To prove that the six hydroxyl bands which were located with triethylphosphate are free hydroxyl bands their optical densities were studied as function of phenol concentration. The results are recorded in Table 3. Due to the increasing association of phenol the optical densities of the free hydroxyl bands shall increase less than proportional to the concentration of phenol. It is seen that the absorbance of the six hydroxyl bands vary with the concentrations of phenol in exactly the same way. The observed variations are just the same as the variation of the free stretching vibration band at 3 611 cm^{-1}.

It is observed that upon increasing the concentration of phenol two new bands appear displaced to higher frequencies of the free hydroxyl bands. These two association bands are located at 1 358 cm^{-1} and 1 215 cm^{-1}. The optical densities of the bands increase more rapidly than proportional to the concentration of phenol. From Table 3 we observe that the increase in optical densities are exactly parallel to the increase of absorbance of the association band at 3 300 cm^{-1} which is due to the hydroxyl stretching vibration of associated phenol.

INTERPRETATION OF THE LOCATED HYDROXYL BONDS

1. Bending vibrations of the hydroxyl group

There has for a long time been disagreement about the location of the bending vibrations of the hydroxyl group. Of the two bending vibrations, δ-OH (in-plane bending) and γ-OH (out-of-plane bending) one has expected to find the δ-OH in the region 1 300—1 200 cm^{-1} and the γ-OH in the region 1 000—600 cm^{-1} [22]. The present findings suggest that the δ-OH and γ-OH vibration bands of phenol are the absorption bands which are found at 1 342 cm^{-1} and 1 178 cm^{-1}.

The arguments for this interpretation are:

a) The bending vibrations of the hydroxyl group are perpendicular to the hydrogen bond. The hydrogen bond should therefore contribute to a stronger restoring force of the bending vibrations. The frequency of the hydroxyl bending vibrations should therefore be expected to increase upon formation of the hydrogen bond. This is also the situation of the two bands which are located at 1 342 cm^{-1} and 1 178 cm^{-1}. Their association bands are found at 1 358 cm^{-1} and 1 215 cm^{-1}, respectively.

b) The hydrogen bond should be expected to decrease the amplitude of the bending vibration. The change in dipole moment during vibration will therefore be smaller, which is tantamount to a lower intensity of the bending vibration of the associated hydroxyl bond. If we compare the absorbance of the free and the associated vibration bands with the free and the associated stretching bands at corresponding phenol concentrations in Table 3 it is seen that the ratios between the absorbances of the free and the associated vibration bands are opposite to the ratio observed for the stretching band. If the breadth of the bands are also considered which must be done when intensities are to be compared, the inverse relationship is still greater than when only the absorbances are compared.

2. Combination between stretching and bending vibrations

The most reasonable interpretation of the 4 hydroxyl bands located in near infrared at 5 222 cm^{-1}, 5 094 cm^{-1}, 4 958 cm^{-1} and 4 796 cm^{-1} seems to be that the two bands of highest frequencies are bands due to combination between the free stretching vibration and the in-plane bending vibration and the two bands at the lowest frequencies are combination bands between the free stretching vibration and the free out-of-plane bending vibration.

The arguments for this view are:

a) From the experiment with phenol and triethylphosphate it was found that the four bands were all due to free hydroxyl groups. The same result was also found in the study of the concentration dependence of the bands.

b) If the two bending vibrations combine with the same stretching vibration to give combination vibrations it is reasonable to expect that the ratio between the absorbance of the two bending vibrations should be identical with the ratio between the corresponding combination vibrations.

Table 4. Bands due to bending of the hydroxyl group in alcohols.

Compounds	Band maxima (cm^{-1})
Methyl alcohol	1 328
Ethyl alcohol	1 236
Propyl alcohol	1 210
Butyl alcohol	1 202
Amyl alcohol	1 200

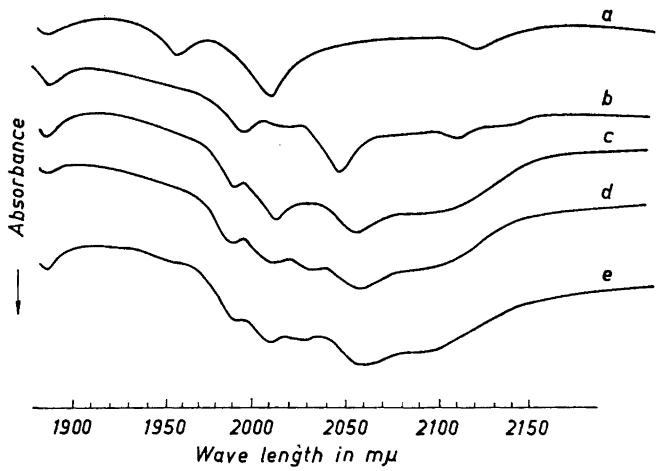

Fig. 4. Combination bands of alcohols in CCl_4 (0.4 M). *a*) Methyl alcohol, *b*) ethyl alcohol, *c*) propyl alcohol, *d*) butyl alcohol, *e*) amyl alcohol.

From Table 3 we calculate that the average ratio between the absorbance of the two bending vibrations at the six different phenol concentrations is 2.9. The average ratio between the absorbances of the bands at 5 222 cm^{-1} and 4 958 cm^{-1} is 2.8, and the average ratio between the absorbances of the bands at 5 094 cm^{-1} and 4 796 cm^{-1} is 2.9. Why the combined vibration of bending and stretching vibrations should give rise to splitting of the combination bands is not known. It seems worthwhile to mention that similar splitting of the overtone bands of the C—H group is also observed [23].

THE BENDING AND COMBINATION BANDS OF ALCOHOLS]

The previous described technique of hydroxyl bands localisation has been used in an attempt to locate the bending and the combination bands of alcoholic hydroxyl groups. In this case we have been able to locate with certainty only one bending vibration band in the region 1 400—1 100 cm^{-1}. The frequencies of the bending vibrations of different alcohols are recorded in Table 4. The observed frequencies correspond with the frequencies of δ-OH vibrations put forward of Stuart and Sutherland [24]. The interesting observation which is also mentioned by Stuart and Sutherland [24] is that the frequency of the bending band of methyl alcohol is abnormally high. This anomaly of the methyl alcohol gives an argument that the combination vibration of the hydroxyl groups of alcohols observed in near infrared are composed of stretching and bending vibrations. The combination vibrations of the hydroxyl in methyl alcohol must in this case show the same strong displacement towards higher frequencies when it is compared with the other alcohols. This is exactly the case as shown in Fig. 4.

Another observation is that in methyl alcohol there are only two free hydroxyl bands in near infrared. In ethyl- and propyl alcohol we can recognize three and in the higher members of alcohols four free hydroxyl bands (Fig. 4.)

The intensities of the combination bands of alcohols are much lower than the intensities of the corresponding phenol bands. The same relation should therefore be expected to hold for the bending vibrations, and this may explain why the bending vibration bands of alcohols are more difficult to locate.

EXPERIMENTAL

The infrared spectra of the compounds studied were recorded on a Perkin-Elmer Spectrometer Model 21. The measurements were performed in carbon tetrachloride in sodium chloride cells of 1 mm thickness compensated against carbon tetrachloride. The temperature was maintained constant within a range of ± 1°C during the measurements.

The spectra in near infrared were recorded on a Beckman instrument, Model DK 2. The measurements were performed in carbon tetrachloride solution in quartz cells of 10 mm thickness compensated against carbon tetrachloride.

The compounds studied were synthesized according to descriptions in the literature [25,26].

Intermolecular Hydrogen Bond Association between Phenol and Organophosphorus Compounds

GUNNAR AKSNES* and THOR GRAMSTAD

Norwegian Defence Research Establishment, Toxicological Group, Kjeller, pr Lillestrøm, Norway

The intermolecular hydrogen bond association constants between phenol and eighteen organophosphorus compounds have been determined at 20°C and 50°C.

The ΔF, ΔH and ΔS values of the equilibrium reactions are found to vary linearly with the hydrogen bond shift in such a way that an increase in enthalpy is counteracted by a decrease in entropy.

The strong influence of the substituents in organophosphorus compounds on the hydrogen bond association constants is discussed in terms of the electronic properties of the phosphorus atom and the substituents.

The connection between hydrogen bond formation and proton transfer reaction is commented upon.

In a previous paper the very strong intermolecular hydrogen bond between phenol and triethylphosphate was reported [1]. It was shown that it is the phosphoryl group which participates in hydrogen bonding. When sufficiently low concentrations of phenol and triethylphosphate are used the only association complex formed is the dimeric intermolecular hydrogen bond complex.

This paper is devoted to the study of the influence of different substituents in the phosphorus compounds on the dimeric hydrogen bond complex. Studies of the self-association of phenol made it clear that the phenol concentration range used in the previous study [1] (0—0.03 M) was not quite low enough to exclude self-association of phenol. To avoid any disturbance of self-association of phenol it was found necessary to reduce the concentration range to 0—0.006 M.

We found it of special interest to evaluate the thermodynamic functions of the hydrogen bond equilibrium reaction. It was therefore necessary to determine the association constants at two different temperatures. An accurate temperature control is difficult to obtain in salt cells, and the ground state

stretching vibration band of phenol is therefore less suitable to use as measure of free phenol concentration. We therefore decided to employ the first overtone band of the hydroxyl group of phenol at 7 052 cm^{-1}. In this spectral region one can use absorption cells of quartz, and a good temperature control is therefore easily obtained.

EXPERIMENTAL

Materials. The phosphorus esters studied were synthesized from the corresponding chlorides. An equivalent amount of alcohol was added to the organophosphorus chloride in carbon tetrachloride in the presence of pyridine. The pyridine salt was filtered off and the phosphorus ester distilled under reduced pressure. The ester was purified by repeated fractionations. The organophosphorus chlorides were synthesized according to descriptions in the literature. The chlorides of the compounds Nos. 1, 3, 9, 11, 13 and 14 in Table 2 were prepared according to the method of Kinnear and Perren [2], and the chloride of the compound No. 15 according to the method of Michaelis [3]. Compounds Nos. 4, 6, 8 and 10 were prepared according to the method of Nylén [4], and the derivatives of phosphine oxide (compounds Nos. 16, 17 and 18) were synthesized according to the description of Kosolapoff [5].

The fluorine-containing compounds (Nos. 2 and 5) were synthesized from the corresponding chlorides. The chloride (20 g) was added to an excess of sodium fluoride (10 g) in benzene (50 ml). The reaction mixture was rapidly stirred, and the temperature in the mixture was kept at 60°C for one hour. The sodium salts were filtered off and the fluorophosphorus compound distilled under reduced pressure.

The method used for the calculation of the association constants was the same as described previously [1]. The concentration of the free phenol was determined from the first overtone band of the stretching vibration of the phenolic hydroxyl group at 7 052 cm^{-1}.

The absorption curves were recorded on a Beckman DK 2 double beam spectrophotometer. Cylindrical quartz absorption cells of 10 cm path length were used. The absorption cell which contained the mixture of phenol and the phosphorus compound in carbon tetrachloride was jacketed with a polyethylene tube. The tube was welded to the absorption cell approximately 5 mm from the windows. A constant temperature circulating water bath maintained the polyethylene jacketed cell at ± 0.1°C. The reference cell contained carbon tetrachloride.

The frequency shifts of the ground state stretching vibration band of the associated hydroxyl group of phenol in CCl_4 were measured with a Perkin Elmer infrared spectrophotometer Model 21. The same instrument was used for the determination of the stretching frequencies of the P=O group of the phosphorus compounds in CCl_4. The values of the association constants recorded in Table 2 are the mean values of seven separate determinations of each association constant. In Table 1 are recorded the experimental results from the determination of K_{ass} of one of the compounds studied.

The indexes of refraction of the phosphorus compounds were determined with a thermostated Abbe refractometer. The molar refractions (M.R.) recorded in column 5, Table 2, are calculated with the atomic refractivities of phosphorus compounds given by Jones, Davies and Dyke [6], Vogel [7] and Holmstedt [8].

DISCUSSION

Previous findings indicate that there exists a linear relation between the logarithms of the association constants (or ΔF) and the frequency shift of different hydrogen bonded systems [9]. In Fig. 1 are plotted our results of log K as function of the frequency shift of the ground state stretching vibration of the hydrogen bonded hydroxyl group of phenol. The straight lines drawn through the calculated log K values at 20°C and 50°C, respectively, are both within the limits of experimental errors. The slopes of the two lines are different at the two temperatures studied. The free energy, ΔF, of the hydrogen bond equilibrium reaction can thus be fairly accurately described as a linear function of the frequency shift. Since the enthalpy is interconnected with the free energy through the thermodynamic relation $\Delta F = \Delta H - T\Delta S$, it is a necessary consequence of the linear relation between ΔF and $\Delta\vartheta$ at different temperatures that both the enthalpy and the entropy are proportional to the frequency shift. In Figs. 2 and 3 are shown the variation of ΔF, ΔH and ΔS with $\Delta\vartheta$ calculated from the smoothed values of log K found from the two straight lines in Fig. 1. From the frequency shift of the hydroxyl group of phenol with the different phosphoryl compounds studied we find that in the observed series of compounds there is an increase of ΔH from approximately 5 to 8 kcal but a decrease of ΔS from −6 to −11 E.U.

We interpret this observation as due to an increase in the polarity of the hydrogen bond complex as compared with the reactants. Such increase of polarity upon hydrogen bonding has in fact been observed in dipole moment studies of hydrogen bond complexes. Thus Sutton *et al.* [10,11] have shown that in the O—H···N bond in the complex of phenol and trimethylamine, using *cyclo*hexane as solvent, there appears to be an additional moment of 0.8 *D*. Further evidence may be found in the work of Eda and Ito [12] on the dipole moment of salicyl aldehyde. An increase of polarity from the reactants to the hydrogen bond complex will contribute to a negative entropy of reaction due to a greater orientation of the solvent molecules around the complex.

The stronger the dipole in the phosphoryl group, the stronger will be the deformation of the electrons in the hydrogen bond. We find therefore that the contribution of a negative entropy difference between reactants and complex shall be greatest for the strongest hydrogen bond. Evidence for the above interpretation are also found from other hydrogen bond measurements[13]. Some calculated ΔH and ΔS values are collected in Table 3. We recognize also here the same tendency of ΔH and ΔS to counteract each other.

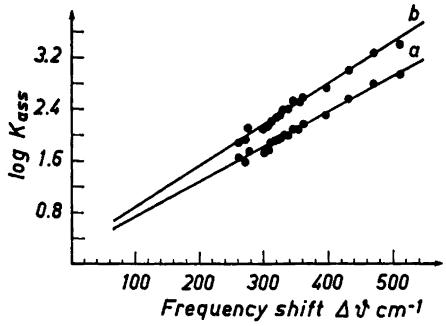

Fig. 1. The relation between the logarithms of the association constants and the frequency shift for the hydrogen bond complexes between phenol and phosphoryl compounds. *a* : 20°C, *b* : 50°C.

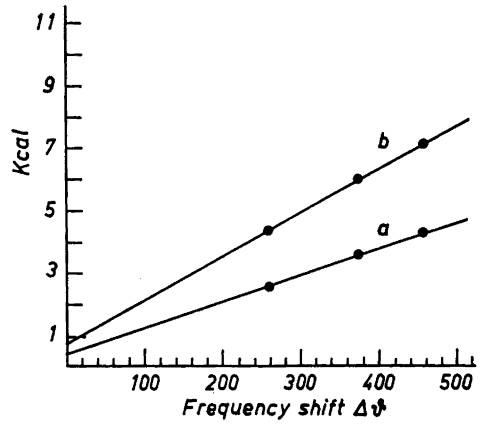

Fig. 2. The relation between ΔF at 20°C (a), respectively, ΔH (b) and the frequency shift for the hydrogen bond complexes between phenol and phosphoryl compounds.

It is of interest that the same opposite operating influence on the activation energy and activation entropy is found in reaction kinetic studies of phosphorus compounds [14].

In Fig. 4 are plotted the observed half bond width $\vartheta\frac{1}{2}$ as function of the frequency shift $\Delta\vartheta$ of the ground state stretching vibration band of phenol when it is hydrogen bonded with different phosphoryl compounds. The straight line drawn through the observed values cuts the $\vartheta\frac{1}{2}$-axis at 35 cm^{-1}. This is

approximately the half band width of the hydroxyl group of phenol in carbon tetrachloride. It is very interesting that the linear relation between $\vartheta_{\frac{1}{2}}$ and $\Delta\vartheta$ seems to be independent of the hydrogen bonded species involved. This conclusion is reached by comparing our results with the observations made by Huggins *et al.*[15]. They find for quite different hydrogen bonding species not only the same linear relation between $\vartheta_{\frac{1}{2}}$ and $\Delta\vartheta$, but also approximately the same slope of the line. The empirical relation seems to be of such general validity that we may suppose that it is connected with some fundamental properties of the hydrogen bond.

To shed further light on this problem we have tried to determine the intensity of the hydrogen bonded hydroxyl groups. Due to the experimental difficulties in the determination of this quantity we have used the product $\vartheta_{\frac{1}{2}} \times \varepsilon_{max}$ (where ε_{max} is the absorption coefficient of the band at the band maximum) as a relative measure of the intensity. The ε_{max} is determined by using so great excess of phosphoryl compound that all of the free phenol has disappeared (0.003 M phenol + 0.2 M phosphoryl compound). The results of the determination of ε_{max} is plotted in Fig. 5. We find in this case a nearly linear relation between ε_{max} and $\Delta\vartheta$ up to frequency shift of approximately 400 cm^{-1}. The ε_{max} of the two last compounds have decreased very markedly. The ε_{max} seems therefore to increase to a maximum value in the neighbourhood of 400 cm^{-1}. The same variation of ε_{max} was also observed by Gordy [16] in his study of hydrogen bond between amines and deuterium oxide. If we consider only the phosphorus compounds which cause frequency shifts of less than 400 cm^{-1} it seems that the intensity as function of the frequency shift can be approximately described by the following equation:

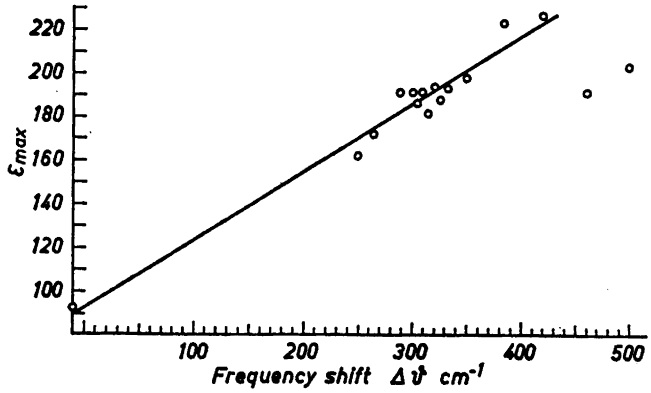

Fig. 5. The relation between ε_{max} and $\Delta\vartheta$ for the hydrogen bond complexes between phenol and phosphoryl compounds.

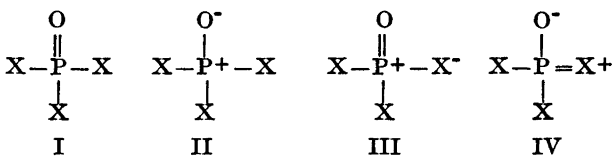
Intensity $\approx \vartheta_{\frac{1}{2}} \times \varepsilon_{max} \approx$

$(\text{const}_1 + f_1 \Delta\vartheta)\ (\text{const}_2 + f_2\Delta\vartheta) = a + b\ \Delta\vartheta + c(\Delta\vartheta)^2$ where a, b and c are constants.

That the variation of the intensity as function of the frequency shift is better described by a parabolic equation than by a linear one, is also clearly observed from the intensity data collected by Huggins and *et al.* [15].

