values of the acidity function H_0 [6]. All these curves have a similar form and a minimum at a water concentration of about 10 moles/litre. The decrease in the rate at water concentrations below about 1 mole/litre is unexpected. Also the third-order rate constants obtained by dividing the second-order rate constant by the concentration of water vary similarly. The values of H_0 are too few in number to permit a decision as to whether they follow a similar course.

The acid hydrolysis of diethoxymethane is a typical example of the unimolecular reaction (3) with a positive entropy of activation [7] $\Delta S^* = +6.9$ e.u., a zero volume of activation [7] $\Delta V^* = 0$ cm^3 mole^{-1}, and a rate proportional to the acidity function H_0 in mixtures of a strong mineral acid and water [8]. The curve plotting the rate of acid hydrolysis of diethoxymethane is closest to the plot of the acidity function H_0 (Fig. 1). A complete agreement cannot be expected for mixtures of a organic solvent and water [8].

On the other hand, the acid hydrolysis of ethyl acetate is a typical example of a reaction occurring by the bimolecular mechanism (2). It has a negative entropy of activation in water [5]: $\Delta S^* = -22.5$ e.u. For methyl acetate which hydrolyses by the same mechanism as ethyl acetate a negative volume of activation [9] $\Delta V^* = -13.3$ cm^3 mole^{-1} was obtained in 44.1 % w/w acetone-water. The rate of acid hydrolysis of ethyl acetate is not proportional to H_0 in concentrated aqueous mineral acid solutions [10]. The curve for ethyl acetate in Fig. 1 deviates most from the H_0 curve.

The two reactions (2) and (3) probably occur concurrently in the acid hydrolysis of acetic anhydride. The activation entropy in water, $\Delta S^* = -12.3$ e.u. (Table 3), is higher than expected for a bimolecular reaction but

Table 3. Activation energies and entropies of the acid-catalysed hydrolysis of acetic anhydride calculated from the second-order rate constants and of the spontaneous hydrolysis calculated from the first-order rate constants in dioxane-water mixtures. Subscript a refers to acid-catalysed reaction and subscript w to the spontaneous reaction.

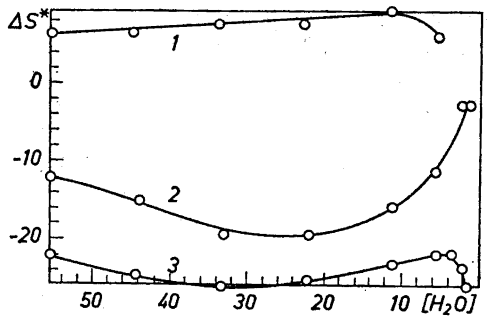

Fig. 2. Plot of ΔS^* against $[H_2O]$. 1. diethoxymethane, dioxane-water. 2. acetic anhydride, acetone-water. 3. ethyl acetate, acetone-water.

lower than expected for a unimolecular reaction (Fig. 2). The rates of unimolecular hydrolyses increase faster than do the rates of bimolecular hydrolyses in aqueous solutions of strong mineral acids when the concentration of the acid is increased. The unimolecular reaction is thus favoured in concentrated mineral acid solutions and this may explain why the rate of acid hydrolysis of acetic anhydride has been found [12] to be proportional to the acidity function H_0.

In a mixture consisting of about half acetone and half water the activation entropy is small and reaches a minimum value $\Delta S^* = -20$ e.u. (Fig. 2). In this range the acid hydrolysis of acetic anhydride is thus mainly a bimolecular reaction. In agreement with this view a small negative volume of activation $\Delta V^* = -17.1$ cm^3 mole^{-1} was obtained [13] for the reaction in 44.1 % acetone-water. At high pressures the bimolecular reaction dominates even more than at low pressures because the rate of a bimolecular reaction is increased by pressure whereas an unimolecular reaction remains almost unaffected. The curve for acetic anhydride lies between those for the ester and the formal in water-rich mixtures (Fig. 1).

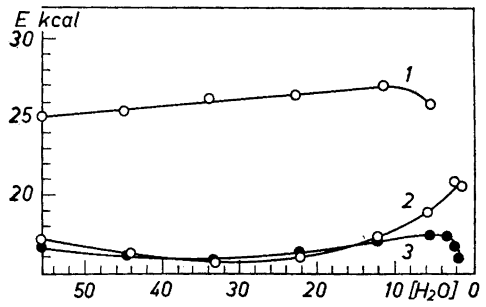

Fig. 3. Plot of E against $[H_2O]$. 1. diethoxymethane, dioxane-water. 2. acetic anhydride, acetone-water. 3. ethyl acetate, acetone-water.

The plots of the activation entropy against water concentration for ethyl acetate and diethoxymethane (Fig. 2) remain fairly horizontal over a wide range of solvent mixtures. The solvent effects in unimolecular and bimolecular reactions are hence small. On the other hand, the activation entropy of the acid hydrolysis of acetic anhydride varies much more when the composition of the solvent mixture is altered. In mixtures containing only small amounts of water the activation entropy ΔS^* reaches a high value of about —2.7 e.u. which is of the order of magnitude typical for unimolecular reactions. If all solvent effects remain insignificant when the concentration of water is decreased, the rate of the bimolecular reaction should be retarded and the unimolecular reaction should remain unaffected because the rate of the former reaction (2) is proportional to the water concentration, whereas the rate of the later (3) is of zero order with respect to water. The solvent effects of a unimolecular and a bimolecular reaction were found to be small. It is then not unexpected that a change occurs in the acid hydrolysis of acetic anhydride from two concurrent reactions in water to a typical unimolecular reaction in acetone containing only small amounts of water. Also the activation energies in Fig. 3 vary in a similar manner as the activation entropies and thus confirm the above conclusions.

Nonaqueous Titration of Phenolic Esters

BENGT SMITH and ÅKE HAGLUND

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

Potentiometric titration of phenolic esters using tetra-*n*-butylammonium hydroxide in acetone has been found suitable for differentiating between various types of phenolic esters. Esters of aliphatic carboxylic acids can be titrated as a rule, provided that strongly electron-repelling groups are absent in the phenolic ring. Unsubstituted esters of aromatic carboxylic acids do not react but replacement of hydrogen atoms in the aromatic nucleus by electron-attracting groups can also render the aromatic esters titratable.

It has been shown by Glenn and Peake [1] that phenolic esters of aliphatic as well as aromatic carboxylic acids can be titrated in ethylenediamine using potassium methoxide in benzene-methanol as titrant. It was assumed that the esters underwent aminolysis with the formation of phenols and amides of ethylenediamine. Attempts in this laboratory to titrate phenolic esters using acetone as solvent and tetra-*n*-butylammonium hydroxide in benzene-methanol as titrant revealed a remarkable difference in reactivity between various types of esters. While certain phenolic esters reacted, consuming about one equivalent of base per ester group, no reaction took place with other esters. In the case of phenyl acetate, which reacted with the tetra-*n*-butylammonium base, the formation of methyl acetate could be proved by gas chromatography. Thus the reaction seems to involve a transesterification of the phenolic ester by methanol under the catalytic influence of base.

$$RCOOAr + CH_3OH \rightleftharpoons RCOOCH_3 + ArOH$$

Methanol is present in the titrant and it has been shown recently [2] that the tetra-*n*-butylammonium base titrant prepared by the Cundiff and Markunas [3] method by reaction of tetra-*n*-butylammonium iodide with silver oxide in anhydrous methanol is an approximately 1 to 1 mixture of methoxide and hydroxide.

The base consumption was generally 10—20 % too high. The reason for this is not clear but it should be pointed out that, if the ester group reacts with a hydroxyl ion, two equivalents of base will be consumed per ester group. Because of the too high base consumption, this method is generally not suited

for the quantitative analysis of phenolic esters. For this purpose, the Glenn and Peake method is superior. However, the structure dependence of the present method makes it useful for differentiating between various types of phenolic esters.

Aryloxysilanes, which have previously been titrated by the Glenn and Peake method [4], were found also to respond to the present method.

The results of the titration of a number of phenolic esters are summarized in Table 1.

EXPERIMENTAL

Materials. Most of the phenolic esters were prepared in this laboratory. Their purity was ascertained by determination of appropriate physical constants.

Titration procedure. The titration was made according to the directions of Fritz and Hammond [5] using 0.1 N tetra-*n*-butylammonium hydroxide in benzene-methanol as titrant and acetone as solvent. Both reagent grade and superdry acetone were used with about the same results. Glass calomel electrodes were used and the titration was followed by means of a Radiometer Titrator model TTT 1.

RESULTS and DISCUSSION

The phenolic esters in Table 1 are arranged in the following order: Unsubstituted phenolic esters of aliphatic acids (Nos. 1—5), phenolic esters of aliphatic acids with various substituents in the phenolic ring (Nos. 6—18), unsubstituted phenolic esters of aromatic acids (No. 19) and phenolic esters of aromatic acids with various substituents in the acid part of the molecule (Nos. 20—25). Compounds Nos. 26 and 27 have been included as examples of lactones and orthoesters. From the material in Table 1, certain conclusions may be drawn concerning the reactivities of various types of phenolic esters.

Phenolic esters of aliphatic carboxylic acids without substituents in the phenolic ring are split (*cf.* Nos. 1—5). Replacement of hydrogen atoms in the phenolic ring by strongly electron-donating groups, *e.g.* hydroxyl and amino groups, however, makes the ester group non-reactive (*cf.* Nos. 6—8). The presence of electron-donating groups of intermediate strength in the phenolic ring like the acetoxy group does not inhibit the splitting of the ester group (*cf.* Nos. 9—11). In diacetates of dihydric phenols, for example, one ester group was split with the formation of a phenoxide ion which then inhibited the splitting of the second ester group. Esters of phenols with weakly activating or deactivating groups can be titrated, as might be expected. An exception to this rule was provided by acetylsalicylic acid which was not split in contrast to its *meta* and *para* isomers (*cf.* Nos. 16—18). The reason for this will be discussed below.

Phenolic esters of aromatic carboxylic acids. For a phenolic ester of this type to be titratable under the conditions used in this work, the presence of electron-attracting groups in the molecule seems to be necessary (*cf.* Nos. 19—25). We have investigated the influence of substituents in the acid part of the molecule only but substituents in the phenolic ring can be expected to exert a similar influence as was found previously for esters of aliphatic carboxylic acids.

Table 1. Titration of phenolic esters in acetone using tetra-*n*-butylammonium hydroxide.

Compound			Base consumption equiv. per mole	Number of phenolic ester groups present	Number of phenolic ester groups split
No.	Name	Formula			
1	Phenyl acetate	$CH_3COOC_6H_5$	1.12	1	1
2	Phenyl *iso*butyrate	$(CH_3)_2CHCOOC_6H_5$	1.30	1	1
3	Diphenyl succinate	$C_6H_5OCOCH_2CH_2COOC_6H_5$	2.30	2	2
4	Phenyl succinate	$C_6H_5OCOCH_2CH_2COOH$	1.87*	1	1
5	β-Naphthyl acetate	$CH_3COOC_{10}H_7$	1.20	1	1
6	*o*-Hydroxyphenyl acetate	$CH_3COOC_6H_4OH$-*o*	1.09	1	0
7	*m*-Hydroxyphenyl acetate	$CH_3COOC_6H_4OH$-*m*	1.09	1	0
8	*p*-Aminophenyl acetate	$CH_3COOC_6H_4NH_2$-*p*	0	1	0
9	Pyrocatechol diacetate	$CH_3COOC_6H_4OCOCH_3$-*o*	1.08	2	1
10	Resorcinol diacetate	$CH_3COOC_6H_4OCOCH_3$-*m*	1.08	2	1
11	Hydroquinone diacetate	$CH_3COOC_6H_4OCOCH_3$-*p*	0.88	2	1
12	*o*-Cresyl acetate	$CH_3COOC_6H_4CH_3$-*o*	1.12	1	1
13	*o*-Chlorophenyl acetate	$CH_3COOC_6H_4Cl$-*o*	1.08	1	1
14	*o*-Nitrophenyl acetate	$CH_3COOC_6H_4NO_2$-*o*	1.11	1	1
15	*p*-Nitrophenyl acetate	$CH_3COOC_6H_4NO_2$-*p*	1.03	1	1
16	Acetylsalicylic acid	$CH_3COOC_6H_4COOH$-*o*	1.00	1	0
17	Acetyl-*m*-hydroxybenzoic acid	$CH_3COOC_6H_4COOH$-*m*	2.02*	1	1
18	Acetyl-*p*-hydroxybenzoic acid	$CH_3COOC_6H_4COOH$-*p*	2.02*	1	1
19	Phenyl benzoate	$C_6H_5COOC_6H_5$	0	1	0
20	Phenyl salicylate	*o*-$HOC_6H_4COOC_6H_5$	2.14	1	1
21	Phenyl *p*-hydroxybenzoate	*p*-$HOC_6H_4COOC_6H_5$	1.08	1	0
22	Phenyl *p*-aminobenzoate	*p*-$NH_2C_6H_4COOC_6H_5$	0	1	0
23	Phenyl *p*-nitrobenzoate	*p*-$NO_2C_6H_4COOC_6H_5$	1.03	1	1
24	Diphenyl phthalate	$C_6H_5OCOC_6H_4COOC_6H_5$-*o*	2.11	2	2
25	Phenyl phthalate	$C_6H_5OCOC_6H_4COOH$-*o*	1.75	1	1
26	Coumarin		0	1	0
27	Phenyl orthoacetate	$CH_3C(OC_6H_5)_3$	0	3	0

* Two inflexion points were obtained.

Mechanism of the phenolic ester splitting. As previously shown in eqn. 1, the reaction is a re-esterification reaction. The results presented in the previous sections are also compatible with a reaction mechanism involving a nucleophilic attack on the carbonyl carbon atom of the ester group. In accordance with this mechanism, the splitting of esters of aliphatic carboxylic acids is inhibited by the presence of strongly electron-donating groups in the phenolic ring because of the increased electron density at the carbonyl carbon atom. The decreased reactivity of esters of aromatic carboxylic acids in comparison with esters of aliphatic carboxylic acids can be ascribed to the conjugation

of the carbonyl carbon atom with the aromatic nucleus in the former case. Electron-attracting groups once again call the splitting mechanism into play.

In Table 1, there are some exceptions from the general rules. Thus, acetylsalicylic acid (No. 16) was not split unlike its *meta* and *para* isomers. The reason for this might be a steric factor, the bulky carboxyl ion or the corresponding tetra-*n*-butylammonium salt hindering the approach of the nucleophilic reagent. The negative charge on the carboxyl ion is also likely to render the attack more difficult. A similar but less pronounced effect of a "neighbouring" carboxyl group is discernable for phenyl succinate (No. 4) and phenyl phthalate (No. 25) for which the splitting of the ester group is only partial.

The other exception is provided by phenyl salicylate (No. 20) in which the ester group is split in spite of the presence of a hydroxyl group. We believe this to be due to hydrogen bonding which increases the electrophility of the carbonyl carbon atom. It must be assumed that the ester group is split prior to the neutralization of the phenolic hydroxyl group.

Coumarin (No. 26) is the only example of a lactone investigated in this work. No splitting occurred. Although coumarin is to be looked upon as a phenolic ester of an aliphatic carboxylic acid, a reaction is hardly to be expected because of the conjugation of the carbonyl group with the aromatic ring. The fixation of the carbonyl group might also be of some significance for the lack of reactivity. The last compound in Table 1 is phenyl orthoacetate. It did not react with the titrant because of the absence of a carbonyl groop.

Use in identification work. The material collected in Table 1 exemplifies the application of the present titration method for the identification of phenolic esters of various types. While, in the analytical investigation of phenolic esters, hydrolysis of the esters to form the free phenols is often performed, the reverse procedure might sometimes be of value, *i.e.* acetylation of a phenol in order to elucidate its structure by means of the ester splitting method described here.

Organophosphorus Analogues of Tropic Acid Esters

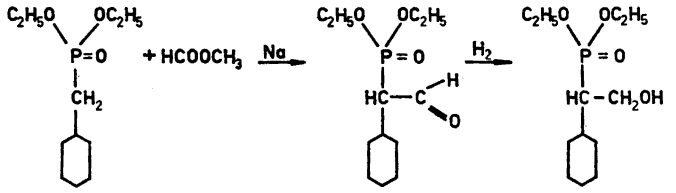
1. 2-Phenyl-2-diethoxyphosphoryl Ethanol

L.-E. TAMMELIN and L. FAGERLIND

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

Phenyl-diethoxyphosphoryl methane, phenyl-diethoxyphosphoryl acetaldehyde and 2-phenyl-2-diethoxyphosphoryl ethanol have been prepared. Infrared spectra, protolytic titration, refractive index, and violet color reaction with iron(III)ions indicate that the aldehyde shows keto-enol tautomerism. The occurrence of tautomerism and the presence of a strong hydrogen bridge in the enol form, support the view that condensation of phenyl-diethoxyphosphoryl methane and methyl formate with sodium results in phenyl-diethoxyphosphoryl acetaldehyde. Catalytic hydrogenation of the aldehyde consequently yields 2-phenyl-2-diethoxyphosphoryl ethanol.

Organophosphorus analogues of acetylcholine have been shown to be of considerable chemical and pharmacological interest [1]. It thus seemed to be of value to prepare phosphoryl analogues to other pharmacodynamically active compounds. This investigation is part of a study on the preparation of organophosphorus analogues of atropine [2,3]. The main purpose with the present part was to show whether phosphoryl compounds react analogously to carbonyl compounds in the ester condensation and hydrogenation reactions used in preparation of tropic acid ester [4]. The following formulae show the sequence of preparations studied.



Carbon and hydrogen content of the obtained compounds, and the analogous reactions described in syntheses of tropic acid ester [4] *per se*, suggest that the studied reaction sequence really gives rise to 2-phenyl-2-diethoxy-

phosphoryl ethanol. However, the structure of the parent compound, phenyl-diethoxyphosphoryl acetaldehyde, is of major importance for establishing the structure of the phenyldiethoxyphosphoryl ethanol. Thus the aldehyde was made the subject of the following supplementary determinations: Infrared spectrum, acid properties and reaction with iron chloride. Finally, the infrared spectrum of phenyl-diethoxyphosphoryl ethanol was recorded.

EXPERIMENTAL

Syntheses

Phenyl-diethoxyphosphoryl methane. Two moles of ethanol and two moles of triethylamine were dissolved in 1 l of ether in a round bottomed flask with stirring. One mole of benzyl phosphoryldichloride was added (prepared according to Kinnear and Perren [5]). The triethylammonium chloride formed was filtered off, and the ester separated by fractional distillation, b.p. 115°/0.2 mm Hg. Phenyl-diethoxyphosphoryl methane is a colorless oil with a geranium-like odour. Refractive index $n_D^{25} = 1.4960$. (Found: C 57.8; H 7.52. Calc. for $C_{11}H_{17}O_3P$ (228.2): C 57.8; H 7.52). Yield 80 %.

Phenyl-diethoxyphosphoryl acetaldehyde. 1.0 moles of sodium were allowed to react with 2 moles of methyl formate in 200 ml ether, in a round bottomed flask with reflux condenser. 1 mole of phenyl-diethoxyphosphoryl methane, together with 250 ml of ether, was added when all sodium had been consumed. The mixture was boiled for 4 h and then stirred at room temperature for 24 h, after which the ether solution was extracted with 2 × 200 ml of water. pH of this extract was adjusted to ~10 and the solution extracted with 3 × 100 ml of ether, the ether extracts being discarded. The aqueous solution was acidified with sulfuric acid to pH ~3 and percolated with ether for 12 h. The ether extract thus obtained was evaporated, giving a viscous residue. The residue was dissolved in benzene and the benzene evaporated; this operation was repeated. Finally, the product was distilled at 110°/0.2 mm Hg, the first 5 ml of distillate being discarded. A few brown drops remained in the distillation flask. The phenyl-diethoxyphosphoryl acetaldehyde preparation thus obtained is an oil with a roselike odour. Refractive index is $n_D^{25} = 1.5195$ immediately after distillation, but increases with time and after a week becomes constant at $n_D^{25} = 1.5320$. After a few days of storage at $n_D^{25} = 1.5320$ the compound solidifies to crystals (m.p. 58°C). (Found C 56.3; H 6.61. Calc. for $C_{12}H_{17}O_4P$ (256.2): C 56.3; H 6.68). Yield: 50 %.

2-Phenyl-2-diethoxyphosphoryl ethanol. Phenyl-diethoxyphosphoryl acetaldehyde in ethanol solution was hydrogenated with hydrogen at 50 atm and 70°C for five days, using Adams platinum catalyst. The alcohol was purified by fractional distillation (b.p. 130°C/0.1 mm Hg), and is a liquid with $n_D^{25} = 1.5040$. (Found: C 55.3 H 7.5 Calc. for $C_{12}H_{19}O_4P$ (258.2): C 55.8; H 7.37). Yield 90 %.

Verification of purity and chemical structure

Phenyl-diethoxyphosphoryl acetaldehyde (51 mg + 1 ml C_2H_5OH + 39 ml 0.1 M KCl) was titrated with 0.1 M NaOH. The sodium hydroxide was added in 0.1 ml portions every third minute.

One drop of 5 % $FeCl_3$ solution was added to 5 ml 1 % aqueous solution of the aldehyde.

Infrared spectra of the aldehyde and ethanol were recorded with a Perkin and Elmer Mod 21 spectrophotometer. 0.2 M solutions in carbon tetrachloride were used. The spectrophotometer was used with a sodium chloride prism, resolution 927, response 2 : 1170, gain 5.7, speed 5, suppression 3, and scale 5 cm/μ. The thickness of the cell was about 0.1 mm.

RESULTS

Phenyl-diethoxyphosphoryl methane, phenyl-diethoxyphosphoryl acetaldehyde and phenyl-diethoxyphosphoryl ethanol have been prepared.

Sodium dissolves in phenyl-diethoxyphosphoryl methane in 10 % ether solution under formation of hydrogen and a white precipitate.

Phenyl-diethoxyphosphoryl acetaldehyde in aqueous solution reacts as an acid, and can thus be determined titrimetrically with sodium hydroxide. 95 % of the actual preparation reacted as acid ($pk_a \sim 7$). In aqueous solution, the aldehyde also forms a brilliant violet complex with iron (III) ions. On extraction with chloroform, the chloroform becomes purple.

The infrared spectrum of phenyl-diethoxyphosphoryl acetaldehyde exhibited the following characteristic features: Absorption bands at 2 800—2 600 cm^{-1} indicating a hydrogen bonded hydroxyl group, at 1 725 cm^{-1} indicating a carbonyl group, at 1 630 cm^{-1} indicating a carbon-carbon double bond, and at 1 200 cm^{-1} indicating a strongly hydrogen bonded phosphoryl group.

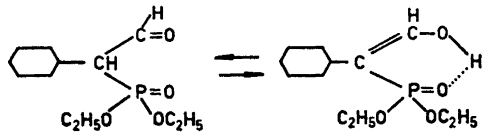
The infrared spectrum of the 2-phenyl-2-diethoxyphosphoryl ethanol showed the following characteristic features: Absorption bands at 3 500—3 200 cm^{-1} indicating a hydroxyl group with weak hydrogen bond, at 1 250 cm^{-1} indicating a normal phosphoryl group, but no bands at 1 725 cm^{-1} or 1 630 cm^{-1} which indicates that the aldehyde has been hydrogenated. Infrared spectra and a more thorough interpretation of them are given in part 2 of this investigation[2].

DISCUSSION

Phenyl-diethoxyphosphoryl methane apparently contains a reactive hydrogen atom, presumably situated in the methane residue. The structure of the condensation product from phenyl-diethoxyphosphoryl methane and methylformate is of major importance for the confirmation of the structure of the corresponding ethanol.

The first problem was to obtain the phenyl-diethoxyphosphoryl acetaldehyde sufficiently pure for identification. Distillation at 110°C and 0.2 mm Hg is a poor method for fractionation, and the carbon-hydrogen content a poor indicator of purity if, which is reasonable, phenyl-diethoxyphosphoryl methane is the main impurity. However, the protolytic titration method employed solved this problem.

Refractive index of the aldehyde increased with time after distillation. Simultaneously, an increase in the absorption band of hydroxyl in the infrared spectrum was observed [2]. This, together with the other results, strongly suggests that the aldehyde shows keto-enol tautomerism. Moreover, the infrared spectrum indicates a strong hydrogen bond between the enol hydroxyl group and the phosphoryl group, which suggests a sixmembered chelate ring with conjugated double bonds. The only structure which fits all these facts is the following, which is also analogous to the intermediate product in the syntheses of tropic acid.



Simpler hydrogenation methods for the aldehyde than the catalytic hydrogenation used in preparation of the phenyl-diethoxyphosphoryl ethanol may exist. However, it was felt that a simple addition of hydrogen is the best way to establish the structure of the ethanol. The infrared spectrum of the ethanol supports the view that in total a hydroxymethylene group has been introduced at the carbon atom between the phenyl and phosphoryl groups.

Our sincere thanks are due to the Director of this Institute, Professor G. Ljunggren, for his kind interest in this work.

The Structure of 2-Deoxy-ribose

S. FURBERG

Institute of Chemistry, University of Oslo, Blindern-Norway

The structure of 2-deoxy-ribose in the crystalline state has been determined by X-ray crystallographic methods. The sugar is found to occur in the pyranose form and to belong to the β-series, the conformation being 1*a*3*e*4*a*. This is explained in terms of a general preference for axial substituents on the anomeric carbon atom. The implications of this view are discussed.

The sugar of deoxyribonucleic acid (DNA), 2-deoxy-ribose, has been rather extensively investigated by chemical methods, and a number of reviews on its chemistry have been published [1,2]. However, several features of the stereochemistry of the free sugar are still in some doubt. The ring form does not seem to be definitely established, although a pyranose structure is to be expected, especially in view of recent work on ribose [3]. The methyl glycosides are isolated and assigned to the α- and β-series [4], but the configuration at the anomeric carbon atom in the free sugar does not appear to be known. Finally, the conformation of the sugar has not been determined.

We have now established the structure of 2-deoxyribose in the crystalline state, using the methods of X-ray crystallography. Details of the structure analysis are given below. Projections in two directions of the electron density in the crystal have been calculated (Fig. 1), showing that the molecule has the structure depicted in Fig. 2. It is seen that the molecule occurs in the pyranose structure with the normal staggered "chair" form found in all sugars hitherto studied. The orientation of the anomeric hydroxyl group relative to the two others shows that the sugar belongs to the β-series. The hydroxyl groups on C_4 and C_1 are axial (*a*) whereas that attached to C_3 is equatorial (*e*). The structure may thus be described as 1*a*3*e*4*a*.

As pointed out by Hassel and Ottar [5], there are two possible conformations for each pyranose sugar, the one being derivable from the other by interconversion of the pyranose ring. In the case of β-2-deoxy-ribose the two conformations are 1*a*3*e*4*a* and 1*e*3*a*4*e*. The stabilities of pyranose conformations have been discussed by a number of investigators. Reeves [6] predicts the preferred conformation by means of three instability factors, whereas Barker and Shaw [3] derive the relative stabilities by adding the "overlaps"

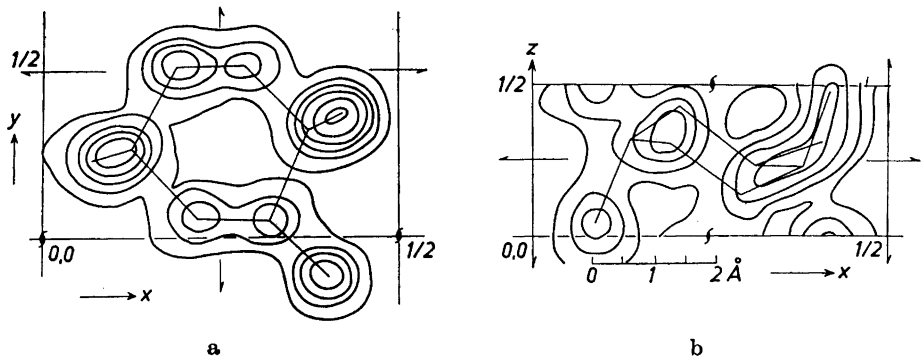

Fig. 1. Electron density projections on the (001) plane (a) and the (100) plane (b). Contours at 2,4,6,. . . e.Å^{-1}.

of non-bonded atoms. These methods have so far not been applied to deoxysugars but as both approaches consist in adding the unfavourable interactions in the molecule, they should be expected to be applicable also to these substances. In fact, the deoxysugars might provide an interesting test of the validity of the principles involved. In the case of 2-deoxy-ribose both methods predict that 1*e*3*a*4*e* is somewhat more stable than the observed form 1*a*3*e*4*a*, equatorial substituents being assumed to be more favourable than axial ones. The difference in stability is not great, and the solid state conformation may be determined by crystal forces. However, it is also possible that the molecular conformation 1*a*3*e*4*a* really is the more stable one, the reason, in case probably being that an equatorial hydroxyl group on the anomeric carbon atom C_1 may be an instability factor of importance in addition to those given by Reeves. This favours 1*a*-conformations, except possibly when there is an axial substituent in positions 3 or 5, in which case the effect is opposed by the repulsion between the two axial groups.

Greater stability of 1*a* substituents has been proposed as a possible explanation of the differences in reaction rates of α- and β-sugars. Thus the methyl β-pyranosides of glucose, mannose and galactose, in which the anomeric methoxyl group is equatorial, are hydrolysed more rapidly than the α-anomers. Edward [7] explained this in terms of electrostatic repulsive forces between the lone-pair electrons on the ring-oxygen atom and the polar group on C_1; this favours axial alkoxyl groups. Similarly, equatorial hydroxyl groups are oxidized more rapidly than axial ones [8]. However, for both types of reactions steric effects may provide an alternative explanation. Recently, the conformations of trans-di-halogeno-dioxanes have been studied in solid state and in solution. The results would seem to be in agreement with the preceding considerations, as the diaxial conformation is found in all cases [9].

The relation between this "1*e*-effect" and the powerful "Δ2-effect" of Reeves [6] should also be noted. The "Δ2-effect" corresponds to the conformation 1*e*2*a*, in other words to the combination of the two unfavourable factors 1*e* and 2*a*. Thus the "1*e*-effect" implies that the Δ2-condition must be unfavourable. Furthermore, it influences the relative importance of the two pyranose chair conformations also in other cases. The most notable deviations from previous stability considerations [3,6] would occur for sugars containing the configuration 1*a*2*a*3*e*⇌1*e*2*e*3*a*. Thus for α-lyxose, 1*a*2*a*3*e*4*e*⇌1*e*2*e*3*a*4*a*,

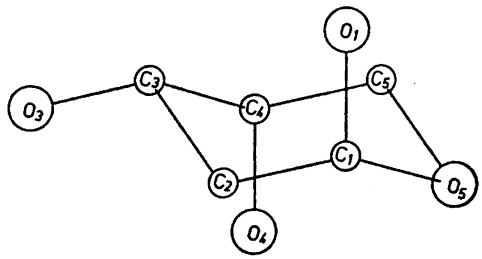

Fig. 2. The molecular structure of 2-deoxy-ribose.

the method of Reeves predicts conformational instability, which was also found in his studies of the cuprammin-complexes of methyl lyxosides. The approach of Barker and Shaw favours 1*e*2*e*3*a*4*a*, whereas the "1*e*-effect" gives preference to 1*a*2*a*3*e*4*e*. Proton magnetic resonance studies [11] have shown that α-lyxose tetra-acetate has the conformation 1*a*2*a*3*e*4*e* in solution.

If a 1*e* hydroxyl group represents an element of instability, the α-anomers of sugars as glucose, galactose and xylose should be more stable than the β-anomers, contrary to the view of Reeves [6]. As heat is evolved during the transformation from α- to β-glucose in aqueous solution, the latter anomer would appear to be the more stable one under these conditions [10]. The composition of the equilibrium mixture, in which the β-anomer predominates, points in the same direction [6]. However, the energy differences are so small that these observations do not represent conclusive evidence as regards the relative stability of the unhydrated molecules.

				H_{04}	0.48	0.14	0.50

In Table 1 the atomic coordinates deduced from the final difference maps are given. The mean deviation in the x coordinates from the two projections is 0.015 Å and largest discrepancy is 0.04 Å. These figures may be taken as an indication of the accuracy of the coordinates. The corresponding bond lengths and bond angles are given in Table 2.

Table 2. Bond lengths (in Å units) and bond angles.

Bond lengths		Bond angles	
C_1-C_2	1.50	$O_5C_1C_2$	111°
C_2-C_3	1.49	$O_1C_1C_2$	118°
C_3-C_4	1.53	$O_1C_1O_5$	107°
C_4-C_5	1.53	$C_1C_2C_3$	107°
C_5-O_5	1.41	$C_2C_3C_4$	111°
O_5-C_1	1.45	$C_3C_4C_5$	108°
C_1-O_1	1.40	$C_3C_4O_4$	109°
C_3-O_3	1.44	$C_5C_4O_4$	112°
C_4-O_4	1.40	$C_4C_5O_5$	109°
		$C_5O_5C_1$	112.5°
		$C_2C_3O_3$	113.5°
		$C_4C_3O_3$	107°

The bond lengths and bond angles derived in the present investigation are given in Table 2. The bond lengths do not deviate significantly from the normal values of 1.53 Å and 1.42 Å for C-C and C-O distances, respectively. The bond angle at the ring oxygen atom is found to be 112.5°, somewhat greater than the other ring angles, which lie in the range 107° to 111°. The mean value of the external angles is 111°, but some of them show possibly significant variations from the tetrahedral angle, as is found also in other sugar structures [12].

Only three intermolecular distances are shorter than 3.0 Å. As there are three hydroxyl hydrogens in the molecule, these interactions are likely to be hydrogen bonds. It will be seen from Fig. 3 that one of the bonds connect O_3 and the ring oxygen atom O_5. Thus the hydrogen at O_3 is forming this bond. The hydrogen at O_4 must then take part in the hydrogen bond O_4——O_3' and that at O_1 in O_1—O_4''. The lengths of these bonds are 2.87 Å, 2.89 Å and 2.82 Å, respectively.

THE STRUCTURE ANALYSIS

A commercial sample of D-2-deoxyribose from Mann Research Laboratories, New York, was used for the investigation. Single crystals big enough for X-ray work were grown by precipitating the compound from a solution in acetone, the solution being placed in a desiccator containing excess of ethyl acetate. The crystals obtained were elongated along the *c* axis, with (100) as the dominating face.

X-Ray single crystals diagrams of the Weissenberg type were taken around the *c* and *b* axis, using copper radiation. They showed that the crystals are orthorhombic, with unit cell dimensions $a = 11.37$ Å, $b = 10.64$ Å and $c = 4.86$ Å (all ± 0.5 %). The space group is $P2_12_12_1$ as reflexions $h00$, $0k0$ and $00l$ are absent for odd values of the indices. Four molecules in the unit cell correspond to a calculated density of 1.51 g/cm³.

The intensities of the reflexions were estimated visually by comparison with a standard scale. Difficulties were encountered, as the crystals which were big enough to give a satisfactory diagram proved to be aggregates of two or more crystals. The true single crystals found were so small that only the strongest reflexions were recorded. The intensity values derived are therefore probably somewhat less accurate than those usually obtained by this procedure. 69 of the 146 $hk0$ reflexions and 22 of the 63 $h0l$ reflexions obtainable with Cu$K\alpha$ radiation were recorded with measurable intensity.

To determine the *c* projection of the structure, the approximate position of the molecule was first deduced by means of Bragg—Lipson structure factor graphs. These graphs

also indicated the signs of four low-order strong reflexions (240, 400, 120 and 320). Using these signs as a basis, the "multiplication rule" was applied to derive the signs of 16 reflexions expressed by the sign of the 340 reflexion. The two corresponding electron density maps both clearly showed a six-membered ring system, but only one of them indicated a 1,3,4-substituted sugar. The very first set of structure factors based on this structure gave a remarkable agreement with the observed values, the reliability factor $R = \Sigma||F_{obs}| - |F_{calc}||/\Sigma|F_{obs}|$ having the value 0.28. The structure was further refined by a number of difference synthesis. The process was complicated by the fact that in the projection there are hydrogen atoms close to nearly all the heavier atoms. It was found essential for the refinement to include their contribution to the structure factors. The positions of most of them were indicated by the difference maps, but some had to be placed by stereochemical considerations. The final value obtained for R was 0.10. A common isotropic temperature factor $\exp(-4.0 \sin^2\Theta/\lambda^2)$ was used for all the atoms. As the experimental data are rather unsatisfactory, further refinements were not carried out. In Table 3 observed and calculated structure factors are compared. It may be remarked that the 16 signs originally deduced all were correct.

The relative z coordinates of the atoms were calculated from the known c projection and from standard values of the bond lengths. The molecule was then placed so as to give reasonable lengths to the intermolecular hydrogen bonds indicated by the c projection. This postulated structure was refined by difference syntheses, the final value of R being 0.10 also in this case. However, the small number of reflexions and the overlap of atoms make the coordinates less reliable than those derived from the c projection. The electron density projection is shown in Fig.1 b.

The investigation was supported by a grant from *Norsk Hydros Fond.*

Studies on Metal Complexes in Aqueous Solution by Infrared Spectrophotometry

I. A Qualitative Investigation of the Iron(III) and Aluminium Oxalate Systems

STURE FRONÆUS and RAGNAR LARSSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The infrared spectra of the iron(III) and aluminium oxalate systems in aqueous solution have been recorded in the range 1 500—1 200 cm^{-1}. Solutions of compositions corresponding to the first, second, and third mononuclear complexes show absorption peaks of almost the same frequency. The positions of the peaks correspond approximately to those of the third complexes in the solid state reported in the literature. Solutions in which the iron(III) concentration has been greatly increased give spectra showing two new absorption peaks. This fact is thought to indicate the existence of polynuclear complexes.

During the past few years a large amount of data has accumulated concerning the infrared light absorption of coordination compounds. The large majority of these investigations, however, has been confined to the solid state. Only in a few instances have equilibria of complex ions in aqueous solution been investigated. There is no doubt, however, that such measurements can be a valuable complement to conventional methods of investigation. This must be so much more the case when considering strongly coloured solutions of transition metals, where the Raman technique cannot be applied.

Inspired by the interesting achievements of Jones and Penneman [1], we have therefore started a project of infrared absorption investigations on some metal complex systems in aqueous solution.

Owing to the strong absorption of water, measurements must be confined to ions having their characteristic vibration frequencies in those parts of the spectrum where the water absorption is not too strong.