An interesting result of the present study is the observed strong influence of the substituents in the phosphorus compounds on the equilibrium constants of the hydrogen bonded complexes. This must be connected with an easy deformation of the electronic atmosphere around the phosphorus atom. The influence of the substituents upon the polarity of the P = O bond is shown in Table 2, column 6, where the frequencies of the stretching vibration band of the phosphoryl group in carbon tetrachloride are recorded. The general tendency is that electron withdrawing substituents on the phosphorus atom strongly reduce the polarity of the P=O bond. The displacement of the stretching vibration frequency of the P=O group upon hydrogen bonding will be a measure of the polarisability of the phosphorus compound involved. The observed frequency shifts are seen in Table 2, column 7. We recognize that the most strongly polarisable substituents, amino and alkoxy groups, give rise to the greatest frequency shifts of the P=O bond. The chlorine substituted phosphorus compounds are seen to stabilize the electronic constitution of the compounds to such a degree that the formation of the hydrogen bond complex occurs almost without any electronic deformation of the phosphorus compounds. The present findings provide further evidence for the view that the phosphorus atom has a marked tendency to expand its valence shell by utilization of its 3*d* orbitals in the formation of a double bond [17,18]. It seems reasonable that the main contributing structures of the resonance hybrid of phosphorus compounds are as follows [18]:



I II III IV

The frequencies of the stretching vibrations of the different phosphorus compounds in carbon tetrachloride summarized in Table 2 indicate that both the inductive and mesomeric effects of the substituents contribute to the observed polarity of the phosphoryl bond. We suppose that the structures I and II will be the main contributing structures of trialkylphosphine oxides. When strongly negative substituents as fluorine and chlorine are present in the molecule, structure III may be expected to contribute to a larger degree due to the strong $-I$ effect. The mesomeric effect ($+M$) of alkoxy and amino substituents should be characterized by an increasing contribution from structure IV. The observed strong frequency shifts of the phosphoryl group in the alkoxy and amino substituted phosphorus compounds upon hydrogen bonding with phenol points to the conclusion that also the electromeric effect of these substituents are considerable. This effect requires a phosphorus π-orbital capable of interacting with the unshared pair of electrons on the oxygen and nitrogen atoms. The above conclusions are in accordance with the interpretation of Larsson summarized in a recent review [18].

In the previous paper [1] it was shown that the carbonyl group of N-diethylacetamide participated in the hydrogen bonding with phenol. When sufficiently strong acid was used (HCl) a proton transfer reaction occurred, but in this case the proton was attached to the nitrogen. It was mentioned that there seems to exist a principal difference between groups which are involved in hydrogen bonding and proton transfer reaction. We have therefore in this paper included the results of the measurements of the association constants of the complex between phenol and pyridine at 20° and 50°C (Table 2). From Table 3 we observe that the calculated ΔH value of 7.5 kcal of the pyridine-phenol reaction is approximately identical with the ΔH value expected from the frequency shift of 465 cm^{-1} (Fig. 5 b). The reason for the low association constant of the phenol-pyridine complex must therefore be found in an unfavorable entropy of reaction.

The calculated value —17.4 E.U. is in fact approximately 7 E.U. lower than the entropy of the phosphoryl complex with the same ΔH. The more unfavorable entropy of the formation of the pyridine-phenol complex as compared with the phosphate-phenol complex may depend on different steric properties of the complexes. Another reasonable explanation may be found in a difference of polarity of the two types of hydrogen bonds.

On the Complex Chemistry of the Tervalent Rare-Earth Ions

V. The Acetate and Glycolate Systems of Yttrium

ARTUR SONESSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The complex formation of the yttrium acetate system and the yttrium glycolate system has been studied potentiometrically. The measurements were performed at 20°C in perchlorate medium of ionic strength 2.0 M. It was found that both the systems show significant similarities with the correspondent systems in the middle of the lanthanum series.

The complexity constants of the yttrium acetate system are lower than the constants of the dysprosium system, but the ratios b_n/b_{n+1} between the consecutive stability constants coincide rather well for the two systems. The complexity constants of the yttrium glycolate system show a rather good agreement with the complexity constants of the gadolinium glycolate system. The values of the ratios b_n/b_{n+1} place the yttrium system between the samarium and the gadolinium systems.

For the tervalent yttrium ion the electron configuration of the outer shell is $4s^2\ 4p^6$. It is thus similar to the electron configuration of the tervalent ions of the lanthanum series — that is, $5s^2\ 5p^6$. Moreover the yttrium ion has about the same ionic radius (0.90 Å) as the middle rare-earth ions (Dy — 0.91 Å, Ho — 0.89 Å). Therefore the chemical similarity between yttrium and the middle rare-earths is rather great. Schwarzenbach *et al.*[1] have shown that the yttrium ions show the greatest similarity with the rare-earth ions in the middle of the lanthanum series when strong complexes are formed, *e.g.* with ethylenediamine tetra-acetate ions.

CHEMICALS USED

A stock solution of *yttrium perchlorate* was prepared by dissolving a weighed amount of yttrium oxide (99.5 % purity) in somewhat more than the calculated amount of perchloric acid. Most of the acid excess was then removed by evaporation.

The remaining excess of acid in the stock solution was determined by electrometric titration with sodium hydroxide.

The yttrium concentration of the stock solution was calculated from the weighed amount of yttrium oxide. The same value of the yttrium concentration was obtained

by means of a cation exchanger column, after having corrected for the free perchloric acid in the stock solution.

The stock solution was examined spectrographically and it was found that no foreign elements absorbing in the range 250 mμ – 900 mμ were present in detectable amounts.

The other solutions used in this investigation were prepared and analyzed in the way described in the preceding parts [2,3,4].

RESULTS

The investigation of the yttrium acetate and the yttrium glycolate systems was performed potentiometrically by means of quinhydrone electrodes as described in Parts I, II and III. The composition of the galvanic cells is shown in I p. 169 and III p. 999. For the notations and the functions used for the calculations of the complexity constants the reader is referred to II p. 1938.

The yttrium acetate system. It was checked that the hydrolysis of the non-complex yttrium ions did not seriously affect the complex formation. Buffer solutions having the composition 2 M HAc + 1 M NaAc and 4 M HAc + 1 M NaAc gave $\bar{n}/[A^-]$-functions coinciding within the limits of the random errors.

As before, when the rare-earth acetate complexes were investigated, a correction has been applied for the decrease of the ionic strength caused by the complex formation. It was found that the relation between ΔE_A, the increase of E_A, and ΔI, the increase of the ionic strength I, was $\Delta E_A = -4.2 \times \Delta I$, *i.e.* about the same function was obtained as for the other rare-earth acetate systems (*cf.* I p. 171). ΔI was computed by means of approximate ligand numbers. Then, the ligand numbers $\bar{n}$ have been computed from $E_A + \Delta E_A$.

The $\bar{n}/[A^-]$-values at low acetate concentrations seem to increase somewhat with increasing yttrium concentrations in the same way as for the higher rare earths (*cf.* II). Then the system probably has a slight tendency to form polynuclear complexes. If only mono- and dinuclear complexes are assumed, the value of the complexity constant for the first dinuclear complex $\beta_1^2 = [M_2A] \cdot [M]^{-2} \cdot [A]^{-1}$ should be 20–30 M^{-2}.

The results of the measurements on the yttrium acetate system are shown in Fig. 1 and in Tables 1 and 2.

The yttrium glycolate system. The yttrium glycolate proved rather slightly soluble as was also found for the lower rare earths (*cf.* Jantsch and Grünkraut [5]). However, the solution remained supersaturated for several minutes. Therefore the complex formation could be studied also at high glycolate concentrations by performing the measurements rapidly.

For the glycolate system the E_A-values measured must be increased by $\Delta E_A = -2.8 \times \Delta I$. Then the E_A-values varied with the ionic strength in about the same way as for the other rare earth glycolate systems.

No significant signs of polynuclear complexes could be detected.

The results of the measurements on the yttrium glycolate system are collected in Fig. 2 and in Tables 1 and 2.

DISCUSSION

If the complexity constants of the yttrium acetate system are compared with the corresponding constants of the rare-earth acetate systems that have

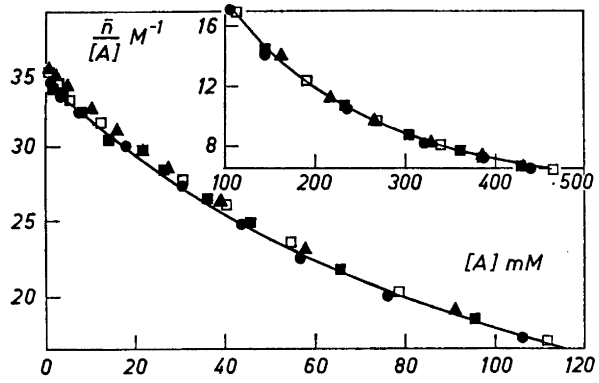

Fig. 1. $\bar{n}/[A^-]$ as a function of $[A^-]$ for the yttrium acetate system. Ionic strength 2.0 M. Open symbols: a buffer solution having the composition 2 M HAc + 1 M NaAc has been added to the yttrium perchlorate solution.
Filled symbols: a buffer solution 4 M HAc + 1 M NaAc has been used.
●: C_M^o (= the initial concentration of yttrium perchlorate) was 20 mM;
■, □: C_M^o = 40 mM; ▲: C_M^o = 80 mM.

been investigated before (I p. 180 and II p. 1952), it is found that the yttrium system has a considerably lower β_1-value than the other rare-earth systems. Also the lanthanum system shows a higher value for β_1. The increase of the complexity constants from β_1 to β_3 is, however, relatively greater for the yttrium system than for the lower rare-earth systems. Therefore the ratios b_n/b_{n+1} indicate a rather significant relationship between the acetate systems of yttrium and of the higher rare earths, especially those of dysprosium and holmium.

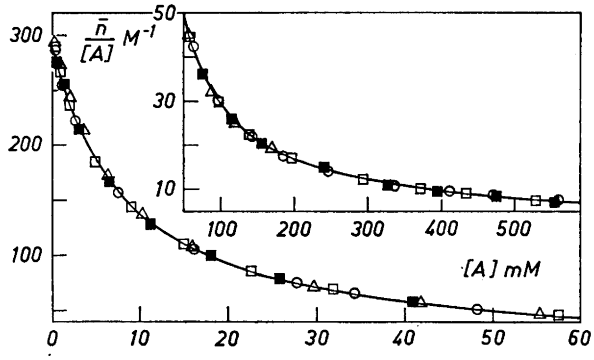

Fig. 2. $\bar{n}/[A^-]$ as a function of $[A^-]$ for the yttrium glycolate system. Ionic strength 2.0 M. Open symbols: a buffer solution 0.5 M HAcOH + 1 M NaAcOH was used.
Filled symbols: a buffer solution 1 M HAcOH + 1 M NaAcOH was used.
○: C_M^o (= the initial concentration of yttrium perchlorate) was 20 mM;
■, □: C_M^o = 40 mM; △: C_M^o = 80 mM.

Table 1. The complexity constants of the yttrium acetate system (Y^{3+} $-Ac^-$) and the yttrium glycolate system (Y^{3+} $-AcOH^-$) with their estimated random errors. $\beta_n = [MA_n] \cdot [M]^{-1} \cdot [A]^{-n}$ means the complexity constants of the mononuclear complexes and $\beta_1' = [M_2A] \cdot [M]^{-2} \cdot [A]^{-1}$ the complexity constant of the first dinuclear complex. The temperature was 20°C and the ionic strength 2.0 M (perchlorate medium).

	$\beta_1 M^{-1}$	$\beta_2 M^{-2}$	$\beta_3 M^{-3}$	$\beta_4 M^{-4}$	$\beta_5 M^{-5}$	$\beta_1' M^{-2}$
Y^{3+} $-Ac^-$	34 ± 2	460 ± 50	2 400 ± 400	~2 000	— — —	~20
Y^{3+} $-AcOH^-$	295 ± 15	$(25 \pm 2) \times 10^2$	$(50 \pm 7) \times 10^4$	$(18 \pm 4) \times 10^5$	$\sim 20 \times 10^5$	— —

Table 2. The stability constants $b_1 = \beta_1$, $b_n = \beta_{n+1}/\beta_n$ and the ratios between the consecutive stability constants for the acetate and the glycolate systems of yttrium.

	b_1	b_2	b_3	b_4	b_1/b_2	b_2/b_3	b_3/b_4
Y^{3+} $-Ac^-$	34	13.5	5.2	0.8	2.5	2.6	6
Y^{3+} $-AcOH^-$	295	85	20	3.6	3.5	4.2	5.5

The complexity constants of the yttrium glycolate system are about the same as those of the gadolinium glycolate system (III p. 1008, 1009). Then there is also a good correspondence between the two glycolate systems concerning the stability constants as well as the ratios b_n/b_{n+1}. The values for b_n/b_{n+1} show possibly a slight tendency towards samarium.

The similarity between yttrium and the other rare earths with about the same ionic radius (especially Ho) is shown also by the ratios between the corresponding complexity constants of the glycolate and the acetate systems, *i.e.* the ratios $\beta_{n,gl}/\beta_{n,ac}$. Thus we find that the ratio $\beta_{1,gl}/\beta_{1,ac}$ is 3—5 for the lighter rare earths, 4.3 for Gd, 7.0 for Dy, 8.2 for Ho, 8.7 for Y, 10.0 for Er, and 11.8 for Yb.

The author is indebted to Professor Sture Fronæus for kind interest and fruitful discussions.

This work is a part of an investigation supported by *Swedish Natural Science Research Council*, which is gratefully acknowledged.

Effect or Urea and Sodium Chloride on the Colloid Osmotic Pressure of Hyaluronate

J. PIKKARAINEN, T. NIKKARI and E. KULONEN

Department of Medical Chemistry, University of Turku, Finland

Colloid osmotic pressure of hyaluronate was measured in solutions containing varying amounts of sodium chloride or urea.

The effect of salt strength was considered physiologically nonsignificant.

In 6.5 M urea the colloid osmotic pressure of 0.25 % solution of hyaluronate increased 2.5-fold. The apparent molecular weight decreased from 110×10^3 to 46×10^3. On the basis of sedimentation and viscosity data molecular weights of 950×10^3 (original) and 600×10^3 (in 6.5 M urea) were calculated.

The purpose of these measurements was to determine whether physiologically possible changes in the sodium chloride content of extracellular fluid could affect the colloid osmotic pressure of hyaluronate and whether the hydrogen bonds were significant. Because the use of urea revealed an apparent dissociating effect, the sedimentation and viscosity data were determined.

EXPERIMENTAL

The osmometer of Bull [1] (immersed in a water bath at $+25 \pm 0.01$°C) was used and the colloid osmotic pressure could be measured with an accuracy of 0.01 mm H_2O.

The material was prepared from human umbilical cords by extraction with sodium chloride and fractional precipitation with »Cetavlon» according to the principle of Scott [2]. It was ascertained by column chromatography [3] that it did not contain chondrosamine and it was homogeneous in the ultracentrifuge (Fig. 3). The sample contained 3.58 % N and 16.7 % ash. The sample was kept in a desiccator above conc. sulphuric acid. For the measurements 0.5 % or 0.25 % solutions were prepared in 0.0067 M phosphate buffer (pH 7.3) containing 1 mg/100 ml sodium azide as preservative.

The salt effect was studied all the time with the same cellulose membrane bag and same 0.5 % hyaluronate solution (37 ml) but the outer fluid (68 ml, containing increasing amounts of sodium chloride in the phosphate buffer) was changed.

The effect of urea was studied similarly, but with 0.25 % solution of hyaluronate. The fluids contained 0.25 M sodium chloride.

The sedimentation studies were carried out with a »Spinco» analytical ultracentrifuge using wedge cells. The calculations were made according to Ogston [4].

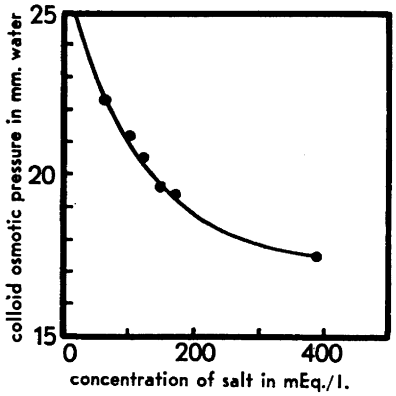

Fig. 1. Colloid osmotic pressure of 0.5 % hyaluronate solution plotted against sodium chloride concentration. (At the zero concentration of salt the colloid osmotic pressure was 66 mm H_2O).

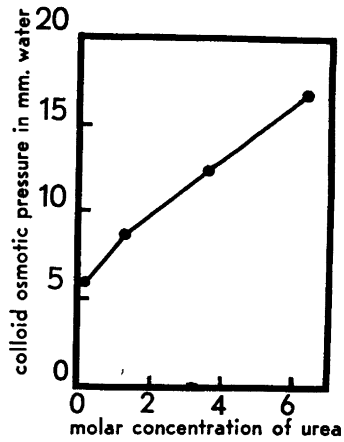

Fig. 2. Colloid osmotic pressure of 0.25 % hyaluronate plotted against urea concentration.

RESULTS

The effect of salt concentration on the colloid osmotic pressure is shown in Fig. 1 and of urea in Fig. 2. At the 140 mequiv./l level of sodium chloride a 10 mequiv./l increase in the salt concentration causes a decrease in the colloid osmotic pressure of only 0.4 mm H_2O at 0.5 % concentration of hyaluronate, which roughly corresponds to that present in tissues. Fig. 3 shows the sedimentation pattern and Table 1 contains the viscosity and sedimentation data with some relevant calculations.

DISCUSSION

The relations between hyaluronate and salt observed earlier [6] seem to be best explained by the different diffusion rates of the electrolytes in solu-

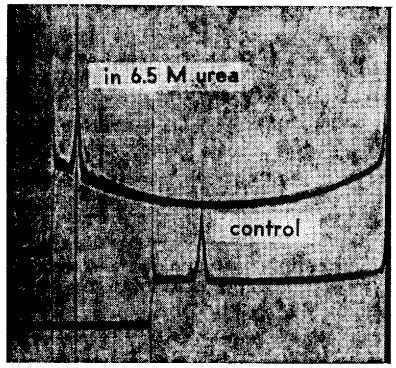

Fig. 3. Sedimentation pattern of hyaluronate (52 min. after reaching the speed of 59 780 rpm., c = 0.25 %, angle 75°). The control cell has leaked.

Table 1. Viscosity and sedimentation data of hyaluronate in urea.

Solvent	0.25 M NaCl in 1/300 M pH 7.3 phosphate buffer	6.5 M urea and 0.25 M NaCl in 1/300 M pH 7.3 phosphate buffer

M from uncorrected s_0-values	920×10^3	670×10^3
from corrected s_0-values	950×10^3	600×10^3
from osmotic pressure (c = 0.25 %)	110×10^3	46×10^3

tions containing hyaluronate. The significance of the Donnan effect on the colloid osmotic pressure of the extracellular fluid is slight.

Bull and Currie [7] studied the effect of urea on the molecular weight of β-lactoglobulin and Gutter, Sober and Peterson [8] the effect on hemoglobin. In both cases a degradation of the protein molecule was observed. The experiments reported above give an analogous result.

There exist controversial opinions on the necessity of a density correction in the ultracentrifugation due to the presence of urea [8,9]. If in the calculations uncorrected s_0-values are used with the density and viscosity of the urea solution, this difficulty is avoided. In this case the corrected s_0-values with density and viscosity of the phosphate-NaCl-solution gave almost identical results.

There is a large difference between the molecular weights obtained from the osmotic pressure and from the sedimentation data. Blumberg and Ogston [10] pointed out that the osmotic pressure of hyaluronate tends to be unduly high because of the high entropy of dilution consequent to the large volume of the particles (*cf.* discussion by Jensen [11] and by Bull [1]). If true, this concept has a physiological implication in the maintenance of the tissue turgor in spite of the low concentration of the polysaccharide.

Secretion of Radioactivity in Milk Fat after a Single Oral Dose of (^{3}H)Myristic Acid to a Goat

L. REINIUS and J. HASAN

Department of Physiology and Biochemistry, Veterinary College, Helsinki
and
Institute of Occupational Health, Helsinki, Finland

Tritium-labelled myristic acid was administered orally as free acid to a lactating goat and then the secretion of the radioactivity in the total milk lipids and milk glyceride fatty acids was followed for thirteen days. Measurable activity was found in the milk fat 4 h after administration and the maximum specific activity occurred within 28 h. About 10 % of the radioactivity administered was recovered during the experimental period and about 25 % of the activity collected during 13 days was secreted in the first 28 h. In the beginning the non-volatile fatty acids had a higher specific activity than the volatile fatty acids and there seemed to be a tendency for the specific activities in the short chain acids to increase with time whereas the long-chain acids appeared to be less active later in the experiment.

The relative importance of various lipid constituents in the diet for the formation of characteristic elements of milk fat is a question of great interest both from the quantitative and qualitative points of view. It has been demonstrated that, in the ruminant, acetate is a precursor of short-chain fatty acids of the milk [1]. Of the total acetate present in the body of the goat at any moment, about 80 % is oxidised within 6 h while some 50 % of the remainder will participate in the fat metabolism of the udder [2]. Evidence for the existence in the mammary gland of a system capable of synthetising fatty acids up to $C_{(18)}$ from acetate has been produced by Popják and Tietz [3], Hele and Popjak [4] and Hele, Popjak and Lauryssens [5].

In a study of the role played by dietary long-chain fatty acids in the formation of ruminant milk fat [6] it was shown that after oral administration of (^{3}H)stearic acid, the short-chain acids in the milk fat had a much lower specific activity than the long-chain acids and the tentative conclusion was drawn that the contribution of the long-chain acids of the blood to the short-chain acids of ruminant milk fat was small.

The work quoted above deals with fatty acids of very short ($C_{(2)}$) or extremely long ($C_{(18)}$) chain length. In the experiment to be described, which is

an extension of the work done by Glascook *et al.*[6], (^{3}H)myristic acid — representing a dietary fatty acid of an intermediate chain length — was fed to a lactating goat and the time of appearance, rate of excretion of radioactivity in the milk lipids, and the distribution of radioactivity in various fractions of milk lipid was studied.

Radioactive myristic acid

EXPERIMENTAL

(^{3}H)Myristic acid was prepared by treating inactive myristic acid (Fluka, purum) in an evacuated and sealed ampoule for two days at 98°—100°C with concentrated sulphuric acid (sp.d. 1.84) and tritiated water (200 mC/ml) according to the method of van Heyningen, Rittenberg and Schoenheimer [7]. The reaction product, diluted with water and dissolved in ether, was extracted with a solution of alcoholic potassium hydroxide. The radioactive myristic acid obtained after acidification and extraction with ether was recrystallised from aqueous acetone. The product had a melting point of 57.6°C (published melting point 58°C) and a specific activity of 2.55×10^6 counts/min/mg H_2O as assayed with our apparatus.

To check the radiochemical purity of the product, a sample was run on a paper chromatogram [8] together with chemically pure, inactive myristic acid. After development the strip containing the radioactive sample was cut into bands 1 cm wide which were eluated with toluene and the eluates were assayed for radioactivity in a liquid scintillation counter (Packard Tri-Carb Scintillation Spectrometer). The radioactivity was found to be incorporated into a single, welldefined area on the chromatogram, the location of which was the same as that of the pure inactive myristic acid.

It was expected that as a result of the tritiation process used, the radioactivity would be bound to $C_{(2)}$. This was checked by brominating the (^{3}H)myristic acid (as described by van Heyningen *et al.*[7]) and then reassaying the radioactivity of the product. By this procedure 46 % of the radioactivity was lost, indicating that most (92 %) of the tritium was bound to the $C_{(2)}$ atom.

Animal experiment

The experimental animal was a goat of Finnish breed yielding about 1 l milk/day. The labelled material consisted of 3.82 g (^{3}H)myristic acid prepared as above and containing a total activity of 1.08×10^{10} counts/min/mg. A mixture of the myristic acid, 40 ml arachis oil, 2 g sodium stearate and 0.5 g sodium carbonate was homogenised at 60°C for 65 min. and at a pressure of 2 600—2 700 lbs/sq.in. The mean diameter of the particles in the resultant emulsion was about 1 μ.

After an injection of oxytocin the goat was milked out and the emulsion, warmed to body temperature, was administered in one dose by mouth followed by 50 ml water. Water and hay were provided *ad libitum* and concentrates according to the calculated need. The goat was kept in an isolation pen and milked three times a day for the first two days and then twice daily for the following 11 days of the experiment. The two milkings of the 4th, 5th and 6th experimental days were combined to give three samples and from the 7th day onwards the milkings of two successive days were pooled to one sample. Altogether, 15 samples were obtained for radioactivity measurements of the total milk fat. The fractionation of the milk fat was done on three pooled milk fat samples representing the total milkings of following successive periods of the experiment —1st day; 2nd, 3rd and 4th day; and 5th to 13th days.

Chemical methods

The isolation of milk fat for radioactivity analysis was made following the description given by Glascock *et al.*[6] The fractionation of the milk fat into non-volatile saturated, non-volatile unsaturated, steam-volatile water soluble and steam-volatile water-insoluble

glyceride fatty acids was done by procedures similar to those described by Popják and Beeckmans [9].

Radioactivity measurements

After combustion of the lipid samples in a stream of oxygen, the tritium content of the combustion water was measured in a gas counter with a stainless steel cathode after conversion into butane with the aid of *n*-butyl magnesium bromide [10]. All combustions and measurements were made in duplicate. The specific activities are given as counts/min/mg of combustion water as observed with our equipment.

RESULTS

The specific activities of the total milk lipids in successive samples are plotted semi-logaritmically against time in Fig. 1, the time for each point on the curve being the mid-point of the period during which the milk was secreted. Measurable radioactivity appeared in the total lipids as early as 4 h after administration of the (^{3}H)myristic acid, and the milk fat with the highest specific activity (1.2×10^4 counts/min/mg) was collected 28 h after dosing. The specific activity then declined rapidly, and the specific activities of the milk lipids on the 12th and 13th experimental days were only about 100 c.p.m.

The cumulative secretion as a percentage of the total dose administered is shown in Fig. 2 plotted against time. The radioactivity collected during the whole experimental period of 13 days was about 10 % of the dose administered. It can be seen that of the total activity collected, about 25 % was secreted during the first 28 h. Some secretion, however, was still going on at the end of the experimental period.

The specific activities of the four glyceride fatty acid fractions from milk collected during successive experimental periods are shown in Fig. 3. It can be seen that the specific activity of the non-volatile saturated fatty acids

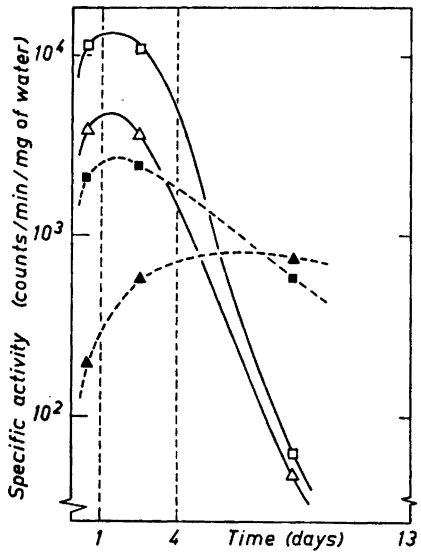

Fig. 3. Mean specific activities of pooled milk glyceride fatty acids on three successive experimental periods after ingestion of (^{3}H)myristic acid administered in one dose. Experimental periods indicated by dotted lines. □ : non-volatile saturated fatty acids; ■ non-volatile unsaturated fatty acids; △ : steamvolatile water-insoluble fatty acids; ▲ : steam-volatile water-soluble fatty acids. A smooth curve drawn arbitrarily through corresponping points.

secreted during the first day is of about the same magnitude as the maximum specific activity of milk fat collected during this period. The radioactivity of this fraction subsequently declined. The other fractions contain considerable less radioactivity, and while the specific activity of long-chain unsaturated fatty acids also declines with time, there seems to be a trend for higher activities in the short-chain fatty acid fractions from samples collected during later periods; the variations, however, are slight and it is difficult to asses their significance. It may be noted that although the short-chain fatty acids contain less radioactivity than the long-chain acids in the beginning, considerable activity is found in these as well.

DISCUSSION

The results described above give information on the role of dietary myristic acid as a precursor of constituents in the milk fat. The appearance, the time curve of secretion, the total amount secreted in the milk lipids, and the distribution of radioactivity between various fractions of the milk fat seem on the whole, to be comparable with corresponding data [6] obtained by using stearic acid in a rather similar experiment. Some divergent points, however, should be noted.

The total amount of secreted radioactivity in the milk was only 10 % of the dose administered. This is a small fraction as compared with the values 25 % and 49 % obtained after 8 and 14 days, respectively, by Glascock *et al.*[3] in the two experiments where free (^{3}H)stearic acid was fed to goats. Since we did not examine the faeces, it is impossible to say whether the results reflect only poor absorption of the (^{3}H)myristic acid or differences in the metabolic

behaviour between myristic and stearic acid of fat in the diet. It seems, however, that in a system including such a multitude of independently variable mechanisms as in the transport of fatty acids from the digestive tract to milk, great differences can exist between different animals as well as considerable short-time variations in the same animal. In both experiments, however, the radioactivity in the milk lipids after administration of the labelled acid was found in the first sample collected 4 h after administration. Maximum activity was reached in the myristic acid experiment after 28 h as compared with 23 h in the stearic acid experiment.

In the experiments of Glascock *et al.*[6] the specific activities of the saturated and unsaturated long-chain fatty acids in the milk were of the same magnitude whereas the unsaturated long-chain acids in our experiment apparently were of significantly lower specific activity than that of the saturated. An explanation for the low specific activity of the unsaturated long-chain fatty acid fraction as compared with the saturated could be the relatively high content of myristic acid in goat milk lipids and the very low content of the corresponding unsaturated acid the myristoleic — 12.3 % for myristic acid (tetradecanoic) and 0.8 % for tetradecenoic. The converse is true for stearic and oleic acids [11]. Our explanation assumes that myristoleic acid is the natural desaturation product of myristic acid in the goat as has been shown [12] to be in the rat and that biological desaturation of myristic acid exclusively labelled at $C_{(2)}$ would not lead to a significant loss of radioactivity. The latter assumption may be valid considering that Hilditch and Longenecker [13] have observed that the double bond in the monoethenoic acids of milk is in the $C_{(9)}$—$C_{(10)}$ position.

Another point of interest in this experiment is the high specific activity in the water-insoluble steam-volatile fraction. From the experiments with (^{3}H)myristic acid, Glascock *et al.*[6] concluded that no significant formation of milk short-chain fatty acids occurred through break-down of dietary long-chain acids. If this also applies for myristic acid, the activity of the short-chain acids in our experiment should originate from radioactive precursors (acetate) formed by degradation of myristic acid. In this case, however, even greater specific activities would be expected in the water-soluble portion of the steam-volatile fatty acids which, in our experiment, actually contain very little activity. Even if small quantities of $C_{(8)}$—$C_{(10)}$ acids are known to pass over into the steam distillate [14,15] it is highly improbable that radioactive contamination from myristic acid $C_{(14)}$ could account for this finding. Considering the specific activity of the long-chain unsaturated fatty acids (highest value about 4 000 counts/min/mg of H_2O), it does not seem possible that the traces of oleic acid, which may also be carried over in the distillation, could cause contamination of the steam-volatile water-insoluble acids (about 2 000 counts/min/mg of H_2O) to the extent observed.

Of interest is the apparent trend for higher specific activities in the short-chain acids during later experimental periods while the radioactivity secreted in the long-chain acids seems to decline with time. This could indicate that a chain-shortening is actually going on in the organism with a fairly slow reaction velocity, but a more probable explanation would be the successively higher radioactivity gained by the metabolic pool of small-molecular entities available for resynthesis from degradation of (^{3}H)myristic acid.

We wish to thank Dr. R. F. Glascock for some complementary ^3H determinations and for helpful advise in presenting the data. Dr. O. Perilä kindly prepared the myristic acid paper chromatogram using his system. We are also most grateful to Prof. L. Paloheimo and Dr. S. Ullberg who offered their help during different phases of the work. This study was aided by a grant from the *State Commission for Natural Sciences (Valtion Luonnontieteellinen Toimikunta)*.

Equilibrium Studies on the Disproportionation Reaction Between Some Dialkyl Disulfides

L. HARALDSON*, C. J. OLANDER, S. SUNNER and E. VARDE**

Thermochemistry Laboratory ***, *University of Lund, Lund, Sweden*

The disproportionation equilibrium between two symmetric disulfides and the corresponding mixed one has been determined at 25° and at 60° by use of vapor phase chromatographic technique. For diethyl disulfide in mixture with dimethyl- and di-*i*-propyl disulfide, respectively, the equilibrium constant is close to the statistically expected value, 4. For the pair diethyl- and di-*t*-butyl disulfide, the constant is 24. Within the uncertainty of the experiments, the equilibrium constant is temperature independent and thus ΔH is equal to zero. The strongly restricted internal rotation in di-*t*-butyl disulfide is responsible for the high value of the equilibrium constant.

It is a well-known fact that disulfides undergo disproportionation reactions according to

$$R_1SSR_1 + R_2SSR_2 \rightleftharpoons 2\ R_1SSR_2 \qquad (1)$$

This reaction has been used particularly for the synthesis of mixed disulfides [1–5].

McAllan *et al.*[5] have shown by distillation of equilibrium mixtures that the position of the equilibrium depends on the nature of R_1 and R_2. When R_1, R_2 were *n*-alkyl groups, the expected statistical distribution $(R_1S)_2$:$R_1R_2S_2$:$(R_2S)_2$ = 1:2:1 was reached, whereas for R_1 = Et and R_2 = *s*-Bu and *t*-Bu, the ratios were found to be close to 1:4.5:1 and 1:6:1, respectively.

During the course of an extended investigation on the energetics of the disulfide bond it was found of importance to determine rather precisely the equilibrium constant for a number of dialkyl disulfides. Calvin *et al.*[6] studied a slightly different system, namely

$$BzSSBz + HS(CH_2)_3SH \rightleftharpoons 2\ BzSH + \overline{\text{S-(CH}_2)_3\text{-S}} \qquad (2)$$

They were able to determine the equilibrium constant utilizing the fact that the disulfide 1,2-dithiolane has an absorption maximum at 330 mμ, whereas open chain dialkyl disulfides show a peak at 250 mμ. It is evident that this technique does not work in the case of a mixture of dialkyl disulfides.

The distillation method suffers from several disadvantages — it is slow and poorly quantitative, the separation efficiency is rather low, and, most important, it is difficult, if not impossible, to prevent completely the disulfide from further disproportionation during the distillation.

The vapor phase chromatographic technique was chosen as the analytical tool for the separation and quantitative determination of the homologous disulfides. This technique seemed to offer a number of advantages. The method is rapid and the separation is quantitative and of high efficiency. The duration of the sojourn of the unseparated mixture on the column is very short, decreasing the risk for any reaction to take place during the analysis. In a symmetric reaction like the one under investigation where absolute concentration values do not enter into the equilibrium equation, the relative concentrations can easily be determined from the evaluation of the areas under the peaks of the chromatogram and with an error of only a few per cent. By using an appropriate detector, the size of the sample can be kept very small, allowing the study of gas equilibria at low pressures without increasing the volume of the system inconveniently. Finally, the presence of impurities from side reactions will usually be immediately revealed during the analysis and is of no influence upon the desired result, provided the main reaction equilibrium has been attained.

Two conditions must be fulfilled in order to make the vapor phase chromatographic method useful. Reactions of any kind must not occur on the column, and a linear relationship must exist between the area under the peak on the chromatogram and the amount of substance passing the detector. Both conditions could be experimentally tested in our case and shown to be fulfilled.

CALCULATION

For reaction (1), the equilibrium constant K is given by

$$K = \frac{m_{12}^2}{m_{11} \cdot m_{22}} = \frac{n_{12}^2}{n_{11} \cdot n_{22}} \qquad \text{(I)}$$

where m represents molarities and n the total number of moles present in a given sample; index 11 stands for diethyl disulfide, 22 for another symmetrical dialkyl disulfide, and 12 for the mixed disulfide.

The chromatograph is operated under such conditions as to fulfil the relation $n_i = k_i \cdot y_i$, where k_i is a constant and y_i the area under the peak on the chromatogram, related to the component i. In the present case, one of the reaction participants can be used as a reference substance, *e.g.*

$$n_{11} = k_{11} \times y_{11} \qquad \text{(IIa)}$$
$$n_{22} = k_{22} \times y_{22} \qquad \text{(IIb)}$$

which gives

$$\frac{n_{11}}{n_{22}} = k_{11,22} \times \frac{y_{11}}{y_{22}} \qquad \text{(III)}$$

By calibrating the apparatus with known amounts of pairs of disulfides, the constants $k_{11,22}$, $k_{11,12}$ and $k_{12,22}$ can be separately determined and the relation

$$k_{11,22} = k_{11,12} \times k_{12,22} \qquad \text{(IV)}$$

can be checked.

Finally, the equilibrium constant is

$$K = \frac{k_{12,22}}{k_{11,12}} \times \frac{y_{12}^2}{y_{11} \cdot y_{22}} \qquad \text{(V)}$$

EXPERIMENTAL

Materials

Dimethyl disulfide and *diethyl disulfide* (Eastman chemicals) were distilled twice under reduced pressure to give pure fractions as judged from the chromatograms. *Di-i-propyl disulfide* and *di-t-butyl disulfide* were prepared from the corresponding mercaptans by oxidation with iodine, and distilled twice. After a final distillation at room temperature the purity was checked on the chromatograph.

Ethyl methyl disulfide was prepared both from dimethyl disulfide and ethyl mercaptan, as well as from a mixture of the symmetric disulfides with NaSEt as a catalyst. It was not feasible to obtain a completely pure sample by distillation (*cf.* Ref.[5]). The purest fraction contained 4 % of Me_2S_2 and no detectable amount of Et_2S_2. It was used in the experiments and proper correction was applied in the calibration runs.

Ethyl i-propyl disulfide and *t-butyl ethyl disulfide* were prepared according to method I and II, respectively, in Ref.[5]. They did not contain amounts of the symmetrical disulfides detectable on the chromatogram.

Methods

In the present investigation a Pye Argon chromatograph was used with a 5 mm column, 120 cm in length, filled with 100–120 mesh crushed brick stone, containing 5 % by weight of apiezon grease L. In the experiments with R_2 = Me the temperature was kept at *ca.* 105°C, when R_2 = *i*-Pr and *t*-Bu the temperature was *ca.* 115° and 125°C, respectively.

Calibration was carried out with all pairs of disulfides in molar ratios well covering the expected concentration ratios in the equilibrium mixtures. With the set-up given, in no case was the third disulfide formed which could be easily seen on the chromatogram. A possible disproportionation reaction occurring on the column was therefore judged to be completely insignificant *.

The equilibration experiments were carried out in a *cyclo*hexane solution (R_2 = Me, *i*-Pr) and the total concentration of disulfides was in most cases kept close to one mole per liter. The equilibrium was reached from both sides by use of an ionic catalyst (NaOH, method Ia), or by irradiation with light from a low pressure mercury lamp (method Ib). Experiments were carried out at 25° and 60°C. The solutions treated with sodium hydroxide were kept in 7 × 100 mm test tubes with ground glass stoppers. The catalyst was deposited from an ethanol solution as a very thin film on the inner surface of the

* Note: With metal columns and high boiling esters as the stationary phase disproportionation occurred frequently on the column (*cf.* Ref. [7]).

tube before it was filled with the solution. The irradiated solutions were kept in quartz tubes with ground Pyrex glass stoppers.

Neither method Ia, nor method Ib worked very well. The equilibration time was often of considerable length and in many experiments the initial rate of reaction was extremely slow. The results from the experiments with R_1 = Me did indicate that a true equilibrium was not reached either from one or from both sides. For unknown reasons, all attempts to obtain an equilibrium mixture at 60°C with R_1 = *i*-Pr failed. Finally, when R_1 = *t*-Bu, neither method for equilibration was applicable. The reaction rate was extremely slow using the two-phase ionic system and the decomposition during irradiation was much faster than the disproportionation reaction. The equilibration runs were therefore carried out in the following solution (method II).

Freshly cut sodium (40 mg) was dissolved in 0.4 ml of ethanol, 96 % by volume, and 0.03 ml of *t*-BuSH was added together with 0.3 ml each of the symmetrical (or 0.6 ml of the mixed) disulfides. The solution was enclosed in a sealed Pyrex ampoule which was placed in a thermostat. In preparing the sample for the analysis, water was added to the content of the ampoule, the disulfide layer was washed once with water, and *iso*-pentane was added. The organic solution was washed twice with water, dried, and directly used for the analyses.

The same series of runs were performed with R_1 = Me, substituting EtSH for *t*-BuSH.