In order to test the possibilities of the method we have made a qualitative investigation of the iron(III) and aluminium oxalate systems by studying the oxalate absorption frequencies in the region 1500—1200 cm^{-1}. Solid state studies

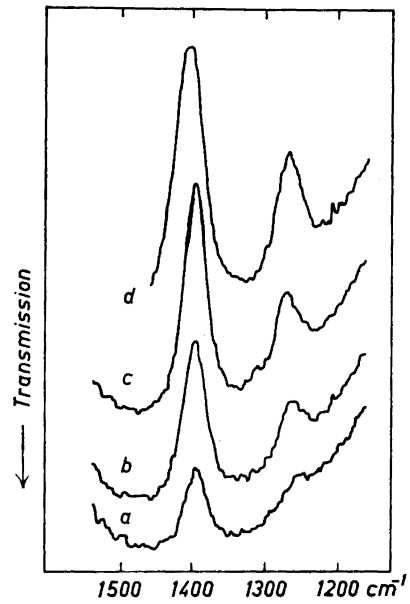

Fig. 1. Spectra of the iron (III)-oxalate system. The compositions of the solutions are found in Table 1. As in all figures of this paper the curves are arbitrarily displaced along the ordinate- (transmission-)axis to increase the readability.

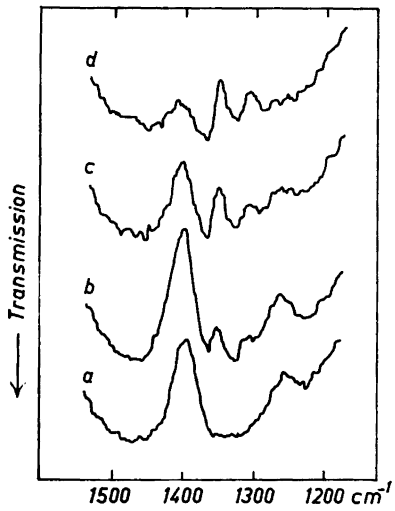

Fig. 2. Spectra of the iron (III-)oxalate system for large metal concentrations. The compositions of the solutions are found in Table 1.

[2,3] of these systems have shown definite shifts of the oxalate ion frequencies to occur as a result of coordination. Conventional investigations have also been reported in the literature [4], the results of which indicate that the complexity is quite strong.

EXPERIMENTAL

General technique. The general procedure was that of Jones and Penneman [1]. The instrument was a Hilger H 800 Infrared Absorption Spectrophotometer fitted with a

rocksalt prism. The window material of the cell was calcium fluoride. Platinum spacers measuring 8.8 and 12.5 μ defined the thickness of the cell. The instrument was used in the double-beam setting but without any compensation cell, The wave number setting was calibrated against benzene and toluene spectra. The reported wave numbers are correct within 2 cm^{-1}.

The solutions to be investigated were made up by dissolving weighed amounts of the salts. The weighing accuracy was limited to about 1 % in view of the qualitative nature of the investigation. For the same reason chlorides were used instead of perchlorates.

Ferric chloride, sodium and *potassium oxalate* were of analytical grade, whereas the *aluminium chloride* was of *purum* quality.

Table 2. Wave numbers of the peaks of the aluminium-oxalate system.

4:a	1.50	0.75	1 415	1 286
4:b	1.87	0.75	1 416	1 285
4:c	1.83	0.61	1 417	1 285

RESULTS

In Fig. 1 are given the absorption curves for some solutions of iron(III) chloride and sodium oxalate in various proportions. Because of the strong complexity we can assume that the curves correspond to the first, second and third complexes, respectively. The wave numbers of the peaks of the third complex agree rather well with those given by Schmelz *et al.*[2] and by Fujita *et al.*[3]

In Fig. 1 is also included the absorption curve of the first complex at a much higher concentration. A shift of the absorption peak at 1 400 cm^{-1} towards a somewhat higher wave number is observed. This fact led us to investigate some solutions in which the ratio between the iron(III) and the oxalate concentration was successively increased. The results given in Fig. 2 indicate the very interesting fact that, in addition to the above-mentioned shift of the 1 400 cm^{-1} peak, two new peaks appear.

Analogous experiments were performed with aluminium in place of iron(III). The results are reported in Figs. 3 and 4. In this case as well (Table 2 and Fig. 3, curve c) the agreement with solid state data [2,3] is fairly good. An examination of Fig. 4 shows that no new peaks appear at high aluminium concentrations, although the shift of the 1 400 cm^{-1} peak towards higher wave numbers is quite obvious.

DISCUSSION

The first point of interest emerging from the presented observations is the very small variation of the position of the absorption peaks as the number of coordinated ligands in increased (Figs. 1 and 3). This fact is quite contrary to the findings of Jones and Penneman [1] for the silver cyanide system. To explain this difference we suggest that a significant wave-number shift will be observed only when the total enthalpy of coordination per ligand is appreciably different for the sequence of complexes with increasing ligand number. For all so-called normally built complex systems the enthalpy of addition of a ligand is almost constant within a given system (*cf.* Bjerrum [5,6]). The total coordination enthalpy per ligand will then also be approximately constant.

For the silver cyanide system, having a "characteristic coordination number" of two and maximum coordination number of four, we can with confidence assume a large difference in the enthalpy of addition of the two last ligands compared to that of the first two. Hence a considerable difference in the positions of the peaks of the second, third and fourth complexes might be expected, as is in fact observed. [1]

The oxalate systems investigated here are most probably quite normally built. The variation in the consecutive formation constants [4] is what might be expected for such a highly charged ligand. The absence of a pronounced shift of the peaks of successive complexes is thus understood.

Hence we conclude that, in general, there is little hope of using infrared spectroscopy as a "finger-print method" to prove the existence of step-wise complex formation.

The second point of interest is the effects produced by increasing the iron(III) concentration. The appearance of two new peaks at 1 352 cm^{-1} and

1 309 cm^{-1} is obviously an indication of a new molecular species (Fig. 2). We assume that this is a polynuclear complex. Whether the displacement of the peak at about 1 400 cm^{-1} is also an indication of polynuclear complex formation or if it is some kind of a "medium effect" is difficult to say. It might be noted, however, that the shift is away from the position of the peak in question for the solid complexes [3,4]. If the first alternative is true, two kinds of polynuclear complexes must be considered. A confirmative correlation between metal — oxalate structure and the infrared spectrum of the oxalate ligand may — in a way — be obtained by a comparison between the solid-state spectra [7,2] of CuC_2O_4 and $Na_2Cu(C_2O_4)_2$. Whereas the first compound shows oxalate peaks that coincide approximately with the peaks ascribed here to polynuclear complexes, the latter one shows a spectrum similar to that of the mononuclear complexes.

The Hilger spectrophotometer used was put at our disposal on loan for a considerable period of time by Messrs. Hilger & Watts, Ltd., London. We wish to express our appreciation of the generosity of this Company as well as of the kind cooperation of its Swedish representatives, Messrs. Bergman & Beving AB, Stockholm.

Studies on Monoalkyl Carbonates

XVII. The Monoalkyl Carbonate of the Glycolate Ion

LEO TOFT

The Royal Danish School of Pharmacy, Copenhagen, Denmark

The velocity constant of the reaction '$^-OOC \cdot CH_2OH + OH^- + CO_2 = {}^-OOC \cdot CH_2CO_3^- + H_2O$' and the equilibrium constant of the reaction '$^-OOC \cdot CH_2 \cdot CO_3^- + H_2O = {}^-OOC \cdot CH_2OH + HCO_3^-$' have been determined. The velocity of the decomposition of the monoalkyl carbonate, $^-OOC \cdot CH_2CO_3^-$, in strongly basic medium is investigated and may be explained by assuming that the decomposition is a twostage reaction *viz.* 1) $^-OOC \cdot CH_2CO_3^- = {}^-OOC \cdot CH_2O^- + CO_2$; 2) $CO_2 + OH^- = HCO_3^-$.

1. The present investigation deals with the equilibrium conditions and the reaction mechanisms for the formation and decomposition of the monoalkyl carbonate of glycolate ion in aqueous medium.

The glycolate ion solution was prepared from glycolic acid and the equivalent amount of sodium hydroxide by gentle boiling, so that anhydrides that might be present were converted into sodium glycolate.

2. The glycolic acid employed was obtained partly from the Riedel-de Haen A. G. as an aqueous solution, and partly from The Fischer Scientific Company as crystals stated to be pure. Upon analysis the solution was found to contain 53.5 % of acid by direct titration with 1 N sodium hydroxide, and 57.3 % of glycolic acid and its anhydrides, determined by boiling with extra sodium hydroxide and titration the excess of sodium hydroxide with hydrochlorid acid. The crystals of glycolic acid — having a rather moist appearance — were dried over phosphorus pentoxide losing about 1.9 % in weight. Thereafter they contained 99.5—100.3 % of glycolic acid. Both samples were free of heavy metals and of halides and gave identical results during the investigations.

3. No attempt was made to prepare the solid monoalkyl carbonate. Solutions were made by dissolving carbon dioxide in solutions which were 0.5—2 M with regard to sodium glycolate and 0.1—0.75 M with regard to sodium hydroxide, thus converting 25—60 % of the carbon dioxide into monoalkyl carbonate and the rest of it into ordinary carbonate.

4. The method of analysis was in principle as in previous investigations [1], *viz.* separation of the monoalkyl carbonate from the ordinary carbonate by precipitating the carbonate with barium chloride and separating the barium carbonate by centrifugation. The supernate was then analysed by means of an apparatus for determination of carbon dioxide introduced by Tovborg Jensen [2]. To the supernate is added a large excess of 2 M hydrochloric acid causing an immediate decomposition of the monoalkyl carbonate. The carbon dioxide evolved is then absorbed in 0.1 N barium hydroxide after which the excess of barium hydroxide is titrated electrometrically with 0.1 N hydrochloric acid to pH = 8.5.

By analogy with the investigations on the monoalkyl carbonate of the lactate ion [3] there has, however, been certain difficulties in separating the barium carbonate from the monoalkyl carbonate. Barium chloride added to the solution containing monoalkyl carbonate and carbonate causes no immediate precipitation of barium carbonate. Only after ½—3 min. a fine-grained precipitate consisting of barium carbonate began to settle, the precipitation of which lasted about 15 min.

In order to accelerate the precipitation a good deal of sodium carbonate solution was set to the solution of barium chloride before the reaction mixture was added. Furthermore the 2 M solutions — due to their rather high viscosity — were diluted with equal parts of water before the centrifugation. After shaking for 2 min. and centrifugating for 3 the precipitation of the barium carbonate succeeded. Due to these difficulties it may be taken in consideration that the data presented may be encumbered with larger errors than usual on analogous investigations.

The data presented are, unless otherwise stated, corrected not only with regard to blank values but also with regard to the decomposition of monoalkyl carbonate taking place during the analysis, see later.

5. The experiments were carried out at 0°C. Velocity constants are expressed on the basis of the Brigg's logarithms, the unit of time being the minute.

On the formation of the monoalkyl carbonate from carbon dioxide and glycolate ion and on the reaction

$$^{-}OOC \cdot CH_2O^{-} + CO_2 \rightleftharpoons {}^{-}OOC \cdot CH_2CO_3^{-}$$

The experiments were carried out in a 0.5 litre flask by vigorously shaking 200 ml of a basic solution of sodium glycolate with atmospheric air of which about 100 ml was substituted by carbon dioxide. The solutions were immediately analysed to determine the percentage of monoalkyl carbonate.

By introduction of the adjusted results in the expression:

$$k' = \frac{\%\ \text{monoalkyl carbonate} \cdot k_{CO_2OH^-}}{\%\ \text{carbonate} \cdot c_{\text{alcohol}}},$$

the k' values presented in Table 1 are calculated, k' being the velocity constant of the overall reaction: $CO_2 + {}^{-}OOC \cdot CH_2OH + OH^- = {}^{-}OOC \cdot CH_2CO_3^- + H_2O$.

Table 1. Carbon dioxide in sodium glycolate + sodium hydroxide. 0°C.

c_{NaOH}	$c_{glycolate}$	Absorbed CO_2 mole/litre	% Alkyl-carbonate	log k'	Mean of log k'
0.25	0.50	0.0233	25.2	4.22	
0.10	0.50	0.0167	25.2	4.22	
0.20	1.00	0.0208	40.5	4.22	4.23
0.50	1.00	0.0208	38.5	4.19	
0.75	2.00	0.0312	59.5	4.26	
0.50	2.00	0.0184	60.8	4.28	

For the value of the velocity constant of the reverse process $k_{-OOC\cdot CH_2CO_3^-}$ we get 0.0079 employing the value of K_{eq} mentioned in Table 2.

The equilibrium of the reaction

$$^-OOC\cdot CH_2CO_3^- + H_2O = HCO_3^- + {}^-OOC\cdot CH_2OH$$

The above equilibrium was established in aqueous solutions of glycolate ion, potassium bicarbonate and sodium carbonate. The content of monoalkyl carbonate has been calculated as a percentage of HCO_3^- initially present; thus no attention was paid to the carbonate.

In Table 2 are presented not only the '% monoalkyl carbonate' corrected for blank values and the decomposition taking place during the analysis but the uncorrected as well. This has been done in order to illustrate the accuracy that may be attached to the values found. From the experimental results the equilibrium constant of the reaction

$$K_{eq} = \frac{c_{-OOC\cdot CH_2OH}\cdot f \cdot c_{HCO_3^-}\cdot f}{c_{-OOC\cdot CH_2CO_3^-}\cdot f^2}$$

may be calculated, the activity constants neutralizing each other as a first approximation.

On the velocity of the reactions

$$^{-}OOC \cdot CH_2CO_3^{-} + H_2O = {}^{-}OOC \cdot CH_2OH + HCO_3^{-}$$

Determinations have been made from the monoalkyl carbonate side only and in strongly basic medium, the monoalkyl carbonate thus being practically converted into carbonate. The monoalkyl carbonate has been made by shaking the basic solutions with carbon dioxide as stated in the introduction. The solutions, therefore, contain ordinary carbonate, which, however, is of no importance in the present investigations.

In Table 3 are listed the experimental results of the decomposition of the monoalkyl carbonate. k_{mono} stands for $1/t \log a/a—x$.

The experiments are interpreted in a similar way to the one applied to the monoalkyl carbonates previously investigated, the decomposition being a two-stage reaction, *viz.* 1) $^{-}OOC \cdot CH_2CO_3^{-} = {}^{-}OOC \cdot CH_2O^{-} + CO_2$; 2) $CO_2 + OH^{-} = HCO_3^{-}$

k_{mono} may be calculated at $pa_H > 10$ by means of the following expression

$$k_{mono} = \frac{k' \cdot K_{eq} \frac{K_{H_2O}}{K_{CO_2}}}{1 + k' \cdot \frac{c_{^{-}OOC \cdot CH_2OH}}{k_{CO_2OH^{-}}}}$$

the values of K_{H_2O} and K_{CO_2} being $10^{-14.93}$ and $10^{-6.65}$, respectively.

Upon introduction of the constants the equation is

$$k_{mono} = \frac{0.0065}{1 + 0.69\, c_{^{-}OOC \cdot CH_2OH}}$$

and k_{mono} in 0.5 M, 1 M, and 2 M solutions of glycolate ion, $pa_H > 10$, will be calculated to 0.0048, 0.0038, and 0.0027, respectively.

The experimental and calculated values agree fairly good.

The author wishes to express his thanks to Professor Carl Faurholt for his kind interest in the investigation.

Studies on Carbamates

XIII. On the Catalytic Action of Zinc Tetrammine on the Process 'Carbon Dioxide ⇌ Carbonic Acid'

MARIANNE GRØNVALD and CARL FAURHOLT

The Royal Danish School of Pharmacy, Copenhagen, Denmark

$Zn(NH_3)_4^{++}$ catalyses the process 'carbamate ⇌ carbonate'. The effect is explained by the catalysis of the $Zn(NH_3)_4^{++}$ on the process '$CO_2 + H_2O \rightleftharpoons H_2CO_3$'.

1. The rate of equilibration of the process '$NH_2COONH_4 + H_2O \rightleftharpoons (NH_4)_2CO_3$' in aqueous medium has previously been studied [1,2]. The decomposition is a two-step reaction, *viz.*

carbamic acid ⇌ ammonia + carbon dioxide
carbon dioxide ⇌ carbonic acid

and for a moderately basic solution the last step will be the rate determining step exclusively.

The zinc-containing enzyme carbonic anhydrase, isolated by Meldrum and Roughton [3], catalyses the process '$CO_2 + H_2O \rightleftharpoons H_2CO_3$'. It was therefore of interest to know if other zinc complexes also could have such an effect. This was examined by means of the process '$NH_2COONH_4 + H_2O \rightleftharpoons (NH_4)_2CO_3$'. We have in the present investigation used zinc tetrammine in NH_4Cl/NH_3 buffers.

2. The method of analysis was in principle that described in previous investigations [4]. The samples were adjusted to 0.1 N with regard to hydroxyl ion. Carbonate but not carbamate was precipitated when barium chloride was added. The barium carbonate was removed by centrifugation. The supernatant was in the previous method heated until the carbamate had been decomposed and precipitated as barium carbonate. The carbonate was then titrated acidimetrically. However, in the presence of zinc tetrammine it appears that the precipitate involves zinc, probably in the form of zinc hydroxide. The supernatant therefore was analysed for carbon dioxide by means of an apparatus introduced by Tovborg-Jensen [5]. The supernatant was acidi-

fied by means of hydrochloric acid and the carbamate decomposes practically instantaneously to carbon dioxide. The carbon dioxide was absorbed in 0.1 N sodium hydroxide. This solution was titrated using a Radiometer-titrigraf, type TTT 1 a. The amount of 0.05 N hydrochloric acid used from pH 8.4 to 4.5 corresponds to the content of carbamate since 1 mole HCl ~ 1 mole CO_2 ~ 1 mole carbamate.

It was necessary to correct all the determinations for blank values since the air in the apparatus at the beginning contains a small amount of carbon dioxide.

The method of analysis was tested by means of solutions containing per litre 0.4 mole NH_4Cl, 0.2 mole NH_3, 0.01 mole $Zn(NH_3)_4(CH_3COO)_2$ and about 0.02 mole carbonate + carbamate. Zinc tetrammine did not interfere with the precision of the method.

3. Ammonium carbamate was prepared from dry ice and liquid ammonia [6]. Anhydrous liquid ammonia was placed in a Dewar flask and powdered dry ice was slowly added. The excess of ammonia was allowed to evaporate, when the mixture had attained a slushy consistency. This material was transferred to a desiccator and kept under slightly reduced pressure for 24 h. The ammonium carbamate was stable when kept in a desiccator over dry calcium chloride. It contained about 5 % carbonate.

The concentrations of zinc acetate and zinc perchlorate were determined by complexometric titrations.

The salts of zinc tetrammine have not been prepared in the solid state. The solutions of zinc tetrammine were prepared by adding zinc acetate or zinc perchlorate to the NH_4^+/NH_3 buffers. In the calculation of the concentrations of ammonia we have taken into account the ammonia used by the process '$Zn^{++} + 4NH_3 = Zn(NH_3)_4^{++}$'.

4. All the experiments were carried out at 0°C. The data presented in the tables were corrected for blank values, *viz.* about 3 units of the percentage. The velocity constants were calculated by means of Brigg's logarithms, the unit of time being the minute. The activity coefficient f was calculated as in earlier investigations from the expression of Bjerrum [7]: $-\log f = 0.3\sqrt[3]{C_{ion.}}$.

The experiments concerning the process 'carbamate ⇌ carbonate'

Two different NH_4^+/NH_3 buffers, 0.40 M NH_4Cl/0.20 M NH_3, and 0.50 M NH_4Cl/0.05 M NH_3 have been used. Experiments were carried out with zinc acetate and zinc perchlorate and, within the experimental error, we attained the same results under the same conditions. Experiments were carried out with and without zinc tetrammine.

Some of the experiments are listed in Tables 1 and 2 and illustrate the precision of the method. The values $k_{amate} + k_{onate}$ are calculated from the expression $k_{amate} + k_{onate} = 1/t \cdot \log \frac{Ka-b}{Ka-b-(1+K)x}$, the expression for a process which is unimolecular from both sides. a and b represent the starting

values of carbamate and carbonate, respectively. The constant K signifies the ratio between the equilibrium values of the concentrations of carbonate and carbamate.

It is seen from the tables that the influence of zinc tetrammine is greatest at lower pH values.

It should be pointed out that the value of K is not constant in analogous experiments with and without $Zn(NH_3)_4^{++}$. This may be explained by the fact that the determination of carbamate is relatively inexact in the equilibrium where the percentage of carbamate is rather small. But there is a marked drift, so it is possible that other factors come into play, *e.g.* the formation of zinc carbonato ions.

All experiments are listed in Table 3.

An experiment with $Cu(NH_3)_4^{++}$ is furthermore listed in Table 3, but the effect is small and therefore not reliable. Further experiments are necessary to state a catalytical effect of $Cu(NH_3)_4^{++}$.

Calculations on the experiments concerning the process 'carbamate ⇌ carbonate'

Without zinc the conversion of the carbon dioxide into carbonate and the reciprocal conversion take place through the two reactions:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$
$$CO_2 + OH^- \rightleftharpoons HCO_3^-$$

and between pH 8 and 10 the velocity of the processes proceeds with the same order of magnitude.

We have the following expression for the conversion of carbamate:

$$\frac{dc_{carbamate}}{dt} = -(k_{CO_2} + k_{CO_2 \cdot OH^-} \cdot c_{OH^-}) \cdot c_{CO_2}$$

$$= -(k_{CO_2} + k_{CO_2 \cdot OH^-} \cdot c_{OH^-}) \cdot a \cdot c_{carbamate} = -k_{amate} \cdot c_{carbamate}$$

where a indicates the part of the carbamate being dissociated into CO_2. a is calculated from:

$$a = \frac{c_{CO_2}}{c_{carbamate}} = \frac{K_{NH_4^+} \cdot K_{Eq}}{K_{CO_2}} \cdot \frac{c_{NH_4^+} \cdot f^2}{c_{NH_3}^2}$$

and then we have

$$k_{amate} = \frac{(k_{CO_2} + k_{CO_2 \cdot OH^-} \cdot c_{OH^-}) \cdot K_{NH_4^+} \cdot K_{Eq} \cdot c_{NH_4^+} \cdot f^2}{K_{CO_2} \cdot c_{NH_3}^2}$$

In the presence of zinc tetrammine the expression must be:

$$\frac{dc_{carbamate}}{dt} = -(k_{CO_2} + k_{CO_2 \cdot OH^-} \cdot c_{OH^-} + k'_{Zn} \cdot c_{Zn(NH_3)_4^{++}}) \cdot c_{CO_2}$$
$$= -k_{amate} \cdot c_{carbamate}$$

This can be transformed to:

$$k_{amate} = \frac{(k_{CO_2} + k_{CO_2 \cdot OH^-} \cdot c_{OH^-} + k'_{Zn} \cdot c_{Zn(NH_3)_4^{++}}) \cdot K_{NH_4^+} \cdot K_{Eq} \cdot c_{NH_4^+} \cdot f^2}{K_{CO_2} \cdot c^2_{NH_3}}$$

For the conversion of carbonate we have:

$$\frac{dc_{carbonate}}{dt} = -k_{H_2CO_3} \cdot c_{H_2CO_3} - k_{HCO_3^-} \cdot c_{HCO_3^-} = -k_{onate} \cdot c_{carbonate}$$

By means of

$$c_{carbonate} = c_{H_2CO_3} + c_{HCO_3^-} + c_{CO_3^{--}}$$

$$a_{H^+} \cdot c_{HCO_3^-} \cdot f = K_{H_2CO_3} \cdot c_{H_2CO_3}$$

$$a_{H^+} \cdot c_{CO_3^{--}} \cdot f^2 = K_{HCO_3^-} \cdot c_{HCO_3^-} \cdot f$$

and

$$a_{H^+} \cdot c_{NH_3} = K_{NH_4^+} \cdot c_{NH_4^+} \cdot f$$

the expression is transformed to

$$k_{onate} = \frac{\dfrac{k_{H_2CO_3} \cdot K_{NH_4^+} \cdot c_{NH_4^+} \cdot f^2}{c_{NH_3}} + k_{HCO_3^-} \cdot K_{H_2CO_3}}{\dfrac{K_{NH_4^+} \cdot c_{NH_4^+} \cdot f^2}{c_{NH_3}} + K_{H_2CO_3} + \dfrac{K_{H_2CO_3} \cdot K_{HCO_3^-} \cdot c_{NH_3}}{K_{NH_4^+} \cdot c_{NH_4^+} \cdot f^2}}$$

In the presence of zinc tetrammine we have:

$$\frac{dc_{carbonate}}{dt} = -(k_{H_2CO_3} \cdot c_{H_2CO_3} + k_{HCO_3^-} \cdot c_{HCO_3^-} + k''_{Zn} \cdot c_{H_2CO_3} \cdot c_{Zn(NH_3)_4^{++}})$$
$$= -k_{onate} \cdot c_{carbonate}$$

which can be transformed into:

$$k_{onate} = \frac{\dfrac{k_{H_2CO_3} \cdot K_{NH_4^+} \cdot c_{NH_4^+} \cdot f^2}{c_{NH_3}} + k_{HCO_3^-} \cdot K_{H_2CO_3} + k''_{Zn} \cdot c_{Zn(NH_3)_4^{++}} \cdot \dfrac{K_{NH_4^+} \cdot c_{NH_4^+} \cdot f^2}{c_{NH_3}}}{\dfrac{K_{NH_4^+} \cdot c_{NH_4^+} \cdot f^2}{c_{NH_3}} + K_{H_2CO_3} + \dfrac{K_{H_2CO_3} \cdot K_{HCO_3^-} \cdot c_{NH_3}}{K_{NH_4^+} \cdot c_{NH_4^+} \cdot f^2}}$$

		0.04	0.0308		0.0029		132	6.8

The ratio $c_{NH_4^+}/c_{NH_3}$ is not constant during the experiments with $c_{NH_4Cl}/c_{NH_3} = 0.5/0.05$. The ratio $c_{NH_4^+}/c_{NH_3}$ is in the equilibrium 0.52/0.065, 0.52/0.065 and 0.52/0.068 for $c_{Zn(NH_3)_4^{++}} = 0.00$, 0.02 and 0.04, respectively.

K_{Eq} ($10^{-0.48}$) is the equilibrium constant for the process '$NH_2COO^- + H_2O \rightleftharpoons HCO_3^- + NH_3$', K_{CO_2} ($10^{-6.65}$) is the equilibrium constant for '$CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$', $K_{H_2CO_3}$ ($10^{-3.7}$) for '$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$' and $K_{HCO_3^-}$ ($10^{-10.5}$) for '$HCO_3^- \rightleftharpoons H^+ + CO_3^{--}$'. For K_{H_2O} and $K_{NH_4^+}$ are used $10^{-14.93}$ and $10^{-10.08}$, respectively. k_{CO_2} (0.078) is the velocity constant for '$CO_2 + H_2O \rightleftharpoons H_2CO_3$' from left to right and $k_{H_2CO_3}$ (69.6) from right to left. $k_{CO_2 \cdot OH^-}$ (2.43×10^4) is the velocity constant for '$CO_2 + OH^- \rightleftharpoons HCO_3^-$' from left to right and $k_{HCO_3^-}$ (15.6×10^{-5}) from right to left.

The experimental and calculated values for k_{amate} and k_{onate} are listed in Table 4. Furthermore are listed k'_{Zn} and k''_{Zn} calculated from experimental values of k_{amate} and k_{onate}. The ratio $c_{NH_4^+}/c_{NH_3}$ may be regarded as constant in the experiments with $c_{NH_4Cl}/c_{NH_3} = 2$, but not in the experiments with $c_{NH_4Cl}/c_{NH_3} = 10$. The mean value therefore is used in the calculation.

Table 5.

Metal ammine, M	Initial solution c_{NaOH}	Initial solution c_{NH_3}	Absorbed CO_2 mole/l	% Carbamate	Final solution c_{NaOH}	Final solution c_{NH_3}	Mean c_{NaOH}	Mean c_{NH_3}	log $k_{CO_2 \cdot NH_3}$
	0.2	0.5	0.0191	23.6	0.17	0.5	0.185	0.5	3.45
	0.2	1.0	0.0187	31.9	0.17	1.00	0.185	1.0	3.33
	0.2	1.0	0.0191	31.9	0.17	1.00	0.185	1.0	3.33
0.01 Zn	0.2	0.5	0.0186	26.1	0.17	0.5	0.185	0.5	3.51
0.01 Zn	0.2	1.0	0.0137	33.7	0.18	1.0	0.190	1.0	3.38
0.01 Cu	0.2	1.0	0.0204	32.6	0.17	1.0	0.185	1.0	3.34
0.01 Co	0.2	1.0	0.0209	35.1	0.17	1.0	0.185	1.0	3.39
0.02 Ag	0.2	1.0	0.0194	35.8	0.17	1.0	0.185	1.0	3.40

It is seen that the process '$CO_2 + H_2O \rightleftharpoons H_2CO_3$' in 1 M $Zn(NH_3)_4^{++}$ solution proceeds about 2 000 times faster than in a solution without $Zn(NH_3)_4^{++}$.

Some experiments in strongly basic solution

500 ml of an aqueous solution containing both ammonia and sodium hydroxide were placed in a 2 litre flask. Approximately 225 ml of carbon dioxide were substituted for an equal amount of atmospheric air in the gas phase above this solution, and the flask was shaken vigorously for about 2 min. to obtain absorption of the carbon dioxide.

Other experiments were carried out with the same concentrations of ammonia, sodium hydroxide and carbon dioxide. The solutions furthermore contained 0.01 M $Zn(NH_3)_4(CH_3COO)_2$, 0.01 M $Cu(NH_3)_4Cl_2$, 0.01 M $Co(NH_3)_6Cl_3$ and 0.02 M $Ag(NH_3)_2NO_3$, respectively.

The solutions were immediately analysed in order to determine, how many per cent of the carbon dioxide absorbed had been converted to carbamate and carbonate, respectively. The results are presented in Table 5. It is seen from the table that the influence of the metal ammines is very little. The lack of influence may be due to the predominance of the process '$CO_2 + OH^- \rightleftharpoons HCO_3^-$' in strongly basic solution. Neither the process '$H_2O + CO_2 \rightleftharpoons H_2CO_3$' nor the zinc tetrammine catalysed process can manifest itself appreciably. Furthermore probably all $Zn(NH_3)_4^{++}$ is transformed to $Zn(OH)_4^{--}$.

The Diffusion Process and the Diffusion Potential in Relation to the E.M.F. of Concentration Cells

TORMOD FÖRLAND

N.T.N.F.'s Institute of Silicate Science, N.T.H., Trondheim, Norway

Equations are given for the E.M.F. of a concentration cell with transference and for the electrostatic potential drop over the concentration gradient. The change in electrostatic energy by charge transfer is calculated and found to be very small. It is shown that the diffusion process does not interfere with the cell reaction.

In a previous paper Förland and Krogh-Moe[1] calculated the E. M. F. of a concentration cell with transference. For a cell

$$\mathrm{A;\ (A,B)_I\ Y : (A,B)_{II}\ Y;\ A}$$

with an electrolyte of the two components A^+Y^- and B^+Y^- and with electrodes reversible to A only, the E.M.F. may be expressed by the equation:

$$E \cdot \mathcal{F} = t_{B+(I)}(\Delta\overline{F}_{AY(I)} - \Delta\overline{F}_{BY(I)}) - t_{B+(II)}(\Delta\overline{F}_{AY(II)} - \Delta\overline{F}_{BY(II)} - \int_{N_{A+(I)}}^{N_{A+(II)}} \frac{d\,\Delta F}{d\,N_A^+} \frac{d\,t_A^+}{d\,N_A^+}\, d\,N_A^+ \quad (1)$$

Here E is the E.M.F., $\mathcal{F}$ is Faradays number, the index (I) and (II) refer to the two compartments of the concentration cell, t_A^+ and t_B^+ are transport numbers for the ions A^+ and B^+ referring to the Y^- ions as a reference frame, N_A^+ and N_B^+ are the ionic fractions of the two kinds of ions. $\Delta\overline{F}$ with index is partical molar free energy of mixing and ΔF with index is free energy of mixing per mole mixture. The first and second term of the equation are the free energy changes taking place in the electrolyte close to the two electrodes. The last term is the free energy change over the region of the concentration gradient.

The above equation can be rearranged to the more convenient form:

$$E \cdot \mathcal{F} = \Delta\overline{F}_{AY(I)} - \Delta\overline{F}_{AY(II)} + \int_{\Delta\overline{F}_{AY(I)}}^{\Delta\overline{F}_{AY(II)}} \frac{t_A^+ - N_A^+}{N_B^+} \, d\,\Delta\overline{F}_{AY}$$

From the equation in the differential form:

$$dE \cdot \mathcal{F} = -d\,\Delta\overline{F}_{AY} + \frac{t_A^+ - N_A^+}{N_B^+} \, d\,\Delta\overline{F}_{AY}$$

one can also derive:

$$\Delta\overline{F}_{AY(II)} = \Delta\overline{F}_{AY(I)} - \frac{1}{\mathcal{F}} \int_I^{II} \frac{N_B^+}{t_B^+} \, dE \qquad (2)$$

Thus by plotting corresponding values of N_B^+/t_B^+ and E as coordinates the partial free energy of the component AY is obtained as an area.

In the derivation of eqn. (1) it was assumed that dipol layers in the concentration gradient will not change their electrostatic energy significantly when an electrical charge is transported through the cell. It was further assumed that the diffusion process did not interfere with the cell reaction so the two processes could be treated separately.

It is the object of this paper to show that these assumptions are valid.

First it should be emphasized that an electrostatic potential in the concentration gradient of a concentration cell will in itself not affect the E.M.F. of the cell, since the process taking place is a transport of a neutral component from one side of the cell to the other. Only a change in the electrostatic energy in the concentration gradient may be observed in the outer circuit by the E.M.F. measurement.

THE ELECTROSTATIC POTENTIAL GRADIENT

The electrostatic potential gradient in a concentration gradient has been calculated by Sundheim [2]. As Sundheims reference system seems to be less practical for the present problem, a slightly different derivation of the electrostatic potential gradient (grad φ) will be given below.

We will consider the transports taking place in the gradient of the concentration cell:

$$A;(A^+, B^+)_I \; Y^- : (A^+, B^+)_{II} \; Y^- ; A$$

As a reference for the velocities of the particles in the system we will choose the average velocity of the Y^- ions. We designate by $\vec{J}_A^+$ ($\vec{J}_B^+$) the flux in moles/cm²sec of ions $A^+(B^+)$ and by $\vec{I}$ the electric current density in Faradays/cm²sec, all measured with respect to the average velocity of the Y^- ions. Thus $J_A^+ + \vec{J}_B^+ = \vec{I}$.

The forces corresponding to the above fluxes are grad $\Delta\bar{F}_{AY}(\Delta\bar{F}_{BY})$ and grad φ, respectively. Here $\Delta\bar{F}_{AY}$ ($\Delta\bar{F}_{BY}$) is the partial free energy of the component AY (BY) in cal/moles and φ is the electrostatic potential in cal/Faradays.

The fluxes and forces are connected by the following linear equations:

$$\vec{J}_A+ = -L_{11}\text{grad}\,\Delta\bar{F}_{AY} - L_{12}\text{grad}\,\Delta\bar{F}_{BY} - L_{13}\text{grad}\,\varphi \quad (3)$$

$$\vec{J}_B+ = -L_{21}\text{grad}\,\Delta\bar{F}_{AY} - L_{22}\text{grad}\,\Delta\bar{F}_{BY} - L_{23}\text{grad}\,\varphi \quad (4)$$

$$\vec{I} = -L_{31}\text{grad}\,\Delta\bar{F}_{AY} - L_{32}\text{grad}\,\Delta\bar{F}_{BY} - L_{33}\text{grad}\,\varphi \quad (5)$$

According to Onsager's theory for microscopically reversible processes, we have the following relations between coefficients:

$$L_{12} = L_{21};\ L_{31} = L_{13};\ L_{23} = L_{32}$$

The coefficient L_{33} is the specific elecrical conductance, $\varkappa$, measured in Faradays ^{2}/cal cm sec. By defining $L_{13} = \varkappa t_1$ and $L_{23} = \varkappa t_2$ and further introducing the Gibbs-Duhem equation

$$N_A+\ \text{grad}\,\Delta F_{AY} + N_B+\ \text{grad}\,\Delta F_{BY} = 0 \quad (6)$$

(in which it is assumed that the partial free energy of a neutral component is not changed when the system is electrically charged) we obtain:

$$\vec{J}_A+ = -\left(L_{11} - L_{12}\frac{N_A+}{N_B+}\right)\text{grad}\,\Delta\bar{F}_{AY} - \varkappa t_1\,\text{grad}\,\varphi \quad (7)$$

$$\vec{J}_B+ = -\left(L_{21} - L_{22}\frac{N_A+}{N_B+}\right)\text{grad}\,\Delta\bar{F}_{AY} - \varkappa t_2\,\text{grad}\,\varphi \quad (8)$$

$$\vec{I} = -\varkappa\left(t_1 - t_2\frac{N_A+}{N_B+}\right)\text{grad}\,\Delta\bar{F}_{AY} - \varkappa\,\text{grad}\,\varphi \quad (9)$$

Dividing eqns. (7) and (8) by (9) for the case that the composition is uniform we have:

$$t_1 = \left[\frac{\vec{J}_A+}{\vec{I}}\right]_{\Delta\bar{F}_{AY}} = t_A+ \text{ and } t_2 = \left[\frac{\vec{J}_B+}{\vec{I}}\right]_{\Delta\bar{F}_{AY}} = t_B+$$

where t_A+ and t_B+ are the transport numbers of the cations referring to the anions as a reference frame.