RESULTS

The results from the calibration experiments are found in Table 1. The concentration ratios between the two disulfides compared in each run were 1:2; 1:1 and 2:1 (R_2 = Me, *i*-Pr all combinations, and R_2 = *t*-Bu in mixtures between the symmetrical compounds). For both mixtures Et_2S_2-*t*-BuEtS_2 and *t*-Bu_2S_2-*t*-BuEtS_2, the ratios tested were 1:1; 1:2; 1:4 and 1:6. The same concentration ratio was measured in three parallel runs and each chromatogram was planimetered at least 6 times. The agreement between the calculated and the found $k_{11,22}$-values is satisfactory.

Table 2 gives a summary of the equilibrium measurements. Although the time for the experiments extended over several months, equilibrium was not reached with method I (R_2 = Me). The experiments according to method II indicate that the true equilibrium is close to the value obtained with method I starting with the unsymmetrical disulfide. Although a number of trials were performed with R_2 = *i*-Pr at 60°C no acceptable values of the equilibrium constant were obtained.

Method II gave much more reproducible results. For R_2 = *t*-Bu, altogether 12 equilibrium experiments were started. In three cases at 25°C, however, equilibrium was not attained within 6 months.

The *K*-values of the disproportionation reaction have been used to calculate the accompanying changes in free energy at 25°C, ΔF_{298}, and in enthalpy at the average temperature 42°, ΔH_{313} (Table 3). Assuming ΔH to be temperature independent within the small interval studied and thus zero at 25°, the corresponding changes in entropy have been calculated and are given in the table.

DISCUSSION

Provided the statistical distribution is the only factor governing the equilibrium between the two symmetric and the corresponding mixed disulfide, the equilibrium constant should be 4, ΔH should equal zero and ΔS should be R ln 4 = 2.76 e.u. The experimental results clearly lend support to the suggestion that this is principally true for R_2 = *i*-Pr and also almost so for R_2 = Me. When R_2 = *t*-Bu the equilibrium constant is 6 times as large as is

* ΔH assumed to be = 0. The statistical value of K = 4 gives ΔS = 2.76 e.u.

required from statistical grounds. One explanation could be that the di-*t*-butyl disulfide is sterically strained while *t*-butyl ethyl disulfide is not or only to a small extent. However, this should be reflected in the ΔH-value which then must be negative with about 1 kcal·mole^{-1} for the forward reaction. The experimentally found value, $\Delta H \simeq 0$, rules out this possible explanation. The di-*t*-butyl disulfide molecule may be constructed from atomic models without introduction of strain from angle distortions and with a normal value (100°) of the dihedral angle between the C—S—S and S—S—C planes. In this model, however, the two *t*-butyl groups are very close together and any rotation round the C—S bonds seems to be highly hindered. The free independent rotations of the two *t*-butyl groups can be accomplished only when the dihedral angle exceeds *ca.* 135°. On the other hand, the intramolecular freedom in the *t*-butyl ethyl disulfide is much greater. Thus, the increased probability for the formation of the mixed disulfide in this case is caused by the "release" of conformations when the di-*t*-butyl disulfide molecule breaks up.

Nucleophilic Displacements on Phosphorus

Reaction of Hydroxyl Ion and *Iso*nitroso Acetone with Organofluorophosphorus Compounds

GUNNAR AKSNES*

Norwegian Defence Research Establishment, Toxicological Group, Kjeller, pr Lillestrøm, Norway

The reactions of hydroxyl ion and of *iso*nitroso acetone with three organofluorophosphorus compounds have been studied. The three compounds are dimethoxyphosphoryl fluoride, methoxyethylphosphoryl fluoride and diethylphosphoryl fluoride. The thermodynamic functions, activation energy and activation entropy have been calculated and discussed in relation to physical and chemical behaviour of substrates and nucleophilic reagents. This study together with observations made by other workers indicate that nucleophilic displacements on phosphorus depend on an intimate cooperation between the polarity and polarisability of the phosphorus compounds and the basicity and polarisability of the nucleophilic reagent.

Many organofluorophosphorus compounds are known to be highly toxic to insect and animal life [1,2]. The main reason for their toxicity is their ability to inhibit the cholinesterase enzymes. The inhibition of the enzymes by these compounds cannot be reversed by dilution or dialysis. Aldridge [3] and later Tammelin [4] have shown that the process of inhibition is due to phosphorylation of the enzyme. It has been observed that several nucleophilic reagents as hydroxylamine and some of its derivatives, in particular hydroxamic acids and oximes, react quickly with the phosphorylated enzyme and in this way restore its original activity [5,6]. Due to their ability to restore the enzyme activity, these groups of compounds have been named reactivators. In the last years it has been found that the reactivators also very quickly react with organofluorophosphorus compounds in nearly neutral water solution [7–9]. In the present work we have been interested in correlating the alkaline hydrolysis of some organofluorophosphorus compounds with the nucleophilic reaction between a reactivator and the same phosphorus compounds. The investigations have been performed by an electrometric titration method. The instrumental set up in very similar to that developed by Larsson and Hansen [10].

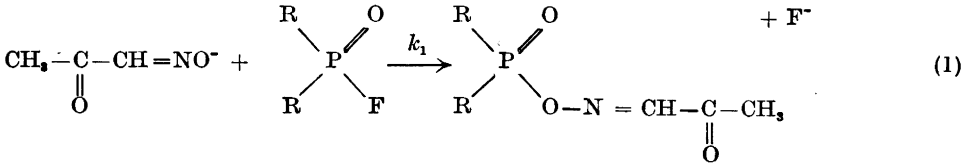
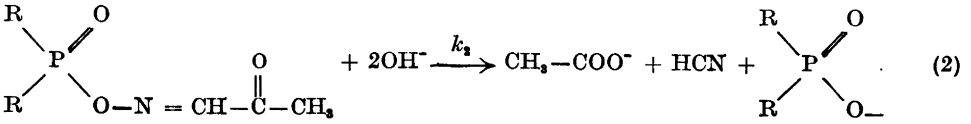
KINETICS OF THE REACTION BETWEEN ORGANOFLUOROPHOSPHATES AND *iso*NITROSO ACETONE

The kinetics of the reaction between several organofluorophosphates and different oximes were studied by Green and Saville [8]. When a great excess of oximes was used they found that the decomposition of the organofluorophosphates followed a first order law. The rate was proportional to the ionized form of the oximes. The rate was followed by titration of the total amount of acids formed. For every mole of organofluorophosphate decomposed 3 moles of acid were neutralized. They postulated a two steps reaction mechanism:



(1)



(2)

In the pH region of pH 7.5 Green and Saville [8] found that step (1) was rate determining. The total amount of acid produced as function of time obeyed a first order law. They concluded therefore that the second step in the reaction was immeasurably rapid.

The three organofluorophosphates studied in this paper were very reactive and it was found preferable to study the reaction between the oxime *iso*nitroso acetone and the organofluorophosphates in the pH-interval 6.00—6.70. In this region it was observed that the production of acid during the course of reaction did not follow a first order law. In Fig. 1 is plotted the acid production of the reaction as function of time. The curve shows an inflection in the first minutes of hydrolysis. An analysis of the experimental values showed that the rate of the second step in the above reaction was slow enough to influence on the kinetic of the decomposition reaction.

In the two-step reaction between organofluorophosphates and *iso*nitroso acetone (eqns. (1) and (2)) one mole of hydroxyl ions is consumed in the first step and two moles in the second step. The reaction is studied at so low pH that the dissociation of hydrocyanic acid is negligible. When great excess of *iso*nitroso acetone is used (*i.e.* the concentration of *iso*nitroso acetone remains approx. constant during the reaction) we get for the decomposition of organofluorophosphate:

$$-\frac{dC_N}{dt} = k_1 \cdot C_N \qquad (3)$$

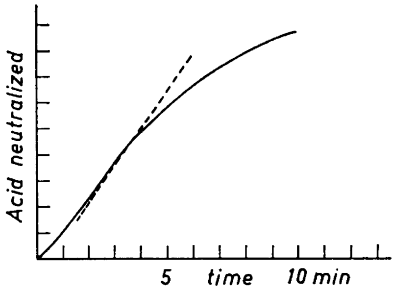


Fig. 1. Acid production in the hydrolysis of methoxyethylphosphoryl fluoride with *iso*nitroso acetone as function of time.

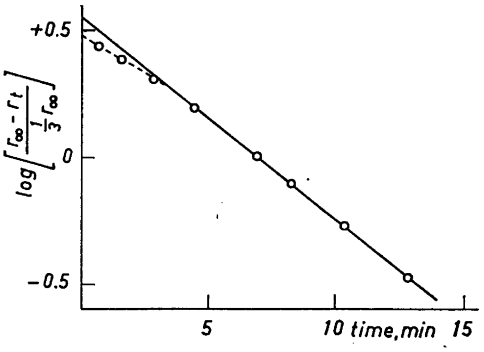

Fig. 2. Determination of the rate constant for the reaction between methoxyethylphosphoryl fluoride and *iso*nitroso acetone at pH = 6.00 according to eqn. (13).

where k_1 = pseudo first order rate constant of the first step. C_N = concentration of organofluorophosphate. The rate of formation and disappearance of the phosphorylated *iso*nitroso acetone is governed by the following equation:

$$\frac{dC_{NR}}{dt} = k_1 \cdot C_N - k_2 \cdot C_{NR} \quad (4)$$

C_{NR} = concentration of the phosphorylated *iso*nitroso acetone,
k_2 = pseudo first order rate constant of the second step.

The amount of hydroxyl ions used during the first step as function of time is:

$$C_{OH^-(1)} = C_{N_0} - C_N \quad (5)$$

where, by integration of eqn. (3)

$$C_N = C_{N_0} \cdot e^{-k_1 t} \quad (6)$$

C_{N_0} = the initial concentration of organofluorophosphate.

Integration of eqn. (4) after inserting the value of C_N from eqn. (6) gives:

$$C_{NR} = \frac{k_1 C_{N_0}}{k_2 - k_1} (e^{-k_1 t} - e^{-k_2 t}) \quad (7)$$

The material balance gives for the amount of hydroxyl ions used during the second step:

$$\tfrac{1}{2} C_{OH^-(2)} = C_{N_0} - C_N - C_{NR} \quad (8)$$

The total amount of hydroxyl ions consumed as function of time is thus:

$$C_{OH^-(total)} = C_{OH^-(1)} + C_{OH^-(2)} = 3(C_{N_0} - C_N) - 2\ C_{NR} \quad (9)$$

which by insertion of eqns. (6) and (7) gives:

$$C_{OH^-(total)} = C_{N_0}\left[3 + \frac{k_1 - k_2}{k_2 - k_1} e^{-k_1 t} + \frac{2k_1}{k_2 - k_1} e^{-k_2 t}\right] \quad (10)$$

An exact solution of k_1 and k_2 from eqn. (10) cannot be found. In this work we have used a graphical extrapolation method. The experimental values showed that $k_2 \gg k_1$, and thus, at high values of t the second exponential term of eqn. (10) goes rapidly towards

zero. Therefore, if we only use the experimental values of $C_{OH^-(total)}$ at relatively high t-values we get a good approximation for k_1 by taking only the first exponential term of eqn. (10):

$$C_{OH^-(total)} = 3\,C_{N_0} + C_{N_0} \cdot \frac{k_1 - 3\,k_2}{k_2 - k_1} \cdot e^{-k_1 t} \tag{11}$$

or in logarithmic form:

$$\log\left(\frac{3\,C_{N_0} - C_{OH^-(total)}}{C_{N_0}}\right) = -\log\left(\frac{k_1 - 3\,k_2}{k_2 - k_1}\right) - \frac{k_1 t}{2.303} \tag{12}$$

We therefore find k_1 by plotting $\log\left(\frac{3\,C_{N_0} - C_{OH^-(total)}}{C_{N_0}}\right)$

as function of t. If the method can be used we shall get a straight line with tangens $-\frac{k_1}{2.303}$. The intercept which the line cuts of the ordinate-axis is $-\log\frac{k_1 - 3\,k_2}{k_2 - k_1}$. Inserting k_1 in the latter equation gives k_2. The automatic recording instrument which is connected with the titrator, plots the number of turns of the micrometer screw as measure of concentration. Eqn. (12) is then transformed to:

$$\log\frac{r_\infty - r_t}{1/3\,r_\infty} = -\log\frac{k_1 - 3\,k_2}{k_2 - k_1} - \frac{k_1}{2.303} \cdot t \tag{13}$$

where r_∞ = number of turns of the micrometer screw when all the organofluorophosphate is transformed to end products (3 moles OH^- are consumed per mole organofluorophosphate). r_t = number of turns at the time t.

Fig. 2 shows the plot of the experimental values for the reaction between methoxyethylphosphoryl fluoride and *iso*nitroso acetone according to eqn. (13).

The second order rate constants, k_{R^-} recorded in Table 1 are found from the formula:

$$k_{R^-} = \frac{k_1}{C_{A^-}} \tag{14}$$

where C_{A^-} is the concentration of the anion of the *iso*nitroso acetone at the pH used. C_{A^-} is calculated from the following equation:

$$C_{A^-} = a_0 \frac{\text{antilog}\,(\text{pH} - \text{p}K - \log\gamma)}{1 + \text{antilog}\,(\text{pH} - \text{p}K - \log\gamma)} \tag{15}$$

where a_0 is the total concentration of *iso*nitroso acetone and γ is the activity coefficient of the hydrogen ions.

The rate constants of the reaction with hydroxyl ion were calculated according to the following equation [11]:

$$k_1 = k_{OH^-} \cdot C_{OH^-} = k_{OH^-} \cdot \frac{a_{OH^-}}{f_{OH^-}} \tag{16}$$

k_1 is the first order rate constant at a fixed pH determined by the extrapolation method of Guggenheim [12]. k_{OH^-} is the second order rate constant for the reaction with hydroxyl ion. a_{OH^-} and f_{OH^-} are the activity and activity coefficients, respectively, of the hydroxyl ions.

Values of the Arrhenius activation energy E_A were obtained in the usual fashion from the gradients of plots of $\log k$ *vs.* $\frac{1}{T}$.

The entropy of activation was calculated according to the formulae of Eyring [13] for reaction in solution:

$$k_r = e \cdot \frac{k\,T}{h} \cdot e^{-E_A/RT} \cdot e^{\Delta S^{\neq}/R} \tag{17}$$

EXPERIMENTAL

Materials. Dimethoxyphosphoryl fluoride, methoxyethylphosphoryl fluoride and diethylphosphoryl fluoride were synthesized in this institute [14]. The compounds were redistilled immediately before use and their equivalent weights were determined by hydrolysis of the compounds with excess of 0.1 N $Ba(OH)_2$ followed by back-titration with 0.1 N HCl.

Dimethoxyphosphoryl fluoride, b.p. 54°/20, equiv. wt, found: 63.9, calc. 64.0. Methoxyethylphosphoryl fluoride, b.p. 58°/20, equiv. wt, found 63.3, calc. 63.0. Diethylphosphoryl fluoride, b.p. 72°/9, equiv. wt, found 61.7, calc. 62.0. *Iso*nitroso acetone was synthesized according to description in the literature [15].

Kinetic measurements. The rates of the hydrolysis were studied by means of an automatic recording titrator. The instrument used was a Radiometer Titrator, type TTTI. The principle of the instrumental set up is that the acid products formed during the hydrolysis of the organofluorophosphates are neutralized by automatic addition of alkali at such a rate that the pH of the reaction solution is maintained constant. The alkali is delivered from a 5 ml syrette driven by a micrometer screw connected with a motor. The motor is started and stopped automatically by the titrator when the pH of the solution drifts below or above the required value. A Radiometer glass electrode, type G 202 A was employed and a saturated calomel electrode type K 300 was used as reference electrode. The fluctuation during the reaction was approximately ± 0.02 pH-units. A constant temperature circulating water bath maintained the jacketed reaction vessel at ± 0.05°C. The capacity of the reaction vessel was 50 ml. An automatic recording device connected with the micrometer screw records the number of turns of the micrometer screw as function of time. The number of turns are used as relative measure of the amount of alkali added. The pH-meter in the titrator was standardized against a known buffer before each run. The procedure for the titration was the following:

The phosphorus compound was immediately before use weighed out and diluted with 50 ml 0.1 N KCl to a concentration of approximately 2×10^{-4} M. When the reaction with hydroxyl ion was studied, the titrator was standardized against a known buffer, the instrument set at the required pH and the automatic titration started. This reaction was studied in the pH-range 7.70—9.00. When the rate of the reaction between *iso*nitroso acetone and the organofluorophosphate was determined the 0.1 N potassium chloride solution contained a hundred fold excess of *iso*nitroso acetone. The drop in concentration of *iso*nitroso acetone during the reaction could therefore be neglected. The reaction was studied in the pH-range 6.00—6.70. The concentration of sodium hydroxide added from the syrette was 0.05 N. The slight dilution of the reaction solution during the hydrolysis due to the added alkali was neglected in the calculation of the rate constants.

The second order rate constants k_{OH^-} and k_{R^-} were calculate according to eqns. (13), (14) and (16). The pK values of *iso*nitroso acetone were determined by potentiometric titration and found to be 8.30 and 8.15 at 25°C and 35°C, respectively. The activity coefficients of hydrogen ions in 0.1 N KCl are 0.782 and 0.778 at 25°C and 35°C [16]. The activity coefficients of the hydroxyl ions in 0.1 N KCl (0.776 and 0.762) at 25°C and 35°C were taken from the paper of Larsson [11]. In Table 1 are recorded the data from the present study. The estimated errors in the rate constants are approximately ± 3 %. This corresponds to the accuracy of the rate constants found by Larsson and Hansen [10], determined by a similar instrumental set up.

DISCUSSION

The reactions between organic chloro- or fluorophosphorus compounds and nucleophilic reagents are generally believed to belong to A-2 mechanisms [11,18]. From theoretical reasons one must assume that during formation of the transition state the collision complex adapts a bipyramidal (sp^3d hybridised) transition state with the reacting groups and the phosphorus atom collinear:

Table 1. Rate constants and thermodynamic functions for nucleophilic reactions of dimethoxy-, methoxyethyl- and diethylphosphoryl fluoride.

Compound	Reaction with hydroxyl ion

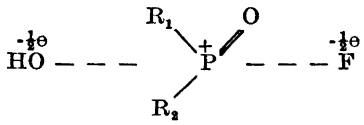
	1 308	864	26.3
	1 295	858	82.5
	1 278	845	129.9



(I)

Displacement reactions of optically active phosphorus compounds give strong evidence for this interpretation [19]. The activation energy necessary to form the transition complex according to (I) should be expected to decrease with increasing residual positive charge on the phosphorus atom. This increase will render the P-atom more susceptible to attack from the nucleophile. The activation energy for the nucleophilic reaction between hydroxyl ion or the anion of *iso*nitroso acetone with the three different fluorophosphorus compounds studied in this paper (Table 1), decreases successively when methoxy groups are replaced by alkyl substituents. This observation is attributed to the mesomeric effect ($+M$) of alkoxy groups. Such an effect will reduce the positive charge on the phosphorus atom and in this way counteract the attack from nucleophilic agents. The observed results are in accordance with the general electronic picture of the phosphorus compounds discussed in the previous paper [14]. In Table 2 are recorded the stretching frequencies of the P=O and P—F bonds of the three fluorophosphorus compounds studied. In the same table are also included the association constants of the dimeric hydrogen bond complexes between phenol and the same compounds in carbon tetrachloride. The increase of the polarity of the P=O and P—F bonds from the dimethoxyphosphoryl fluoride to diethylphosphoryl fluoride is consistent with the above conclusions. The same conclusion can also be drawn from the activation energy of the reaction with hydroxyl ion of the three last phosphorus compounds recorded in Table 3.

○ Values calculated from the paper of Epstein, Demek and Rosenblatt [24].
□ Values taken from the papers of Larsson [11,25].
■ Values calculated from the papers of Epstein *et al.*[26].

It has been observed that the reactions between organophosphorus compounds and substituted hydroxamic acids obey a linear relation between the logarithms of the rate constants and the logarithms of the dissociation constants of the corresponding hydroxamic acids [9,17]:

$$\log k = \log G + \beta(\mathrm{p}K\text{—}14) \qquad (16)$$

where G and β are constants. The proportionality factor β decreases when alkyl groups in the phosphorus compounds are substituted with alkoxy groups[9]. The importance of the basicity of the nucleophilic reagent in substitution reactions with the phosphorus compounds must therefore decrease from the alkyl to the alkoxy substituted compounds. According to Hammet [20] we must assume that the thermodynamic reason for the above mentioned linear relationship is that the entropy of reaction remains approximately constant for the reactions between the particular phosphorus compound and the different hydroxamic acids. This assumption is based on the similarity between the above linear relation and the expression of the rate constant according to the transition state theory (eqn. (17)) [20]. It seems therefore reasonable to assume that the importance of the basicity of the nucleophilic reagent in substitution reactions with phosphorus compounds should be reflected largely in the activation energy term. We arrive also to the conclusion that the activation energies of nucleophilic reactions with alkoxy substituted phosphorus compounds as compared with alkyl substituted compounds, should be less susceptible to changes of the basicity of the attacking reagents. The last assumption is supported by the activation energy data in Table 1.

The general tendency of the calculated entropy of activation for the nucleophilic displacement on phosphorus is to oppose the effect of the activation energy (Tables 1 and 3). A favourable activation energy is compensated by an unfavourable activation entropy and *vice versa*. We assume that this effect is connected with the differences in the polarisability of the reacting molecules. In a previous paper [14] where the hydrogen bond formation between phenol and organophosphorus compounds was studied, a similar compensating action between the enthalpy and entropy of the equilibrium reaction was observed. It was postulated that the polarity of the hydrogen bond successively increased with increasing strength of the hydrogen bond. Due to the polarity or the polarisability of the solvent molecules an increase in the polarity of the hydrogen bond will contribute to a stronger orientation of solvent molecules and a corresponding decrease in entropy. At the beginning of this discussion was mentioned that there is strong evidence for the view that the nucleophilic reaction of fluorophosphorus compounds belong to an A-2 mechanism. It appears to be well established that bimolecular reactions of type A-2 are always accompanied by a large negative activation entropy due to the partial valence bonds which are formed in the transition state [21,22]. A considerable part of the reaction entropy is attributed to the difference in the orientation of solvent molecules in the transition state and the reacting molecules [21,22]. If the electronic effects in the reacting molecules are of such character that they are able to decrease the charge concentration in the transition state we should expect an increase in the activation entropy. During the formation

● Values taken from the work of Green *et al.*[9]

of the transition state in the reactions between the nucleophiles and the phosphorus compounds recorded in Table 1, the electronic effect of the methoxy groups will be expected to contribute to a delocalization of the charge in the collision complex. We therefore attribute the observed favourable entropies of the reactions of the methoxy substituted compounds to this delocalization effect which correspondingly will decrease the solvent constriction in the transition state.

The strong influence of substituents in phosphorus compounds upon delocalization of the charge in nucleophilic substitution may be attributed to the fact that the available *d*-orbitals of phosphorus are involved in π-bonding and that these orbitals during the formation of the transition state also can enter the σ-bond structure of the activated complex. The character of the partial valence bonds of the activated complex will thus approach the character of true chemical bonds rather than a special orientation of reacting molecules with correspondingly great charge separation.

From Table 1 it is observed that the reactions of *iso*nitroso acetone with the phosphorus compounds proceed with much higher entropies of reaction than the corresponding reactions of the hydroxyl ion. We suggest that in this case the transition state has the possibility to delocalize the charge due to the partial valence bonds by mutual electromeric cooperation between the phosphorus compound and the attacking reagent.

A favourable entropy of reaction seems to be a common feature for all the reagents of low basicity which show abnormally high rate of reaction with the organophosphorus compounds, the reactivators included. In Table 4 are collected some results from the literature [11,23–26]. It is observed that all of the reactive nucleophiles are strongly polarisable molecules. It seems therefore possible that the explanation put forward for the *iso*nitroso acetone will apply to all of the different nucleophilic reagents studied.

Studies of nucleophiles with very high reactivity with phosphorus compounds reveal that it is an oxygen atom in the reagents which participates in

the displacement reaction (Table 4)[9]. The preference of the oxygen atom to participate in the displacement reaction with phosphorus compounds is most likely due to its high negativity and its small size. These qualities will make the oxygen atom favourable for π-bond formation with the *d*-orbitals of phosphorus. Linear polarisable groups as HOO^-, ClO^-, $O=N-O^-$, $-NHO^-$, $-C=N-O^-$ appear to be a common feature of the highly reactive nucleophiles (Table 4). Substitution in the atom adjacent to the reacting oxygen atom with greater groups than hydrogen (*e.g.* methyl) always reduce the reactivity of the nucleophiles with the phosphorus compounds. It seems reasonable to attribute this effect to steric retardation.

Nucleophilic reactions with the phosphorus compounds seems to be strongly dependent on two main factors of the nucleophilic reagent: its basicity and its polarisability[9,27,28]. The above mentioned observations indicate that the basicity effect is chiefly reflected in the activation energy term and the polarisability effect especially in the entropy term. Nucleophilic displacements on phosphorus depend also on the polarity and the polarisability of the phosphorus compounds[9]. The basicity effect of the nucleophilic reagent is most pronounced in reactions with phosphorus compounds of the highest polarity, and the polarisability effect of the reagent is most effective in reactions with the strongest polarisable substrate.

The kinetic studies in this paper together with the previous hydrogen bond studies of phosphorus compounds[14] point to the conclusion that the significance of the mutual polarisability of reactants is much greater in the reactions of phosphorus compounds than in the reactions of carbon compounds. It seems possible that just this property of phosphorus may play an important role in the wide-spread transphosphorylation processes which occur in all living tissues. A kinetic study of the biochemical reaction between cholinesterase and the three organofluorophosphorus compounds which have been studied in this paper (Table 1) has shown that the relative rates of reaction between cholinesterase and the phosphorus compounds correspond to the relative rates between *iso*nitroso acetone and the same phosphorus compounds. In both cases methoxyethylphosphoryl fluoride was found to react most rapidly with cholinesterase resp. *iso*nitroso acetone. This observation points to the conclusion that the rate determining factors in the phosphorylation of cholinesterase and *iso*nitroso acetone appear to be governed by the same fundamental properties of the reactants. In our opinion the relationship in reaction properties of cholinesterase and *iso*nitroso acetone gives reasonable explanation of the effectiveness of the reactivators to regenerate phosphorylated cholinesterase.

The kinetic study of the phosphorylation of cholinesterase will be published elsewhere.

A Comparison between Hydrogen Bond Formation and the Acid Hydrolysis of Phosphoryl and Carbonyl Compounds

GUNNAR AKSNES*

Norwegian Defence Research Establishment, Toxicological Group, Kjeller, pr Lillestrøm, Norway

The acid catalysed reactions of trialkylphosphites, di*iso*propyl fluorophosphate and acetamide are discussed in relation to their ability to form hydrogen bonds. Their special behaviour in acid hydrolysis, the decrease of the specific rate constant of the hydrogen ions with increasing concentration of acid, is assumed to be due to hydrogen bonding between the hydroxonium ions and the substrate.

In two previous papers [1,2] we have examined the very strong hydrogen bonds which are formed between phenol and the phosphoryl group in organophosphorus compounds and between phenol and the carbonyl group in N-diethylacetamide. In a third paper [3], nucleophilic displacements on phosphorus are discussed. Evidence has been gathered that the chemical reactivity with regard to nucleophilic substitution on phosphorus depends strongly on both the polarity and the polarisability of the phosphorus compounds. The purpose of this paper is to examine the connection between the ability of hydrogen bond formation of some phosphoryl and carbonyl compounds and their chemical reactivity in acid catalysis.

PREVIOUS FINDINGS CONCERNING THE ACID HYDROLYSIS OF AMIDES AND ORGANOPHOSPHORUS COMPOUNDS

It has been known for a long time that the acid hydrolysis of amides and organophosphorus compounds show exceptional behaviour. Euler [4] showed that in the acid hydrolysis of acetamide the first order rate constant of the hydrogen ion catalysis increased less than directly proportional to the acid concentration. Later it was observed that this behaviour was a common feature of all amides [5]. Nylén [6] found that the acid catalysis of dialkylphosphites depended on the hydrogen ion concentration in the same way as

* Present address: Chemical Institute, University of Bergen, Bergen, Norway.

for the amides. The same observation was made by Kilpatrick and Kilpatrick[7] in their study of the acid catalysis of di*iso*propylfluorophosphate.

Euler explained the results from his ionization theory of catalysis[8]. He considered the substrate (S) and the acid HA to be in equilibrium with the conjugated acid SH^+ of the substrate:

$$S + HA \underset{k_{1-}}{\overset{k_1}{\rightleftharpoons}} A^- + SH^+ \qquad (1)$$

The rate of hydrolysis was then determined by the rate of splitting of SH^+

$$SH^+ \xrightarrow[\text{slow}]{k^*} \text{product} \qquad (2)$$

He assumed than that the base strength of S was of the same order as A^-, *i.e.* $k_1 \sim k_{1-}$. If now $k^* \ll k_{1-}$ it is easily found that the observed rate of hydrolysis (k_{obs}) is satisfied by the following equation

$$k_{obs} = \frac{k^* \cdot H^+ \cdot K_B}{1 + H^+ \cdot K_B} \qquad (3)$$

where k^* is the specific rate constant of the hydrogen ions. H^+ is the concentration of hydrogen ions. K_B is the base constant of the substrate defined as: $K_B = K_1/K_W$, where K_1 is the ionization constant of the base referred to water solution, and K_W is the ion product of water.

When eqn. (3) above is rearranged we get:

$$\frac{k_{obs}}{H^+} = -k_{obs} \cdot K_B + k^* \cdot K_B \qquad (4)$$

We find therefore that k_{obs}/H^+ shall vary linearly with k_{obs}. The slope of the line is equal to K_B.

The experimental data of Euler[4], Nylén[6], Kilpatrick and Kilpatrick[7] obey all a linear relation according to eqn. (4). In Table 1 are recorded the base constants of different substrates calculated according to eqn. (4).

Table 1. K_B-values calculated from reaction kinetic data (eqn. 4).

Diethylphosphite	167
Di-*n*-propylphosphite	200
Di*iso*propylphosphite	237
N-Diethylacetamide	170

HYDROGEN BOND ASSOCIATION CONSTANTS

In Table 2 are recorded the association constants for the hydrogen bond association between phenol and dialkylphosphites and between phenol and N-diethylacetamide in carbon tetrachloride [1,2].

From the presence of the stretching vibration band of the phosphoryl group and its displacement upon hydrogen bonding we conclude that the dialkylphosphites have phosphoryl structure and that it is the P=O bond which participates in hydrogen bonding [2].

THE CONNECTION BETWEEN pK_B OF SOLVENTS AND THE FREQUENCY SHIFT OF THE O–D BAND IN THE SAME SOLVENTS

Gordy [9] has shown that there exist a simple relation between the basicity of solvents and their ability to form hydrogen bonds. He observed that the frequency shifts of the O—D stretching band of deuterium alcohol and deuterium oxide in different basic solvents are proportional to the pK_B of the solvents. In Fig. 1 are reproduced his observations of the frequency shift of the O—D stretching band of deuterium oxide in 19 different solvents. The equation of the line is according to Gordy [9]:

$$\Delta\mu = 0.0175 \log K_B + 0.297 \quad (5)$$

where $\Delta\mu$ is the frequency shift of the O—D band. K_B is defined as: $K_B = K_1/K_W$, where K_1 is the ionization constant of the base referred to water solution and K_W is the ion product of water.

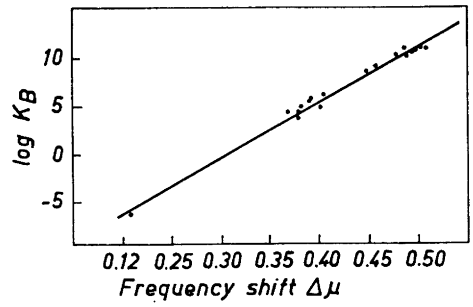

Fig. 1. Relation of basicity constants of solvent to their shifts of the vibrational band of D_2O. (Reproduced from the paper of Gordy [9]). Lowest point in fig.: acetophenone; middle points in fig.: pyridine and aniline derivatives; upper points in fig.: aliphatic and alicyclic amines.

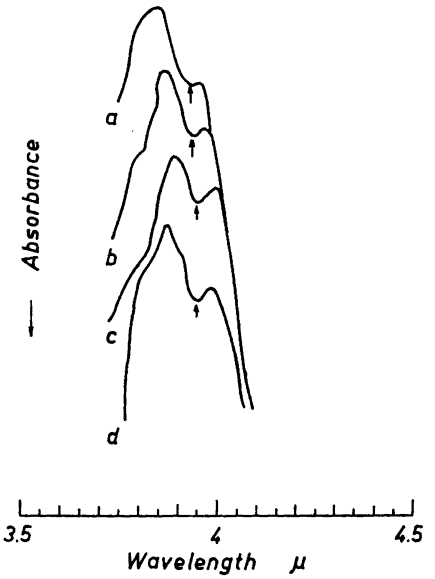

Fig. 2. The vibrational bands of D_2O in dialkylphosphites. a) Dimethylphosphite, b) diethylphosphite, c) dipropylphosphite, d) di*iso*propylphosphite.

We have used this equation to estimate the apparent basicity constants of the trialkylphosphites, di*iso*propylfluorophosphate and acetamide. In Fig. 2 are shown the absorption bands of the O—D stretching vibration of deuterium-oxide when it is dissolved in the different dialkylphosphites. Due to the broadness of the O—D band it is difficult to get a very accurate measure of the O—D displacement, but there is a distinct increase of $\Delta\mu$ of the O—D band from dimethyl to di*iso*propylphosphite. The calculated basicity constants are recorded in Table 3.

DISCUSSION

If we compare the basicity constants calculated from eqn. (4) in Table 1 with the basicity constants of the compounds determined from the frequency shift of the O—D band in Table 3, we find in both cases K_B values of the same order of magnitude. The K_B values calculated from the kinetic data show the ordinary variation with ionic strength. None of the methods can be expected to give very accurate values of K_B. The K_B values of the dialkylphosphites calculated from the kinetic measurements indicate an increase in basicity of the dialkylphosphites from dimethyl- to di*iso*propylphosphite. This is in agreement with the determined association constants between phenol and dialkylphosphites in carbon tetrachloride recorded in Table 2. The same general tendency is shown by the K_B-values of the dialkylphosphites determined by the frequency shift method in Table 3.

The kinetic picture given by Euler [4,8] is apparently in good agreement with the above results. But there is a serious objection to the application of the theory of Euler. If there existed a proton transfer equilibrium between the

Table 3. K_B-values calculated from the frequency shift of the stretching band (eqn. 5).

Compound	$\Delta\mu$ of O—D band	Calculated K_B
Dimethylphosphite	0.282	0.2
Diethylphosphite	0.290	0.4
Di-*n*-propylphosphite	0.295	0.8
Di*iso*propylphosphite	0.300	1.5
Acetamide	0.285	0.3
Di*iso*propylfluoro-phosphate	0.300	1.5

hydrogen ions and the substrate we should expect a measurable change in the pH of the solution when the substrate is dissolved in water.

Nylén [6] was unable to find any significant change in the pH of water solutions of dialkylphosphites. We have repeated the pH-measurements not only for the dialkylphosphites but also for the extremely strong hydrogen bonding substrate trimethylphosphine oxide which, according to the relation found by Gordy [9], should have a K_B value of approximately 10^4. In none of the cases have we been able to demonstrate the expected changes in the pH of their water solutions.

We conclude therefore that the observed reaction kinetics do not deal with proton transfer equilibrium but with hydrogen bond equilibrium. The following kinetic scheme is postulated:

$$S + H_3O^+ \ldots nH_2O \overset{K_{ass}}{\rightleftharpoons} S \ldots H_3O^+ + nH_2O \qquad (6)$$

$$S \ldots H_3O^+ + H_2O \xrightarrow[\text{slow}]{k^*} \text{product} \qquad (7)$$

The reaction (6) shows that the substrate due to its tendency of hydrogen bond formation will compete with water in capturing hydroxonium ions. The kinetics of the reaction will be the same as in theory of Euler [4]. The difference lies in the meaning of the equilibrium constants. K_{ass} in eqn. (6) is not the base constant of the substrate but the hydrogen bond association constant between substrate and hydroxonium ions relative to that of water. But since the hydrogen ions are not lost from the water to the substrate through a proton transfer reaction but are only gathered in the neighbourhood of the substrate due to hydrogen bonding, we cannot expect the same influence on the acidity in the last case as compared with a proton transfer reaction. It seems more correct to speak about a small influence upon the activity of the hydrogen ions due to their hydrogen bonding with the substrate.

The hydrolysis of dialkylphosphites and di*iso*propylfluorophosphate shows general acid catalysis [6,7,10]. This observations are in complete agreement with

the postulated reaction scheme. In this case one will in addition to the equilibrium reaction (6) have to include an eqilibrium reaction of the general type:

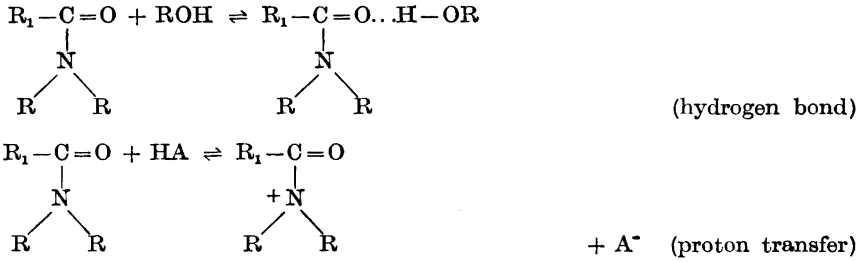
$$S + HA \overset{K_{ass}}{\rightleftharpoons} S \ldots HA \qquad (8)$$

where HA means an undissociated acid, and

$$S \ldots HA + H_2O \xrightarrow[\text{slow}]{k_{HA}} \text{product} \qquad (9)$$

where k_{HA} is the rate constant of hydrolysis due to the undissociated acid.

The hydrolysis of amides gives also support to the hydrogen bond mechanism of hydrolysis. It was mentioned in a previous paper [1] that it is the C=O bond in amides which participates in hydrogen bonding, but when a sufficiently strong acid is used to produce a proton transfer reaction the proton is captured by the nitrogen:



Now it is known that the rate of acid hydrolysis of amides goes through a maximum at about 5—6 M acid [5]. The maximum in rate has been explained as caused by the drop of water concentration (or of its activity) at high acid concentrations [5].

Lately it has been observed that the amides in nearly water-free strong acids are also hydrolysed at a relative high rate and that the rate decreases upon adding small amounts of water [11].

The only reasonable explanation of this behaviour is that there exists two different mechanisms of hydrolysis of the amides. In water-free strong acids all of the amides will exist in the protonised form with the proton attached to the nitrogen. The splitting of the protonised form in concentrated acids will most likely be a unimolecular reaction which is retarded in the presence of too much water. The logical interpretation of the hydrolysis of amides in dilute water solution (which are the measurements referred to in this paper) is therefore that the reaction follows a bimolecular reaction scheme (A-2) according to eqns. (6) and (7) where the C=O group participates in a hydrogen bond equilibrium reaction with the hydroxonium ions.

The phosphoryl and carbonyl compounds discussed in this paper show a common feature in their strong ability of hydrogen bond formation. It seems unlikely that other carbonyl and phosphoryl compounds with less polar C=O or P=O bonds should behave in a different manner. But their hydrogen bond

association constants with hydroxonium ions should be expected to be so small that the measured rate constants will appear to be proportional to the acid concentration. From the paper of Gordy [9] we find that the O—D shift, $\Delta\mu$, of deuterium oxide in ethylacetate is 0.21, which corresponds to an apparent K_B-value of approximately 10^{-5}. Such a low K_B-value incerted in eqn. (3) will not give observable deviation of k_{obs} from proportionality. A consequence of this view is that the acid catalysed reaction of compounds where the C=O or P=O bonds are attacked by the acid previous to the formation of the transition state should be expected to belong to the bimolecular reaction scheme (A-2). This follows from eqn. (7).

In a previous paper [12] where the acid hydrolysis of quaternary ammonium esters were studied, it was found that the carbonyl oxygen was attacked by the hydroxonium ions during the hydrolysis of the esters. There is now convincing evidence that the hydrolysis of aliphatic esters belong to a bimolecular mechanism (A-2) [13]. The hydrolysis of esters will therefore fit into the reaction scheme proposed in this paper.