For $\vec{I} = 0$ eqn. (9) gives:

$$\text{grad}\,\varphi = \left(t_B+\frac{N_A+}{N_B+} - t_A+\right)\text{grad}\,\Delta\bar{F}_{AY} \quad (10)$$

To simplify calculations we introduce

$$m = t_B+\frac{N_A+}{N_B+} - t_A+ = -\frac{t_A+ - N_A+}{N_B+}$$

The electrostatic diffusion potential is equal to

$$\Delta\varphi = \int m \operatorname{grad} \Delta\bar{F}_{AY}\, dx = -\int_{\Delta\bar{F}_{AY(I)}}^{\Delta\bar{F}_{AY(II)}} \frac{t_A+ - N_A+}{N_B+}\, d\,\Delta\bar{F}_{AY} \text{ cal/Faraday}$$

where x is the distance from one side of the cell. This integral is finite over the whole concentration interval from $N_A+ = 0$ to $N_A+ = 1$ as long as the $\frac{t_A+}{N_A+}$ or $\frac{t_B+}{N_A+}$ is finite for small values of N_A+ and N_B+, respectively. It appears that the expression for the diffusion potential does not contain the concentration gradient. This also implies that the electrostatic potential is not changed when a small charge is transported through the cell.

If we express the E.M.F. of the cell in cal/Faraday and count it positive from left to right, we see that the E.M.F. can also be expressed by the equation:

$$E' = \Delta F_{AY(II)} - \Delta F_{AY(I)} + \Delta\varphi \tag{12}$$

THE ELECTROSTATIC ENERGY CHANGE

Knowing the gradient of the electrostatic potential, grad φ, the electrostatic energy (U) in the concentration gradient can be calculated

$$U = \tfrac{1}{2}\int_v \varepsilon\, (\operatorname{grad}\varphi)^2\, d\,v \tag{13}$$

where ε is the absolute dielectric constant of the medium measured in Faraday^2/cal cm, and v is a volume covering the concentration gradient. The change in this electrostatic energy by the transport of electrical charge (Q measured in Faradays) through the gradient is given by

$$\frac{\partial U}{\partial Q} = \frac{\partial}{\partial Q}\left(\tfrac{1}{2}\int_v \varepsilon m^2\, (\operatorname{grad}\Delta\bar{F}_{AY})^2\, dv\right) = \frac{q}{2}\frac{\partial}{\partial Q}\int_{\bar{F}_{AY(I)}}^{\bar{F}_{AY(II)}} \varepsilon\, m^2 \operatorname{grad}\Delta\bar{F}_{AY}\, d\,\Delta\bar{F}_{AY} \tag{14}$$

where q is the cross-section of the cell. The only factor of the integral which is changed by the transfer of dQ is grad ΔF_{AY}. We thus have

$$\frac{\partial U}{\partial Q} = \frac{q}{2}\int \varepsilon m^2 \left[\frac{\partial \operatorname{grad}\Delta\bar{F}_{AY}}{\partial Q}\right]_{\Delta\bar{F}_{AY}} d\,\Delta\bar{F}_{AY} \tag{15}$$

Here

$$\left[\frac{\partial \operatorname{grad}\Delta\bar{F}_{AY}}{\partial Q}\right]_{\Delta\bar{F}_{AY}} = \frac{d\,\Delta\bar{F}_{AY}}{d\,N_A+}\left[\frac{\partial}{\partial Q}\left(\frac{\partial N_A+}{\partial x}\right)\right]_{N_A+}$$

$$= \frac{d\,\Delta\bar{F}_{AY}}{d\,N_A+}\left[\frac{\partial}{\partial Q}\left(\frac{1}{\partial x/\partial N_A+}\right)\right]_{N_A+}$$

$$= \frac{\mathrm{d}\,\Delta\overline{F}_{AY}}{\mathrm{d}\,N_{A}+}\left[-\left(\frac{\partial\,N_{A}+}{\partial x}\right)^{2}\frac{\partial}{\partial Q}\left(\frac{\partial\,x}{\partial\,N_{A}-}\right)\right]_{N_{A}+}$$

$$= -\frac{\mathrm{d}\,\Delta\overline{F}_{AY}}{\mathrm{d}\,N_{A}+}\left(\frac{\partial N_{A}+}{\partial\,x}\right)^{2}\frac{\partial}{\partial\,N_{A}+}\left(\frac{\partial x}{\partial Q}\right)_{N_{A}+} \qquad (16)$$

According to derivations (eqn. (8)) in the previous paper [1] (compare the present eqn. (26)), we have

$$\left(\frac{\partial x}{\partial Q}\right)_{N_{A}+} = -\frac{V}{q}\,t'(N_{A}+) \qquad (17)$$

where V is the molar volume of the mixture and $t'(N_{A}+) = \dfrac{\mathrm{d}\,t_{A}+}{\mathrm{d}\,N_{A}+}$.

Introducing eqn. (17) into (16) we have:

$$\left(\frac{\partial\,\mathrm{grad}\,\Delta\overline{F}_{AY}}{\partial\,Q}\right)_{\Delta\overline{F}_{AY}} = \frac{\mathrm{d}\,\Delta\overline{F}_{AY}}{\mathrm{d}\,N_{A}+}\left(\frac{\partial\,N_{A}+}{\partial\,x}\right)^{2}\cdot\frac{V}{q}\,t''(N_{A}+) \qquad (18)$$

neglecting changes in V with changes in composition, and introducing this into eqn. (15) we obtain

$$\frac{\partial\,U}{\partial\,Q} = \frac{V}{2}\int_{N_{A}+_{I}}^{N_{A}+_{II}}\varepsilon\,m^{2}\,t''(N_{A}+)\left(\frac{\mathrm{d}\,\Delta\overline{F}_{AY}}{\mathrm{d}\,N_{A}+}\right)^{2}\left(\frac{\partial\,N_{A}+}{\partial\,x}\right)^{2}\mathrm{d}\,N_{A}+ \quad \text{or}$$

$$\frac{\partial\,U}{\partial\,Q} = \frac{V}{2}\int_{N_{A}+_{I}}^{N_{A}+_{II}}\varepsilon\,m^{2}\,t''(N_{A}+)\,(\mathrm{grad}\,\Delta\overline{F}_{AY})^{2}\,\mathrm{d}\,N_{A}+ \qquad (19)$$

The absolute dielectric constant ε may be expressed by the absolute dielectric constant of vacuum ε_{0} and the relative dielectric constant of the medium ε_{r}:

$$\varepsilon = \varepsilon_{0}\cdot\varepsilon_{r}$$

where $\varepsilon_{0} = \dfrac{1}{\pi\cdot 36}\times 10^{-9}\,(\mathrm{coulomb}^{2}/\mathrm{joule}\cdot\mathrm{m}) = 3.98\times 10^{-23}\left(\dfrac{\mathrm{Faraday}^{2}}{\mathrm{cal}\cdot\mathrm{cm}}\right)$

Due to the small numerical value of ε_{0}, one may expect to find that the change in electrostatic energy in the region of the concentration gradient is negligible compared to the other free energy changes in the cell.

EFFECT OF THE CURRENT DENSITY

In eqn. (14) it is assumed that the current density is zero. However, in a real measurement a small current will generally be drawn. The transport of charge is therefore connected with a loss in electric energy as joule heat. This energy loss will be symmetrical with respect to the sign of the current density, and it will usually not disturb the E.M.F. measurement.

The change in electrostatic energy will, however, have terms in addition to the expression in eqn. (14) when current flows through the cell. According to eqn. (9) the potential gradient is:

$$\text{grad } \varphi = m \text{ grad } \Delta\bar{F}_{AY} - R\vec{I} \qquad \text{where } R = \frac{1}{\varkappa} \tag{20}$$

and $$(\text{grad } \varphi)^2 = m^2 (\text{grad } \Delta\bar{F}_{AY})^2 - 2\, R\vec{I}\, m \text{ grad } \Delta\bar{F}_{AY} + (RI)^2$$

For constant I we have:

$$\frac{\partial}{\partial Q}\left[\frac{1}{2}\int_v \varepsilon\,(2\, R\vec{I}\, m \text{ grad } \Delta\bar{F}_{AY})\, dv\right] = \vec{I}\, q\, \frac{\partial}{\partial Q}\int \varepsilon\, R\, m \text{ grad } \Delta\bar{F}_{AY}\, dx$$

$$= I\, q\, \frac{\partial}{\partial Q}\int_{N_{A^+(I)}}^{N_{A^+(II)}} \varepsilon \cdot R\, m\, \frac{d\, \Delta\bar{F}_{AY}}{d\, N_{A^+}}\, d\, N_{A^+} = 0 \tag{21}$$

As the integral contains only properties of the electrolyte, it is not changed by the transport of a small charge.

The contribution by the term $(RI)^2$ to the change in electrostatic energy for a given current density is equal to:

$$\frac{\partial}{\partial Q}\left(\frac{1}{2}\int_v \varepsilon\,(RI)^2\, dv\right) = \frac{1}{2} I^2 \cdot q \int \varepsilon\, 2\, R \left(\frac{\partial R}{\partial Q}\right)_x dx$$

$$= I^2 \cdot q \int \varepsilon\, R\, \frac{\partial R}{\partial N_{A^+}} \left(\frac{\partial N_{A^+}}{\partial Q}\right)_x dx \tag{22}$$

$$= -I^2\, V \int_{N_{A^+(I)}}^{N_{A^+(II)}} \varepsilon\, R \cdot R'(N_{A^+}) \cdot t'(N_{A^+})\, d\, N_A$$

where eqn. (5) from the previous publication [1]:

$$\frac{\partial\, N_{A^+}}{\partial\, Q} = -\frac{V}{q}\, t'(N_{A^+})\, \frac{\partial\, N_{A^+}}{\partial\, x}$$

has been used (compare the present eqn. (25)). ε is considered constant. One will generally find that this contribution to the measured E.M.F. is negligible. In addition to this the current will cause polarization at the electrodes.

EFFECT OF THE DIFFUSION PROCESS

It may finally be shown that the outer electrical work carried out by the E.M.F. measurement is not influenced by the diffusion process, which is proceeding during the time of the measurement.

At the E.M.F. measurement a small charge ΔQ is transferred through the cell. This transfer is carried out over a short time period Δt. The electrical current is in average

$$I = \frac{1}{q} \frac{\Delta Q}{\Delta t}$$

The number of A^+ ions passing through an unit cross-section of the cell at a distance x from one side of the cell, we denote by $\vec{J}_{A^+(x)}$. The change in content of AY in a volume ranging between two unit cross-sections at the two distances x and $x + dx$ is given by:

$$\Delta\, dn_{A^+} = (\vec{J}_{A^+(x)} - \vec{J}_{A^+(x+dx)})\, \Delta t = -\left(\frac{\partial \vec{J}_{A^+}}{\partial x}\right) dx \cdot \Delta t \qquad (23)$$

From eqns. (7) and (20) we have

$$\vec{J}_{A^+} = -\left(L_{11} - L_{12} \frac{N_{A^+}}{N_{B^+}}\right) \operatorname{grad} \Delta \bar{F}_{AY} - \varkappa t_{A^+} \cdot m \operatorname{grad} \Delta \bar{F}_{AY} + t_{A^+} \cdot \vec{I} \qquad (24)$$

which will be abbreviated to

$$\vec{J}_{A^+} = -\vec{f}(N_{A^+}, \operatorname{grad} N_{A^+}) + t_{A^+} \cdot \vec{I}$$

which combined with eqn. (23) gives

$$\Delta\, d\, n_{A^+} = f'\,(N_{A^+}, \operatorname{grad} N_{A^+})\, dx \cdot \Delta t - t'_{(N_{A^+})} \frac{\partial N_{A^+}}{\partial x}\, dx \frac{\Delta Q}{q}$$

where $f'(N_{A^+}, \operatorname{grad} N_{A^+})$ is the derivative of $\vec{f}(N_{A^+}, \operatorname{grad} N_{A^+})$ with respect to x. As $dn_{A^+} = \frac{dx}{V} \cdot N_{A^+}$, we obtain

$$\Delta\, N_{A^+}{}_{(x = \text{constant})} = V \cdot f'\,(N_{A^+}, \operatorname{grad} N_{A^+}) \cdot \Delta t - \frac{V}{q}\, t'_{(N_{A^+})} \frac{\partial N_{A^+}}{\partial x} \cdot \Delta Q \qquad (25)$$

and $$\Delta x_{(N_{A^+} = \text{const.})} = V \cdot f'\,(N_{A^+}, \operatorname{grad} N_{A^+}) \frac{\partial x}{\partial N_{A^+}} \Delta t - \frac{V}{q}\, t'_{(N_{A^+})} \cdot \Delta Q \qquad (26)$$

The free energy of the electrolyte in the region of the concentration gradient will thus change due to both the charge transfer and the diffusion process. The total free energy change is given by:

$$\Delta F_1 = \int_{\mathrm{I}}^{\mathrm{II}} \frac{q\, dx}{V} \frac{d\, \Delta F}{d\, N_{A^+}}\, \Delta\, N_{A^+}$$

$$= \Delta t \cdot \int_{\mathrm{I}}^{\mathrm{II}} q \cdot \int (N_{A^+}, \operatorname{grad} N_{A^+}) \frac{d\, \Delta F}{d\, N_{A^+}}\, d\, x - \Delta Q \int_{\mathrm{I}}^{\mathrm{II}} \frac{d\, \Delta F}{d\, N_{A^+}}\, t'_{(N_{A^+})}\, d\, N_{A^+} \qquad (27)$$

where the last term is the only term considered in the previous publication [1].

Thus the equations for the change in free energy by the simultaneous diffusion process and charge transfer can be separated into two terms: one containing time and one containing the amount of charge transferred and no term containing both time and charge.

By a similar procedure using eqns. (26) and (14) one can show that the equation for the change in electrostatic energy can be separated in the same way.

It may thus be concluded that there is no interference between the diffusion process and the cell reaction.

The derivation does not contain any assumptions regarding the bonds between the three particles A^+, B^+ and Y^-. The above equation may thus be applied on a concentration cell having, *e.g.*, HCl — H_2O mixtures as electrolyte. This electrolyte can formally be describes as a mixture of the three kinds of particles Cl^-, OH^- and H^+. The fact that the OH^- particles most of the time are associated with H^+ does not affect the derivation of the above equation.

An equation similar to eqn. (1) has been derived by Wagner [3] and later in a modified way by Guggenheim [4]. Wagner's derivation is based on the assumption that the different ions move independent of each other. The more general derivation by Guggenheim is based on the electrochemical potential of a single ion, and the application of the Onsager reciprocal relations to the transfer of single ions. In the present derivation on the other hand unmeasureable quantities like the electrochemical potential of a single ion have been avoided.

Guggenheims equation has been applied to systems of fused salts by Laity [5]. Laity [6,7] has also shown that the derivation by Guggenheim is valid also in cases where the Nernst-Einstein equation connecting diffusion constant and mobility does not hold, and he has extended the treatment of single ion properties to give correlation between coefficients obtained from different kinds of transport measurements.

The Effect of Atabrine and Promazine Derivatives on the Activity of the Old Yellow Enzyme

STEN KISTNER

Medicinska Nobelinstitutet, Biokemiska avd. Stockholm, Sweden

Atabrine, chlorpromazine, and other promazine derivatives inhibited the activity in the aerobic Zwischenferment-OYE * system, but only when preincubated with the apoprotein of the OYE. The inhibition was independent of the FMN concentration. Fluorimetric studies of the apoprotein-FMN association reaction showed that compounds which inhibited the enzyme activity slowed down the reaction rate immediately after being added to the apoprotein, but did not lower the binding capacity for FMN. The mechanism of reaction between inhibitors and enzyme is discussed.

Chlorpromazine potentiated the aerobic OYE activity when added to the apoprotein at the same time as or after the FMN. Other promazine derivatives had the same ability, whereas the corresponding sulphoxides were ineffective. The anaerobic OYE activity was inhibited but not potentiated by chlorpromazine. The potentiating effect could not be explained by the experimental results, although these allowed certain conclusions.

The dissociation constants of complexes, formed between FMN and some promazines, were determined by spectrophotometric measurements.

Certain compounds with chemotherapeutical activity act as flavoprotein inhibitors. The effect of atabrine on respiration in tissue slices [1] and on oxidative phosphorylation in mitochondrial systems [2] has been explained by inhibition of flavin containing enzymes [3,4]. Studying cytochrome c reductase from yeast, Haas [3] found evidence of an irreversible reaction between the apoprotein and atabrine in competition with the coenzyme FMN. Hellerman *et al.*[5] studied the effect of this drug on D-amino acid oxidase and found a competitive inhibition, to which a simple kinetic interpretation could, however, not be applied. They concluded that the reaction between atabrine and apoprotein is complicated and reflects a general effect on proteins by the drug

* Abbreviations: OYE = Old Yellow Enzyme, FMN = flavin mononucleotide, FAD = flavin adenine dinucleotide, TPN = triphosphopyridine nucleotide, TPNH = reduced TPN, DPNH = reduced diphosphopyridine nucleotide, EDTA = ethylene diamine tetraacetic acid.

rather than a specific antagonism with flavin. Other flavoproteins are also inhibited by atabrine [6,7]. Using a fluorimetric technique, Nygaard and Theorell [8] found a reaction between the apoprotein of the OYE and atabrine, similar to that occurring between the apoprotein and FMN. Because of the strong fluorescence of atabrine its influence on the latter reaction was not studied.

Yagi *et al.*[9] showed an inhibition of D-amino acid oxidase by chlorpromazine in competition with the coenzyme FAD and calculated the dissociation constant of the enzyme-inhibitor complex. Inhibition of flavoproteins in the brain was suggested as a possible mechanism of action for the drug. Other investigators [10] found that the inhibition was due to a slow reaction between enzyme and drug and that, once established, it could not be easily reversed even by large excess FAD. The effect upon oxidative phosphorylation in mitochondria by chlorpromazine is similar to that of atabrine [11], and has been suggested to be caused by inhibition of flavoproteins [11,12]. The interaction between chlorpromazine and flavoproteins may also be influenced by the fact that a complex formation occurs between the drug and free flavin [13,14]. Yagi *et al.*[15] determined the dissociation constants for such complexes using a fluorimetric technique and concluded that, due to the high values of these constants, this type of complex formation is not responsible for the inhibition of D-amino acid oxidase by chlorpromazine.

Although many experimental data show that atabrine and chlorpromazine inhibit flavoproteins, the specificity of their activity has not been established. Both of them have also been found to cause inhibition of other isolated enzymes [5,16].

In the present work the effect of atabrine and chlorpromazine upon the activity of the OYE has been studied. Since it was found that chlorpromazine often caused a potentiation of the activity, the investigation was extended to include some other promazine derivatives and compounds of similar structure.

MATERIALS

OYE was prepared from brewer's bottom yeast (kindly supplied by Hamburgerbryggeriet, Stockholm) by the method of Theorell and Åkeson [17], and the *apoprotein* obtained according to Warburg and Christian [18]. Determination of concentration and purity was carried out as described before [19]. All enzyme preparations used in the experiments were of purity 0.75 or more.

Glucose-6-phosphate (di-sodium salt), *glucose-6-phosphate dehydrogenase (Zwischenferment)*, *TPN*, *FMN*, and *cytochrome c* (type III from horse heart) were all commercial preparations (Sigma Chemical Company).

Chlorpromazine [2-chloro-10-(3-dimethylaminopropyl)phenothiazine hydrochloride] was kindly supplied by AB Leo, Hälsingborg. The sulphoxide was obtained by oxidation with H_2O_2 in the presence of peroxidase [20]: To 2 ml of 3×10^{-3} M chlorpromazine solution were added 1 μl 3×10^{-4} M horse radish peroxidase (a gift from Dr. K. G. Paul) and 2μl 8 M H_2O_2 at +4°C. A red colour appeared. The UV-spectrum of the solution was identical with that of chlorpromazine sulphoxide [20], and paper chromatography (see Methods) showed a single spot with R_F value 0.82. *Atabrine* [6-chloro-9-((4-diethylamino-1-methylbutyl)amino)-2-methoxyacridine hydrochloride], *promazine* [10-(3-dimethylaminopropyl)phenothiazine hydrochloride], *promazine sulphoxide* oxalate, *2-methoxypromazine*, *2-methoxypromazine sulphoxide*, and *imipramine* [(3-dimethylaminopropyl)-dibenzyl amine] were all gifts from Dr. H. Löw. *Transergan* [2-diethylaminoethyl phenothiazine-10-carboxylate hydrochloride] was kindly supplied by AB. Astra, Södertälje.

METHODS

Determination of aerobic OYE activity. The same procedure as outlined in a previous publication [21] was used. The total volume of the reaction mixture was always 3.0 ml and contained 0.1 M sodium phosphate buffer pH 6.5. This pH was chosen because of the low solubility of chlorpromazine at higher pH. When not otherwise stated in the section on results, the reaction mixture contained 1.9×10^{-2} M glucose-6-phosphate, 4.5×10^{-4} M TPN, 1 Kornberg Unit Zwischenferment, and 2.7×10^{-3} M KCN. 0.1 mg OYE was added to give a final concentration of 3.2×10^{-7} M. This concentration was rate limiting and gave an oxygen uptake of approximately 100 μl per 30 min, (O_2-atmosphere). When apoprotein was used, an equivalent amount was added, and FMN was added in excess (3×10^{-6} M). All concentrations are given as final concentrations in the reaction mixture. In preincubation experiments drug and enzyme were mixed in the sidearm of the Warburg vessel and allowed to react for 30 min before being added to the other reactants. The volume in the sidearm was 0.2 ml, and thus the concentrations were here 15 times larger than in the final reaction mixture. The reaction velocity was expressed as μl oxygen consumed during a 30 min period. The activity in the vessels, where drug was added, was expressed as per cent of the activity in the control vessels. All experiments were performed at +37.0° C.

Determination of anaerobic OYE activity. The method described by Theorell [22] was used. A Thunberg cuvette contained in a total volume of 3.0 ml 0.1 M sodium phosphate pH 6.5, 9.9×10^{-3} M glucose-6-phosphate, 1 Kornberg Unit Zwischenferment, 4.0×10^{-5} M cytochrome c, and OYE. In the sidearm 0.1 ml 1.3×10^{-2} M TPN was added. The OYE concentration varied in different experiments, and in some experiments chlorpromazine was added in the main compartment. The cytochrome c stock solution was made up in 0.02 N HCl to achieve total oxidation of the cytochrome [22]. The air in the cuvette was replaced by argon, and the cuvette was carefully shaken during 5 min to obtain equilibrium. The cuvette was placed in a Beckman DU spectrophotometer, and the absorption at 550 mμ read against a buffer blank. It was approximately 0.38 in all experiments, and constant during a 10 min period. The cuvette was tilted, and the content of the sidearm mixed with that of the main compartment. The absorption at 550 mμ was measured until a constant value was obtained. The total amount cytochrome c reduced was determined, using the values $\beta = 2.20 \times 10^7$ cm$^2 \cdot$ mole^{-1} for oxidized cytochrome [23] and $\beta = 6.36 \times 10^7$ cm$^2 \cdot$ mole^{-1} for the reduced form [24]. The reaction rate was determined during the early phase of the reaction, when a rectilinear relationship was obtained between the amount of cytochrome reduced and the reaction time. The experiments were run at + 21.0°C.

Fluorimetric study of the apoprotein—FMN association reaction. The apparatus and method described by Theorell and Nygaard [25] was used. This allowed determination of the association velocity constant k_1 and the amount FMN bound by a certain amount of apoprotein. The reactions were performed in 0.1 M sodium phosphate buffer pH 6.5 at + 23.0°C.

Spectrophotometric determination of complex formation with FMN. The change in the absorption spectrum of FMN caused by chlorpromazine [15] and other compounds was used to determine the dissociation constants of the complexes. The solutions were made in 0.1 M sodium phosphate buffer pH 6.5. The experiments were performed at room temperature (+ 21°C).

Paper chromatography of chlorpromazine was carried out as described by Salzman *et al.*[26]

All experiments were done at least twice. Care was always taken to keep out light as much as possible.

RESULTS

The effect of atabrine on the aerobic OYE activity. When atabrine was mixed with FMN and other reactants in the main compartment of the Warburg flask, and the reaction was started by introducing apoprotein from the sidearm, no inhibition occurred even at the highest atabrine concentration tested,

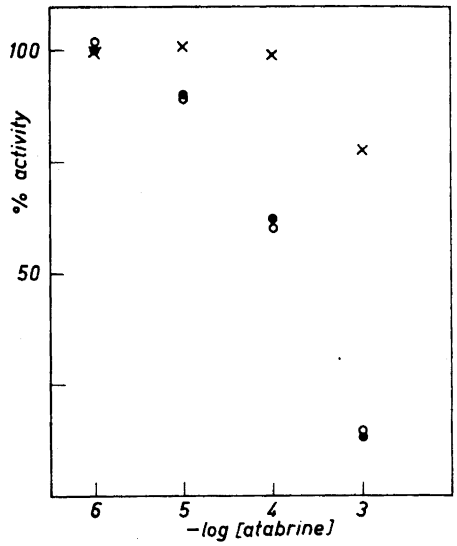

Fig. 1. The effect of atabrine on the aerobic OYE activity. The activity is expressed as per cent of the activity in control experiments, where no drug was added, and marked along the ordinate. Along the abscissa the negative logarithm of the atabrine concentration is marked. Atabrine and enzyme were preincubated in a sidearm of the Warburg flasks, where the volume was 0.2 ml. The total volume of the reaction mixture was 3.0 ml. The concentration of TPN was 4.5×10^{-4} M and of enzyme 3.2×10^{-7} M. All concentrations are expressed as final concentrations in the reaction mixture. Points marked × indicate experiments, where holoenzyme was used. O marks experiments where apoprotein was used, and 3.2×10^{-6} M FMN was added in the main compartment, ● experiments with apoprotein and 3.8×10^{-7} M FMN.

1×10^{-3} M. In different experiments the TPN or FMN concentration was lowered to 1.8×10^{-5} M or 3.8×10^{-7} M, respectively, to become rate limiting in the reaction, other experimental conditions being unchanged. 1×10^{-3} M atabrine was still without effect. However, when atabrine and apoprotein were mixed in the sidearm and thus preincubated during 30 min., inhibition occurred. It was of the same magnitude at low, rate limiting FMN concentrations as when FMN was added in excess. Some effect, although much less pronounced, was noticed also when atabrine was preincubated with the holoenzyme (Fig. 1). The inhibition of the apoprotein after preincubation was reversed by approximately 2/3 when dialysis against buffer was performed overnight at + 4°C immediately after the preincubation.

The effect of chlorpromazine on the aerobic OYE activity. Under various experimental conditions chlorpromazine caused potentiation of the enzymatic activity. This always occurred when the holoenzyme was used. It was of the same magnitude whether preincubation of OYE and chlorpromazine was performed or not. Also in experiments with apoprotein, potentiation occurred if FMN and drug were added simultaneously to the enzyme. On the other hand, if apoprotein and chlorpromazine were preincubated in the sidearm

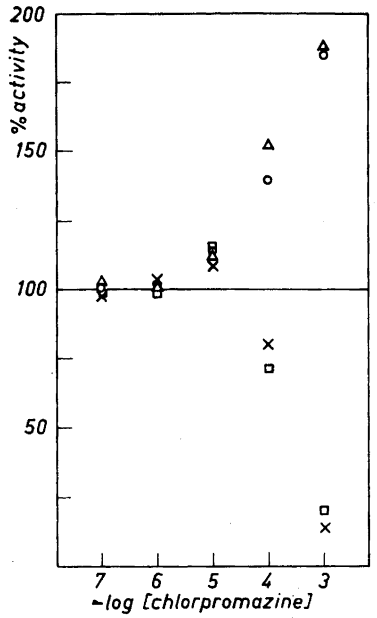

Fig. 2. The effect of chlorpromazine on the aerobic OYE activity. Activity and drug concentrations are marked as in Fig. 1. O marks experiments, where holoenzyme and chlorpromazine were preincubated in the sidearm, △ experiments, where 3.7×10^{-7} M FMN and chlorpromazine were preincubated, and apoprotein kept in the main compartment, × indicates preincubation of apoprotein and drug, when the main compartment contained 3.1×10^{-6} M FMN. □ indicates the same prodedure, but FMN concentration was 4.2×10^{-7} M. Other experimental conditions were as described under Fig. 1.

before being added to the other reactants, high concentrations of chlorpromazine caused inhibition, whereas low concentrations potentiated. Essentially the same effect was obtained at high and low FMN concentrations. In Fig. 2 some experiments are summarized to show the effect of chlorpromazine under various experimental conditions. Higher concentrations of chlorpromazine than those shown in the figure caused precipitation and lowering of the activity.

When the activity in the test system was lowered by diminishing the OYE concentration, the potentiating effect of chlorpromazine remained unchanged. When a lower activity was obtained by diminishing the TPN concentration, the effect of the drug was much less marked. This is shown in Table 1, where the OYE concentration was rate limiting in the first two groups of experiments, and the TPN concentration in the last group.

Paper chromatography was performed on reaction mixtures containing 3.2×10^{-7} M OYE, excess TPN, and 1×10^{-3} M chlorpromazine, which had caused a maximal potentiation of the OYE activity. In different experiments samples containing 10—18 μg chlorpromazine were tested. They all showed the same R_F values as the chlorpromazine blanks, 0.92, and only one spot

Table 1. The effect of chlorpromazine on the aerobic OYE activity. Chlorpromazine and OYE were preincubated in the sidearm for 30 min, then added to TPN and other reactants. In the first two groups of experiments the enzyme concentration was rate limiting in the reaction mixture without drug. In the last group TPN concentration was rate limiting.

OYE concentration	TPN concentration	Chlorpromazine concentration	O_2 uptake during 30 min	Activity in the presence of chlorpromazine
3.2×10^{-7} M	4.5×10^{-4} M	0	100.7	—
3.2×10^{-7} M	4.5×10^{-4} M	5×10^{-4} M	158.3	157.7 %
1.6×10^{-7} M	4.5×10^{-4} M	0	52.4	—
1.6×10^{-7} M	4.5×10^{-4} M	5×10^{-4} M	82.1	156.6 %
3.2×10^{-7} M	1.1×10^{-5} M	0	60.0	—
3.2×10^{-7} M	1.1×10^{-5} M	5×10^{-4} M	66.7	111.1 %

appeared in the chromatograms. Control runs of reaction mixtures without chlorpromazine did not cause any spots.

The effect of other compounds on the aerobic OYE activity. The different compounds tested were preincubated with OYE or apoprotein. The results are summarized in Table 2, where it can be seen that other promazines than the 2-chloro derivative also potentiated the OYE activity, whereas many

Table 2. The effect of various compounds on the aerobic OYE activity. The different compounds and OYE or apoprotein were preincubated for 30 min in the sidearm of the Warburg flask, then added to the other reactants in the main compartment. In experiments with apoprotein this contained also 3.0×10^{-6} M FMN. Other experimental conditions were as described under Fig. 1.

Compound	Concentration M × 10^4	Activity of OYE compared with control %	Activity of apoprotein compared with control %
Chlorpromazine	1	140	80
Daylight exposed chlorpromazine	1	108	77
UV-irradiated chlorpromazine	1	114	
Chlorpromazine sulphoxide	1	100	90
Promazine	1	135	73
Promazine sulphoxide	1	97	99
Methoxypromazine	1	120	94
Methoxypromazine sulphoxide	1	102	84
Imipramine	1	100	93
Transergan	1	98	92
Methylene blue	1	151	154
Adenine	1	98	
Caffeine	10	99	
D-Tryptophan	10	97	
L-Tryptophan	10	101	
EDTA	1	103	

structurally related compounds did not. When chlorpromazine is left in the light, the solution rapidly darkens [27] and becomes strongly fluorescent. Chlorpromazine, which had been left in daylight for 2 days at room temperature had lost most of its potentiating effect. The same change could be accomplished by irradiating the solution for 2 h with the mercury lamp of the fluorimeter.

Most of the promazines and other compounds with a similar structure caused the same degree of inhibition when preincubated with the apoprotein. The irradiated chlorpromazine, which had lost most of its potentiating activity, still caused inhibition.

Methylene blue potentiated the OYE more strongly than chlorpromazine. At 1×10^{-3} M it doubled the activity. When preincubated with the apoprotein, the potentiating effect remained unchanged.

Table 2 shows that adenine, caffeine, and tryptophan did not cause potentiation. These compounds form complexes with FMN of the same type as chlorpromazine [28,29]. EDTA was also without effect.

The effect of chlorpromazine on the anaerobic OYE activity. The results are shown in Table 3. The same amount of cytochrome c was reduced, regardless of the concentration of OYE in the reaction mixture. The variations obtained are explained by experimental error. Without OYE no reduction occurred in the absence or in the presence of chlorpromazine. The reaction rate varied with the amount OYE added, and approximately the same turnover number was obtained. The addition of chlorpromazine caused some inhibition.

Fluorimetric studies of the apoprotein-FMN association reaction. Chlorpromazine showed a slow, constant increase in fluorescence when irradiated by the lamp of the fluorimeter and was therefore excluded from these studies. Promazine, on the other hand, had a low fluorescence that remained unchanged when the solution was illuminated, at least during the period of time necessary for the experiment. Its effect on the fluorescence of FMN at the concentrations used in these experiments was negligible. When promazine was added to apoprotein solutions to give a final concentration of 1×10^{-4} M a few minutes

Table 3. The effect of chlorpromazine on the anaerobic OYE activity. The amount of cytochrome c reduced is calculated from the change in absorption at 550 mμ. The reaction rate is calculated from the beginning of the reaction (10th—30th min) when a constant amount of cytochrome c was reduced per unit time. The last column gives the turnover number of the OYE.

OYE concentration M	Chlorpromazine concentration M	Total change in absorption at 550 mμ	Absorption change at 550 mμ per min	Total amount cytochrome reduced, M	M cytochrome reduced per min	Mole cytochrome reduced per mole OYE per min
1.28×10^{-7}	0	0.719	0.0120	3.97×10^{-5}	6.96×10^{-7}	5.44
2.56×10^{-7}	0	0.760	0.0254	4.21×10^{-5}	14.04×10^{-7}	5.49
2.56×10^{-7}	1.94×10^{-4}	0.756	0.0215	4.18×10^{-5}	11.89×10^{-7}	4.64
1.66×10^{-7}	0	0.720	0.0151	3.98×10^{-5}	8.35×10^{-7}	5.03
1.66×10^{-7}	1.94×10^{-4}	0.734	0.0114	4.05×10^{-5}	6.30×10^{-7}	3.99

Table 4. The effect of promazine on the apoprotein-FMN reaction, studied by fluorimetric technique. The volume of the test solutions was 3.55 ml, containing a constant amount of apoprotein, 0.1 M sodium phosphate buffer pH 6.5 and 1×10^{-4} M promazine when added. To these solutions 2 µl aliquots of 1.17×10^{-4} M FMN were added. The temperature + 23.0°C.

Conditions	Reaction mixture	FMN coupled M	Association velocity constant, k_1 $M^{-1} \cdot sec^{-1}$
FMN added immediately to reaction mixture	Apoprotein	7.08×10^{-7}	11.17×10^4
	Apoprotein + promazine	6.90×10^{-7}	6.41×10^4
Reaction mixture dialyzed before FMN was added	Apoprotein	6.50×10^{-7}	11.97×10^4
	Apoprotein + promazine	6.68×10^{-7}	11.08×10^4

before titration with FMN was undertaken, the association velocity of the apoprotein-FMN reaction was lowered. However, the same amount of FMN was bound on each addition. Incubating promazine and apoprotein for 30 min. at +37°C before adding FMN did not alter the result. When the promazine-apoprotein mixture was dialyzed against buffer at +4°C overnight, the effect of the promazine was completely abolished. Table 4 shows a typical experiment.

Some other compounds structurally related to promazine that had been tested in the Warburg experiments showed the same fluorescence properties as promazine. They were added to apoprotein solutions a few minutes before titration with FMN was undertaken. Results from one experiment are shown in Table 5. Some compounds were much less effective than promazine, but they all influenced the reaction in a similar way.

Although atabrine is strongly fluorescent, attempts were made to study its influence on the apoprotein-FMN reaction with the fluorimetric technique. 5×10^{-6} M atabrine had the same fluorescence as 7×10^{-7} M FMN, which was half of the concentration that began to give self-quenching. Using similar experimental conditions as those, outlined under Table 4, the same increase

Table 5. The effect of various compounds on the apoprotein-FMN reaction. Their concentration was 1×10^{-4} M. FMN was added in 5 µl aliquots of an 1.55×10^{-4} M solution. Other experimental conditions as described under Table 4.

Compound added to apoprotein solution	FMN coupled M	Association velocity constant, k_1 $M^{-1} \cdot sec^{-1}$
None	9.04×10^{-7}	10.55×10^4
Promazine	9.34×10^{-7}	5.72×10^4
Promazine sulphoxide	8.99×10^{-7}	8.96×10^4
Methoxypromazine	8.87×10^{-7}	6.43×10^4
Methoxypromazine sulphoxide	8.95×10^{-7}	7.57×10^4
Imipramine	9.27×10^{-7}	6.70×10^4
Transergan	8.90×10^{-7}	8.26×10^4

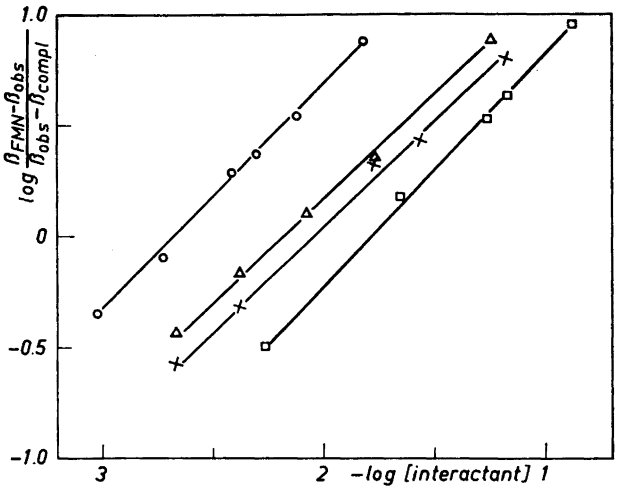

Fig. 3. Graphical determination of dissociation constants of FMN complexes after measuring the absorption at 445 mμ of FMN in the presence of various interactants. β_{FMN} is the absorption of free FMN, β_{obs} the absorption of FMN at different concentrations of interactant, shown on the abscissa, and $\beta_{compl.}$ the absorption of FMN when further addition of interactant did not cause further change in absorption. Readings were made against blanks containing the same amount of interactant as the samples. All solutions contained 0.1 M sodium phosphate pH 6.5. Temperature was + 21°C. O—O chlorpromazine, $K = 2.1 \times 10^{-3}$ M; △—△ promazine sulphoxide, $K = 6.6 \times 10^{-3}$ M; × — × promazine, $K = 9.3 \times 10^{-3}$ M; □—□ transergan, $K = 1.7 \times 10^{-2}$ M. The slopes of all curves equalled 1.

in fluorescence was caused by the FMN additions in samples containing 5×10^{-6} M atabrine as in the controls. The addition of atabrine caused a 20 % decrease of k_1, whereas the amount FMN bound was not affected.