Direct evidence for an acid catalysed ester hydrolysis by the unimolecular mechanism (A-1) was obtained in the hydrolysis of esters of mesotoic acids [14] (2,4,6-trimethylbenzoic acid). These esters give with concentrated strong acids benzoylium ions. But this observation proves that the proton transfer reaction in this case must have occurred at the ether oxygen of the esters.

Electrochemical Behaviour of Iron

TOR HURLEN

Central Institute for Industrial Research, Blindern, Oslo, Norway

As part of a research programme on the kinetics of metal/metal-ion electrodes in aqueous solutions, investigations have been made on the anodic dissolution and cathodic deposition of iron in acid chloride solutions at 20°C by means of a slow amperostatic technique. The reactions are found to obey the Tafel relationship (except at higher current densities) and to have mutually symmetric Tafel lines with slopes of numerically 0.029 V ($2.303RT/2F$). The rate of either reaction is moreover found to be proportional to the hydroxyl ion activity, and the rate of deposition to be proportional to the square of the ferrous ion activity. This indicates a mechanism covered by the equation:

$$2Fe + OH^- \rightleftharpoons 2Fe^{++} + OH^- + 4e^-$$

This mechanism is discussed, and a possible explanation is suggested.

For the exchange current (i_o) and the standard potential (E_o) of the Fe/Fe^{++}, aq-electrode, it is found:

$$\log i_o\ (A/cm^2) = 3.58 - pOH - pFe$$
$$E_o = -0.467\ V$$

The latter value includes a (probably small) liquid junction potential, and both equations depend somewhat on the validity of the activity data applied.

Some measurements have also been made on the hydrogen evolution reaction at iron cathodes. The results indicate a Tafel slope of -0.116 V ($-2.303 \cdot 2RT/F$) and an exchange current of

$$\log i_o(A/cm^2) = -5.36 - 0.5\ pH$$

for this reaction in acid solutions. It is further found that the hydrogen evolution reaction is positively affected (stimulated) by the iron dissolution reaction and negatively affected (depressed) by the iron deposition reaction, and that it transforms from a pH-dependent to a pH-independent mechanism at a pH quite near to the neutral point. The Tafel slope is not affected by this change in reaction mechanism.

1.0 INTRODUCTION

A most important trend in recent studies of electrochemical kinetics is the development of theoretical equations for the rate of activation controlled electrode reactions [1–3]. These equations enable the identification of the rate

determining step and the determination of stoichiometric factors from suitable polarization measurements. The theory has so far mainly been used in elucidating the mechanism of hydrogen evolution at metal cathodes as this is by far the best known electrode reaction [1,2]. It has in this case apparently met with considerable success, making it a promising basis also for the study of other electrode reactions. On the other hand, such studies may also be of value in providing further data for testing the validity and applicability of the theory (see the criticism given by Horiuti [4] and Rüetschi [5]).

Metal deposition and dissolution constitute an important class of electrode reactions showing strong technological and practical implications (metal production, metal refining, electro-plating, corrosion, *etc.*). In spite of this, little seems to be known concerning their kinetics. This has been clearly demonstrated by Bockris [2] and Hoar [6], who have collected and discussed most of the relevant data available. These authors ascribe this state of affairs partly to experimental difficulties which have prevented many results being expressed in a form which allows theoretical analysis. Several of the results do also indicate that the polarization data to some extent depend on the method by which they have been obtained.

On this basis, it was assumed desirable to make renewed and extended investigations on a series of metal/metalion electrodes, using the same method for polarization measurements on all the metals. The metals which have been included in this programme, are *iron*, *cobalt*, *nickel*, *copper*, and *zinc*. The polarization method adopted, is a "slow" amperostatic method which allows the partial current density of the reactions to be estimated from the weight change of the electrodes. For checking the reliability of the method, parallel measurements have been made on the hydrogen evolution reaction at cathodes of the various metals involved. Other methods have also been applied.

This work will be presented in a series of papers of which this is the first. Experiments on *iron* in de-aerated acid chloride solutions at 20°C are here described and the kinetics of the anodic dissolution and cathodic deposition of this metal is discussed.

2.0 PREVIOUS WORK

Most of our present knowledge of the electrochemical behaviour of iron has come from the study of corrosion and allied processes. General reference may therefore be given to the corrosion monographs by Gatty and Spooner [7], Evans [8], Uhlig [9], Speller [10], Tödt [11], and Klas and Steinrath [12] and to the corrosion review by Grubitsch [13] where further references to original work — except the most recent — will be found. A general reference may also be given to the monograph by Fischer [14] on electrocrystallization of metals.

As already mentioned, most of the few data from this work which allow direct analysis on the basis of modern theory, have been collected and discussed by Bockris [2] and Hoar [6]. A great many of the additional data, however, may be used in testing the validity of the more direct ones by comparison with consequences deduced from these. Important data in this connection are for instance those on the relations between corrosion potential, corrosion rate

and pH. This will be discussed separately in a subsequent paper, and we will here only deal with the more direct results.

A complete analysis of the kinetics of an electrode reaction often requires data also for its reverse reaction [1,2]. This is especially the case for metal dissolution processes, as we here have no means of altering the activity of the main reactant, the solid metal itself. The work of Hoar and Hurlen [15-17] on iron and mild steel in acid sulphate solutions is the only work we are aware of in which the potential/rate relationship for anodic dissolution and cathodic deposition of iron has been studied under equivalent conditions. They found the Fe/Fe^{++}.aq-electrode to behave symmetrically and to have a Tafel slope of numerically 2.303 $RT/2F$ (0.029 V at 25°C) for either of its reactions. The rate of both reactions was moreover found to be proportional to the hydroxyl ion activity, the rate of deposition to be proportional to the square of the ferrous sulphate activity, and the rate of dissolution to be independent of the latter activity. The extrapolated Tafel curves gave reasonable values for the reversible potential and exchange current values directly proportional to both the above mentioned activities, *e.g.* —0.507 V (normal hydrogen scale) and 2.6×10^{-11} A/cm^2 in 0.1 M sodium hydrogen sulphate + 0.05 M ferrous sulphate at 25°C. This work includes experiments at 0, 25, and 50°C, and the method used was the same as in the present work.

Rojter, Juza, and Polujan [18] determined the exchange current of the Fe/Fe^{++}.aq-electrode in 1.25 M ferrous sulphate presumably at room temperature (not specified) from oscillographically determined charging curves and obtained approximately 10^{-8} A/cm^2. This is in reasonable agreement with the results of Hoar and Hurlen when the effect of ferrous ion activity and pH is considered.

Bonhoeffer and Heusler [19-21], from rapid oscillographic potential measurements, found a Tafel slope of 0.030 V for the stationary anodic dissolution of iron in acid sulphate and perchlorate solutions. They further found proportionality between the dissolution rate and the hydroxyl ion activity raised to a power of 1.55. Heusler [21] assumes 2 to be the correct value of this exponent. These results are only partly in accordance with those of Hoar and Hurlen.

Kabanow, Burstein, and Frumkin [22] found an anodic Tafel slope varying from 0.02 to 0.04 V for iron in 2 N sodium hydroxide. By comparing with corresponding results in 1 N hydrochloric acid (obtained by Kusnezov [23]), they further found indications that the dissolution at equal potentials was several orders of magnitude faster in alkaline than in acid solutions. These authors were thereby probably the first to draw attention to the effect of pH on the anodic dissolution of active iron. They also discussed the effect of chloride ions on the anodic dissolution reaction in alkaline solutions.

Values for the Tafel slope of anodic dissolution have been given also by a few other authors. Kaesche [24] found 0.03 V for iron in acid perchlorate solutions at 25°C. Makrides, Komodromos, and Hackerman [25] found 0.04 V for iron in 2 M hydrochlorid acid and Gatos [26] 0.06 V in 1 N sulphuric acid when the dissolution was caused by depolarizers. Hoar and Holliday [27] found 0.051 V for mild steel in 0.5 M sulphuric acid at 40°C, and Hoar and Farrer [28] 0.05 to 0.07 V for mild steel in 0.001 N solutions of various magnesium, calcium, and sodium salts at 25°C. Okamoto, Nagayama, and Sato [29] found about 0.1

V for iron in 0.3 N sulphuric acid when varying the current density be about twice every 0.1 sec. Stern and Roth [30] have moreover given an estimated value of 0.078 V for iron in an acid chloride solution.

According to Bockris [2], little relevant work has been done on the cathodic deposition of iron. A detailed discussion of results obtained up to 1954 has been given by Fischer [14]. A description of modern ideas on the mechanism of metal deposition reactions has more recently also been given by Conway [31]. Lyons [32] has described how the discharge process of cations may be visualized on the basis of electron configurations, and Conway and Bockris [33] have made a theoretical treatment of the mechanism of metal deposition. The most recent work we are aware of as to the deposition of iron, is that of Hoar and Hurlen [15-17] mentioned above.

A detailed description of the hydrogen evolution reaction at iron cathodes is outside the scope of the present work, and a few references will be given for comparison and checking purposes only. The most usual Tafel slope for hydrogen evolution at metal cathodes is 4.606 RT/F (0.117 V at 25°C), a value also easily derivable by theory [1,2]. The results obtained for this reaction on iron in acid sulphate solutions by Hoar and Hurlen [15-17], in acid sulphate and perchlorate solutions by Bonhoeffer and Heusler [19,21], in acid perchlorate solutions by Kaesche [24], in acid chloride solutions by Stern [34,35], and by Fischer and Thoresen [35] (just to mention some of the most recent results) are partly in excellent agreement with this value. It is further to be expected that the rate of hydrogen evolution in this case should be proportional to the hydrogen ion activity provided the pH is not too high and excess indifferent salt is present [1,2]. The results of Hoar and Hurlen [16,17] show an effect of pH in accordance with this, while those of Stern [34,35] and of Bonhoeffer and Heusler [19,21] show a somewhat smaller pH effect. A modern analysis of the effect of the electrode material on the hydrogen evolution reaction is given by Parsons [37].

Stern [35] and Hoar and Hurlen [15-17] have recently studied the effect of impurities in iron on its electrode behaviour (the latter authors by comparing the behaviour of pure iron with that of a relatively clean mild steel). In both these investigations, a distinct stimulating effect especially of non-metallic impurities (as sulphur and phosphor) on the hydrogen evolution reaction was observed. Hoar and Hurlen found no differences in the pure dissolution and deposition characteristics of their iron and mild steel electrodes. Some earlier indications [38-40] that sulphur should promote also the anodic dissolution reaction were thereby not confirmed.

Most of the work on the electrochemical behaviour of iron has been performed with polycrystalline electrodes. Engell [41] and Buck and Leidheiser [42], however, have made some investigations on single crystals of α-iron. Engell found that the dissolution was nearly independent of the orientation of the crystal surfaces at low current densities (less than about 2 mA/cm^2), whereas the (111) and (110) surfaces dissolved faster than the cube faces by a factor of about 2 at higher anodic loads. These investigations were performed in dilute sulphuric, perchloric, and nitric acid. Similarly, Buck and Leidheiser found that the rate of corrosion of the (321) face was approximately twice that of the (100) face in 0.2 M citric acid. The corrosion potential of the latter face was moreover more cathodic than that of the former face. This indicates that,

besides a possible difference in the cathodic hydrogen evolution reaction at these faces there is also a difference in the anodic dissolution reaction.

Buck and Leidheiser [42] further found that the rate of corrosion of the polycrystalline starting material from which the single crystals were prepared was several times greater than those of the single crystals, and that the conversion of the single crystals to polycrystalline material resulted in a considerably increased corrosion. They ascribe this to an effect of grain boundaries on the dissolution reaction. The effect of dislocation steps in the surface on the rate of dissolution and deposition has recently been treated theoretically by Vermilyea [43].

Reviews and dicussions of recent work of general interest to electrochemical kinetics are moreover presented by Grahame [44], Butler [45], Delahay [46,47], Breyer [48], Thirsk [49], Fleischmann and Oldham [50], and Frumkin [51].

The passivity of iron is not considered here as the present work solely deals with the electrochemistry of active iron.

3.0 MATERIALS AND METHODS

Electrodes of iron (0.03 % C, 0.01 % Si, 0.19 % Mn, 0.027 % P, 0.030 % S), presented by Domnarfvets Jernverk (Sweden), were used in the form of circular sheets (about 4.5 cm diameter and 0.5 mm thickness) punched out from cold-rolled strips. Prior to use, the electrodes were vacuum annealed for about one hour at about 700°C, polished with emery paper, etched in dilute nitric acid, washed in running water, distilled water, and acetone, dried, and weighed.

Electrolytes were prepared from A.R. quality ferrous chloride, potassium chloride, and hydrochloric acid in water distilled from a "pure" and soft fresh water. The solutions were presaturated with hydrogen which first was purified by passing a palladium catalyst at about 250°C. For the ferrous chloride solutions, the presaturation was performed in the presence of a large piece of platinized platinum. This reduced the ferric ion content to a very low level (as judged from the red-ox potential). The electrolytes were also stored under hydrogen and were further transferred to the test cell by hydrogen pressure. A sketch of the electrolyte preparation and storage unit is shown in Fig. 1.

The test cell was a cylindrical Pyrex glass cell (about 10 cm^3 internal cross section and about 15 cm long) carrying tubes for the ingress and egress of liquid and gas. Two

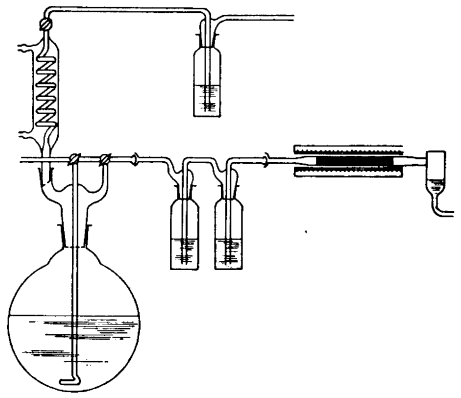

Fig. 1. The unit for preparation, pretreatment, and storage of electrolyte solutions.

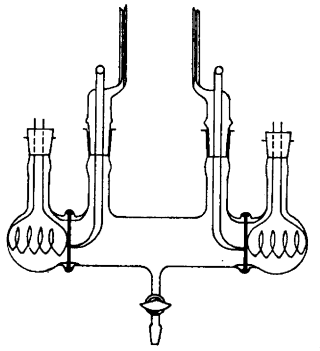

Fig. 2. The experimental cell.

electrodes could here be placed so as to form the two end walls of the cell. After having been clamped in position, the electrodes were covered around their outer edge with polystyrene (dissolved in chloroform) and paraffine wax. The cell further had two Haber-Luggin capillaries for electrolytic connections to two external reference electrodes, and copper wires for metallic connections to the potentiometer and to the current source. A sketch of the test cell, which could hold about 200 ml electrolyte, is shown in Fig. 2. In this cell, the electrolyte is exposed to the atmosphere only in two capillaries of about one millimeter diameter.

The experiments were performed galvanostatically. The current was supplied from an assembly of four 12 V accumulators connected in series. It was read on a calibrated Avo-meter and controlled by a number of variable resistances in series with the cell. The electrode potential of each electrode as a function of time was measured against a saturated calomel electrode by means of a Cambridge pH-meter.

The partial current density of the iron electrode reactions was estimated from the weight change of the electrodes over a considerable time at constant total current density. A Mettler semi-micro balance was used for these weighings. The duration of the runs varied from about one hour to two days, depending on the current applied (10^{-5} — 10^{-2} A/cm^2). The experiments were performed in a thermostated room at 20 ± 0.5°C.

4.0 THE ELECTROLYTE SOLUTIONS

The electrolyte solutions (I—IX) used in the present work, are described in Table 1. Data are there given for the composition and for the "molal ionic strength" defined by:

$$I(m) = \frac{1}{2} \sum_i m_i \cdot z_i^2$$

$I(m)$ is nearly equal to the ionic strength divided by the density of the solution (I/d). Values are moreover given for the mean molal activity coefficient (γ) of the solutes and for the activity (a) of the solvent (water). The dissociation constant of water (K_w) at 20°C is given by [52]

$$-\log K_w = 14.1666$$

The mean molal activity coefficients of hydrochloric acid and of potassium chloride have been calculated from the recent results of Harned and Gancy [53] on mixtures of these two electrolytes. For the ferrous chloride containing solutions, it has been assumed as an approximation that γ_{HCl} and γ_{KCl} have the same values as in corresponding solutions in which the ferrous ions have been substituted by an equivalent amount of potassium ions. The mean molal activity coefficients of ferrous chloride have been estimated graphically, $\log \gamma$ *vs.* $I(m)$, from data tabulated by Robinson and Stokes [52].

The activity of water in the solutions I—IV has been calculated from the data given by Harned and Gancy [53] for the osmotic coefficient of such solutions. For solution V, in which ferrous chloride is the main electrolyte, the water activity has been calculated from the molal osmotic coefficient of 0.5 m ferrous chloride [52]. For the solutions VI—IX, a_{H_2O} has been estimated on the basis of data from the above mentioned sources.

All the data used in these calculations apply to 25°C. It will here be assumed, however, that the values in Table 1 are sufficiently valid also at 20°C.

Table 1. Composition, ionic strength, and thermodynamic activity data for the applied solutions (I—IX).

	Molality			$I(m)$	$-\log \gamma$			$-\log a$
	HCl	KCl	$FeCl_2$	$(\approx I/d)$	HCl	KCl	$FeCl_2$	H_2O
I	1	0	0	1.0	0.0908	0.1502		0.016

VII	0.001	0.8	0.1	1.1	(0.146)	(0.218)	(0.348)	(0.013)
VIII	0.001	0.9	0.05	1.05	(0.146)	(0.218)	(0.347)	(0.014)
IX	0.0001	1.8	0.1	2.1	(0.120)	(0.240)	(0.334)	(0.014)

In electrode kinetics, we are interested in knowing single ion activities. These cannot be calculated from thermodynamic data (as those in Table 1) without the introduction of some non-thermodynamic (or extrathermodynamic) assumptions [52,54-57]. For solutions of single univalent chlorides, two approaches have often been used:

a) *The MacInnes assumption*, which states that the chloride ion activity in a solution of any chloride is the same as the mean ionic activity in a solution of potassium chloride at the same total concentration.

b) *The Guggenheim assumption*, which states that the activity of the chloride ion of any univalent chloride is equal to the mean ionic activity.

The first of these assumptions may directly and equally well be applied to mixed electrolytes, and this gives for the ferrous chloride free solutions (I—IV):

$$\log \gamma_H = 2 \log \gamma_{HCl} - \log \gamma_{KCl(o)} \quad (1)$$

where γ_H is the activity coefficient of the hydrogen ions in the mixed electrolyte, and $\gamma_{KCl(o)}$ is the mean activity coefficient of potassium chloride in a pure solution of this salt at the same total concentration. Results of calculations of pH ($= -\log a_H$) on this basis are given in Table 2.

The Guggenheim assumption allows us to calculate the activity coefficent of hydrogen ions in a pure hydrochloric acid solution, $\gamma_{H(o)}$, as well as their limiting activity coefficient, $\gamma_{(o)H}$, in a mixed electrolyte of hydrochloric acid and potassium chloride by the relations:

$$\log \gamma_{H(o)} = \log \gamma_{HCl(o)} \quad (2a)$$

$$\log \gamma_{(o)H} = 2 \log \gamma_{(o)HCl} - \log \gamma_{KCl(o)} \quad (2b)$$

From the Guggenheim theory [52] of mixed electrolytes, one further has:

$$\log \gamma_H = \log \gamma_{(o)H} + x(\log \gamma_{H(o)} - \log \gamma_{(o)H}) \quad (3)$$

where x is the mole fraction of hydrochloric acid in the two component mixed electrolyte. Results of calculations of pH from these equations are also given in Table 2. As the *Guggenheim assumption* seems the thermodynamically most sound, the pH-values obtained on this assumption (together with the a_{H_2O}-values in Table 1) have been used in calculating the pOH-values given in Table 2.