Spectrophotometric studies of flavin complexes. All promazines as well as imipramine and transergan caused a change in the absorption spectrum of FMN, similar to that described for chlorpromazine [15], indicating the formation of a complex. Atabrine was excluded from these studies because of its strong absorption at 445 mμ. The dissociation constants of some of the complexes were determined. The results are shown in Fig. 3.

Spectrophotometric measurements were also made to determine whether complex formation occurred between chlorpromazine and FMN bound to protein in the OYE *. The absorption of 1.95×10^{-5} M OYE and 1×10^{-3} M chlorpromazine, read against a chlorpromazine blank, was compared to that of 1.95×10^{-5} M OYE alone. Certain difficulties were encountered since a slight opalescence occurred when enzyme and chlorpromazine were mixed. After centrifugation the two OYE solutions showed identical spectra in the visible region.

* Experiments concerning the OYE spectra were performed in collaboration with Dr. A. Ehrenberg. The author wishes to thank him for the right to use the results in this connection.

When OYE is reduced with excess TPNH and reoxidized with oxygen, the spectrum is shifted towards the red region [30,31]. The same shift was found in the absence and in the presence of 1×10^{-3} M chlorpromazine.

DISCUSSION

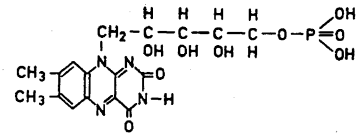
The results of the inhibition studies of the OYE give some support to the idea that atabrine and chlorpromazine, as well as other compounds of similar structure, may act as flavoprotein inhibitors. The potentiation obtained with some of the promazine derivatives is more difficult to explain. Inhibition and potentiation were in some cases caused by the same compound, depending on the experimental conditions, and thus seemed to reflect two different mechanisms of action. The effect of the drugs depended on whether they reacted with the enzyme before or after the coenzyme was bound.

Both atabrine and chlorpromazine caused inhibition of the oxygen uptake in the Zwischenferment-OYE system but, except for atabrine at high concentration, only when preincubated with the apoprotein. This leads to the conclusion that the observed inhibition was due to interference with the activity of the OYE and did not concern any of the other reactants. Also, the inhibitors interferred with the reaction between apoprotein and FMN. The effect was the same at high and low FMN concentrations. These findings bear some resemblance to results obtained with other flavoproteins [3,10], suggesting a little reversible reaction between drug and enzyme that prevents the binding of flavin. That the reaction was reversible to some extent was shown when the effect of atabrine could be partially abolished after dialysis.

Similar results were obtained with promazine and other, structurally related compounds. The formulas of some of the compounds are shown below. They all have a certain structural resemblance to FMN but lack groups of the same type as the special combining groups [8,32] which have been suggested to participate in the binding of the coenzyme to the apoprotein. The binding of the inhibitors to the protein must therefore be supposed to be of a different character, even if they might compete for the same sites as FMN. Considering the great affinity of the apoprotein for FMN [25], one would assume that this could easily replace the inhibitors, even if added later.

Further information was obtained from the fluorimetric studies of the apoprotein-FMN reaction that showed that promazine and structurally related compounds, as well as atabrine in low concentration, slowed down the reaction rate but did not influence the binding capacity of apoprotein for FMN. It did not seem likely that this interferance was due to complex formation with FMN, because of the high values obtained for the dissociation constants of the promazine-FMN and other complexes. Thus it appeared that the inhibitors were bound to the apoprotein without occupying the binding sites of the FMN but making these less accessible. A similar effect on the reaction has been obtained by treating the apoprotein with functional group reagents, which block only some of the binding groups for each FMN molecule [8].

The effect upon the activity of the enzyme by atabrine and promazine derivatives is not explained by a change in the equilibrium between the apopro-



FMN.

tein and FMN, since the inhibition would then have depended upon the FMN concentration. To offer an explanation of the present results it might be assumed that the apoprotein of the OYE, inhibitor, and FMN form a ternary complex with low or no activity. The presence of the inhibitors disturbs but does not prevent the binding of FMN to the apoprotein. The presence of FMN completely prevents a binding of inhibitors that can reduce the activity. This suggests that FMN and the inhibitors have binding sites located close to each other. No conclusions can be drawn as to whether the inhibitors are also bound to other parts of the enzyme molecule.

The experimental results do not explain the nature of the interaction between enzyme and drug that resulted in increased activity. However, certain conclusions may be drawn that allow a discussion. It is interesting to note that potentiation by chlorpromazine has been observed in other enzyme systems [10,33].

The potentiating effect of the promazines was quite similar to that of methylene blue, which is known to oxidize reduced OYE [34]. This reaction occurs at a faster rate than the oxidation by oxygen in reaction mixtures, where the reducing system (glucose-6-phosphate, Zwischenferment, TPN) is in excess.

In such cases the velocity is determined by the oxidation of the reduced OYE [35]. On the other hand, at low concentrations of the reducing system the velocity depends on the reduction of the OYE, and the enzymatic activity is equally high with oxygen or methylene blue as electron acceptor [35]. In the present experiments it was found that the potentiating effect of chlorpromazine was much less pronounced in reaction mixtures with low concentration of TPN. It appeared that chlorpromazine interfered with the reoxidation of the reduced OYE by oxygen.

It is difficult to believe, however, that chlorpromazine, which has been characterized as an exceptionally good electron donor [14], could act as an oxidant like methylene blue. Metabolites, possibly possessing this property, were not found in paper chromatograms of reaction mixtures, where chlorpromazine had caused potentiation. A comparison between the different compounds tested gives a clue to which parts of the promazine molecule that might be responsible for the effect. Substitution in the 2-position had little influence, whereas oxidation at the sulphur atom abolished the effect. Negative results obtained with imipramine also indicate the importance of the sulphur atom, and those obtained with transergan the importance of the substitution at the nitrogen.

It may be remarked that phenothiazines are considered to form resonance stabilized free radicals [36], where the nitrogen and sulphur atoms hold key positions. Bindings to these atoms may interfere with this activity. The radical formation in chlorpromazine has been suggested as the reason for its antioxidant effect on the formation of lipid peroxides in tissue homogenates [27]. This reaction is also inhibited by methylene blue. It may be postulated that in the OYE system, the promazine radical structure may act as an intermediate in the electron transport system.

The different effect of chlorpromazine on the OYE activity in the aerobic and anaerobic system brings up the question, whether the formation of hydrogen peroxide in the former had any importance. The presence of hydrogen peroxide did not in itself influence the enzymatic activity. Hydrogen peroxide is known to oxidize phenothiazines to sulphoxides under different conditions [37]. In aqueous solutions the oxidation of chlorpromazine requires the presence of catalase or peroxidase to occur at a fast rate [20]. Possibly the nascent peroxide in the Zwischenferment-OYE system, although unable to complete the oxidation, could form a postulated intermediate radical form [38]. This is, however, supposed to appear upon UV irradiation of chlorpromazine solutions. In the present experiments such treatment lead to the disappearance of the potentiation.

Potentiation of aerobic and inhibition of anaerobic activity has also been found in microsomal cytochrome reductase [39] by substituting DPNH with TPNH, or by adding competing nucleotides when DPNH is the substrate. When oxygen is the electron acceptor, the rate limiting step is the oxidation of the reduced enzyme, and this reaction occurs faster when the oxidized pyridine nucleotides dissociate more easily from the enzyme. If the same explanation is applicable to the present experiments, it would mean that the promazines interfered with the binding of TPN, and thus potentiation and inhibition could be attributed to the same type of mechanism. Observations

recently made with horse liver alcohol dehydrogenase [40] give further support to this possibility. Some compounds that do not participate in the enzymatic reaction have been found to form a ternary complex with the enzyme. Depending upon the concentrations of the reactants this sometimes leads to inhibition and sometimes to potentiation of the activity. The potentiation is due to an easier dissociation of the ternary than the binary complex. — Nevertheless, it was possible to form the red intermediate of the OYE [30,31] in the presence of chlorpromazine.

The complex formation that occurs between chlorpromazine and flavin is supposed to involve a transfer of electrons [14]. It did not appear that such a reaction had anything to do with the potentiation. No experimental evidence was found for the formation of a complex between chlorpromazine and protein bound FMN, and other compounds able to form flavin complexes did not potentiate.

Although unexplained, the potentiation of the OYE activity is interesting, considering the exceptionally low turnover number of this enzyme. Whether this type of action has anything to do with the pharmacological properties of the promazines is completely uncertain. It may be remarked, however, that chlorpromazine and its sulphoxide, which behaved differently with regard to the potentiation, also differ to a certain extent in pharmacological activity [41].

Acknowledgements. The author wishes to express his thanks to Professor Hugo Theorell for valuable discussions and criticism during the course of this work. Thanks are also due to Drs. A. Ehrenberg, H. Löw, K. G. Paul and B. Sörbo for helpful suggestions and discussions.

X-Ray Investigations on Me-Si-B Systems (Me = Mn, Fe, Co)

II. Some Features of the Fe-Si-B and Mn-Si-B Systems

BERTIL ARONSSON and INGVAR ENGSTRÖM

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The main features of the Fe—Si—B system at temperatures around 1 000°C have been determined using X-ray diffraction methods. Four ternary phases exist in the metal-rich part of this system. $Fe_{4.86}Si_2B$ is isomorphous with $Co_{4.7}Si_2B$ but has a more metal-rich composition. Fe_5SiB_2 has the Cr_5B_3 ($D8_l$)-structure, while the structure of a phase with the approximate composition $Fe_2Si_{0.4}B_{0.6}$ has not been solved. There is also a ternary Fe—Si—B phase that crystallizes in the cementite-structure, but the equilibria in which this phase is involved have not been clarified.

In the Mn—Si—B system, which seems to be quite complicated, particularly in the metal-rich part, a phase Mn_5SiB_2 (isomorphous with Fe_5SiB_2) has been identified.

In the previous communication [1] on Me—Si—B systems, the Co—Si—B system was dealt with and, in addition, some crystallographic data on intermediate phases in the Fe—Si—B and Mn—Si—B systems were reported. In this paper we shall present the main features of the Fe—Si—B system at temperatures around 1 000°C and, in particular, discuss the structures and homogeneity ranges of the phases with the composition Fe_5X_3 (X = Si,B). We shall also give some qualitative information on the Mn—Si—B system.

Except for phases with compositions around $MnSi_2$ and in the metal-rich part of the Mn—Si system, intermediate phases in the boundary binary systems Fe—B, Fe—Si, Mn—B and Mn—Si are crystallographically well characterized. Information on these binary phases may be found in a recent review article [2] and, therefore, will not be repeated here. No systematic studies on the ternary systems Fe—Si—B and Mn—Si—B seem to have been made previously.

EXPERIMENTAL

The alloys were prepared from the following chemicals,

Iron rods, from Johnson, Matthey and Co., London, claimed to contain about 0.03 % carbon, 0.01 % oxygen, 0.01 % nitrogen and a few p.p.m. of other elements.

Iron sponge, from Johnson, Matthey and Co., analyzed to contain 95.3 % iron, 2—3 % oxygen (this figure is probably too low), less than 0.001 % nitrogen and about 0.002 % carbon. According to the manufacturer the content of other elements is very low (a few p.p.m.).

Manganese (electrolytic), kindly donated by AB Ferrolegeringar, Stockholm, claimed purity 99.8 %.

Silicon powder, from Pechiney, Paris, claimed purity 99.9 %.

Boron powder, kindly donated by Borax Consolidated, London, claimed purity 99.0—99.7 %.

In some preliminary experiments we also used,

Iron powder, from Baker, Phillipsburg, New Jersey, analyzed to contain 97.8 % iron, ~1.1 % oxygen (this figure is probably too low) less than 0.001 % nitrogen and about 0.004 % carbon).

Carbonyl iron powder, analyzed to contain 98.5 % iron, 0.18 % oxygen, 0.69 % nitrogen and 0.77 % carbon.

Those iron-silicon-boron samples which have been chemically analyzed were prepared from three master alloys:

Fe_2B, analyzed to contain 90.38 % iron and 9.33 % boron, most of the remainder very probably being oxygen, was prepared by repeated sintering and arc-melting mixtures of iron sponge (Johnson, Matthey & Co) and boron, the ferro-magnetic iron boride being magnetically separated after each treatment.

$FeSi_{\sim 0.25}$ was prepared by reacting iron rods with silicon powder in a high-frequency furnace under vacuum so as to obtain a reasonably brittle iron-rich master alloy.

$FeSi_2$, analyzed to contain 46.71 % iron and 52.68 % silicon, most of the remainder very probably being oxygen, was prepared in the same way as $FeSi_{\sim 0.25}$.

The samples were synthesized by arc-melting or sintering mixtures of the master alloys and, depending on the composition of the samples, they were given different heat-treatments as reported in the following paragraph.

In the preliminary studies of the Fe—Si—B system we prepared alloys by sintering mixtures of the elements for 7—10 days at 975 ± 20°C in evacuated and sealed silica tubes which were subsequently quenched in oil. After this time no further changes were observed in the powder photographs of the samples on continued sintering and it was concluded that equilibrium had been attained. Several samples were made in each of the three-phase regions shown in Fig. 1, using the iron sponge, Baker's iron powder and the carbonyl iron powder, and within the experimental error (± 0.05 %) the same l.p. (lattice parameter) of the phases were found. Samples containing α(Fe,Si) were recovered for two hours at 700°C before the exposure in the powder camera.

The Mn—Si—B alloys, which were also prepared by sintering or arc-melting weighed amounts of the elements, were not chemically analyzed.

Powder photographs were taken in cameras of the Guinier type using Cr$K\alpha$- and Cr$K\alpha_1$-radiation with silicon (a = 5.4306 Å) or CaF_2 (a = 5.4630 Å) as internal standards for the l.p. determinations. Because of the low background and the sharp lines on the powder photographs obtained in Guinier cameras, quite small amounts of well-crystallized phases present in a sample can be detected. By mixing small amounts of $Fe_{4.86}Si_2B$ in Fe_5SiB_2, we found that less than 0.5 % of the former phase was sufficient for its identification in Fe_5SiB_2 + $Fe_{4.86}Si_2B$ samples. Since the powder photographs of phases involved in this study have a rather similar complexity, it may be assumed that when the diffraction lines of a well-crystallized phase are not discernable on a powder film, the sample does not contain more than about 0.5 % of that phase.

The chemical analyses of the Fe—Si—B samples were carried out by Dr. Lilly Gustafsson at the analytical department of this Institute. For the determination of iron, a sample was dissolved in HF + HNO_3, the hydrofluoric acid being subsequently removed by evaporation with sulfuric acid. After reduction in a cadmium-reductor, iron was determined through titration with cerium sulphate. The accuracy of this analysis is estimated to be ± 0.1 %.

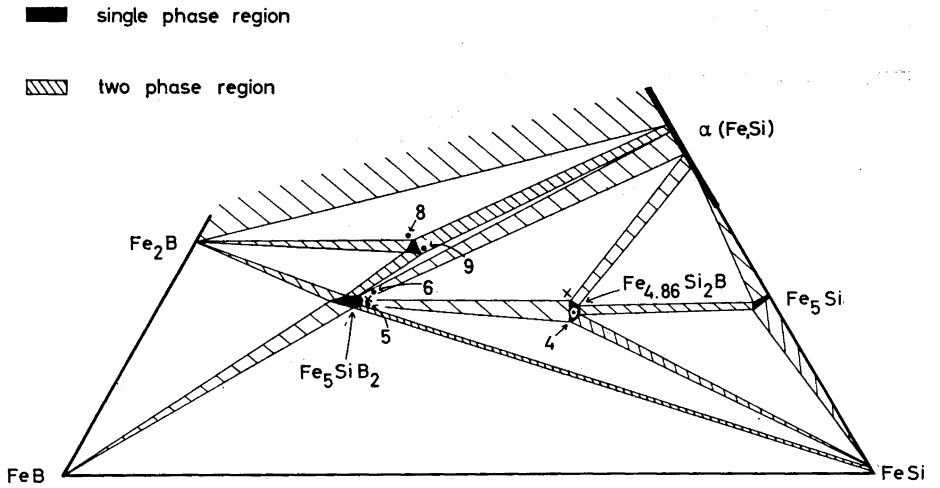

Fig. 1. The Fe—Si—B system in the composition range 50—70 atom per cent iron at temperatures around 1 000°C. The numbers refer to those samples the compositions and heat-treatments of which are given in Table 6. For clarity the narrow α(Fe,Si,B) single phase region is only represented by a line. The compositions Fe_5SiB_2 and Fe_5Si_2B are marked with ×. Error in figure: Fe_5Si should read Fe_5Si_3.

For the determination of silicon and boron, a sample was melted with Na_2CO_3 + KNO_3 in a platinum crucible and the melt was dissolved in diluted hydrochloric acid. Silicon was determined gravimetrically as SiO_2 after the boric acid had been removed by evaporation with methanol. The small amounts of silicon present in the filtrate were determined colorimetrically. For the boron analysis, the acid solution was passed through a hydrogen saturated ion exchanger and, after addition of mannitol, the solution was titrated with sodium hydroxide. The accuracy of the silicon and boron analyses is estimated to be ± 0.5 %.

The oxygen and nitrogen content of the samples was determined by a vacuum fusion technique. These analyses were carried out at the analytical department of Avesta Jernverk, where also the carbon content was determined by standard methods.

RESULTS

The Fe—Si—B system. In Figs. 1 and 2 the Fe—Si—B system at 1 000°C is outlined. (The samples containing less than 50 atomic per cent iron were synthesized by sintering mixtures of the elements at 1 100°C.) The system is characterized by four ternary metal-rich intermediate phases with the approximate compositions $Fe_3(Si,B)$, $Fe_2Si_{0.4}B_{0.6}$, Fe_5SiB_2 and $Fe_{4.86}Si_2B$, respectively. X-Ray powder data of nearly single-phase alloys are presented in Tables 1—4. The powder photographs of all phases, except $Fe_2Si_{0.4}B_{0.6}$, could be indexed. $Fe_3(Si,B)$ has the cementite ($D0_{11}$)-structure, Fe_5SiB_2 is isomorphous with Cr_5B_3 ($D8_l$-type), while $Fe_{4.86}Si_2B$, similar to $Co_{4.7}Si_2B$, crystallizes in the W_5Si_3 ($D8_m$)-structure. The l.p. of the phases in the different three-phase regions (at 975 ± 20°C) are collected in Table 5.

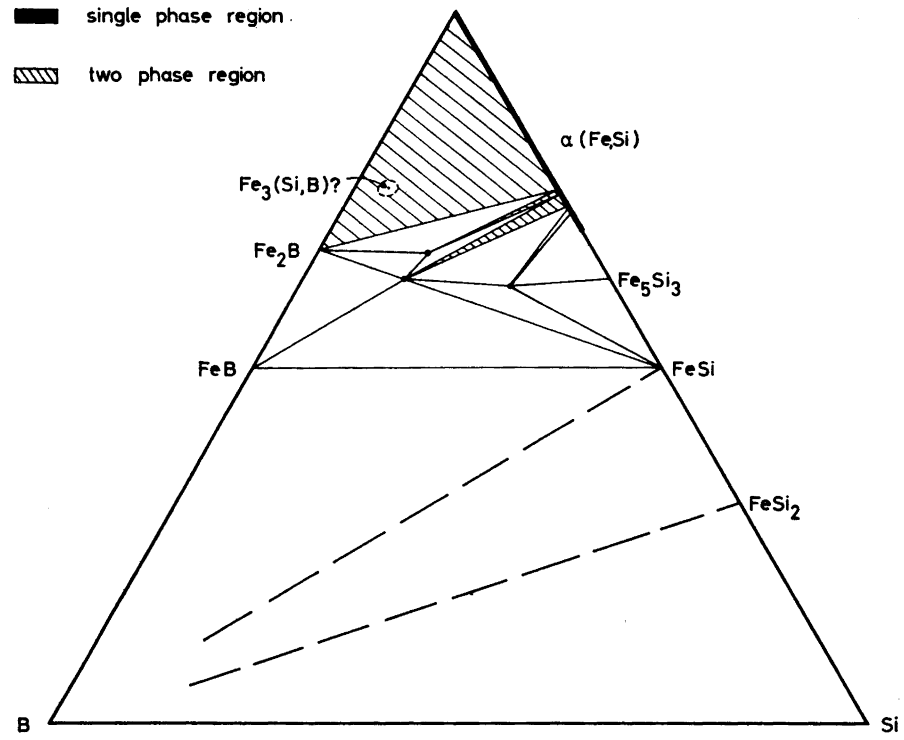

Fig. 2. An outline of the Fe—Si—B system. Most of the two-phase regions are only represented by a line.

Except for Fe_5Si_3 the l.p. of the boundary phases are within 0.1 % equal to those reported for the binary iron-borides and -silicides indicating that the two non-metals do not substitute for each other to any appreciable extent in these phases.

In view of the fact that boron is very little soluble in α- and γ-iron, it seems probable that also its solubility in α(Fe,Si) is very small. This is supported by the observation that Fe_2B is present in metal-rich alloys containing very small amounts of boron. Thus, no great error is likely to be made if the composition of the α(Fe,Si) phase, present in Fe—Si—B alloys, is derived from the l.p. *vs.* composition curve, which Farquhar *et al.*[3] have determined for solid solutions of silicon in α-iron. The composition of α(Fe,Si) in the three-phase equilibria involving this phase are given below

Three phase range	l.p. of α(Fe,Si)	iron content (atom %) of α(Fe,Si)
$Fe_2B + Fe_2Si_{0.4}B_{0.6} + \alpha$(Fe,Si)	$a = 2.826_3$ Å	74.9
$Fe_5SiB_2 + Fe_2Si_{0.4}B_{0.6} + \alpha$(Fe,Si)	$a = 2.826_1$ Å	74.5
$Fe_5SiB_2 + Fe_{4.86}Si_2B + \alpha$(Fe,Si)	$a = 2.821_6$ Å	72.6
$Fe_{4.86}Si_2B + Fe_5Si_3 + \alpha$(Fe,Si)	$a = 2.820_2$ Å	72.0

The l.p. of Fe_5Si_3 are slightly larger in ternary Fe—Si—B alloys than in binary Fe—Si (or ternary Fe—Si—O) alloys, indicating that a small number of boron atoms may be interstitially accomodated in Fe_5Si_3. As pointed out earlier [4], the iron-silicon skeleton of Fe_5Si_3 (Mn_5Si_3 ($D8_8$)-type) contains octahedral holes of convenient size for small non-metal atoms and it seems likely that the boron atom are located in these holes. (It was recently shown [5] that in the isomorphous Mn_5Si_3, the distances from the centre of the "hole" to the surrounding metal atoms is 2.03 Å, which is a short but not unreasonably short Fe—B distance.)

The l.p. variations observed for FeSi and $FeSi_2$ in ternary Fe—Si—B alloys are not greater than those reported for binary FeSi and $FeSi_2$, and thus may be explained as depending on a variation of the Fe/Si ratio in these phases.

As reported in the previous paper [1] a Fe—Si—B phase isomorphous with cementite and tentatively denoted as $Fe_3(Si,B)$ has been identified in metal-rich alloys, sintered at 975°C. A powder photograph of a $Fe_3(Si,B)$ + Fe_2B alloy is given in Table 1. The exact composition of $Fe_3(Si,B)$ and the equilibria

in which this phase are involved have not been clarified. The relation between the composition and the l.p. variations displayed by $Fe_3(Si,B)$ is also unknown, although it has been observed [2] that the unit volume increases as the boron content increases.

The composition of the other three ternary phases could be fairly well determined from samples prepared from the master alloys. The compositions

* Only the diffraction lines originating from Fe_5SiB_2 and Mn_5SiB_2 are given in the table. The iron-boron-silicon alloy was a two-phase alloy and contained, besides Fe_5SiB_2, α(Fe,Si) with an observed $\sin^2\Theta$-value for the 110-line of 0.3292. The manganese-boron-silicon alloy was a three-phase alloy, containing Mn_5SiB_2, Mn_5Si_3 and MnB.

** As silicon and phosphorus as well as iron and manganese have very similar scattering factors, we have compared the observed intensities of Fe_5SiB_2 and Mn_5SiB_2 with those calculated for Fe_5PB_2. The structure of the latter phase has been refined from single crystal data by Dr. Rundqvist [6] who was so kind as to put his values at our disposal. In the computations of the $p|F|^2$-values of Fe_5PB_2 the following atomic parameters were used (space-group $I\ 4/mcm$):

16 Fe in 16(l), $x = 0.169_0$, $z = 0.140_5$
4 Fe in 4(c)
8 B in 8(h), $x = 0.37_5$
4 P in 4(a)

and heat-treatments of these samples are given in Table 6. On basis of this information, Fig. 1 has been constructed and the compositions of the ternary phases have been found to be well represented by the formulæ $Fe_2Si_{0.40}B_{0.60}$, $Fe_5Si_{1-x}B_{2+x}$ ($x \sim 0.0$—0.1) and $Fe_{4.86}Si_2B$, respectively.

(Because of the presence of oxygen the amounts of iron, silicon and boron that participate in the Fe—Si—B equilibrium are not likely to be precisely proportional to the total concentration of these elements in a sample as has been assumed in the construction of Fig. 1 and in the determination of the compositions of the ternary phases. The uncertainties in these compositions are larger than the errors in the chemical analyses.)

X-Ray data for $Fe_2Si_{0.4}B_{0.6}$ are given in Table 2. We did not succeed in indexing the powder photograph of this phase and attempts to prepare single crystals were also unsuccessful. $Fe_2Si_{0.4}B_{0.6}$ decomposes at temperatures ~1 100°C and above this temperature there exists a three-phase region $Fe_2B + Fe_5SiB_2 + \alpha$(Fe,Si).

The powder photograph of a $Fe_5SiB_2 + \alpha$(Fe,Si) alloy is given in Table 3 and by assuming Fe_5SiB_2 to possess the Cr_5B_3-structure (as does[6] Fe_5PB_2) good agreement between observed and calculated intensities is obtained. It seems probable that (similar to the situation in Mo_5SiB_2[4] and Fe_5PB_2[6]) the non-metal atoms are ordered in Fe_5SiB_2, the silicon atoms occupying the 4(*a*)-positions and the boron atoms the 8(*h*)-positions. The observed l.p. variations (Table 5) are compatible with the assumption that the homogeneity

Table 6. Composition and heat-treatment of samples prepared from the master alloys.

Sample	Composition	Heat-treatment	Observed phases
4	% Fe: 79.62 % Si: 16.82 $Fe_{4.856}Si_{2.043}B_{1.060}$ % B: 3.18 Σ *: 99.62	arc-melted	$Fe_{4.86}Si_2B$ (and perhaps a trace of α(Fe,Si))
5	% Fe: 83.60 % Si: 8.54 $Fe_{4.923}Si_{1.001}B_{2.000}$ % B: 6.58 Σ *: 98.72	arc-melted, annealed in evacuated tubes for three days at 1 060°C	Fe_5SiB_2 and a small amount of $Fe_{4.86}Si_2B$. The ratio $Fe_{4.86}Si_2B/Fe_5SiB_2$ is estimated to be not greater than 1/99.
6	% Fe: 84.04 % Si: 8.51 $Fe_{5.152}Si_{1.038}B_{2.000}$ % B: 6.32 Σ *: 98.87	as sample 5	Fe_5SiB_2 + small amounts of α(Fe,Si)
8	% Fe: 85.65 % Si: 8.19 $Fe_{2.000}Si_{0.381}B_{0.607}$ % B: 5.03 Σ *: 98.87	sintered in evacuated silica tubes for 11 days at 1 050°	$Fe_2Si_{0.4}B_{0.6}$ + Fe_2B + + α(Fe,Si)
9	% Fe: 84.90 % Si: 9.27 $Fe_{4.000}Si_{0.435}B_{0.594}$ % B: 4.88 Σ *: 99.05	arc-melted, annealed in evacuated silica tubes for 8 days at 1 040°	$Fe_2Si_{0.4}B_{0.6}$ + α(Fe,Si)

* Samples prepared in exactly the same way as those above were analyzed to contain 0.1 weight % oxygen (arc-melted) to 0.5 weight % oxygen (arc-melted and annealed in silica tubes for 7—10 days), while the carbon content was found to be 0.02—0.03 weight % and the nitrogen content less than 0.001 %. We believe that the figures obtained for the oxygen content are too low (as was also found to be the case when different iron powders were analyzed) and that most of the impurity in the samples is oxygen.

range of Fe_5SiB_2 is associated with a B/Si substitution, the l.p. decreasing with increasing boron content. As the B/Si ratio in silicon-rich Fe_5SiB_2 (as determined from sample 5) is 2.05/1.00, this ratio is greater than 2.00 for all compositions of Fe_5SiB_2. This indicates that the boron atoms may substitute for a fraction of the silicon atoms in the 4(*a*)-positions (which correspond to anti-prismatic holes in the metal atom skeleton) whereas the 8(*h*)-positions (which correspond to smaller triangular prismatic holes in the metal atom skeleton) are only occupied by boron atoms over the whole homogeneity range. The composition of Fe_5SiB_2 may thus be represented by the formula $Fe_5Si_{1-x}B_{2+x}$ ($x \sim 0.0$—0.1).

The arc-melted sample 4 gave a powder photograph on which only the sharp lines originating from $Fe_{4.86}Si_2B$ were observed. As the oxygen content of this sample is very low, it is no doubt that the iron content of $Fe_{4.86}Si_2B$ is lower than that corresponding to the stoichiometric formula Fe_5Si_2B. As pointed out in the previous communication [1], the isomorphous phase $Co_{4.7}Si_2B$

also has a composition deviating from the ideal formula, depending on the fact that the metal position in 4(*b*) is only partially occupied. In Table 4 we have calculated the intensities for the Fe_xSi_2B phase (x = 4.67, 4.86, 5.00) assuming that the 4(*b*) position is occupied by iron atoms to 67, 86 and 100 %, respectively, and that the atomic parameters are the same in $Fe_{4.86}Si_2B$ as in $Co_{4.7}Si_2B$. The marked differences in the observed intensities of 110, 220, 211 and 400 for which $I_{110} << I_{400} < I_{211} < I_{220}$ is in good agreement with the intensities calculated for $Fe_{4.86}Si_2B$ but hardly with those calculated for $Fe_{4.67}Si_2B$ and Fe_5Si_2B. Thus, the X-ray data of $Fe_{4.86}Si_2B$ are not inconsistent with the assumption that the deviation from stoichiometry of this phase depends on the 4(*b*) positions being only partially occupied by iron-atoms. The observed l.p. variations of $Fe_{4.86}Si_2B$ (Table 5) indicates that the homogeneity range of $Fe_{4.86}Si_2B$ may mainly depend on a variation of the number of vacant 4(*b*) positions.

The Fe—Si—B system is of interest since it contains one representative for each of the three common Me_5Si_3 structure types, in which a number of transition metal silicides and silico-borides have been found to crystallize. These structure types are discussed in a recent review article [2] and, therefore, will not be commented on in this paper. It is noteworthy, however, that the variation in composition displayed by $Fe_5Si_3(B)$, Fe_5SiB_2 and $Fe_{4.86}Si_2B$ seems to have quite different causes. In $Fe_5Si_3(B)$ a varying number of boron atoms are interstitially dissolved in the iron-silicon skeleton, in Fe_5SiB_2 the extended homogeneity range is mainly associated with a B/Si substitution, while in $Fe_{4.86}Si_2B$ one of the iron positions is occupied to a varying degree.

The Mn—Si—B system. Our qualitative study of the Mn—Si—B system only aimed at seeing to which extent this system displays similarities to the more comprehensively investigated Fe—Si—B and Co—Si—B systems.

The metal-rich part of the Mn—Si—B system seems to be much more complicated than is the case in the Fe—Si—B and Co—Si—B systems. We found no Mn—Si—B phase isomorphous with $Fe_{4.86}Si_2B$ and $Co_{4.7}Si_2B$, but in alloys sintered at 900—1 000°C, a phase with the Cr_5B_3 structure was identified (Table 3) and this phase is tentatively denoted as Mn_5SiB_2.

The equilibria in the non-metal-rich part of the Mn—Si—B system are also different from those in the Fe—Si—B and Co—Si—B system. Thus, the boron-rich manganese borides Mn_3B_4 and MnB_2 seem to be in equilibrium with silicon, whereas in the other systems no boride is stable in the presence of silicon.

Acknowledgements. We wish to thank Professor G. Hägg for his kind interest in this work and for the facilities put at our disposal. We are also much indebted to the Head of the analytical department of this Institute, Dr. F. Nydahl, and to Dr. Lilly Gustafsson for her courtesy in carrying out the chemical analyses. We want to thank Dr. J. Baecklund and Mr. E. Gunnarsson at Avesta Jernverk for help with the oxygen, nitrogen and carbon analyses.

Many thanks are due to Miss B. Pettersson and Mr. S. Wahlgren for excellent technical assistance.

We sincerely acknowledge financial support from the *Air Force Office of Scientific Research and the Research and Development Command, United States Air Force,* through its European Office under Contract No. AF 61(052)—40 and from the *Swedish State Council of Technical Research.*

A Note on the Compositions and Crystal Structures of MnB_2, Mn_3Si, Mn_5Si_3 and $FeSi_2$

BERTIL ARONSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The existence of a manganese diboride, MnB_2, with the AlB_2-structure has been confirmed. Faint super-structure lines on the powder photographs of alloys containing Mn_3Si indicate that in this phase, as in Fe_3Si, some ordering of the silicon and metal atoms takes place at temperatures below 1 000°C. The reported crystal structures of Mn_5Si_3 and $FeSi_2$ have been confirmed and refined with single crystal data.

In connection with investigations on the Mn—Si—B and Fe—Si—B systems [1] some crystallographic studies of the binary phases MnB_2, Mn_3Si, Mn_5Si_3, and $FeSi_2$ were made. It was found appropriate to present the results (which are commented on in a recent review article [2]) in a separate paper.

EXPERIMENTAL

The alloys were prepared by arc-melting or sintering mixtures of the elements. The same chemicals were used as in the study [1] of the Mn—Si—B and Fe—Si—B systems, and the chemical analyses for silicon and boron were also carried out in the same way. Manganese was determined by the bismuthate method after the sample had been dissolved in HF + HNO_3, the hydrofluoric acid removed by evaporating with sulfuric acid, and the solution passed through a cadmium reductor. The accuracy of the manganese analyses is estimated to be ± 0.2 %.

Powder photographs were taken in cameras of the Guinier type with silicon (a = 5.4306 Å) as internal standard for the l.p. (lattice parameter) determinations. Single crystals of Mn_5Si_3 and $FeSi_2$ with cross-sections of about 0.02 mm were examined in a Weissenberg camera. The multiple film technique was used and the intensities were visually estimated. The atomic scattering factors were taken from the tables by Tomas and Umeda [3] (manganese, iron), Tomiie and Stam [4] (silicon) and Ibers [5] (boron). The final structure factors for Mn_5Si_3 were computed on the digital electronic computer BESK with a program devised by Åsbrink *et al.*[6] The scattering factors were approximated with the formula:

$$f_i = A_i \exp(-a_i/\lambda^2\sin^2\Theta) + B_i \exp(-b_i/\lambda^2\sin^2\Theta) + C_i \exp(-c_i/\lambda^2\sin^2\Theta) + D_i$$

On basis of the above mentioned structure factor tables, Appel [7] has calculated the following constants:

	A	B	C	a	b	c
Mn	8.630	9.427	6.744	0.345	3.724	26.541
Si	2.8315	6.8065	4.3870	0.3235	2.2965	51.770

The real part of the dispersion correction, (D_i in the above expression) for manganese was taken from the tables by Dauben and Templeton [8]. No corrections were made for extinction or absorption.

RESULTS

MnB_2. Arc-melted manganese-boron alloys with a boron content higher than 67 atom per cent gave a powder photograph that could be indexed with a small hexagonal cell. From the unit cell dimensions it was evident that the photograph originated from a phase isomorphous with AlB_2, and with this assumption excellent agreement between observed and calculated intensities was obtained (see Table 1). The l.p. of MnB_2, $a = 3.009$ Å, $c = 3.039$ Å, agree very well with those recently reported by Binder and Post [9] who found $a = 3.007$ Å and $c = 3.037$ Å. No variations greater than 0.05 % were observed for the l.p. of MnB_2 in alloys with compositions from $MnB_{1.7}$ to MnB_3, which indicates that the homogeneity range of MnB_2 is narrow. An alloy containing small amounts of Mn_3B_4 was analysed to contain 70.71 (± 0.15) % manganese and 28.12 (± 0.15) % boron most of the remainder very probably being oxygen. Thus, the atomic ratio B/Mn in this sample is 2.019/1.000, indicating that the composition of the manganese diboride is about $MnB_{2.05}$. However, if it is assumed that the oxygen present in the sample is bound to boron as B_2O_3, the composition of the manganese boride is found to correspond to the formula $MnB_{2.01}$, not significantly deviating from the stoichiometric formula $MnB_{2.00}$. Interatomic distances in MnB_2 are collected in Table 2.

Mn_3Si. The simple body-centered cubic structure of Mn_3Si was determined by Laves [10] who found the manganese and silicon atoms to be statistically distributed in the structure. The powder photographs of alloys sintered at 950°C and containing Mn_3Si and Mn_5Si_3 showed some faint lines the positions and intensities of which could be satisfactorily accounted for by assuming the atoms in Mn_3Si to be ordered. Thus, it seems very likely that, similar to the situation in Fe_3Si, the distribution of metal and silicon atoms in Mn_3Si becomes ordered at lower temperatures. The cube-edge of Mn_3Si as determined is this study is 5.722 Å (2 × 2.861) in reasonable agreement with the older values 2.85 Å[10] and 2.857 Å[11].

Mn_5Si_3. The approximate formula of Mn_5Si_3 was determined by Vogel and Bedarff [12] and was confirmed by Åmark *et al.*[11] who also solved the crystal

201	0.4145	0.4144	m	10.3	26.1

Table 2. Interatomic distances in MnB_2 (in Å).