For a pure ferrous chloride solution, the Debye-Hückel theory gives

$$\log \gamma_{Cl(Fe)} = \tfrac{1}{2} \log \gamma_{FeCl_2(o)} \quad (4)$$

when also the definition of the mean ionic activity coefficient is considered. On this basis and on the basis of the Guggenheim theory of mixed electrolytes, one may further assume the activity coefficient of chloride ions in a mixed solution of ferrous chloride and potassium chloride to be given by:

$$\log \gamma_{Cl(K,Fe)} = x_{KCl} \log \gamma_{KCl(o)} + \tfrac{1}{2}\, x_{FeCl_2} \log \gamma_{FeCl_2(o)} \quad (5)$$

where all the activity coefficients apply to the same ionic strength and x means the ionic strength fraction of the salts in the mixed solution. This equation has been used in calculating γ_{Cl} for the solutions V—IX (neglecting the possible effect of the small amount of hydrochloric acid present). γ_H and γ_{Fe} have then been calculated from the relationships:

$$\log \gamma_H = 2 \log \gamma_{HCl} - \log \gamma_{Cl} \quad (6a)$$

$$\log \gamma_{Fe} = 3 \log \gamma_{FeCl_2} - 2 \log \gamma_{Cl} \quad (6b)$$

where all the activity coefficients apply to the same solution. The ion activities thus obtained, are given in Table 2.

The values of γ_{FeCl_2} (see Table 1) needed in the just described calculations of γ_{Fe}, have been obtained on the assumption that the former coefficient is the same in any of the mixed solutions as in a pure ferrous chloride solution of the same $I(m)$-value. The ferrous ion activity coefficient may also be calculated on the assumption that this coefficient (instead of the mean ionic activity coefficient) obeys the above equality. This means, when eqn. 4 is considered, that

$$\log \gamma_{Fe} = 2 \log \gamma_{FeCl_2(o)} \quad (7)$$

where the two activity coefficients apply to solutions of the same ionic strength. The results of such calculations are also given in Table 2, and it will here be assumed that the thereby obtained activity values are the most correct ones.

Ferrous chloride has here been treated as a non-associated electrolyte. This may seem justified by the fact that its mean acitivity coefficient is well described by the Stokes-Robinson two-parameter equation [52] for this type of electrolytes. A possible hydrolysis of the ferrous ion has also been ignored, and this seems justified on the basis of the low value ($10^{-9.5}$) found by Hedström [58] for the hydrolysis constant of this ion.

5.0 RESULTS AND INTERPRETATIONS

Examples of potential-time curves obtained for hydrogen evolution at iron cathodes and for anodic dissolution and cathodic deposition of iron, are given in Figs. 3, 4, and 5, respectively. The applied current density is given in A/cm^2 for the various curves in the diagrams. Due to corrosion and to simultaneously occurring hydrogen evolution and iron deposition, the partial current density of the reactions (as determined by weight change measurements) sometimes was quite different from the applied current density (see below). The former of these current densities and potential data from the potential-time curves have been used in constructing Tafel diagrams for the three reactions studied. The potentials most representative for the hydrogen evolution reaction at the initial pH of the solutions have been assumed to be those obtained by extrapolating the potential-time curves to zero time. For the dissolution and the deposition reaction, the stationary potentials (or in some cases the potential in the beginning of a period of nearly stationary potential) have been assumed the most representative ones. The Tafel diagrams obtained in this way are shown in Figs. 6—10.

In transforming the readings made against the saturated calomel electrode, to potentials on the normal hydrogen scale, a value of + 0.245 V has been used for the calomel electrode at 20°C (Potter [59]). No attempts have been made to correct for the possible liquid junction potentials between the test solutions and the saturated potassium chloride solution. On the basis of data tabulated by Milazzo [60], however, it is believed that these junction potentials are small.

Hydrogen evolution

The hydrogen evolution reaction has mainly been studied in the ferrous ion free solutions (I—IV), but partly (at low current densities) also in the solution of the lowest ferrous chloride content (VIII). The polarization data obtai-

ned are given in Fig. 6, where the closed circles apply to cathodically polarized electrodes, the open circles to anodically polarized electrodes, and the centred circles to freely corroding electrodes. The terms *anodic* and *cathodic* are here used in reference to the corrosion potential so as to indicate the direction of the applied current.

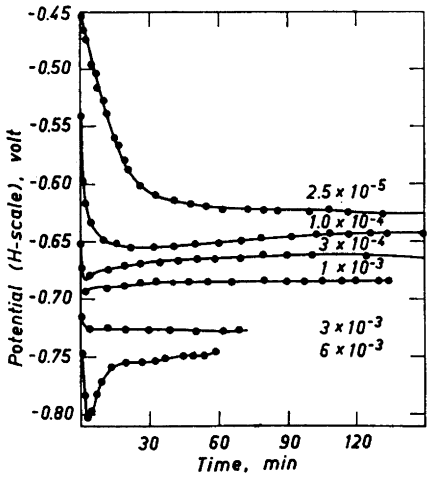

Fig. 5. Potential-time curves for cathodic deposition of iron in solution VII at various applied current densities (A/cm²).

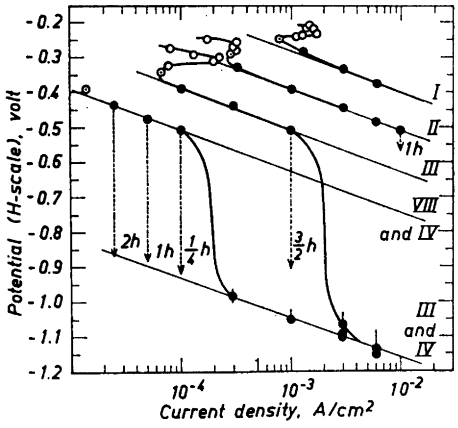

Fig. 6. Tafel diagram for hydrogen evolution at iron cathodes.

The partial current density of hydrogen evolution on anodically polarized electrodes has been estimated by the difference between the gravimetrically determined and the applied current density with corrections for the corrosion occurring prior to and after the application of current. On cathodically polarized electrodes, it has similarly been taken as the sum of the applied and the gravimetrically determined corrosion current. It is only at the lowest current densities in the two most acid solutions that a measurable corrosion occurred on electrodes of this kind, however.

The results (Fig. 6) clearly show that the hydrogen evolution reaction in these cases is strongly stimulated by a simultaneously occurring iron dissolution reaction when the rate of the latter approaches and exceeds that of the former (see the position of the corrosion points and the higher lying points in the diagram). This stimulating effect seems otherwise to be a complex function of the dissolution rate and possibly also of pH. It may here be of interest also to note that there both in the present work and especially in the previous work of Hoar and Hurlen [15,16] are indications that the hydrogen evolution reaction is affected in the opposite way by a simultaneously occurring iron deposition reaction.

The results further show that the hydrogen evolution reaction, when being the main or the only process occurring, follows the Tafel relationship with a Tafel slope (b) of very nearly —0.116 V. This indicates that

$$b = -2.303(2RT/F) \tag{8}$$

which is in agreement with previous results (see above). The data in Fig. 6 and in Table 2 with very good approximation also give the following corresponding relationships for the effect of pH on this reaction in the acid chloride solutions (when the current density is not too high):

$$(\partial \log i/\partial \text{ pH})_V = -1 \tag{9a}$$

$$(\partial V/\partial \text{pH})_i = -2.303(2RT/F) \tag{9b}$$

This is the same as previously found by Hoar and Hurlen [15-17] in acid sulphate solutions.

At the higher current densities in the less acid solutions (III and IV) the polarization points fall on a much lower lying and apparently pH-independent Tafel line with the same slope as the other ones. Also at the lower current densities in the solution of the highest pH (IV) does the potential seem to reach this Tafel line after some time (as indicated in Fig. 6) and then to stabilize there. It may certainly be that the potential at the higher current densities also starts at the pH-dependent Tafel line, but falls so rapidly (in less than half a minute) down to the pH-independent line that this possible happening escapes observation by the technique used.

According to the present results and the data given in Table 2, the pH-independent Tafel line has a position corresponding to that to be expected for the pH-dependent lines at a pH of 6.8. This is not far from the neutral point in these solutions which is near to pH 7.07 at 20°C. It seems thus natural to assume that the pH-dependent and the pH-independent Tafel lines represent

a reduction of hydrogen ions and water molecules, respectively, and that the observed transition from the former to the latter of these lines is due to the pH-change accompanying the hydrogen evolution reaction. Such a transition has also been observed by Stern [34] for hydrogen evolution on iron in acid chloride solutions. The slope of the pH-independent Tafel line was by him found to be — 0.174 V at 25°C, however.

The values obtained for the exchange current (i_o) of the H_2/H^+.aq-electrode on iron by extrapolating the Tafel lines in Fig. 6 to the reversible potential of this electrode in the corresponding solutions are covered by the equation

$$-\log i_o \ (20°C) = 5.36 + 0.5 \ pH \qquad (10)$$

where the exchange current is given in A/cm^2. This equation tells that the exchange current is inversely proportional to the square root of the hydrogen ion activity, and that (at 20°C) it should be $10^{-5.36}$ A/cm^2 when pH = 0. One should be aware of the fact, however, that the above results have been obtained mainly in the presence of excess neutral salt, and that divergences very well may occur in the absence of such salt [2]. On this basis, the results compare well with those tabulated by Parsons [60]: $-\log i_o$ = 5.9, 6.29, and 6.19 in 1 M HCl (16°C), 0.01 M HCl (20°C), and 0.001 M HCl (20°C), respectively. Stern [34], however, found an essentially pH-indenpendent exchange current of the order of 10^{-4} A/cm^2 in acidified 4 % sodium chloride solutions at 25°C. It may also be of interest to compare the present results with those of Hoar and Hurlen [15-17] in acid sulphate solutions at 25°C: $-\log i_o$ = 5.9 and 6.3 at pH = 1.5 and 2.4, respectively. The difference in temperature taken into account, it may thus seem that the rate constant of the hydrogen evolution reaction at iron cathodes is very much the same in sulphate as in chloride solutions. In this respect, iron differs distinctly from nickel as electrode material [61,62]. This will be discussed in a subsequent paper.

Iron dissolution

The anodic dissolution reaction has been studied in all the solutions (I—IX) described above, and the polarization data obtained are given in Figs. 7 and 8. In the least acid solution (IX), the tendency of passivation was more marked and the reproducibility somewhat poorer than in the other solutions, and the anodic data obtained in this solution have therefore been omitted.

The results clearly show that the anodic dissolution reaction follows the Tafel relationship except at the higher current densities in the less acid solutions (IV—IX). The deviation from this relationship in the latter cases may be due to an initiation of passivation. The Tafel lines in Figs. 7 and 8 have been drawn with a slope of 0.029 V, and the reasonable fit of these lines to the experimental points (which apply to 20°C) indicates that the Tafel slope (b) of anodic dissolution of active iron is given by

$$b = 2.303(RT/2F) \qquad (11)$$

This is in agreement with the previous results of Hoar and Hurlen [15-17] in acid sulphate solutions, of Bonhoeffer and Heusler [19-21] in acid perchlorate solutions, and also with some of the other results quoted above.

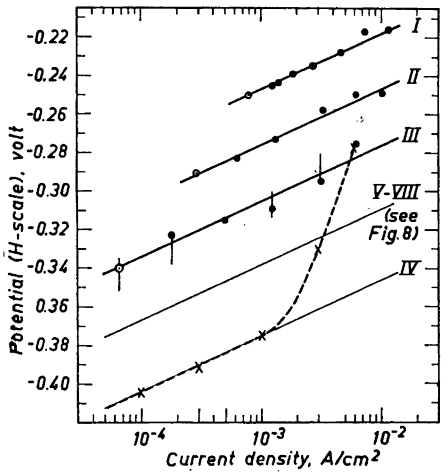

Fig. 7. Tafel diagram for anodic dissolution of iron.

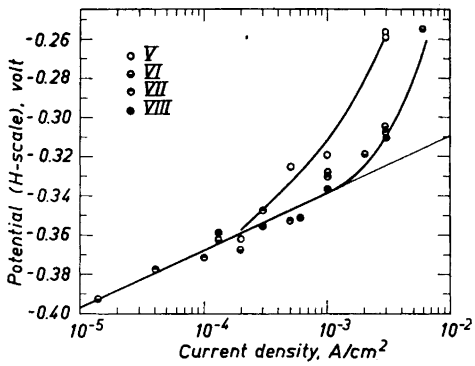

Fig. 8. Tafel diagram for anodic dissolution of iron in the ferrous ion containing solutions V—VIII.

The present data also agree with those of Hoar and Hurlen [15-17] and of Bonhoeffer and Heusler [19-21] in indicating a strong stimulating effect of hydroxyl ions on the dissolution reaction. Fig. 7 shows that the relationships

$$(\partial \log i/\partial \text{ pOH})_V = -1 \tag{12a}$$

$$(\partial V/\partial \text{pOH})_i = 2.303(RT/2F) \tag{12b}$$

with relatively good approximation apply to the results except for those obtained in solution IV. In this solution, the dissolution occurred much faster (by a factor of about twenty) than is to be expected from the above relationships and the results in the other solutions. This exception seemed so strange, especially when compared with the "normal" behaviour of the ferrous chloride containing solutions of very nearly the same pH (V—VIII), that three independent series of experiments were made with solutions of this type. As very nearly idential results were obtained in these series, this matter obviously needs further investigation. It may be that we here have some reason for the somewhat larger pOH-effect found by Bonhoeffer and Heusler [19-21].

The data in Fig. 8 further show that the rate of anodic dissolution reaction on active iron is essentially independent of the ferrous ion activity. Also in this connection, however, solution IV represents an exceptional, although extreme case.

There are no indications that a simultaneously occurring hydrogen evolution reaction does have any effect on the iron dissolution reaction comparable to that found for the opposite case (see above).

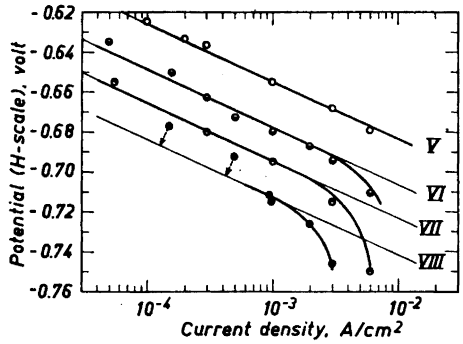

Fig. 9. Tafel diagram for cathodic deposition of iron (effect of ferrous ion activity).

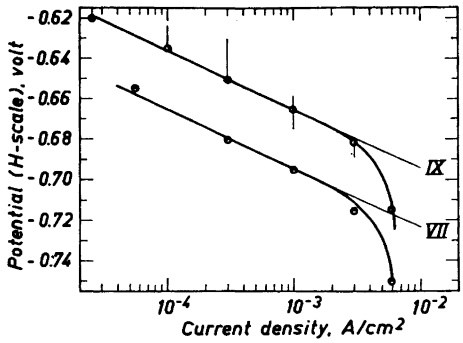

Fig. 10. Tafel diagram for cathodic deposition of iron (effect of pH).

Iron deposition

The polarization data obtained for the iron deposition reaction are given in Figs. 9 and 10. Also this reaction evidently follows the Tafel relationship except at the highest current densities applied. These deviations, however, are easily explained by the transition from activation control to diffusion control when approaching the limiting current. Especially in the solution of the lowest ferrous chloride content (VIII), there also are some distinct deviations at low current densities. In these cases, however, there was a relatively strong simultaneous evolution of hydrogen, and the deviations may very well be due to the pH-change accompanying this process (see below).

The Tafel lines in Figs 9 and 10 have been drawn with a slope of —0.029 V corresponding to

$$b = -2.303(RT/2F) \tag{13}$$

for the iron deposition reaction. This is numerically the same value as for the dissolution reaction, indicating that the Fe/Fe^{++}.aq-electrode behaves symmetrically. Also this is in agreement with the previous results of Hoar and Hurlen [15-17] for iron in acid sulphate solutions.

The results in Fig. 9 further show that the effect of the ferrous ion activity on the rate of the activation controlled deposition reaction is very nearly given by the following corresponding equations:

$$(\partial \log i/\partial \mathrm{pFe})_{V,\ \mathrm{pOH}} = -2 \tag{14a}$$

$$(\partial V/\partial \mathrm{pFe})_{i,\ \mathrm{pOH}} = -2.303(RT/F) \tag{14b}$$

This means that the deposition rate at any given potential and hydroxyl ion activity is proportional to the square of the ferrous ion activity, or, correspondingly, that the variation of the deposition potential with the ferrous ion activity at any given hydroxyl ion activity and deposition rate is twice that of the reversible potential of the Fe/Fe^{++}.aq-electrode. This, which also is in

accordance with the previous results of Hoar and Hurlen [16,17], is simply what thermodynamics requires on the basis of the Tafel slope values and the independence of the anodic Tafel line on the ferrous ion activity.

On the further basis of the pOH-dependence of the anodic Tafel line, thermodynamics also requires that the relationships

$$(\partial \log i/\partial \text{ pOH})_{V,\text{pFe}} = -1 \tag{15a}$$

$$(\partial V/\partial \text{pOH})_{i,\text{pFe}} = -2.303(RT/F) \tag{15b}$$

should apply to the deposition reaction. The results shown in Fig. 10 are in good agreement with these corresponding requirements.

The Fe/Fe^{++}.aq-Electrode

The values obtained for the reversible potential (E) and the exchange current (i_o) of the Fe/Fe^{++}.aq-electrode by extrapolating the Tafel lines for the dissolution and the deposition reaction (Figs. 8—10) to intersection, are covered by the following equations:

$$E(20°C) = -0.467 - 0.029 \text{ pFe} \tag{16a}$$

$$\log i_o(20°C) = 3.58 - \text{pFe} - \text{pOH} \tag{16b}$$

when the activity data in Table 2 are applied, and E and i_o are given in V and A/cm^2, respectively.

Eqn. 16a apparently gives a value of —0.467 V for the standard potential of this electrode at 20°C. However, this value includes both the uncertainties attached to the single ion activities used for the ferrous ion, and the unknown liquid junction potentials between the test solutions and a saturated potassium chloride solution. The observed effects of the ion activities do suggest that these junction potentials are very much the same for all the solutions applied, and the data tabulated by Milazzo [63] for such potentials, do suggest that it should be very small, probably not more than 1—2 mV. The same data also show that the liquid junction in the present cases should be expected to make the experimentally obtained potentials too negative.

The previous work of Hoar and Hurlen [15-17] similarly led to a value of —0.442 V for the standard potential at 25°C. This is close to the so far accepted value [64] of —0.440 V. However, these measurements were made in more acid solutions (pH 1.5—2.4) of relatively low ferrous ion concentration (0.05—0.15 M), and the deposition reaction was accompanied by a much stronger simultaneous hydrogen evolution reaction than in the present work (in which many of the results have been obtained at very nearly 100 % deposition). Even though the sulphate solutions have a better buffer action than the chloride solutions, it may be that the potentials of iron deposition in the previous Hoar-Hurlen work have been affected by a pH-change caused by the hydrogen evolution reaction, and thereby got a too high position in the Tafel diagram (see eqn. 15b).

On this basis, and assuming the applied activity data to represent a fair approximation, the author is inclined to believe that the standard potential of the Fe/Fe^{++}.aq-electrode should be more negative than the at present accepted value of —0.440 V.

Eqn. 16b for the exchange current (as well as eqns. 12 and 15) is written according to the assumption that the observed effect of pH on the iron electrode reactions is caused by the hydroxyl ions and not directly by the hydrogen ions. This assumption is based on the facts

a) that the effect is stoichiometric,
b) that it is positive (stimulating) with regard to hydroxyl ions, but negative (inhibiting) with regard to hydrogen ions,
c) that it is easily explained by a direct interaction of hydroxyl ions in the reactions, and
d) that there seems no reason why a possible inhibiting effect of hydrogen ions should be stoichiometric.

Some evidence for the validity of this assumption is provided by the previous data of Hoar and Hurlen [15,16] on the effect of temperature on the ion electrode reactions in acid sulphate solutions. These results, when treated conventionally, give an unreasonably high value for the virtual heat of activation [2] at the reversible potential. This is most probably due to a relatively strong variation in the activity of some of the reaction participants (what is not accounted for in the conventional treatment). The change in ferrous ion activity and pH with temperature in the applied solutions is relatively small, but pOH changes by more than one and a half unit over the temperature range concerned (0—50°C). This will be more thoroughly discussed in a subsequent paper [65].