Mn— 8Mn: 3.01(6), 3.04(2)	B—6Mn: 2.31(6)
—12B : 2.31(12)	—3B : 1.74(3)

structure of Mn_5Si_3. The chemical and X-ray analyses of two arc-melted alloys with compositions approximating to Mn_5Si_3 gave the following results

% Mn	% Si	Σ	atomic composition	observed phases	l.p. of Mn_5Si_3
76.61	22.15	98.76	$Mn_5Si_{2.83}$	Mn_5Si_3 and small amounts of Mn_3Si	$a = 6.910$ Å $c = 4.814$ Å
75.94	23.45	99.39	$Mn_5Si_{3.02}$	Mn_5Si_3 and traces (~ 1 %) of MnSi	$a = 6.910$ Å $c = 4.814$ Å

No l.p. variations could be observed for Mn_5Si_3, indicating that its homogeneity range is small. The results of the chemical analyses show that the composition closely corresponds to the stoichiometric formula.

The crystal structure of Mn_5Si_3 was refined from single crystal data. The space-group $P6_3/mcm$ derived by Åmark *et al.*[11] was confirmed and, starting with the atomic parameters given by these authors, the atomic parameters were refined from successive $\varrho_o(xz)$ and $\varrho_o(xz)$—$\varrho_c(xz)$ syntheses until the final back-shift corrections were less than half the standard deviation as estimated with Cruickshank's formula [18]. The final parameters are as follows:

4 Mn in 4(*d*)
6 Mn in 6(*g*) $x = 0.2358 \pm 0.0006$
6 Si in 6(*g*) $x = 0.5992 \pm 0.0015$

The final *R*-value for 51 observed *h*0*l*-reflexions was 8.0 % when an empirical isotropic temperature factor with $B = 0.34_0$ Å^2 had been applied. Observed and calculated structure factors are collected in Table 3 and interatomic distances are given in Table 4. In the last difference synthesis a negative region was observed at the silicon position, indicating that the scattering parameter of the atom in this position is slightly less (about 1 electron) than had been assumed. The experimental data, however, are hardly so accurate that this effect can be regarded as significant.

$FeSi_2$. Phragmén [14] has suggested a very simple structure for this phase, the homogeneity range of which does not include the stoichiometric composition. Phragmén's observations that $FeSi_2$ is tetragonal and that there is one formula unit in the elementary cell were corroborated. There are no systematic extinctions and thus the most symmetrical possible space-group is *P*4/*mmm*. During the refinement no evidence was found indicating that a space-group of lower symmetry should be chosen. The distribution of intensities showed that the structure proposed by Phragmén [13] was approximately correct and starting with his parameter for the silicon atom in 2(*h*) the $\varrho(xz)$ electron density projection was refined by successive F_o and F_o—F_c syntheses. The following atomic and scattering parameters were found for a crystal picked out of an alloy which contained $FeSi_2$ with the l.p. $a = 2.684$ and $c = 5.128$ Å.

	atomic par.	scattering par.
Fe(?) in 1(*a*)		24.0_5
2 Si in 2(*h*)	$z = 0.270_0$	14.0

The final R-value for the 33 observed $h0l$-reflexions was 7.4 % after an empirical isotropic temperature factor with $B = 0.40_3$ Å^2 had been applied. Interatomic distances are collected in Table 5. The scattering parameter of the atom in 1(a) is (probably significantly) less than 26/14 of that of the atom in 2(h). This indicates that the former position is not completely occupied by

Synthetic Aminosugar Derivatives as Potential Antimicrobials; N-Substituted Derivatives of 6-Amino-6-Deoxy-D-glucose Ethylene Dithioacetal

ALF WICKSTRØM and JENS KRISTIAN WOLD

Universitetets Farmasøytiske Institutt, Blindern-Oslo, Norway

A series of N-substituted derivatives of 6-amino-6-deoxy-D-glucose ethylene dithioacetal has been prepared and tested as antimicrobials.

The occurrence of aminosugars is a general characteristic of the structures of several antibiotics [1,2]. Recent developments in the chemistry of antibiotics, therefore, have stimulated the interest in synthetic aminosugar derivatives as potential antimicrobials.

In some of the antibiotics the aminogroup is found in position 3 of the sugar moiety in question. Thus, 3-amino-3-deoxy-D-ribose is the carbohydrate component of puromycin, and rare 3-dimethylamino-hexoses (desosamine, mycaminose) occur in the so-called macrolide antibiotics. Streptomycin is a well-known example of an antibiotic containing a 2-aminosugar (2-methylamino-2-deoxy-L-glucose) and an ω-aminosugar (6-amino-6-deoxy-D-glucose) occurs in the recently described antibiotic kanamycin [3].

Among these aminosugars constituting a part of the specific structure of antibiotics, 6-amino-6-deoxy-D-glucose is of interest because of the possibility of replacing its terminal primary aminogroup by a variety of amine components according to known synthetic methods [4]. The 6-amino-6-deoxy-D-glucose derivatives described in the present work have a tertiary aminogroup linked to carbon 6 and their reducing function blocked in a cyclic dithioacetal group, these features creating a structure which may be expected not to fit into the pattern of the general metabolism of D-glucose. In order to obtain some information about the possible antimicrobial effect of compounds possessing this structure only a short series of derivatives has been prepared, Table 1. One reason for choosing the ethylene dithioacetal group to block the reducing function was that derivatives of 1,3-dithiolane apparently have received some attention as fungicides [5].

The compounds listed in Table 1 were tested by the "agar cup" method against a selection of pathogenic bacterium strains (*Pseudomonas aeruginosa, Escherichia coli, Staphylococcus aureus, Streptococcus faecalis*) growing on 10 % peptone-free horse-blood agar, and found to be without antibacterial activity. The same substances were also tested against a selection of pathogenic fungus strains (*Candida albicans, Cryptococcus neoformans, Aspergillus flavus, Aspergillus niger, Trichophyton mentagrophytes*) using the same experimental technique (10 % peptone-free horse-blood agar containing 1 % of D-glucose). The results were in most cases completely negative as to antifungal activity. But two of the compounds of Table 1, A and C, were able at a high concentration (1 %) to inhibit the growth of the highly resistant fungus strains *Cryptococcus neoformans* and *Aspergillus niger*. Since the parent nitrogen-free sugar derivative, D-glucose ethylene dithioacetal [6], was inactive towards all the microorganisms tested, the observed activity of substances A and C (Table 1) should encourage further research on aminosugar derivatives of a structure corresponding to the pattern outlined in the present work.

The synthesis of each of the compounds listed in Table 1 was achieved by classical reactions using 5,6-anhydro-1,2-*iso*-propylidene-D-glucofuranose as starting material: after opening of the epoxide ring by various amines, the *iso*propylidene residue was removed under mild conditions and the resulting aminosugar (without isolation) condensed with ethane-1,2-dithiol. The starting material was prepared from 1,2-*iso*propylidene-D-glucofuranose obtainable either from 1,2-5,6-di-*iso*propylidene-D-glucofuranose or direct from D-glucose. The modification of the direct method [7] described in the experimental section gave in repeated experiments a satisfactory yield of pure 1,2-*iso*propylidene-D-glucofuranose.

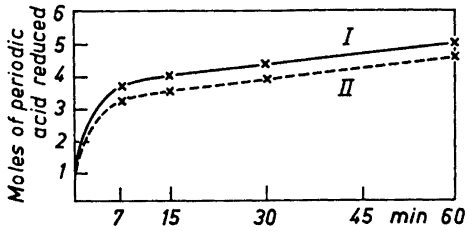

Fig. 1. Periodate uptake in acid solution of D-glucose ethylene dithioacetal, curve I, and of the corresponding 6-amino-6-deoxy-derivatives of Table 1, curve II. Curve II represents the arithmetic mean of the titrations of all four compounds of Table 1, the average deviation of a single measurement at each time interval being 1 % or less. Experimental conditions: 10^{-5} mole of each substance (1 ml) + 10^{-4} mole of sodium metaperiodate (10 ml) + 1 N sulphuric acid (5 ml). Periodate uptake by iodometry.

The opening of the epoxide ring of 5,6-anhydro-1,2-*iso*propylidene-D-glucofuranose by the various amines is, according to the theory [8], expected to proceed as a nucleophilic attack exclusively on carbon 6 and without inversion on carbon 5. Oxidation of the final products (of Table 1) with periodate gave results which tend to confirm that the aminogroup — as predicted by the general reaction mechanism — is located in position 6 of the sugar derivatives prepared.

In strongly acid solution α-amino-alcohols are oxidized by periodate at a considerably slower rate than the corresponding α-glycols [9]. A comparison between the oxidation in acid solution of D-glucose ethylene dithioacetal and the corresponding 6-aminoderivatives (of Table 1) gave results as shown in Fig. 1. The aminosugar derivatives consume about half a molecule of periodate less than the corresponding unsubstituted D-glucose mercaptal and, in contrast to the latter, they do not liberate formaldehyde at the end of one hour's oxidation (colorimetry with chromotropic acid [10]). These results are consistent with the expected effect of the replacement of the hydroxyl group on carbon 6 by an aminogroup, which is to render one carbon to carbon bond (C_6—C_5) more resistant towards periodate in acid solution. The periodate uptake (Fig. 1) is however, always higher than the quantity required to split the α-glycol groups of the compounds studied. A similar over-oxidation of non-cyclic sugar mercaptals has been observed previously [11].

EXPERIMENTAL

All melting points are micro melting points (Kofler's hot-stage microscope).

1. *1,2-Isopropylidene-D-glucofuranose.* D-Glucose (50 g) is shaken for 3—4 h with acetone (1 litre) containing concentrated sulphuric acid (40 ml). After filtration the reaction mixture is neutralized with sodium carbonate monohydrate (100 g) dissolved in water (200 ml). Solid material is removed by filtration and the filtrate concentrated at reduced pressure to 150—200 ml. The solution is heated to 60° and acidified by concentrated hydrochloric acid (about 0.5 ml); the colour of the solution changes from yellowish brown to brown upon acidification. One minute after the acid has been added the solution is cooled and extracted with chloroform (3 × 25 ml), which removes remaining diacetone-glucose and impurities. The colourless aqueous layer is neutralized to pH about 8

by means of a little sodium carbonate solution and then concentrated to dryness at a temperature below 40°. The residue is dried (15 mm Hg, P_2O_5) and then extracted with methanol (30°—40°) which on cooling gives crude, crystalline 1,2-*iso*propylidene-D-glucofuranose, m.p. 150°—160°, yield 50 %. Purification to m.p. 160—161°[7] by recrystallizations from light petroleum (b.p. 60°—80°).

2. *5,6-Anhydro-1,2-iso*propylidene-D-*glucofuranose.* 1,2-*Iso*propylidene-D-glucofuranose was tosylated[12,13] and the 6-tosyl-derivative (m.p. 106°) converted[14,15] into 5,6-anhydro-1,2-*iso*propylidene-D-glucofuranose (m.p. 133°—134°).

3. *Opening of the epoxide ring with amines.* 5,6-Anhydro-1,2-*iso*propylidene-D-glucofuranose (2×10^{-2} mole) dissolved in anhydrous methanol (75 ml) is poured into a solution of 4×10^{-2} mole of the amine in the same solvent (30 ml). Allow to react for half an hour and complete the reaction by smooth reflux for 2 h. The solvent and the majority of the unreacted amine are removed at reduced pressure below 50°. The residual syrups crystallize when kept in a vacuum over P_2O_5. The products were purified by recrystallization from light petroleum (b.p. 60°—80°). Yields 60 to 80 %. Melting points, optical rotations, and the results of potentiometric titration of the various N-substituted 6-amino-6-deoxy-1,2-*iso*propylidene-D-glucofuranoses are enumerated below; the parent amine in brackets: [1: (piperidine) 109—110°; $[\alpha]_D^{20} = +2.8°$ (chloroform, $c = 5$); 98,8 %. [2: (morpholine) 99.5°; $[\alpha]_D^{20} = +7.1°$ (water, $c = 5$); 99.4 %. [3: (pyrrolidine) 92—93°; $[\alpha]_D^{20} = +10.3°$ (water, $c = 5$); 98,0 %. [4. (dibenzylamine) 114—115°; $[\alpha]_D^{20} = +35.6°$ (chloroform, $c = 3.5$); 99.1 %.

The potentiometric titrations were carried out in aqueous solution except for the dibenzylamine derivative which was titrated with perchloric acid in a solution of acetic acid and dioxane.

Two of the four compounds listed above (Nos. 1 and 4) have been described previously by Ohle *et al.*[4]. The melting point (133°) and the optical rotation, $[\alpha]_D^{21} = +1.5°$ (chloroform, $c = 4.41$), attributed to 6-dibenzylamino-6-deoxy-1,2-*iso*propylidene-D-glucofuranose by these authors differ widely from the data recorded in the present work. The substance in question (No. 4) was therefore submitted to a degradation by periodate which gave results in complete agreement with the formula of 6-dibenzylamino-6-deoxy-1,2-*iso*propylidene-D-glucofuranose: In alcaline solution (pH 8) it reduced one molecule of periodate and gave rise to dibenzylamine (detected by paper chromatography) and a reducing compound which on chromatograms (solvent system: acetone, *n*-propanol, water 45:45:10 v/v)) could not be distinguished from 5-aldo-1,2-*iso*propylidene-D-xylofuranose[16] obtained by oxidation of 1,2-*iso*propylidene-D-glucofuranose by periodate (spots, $R_F^{20} = 0.83$, revealed by silver nitrate and ethanolic sodium hydroxide[17]). Further, after removal of the *iso*propylidene residue by mild hydrolysis, our dibenzylamine derivative reduced in acid solution one molecule of periodate less than D-glucose, as expected for an ω-amino-glucose.

4. *Conversion of the N-substituted derivatives of 6-amino-6-deoxy-1,2-iso*propylidene-D-*glucofuranose to the corresponding derivatives of 6-amino-6-deoxy-*D-*glucose ethylene dithioacetal.* Removal of the *iso*propylidene residue is achieved by hydrolysis at room temperature (controlled by paper chromatography): 2×10^{-2} mole of each of the products described above (3) are dissolved in 1 N hydrochloric acid (150 ml) and kept for three days. The hydrolysate is concentrated at reduced pressure (bath temperature below 30°) to 10—15 ml and then completely saturated with HCl gas under cooling in crushed ice. Ethane-1,2-dithiol (equimolecular quantity + 10 % excess) is then added and the mixture is shaken under continuous cooling until it becomes homogeneous. After standing for 2 h in the ice bath the faintly yellow solution is poured into water (100 ml) and left over night. The mixture is made weakly alkaline with 2 N sodium hydroxide and extracted with chloroform (4×200 ml). The combined chloroform extracts are dried (sodium sulphate) and concentrated to dryness at 20°. The partly crystalline residue is (after drying in vacuum over silica gel) recrystallized from benzene. The products are further purified by recrystallization from acetone-ether mixtures. Substance remaining in the mother liquids may be recovered by precipitation with light petroleum (b.p. 60°—80°). Yields are in the range of 50 % of the theoretical. Analysis and properties of the products are summarized in Table 1.

The microbiological tests were carried out at the Department of Bacteriology (head: Dr. Ole G. Clausen) at Universitetets farmasøytiske institutt, Oslo. The authors are indebted to Mr. E. Manser, E.T.H., Zürich, for performing the elementary micro analyses. Gratitude is also expressed to *Norges Almenvitenskapelige Forskningsråd* for the award of a Research Fellowship to one of us (J.K.W.).

Mechanical Losses of Polystyrenes with Different Molecular Weight Distributions

HILDING HÖGBERG,* STUART E. LOVELL, and JOHN D. FERRY

Department of Chemistry, University of Wisconsin, Madison, Wisconsin, U.S.A.

Dynamic mechanical measurements have been made on two polystyrene samples with sharp molecular weight distributions and one with a broad distribution, at temperatures and frequencies corresponding to the plateau zone where the mechanical losses pass through minima. The losses are calculated in terms of the loss compliance J'', loss modulus G'', and loss tangent tan δ. For the sharp distributions, the minima in G'' and tan δ increase in magnitude and shift to higher frequencies with decreasing molecular weight; the frequency dependences of all three loss functions agree approximately with the predictions of a new theory of Marvin, with the molecular weight between entanglement coupling points chosen as 24 000. The results for the broad distribution indicate that molecular weight heterogeneity increases tan δ and J'' but decreases G''.

It is well known that the viscoelastic properties of polymers depend strongly on molecular weight distribution in the terminal zone of the time scale, where transient measurements at long times or dynamic measurements at low frequencies reflect the slowest configurational rearrangements of flexible macromolecules [1,2]. Less attention has been devoted to the effects of molecular weight and molecular weight distribution in the plateau zone, where the mechanical properties of linear polymers are dominated by entanglement coupling and a consequent transient network structure [3–5].

In the plateau zone, so-called because the viscoelastic relaxation spectrum here can be approximated roughly by a plateau or box [6,7] (although in many cases this is a rather crude representation), the dynamic mechanical losses pass through minima. Qualitatively these arise because at lower frequencies large losses occur from the onset of entanglement slippage and flow deformation while at high frequencies large losses occur as the transition from rubberlike to glasslike consistency is approached. At intermediate frequencies, where the entanglements do not slip but between the entanglements the chains

* Telefonaktiebolaget L. M. Ericsson, Stockholm, Sweden.

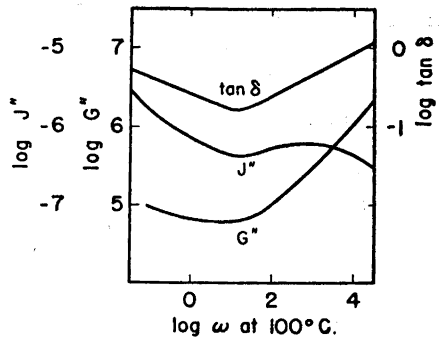

Fig. 1. Mechanical losses of poly-*n*-octyl methacrylate in the plateau zone, plotted logarithmically against radian frequency ω at 100°C. G'', loss modulus (dyne/cm²); J'', loss compliance (cm²/dyne); tan δ, loss tangent.

rearrange freely, the system partakes to a certain extent of the nature of an elastic network with relatively low loss.

The losses (associated with dissipation of heat in oscillating, sinusoidal mechanical deformation) can be described in various ways: [8] the loss modulus G'' or stress 90° out of phase with strain divided by strain; the loss compliance J'' or strain 90° out of phase with stress divided by stress; or the loss tangent tan δ, δ being the phase angle between stress and strain. Typical examples of these functions are shown in Fig. 1, for the plateau region of poly-*n*-octyl methacrylate.[9,10] Each shows a minimum on the frequency scale, though not at exactly the same location.

It is often supposed that mechanical properties in this region are insensitive to the molecular weight. However, the losses, especially tan δ, depend rather considerably on both molecular weight and molecular weight distribution. The present paper cites measurements on certain polystyrene samples and an interpretation in terms of a recent theory of Marvin [11] to illustrate this fact.

MATERIALS AND METHOD

Two polystyrene samples (S8 and S1160) of sharp molecular weight distribution were generously furnished by Dr. H. W. McCormick of Dow Chemical Company [12]. They had been prepared by anionic polymerization followed by terminating the chains with water. A third sample (19F), previously furnished also by Dow, had been prepared by conventional free radical polymerization procedures and presumably had a "most probable" distribution of molecular weights. The initial number and weight average molecular weights are given in Table 1.

For measurements of dynamic mechanical properties at low frequencies with the torsion pendulum apparatus of Plazek, Vrancken, and Berge [13], the samples were molded into discs. Those with the sharp distributions, furnished in finely divided form, were first sintered by heating *in vacuo* a few degrees above the softening point for several hours. Molding was performed in a press at about 100 lbs. per sq. in. at 150°C. Measurements of characteristic frequencies and decrements of free oscillations were made as described elsewhere [13] at temperatures between 125° and 160°C.

After completion of the measurements, borings were taken from the centers of the discs and their intrinsic viscosities were measured in methyl ethyl ketone. Viscosity-average molecular weights calculated therefrom [14] are given in the last column of Table 1, and indicate some but not excessive degradation during the molding and measurements. (Two other samples with sharp distributions and considerably higher molecular weights

Table 1. Initial number and weight-average molecular weights of polystyrene samples, and final viscosity-average molecular weights.

Sample	Initial $\overline{M}_n \times 10^{-3}$	Initial $\overline{M}_w \times 10^{-3}$	Final $\overline{M}_\eta \times 10^{-3}$
S8	159	171	135
S1160 ("60")	279	286	240
19F	190	370	276

were also studied, but experienced more serious degradation, probably because of the longer times necessary for molding; the final $\overline{M}_\eta$ was only about half the initial $\overline{M}_w$. The data from these samples are not reported.)

RESULTS

The measured characteristic frequencies and decrements were converted to the storage and loss moduli and compliances, G', G'', J', and J'', by well-known formulas [8,13]. Although the range of actual frequencies was only from about 0.4 to 7 cycles/sec., the effective range was increased by reducing the measurements at all temperatures to 125°C with the method of reduced variables [15]. The shift factors a_T were calculated from the equation of Williams, Landel, and Ferry [18] in the form

$$\log a_T \frac{9.82(T-T_0)}{91.6 + T-T_0} \tag{1}$$

with $T_0 = 125.0°$. The numerical coefficients here are derived from measurements by Grandine and Ferry [16], and fit quite well also the temperature dependence of stress relaxation data of Ninomiya and Fujita [17]. Logarithmic plots

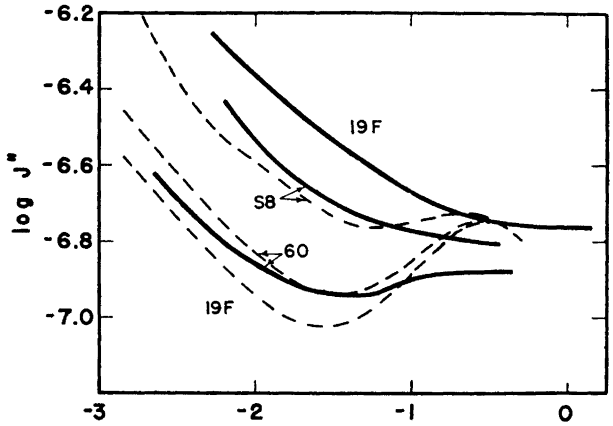

Fig. 2. Log J'' reduced to 125°C., plotted against log ωa_T for three polystyrene samples identified by numbers; "60" is S1160. Solid curves, experimental; dashed curves, calculated from Marvin theory.

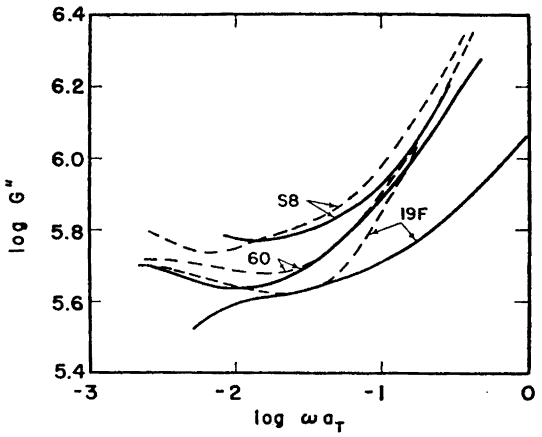

Fig. 3. Log G'' plotted as in Fig. 2.

of J' and J'' (multiplied by the usual temperature and density ratios [15]) against ωa_T gave excellent composite curves for each sample.

The storage compliance, J', ranged from 0.25 to 1 $\times$ 10^{-6}, decreasing monotonically with increasing frequency. To save space, only the loss functions J'', G'', and tan δ are presented here. Logarithmic plots (without points, to avoid confusion) are shown in Figs. 2, 3, and 4. Here ω is the radian frequency per second. The characteristic minima appear, and their dependence on mole-

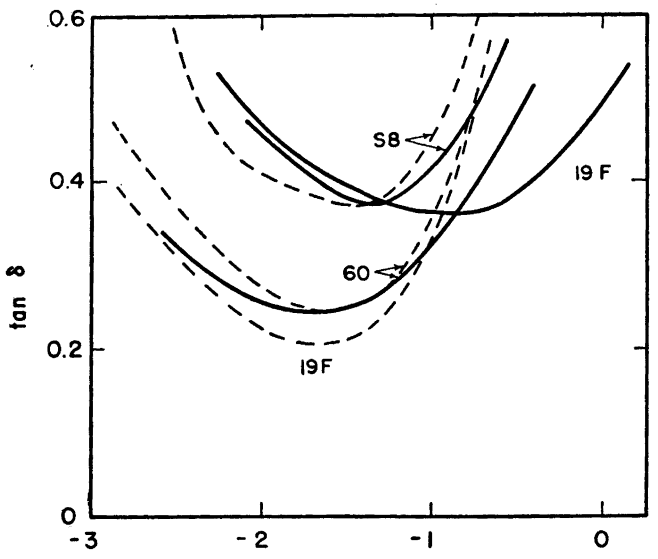

Fig. 4. Tan δ plotted as in Fig. 2.

cular weight and heterogeneity can be summarized as follows. The *loss compliance* increases with decreasing molecular weight and the minimum tends to shift to higher frequencies and disappear. Molecular weight heterogeneity increases the magnitude of J''. The *loss modulus* also increases with decreasing molecular weight, but the effect of heterogeneity is in the opposite direction. The *loss tangent* increases with decreasing molecular weight and the minimum shifts to higher frequencies. Heterogeneity also shifts the minimum to a higher magnitude and a higher frequency.

DISCUSSION

The effects illustrated here can be best interpreted with a very recent theory of Marvin [11], in which viscoelastic properties in the plateau region are described by two ladder network models in series. One ladder represents a mechanical model for the Rouse-Bueche molecular theory of a cross-linked polymer, corresponding to the motions of chain segments between entanglement coupling points as reflected in measurements at high frequencies; the other represents an uncross-linked polymer with a much higher internal friction coefficient, corresponding to long-range motions which are greatly retarded by the entanglements, as reflected in measurements at very low frequencies. The Marvin theory predicts the following frequency dependence for the storage and loss moduli, expressed in slightly modified form: [18]

$$G'_R + iG''_R = P_R^{1/2} \frac{\tanh P_R^{1/2} + Q_e^{1/2} \tanh R_e Q_e^{1/2} P_R^{1/2}}{1 + Q_e^{1/2} \tanh P_R^{1/2} \tanh R_e Q_e^{1/2} P_R^{1/2}} \qquad (2)$$

where $G'_R/G' = G''_R/G'' = 1/K_1$

$P_R = i\omega_R = i\omega K_2$

$Q_e = (M/2M_e)^{2.4}$

$R_e = M/2M_e - 1$

M_e = molecular weight between entanglement coupling points

The molecular interpretation of the parameters K_1 and K_2 will be mentioned later; they are both independent of M, but K_1 is inversely proportional to M_e. Aside from this, the reduced viscoelastic properties G'_R and G''_R (also J'_R and J''_R) are fully determined by the ratio $M/2M_e$, and tan δ as a function of ω_R is determined by this ratio *alone*. An important equalification is that both M and M_e are assumed to be devoid of heterogeneity.

To compare theory with experiment, M_e must be known. Estimates from different kinds of rheological information vary, ranging from 10 000 to 30 000 for polystyrene [19]. For the present purpose, utilization was made of the fact that the level of the minimum in tan δ, a quantity known experimentally with confidence, is a unique function of $M/2M_e$. Calculations of tan δ were made from eqn. (2) with a Bendix G-15D computer for various values of $M/2M_e$; the results near the minima are portrayed in Fig. 5. The level of the minimum

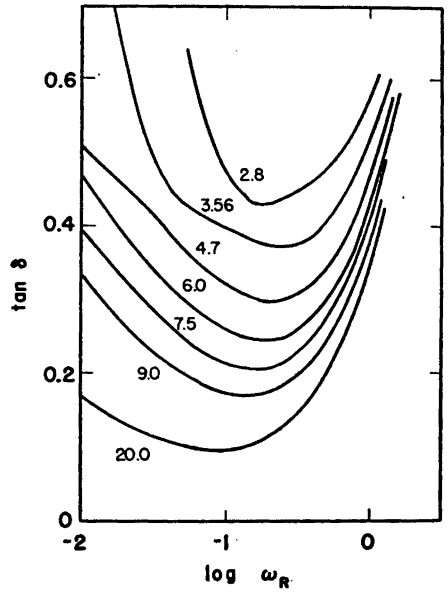

Fig. 5. Tan δ calculated from eqn. (2), plotted against log ω_R, for various values of $M/2M_e$ as indicated by numbers opposite the curves.

increases monotonically with decreasing M_e. In fact, over the range covered it can be represented very well by the following equation:

$$(\tan \delta)_{min} = 1.02(M/2M_e)^{-0.80} \quad (3)$$

Now, by substituting the experimental values for the minimum in eqn. (3), M_e can be calculated. If the weight-average values of M are used, M_e is found to be 24 100 and 23 800 for samples S8 and S1160, respectively. Accordingly, M_e was chosen as 24 000 and the functions G''_R, J''_R, and tan δ were calculated from eqn. (2) for the three experimental samples.

It may be remarked that eqn. (3) provides, in principle, a very simple method for determining molecular weights of any polymer for which M_e is known. The magnitude of tan δ can be easily measured by various experimental methods which do not require absolute calibration [20]. The serious limitation, of course, is the restriction to samples with sharp molecular weight distribution. Heterogeneity causes abnormally high values of tan δ at the minimum, as seen in Fig. 4 and also in the data for the two samples which experienced degradation and consequent heterogeneity, not reported here.

The value of K_2 associated with eqn. (2) was obtained by matching the calculated and experimental minima of tan δ on the logarithmic frequency scale, and was found to be 7.1 sec. To determine the remaining parameter K_1, logarithmic plots of J''_R and G''_R were matched to the corresponding experimental plots of J'' and G'' for the sharp samples S8 and S1160; the best concurrence was obtained for $K_1 = 10^{6.38}$ cm²/dyne. The theoretical predictions for J'', G'', and tan δ as specified by these parameters are drawn in Figs. 2 to 4 as dashed curves.

For the two sharp samples, the respective theoretical and experimental functions agree rather well in shape, supporting the validity of the theory of Marvin as an approximate description of the viscoelastic properties in the plateau zone. For 19F, with a broad molecular weight distribution, the theoretical and experimental functions diverge widely. Of course, the use of $\bar{M}_w$ for M in eqn. (2) for this sample is arbitrary and in a sense meaningless. If $\bar{M}_z$ had been used, the calculated curves would be close to those for S8. In either case, the observed loss compliance is greater than that calculated, while the observed loss modulus is smaller. It appears that viscoelastic measurements in this region could potentially yield information about molecular weight distribution; they have experimental advantages over measurements in the terminal zone, which have previously been explored for this purpose [1,21], but require higher temperatures and/or longer times.

The parameter K_1 has been identified in molecular terms [11,18] as a constant of the order of $\varrho RT/M_e$, where ϱ is the polymer density in g/cc. The value given above corresponds to 1.75 $\varrho RT/M_e$, in reasonable agreement. The parameter K_2 is related to the mobility of short molecular segments. One method of formulating it in molecular terms based on the Rouse theory [18] gives $K_2 = 3a^2 \zeta_0 M_e^2/50 M_0^2 kT$, where a is a characteristic monomeric length, M_0 is the molecular weight of a monomer unit, and ζ_0 is the translational friction coefficient per monomer unit. Substitution of the value of K_2 given above provides $\log \zeta_0 = -1.65$ at 125°C (units dyne-sec/cm.) An independent calculation made from stress relaxation measurements of Fujita and Ninomiya on polystyrene [17] gives $\log \zeta_0 = -2.18$. Considering the widely different sources of information, this represents fair agreement. It may be concluded, therefore, that the Marvin theory provides a semiquantitative description not only of the relative frequency dependence of the viscoelastic losses but also of the parameters which specify their magnitudes and their positions on the frequency scale.

Relaxation (H) and retardation (L) spectra were also calculated from the frequency dependence of G'' and J'', and of the associated storage components G' and J', using customary approximation methods [10]. In each case, the agreement between calculations from the storage and loss components was very satisfactory. The spectra H and L show minima similar to those in G'' and J'' respectively, but shallower; over the limited range of time scale available, they do not provide enough additional information to warrant reproduction here.

Some conclusions qualitatively similar to those presented here were reported very recently by Cox, Isaksen, and Merz.[22]

An Electrophoretic Investigation of the Degradation of α-Casein by Means of Pepsin and Trypsin

BÖRJE LINDQVIST and TORSTEN STORGÅRDS

The Central Laboratory of Mjölkcentralen, Stockholm, Sweden

Pepsin and trypsin degrade α-casein in completely different ways. If this process (the tertiary phase) is followed by electrophoresis and by the increase of nonprotein nitrogen (NPN), it is then found that pepsin and the previously studied rennin behave similarly in certain respects. Of these three enzymes rennin attacks the α-casein structure more specifically than pepsin and the latter in its turn more specifically than trypsin. The changes in the mobilities of the degradation products which can be observed during the process are different for different pH-values in the reaction mixture. In the pepsin investigations, the changes in the mobilities were proportional to the logarithm of the time. With trypsin, an electrophoresis pattern is obtained, after a few hours, which does not then change character throughout the rest of the experiment. The peaks decrease in height but they do not move or split up into several separate peaks. In the degradation experiments using pepsin, it was found that log NPN is proportional to log time. With trypsin, the process is however more complicated.

In a previous investigation in this series [1] it was shown that the degradation of α-casein by rennin follows completely different paths for different pH-values in the reaction mixture. A similar effect has also been shown for the system β-casein — rennin [7].

In the present investigation, the work has been extended to include in addition α-casein — pepsin and α-casein — trypsin. Pepsin is of interest because of its physiological relationship to rennin. Trypsin was studied because of its ability to break certain known peptide bonds in the protein molecule [4]. For this reason, it may be possible eventually to use the results from the α-casein — trypsin investigations as a standard for judging the specific ability of other enzymes to degrade α-casein.

The action of pepsin on α-casein has been studied by several investigators. Groves and co-workers [2] have, for example, investigated phosphorus peptones which were formed as final products from the attack of pepsin on casein. Zittle and Cerbulius [3] have studied the coagulation of casein with pepsin and inves-

tigated the peptides formed during the so-called primary phase from, amongst other things, α-casein.

The action of trypsin on α-casein has been studied by Christensen [5] by means of viscosity measurements and NPN investigations. Lembke and Kaufmann [6] have investigated the effect of trypsin on total casein by means of electrophoresis. The conclusions which they have drawn concerning the changes in the α- and β-casein peaks upon electrophoresis cannot be considered to be without objection if one takes into account the very large changes in the position of the degradation products relative to the position of the starting substance which has afterwards been observed for β-casein [7].

In all of these investigations, only the degradation process occurring during the primary phase or at the end of the tertiary phase of the casein decomposition was studied while the main process occurring in the tertiary phase has not been touched at all. Just as in the investigation of the effect of rennin on α-casein, the present investigation deals with the process occurring during the whole of the tertiary phase.

EXPERIMENTAL

Casein. The same α-casein sample was used as in the previous investigation. The casein was stored in a tightly closed vessel containing silica gel. A check on the electrophoretic properties of the sample showed that it was completely unchanged at the time at which the investigations were performed.

Enzymes. Pepsin, twice crystallized, was prepared from a commercial product with an activity of 1:10 000 according to Northrop's method [8].

Trypsin, twice crystallized, with 50 % $MgSO_4$ from the Nutritional Biochemicals Corporation was employed.

Procedure and Analyses. In the preparation of the substrate and enzyme solutions as well as in the mixing of these solutions, the same procedure was used as in the previous investigation. This means, in brief, that a 4 % sodium caseinate solution was mixed with a NaCl-phosphate buffer solution containing the enzyme sample in question in such a way that the final solution was 3 % with respect to casein and had at the same time the desired pH-value. The NaCl, phosphate and enzyme concentrations were likewise automatically given the desired values. Upon mixing, the casein coagulates and thus many mixtures containing a suitable amount for one analysis of the type in question must be made. In order to perform the analysis, the whole of the content of the tube was then used.

Certain limits were applied to the experimental conditions, *viz.* the pH interval in the pepsin investigations was 4.6—5.7 and in the trypsin one 5.1—6.3. The enzyme activity of the pepsin was adjusted so that, when measured according to Berridge's method for the determination of rennin activity, it corresponded to 400 Ru/l reaction mixture. The activity of the trypsin could not be determined in this way since a calcium caseinate sol is not coagulated, but rather dissolved, by trypsin. Instead, an amount of pure trypsin was weighed out which corresponded to the amount by weight of rennin which upon solution gave 400 Ru/l, *viz.* 5 mg/l.

The nature and the extent of the analyses were the same as in the previous work, with the exception that the pepsin experiments were allowed to run for 15—36 days and the trypsin experiments for about 12 days.

RESULTS AND DISCUSSION

A. Formation of soluble nitrogen (NPN)

The NPN values of the reaction mixtures after various times are shown in Figs. 1 and 2. A comparison with the previously performed investigations

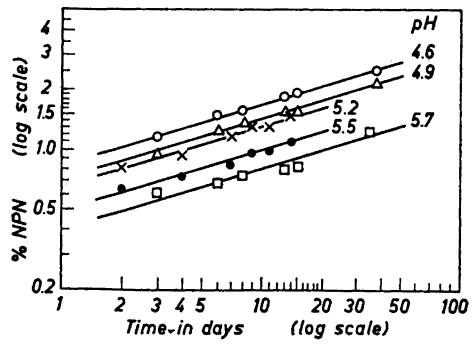

Fig. 1. Release of NPN, as a function of time, from α-casein due to the influence of pepsin. Reaction rate at different pH-values plotted using log NPN and log time scales.

on the properties of rennin shows that the NPN formation occurs in a different way. The reaction for the degradation of both α-casein and β-casein by rennin follows the empirical expression

$$\text{NPN} = k_1 \log \text{time} + C_1$$

For pepsin — α-casein, it was found on the other hand that

$$\log \text{NPN} = k_2 \log \text{time} + C_2$$

where k and C are constants.

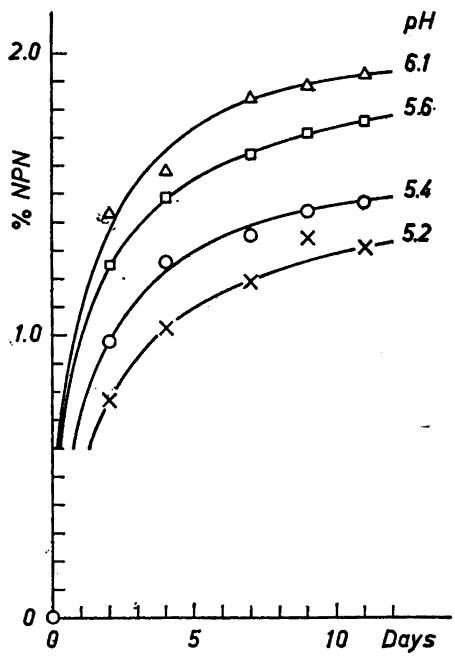

Fig. 2. Release of NPN, as a function of time, from α-casein due to the influence of trypsin. Reaction rate at different pH-values plotted using linear scales.

Table 1. Constants in the equations for the formation of NPN from α-casein.
Rennin: % NPN = k_1 log time + C_1
Pepsin: log % NPN = k_2 log time + C_2

pH	Rennin				Pepsin	
	α-casein		β-casein *		α-casein	
	k_1	C_1	k_1	C_1	k_2	C_2
4.21	1.73	0.42				
4.48	1.84	0.44				
4.6					0.306	−0.07
4.9					0.306	−0.14
5.2					0.306	−0.17
5.21	1.36	0.33	0.29	0.26		
5.45	0.98	0.23				
5.5					0.306	−0.30
5.7					0.306	−0.40
5.75	0.75	0.18				
6.4	0.45	0.11				
6.7	0.36	0.09				
7.0	0.23	0.05				

* The constants apply, approximately, for all pH-values within the interval investigated.

For trypsin — α-casein, the relationship was even more complicated. No simple transformations could be found which could make the experimental values fall on straight lines as in Fig. 1.

In Table 1, the values of the constants have been collected for several cases hitherto investigated for which calculations could be performed. It should be pointed out that the differences in NPN amounts in the cases, α-casein — rennin, α-casein — pepsin, and α-casein — trypsin, are not especially large despite the differences in the respective processes. It is of interest to compare these results with NPN determinations performed on ripening hard cheeses [9]. The casein degradation which occurs in that case is caused by rennin together with different bacterial enzymes that are formed successively. The process leads to higher NPN values and the formation follows the same mathematical expression as given above for the action of pepsin on α-casein.

B. Electrophoretic investigations

A total of about 60 electrophoretic results were obtained from each of the investigations on pepsin and trypsin. The calculation of the results has been performed in such a way that the differences caused by pH and time appear most noticeably. The results from the pepsin experiments resemble in several respects those obtained from the experiments with α-casein — rennin. The trypsin results are quite different.

The main features of the results obtained are as follows:

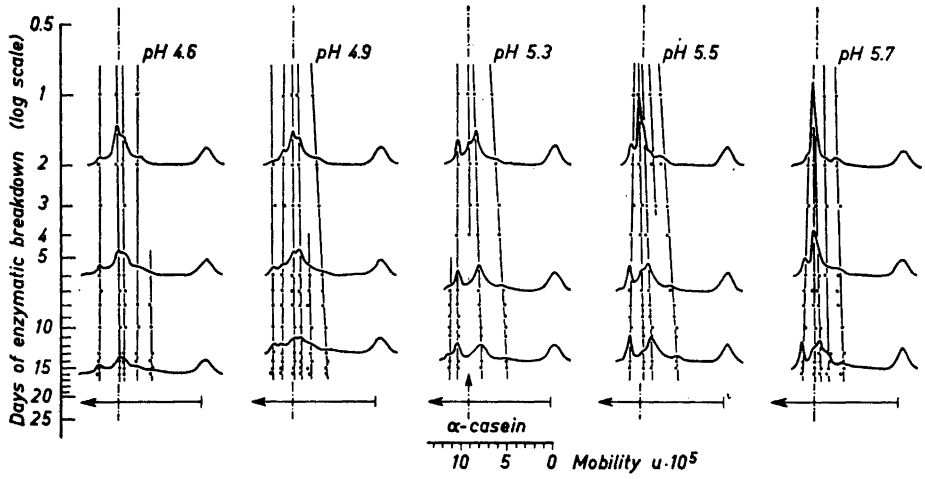

Fig. 3. Summary of the changes in the electrophoresis curves obtained during the degradation of α-casein by pepsin at different pH-values. The changes in mobility are shown by the vertical lines which pass through the points for the mobility of certain peaks in the curves. (To save space, only some of the curves have been drawn in, the positions of peaks in opposite case being marked only with points corresponding to the mobility of the peak). The time scale is logarithmic.

Pepsin experiments. Fig. 3 shows the degradation process occurring in these experiments for different pH-values. The conclusions which can be drawn are:

1) With pepsin, electrophoresis curves of a flatter and more diffuse appearance than with rennin were obtained. This indicates a weakly selective attack on the α-casein molecule.

Instead of getting, as is the case with rennin, a small number of sharp electrophoretic peaks, each of which probably consisting of individual molecules, there is obtained with pepsin a main peptide in each electrophoretic peak together with a large number of other peptides lying close to it.

2) Because of the spreading of these peptides, with respect to their electrophoretic mobilities, around the main substance, the mean mobility of each peak in the electrophoretic diagram will be somewhat different from the corresponding one in the rennin experiments.

3) The difference in mobility of the substances split off from the α-casein was found as previously observed with several corresponding enzyme-substrate systems, *viz.* from a primary component with a certain mobility, various substances with higher and lower mobilities than that of the primary component are obtained. These reaction products are then degraded further, either as just described by cleavage or by a splitting off of dialysable peptides only which outwardly produce a decrease or increase of the mobility as the only effect. Whether a decrease or increase occurs depends on whether mainly

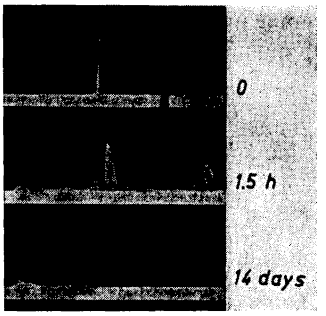

Fig. 4. Electrophoresis diagrams from the degradation of α-casein by trypsin at pH 5.6. Immediately after the start of the experiments, a certain shape for the curve is obtained which remains unchanged throughout the whole of the experiments.

acid or mainly basic amino acids are split off in the form of oligopeptides or as free amino acids.

In the α-casein — pepsin experiments, the mobility changes linearly with log time while, in the α-casein — rennin experiments, the corresponding process was not linear, the various parts of the main processes occurring at different rates, each ebbing out at different times. A process which is linear within a limited time interval should indicate that the degradation process occurs rather independently of the amino acid sequence of the secondary products.

The conclusions which can be drawn from this work is that both the pepsin and the rennin attack α-casein at about the same points in the molecule. While the attack of the rennin is, at least in the beginning, absolutely specific, the pepsin attack occurs rather unspecifically right from the beginning of the process. The tendency towards a more general attack on the molecule increases with increasing degree of degradation of the peptide complex.

The trypsin experiments. A characteristic property for the trypsin is that the degradation products from α-casein are very similar from an electrophoretic point of view, independent of the pH during the reaction. As appears from Fig. 4, the characteristic shape of the curve is obtained within 1.5 h after the start of the experiment and thereafter retains its main features for 14 days, even if the height of the curve has then decreased somewhat. The electrophoresis curve can be described as consisting of one single main peak at the α_{a2} position [1], *i.e.* the mobility of the peak is smaller than that of the α-casein.

Judging by the shape of the curve, there are several components which make up the peak. It is only in exceptional cases that the mobilities of these components have such values that the resulting peak is markedly unsymmetrical or gets a shape differing from the normal distribution curve.

Besides this main peak, there are negligible amounts of components with high and low mobilities. In the electrophoretic diagram, one can observe amongst them a slight majority of very quickly moving substances over those with medium or low mobilities.

The electrophoresis curve does not belie the statement that trypsin splits the protein with a certain selectivity. However, if the attack of rennin on α-casein is compared with the trypsin attack studied here, then it is seen that

the rennin attack is far more specific, expecially in the early stages of the degradation. It is true that the rennin gives eventually rise to several peaks with quite different speeds, in contrast to trypsin's single peak, but on the other hand these more spread-out peaks are much more uniform.

If therefore, when comparing rennin and trypsin, we neglect any possible difference in the total number of components formed, it is nevertheless evident that the following differences in behaviour can be demonstrated:

Rennin gives a few, electrophoretically well-defined substances of about equal amounts with a certain spreading in the mobility values.

Trypsin gives a few, electrophoretically less well-defined substances with a negligible spreading in the mobility values. In addition and in contrast to rennin, trypsin gives small amounts of substances with a considerable spreading in mobility values.

Short Communications

Myrosin-Catalyzed Formation of Turbidity and Hydrogen Sulfide from Sinigrin

SIGMUND SCHWIMMER*

Organic Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark and Western Regional Research Laboratory Albany, California, USA **

Recent investigations have demonstrated the formation of thiocyanate ion [1,2] and organic thiocyanates from S-glucosyl-thiohydroximyl sulfates (*iso*thiocyanate glucosides), separation of the sulfatase and thioglucosidase functions of myrosin [4], as well as the stimulation of the myrosin action by ascorbic acid [5]. These observations demonstrate that the fate of these thioglucosides can be enzymatically more diverse than that of a simple thioglucosidase action accompanied by Lossen rearrangement with concomitant sulfate displacement and formation of *iso*thiocyanates [6]. The present paper presents hitherto unreported observations which suggest that both the pathway as well as the rate of degradation of these thiohydroximyl sulfates are dependent upon the pH of the medium and upon the presence of foreign protein and ascorbic acid.

A myrosin-sinigrin reaction mixture develops a turbidity at pH 3.0 (glycine-HCl or HCl) (but not at pH 4 or above) which increases with time until a maximum value is reached (Fig. 1). The results

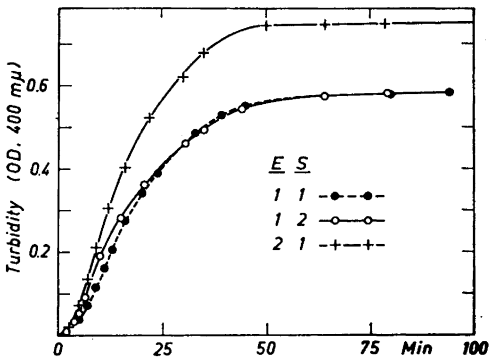

Fig. 1. Development of turbidity in a sinigrin-myrosin reaction mixture at pH 3.0 (0.033 M glycine-HCl). Six ml of reaction mixture at 25° contained 10 μmoles of sinigrin (S = 1) and 1 mg of myrosin (E = 1). Myrosin was prepared by lyophilization of the precipitate obtained from the dialyzed protein fraction (of a water extract of ground black mustard seed) precipitating between 30 and 70 % ethanol. Turbidity measured as optical density at 400 mμ using an Evelyn Colorimeter.

of Fig. 1 show that doubling the enzyme concentration caused an increase in both the rate and the extent of the development of the turbidity, whereas doubling the substrate concentration did not affect these parameters to any appreciable extent. The turbidity did not develop in the absence of substrate at this pH, nor in the presence of glucose, $KHSO_4$ and allyl *iso*thiocyanate added in amounts equivalent to that of the initial substrate. Nor did this turbidity develop when these end-products were added to sinigrin in the absence of enzyme at this pH. Furthermore, when the myrosin was incubated with sinigrin at pH 5.8 (acetate buffer) at 37° for one hour, or at pH 2.1 for 10 min. no turbidity developed after the pH was adjusted to 3.0.

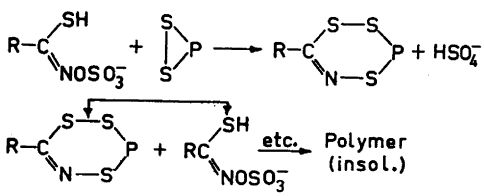
* Senior Post-doctoral Fellow, National Science Foundation, 1958—1959.

** A Laboratory of the Western Utilization Research and Development Division, Agricultural Research Service, U.S. Department of Agriculture.

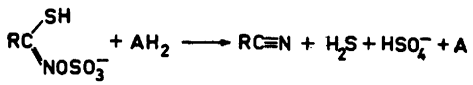
When centrifuged at 100 000 × *g*, a large proportion but not all of the turbid material sedimented. The precipitate gave a positive biuret test (protein) and a negative Molisch test (carbohydrate) whereas the supernatant fraction gave a strong positive Molisch and a much decreased positive biuret reaction. The UV absorption spectrum of the supernatant liquid exhibited no supplementary absorbency at 280 mμ in the background turbidity absorption as one might expect if residual protein had remained in solution.

In corroboration of the observations of Nagashima and Uchiyama [5], ascorbic acid was found to increase the rate of liberation of glucose and the formation of *iso*thiocyanate at pH 5.8 At pH 3.0, in the presence of ascorbic acid in concentrations equivalent to that of the substrate, immediate evolution of hydrogen sulfide (detected by odor and with lead acetate paper) concomitant with the development of turbidity was observed. Exactly the same conditions which were previously observed to produce turbidity also produced hydrogen sulfide in the presence of ascorbic acid. Additional controls in which ascorbic acid was added after extended reaction time at both pH 5.8 and at pH 3.0, did not evolve hydrogen sulfide. A modification of the test for nitriles of Soloway and Lipschitz [7] showed that nitrile was present in an enzyme reaction mixture containing ascorbic acid at pH 3.0 but not at pH 5.8.

Inasmuch as the turbidity appears to rise as the results of insolubilization of the protein of the myrosin preparation during its action and since the existence of a thiol intermediate as a distinct entity at pH 3.0 appears to be likely in view of the above-mentioned findings of Gaines and Goering , it is suggested that at pH 3.0 this intermediate can react with the protein (P) of the myrosin preparation, possibly *via* a chain type sulfhydryl-disulfide interchange as discussed recently by Jansen [8]:



whereas in the presence of ascorbic acid (AH_2), this intermediate decomposes to hydrogen sulfide and nitrile.



Thus the appearance of nitriles in the myrosin-thioglucoside digests, frequently reported in the literature and outlined, *e.g.*, by Kjær [9], may have arisen as the result of the presence of ascorbic acid in unbuffered crude digests. The interpretation of the results herein obtained may reconcile the apparently contradictory conclusions by Nagashima and Uchiyama [5] and those of Gaines and Goering [4]. The former authors concluded that only one enzyme, a thioglucosidase, is present in myrosin preparations, since application of a variety of fractionation procedures and environmental conditions (including low pH-values) yielded a glucose → sulfate ratio of unity. On the other hand, Gaines and Goering [4] have recently presented convincing evidence that myrosin can indeed be separated into two distinct enzymes, an oxime sulfatase and a thioglucosidase and that only the latter acts appreciably on sinigrin at pH 3.0. According to the postulated mechanism of action of myrosin presented herein, a highly purified preparation containing both enzymes but very little foreign protein would liberate and accumulate only glucose and the above mentioned 3-butenyl thiohydroximyl sulfate at pH 3.0 In relatively crude myrosin preparations, this intermediate reacts with the protein impurities as depicted thus liberating inorganic sulfate non-enzymatically.

Detection of nitrile. Both acrylonitrile (the next lower homologue of the postulated end product, vinylacetonitrile) and sinigrin, but not allyl *iso*thiocyanate, reacted positively in the absence of aqueous solvent as described by Soloway and Lipschitz (Procedure II) [7]. Under conditions of the enzyme reaction, in aqueous solution, a brown color developed after boiling for 4 min. in the presence of hydroxylamine, KOH, and propylene glycol when acrylonitrile was present. No color developed in the presence of sinigrin under the same conditions. Upon the subsequent addition of the $FeCl_3$ reagent, the nitrile containing sample developed a muddy brown color. A

sample from the prolonged digestion of sinigrin by myrosin in the presence of ascorbic acid at pH 3.0 gave a positive modified nitrile test, whereas a positive test for neither nitrile nor sinigrin was observed with a sample from a similar enzyme digestion conducted at pH 5.8.

The author wishes to thank Prof. A. Kjær for his encouragement and advice.

Further Observations on the Immunologic Reactions of the Old Yellow Enzyme

STEN KISTNER

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The OYE* and its apoprotein were found to react identically with specific antibodies against the enzyme in agar gel diffusion experiments [1]. The antiserum inhibited the enzymatic activity [2], but no influence was noticed upon the association reaction between the apoprotein and the coenzyme FMN which was studied by fluorimetric technique. The inhibition was non-competitive with regard to the substrate TPNH. These results indicate that the antibodies are bound to other parts of the enzyme molecule than the coenzyme or the substrate.

Atabrine and promazines have been found to inhibit the activity of the OYE after preincubation with the apoprotein [3]. Fluorimetric studies showed that the inhibitors did not prevent the binding of FMN to the apoprotein but slowed down the rate of this reaction. It is suggested that the inhibitors are bound to the apoprotein molecule close to the sites of the FMN. The two different types of inhibitors, drugs and antibodies, thus seemed to exert their effect on different parts of the enzyme molecule. The inhibition studies did not allow any conclusions, however, as to whether the drugs are exclusively bound to sites where they interfere with the coupling of the coenzyme, or whether they affect other parts of the enzyme molecule as well.

In the present work the inhibition of the OYE by anti-serum has been studied at different FMN concentrations. The quantitative precipitation reactions of the OYE and its apoprotein with antibodies, and the influence of atabrine upon these reactions, has been investigated. The effect of the promazines could not be studied, since it was found that precipitation occurred upon mixing promazine or chlorpromazine with rabbit serum.

Materials and methods. The OYE used had been recrystallized once, and the apoprotein was obtained from the same preparation. Immunization with OYE and collection of serum was carried out as described before [1]. The manometric technique used for the inhibition studies has already been described in detail [3]. Quantitative precipitin reactions were performed after the serum had been inactivated at +56°C for 20 min. Varying amounts of antigen in 0.3 ml 0.15 M sodium phosphate buffer pH 7.4 were added to 0.25 ml serum and incubation performed at +37°C for 30 min, followed by 24 h at +4°. After being washed several times in buffer and distilled water, the precipitates were dissolved in 0.3 ml 1 N NaOH and the protein content determined according to Lowry *et al.* [4] The absorption values were compared to those of a bovine serum albumin (Armour) standard. In some experiments antigen solutions containing 0.25 mg OYE or apoprotein per ml were incubated with 2×10^{-4} M atabrine at +37°C for 30 min before being added to the serum. The concentration of atabrine in the antigen-serum mixture was 1.1×10^{-4} M.

* Abbreviations: OYE = old yellow enzyme, FMN = flavin mononucleotide, TPNH = reduced triphosphopyridine nucleotide.

sample from the prolonged digestion of sinigrin by myrosin in the presence of ascorbic acid at pH 3.0 gave a positive modified nitrile test, whereas a positive test for neither nitrile nor sinigrin was observed with a sample from a similar enzyme digestion conducted at pH 5.8.

Further Observations on the Immunologic Reactions of the Old Yellow Enzyme

STEN KISTNER

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The OYE* and its apoprotein were found to react identically with specific antibodies against the enzyme in agar gel diffusion experiments [1]. The antiserum inhibited the enzymatic activity [2], but no influence was noticed upon the association reaction between the apoprotein and the coenzyme FMN which was studied by fluorimetric technique. The inhibition was non-competitive with regard to the substrate TPNH. These results indicate that the antibodies are bound to other parts of the enzyme molecule than the coenzyme or the substrate.

Atabrine and promazines have been found to inhibit the activity of the OYE after preincubation with the apoprotein [3]. Fluorimetric studies showed that the inhibitors did not prevent the binding of FMN to the apoprotein but slowed down the rate of this reaction. It is suggested that the inhibitors are bound to the apoprotein molecule close to the sites of the FMN. The two different types of inhibitors, drugs and antibodies, thus seemed to exert their effect on different parts of the enzyme molecule. The inhibition studies did not allow any conclusions, however, as to whether the drugs are exclusively bound to sites where they interfere with the coupling of the coenzyme, or whether they affect other parts of the enzyme molecule as well.

In the present work the inhibition of the OYE by anti-serum has been studied at different FMN concentrations. The quantitative precipitation reactions of the OYE and its apoprotein with antibodies, and the influence of atabrine upon these reactions, has been investigated. The effect of the promazines could not be studied, since it was found that precipitation occurred upon mixing promazine or chlorpromazine with rabbit serum.

Materials and methods. The OYE used had been recrystallized once, and the apoprotein was obtained from the same preparation. Immunization with OYE and collection of serum was carried out as described before [1]. The manometric technique used for the inhibition studies has already been described in detail [3]. Quantitative precipitin reactions were performed after the serum had been inactivated at +56°C for 20 min. Varying amounts of antigen in 0.3 ml 0.15 M sodium phosphate buffer pH 7.4 were added to 0.25 ml serum and incubation performed at +37°C for 30 min, followed by 24 h at +4°. After being washed several times in buffer and distilled water, the precipitates were dissolved in 0.3 ml 1 N NaOH and the protein content determined according to Lowry *et al.* [4] The absorption values were compared to those of a bovine serum albumin (Armour) standard. In some experiments antigen solutions containing 0.25 mg OYE or apoprotein per ml were incubated with 2×10^{-4} M atabrine at +37°C for 30 min before being added to the serum. The concentration of atabrine in the antigen-serum mixture was 1.1×10^{-4} M.

* Abbreviations: OYE = old yellow enzyme, FMN = flavin mononucleotide, TPNH = reduced triphosphopyridine nucleotide.

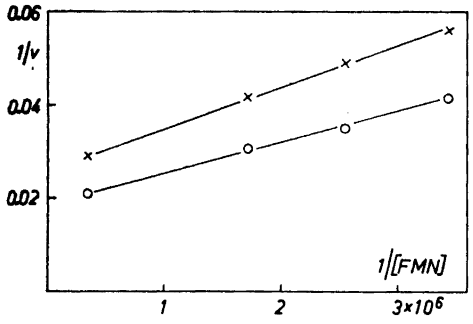

Fig. 1. The inhibition of the OYE activity by antiserum at different concentrations of FMN, measured by Warburg technique. Along the ordinate $1/v$ is marked, where v means the oxygen uptake during 30 min. The total volume of the reaction mixture was 3.0 ml, containing 1.9×10^{-2} M glucose-6-phosphate, 1 Kornberg Unit of Zwischenferment, 4.5×10^{-4} M TPN, 2×10^{-7} M apoprotein, 2.7×10^{-3} M KCN, 0.13 M sodium phosphate buffer pH 7.4, and varying concentrations of FMN, which are marked along the abscissa. Points marked × indicate experiments where the reaction mixture contained 0.5 ml rabbit anti-OYE serum, and points marked O experiments where 0.5 ml normal rabbit serum was added. The reactions were started by introducing the apoprotein from the sidearm.

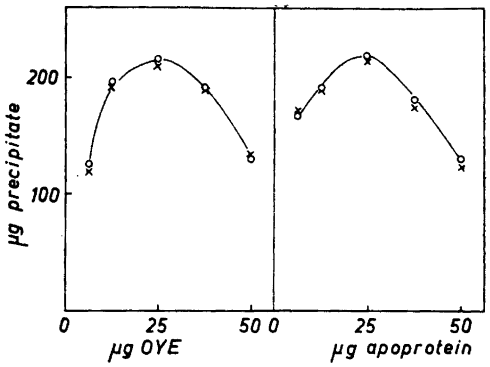

Fig. 2. Two experiments where the influence of atabrine on the quantitative precipitin reaction between the OYE and antiserum was studied. To the left is an experiment where the holoenzyme was used as antigen. O marks results obtained in the absence of atabrine, and × results obtained in the presence of 1.1×10^{-4} M atabrine. To the right is a similar experiment with the same marking, where the antigen used was the apoprotein of the OYE. The same serum, obtained after immunization with OYE, was used in both experiments.

Fig. 1 shows a non-competitive inhibition of the OYE by antiserum, when the concentration of FMN was varied in the reaction system. Essentially identical results were obtained in the quantitative precipitin reactions when either holoenzyme or apoprotein was used as antigen (Fig. 2). These results thus confirm previous conclusions that the antibodies and FMN are bound to different parts of the molecule. Fig. 2 also shows that the presence of atabrine did not disturb the reaction of the enzyme with antibodies. Atabrine was only slightly soluble in the reagent used for the protein analysis, and tests using a saturated solution showed no influence on the readings of the standard. The failure of atabrine to influence the reaction between enzyme and antibody supports the conclusions of the inhibition studies that different binding sites are concerned in the reactions of the drug and the antibodies with the enzyme.

Crystal Structure of the Perhydroanthracene Isomeride of M.P. 121° C

K. E. HJORTAAS

Universitetets Kjemiske Institutt, Blindern, Oslo, Norway

Structure determinations by physical methods of the isomeric perhydroanthracenes have proved to be far from easy. In the case of the 90° isomer however, an X-ray crystallographic analysis has been carried out [1] which shows the molecule to be of the »*trans-trans*» type with three parallel »chair» *cyclo*hexane rings.

The new isomer (m.p. 123°C) [2] has been investigated by both X-ray crystallographic and electron diffraction [3] (vapour phase) techniques by members of this department. The results show conclusively that in this isomer the six-membered rings have the »chair» form, both outer rings being connected to the central ring in *cis* position.

Some details of the X-ray analysis are given:

The crystals are *monoclinic*, space group $P2_1/c$ with two (centrosymmetrical) molecules in the unit cell.

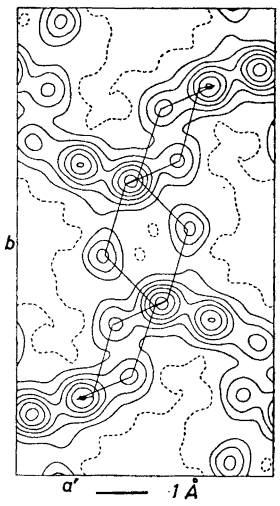

Fig. 2. Projection on the plane normal to [1 0 1]. Contours at 2 (dotted), 4, 6 ··· eÅ^{-3}.

The crystal parameters are: a = 5.36, b = 9.55, c = 12.07 (Å), β = 112.6°. Two-dimensional Fourier maps with projections along [1 0 0] and [1 0 1] are reproduced in Figs. 1 and 2.

The final coordinates of an asymmetrical unit based on least squares refinements

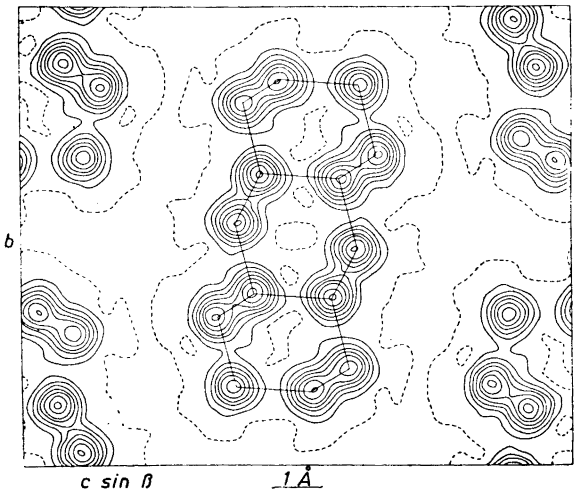

Fig. 1. Projection on the plane normal to [1 0 0]. Contours at 1 (dotted), 2, 3 ··· eÅ^{-3}.

Die Umsetzung des Trichlormethylphenylsulfids mit Grignardreagenz

ALEXANDER SENNING und SVEN-OLOV LAWESSON

Laboratorium für Organische Chemie, Chemisches Institut der Universität Uppsala, Uppsala, Schweden

Die von Sanna [1] beschriebene Darstellung von Trichlormethylphenylsulfid durch Umsetzung von Trichlormethansulfenylchlorid mit Phenylmagnesiumbromid ist u.a. von Egen [2] und Böhme [3] widerlegt worden, wird aber andererseits in neueren Übersichten, wie denen von Schöberl und Wagner [4], Sosnovsky [5] und Reid [6] ohne Kritik zitiert. Egen und Böhme bezweifelten die Angaben Sannas auf Grund der physikalischen Eigenschaften seines Produkts (und der von ihm als Trichlormethylphenylsulfon beschriebenen Verbindung), die mit denen des von ihnen auf anderem Wege dargestellten Trichlormethylphenylsulfids (bzw. Trichlormethylphenylsulfons) in keiner Weise übereinstimmten. Dagegen ist Sannas Artikel unseres Wissens noch nicht nachgearbeitet worden. Wir haben diese Nacharbeitung durchgeführt und festgestellt, dass bei dieser Reaktion keine definierten Produkte zu erhalten sind. Interessant ist in diesem Zusammenhang, dass das Trichlormethylphenylsulfid, das 1951 von Egen und 1953 von Böhme dargestellt und als neue Verbindung beschrieben wurde, bereits 1938 in einem amerikanischen [7] und einem gleichlautenden französischen [7] Patent als Ausgangsmaterial für ein technisches Verfahren genannt wird, allerdings ohne nähere Angaben.

Zwei in der Literatur beschriebene Umsetzungen organischer Schwefelverbindungen mit Grignardreagenz liessen vermuten, dass Trichlormethylphenylsulfid mit Grignardreagenz reagiert und es erschien von Interesse zu untersuchen, welcher der beiden denkbaren Reaktionswege beschritten wird. Adams und Mitarbeiter [8] erhielten bei der Umsetzung organischer Rhodanide mit Grignardreagenz Merkaptane und/oder Sulfide in wechselnden Ausbeuten, während Brintzinger [9] aus Chlormethansulfenylchlorid und Phenylmagnesiumbromid in 55 %-iger Ausbeute Phenylbenzylsulfid darstellen konnte.

Wir setzten Trichlormethylphenylsulfid mit Phenyl- bzw. 1-Naphthylmagnesiumbromid um und erhielten Diphenylsulfid bzw. 1-Naphthylphenylsulfid in 47 bzw. 33 % Ausbeute.

VERSUCHE

Trichlormethansulfenylchlorid und Phenylmagnesiumbromid. Die beiden Verbindungen wurden in Ätherlösung in wechselnden Mengenverhältnissen bei Temperaturen zwischen −70° und +34° miteinander umgesetzt. Die stark exotherme Reaktion lieferte keine definierten Produkte.

Trichlormethylphenylsulfid und Phenylmagnesiumbromid. Zu einer Lösung von 20,0 g (0,088 Mol) Trichlormethylphenylsulfid in Äther wurden unter Rühren in Stickstoffatmosphäre 148 ml einer 1,78-molaren ätherischen Phenylmagnesiumbromidlösung (0,264 Mol) zugetropft. Anschliessend wurde noch 2 Stunden gekocht, mit Eiswasser und Salzsäure zersetzt und wie üblich aufgearbeitet. Zwischen 80°/0,4 mm und 96°/0,4 mm gingen 7,8 g (47 % der Theorie) Diphenylsulfid über. n_D^{20} = 1,6236 (Literatur 1,6312). Das Sulfon schmolz zwischen 122° und 127° (Literatur 128°), der Mischschmelzpunkt mit authentischem Diphenylsulfon (F: 127°) war 123°—127°. Das Produkt war mit Diphenyl (von der Bereitung des Grignardreagenz) verunreinigt, das sich nicht vollständig abtrennen liess.

Trichlormethylphenylsulfid und 1-Naphthylmagnesiumbromid. Die Umsetzung wurde wie oben durchgeführt, zur besseren Lösung der Grignardverbindung wurde etwas Benzol zugesetzt. Zwischen 211°/11 mm und 225°/11 mm gingen 7,0 g (33 % der Theorie) 1-Naphthylphenylsulfid über. Die Substanz schmolz nach Umkristallisieren aus Alkohol zwischen 37° und 39° (Literatur 41,8°). Das Sulfon schmolz zwischen 97° und 99° (Literatur 99,5°—100,5°). Das Produkt war mit Dinaphthyl-(1,1') verunreinigt.

Wir danken Herrn Professor A. Fredga für das Interesse, das er unserer Arbeit entgegengebracht hat. Wir sind Herrn Professor A. Fredga für die Überlassung des Arbeitsplatzes und *Jordbrukets Forskningsråd* für die finanzielle Unterstützung unserer Arbeit zu Dank verpflichtet.

Studies on Peroxy Compounds VI.* A Novel Method for the Preparation of Acyloins

SVEN-OLOV LAWESSON and SUSANNE GRÖNWALL

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Uppsala, Sweden

In connection with our current studies of the reaction between benzoyl peroxide and sodium compounds of so called active methylene compounds [1], we have recently completed a project on ethyl acetoacetate and ethyl benzoylacetate. Inspired by the work of Treibs and Hintermeier [2] we directed our attention to *t*-butyl acetoacetate which is easily prepared in high yields from *t*-butyl alcohol and diketene. First we synthesized a series of *α*-alkyl and *α*-aralkyl substituted homologues of *t*-butyl acetoacetate with sodium ethoxide in ethanol as condensation agent. The benzoyloxy group is then easily introduced into the *α*-position of the ester by reacting its sodium compound with benzoyl peroxide in an inert solvent at 0—4°C. The benzoate, however, decomposes upon distillation. By reacting the crude ester with a catalytic amount of *p*-toluenesulphonic acid (TS) the carbo *t*-butoxy group is eliminated, and a benzoyl derivative of the corresponding acyloin is obtained. Hydrolysis may then give the acyloin according to the following formulas.

With certain limitations, it would be possible to prepare *t*-butyl esters of different *β*-keto acids according to well-known methods, and therefore the synthetic route outlined above appears to be general for the preparations of acyloins. As a full paper will be published at a later date,

VERSUCHE

Trichlormethansulfenylchlorid und Phenylmagnesiumbromid. Die beiden Verbindungen wurden in Ätherlösung in wechselnden Mengenverhältnissen bei Temperaturen zwischen −70° und +34° miteinander umgesetzt. Die stark exotherme Reaktion lieferte keine definierten Produkte.

Trichlormethylphenylsulfid und Phenylmagnesiumbromid. Zu einer Lösung von 20,0 g (0,088 Mol) Trichlormethylphenylsulfid in Äther wurden unter Rühren in Stickstoffatmosphäre 148 ml einer 1,78-molaren ätherischen Phenylmagnesiumbromidlösung (0,264 Mol) zugetropft. Anschliessend wurde noch 2 Stunden gekocht, mit Eiswasser und Salzsäure zersetzt und wie üblich aufgearbeitet. Zwischen 80°/0,4 mm und 96°/0,4 mm gingen 7,8 g (47 % der Theorie) Diphenylsulfid über. n_D^{20} = 1,6236 (Literatur 1,6312). Das Sulfon schmolz zwischen 122° und 127° (Literatur 128°), der Mischschmelzpunkt mit authentischem Diphenylsulfon (F: 127°) war 123°—127°. Das Produkt war mit Diphenyl (von der Bereitung des Grignardreagenz) verunreinigt, das sich nicht vollständig abtrennen liess.

Trichlormethylphenylsulfid und 1-Naphthylmagnesiumbromid. Die Umsetzung wurde wie oben durchgeführt, zur besseren Lösung der Grignardverbindung wurde etwas Benzol zugesetzt. Zwischen 211°/11 mm und 225°/11 mm gingen 7,0 g (33 % der Theorie) 1-Naphthylphenylsulfid über. Die Substanz schmolz nach Umkristallisieren aus Alkohol zwischen 37° und 39° (Literatur 41,8°). Das Sulfon schmolz zwischen 97° und 99° (Literatur 99,5°—100,5°). Das Produkt war mit Dinaphthyl-(1,1') verunreinigt.

Wir danken Herrn Professor A. Fredga für das Interesse, das er unserer Arbeit entgegengebracht hat. Wir sind Herrn Professor A. Fredga für die Überlassung des Arbeitsplatzes und *Jordbrukets Forskningsråd* für die finanzielle Unterstützung unserer Arbeit zu Dank verpflichtet.

Studies on Peroxy Compounds VI.* A Novel Method for the Preparation of Acyloins

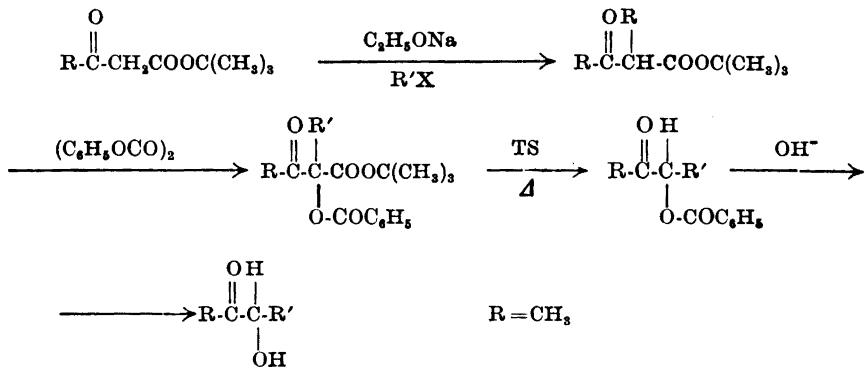
SVEN-OLOV LAWESSON and SUSANNE GRÖNWALL

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Uppsala, Sweden

In connection with our current studies of the reaction between benzoyl peroxide and sodium compounds of so called active methylene compounds [1], we have recently completed a project on ethyl acetoacetate and ethyl benzoylacetate. Inspired by the work of Treibs and Hintermeier [2] we directed our attention to *t*-butyl acetoacetate which is easily prepared in high yields from *t*-butyl alcohol and diketene. First we synthesized a series of *α*-alkyl and *α*-aralkyl substituted homologues of *t*-butyl acetoacetate with sodium ethoxide in ethanol as condensation agent. The benzoyloxy group is then easily introduced into the *α*-position of the ester by reacting its sodium compound with benzoyl peroxide in an inert solvent at 0—4°C. The benzoate, however, decomposes upon distillation. By reacting the crude ester with a catalytic amount of *p*-toluenesulphonic acid (TS) the carbo *t*-butoxy group is eliminated, and a benzoyl derivative of the corresponding acyloin is obtained. Hydrolysis may then give the acyloin according to the following formulas.

With certain limitations, it would be possible to prepare *t*-butyl esters of different *β*-keto acids according to well-known methods, and therefore the synthetic route outlined above appears to be general for the preparations of acyloins. As a full paper will be published at a later date,

* Part V: *Acta Chem. Scand.* **14** (1960) 944.



only one series of experiments is described here.

Preparation of t-butyl-α-n-amyl acetoacetate. To a sodium alcoholate solution prepared from 6.9 g of sodium in 150 ml of absolute ethyl alcohol, 47.4 g (0.3 mole) of *t*-butyl acetoacetate is added. After 10 min, 45.3 g (0.3 mole) of redistilled *n*-amyl bromide is added droppwise during 25 min and thereafter the mixture is refluxed for half an hour. The excess of ethanol is then immediately stripped off at reduced pressure, and the remainder poured onto water. The water phase is twice extracted with ether, and the combined ether extracts washed with water until neutral and then dried over sodium sulphate. Distillation gives the main fraction at b.p. 120—122°/10 mm Hg (Found: C 67.85; H. 10.57; Calc. C 68.38; H 10.59) $n_D^{20} = 1.4308$. Weight 46 g, yield 67 %.

The purity of the product has been verified by gas chromatographic analysis. When the *t*-butyl ester is heated, *iso*butylene rapidly splits off, and its incomplete combustion causes the low carbon yield percentage.

Preparation of octan-2-one-O-benzoyl-3-ol. In a 1 l three-necked flask, fitted with a mechanical stirrer, a reflux condenser, and a dropping funnel, is placed 4.8 g of sodium hydride and covered with 200 ml of dry benzene. 45.6 g (0.2 mole) of *t*-butyl-α-*n*-amyl acetoacetate is added dropwise to the sodium hydride, and after 2 h of rapid stirring almost all hydride has reacted, the evolution of hydrogen has ceased and a clear solution is formed. Then the flask is cooled in an ice-water bath to about 0° and 36.3 g (0.15 mole) of benzoyl peroxide in 200 ml of dry benzene is added droppwise through the dropping funnel during 45 min. After another 15 min, the peroxide test is negative and the porridge-like mixture is poured into water. The benzene phase is separated, the water phase extracted once with ether and the combined organic extracts washed neutral with water; 15.2 g of benzoic acid is isolated. From the organic phase, solvents and excess of starting material are distilled off. To the residue, 0.25 g *p*-toluene sulphonic acid is added. The distillation vessel is connected to a water pump and warmed on an oil bath maintained at a temperature of 160°C. When the decomposition is complete (constant pressure), the product is distilled. The main fraction is obtained at b.p. 114—115°/0.1 mm Hg. (Found: C 72.55; H 8.19. Calc. C 72.55; H 8.12). $n_D^{20} = 1.4959$. Weight 31 g, yield 83 %.

Preparation of octan-2-one-3-ol. In a flask fitted with a mechanical stirrer and a reflux condenser is placed 27 g of octan-2-one-O-benzoyl-3-ol and 200 ml of 10 % sodium hydroxide solution. Gentle heat is applied(inner temperature of the flask 60°C); after one hour's violent stirring, the mixture becomes homogeneous and turns a deep yellow colour. It is then extracted three times with ether and the organic layers are poured together, washed neutral with water and dried over sodium sulphate. 13 g of benzoic acid is obtained from the water phase. By vacuum distillation, 8 g of octan-2-one-3-ol at b.p. 93—94°/12 mm Hg is obtained (Found: C 66.57; H 11.03. Calc. 66.63; H 11.18). $n_D^{20} = 1.4340$, yield 51 %.

Surface Tension of Water Solutions of Fluorophosphorus Compounds

GUNNAR AKSNES

Norwegian Defence Research Establishment, Toxicological Group, Kjeller pr Lillestrøm, Norway

In connection with a study of the action of fluorophosphorus compounds as potent inhibitors of cholinesterases it was desirable to investigate whether these compounds possessed surface active properties. Such properties may be expected to exert influence upon biochemical reactions due to the fact that enzymatic processes depend to a great extent upon the presence of lipoid-water interfaces. The observation of the very strong polar character of the phosphoryl group [1] suggests that fluorophosphorus compounds with sufficient large hydrocarbon groups may possess considerable surface activity.

Materials. The preparation of the fluorophosphorus compounds was performed as previously described [1]. The water used for making

Table 1. Surface tension of water solutions of fluorophosphorus compounds (1 %). Temperature: 20°C.

Compound	Observed values	Corrected values, dyn/cm	Distribution coefficients CCl_4/H_2O
Pure water	77.4, 77.2, 77.0	72.6	—
	70.0, 70.1, 69.8	65.8	0.9
	56.7, 56.8, 56.9	53.3	3.46
	37.2, 38.2, 38.0	35.5	38.3
	65.7, 66.4, 66.2	62.0	—
	52.3, 52.4, 52.6	49.3	—

the solutions was distilled twice in a glass apparatus.

Apparatus. The measurements of the surface tension of the water solutions were performed with a torsion weight tensiometer (Cenco, Model No. 70540). All the measurements refer to 1 % solutions of fluorophosphorus compounds. The surface tension was measured at 20°C. Three independent measurements of each solution were taken. The correction factor of the instrument was 0.94.

Results and discussion. In Table 1 are collected the data from the present study. In the same table are included also the partition coefficients for the distribution of some of the fluorophosphorus compounds between water and carbon tetrachloride [2]. We recognize a rapid rise in surface activity of the fluorophosphorus compounds with the increase of their hydrocarbon content. The rise of the surface activities of the compounds is accompanied by a corresponding increase of the partition coefficients in the system CCl_4/H_2O.

From analogy with the present results we expect that fluorophosphorus compounds are capable of changing the interfacial tension between lipoids and water to a considerable degree, and in this way may play a role when the whole picture of the phosphorylating process of the enzyme is considered.

The Rate of Decomposition of Urethane in Acid Solution

KAI JULIUS PEDERSEN

Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark

The rate of the reaction

$$C_2H_5OCONH_2 + H^+ + H_2O \rightarrow C_2H_5OH + NH_4^+ + CO_2$$

was studied manometrically at 37.0°C in concentrated aqueous solutions of hydrochloric and sulphuric acids (c moles per liter solution). Owing to the slowness of the reaction, the final pressure was not observed but calculated from the pressure increase when, instead of urethane, calcium carbonate was dissolved. In general, only 5 to 30 % of the decomposition was observed, but in one experiment (solvent 10 M sulphuric acid) readings were taken till more than 80 % of the urethane had decomposed, and it was shown that the reaction follows the first-order law. The initial concentrations of urethane varied from 0.02 to 0.1 M. The urethane (m.p. 48.1°C) had been purified by melting and partly crystallising the commercial preparation. Velocity constants k (in sec^{-1}) are given in Table 1 together with values of the Hammett H_0 acidity function [1] and the water activities a_{H_2O} of the solutions computed from vapour-pressure data [2,3]. The velocity constant k increases more rapidly than c, but less rapidly than h_0 (where $H_0 = -\log h_0$). When the three most concentrated solutions are left out of consideration, k is roughly proportional to $h_0 a_{H_2O}^4$ as shown in Fig. 1 where log k has been plotted against $-H_0 + 4 \log a_{H_2O}$. The points fall fairly close to a straight line with the

The Rate of Decomposition of Urethane in Acid Solution

KAI JULIUS PEDERSEN

Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark

The rate of the reaction

$$C_2H_5OCONH_2 + H^+ + H_2O \rightarrow C_2H_5OH + NH_4^+ + CO_2$$

was studied manometrically at 37.0°C in concentrated aqueous solutions of hydrochloric and sulphuric acids (c moles per liter solution). Owing to the slowness of the reaction, the final pressure was not observed but calculated from the pressure increase when, instead of urethane, calcium carbonate was dissolved. In general, only 5 to 30 % of the decomposition was observed, but in one experiment (solvent 10 M sulphuric acid) readings were taken till more than 80 % of the urethane had decomposed, and it was shown that the reaction follows the first-order law. The initial concentrations of urethane varied from 0.02 to 0.1 M. The urethane (m.p. 48.1°C) had been purified by melting and partly crystallising the commercial preparation. Velocity constants k (in sec^{-1}) are given in Table 1 together with values of the Hammett H_0 acidity function [1] and the water activities a_{H_2O} of the solutions computed from vapour-pressure data [2,3]. The velocity constant k increases more rapidly than c, but less rapidly than h_0 (where $H_0 = -\log h_0$). When the three most concentrated solutions are left out of consideration, k is roughly proportional to $h_0 a_{H_2O}^4$ as shown in Fig. 1 where log k has been plotted against $-H_0 + 4 \log a_{H_2O}$. The points fall fairly close to a straight line with the

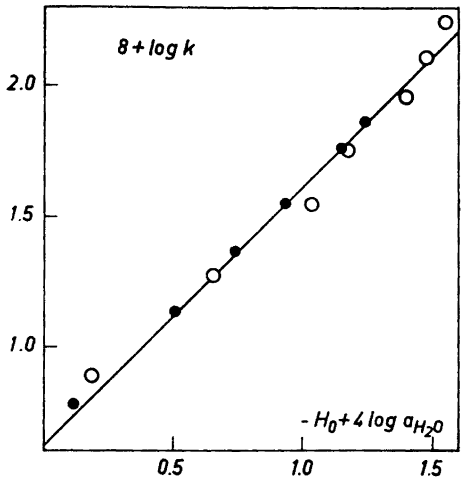

Fig. 1. Plot of log k against $-H_0 + 4 \log a_{H_2O}$ for the decomposition of urethane in solutions of hydrochloric acid (closed circles) and sulphuric acid (open circles). The straight line has the slope unity.

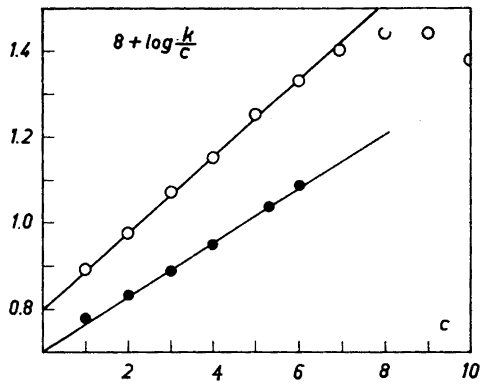

Fig. 2. Plot of $\log \frac{k}{c}$ against c for the decomposition of urethane in solutions of hydrochloric acid (closed circles) and sulphuric acid (open circles).

slope unity. This indicates that a bimolecular reaction between a urethane molecule (U) and the ion $H(H_2O)_4^+$ is rate-determining, since, in this case, the rate will be proportional to

$$a_U a_{H(H_2O)_4^+} / f_{UH(H_2O)_4^+} \quad (1)$$
$$= [U] f_U a_{H^+} a_{H_2O}^4 / f_{UH(H_2O)_4^+}$$
$$\simeq [U] h_0 a_{H_2O}^4$$

It has recently been derived in different ways [4-6] that the hydrogen ion in aqueous solution is hydrated with 4 molecules of water. If it is assumed that $[H(H_2O)_4^+] = c$, we obtain from expression (1) that

$$k = A c f_U / f_{UH(H_2O)_4^+}$$

where A is a constant. Since it may be expected that to a first approximation

$$\log (f_U / f_{UH(H_2O)_4^+}) = Bc$$

where B is a constant, we obtain the following approximate formula

$$\log \frac{k}{c} = \log A + Bc$$

In Fig. 2 it is shown that the experimental data agree well with this formula up to $c = 6$. From the graph is obtained for solutions of hydrochloric acid

$$\log \frac{k}{c} = 0.705 - 8 + 0.063\ c$$

and for solutions of sulphuric acid

$$\log \frac{k}{c} = 0.801 - 8 + 0.0895\ c$$

By extrapolation to $c = 0$ is found for hydrochloric acid $k = 5.07 \times 10^{-8} \times c$, and for sulphuric acid $k = 6.32 \times 10^{-8} \times c$. The larger value for sulphuric acid may possibly be attributed to catalysis by hydrogen sulphate ions in addition to the hydrogen ion catalysis.

Redetermined Lattice Constants of PtP_2, $PtAs_2$, $PtSb_2$, and α-$PtBi_2$

ARNE KJEKSHUS

Kjemisk Institutt A, Universitetet i Oslo, Blindern, Norway

A number of compounds have earlier been prepared and investigated in the binary systems between platinum and elements of group V in the periodic table. Compounds with composition metal : metalloid = 1 : 2 are found in all systems, except the platinum-nitrogen system, where no intermediate compounds are known at present. The compounds PtP_2, $PtAs_2$, $PtSb_2$, and α-$PtBi_2$ have been studied by means of X-ray methods and all of them have structures of the pyrite ($C2$) type.

Platinum diphosphide was first prepared by Davey [1]. The structure was established by Thomassen [2] and later confirmed by Biltz *et al.* [3] and Rundqvist [4].

Platinum diarsenide was first synthesized by Gehlen [5]. It occurs in nature as the mineral sperrylite. The structural identity of sperrylite and artificial $PtAs_2$ was established by Ramsdell [6] and De Jong [7] by means of X-rays. The structure of $PtAs_2$ has later been investigated by Aminoff and Parsons [8] and Thomassen [2].

Platinum diantimonide was first obtained by Roessler [9]. The structure, *i.e.*, its lattice constant and atomic parameter, was determined by Thomassen [10].

Platinum dibismuthide was also first prepared by Roessler [9]. The crystal structure was established by Wallbaum [11] and its correctness later confirmed by Zhuravlev and Kertes [12]. By thermal, metallographic and X-ray studies these authors found the existence of one more $PtBi_2$ phase, β-$PtBi_2$, which was found to be hexagonal.

The *alloys* were prepared by heating accurately weighed quantities of platinum and phosphorus, arsenic, antimony or bismuth, respectively, in evacuated and sealed silica tubes. In each system alloys with 25.00, 33.33 and 40.00 atomic % platinum were made. All samples were heated at 650°C for 30 days and cooled slowly to room temperature over a period of another 30 days.

All samples were crushed and X-ray powder photographs taken in cameras with 114.6 mm effective diameter and asymmetric film mounting. The lattice constants, which were found by extrapolation according to the method of Nelson and Riley [13], are expressed in Ångstrøm units on the basis of λ $CuK\alpha_1$ = 1.54050 Å. Results from earlier investigations expressed in kX-units have been transformed to Å by multiplication by the factor 1.00202.

Table 1. Lattice constants of PtP_2, $PtAs_2$, $PtSb_2$, and α-$PtBi_2$.

Sample	a (Å)	Reference
PtP_2	5.6956 ± 0.0005	Present
	5.694 ± 0.004	Thomassen [2]
	5.694	Rundqvist [4]
$PtAs_2$	5.9665 ± 0.0004	Present
	5.97	Ramsdell [6]
	5.95 (sperrylite)	Ramsdell [6]
	5.93 (sperrylite)	De Jong [7]
	6.01 (sperrylite)	Aminoff and Parsons [8]
	5.969 ± 0.003	Thomassen [2]
$PtSb_2$	6.4400 ± 0.0004	Present
	6.441 ± 0.003	Thomassen [10]
α-$PtBi_2$	6.7022 ± 0.0006	Present
	6.696 ± 0.005	Wallbaum [11]

The lattice constants of the samples with composition PtX_2 are found in Table 1 together with the previous lattice constant values. The lattice constants of the different compounds are found to be independent of the composition of the alloys within the experimental error, indicated by the limits in Table 1. Thus, the homogeneity ranges of the phases are supposedly rather narrow. The earlier data agree well within their limited accuracy except for α-$PtBi_2$.

The redetermination of the atomic parameters in these compounds will be discussed in a forth-coming paper.

Acknowledgements. The author wishes to thank Professor Haakon Haraldsen and Dosent Fredrik Grønvold for their kind interest in this study.

The Alkaline Hydrolysis of Diethyl Acetomalonate

KAI JULIUS PEDERSEN

Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark

When diethyl acetomalonate is dissolved in an aqueous solution of a strong base it will react with 3 hydroxyl ions according to the scheme

$$CH_3COCH(COOEt)_2 + 3\,HO^- \rightarrow CH_2(COO^-)_2 + CH_3COO^- + 2\,EtOH \quad (1)$$

One hydroxyl ion disappears immediately, while the other two are consumed at a measurable rate which is proportional to the ester concentration but independent of the hydroxyl ion concentration. This experimental result is explained as follows. The keto-form of the diethyl ester is rapidly and nearly completely transformed into enolate ion by the balanced reaction

$$CH_3COCH(COOEt)_2 + HO^- \rightleftharpoons CH_3C\bar{O}{:}C(COOEt)_2 + H_2O \quad (2)$$

The rate-determining reaction is

$$CH_3COCH(COOEt)_2 + HO^- \rightarrow CH_3COCH(COOEt)COO^- + EtOH \quad (3)$$

It is followed by the two rapid reactions

$$CH_3COCH(COOEt)COO^- + HO^- \rightarrow CH_3COCH(COO^-)_2 + EtOH$$

$$CH_3COCH(COO^-)_2 + HO^- \rightarrow CH_3COO^- + CH_2(COO^-)_2$$

The rate of reaction 3 will be proportional to the product of the hydroxyl ion concentration and the concentration of the keto-form of the diethyl ester, but since the latter, according to scheme 2, is inversely proportional to the hydroxyl ion concentration, the rate will be independent of the hydroxyl ion concentration and of first order with respect to the total concentration of diethyl acetomalonate (keto-form and enolate ion).

Diethyl acetomalonate was prepared according to Lund [1] and was distilled twice under reduced pressure in an all-glass apparatus fitted with a Widmer stillhead. The fraction used in the experiments distilled within less than 1°C. It was found that the ester could be titrated as a monobasic acid when thymolphthalein was used as indicator and a rather strongly blue colour was chosen as end-point. The average of several titrations was that 99.7 % of the calculated amount of base was used. When the ester is dissolved in an excess of strong base, it will therefore be rapidly and nearly completely transformed into enolate ion by reaction 2.

To 60 ml of 0.2 N barium hydroxide in a glass-stoppered flask was added 0.8 g of the ester. The clear solution was left at room temperature. After half an hour the first crystals were noticed, and the next day a large crystalline precipitate had been formed. The crystals were isolated by suction, washed with ice-cold water, and air-dried to constant weight. It was shown that they did not contain carbonate, from which it is concluded that no decarboxylation takes place in the reaction. In order to show that the crystals consisted of barium malonate this substance was prepared by mixing solutions of malonic acid and barium acetate. The crystals obtained here were isolated and dried in the same way as before. Weighed amounts of the two preparations were transformed into carbonate by ignition in a platinum crucible, and the residues were weighed. On the assumption that one molecule of both substances gives one molecule of barium carbonate, it was found that the molecular weight of the substance prepared from diethyl acetomalonate was 254.5 while that of the salt prepared from malonic acid was 255.0 (calc.

The Alkaline Hydrolysis of Diethyl Acetomalonate

KAI JULIUS PEDERSEN

Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark

When diethyl acetomalonate is dissolved in an aqueous solution of a strong base it will react with 3 hydroxyl ions according to the scheme

$$CH_3COCH(COOEt)_2 + 3\,HO^- \rightarrow CH_2(COO^-)_2 + CH_3COO^- + 2\,EtOH \quad (1)$$

One hydroxyl ion disappears immediately, while the other two are consumed at a measurable rate which is proportional to the ester concentration but independent of the hydroxyl ion concentration. This experimental result is explained as follows. The keto-form of the diethyl ester is rapidly and nearly completely transformed into enolate ion by the balanced reaction

$$CH_3COCH(COOEt)_2 + HO^- \rightleftharpoons CH_3C\bar{O}{:}C(COOEt)_2 + H_2O \quad (2)$$

The rate-determining reaction is

$$CH_3COCH(COOEt)_2 + HO^- \rightarrow CH_3COCH(COOEt)COO^- + EtOH \quad (3)$$

It is followed by the two rapid reactions

$$CH_3COCH(COOEt)COO^- + HO^- \rightarrow CH_3COCH(COO^-)_2 + EtOH$$

$$CH_3COCH(COO^-)_2 + HO^- \rightarrow CH_3COO^- + CH_2(COO^-)_2$$

The rate of reaction 3 will be proportional to the product of the hydroxyl ion concentration and the concentration of the keto-form of the diethyl ester, but since the latter, according to scheme 2, is inversely proportional to the hydroxyl ion concentration, the rate will be independent of the hydroxyl ion concentration and of first order with respect to the total concentration of diethyl acetomalonate (keto-form and enolate ion).

Diethyl acetomalonate was prepared according to Lund [1] and was distilled twice under reduced pressure in an all-glass apparatus fitted with a Widmer stillhead. The fraction used in the experiments distilled within less than 1°C. It was found that the ester could be titrated as a monobasic acid when thymolphthalein was used as indicator and a rather strongly blue colour was chosen as end-point. The average of several titrations was that 99.7 % of the calculated amount of base was used. When the ester is dissolved in an excess of strong base, it will therefore be rapidly and nearly completely transformed into enolate ion by reaction 2.

To 60 ml of 0.2 N barium hydroxide in a glass-stoppered flask was added 0.8 g of the ester. The clear solution was left at room temperature. After half an hour the first crystals were noticed, and the next day a large crystalline precipitate had been formed. The crystals were isolated by suction, washed with ice-cold water, and air-dried to constant weight. It was shown that they did not contain carbonate, from which it is concluded that no decarboxylation takes place in the reaction. In order to show that the crystals consisted of barium malonate this substance was prepared by mixing solutions of malonic acid and barium acetate. The crystals obtained here were isolated and dried in the same way as before. Weighed amounts of the two preparations were transformed into carbonate by ignition in a platinum crucible, and the residues were weighed. On the assumption that one molecule of both substances gives one molecule of barium carbonate, it was found that the molecular weight of the substance prepared from diethyl acetomalonate was 254.5 while that of the salt prepared from malonic acid was 255.0 (calc.

for $CH_2(COO)_2Ba,H_2O$: 257.4). From acidimetric titration of the two residues was found 254.2 and 254.8, respectively. It is therefore concluded that the two substances are identical, and that malonate is formed as end-product in the alkaline hydrolysis of diethyl acetomalonate (scheme 1).

Measurements of the rate of hydrolysis of diethyl acetomalonate in solutions of sodium hydroxide were carried out at the two temperatures 25.0 and 37.0°C. A graduated flask filled to a little below the mark with sodium hydroxide solution was placed in a water thermostat. When temperature equilibrium was attained, a weighed-out amount of the ester was dissolved, and the flask was quickly filled to the mark with water of the proper temperature. At suitable time-intervals during the reaction, and after it had come to an end, samples of the solution were pipetted into an excess of 0.1 N hydrochloric acid; thymolphthalein was added, and the solutions were titrated back with 0.03 N sodium hydroxide to a rather strongly blue colour. When x denotes the concentration of titratable base, and c that of diethyl ester in the reacting solution at the time t after the start of the reaction, we have according to our assumptions that $x-x_\infty = 2c$ where subscript ∞ denotes final value. When $\log (x-x_\infty)$ was plotted against t, the points fell in all the experiments very close to straight lines showing that the first-order law holds for the reaction. The composition of the solutions examined, and the rate constants k (in sec^{-1}) found, are given in Table 1. The values of k increase slightly with increasing concentration of strong base in the original solution, and, as shown in one experiment, with addition of sodium chloride. It also appears from the table that the number of hydroxyl ions reacting per molecule of diethyl acetomalonate $(x_0-x_\infty)/c_0$ is always 3 in agreement with scheme 1.

Table 1. Rate of hydrolysis of diethyl acetomalonate (initially c_0 M) in solutions of sodium hydroxide (initially x_0 M). x_∞ is the final concentration of sodium hydroxide and k the rate constant in sec^{-1}.

The Crystal Structures of the Triammines of the Ammonium Halides

IVAR OLOVSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structures of $NH_4Cl \cdot 3NH_3$, $NH_4Br \cdot 3NH_3$ and $NH_4I \cdot 3NH_3$ have been determined from single-crystal X-ray data. No phase transitions were observed from the melting point down to −140°C. The crystals are orthorhombic with four molecules per unit cell; the space group for the chloride and bromide is $P2_12_12_1$ and for the iodide $P2_1nb$. The cell dimensions at −35°C are for $NH_4Cl \cdot 3NH_3$: $a = 8.795$, $b = 8.68$, $c = 8.989$ Å; for $NH_4Br \cdot 3NH_3$: $a = 8.96$, $b = 8.996$, $c = 9.263$ Å; for $NH_4I \cdot 3NH_3$: $a = 8.32$, $b = 9.91$, $c = 9.96$ Å. The ammonium ion is tetrahedrally surrounded by three ammonia molecules and one halide ion. The hydrogen atoms of ammonium are evidently involved in the hydrogen bonds within this group. The forces between the different groups are relatively weak but may restrict the possible rotation of the ammonia molecules about their threefold axes.

The present investigation is the first in a series of planned structure determinations of some ammines formed with salts of the alkali metals and ammonium.

The systems NH_4X—NH_3 (X = F, Cl, Br, I) have been studied in several earlier works and reported compounds are: $NH_4F \cdot NH_3$; $NH_4Cl \cdot 3$ and $6NH_3$; $NH_4Br \cdot 1$, 3, 4, and $6NH_3$; $NH_4I \cdot 1$, 2, 3, 4, 5, and $6NH_3$. A list of references is given in the work by Watt and McBride [1]. The compounds $NH_4Cl \cdot 3NH_3$, $NH_4Br \cdot 3NH_3$, $NH_4I \cdot 3NH_3$ and $NH_4I \cdot 4NH_3$ seem to be established with certainty in these works. The present investigation involves the determination of the crystal structures of $NH_4Cl \cdot 3NH_3$, $NH_4Br \cdot 3NH_3$ and $NH_4I \cdot 3NH_3$ from single crystal X-ray diffraction data obtained at —35°C. A preliminary report of the work on these compounds has been published earlier [2].

EXPERIMENTAL

The crystals were grown from solutions of ammonia and ammonium halide sealed in glass capillaries. The capillaries were made by drawing out one end of a thin-walled glass tube (diameter about 2 mm) to a diameter of 0.1 to 0.2 mm and a wall

thickness of 0.01 to 0.02 mm. The ammonium halide was weighed into the capillary and carefully dried ammonia condensed over it. Reweighing, after sealing with a microflame, gave the amount of ammonia. The desired composition was easily obtained by trial and error. The melting points of the samples were in reasonable agreement with earlier published data; a sample of the chloride used for the X-ray work with a composition 3.0 moles NH_3/mole NH_4Cl melted at + 10°C (reported values 7°, 7.6°, 9.8°, 10.7°). For $NH_4Br \cdot 3NH_3$ (actual composition 2.9 moles NH_3/mole NH_4Br) the melting point was + 8.5°C (reported 6°, 8.7°, 13.7°), for the iodide (3.1 moles NH_3/mole NH_4I) −9°C (reported −8°, −12°).

The X-ray photographs were taken in a special Weissenberg camera [3], modified to make it even simpler to handle. It was then also possible to use an undivided film which has some obvious advantages. The single crystals were grown in the camera in the usual way by blowing a cooled stream of gas parallel to the capillary and following the growth with a polarizing microscope. The crystals apparently grow with no strongly preferred orientation with respect to the capillary as they were differently oriented in each case. In this case the cooling gas was carefully dried air, passed through copper spirals in solid carbon dioxide or liquid air. The consumption of liquid air was 0.5 l/h when working at −140°C. The other details are similar to those described earlier [4].

Equi-inclination Weissenberg photographs were taken at −35°C by use of Cu-K-radiation; for the chloride with rotation about the a and b axes (layers 0−6 and 0−8, resp.), for the bromide about the a axis (layers 0−7) and for the iodide about the a axis (layers 0−6). In addition, exposures were taken at −10°, −85° and −140°C, but no changes in structure were indicated by these photographs.

A crystal grown from a sample of the composition 4.1 moles NH_3/mole NH_4Cl gave the same X-ray photographs as $NH_4Cl \cdot 3NH_3$.

The relative intensities were estimated visually by using the multiple-film technique (five films) and comparing with an intensity scale. The intensities varied from 1 to 8 000. The data were corrected for the Lorentz and polarization effects.

UNIT CELL

The data showed the diffraction symmetry *mmm*, indicating an orthorhombic unit cell. The approximate cell dimensions were first obtained from rotation and Weissenberg photographs; accurate determination with powder methods was impossible as the crystallites could not be obtained sufficiently small. A single crystal method described by Weisz, Cochran and Cole [5] was therefore applied ("the Θ-method"). The selected reflection was located to half a degree on the scale of rotation by Weissenberg oscillations of $\pm$ 2°. A series of exposures was then made with stationary camera and crystal, using a special collimator of 0.15 mm diameter. The crystal was turned 10′ between successive exposures and by interpolation between the estimated intensities, the crystal orientation for maximum reflection intensity could be determined to better than $\pm$ 5′. Systematic errors in the measurements were eliminated by extrapolation to $\Theta = 90°$. The errors due to eccentricity and graduation on the scale of rotation were negligible.

The method as given only determines the axes occurring in the zero layer and to obtain the dimensions of all three axes the crystal must be remounted. According to a modified method by Löfgren [6], the dimension of the rotation axis is obtained directly from the higher layers without reorientation. As the reflections were relatively more diffuse in the higher layers, there was here a larger uncertainty in the determination of the crystal orientation for maximum reflection intensity. The cell dimensions obtained are:

$NH_4Cl \cdot 3NH_3$: $a = 8.795 \pm 0.002$, $b = 8.68 \pm 0.01$, $c = 8.989 \pm 0.002$ Å
$NH_4Br \cdot 3NH_3$: $a = 8.96 \pm 0.01$, $b = 8.996 \pm 0.002$, $c = 9.263 \pm 0.002$ Å
$NH_4I \cdot 3NH_3$: $a = 8.32 \pm 0.02$, $b = 9.91 \pm 0.01$, $c = 9.96 \pm 0.01$ Å
($t = -35$°C, λCu-$K\alpha_1 = 1.54051$ Å, λCu-$K\alpha_2 = 1.54433$ Å.)

From existing literature data, no definite conclusions can be drawn about the extent of solid solutions in these systems.

The approximate density was obtained from the volume and weight of a completely homogeneous crystal in a cylindrical capillary of uniform thickness. The volume was measured with a microscope, the weight being known from the preparation. The densities thus observed, together with those calculated with four molecules per unit cell are ($t = -35$°C):

$NH_4Cl \cdot 3NH_3$: $d_{obs} = 1.0$, $d_{calc} = 1.01$ g.cm^{-3}
$NH_4Br \cdot 3NH_3$: $d_{obs} = 1.4$, $d_{calc} = 1.33$
$NH_4I \cdot 3NH_3$: $d_{obs} = 1.6$, $d_{calc} = 1.59$

SPACE GROUP

Systematic absences for the chloride and bromide compounds were: ($h00$), ($0k0$), ($00l$) for h, k and l odd, resp. This suggests the space group $P2_12_12_1$ (D_2^4), assuming that the absences are space group extinctions. The subsequent refinement of the structure in this space group gave good agreement with the data indicating that this choice is correct.

For the iodide compound the systematic absences were: ($h0l$) for $h + l$ odd, ($hk0$) for k odd. This suggests $P2_1nb$ or $Pmnb$ (with different choice of axes these correspond to $Pna2_1$ and $Pnma$ of the *International Tables* [7]). As will be shown later, the structure could be refined successfully only in $P2_1nb$ (C_{2v}^9).

In the chloride and bromide structure the atomic arrangement is about the same as in the iodide; the differences are discussed in detail later. However, it was evident from the refinements that the iodide structure could not be brought into sufficiently good agreement with the data by the use of $P2_12_12_1$ (see further below). The original choice of axes was made such that all structures were oriented in the same way. The work on the chloride and bromide was finished before the space group of the iodide was established with certainty, and the original choice of axes was then maintained even though this does not correspond to the standard setting of the *International Tables* [7] for the iodide.

The equivalent positions for $NH_4Cl \cdot 3NH_3$ and $NH_4Br \cdot 3NH_3$ in $P2_12_12_1$ are: (x,y,z); $(\frac{1}{2}+x, \frac{1}{2}-y, z)$; $(\frac{1}{2}-x, \bar{y}, \frac{1}{2}+z)$; $(\bar{x}, \frac{1}{2}+y, \frac{1}{2}-z)$. For $NH_4I \cdot 3NH_3$ in $P2_1nb$: (x,y,z); $(\frac{1}{2}+x, \frac{1}{2}-y, z)$; $(\frac{1}{2}+x, \bar{y}, \frac{1}{2}+z)$; $(x, \frac{1}{2}+y, \frac{1}{2}-z)$. The arrangement of the symmetry elements in $P2_1nb$ with the chosen setting is given in Fig. 1.

DETERMINATION OF THE ATOMIC COORDINATES

The positions of the halogen atoms were obtained independently for each substance from the Harker vectors. From three-dimensional F_o and F_o—F_c syntheses based on these positions, the coordinates of the nitrogen atoms were

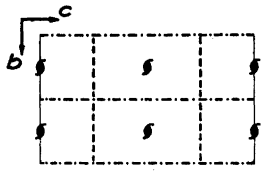

Fig. 1. The arrangement of the symmetry elements in $P2_1nb$.

then determined. The analogue computer by Hägg and Laurent [8] was used for the preliminary Fourier calculations. Subsequent Fourier refinements were made on the IBM 701 computer.

For the chloride and bromide compounds, the refinements gave no indication of deviation from the space group $P2_12_12_1$ suggested by the systematic absences. In the iodide, there was first of all a choice between $P2_1nb$ and $Pmnb$. The latter space group was first tried; the general positions are eightfold and the iodine atom had to be placed in a special fourfold position on a mirror plane. From the F_o—F_c syntheses based on this iodine position, quite acceptable nitrogen peaks could be found for N_0, N_2 and N_3 (N_0 is nitrogen in the ammonium ion; N_1, N_2 and N_3 are the nitrogen atoms in the three ammonia molecules; see further below). N_0 then was in a special fourfold position and N_2 and N_3 together occupied a general eightfold position. Finally, the remaining N_1 had to be placed in a fourfold position on a mirror plane, although the very pronounced elongation of the corresponding Fourier peak rather indicated that it should be about 0.4 Å from this plane. However, the coordinates of this structure were subjected to several cycles of least-squares refinement. It appeared that the temperature factor for N_1 became successively larger, while the other atoms refined rather normally. Soon the temperature factor for N_1 had grown beyond all reasonable limits, thus confirming the indications from the difference synthesis that N_1 should not be placed on the mirror plane. As the structure now discussed was the only one to be considered in $Pmnb$ this space group had to be abandoned and $P2_1nb$ was tried. Here all positions are general fourfold and N_1 could be moved away from the old mirror plane. Also, N_2 and N_3 were of course no longer symmetry-related to each other. Apart from this, no changes were undertaken in the above structure. The subsequent least-squares refinement in $P2_1nb$ now proceeded successfully.

Finally, one possibility that should be considered is that the systematic absences are not real space group extinctions and that the space group of the iodide then might be, for example, the same as for the chloride and bromide, $P2_12_12_1$. The arguments against this alternative are similar to those presented above against $Pmnb$. From the equivalent positions written down earlier, it is evident that if the actual space group is $P2_12_12_1$, but the x coordinates of I, N_0 and N_1 very close to 0.50, the coordinates for N_2 are (x_2,y_2,z_2) and for N_3 very close to $(\bar{x}_2,y_2,z_2)$; the net result is false absences corresponding to those for $P2_1nb$. However, from the difference maps, for example, it was evident that the x coordinate of N_1 should be about 0.45. This is so far from 0.50 that the false space group extinctions would be easily revealed.

The relation between the structures of $NH_4Cl \cdot 3NH_3$ and $NH_4Br \cdot 3NH_3$ on one hand, and $NH_4I \cdot 3NH_3$ on the other, may be described in the following way. The space groups $P2_12_12_1$ and $P2_1nb$ are both subgroups of $Pmnb$ (full symbol $P2_1/m\ 2_1/n\ 2_1/b$) and the two different structures represent two different distortions from that higher symmetry. The practical difference in the two distortions is that in one case the extinction rules change and in the other they do not. The hypothetical structure for $NH_4I \cdot 3NH_3$, discussed in the preceding paragraph, approaches the symmetry $Pmnb$; if the conditions were exact, it would be the ideal structure from which the two actual ones can be considered to be derived.

The coordinates and isotropic temperature factors for the halogen and nitrogen atoms and an over-all scale factor were finally refined by least-squares methods on the IBM 650 computer. R_3, (see below), was the quantity actually minimized. The weighting factor w in this expression and some other details of the program are described elsewhere [4]. In the iodide, the chosen space group ($P2_1nb$) is polar, but with a single heavy atom, the least-squares refinement using only diagonal matrix elements involves no special problems (*cf.* Ref.[9]). The scattering factors for N° and Cl^- were based on *f*-values published by Berghuis *et al.*[10], for Br^- and I^- they were estimated from the *f*-values for Br° and I° published by Thomas and Umeda [11]. The shifts of the atoms in the final cycles were less than about one tenth of the standard deviation for the coordinate in question. The results together with the standard deviations after about 15 cycles of refinement are given in Table 1. (The x coordinate of iodine was arbitrarily set equal to 0.50000. There is no variance for this coordi-

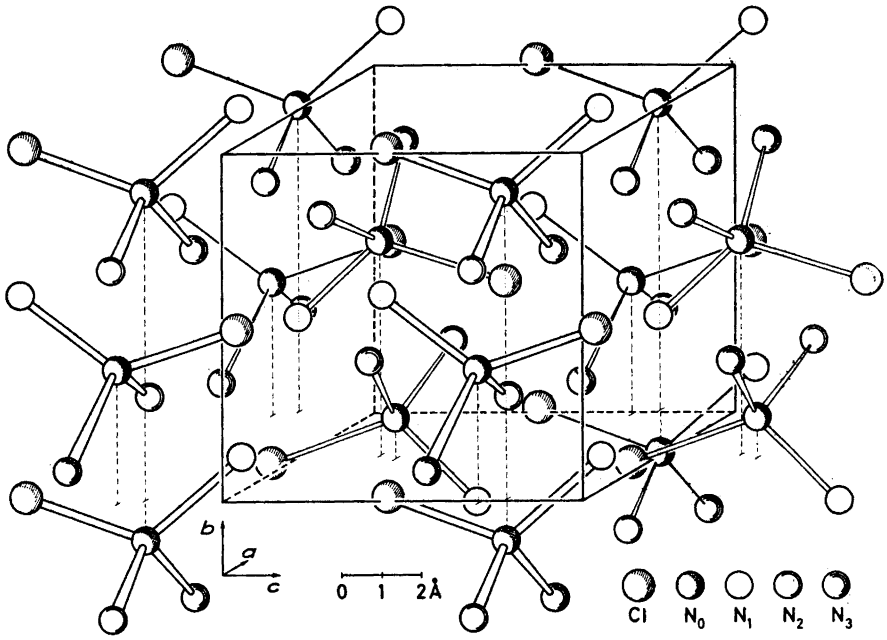

Fig. 2. The crystal structure of $NH_4Cl \cdot 3NH_3$. N_0 is nitrogen in the ammonium ion; N_1, N_2 and N_3 belong to the three ammonia molecules. The hydrogen bonds within the discrete chlorotriammineammonium tetrahedra are indicated.

nate since the iodine atom determines the origin.) The "unreliability factors" at this point were:

For the chloride: $R_1 = \Sigma \| F_o | - | F_c \| / \Sigma | F_o | = 0.117$
$R_2 = [\Sigma (| F_o | - | F_c |)^2 / \Sigma | F_o |^2]^{1/2} = 0.118$
$R_3 = [\Sigma w (| F_o | - | F_c |)^2 / \Sigma w | F_o |^2]^{1/2} = 0.120$
For the bromide $R_1 = 0.115$, $R_2 = 0.138$, $R_3 = 0.142$
For the iodide: $R_1 = 0.101$, $R_2 = 0.121$, $R_3 = 0.138$

The number of reflections recorded (not counting the space group extinctions) was 743 for the chloride, 758 for the bromide and 584 for the iodide *.

DISCUSSION OF THE STRUCTURE

The structure of the chloride and bromide compounds is illustrated in Figs. 2 and 3 (the pictures are based on the parameters of the chloride). The structure of the iodide is shown in Fig. 4. Apart from some shifts in the atomic positions, the main difference between the two structures is that N_2 and N_3 are interchanged in certain cases. In other words, N_2 and N_3 taken together occupy

nearly the same positions in the two structures, which is plainly noticeable when all equivalent positions are written down.

It appears that one of the four non-equivalent nitrogen atoms (N_0) is tetrahedrally surrounded by one halogen and three other nitrogen atoms (N_1, N_2 and N_3). These three nitrogen atoms have very similar environments, completely different from that of N_0. These facts give rather definite indication that N_0 belongs to the ammonium ion and N_1, N_2 and N_3 to the ammonia molecules. A detailed discussion of the bonding situation is given below.

1. Ammonium

The bond distances and angles to the four nearest neighbors of ammonium are shown in Figs. 5 and 6 for the chloride compound. The distances and angles, together with their standard deviations for all three compounds, are given in Table 2. The hydrogen atoms of ammonium are obviously used to form hydrogen bonds to the four neighbors. The somewhat distorted tetrahedral arrangement suggests that the hydrogen atoms may be somewhat removed from the bond axes. The difference synthesis for the chloride, shown schematically in Fig. 7, supports this suggestion and also indicates an expected anisotropy of thermal vibration. The distances N——N are within the usual range for hydrogen bonds of this kind [12], except for the short distance N_0—N_3 in the iodide, 2.66 Å. Compare the distances N_0——X with the corresponding distances in the simple ammonium halides: NH_4Cl (*CsCl-type*, 3.35 Å; *NaCl-type* (250°C), 3.26 Å), NH_4Br (3.50 and (250°C) 3.45 Å, resp.), NH_4I (3.79 (—17°C) and 3.62 Å, resp.). Compare also with other N—H——X distances collected in Ref.[12]

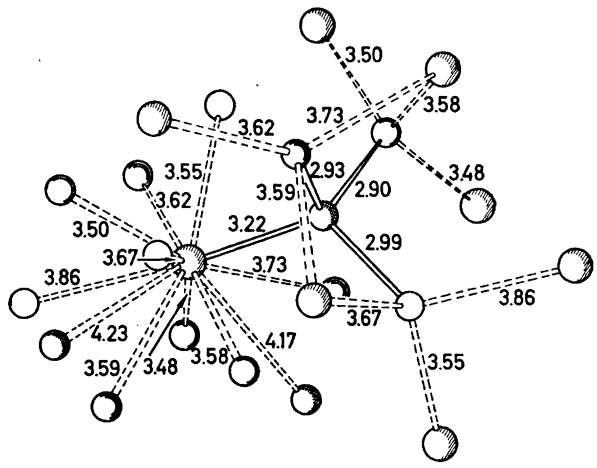

Fig. 5. Bond distances to the neighbors of the different atoms in $NH_4Cl \cdot 3NH_3$. The central atom N_0 is at (0.48, 0.12, 0.28) in Fig. 2. Atoms are designated as in Fig. 2.

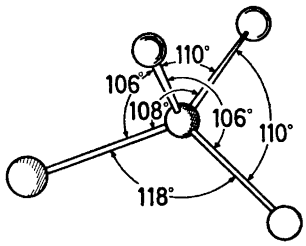

Fig. 6. Bond angles within the tetrahedral groups of Fig. 2 ($NH_4Cl \cdot 3NH_3$). The corresponding distances are shown in Fig. 5.

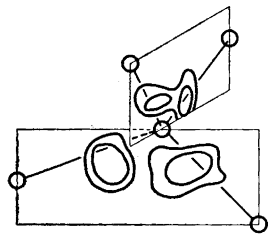

Fig. 7. Schematic representation of the difference synthesis in various sections ($NH_4Cl \cdot 3NH_3$). The atoms are the same as in Fig. 6. The contours are drawn at 0.4 and 0.5 e. Å^{-3}.

2. Ammonia

From the discussion above, it follows that the free electron pairs of the ammonia molecules are involved in hydrogen bonds to the central ammonium ion. Bonding between the ammonia molecules themselves then seems improbable and the large interatomic distances support this (all such distances are larger than 3.5 Å). The other kind of neighbors to be considered are the halogen atoms. Each ammonia molecule forms, together with the three closest halogen neighbors, a fairly symmetric low pyramid; the distances and angles for the chloride are shown in Figs. 5 and 8 and for all three compounds in Table 3. The average distances are: N———Cl = 3.59 Å, N———Br = 3.72 Å, N———I = 3.86 Å (the distances N_1———Cl = 3.86 Å, N_1———Br = 4.01 Å and N_1———I = 4.41 Å are not included in these average values, as they deviate significantly from the rest). The distances to other halogen neighbors are larger than 5 Å.

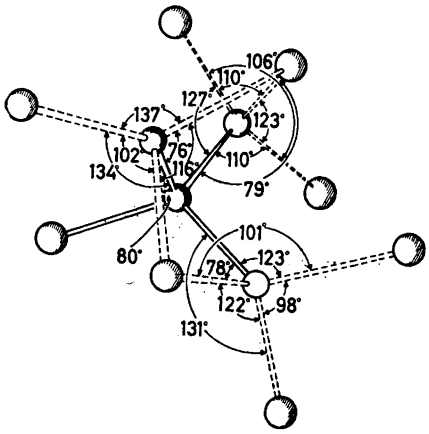

Fig. 8. Angles between the N—N_0 and N—Cl lines of each ammonia molecule. The corresponding distances are shown in Fig. 5.

The interaction of the ammonia molecules with their neighbors is obviously weak and makes it probable that the threefold axis is oriented along the hydrogen bond to the central ammonium ion. An interesting question is then the extent of rotation around the threefold axis. The favorable arrangement of three negatively charged halogen atoms suggests that the hydrogen atoms are preferably oriented towards these atoms; the three-dimensional difference synthesis of the chloride seems to give rather definite support to this suggestion. Two typical sections are illustrated in Fig. 9; the corresponding sections involving the other ammonia molecules are very similar. As expected (if the threefold axis is oriented along N_0—N_2), the "hydrogen atom" appearing in the plane of N_0, N_2 and Cl′ is quite far off the connecting line N_2—Cl′ which gives more reasonable bond angles in the ammonia molecule (the angle N_0—N_2—Cl′ is 79°, see Fig. 8). It seems likely that a phase transition

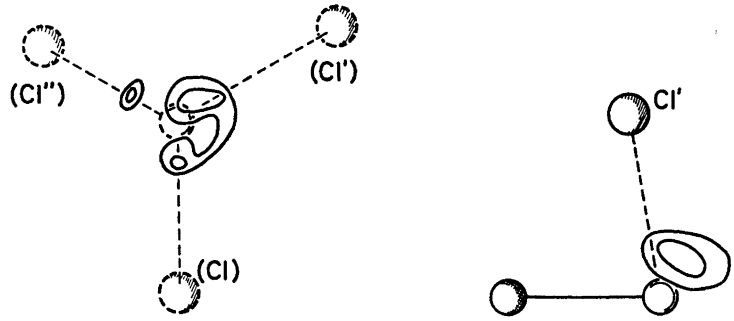

Fig. 9. Difference synthesis in two different sections. In the right picture the section passes through N_0, N_2 and Cl′; in the left it is drawn approximately perpendicular to the N_0—N_2 bond axis and through those places expected for the hydrogen atoms of N_2, as discussed in the text. The contours are drawn at 0.4 and 0.5 e. Å^{-3}.

should be expected if relatively unrestricted rotation around the threefold axis occurred at higher temperatures. As pointed out earlier, no phase transitions were observed in the X-ray photographs as the crystals were cooled down from the melting point to —140°C. So far no heat capacity measurements have been published.

3. Halogen

The closest neighbors to a halogen atom are three nitrogen atoms of each kind. The distances for the chloride are shown in Fig. 5 and for all three compounds in Table 4. Of the three ammonium neighbors, only one points a

* Also: 4.50(5).
** Also: 4.71(9).

hydrogen atom towards this halogen atom as the other two are directly involved in bonds to other halogen atoms. These two ammonium ions are also considerably more distant. If now the hydrogen atoms of the ammonia molecules are also preferably oriented towards halogen as discussed above, this means that altogether ten hydrogen atoms are more or less directed towards halogen. The preceding discussion has to be modified somewhat in the iodide case. From Table 4 it is apparent that the distances $I-N_0'$, $I-N_0''$ and $I-N_1$ are considerably larger than the corresponding distances in the chloride and bromide structure. It is then not too surprising that two extra atoms, other than these twelve, are also situated at comparable distances (see the foot-note in the table). As was pointed out earlier, N_2 and N_3 are interchanged in certain cases when the iodide structure is compared to the chloride and bromide structure, which is also shown in this table.

It may be worth mentioning that the halogen atoms form an approximately face-centered arrangement. If the halogen coordinates were $(\frac{1}{2},0,0)$ instead of those given in Table 1, the face-centering would be perfect.

As a summary, the structures are characterized by rather discrete halidotriammineammonium tetrahedra (Figs. 2 and 4). The forces between these groups are relatively weak; the tetrahedra are arranged in such a way that their centers form a flat (close to) body-centered lattice (Fig. 3). The possible rotation of the ammonia molecules about their threefold axes may be relatively restricted by interaction with the halide neighbors. It must be pointed out that the individuality of the tetrahedral groups is much less pronounced in the iodide than in the other two. Note, for example, that the distance N_0—I within the group is 3.64 Å, while the distance from N_2 to one of the iodine atoms in a neighboring group is not much longer, 3.76 Å.

Acknowledgements. The preliminary work on the bromide and iodide compounds was done in collaboration with Mr Gunnar Larsson and Mr Rune Liminga and I am much indebted to them for their very valuable assistance.

Sincere thanks are due to Professor G. Hägg for his great interest in this work and for all the facilities put at my disposal. The refinements were performed on the IBM 650 and 701 computers during my stay at the Lawrence Radiation Laboratory of the University of California, Berkeley, U.S.A., with support of the U.S. Atomic Energy Commission, and I am much indebted to Professor D. H. Templeton for permission to use these facilities.

This work has been supported by several grants from the *Swedish Natural Science Research Council* which are here gratefully acknowledged.

The Crystal Structure of Tetrammineammonium Iodide

IVAR OLOVSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structure of $NH_4I \cdot 4NH_3$ has been determined from single crystal X-ray data obtained at −140°C. No phase changes were observed between this temperature and the melting point. There are two formula units in the tetragonal cell of the dimensions: a = 8.94 Å, c = 6.55 Å. The space group is $P4/n$. The four ammonia molecules are hydrogen-bonded to ammonium into tetrahedral tetrammine-ammonium groups. The different groups are relatively isolated from each other and are distributed in such a way that an almost close-packed arrangement of twelve nitrogen neighbors is formed around iodine.

In an earlier report on the structures of the triammines of the ammonium halides [1] a general introduction was given to the system NH_4X—NH_3 (X = F, Cl, Br, I). The tetrammine of ammonium iodide has been reported in several earlier works; the corresponding bromide compound so far only by Watt and McBride [2]. For references to earlier works see this article. The present investigation involves the determination of the crystal structure of $NH_4I \cdot 4NH_3$ from single crystal X-ray diffraction data obtained at —140°C. Some preliminary data have been published earlier [3].

EXPERIMENTAL

The crystals were grown from solutions of ammonia and ammonium iodide sealed in glass capillaries. The samples were prepared in the way described earlier [1]. The sample used for the X-ray work had the ratio 4.0 moles ammonia per mole of ammonium iodide. The melting point of this sample was −6°C (earlier reported value −5.1°C).

The single crystals were grown in the usual way by blowing a cooled stream of gas parallel to the capillary; all crystals prepared preferably oriented their a axes along the axis of the capillary. Equi-inclination Weissenberg photographs were taken around the a axis, layers 0−6, at −140°C by the use of Cu-K-radiation. The experimental set-up was the same as that used earlier [1]. Exposures taken at −25°C indicated no changes in structure.

The relative intensities were estimated visually by the use of multiple-film technique (5 films) and comparison with an intensity scale. The data were corrected for the Lorentz and polarization effects.

UNIT CELL AND SPACE GROUP

The data showed the diffraction symmetry of the tetragonal Laue group $4/m$. Systematic absences were: $(hk0)$ for $h + k$ odd. All reflections (hkl) with $h + k + l$ odd were in general considerably weaker than those with $h + k + l$ even. The systematic absences suggest the space group $P4/n$ (C_{4h}^3) and the refinements indicated no deviation from this choice.

The unit-cell dimensions were first approximately determined from rotation and Weissenberg photographs and then somewhat more accurately by the single crystal method described by Weisz, Cochran and Cole [4] ("the Θ-method"). The practical procedure was described earlier [1]. The following values were obtained: $a = 8.94 \pm 0.01$ Å, $c = 6.55 \pm 0.01$ Å. ($t = -140$°C, λCu-$K\alpha_1 = 1.54051$ Å, λCu-$K\alpha_2 = 1.54433$ Å). The approximate density was obtained from the volume and weight of a homogeneous crystal in a cylindrical capillary (the weight was known from the preparation): $d_{obs} = 1.5$ g/cm^3. With two molecules per unit cell a value of 1.35 is calculated.

The general equivalent positions in $P4/n$ are (origin at $\bar{4}$, *cf. International Tables* [5]): (x,y,z); $(\bar{x},\bar{y},z)$; $(\frac{1}{2}+x,\frac{1}{2}+y,\bar{z})$; $(\frac{1}{2}-x,\frac{1}{2}-y,\bar{z})$; $(\bar{y},x,\bar{z})$; $(y,\bar{x},\bar{z})$; $(\frac{1}{2}-y,\frac{1}{2}+x,z)$; $(\frac{1}{2}+y,\frac{1}{2}-x,z)$.

DETERMINATION OF THE ATOMIC COORDINATES

The intensities of the reflections indicated that, among the twofold positions, only those of the form $(0,\frac{1}{2},z)$; $(\frac{1}{2},0,\bar{z})$ were possible for iodine. The z coordinate could be estimated to be about 0.24. This z coordinate was refined in two cycles of least-squares refinement and a three-dimensional F_o-F_c synthesis, based on iodine only, was calculated. From these difference maps,

the nitrogen atoms (N_0) in ammonium could be located in the twofold positions $(0,0,\frac{1}{2})$ and $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$. Finally the nitrogen atoms (N_1) belonging to the four ammonia molecules were found to occupy together the general 8-fold positions written down earlier.

The coordinates and isotropic temperature factors for iodine and nitrogen and an over-all scale factor were finally refined by least-squares methods on the IBM 650 computer. R_3 (see below) was the quantity actually minimized; the weighting factor w and some other details of the program have been described earlier [6]. The scattering factors used in these calculations were those of Berghuis *et al.*[7] for neutral N; for I^- they were estimated from the values for neutral I published by Thomas and Umeda [8]. The shifts in the coordinates in the final cycle were less than 0.00002. The results, together with the standard deviations after 12 cycles of refinement, are given in Table 1. The "unreliability factors" at this point were:

$$R_1 = \Sigma||F_o|-|F_c|| \,/\, \Sigma|F_o| = 0.105.$$
$$R_2 = [\Sigma(|F_o|-|F_c|)^2/\Sigma|F_o|^2]^{\frac{1}{2}} = 0.137$$
$$R_3 = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{\frac{1}{2}} = 0.140$$

The observed and calculated structure factors are compared in Table 2. Notice that the positions of iodine and nitrogen N_0 (but not nitrogen N_1) are consistent with the space group $P4/nmm$. The deviation of the diffraction symmetry from $4/mmm$ is therefore expected to be quite small (but is nevertheless obviously real) which is noticeable in Table 2.

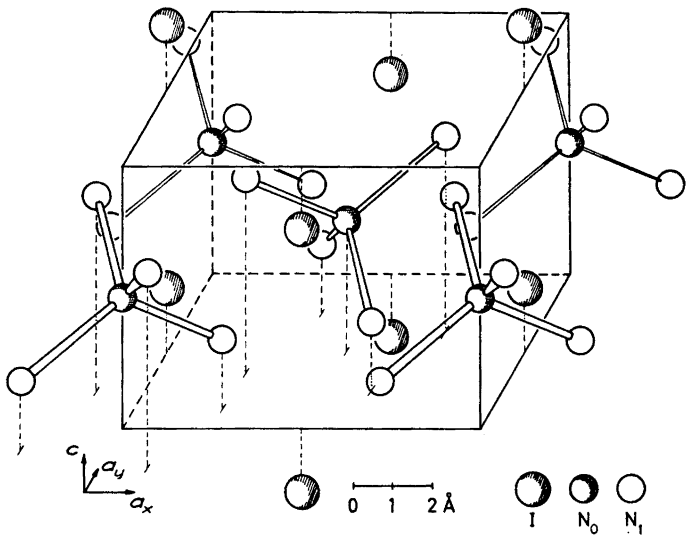

Fig. 1. The crystal structure of $NH_4I \cdot 4NH_3$. N_0 is nitrogen in ammonium, N_1 belongs to ammonia. The hydrogen bonds within the discrete tetrammineammonium tetrahedra are indicated.

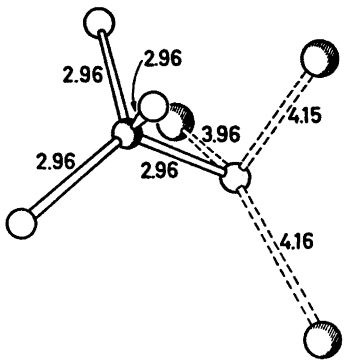

Fig. 2. Bond distances in the tetrammine-ammonium group and the distances between ammonia and its three iodine neighbors.

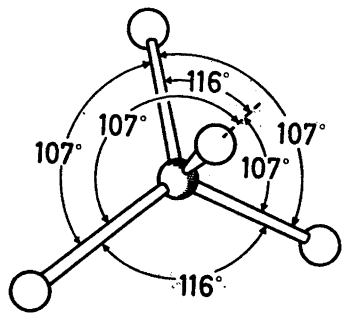

Fig. 3. Bond angles in the tetrammine-ammonium group. The corresponding distances are shown in Fig. 2.

DISCUSSION OF THE STRUCTURE

The structure is shown in Fig. 1. The ammonium ion is tetrahedrally surrounded by the four ammonia molecules, all at 2.96 Å from N_0, see Fig. 2

Table 3. Distances and angles with their standard deviations (compare with Figs. 2—5).

1. Around ammonium

Bond	Distance (Å)	Bonds	Angle (°)
N_0-N_1	2.95(6) ± 0.02(2)	$N_1-N_0-N_1'$	106.5 ± 0.3

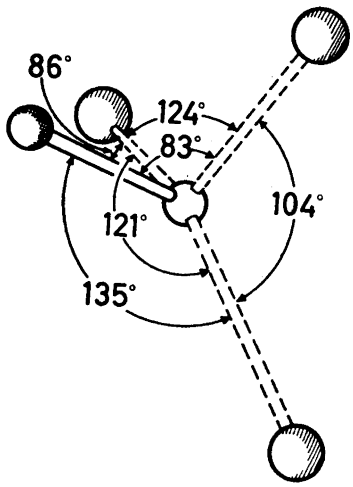

Fig. 4. Angles between the N—N_0 and N—I lines of ammonia. The corresponding distances are shown in Fig. 2.

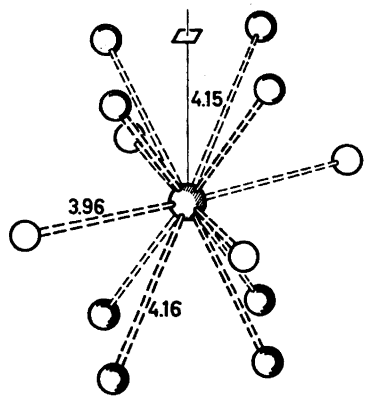

Fig. 5. Distances to the neighbors of iodine. The twelve nitrogen atoms (N_1) form an almost cubic close-packed arrangement around iodine.

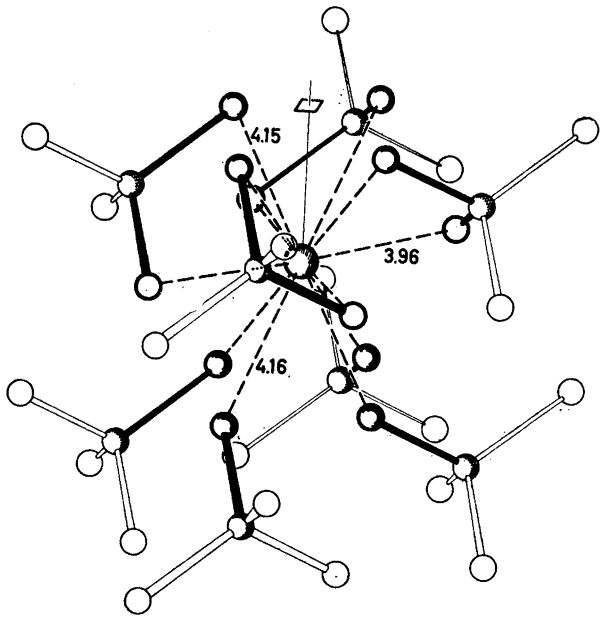

Fig. 6. The distribution of the tetrammineammonium groups around iodine. The twelve closest neighbors (shown separately in Fig. 5) are heavily drawn.

and Table 3. The bond angles are shown in Fig. 3. The central atoms (N_0) are located at $\bar{4}$ and form a *C*-centered arrangement. The hydrogen atoms of ammonium are obviously involved in hydrogen bonds to the ammonia neighbors. The distance $N_0 - - - N_1$, 2.96 Å, is within the usual range for hydrogen bonds of this kind [9]. Compare also with the corresponding distances in $NH_4Cl \cdot 3NH_3$ (2.90, 2.93, and 2.99 Å), $NH_4Br \cdot 3NH_3$ (2.82, 2.92, and 2.95 Å) and $NH_4I \cdot 3NH_3$ (2.66, 2.99, and 3.06 Å) [1].

As the free electron pair of ammonia is obviously involved in the hydrogen bond to ammonium, it seems unlikely that bonding between the different ammonia molecules will occur. All such distances are larger than 3.6 Å. The distances to the iodine neighbors are listed in Table 3. The interaction between ammonia and its neighbors is obviously weak and makes it probable that the threefold axis is oriented along the hydrogen bond to the central ammonium ion. The relatively favorable arrangement of three negatively charged iodine atoms around ammonia (see Figs. 2 and 4) may suggest that the possible rotation around the threefold axis is somewhat restricted and that the molecule is preferably oriented towards these iodide ions. The situation is very similar to that in $NH_4Cl \cdot 3NH_3$, $NH_4Br \cdot 3NH_3$ and $NH_4I \cdot 3NH_3$ [1].

Iodine is located on a fourfold axis and surrounded by twelve nitrogen atoms (N_1) in an almost cubic close-packed arrangement (see Fig. 5). The distribution of the tetrahedral tetrammineammonium groups around iodine is shown in Fig. 6. Compare the distances iodine-ammonia in this compound (3.96, 4.15, and 4.16 Å, *cf.* Table 3) with the corresponding distances in $NH_4I \cdot 3NH_3$ (mean value 3.9 Å)[1]. The iodine atoms form an almost body-centered arrangement (if the *z* coordinate were 1/4 instead of 0.2415, the body-centering would be perfect). This is of course the reason why reflections (*hkl*), with $h+k+l$ odd, are in general considerably weaker than those with $h+k+l$ even.

Acknowledgements. I am much indebted to Prof. G. Hägg for his great interest in this work and for all the facilities put at my disposal. I also wish to thank Mrs E. Hadler Vihovde, Oslo, Mr Rune Liminga and Mr Gunnar Larsson for their valuable assistance during the preliminary work on this compound.

The refinements were performed on the IBM 650 and 701 computers during my stay at the Lawrence Radiation Laboratory of the University of California, Berkeley, U.S.A., with support by the U.S. Atomic Energy Commission, and I am very grateful to Prof. D. H. Templeton for permission to use these facilities.

This work has been supported by grants from the *Swedish Natural Science Research Council* which are here gratefully acknowledged.

Intermolecular Hydrogen Bond Association between Phenol and Compounds which Contain the Phosphoryl and Carbonyl Groups

GUNNAR AKSNES*

Norwegian Defence Research Establishment, Toxicological Group, Kjeller, pr Lillestrøm, Norway

The intermolecular hydrogen bond association between phenol and triethylphosphate respectively N-diethylacetamide gives 1:1 association complexes, where the P=O respectively the C=O group participates in the hydrogen bond. The association constants and molar extinction coefficients of the hydrogen bond complexes have been determined. The salt-like addition compounds between tertiary amides and strong acids (HCl) give proton transfer bond where the hydrogen is attached to the amide nitrogen. By using triethylphosphate it has been possible to locate 6 bands in the infrared spectrum of phenol which are due to vibrations of the free hydroxyl group. Two of the bands are interpreted as bands due to bending vibrations and four as bands due to combination between stretching and bending of the hydroxyl group. The vibrations of the hydroxyl group in alcohols are also discussed.

It has long been recognized that hydroxylic compounds show a strong tendency for hydrogen bond association. In the infrared spectral region the ground state stretching vibration of the free O—H bond will be displaced towards lower frequencies upon association [1–6]. Alcohols and phenols give rise to both dimeric and polymeric association [7–8]. The degree of association is very sensitive to changes in concentration and temperature [8].

It is known that the hydrogen bond association between compounds which contain the hydroxyl and carbonyl groups gives rise to displacement of the stretching frequencies of both the OH and C=O band. This is explained by assuming hydrogen bond between the two groups: ROH...O=C. Examples are dimeric carboxylic acids [9–13] and intramolecular association in hydroxy keto compounds [14–17], but intermolecular associations between unlike species are also known [8,18–20,24].

* Present address: Chemical Institute, University of Bergen, Bergen, Norway.

THEORETICAL

The strong hydrogen bond association between phenol and N-dialkylacetamide respectively orthophosphate esters makes it possible to study the bond formation with sufficiently low concentration of phenol to avoid dimeric and polymeric phenol association. The hydrogen bond must therefore be due to association between unlike species. If we assume the molar ratio of phenol and substrate in the complex to be 1:1 we have for the equilibrium condition:

$$\mathrm{ROH} + \mathrm{S} \rightleftharpoons \mathrm{RO{-}H \cdots S}$$

When the total concentration of phenol and substrate is constant $= c$, and α and $1 - \alpha$ are the mole fractions of phenol and substrate, respectively, and X = concentration of complex we have:

$$K = \frac{X}{[a \cdot c - x]\,[(1 - a)\,c - X]} \tag{1}$$

where K = association constant.

The solution of the equation gives:

$$X = \frac{(K \cdot c + 1) \pm \sqrt{(K \cdot c + 1)^2 - 4K^2\alpha \cdot c^2\,(1-\alpha)}}{2K} \tag{2}$$

where the sign $-$ is the only valid.

Upon derivation we find:

$$X_{\max} = \frac{(Kc - 1) - \sqrt{2Kc + 1}}{2K} \tag{3}$$

when $\alpha = \frac{1}{2}$.

The concentration of phenol or substrate is $\frac{c}{2} - X_{\max}$ when $\alpha = \frac{1}{2}$. The complex is therefore 1:1 if X has maximum at $\alpha = \frac{1}{2}$. A plot of the concentration of X as function of α is symmetrical on both sides of $\alpha = \frac{1}{2}$.

The concentration of phenol and substrates (N-diethylacetamide and triethylphosphate) can be determined from the optical density of the free O-H stretching band, and from the C=O or P=O bands of the substrates when the molar extinction coefficients are known and as a first approximation we assume the Lambert-Beer's law to be valid. The molar extinction of the complex, $\varepsilon_{\max}$, can be calculated from two different sets of values of phenol and substrate.

If we use equimolecular amounts of phenol and substrate we have:

$$K = \frac{X_1}{(A_1 - X_1)^2} = \frac{X_2}{(A_2 - X_2)^2} \tag{4}$$

where: X_1 and X_2 = concentration of complex
A_1 and A_2 = concentration of phenol and substrate.

If we assume Lambert-Beer's law to be valid we get:

$$K = \frac{f \cdot E_1}{(A_1 - f \cdot E_1)^2} = \frac{f \cdot E_2}{(A_2 - f \cdot E_2)^2} \qquad (5)$$

$$\text{where } f = \frac{1}{\varepsilon_{max} \cdot l} \text{ and } E = \log \frac{I_0}{I}.$$

The equation gives for f:

$$f = \frac{1}{\varepsilon_{max} \cdot l} = \frac{(A_2 - A_1) \pm \sqrt{A_2^2 \frac{E_1}{E_2} + A_1^2 \frac{E_2}{E_1} - 2A_2 \cdot A_1}}{E_2 - E_1} \qquad (6)$$

where the sign — is the only valid when $A_2 - A_1 > 0$.

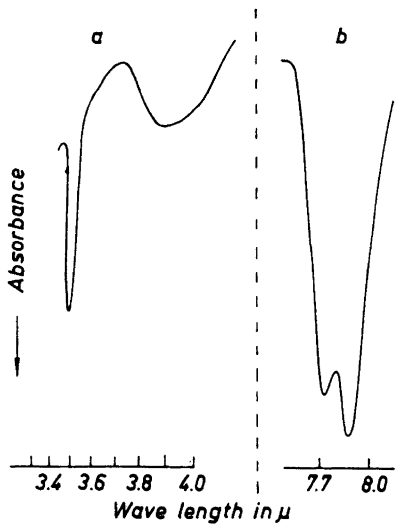

Fig. 1. a). Free and associated stretching bands of HCl (0.03 M) in CCl_4 in the presence of di*iso*propylfluorophosphate (0.03 M). *b*) Free and associated stretching bands of the P=O group of di*iso*propylfluorophosphate (0.03 M) in CCl_4 in the presence of HCl (0.03 M).

RESULTS OF THE MEASUREMENTS

The results of the measurements are collected in Tables 1 and 2. From the approximate constancy of the association constant at different concentrations of phenol and substrate we conclude that the complexes between phenol and diethylacetamide and between phenol and triethylphosphate are 1:1. The same results is also reached by comparing the optical densities of the associated hydroxyl stretching vibration band at different concentrations of phenol and substrate recorded in column 4, Tables 1 and 2. The expected maximum in optical density at $\alpha = \frac{1}{2}$ and the symmetrical distribution of the complex concentration on both sides of $\alpha = \frac{1}{2}$ give a convincing picture of the 1:1 association. In column 7, Tables 1 and 2, are recorded the calculated molar extinction coefficients of the two different complexes. The complex with the highest association constant shows the greatest molar extinction coefficient. A reasonable interpretation of this behaviour is that the complex with the highest association constant gives rise to the strongest change in dipole moment of the hydroxyl group during the vibration and in this way contributes to a greater intensity of absorption.

The stretching vibration band of the free and associated phosphoryl- and carbonyl group at 1 271 cm^{-1} and 1 655 cm^{-1} vary with the mole fraction of phenol in the same manner as the free and associated hydroxyl group. The displacements of the C=O and P=O bands upon hydrogen bonding are approximately 18 cm^{-1} and 30 cm^{-1}, respectively. For quantitative study of the hydrogen bond formation the use of the C=O and P=O bands are less suitable due to the small displacements of the associated bands.

Solid curve: Spectrum of N-dimethylacetamide hydrochloride (0.1 M) in $CHCl_3$; Dotted curve: Spectrum of trimethylamine hydrochloride (0.1 M) in $CHCl_3$. *b*) Solid curve: Spectrum of N-dimethylacetamide (0.5 %) in solid phase (KBr-briquet); Dotted curve: Spectrum of trimethylamine hydrochloride (0.5 %) in solid phase (KBr-briquet).

THE BEHAVIOUR OF ESTERS OF PHOSPHORIC ACID AND TERTIARY AMIDES UPON ASSOCIATION WITH HYDROCHLORIC ACID

Hydrochloric acid gives with esters of phosphoric acid in carbon tetrachloride the normal hydrogen bond association product where the phosphoryl oxygen participates in the hydrogen bond. Fig. 1 shows the free and associated stretching frequencies of the HCl-bond at 2 825 cm^{-1} and 2 440 cm^{-1}. The displacement is practically identical with the displacement of the H—Cl bond which is observed when hydrochloric acid is associated with ethyl ether [22]. The free and the associated P=O stretching frequencies are observed at 1 295 cm^{-1} and 1 268 cm^{-1} (Fig. 1). With tertiary amides the picture is quite different. The salt-like compounds which are formed between hydrochloric acid and tertiary amides were studied both in solid phase (KBr-briquet) and in chloroform solution. The solution showed no free or associated H—Cl stretching vibration and the frequencies of the vibration of the C=O bond were slightly higher than for the vibration of the C=O group in the pure amide solution. The spectrum between 2 300 cm^{-1} and 3 000 cm^{-1} showed the typical character of quaternary ammonium compounds with 3 carbon and 1 hydrogen atom attached to the nitrogen. In Fig. 2 are compared the spectra of trimethylamine hydrochloride with N-dimethyl acetamide hydrochloride in chloroform solution (a) and in solid phase (b). The very similar form of these spectra gives strong support to the quaternary nitrogen structure of the addition compounds between tertiary amides and strong acids. The above observations give evidence that there exist principal differences

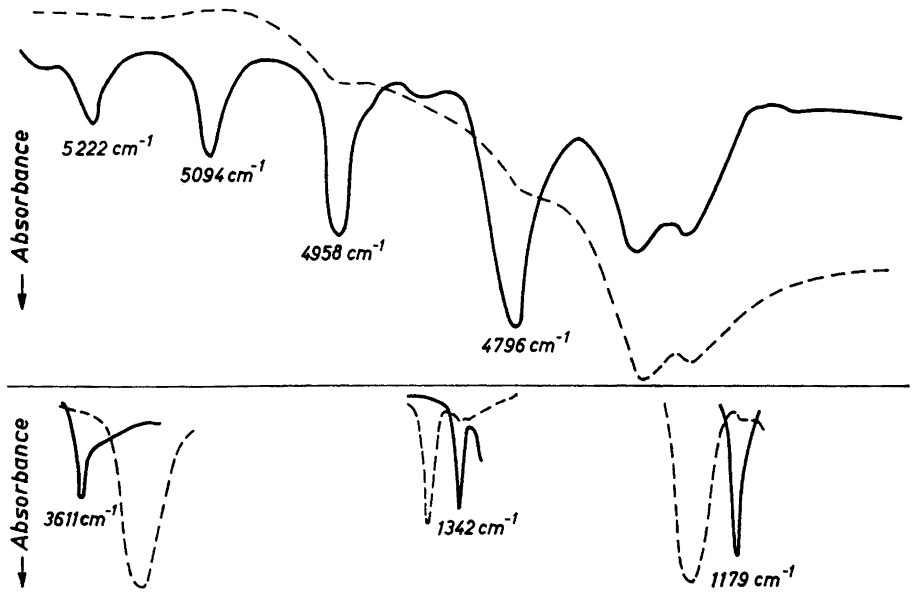

Fig. 3. Solid lines: Absorption bands of the free hydroxyl group of phenol (0.2 M) in CCl_4; Dotted lines: The disappearance of the free hydroxyl group of phenol (0.02 M) in CCl_4 in the presence of triethylphosphate (0.02 M).

between the formation of hydrogen bonds and proton transfer bonds. The explanation may be that the semi-polar oxygen is favoured in hydrogen bonding due to a great polarity of the bond but the nitrogen is favoured in proton transfer due to a greater tendency to share an electron pair with hydrogen.

THE APPLICATION OF TRIETHYLPHOSPHATE FOR THE IDENTIFICATION OF BANDS WHICH ARE DUE TO VIBRATIONS OF THE HYDROXYL GROUP

The very strong hydrogen bond between phenol and triethylphosphate makes the latter compound suitable for identification of the different vibrations of the hydroxyl group. When the hydroxyl group participates in hydrogen bond formation the bands due to the free hydroxyl disappear. The association constant between phenol and triethylphosphate in CCl_4 was found to be approximately 500. By using equimolecular amounts of phenol and triethylphosphate, concentrations of 0.2 M will reduce the concentration of free phenol to about 10 % of its original value. By using a double beam infrared instrument it is easy to compensate for the added triethylphosphate. In this way the disappearance of bands due to vibration of the free hydroxyl group is easily detected. Six hydroxyl bands were found at the following wave numbers: 1 178 cm^{-1}, 1 342 cm^{-1}, 4 796 cm^{-1}, 4 958 cm^{-1}, 5 094 cm^{-1} and 5 222 cm^{-1}. In Fig. 3 are recorded the spectra of the vibrations of the hydroxyl group in the above mentioned regions before and after addition of triethylphosphate.

Table 3. Optical densities of hydroxyl vibration bands of phenol in carbon tetrachloride (Measured at bond maximum).

Conc. of phenol (moles/l)	Optical density (cell length 10 mm)				Optical density (cell length 1 mm)					
	free OH 5 222 cm^{-1}	free OH 5 094 cm^{-1}	free OH 4 958 cm^{-1}	free OH 4 796 cm^{-1}	free OH 3 611 cm^{-1}	ass. OH 3 300 cm^{-1}	free OH 1 342 cm^{-1}	ass. OH 1 358 cm^{-1}	free OH 1 178 cm^{-1}	ass. OH 1 215 cm^{-1}