Accepting the hydroxyl effect assumption as correct, one may rewrite eqn. 16b in the form:

$$-\log i_o\,(20°C) = 10.59 + \mathrm{pFe} - \mathrm{pH} + \mathrm{pH_2O} \qquad (17)$$

in which the constant is equivalent to "pK_w — 3.58". In the present case, the pH_2O-term is almost negligible. The previous work of Hoar and Hurlen [15–17] in sulphate solutions gave:

$$-\log i_o\,(25°C) = 9.7 + \mathrm{pFe} - \mathrm{pH} \qquad (18)$$

in which equation the negligible pH_2O-term is included in the constant.

The difference between the constants in eqns. 17 and 18 is nearly what is to be expected from the temperature difference on the basis of the heats of activation and the effect of temperature on the dissociation constant of water. This strongly indicates that neither chloride ions nor sulphate ions do have any direct effect on the dissolution and the deposition reaction of an active iron electrode. As there further are distinct differences in the chemical and metallurgical conditions (impurity content, coldwork, annealing) of the electrode materials used in these cases, nor these conditions do seem to have any great effect on these reactions in the pH-range 0 to 4. The hydrogen evolution reaction, however, is strongly influenced by some of these conditions (see the above discussion of previous work).

Thermodynamically, the overall reactions of the $Fe/Fe^{++}.aq$-electrode are undoubtedly represented by:

$$Fe \rightleftharpoons Fe^{++}.aq + 2e^- \tag{19}$$

Kinetically, however, this equation gives a too simplified and partly wrong impression. For characterizing such reactions, the modern theory of electrode kinetics [1,2] introduces the stoichiometric number (ν), which is defined as the number of times the rate determining reaction is represented in the overall electrode reaction considered. The theory further gives the following relationships between ν and other reaction parameters:

$$\nu = b_a b_c nF/2.303RT(b_c - b_a) \tag{20a}$$

$$\partial \log i/\partial pQ = -q/\nu \tag{20b}$$

$$\Delta H^*_{o,a} - \Delta H^*_{o,c} = \Delta H_{o,a}/\nu \tag{20c}$$

in which pQ means the negative logarithm of the activity of a reactant Q with stoichiometric factor q in the overall reaction, and the indexes a and c refer to the anodic and the cathodic reaction, respectively. There are just as many equations of type 20b as there are activity variable components in the overall reaction (only one in the present case), and ν may be determined independently from any of these or from eqn. 20a. To be strictly valid, however, eqn. 20b usually requires that excess inert electrolyte be present. Eqn. 20c can only be used for checking, as a knowledge of ν already is required in the determination of the heats of activation. When ν is known, eqn. 20b can also be applied for determining the stoichiometric factor of a possible interacting component not appearing in the equation for the overall reaction (*e.g.* hydroxyl ions in the present case).

On this basis, the data presented in eqns. 11, 13, 14, and 17 above show that

$$\nu = \tfrac{1}{2} \tag{21}$$

for the $Fe/Fe^{++}.aq$-electrode when its overall reactions are represented by eqn. 19. The data presented in eqns. 12 and 15 further show that the hydroxyl ion effect is accounted for by regarding the hydroxyl ion as a catalytic reactant with the stoichiometric factor

$$q_{OH} = \tfrac{1}{2} \tag{22}$$

in the overall reactions. These results simply mean that the reactions occurring for each act of the rate determining step in either direction of the $Fe/Fe^{++}.aq$-electrode is covered by the equation:

$$2Fe + OH^-.aq \rightleftharpoons 2Fe^{++}.aq + OH^-.aq + 4e^- \tag{23}$$

According to the present results, the above equation represents the smallest repeating reaction unit of the $Fe/Fe^{++}.aq$-electrode. In correspondance with

the terminology used in the crystal structure field, the term *unit reaction* or *kinetic unit reaction* may be proposed for reactions of this type. Just as a unit cell may contain more than one atom, ion, or molecule, a unit reaction may very well comprise more than one reaction step. It may even comprise more than one act of the rate determining step if defined as *the smallest reaction having integral values for all the stoichiometric factors and for the stoichiometric number.*

It is easily seen that the kinetic unit reactions arrived at in the present work (eqn. 23), is thermodynamically in accordance with the previously well established overall reactions of the Fe/Fe^{++}.aq-electrode (eqn. 19).

6.0 DISCUSSION

The hydrogen evolution reaction has been discussed in detail by many authors. As the present results on this reaction at iron cathodes moreover are essentially in agreement with previous data and with what is to be expected from theory [1,2], it will here be refrained from a further discussion of this subject, and the discussion will be confined to the Fe/Fe^{++}.aq-electrode reactions.

The results obtained in eight of the nine electrolyte solutions used in the present work, have been shown to indicate that these reactions are governed by a hydroxyl catalyzed double metal ion mechanism as that covered by eqn. 23. The results in the strange behaving solution (IV) are also in agreement with the double metal ion mechanism, but apparently show a relatively stronger hydroxyl ion interaction than found in the other solutions.

The hydroxyl ion interaction seems to occur stoichiometrically even in solutions in which the activity of this ion is as low as 10^{-14}. However, it is not the bulk activity, but the activity at the electrode surface that counts in such a catalytic interaction as in the present case. Due to the ionic distribution at electrified interfaces, to adsorption and perhaps chemisorption, and to corrosion at anodes and partial hydrogen evolution at cathodes, the latter activity may be much higher than the former. The observed stoichiometry may thus be assumed to indicate an approximately constant proportionality between these two activities, and the above mentioned deviation to be due to a breakdown of this constancy for some reason or another. Further work is needed to clarify this matter.

The Tafel slopes obtained are just what to be expected from a double metal ion mechanism without hydroxyl ion interaction, and this may indicate that the activity of the interacting hydroxyl ions does not change very much with the electrode potential over the regions in which the gradients have been determined. That corresponding Tafel lines intersect somewhat below what to be expected from the ferrous ion activity and the accepted standard potential of this electrode, however, could mean that the effective hydroxyl ion activity is somewhat higher at the anodes than at the cathodes.

According to the results of recent experiments in our laboratory [66], hydroxyl ions do also seem to interact with the Co/Co^{++}.aq-electrode reactions, but not with the reactions of the Ni/Ni^{++}.aq.-, the Cu/Cu^{++}.aq-, and the Zn/Zn^{++}.aq-electrode.

The double metal ion mechanism may be one involving two ferrous ions jointly undergoing a 4-electron process in either direction (Hoar [15]). However, it may just as well be one involving the following two steps:

$$Fe + OH^-.aq \rightleftharpoons Fe^{++}.aq + OH^-.aq + 2e^- \quad (24a)$$

$$Fe \rightleftharpoons Fe^{++}.aq + 2e^- \quad (24b)$$

and the author is inclined to believe more in this than in the former possibility.

The above equations may give the impression that the double metal ion mechanism simply is a consequence of the hydroxyl ion interaction, but this impression obviously is an artificial one only. There must be some more basic reason why just half the iron atoms (or ions) do need the assistance of a hydroxyl ion to make the jump through the electrode interface. That the double metal ion mechanism is not a consequence of the hydroxyl ion interaction, has become even more clear by the recent findings in our laboratory [66] that the pOH-independent reactions of the $Cu/Cu^{++}.aq$-electrode and probably those of the $Ni/Ni^{++}.aq$- and the $Zn/Zn^{++}.aq$-electrode also are governed by such a mechanism, and that this also is the case for the $Co/Co^{++}.aq$-electrode reactions in which there probably is an interaction of one hydroxyl ion for each metal ion reacting in either direction. The double metal ion mechanism may thus seem to be almost a general one for metal/metalion electrodes in aqueous solutions. It is likely, therefore, that it also should have an explanation of equally general character.

As already previously suggested by the author [15–17,62], an explanation may be provided on the basis of the steric conditions at the metal/water interface. In liquid water, the volume per molecule (H_2O) is very nearly 30 Å^3 (see Ref.[52], p. 3). If we as a first approximation regard water as consisting of close-packed spherical molecules, we easily calculate that there should be about 9.54×10^{14} water molecules per cm^2 in a close-packed water plane. In α-iron, the approximate number of atoms per cm^2 is [67]:

1.88×10^{15} in the (111)-plane,
1.73×10^{15} in the (110)-plane,
1.22×10^{15} in the (100)-plane.

The (111)-plane is here the plane of closest packing, and we see that it contains very nearly *twice* the number of iron atoms as there are water molecules in a close-packed water plane. Just as there are more and less closely packed planes in a crystal, one may also imagine the existence of more and less closely packed planes of water molecules. It might further be that the special structure of any surface plane of an iron crystal and the interaction between this plane and the water might favour such a packing of the water molecules at the interface as to give very nearly *one* water molecule for every *two* metal atoms even in those cases where there of purely steric reasons should be space for some more water molecules.

On this basis, the anodic reaction of the $Fe/Fe^{++}.aq$-electrode may be imagined somewhat as follows:

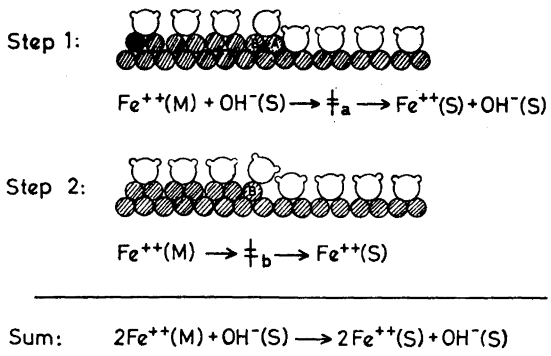

Fig. 11. An illustration to the possible kinetic effect of the steric conditions at an iron/water interface.

Let us consider a "unit" of two iron atoms and one water molecule at the electrode surface. The water molecule interacts with both the iron atoms and is not quite free to "help" only one of them into the solution. The first of these two atoms to dissolve, may therefore need a relatively high energy to make the jump, unless this jump is facilitated by the interaction of a hydroxyl ion. When this atom has left the surface, the water molecule (or another water molecule) may be more free to help the remaining atom to dissolve whereby the energy needed in this case should be smaller. The rate determining step should thus be connected to the removal of the first of these two atoms from the surface. These considerations are illustrated by the sketches in Fig. 11.

Similar considerations could also be given to the cathodic reaction of the Fe/Fe^{++}.aq-electrode and to the reactions of other metal/metalion-electrodes in aqueous solutions.

The hypothesis suggested here could easily be somewhat more elaborated and refined, but it seems unprofitable to do this until more data are available. A more complete discussion will therefore be postponed until the above mentioned work on other metal/metalion-electrodes has been finished.

Corrosion of Iron

Effect of pH and Ferrous Ion Activity

TOR HURLEN

Central Institute for Industrial Research, Blindern, Oslo, Norway

The effect of pH and ferrous ion activity on the corrosion potential (E_c) and the corrosion rate (i_c) of iron is considered on the basis of recent data on the kinetics of the $Fe/Fe^{++}aq$- and the $H_2(Fe)/H^+$ aq-electrode. For solutions of negligible ferrous ion content, it is deduced that dE_c/dpH should be $-(4/5)\,(2.303\,RT/F)$ in acid solutions and $-(2/5)\,(2.303\,RT/F)$ in alkaline solutions until the corrosion potential above a certain pH-value (dependent on the hydrogen pressure) becomes nearly equal to the reversible hydrogen potential. It is further deduced that $d\log i_c/dpH$ in these three pH-ranges should be $-3/5$, $+1/5$, and -1, respectively. For solutions of appreciable ferrous ion content, it is shown that the corrosion potential in a certain pH-range (dependent on the ferrous ion activity) should be nearly equal to the reversible iron potential. It is also shown how this will affect the corrosion rate.

The effect of dissolved oxygen and of the ferrous hydroxide precipitation is somewhat discussed, and all the deductions are compared with experimental data.

1.0 INTRODUCTION

It has long been known that the corrosion potential of iron in many acid solutions varies with pH almost (but not quite) parallel to the reversible potential of the hydrogen electrode [1–4]. Some earlier workers apparently believed that the parallelism should be exact, and that the observed deviations were due to experimental faults. However, through the development of *the theory of mixed potentials* [5,6] for corrosion processes, it has become clear that this relationship cannot be more than an accidental one, whereby the observations very well may be correct.

The theory of mixed potentials allows the relationships between corrosion potential (E_c) and corrosion rate (i_c) and pH to be derived from a knowledge of the kinetics of the electrode reactions simultaneously occurring on the corroding metal surface. Such derivations have been attempted by Thomashov [7], Audubert [8], Uhlig [9], Bockris [10], Stern [11], Stern and Geary [12], and Ammar

and Riad [13], but all these derivations suffer from a poor knowledge of the anodic dissolution reaction.

The kinetics of the iron dissolution reaction has recently been studied by the author and others (see Ref.[14]), and some new data are also available on the hydrogen evolution reaction at iron electrodes. On this basis, a theoretical redetermination will here be made of the effect of pH on the corrosion potential and the corrosion rate of iron in air free solutions. The effect of ferrous ions will also be considered, and comparisons will be made with experimental data.

2.0 THEORETICAL DEDUCTIONS

The following symbols shall here be used:

i_c = rate of corrosion
i_{diss} = rate of iron dissolution
i_{dep} = rate of iron deposition
i_H = rate of hydrogen evolution
$i_o(Fe)$ = exhange current of the $Fe/Fe^{++}aq$-electrode
$i_o(H)$ = exchange current of the H_2/H^+aq-electrode
$i_o(OH)$ = exchange current of the H_2/OH^-aq-electrode
E_c = corrosion potential
$E_o(Fe)$ = standard potential of the $Fe/Fe^{++}aq$-electrode
$E_o(H)$ = standard potential of the H_2/H^+aq-electrode
$E_o(OH)$ = standard potential of the H_2/OH^-aq-electrode
V = electrode potential in general

All the rates will be expressed in equivalent units (*e.g.* as partial current densities) and will be regarded positive (regardless of the reactions being anodic or cathodic).

When iron is immersed in a solution, it acquires a corrosion potential and a corrosion rate defined by:

$$E_c = V \tag{1a}$$

$$i_c = i_{diss} - i_{dep} \tag{1b}$$

We shall here mainly consider cases in which hydrogen evolution is the only reaction occurring in addition to the $Fe/Fe^{++}aq$-electrode reactions themselves. For such cases, stationary conditions require

$$i_H = i_{diss} - i_{dep} \tag{2}$$

and the corrosion potential must obviously be that mixed potential at which this equation is satisfied.

In a previous work [14], it has been shown that:

$$\log i_{diss} = J(Fe) - pOH + (2F/2.303\,RT)\,(V - E_o(Fe)) \tag{3a}$$
$$\log i_{dep} = J(Fe) - pOH - 2pFe - (2F/2.303\,RT)\,(V - E_o(Fe)) \tag{3b}$$
$$\log i_{(H)}(a) = J(H) - pH - (F/4.606\,RT)\,(V - E_o(H)) \tag{3c}$$
$$\log i_{(H)}(b) = J(OH) - (F/4.606\,RT)\,(V - E_o(OH)) \tag{3d}$$

where (a) and (b) refer to acid and alkaline solutions, respectively, and

$$J(\mathrm{Fe}) = \log i_o(\mathrm{Fe}) \text{ at } \mathrm{pFe} = \mathrm{pOH} = 0 \quad (4a)$$
$$J(\mathrm{H}) = \log i_o(\mathrm{H}) \text{ at } \mathrm{pH} = 0 \quad (4b)$$
$$J(\mathrm{OH}) = \log i_o(\mathrm{OH}) \text{ at } \mathrm{pOH} = 0 \quad (4c)$$

Strictly, (3c) and (3d) are not always valid at and above the corrosion potential because of a promoting effect of the iron dissolution reaction on the hydrogen evolution reaction [14]. This effect will certainly affect the corrosion, but not necessarily the pH-dependence of the corrosion, and will therefore be neglected in the present treatment.

By the equations (2) and (3), both the mixed potential (V) of the corroding metal and the partial rate of the various reactions (i_{diss}, i_{dep}, i_H) at this potential are completely determined. Through the definitions (1), the corrosion potential (E_c) and the corrosion rate (i_c) are thereby also given as functions of pH, pOH, and pFe at constant temperature.

Solutions of negligible ferrous ion content

Most corrosion cases of practical importance imply aqueous solutions of relatively low ferrous ion content. This content may for the present purpose be regarded negligible when

$$i_{dep} < i_{diss}/100 \quad (5)$$

which, according to (3a) and (3b), means:

$$E_c > E_o(\mathrm{Fe}) - (2.303\, RT/2F)\,(\mathrm{pFe} - 1) \quad (6)$$

In such cases, the corrosion rate is given within an accuracy of 1 % by:

$$i_c = i_H = i_{diss} \quad (7)$$

Remembering $\mathrm{p}K_w = \mathrm{pH} + \mathrm{pOH}$, we easily have from (1a), 3a), (3c), (3d), and (7):

$$E_c(\mathrm{a}) = (2/5)\,(2.303\, RT/F)\,[J(\mathrm{H}) - J\,(\mathrm{Fe}) + \mathrm{p}K_w - 2\mathrm{pH}] + (1/5)\,[E_o(\mathrm{H}) + 4E_o(\mathrm{Fe})] \quad (8a)$$

$$E_c(\mathrm{b}) = (2/5)\,(2.303\, RT/F)\,[J(\mathrm{OH}) - J(\mathrm{Fe}) + \mathrm{p}K_w - \mathrm{pH}]) + (1/5)\,[E_o(\mathrm{OH}) + 4E_o(\mathrm{Fe})] \quad (8b)$$

$$\log i_c(\mathrm{a}) = (1/5)\,[4J(\mathrm{H}) + J(\mathrm{Fe}) - \mathrm{p}K_w - 3\mathrm{pH}] + (2/5)\,(F/2.303\, RT)\,[E_o(\mathrm{H}) - E_o(\mathrm{Fe})] \quad (8c)$$

$$\log i_c(\mathrm{b}) = (1/5)\,[4J(\mathrm{OH}) + J(\mathrm{Fe}) - \mathrm{p}K_w + \mathrm{pH}] + (2/5)\,(F/2.303\, RT)\,(E_o\,(\mathrm{OH}) - E_o\,(\mathrm{Fe})] \quad (8d)$$

For cases in which $\mathrm{p}K_w$, $J(\mathrm{H})$, $J(\mathrm{OH})$, and $J(\mathrm{Fe})$ are independent of pH (this will usually be the case when excess indifferent electrolyte is present), these equations further show:

$$\mathrm{d}E_c(\mathrm{a})/\mathrm{dpH} = -(4/5)(2.303\, RT/F) \quad (9a)$$
$$\mathrm{d}E_c(\mathrm{b})/\mathrm{dpH} = -(2/5)(2.303\, RT/F) \quad (9b)$$
$$\mathrm{dlog}\, i_c(\mathrm{a})/\mathrm{dpH} = -3/5 \quad (9c)$$
$$\mathrm{dlog}\, i_c(\mathrm{b})/\mathrm{dpH} = +1/5 \quad (9d)$$

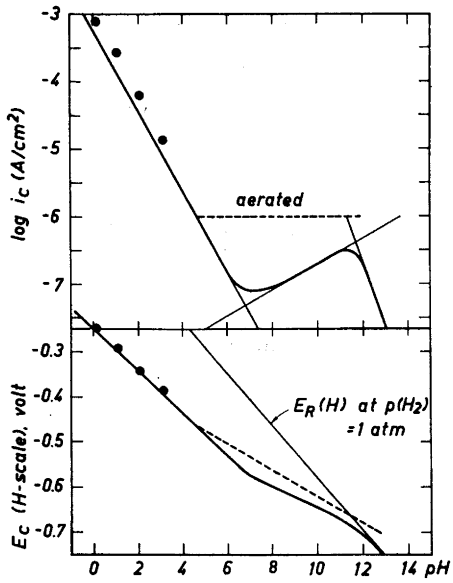

Fig. 1. Calculated effect of pH at a hydrogen pressure of 1 atm. (fully drawn lines) and of dissolved oxygen (stipulated lines) on the corrosion potential and the corrosion rate of iron. The points apply to iron in HCl—KCl—($FeCl_2$) solutions at 20°C (Hurlen[14]).

The deductions represented by eqns. (8) are graphically presented in Fig. 1. The following values have there been used for the various constants [14]:

T = 293° K	pK_w = 14.17		
E_o(H) = 0	E_o(OH) = — 0.82	E_o(Fe) = — 0.46	
J(H) = — 5.36	J(OH) = — 5.07	J(Fe) = 3.58	

By these values, the corrosion rate is given in A/cm² and the corrosion potential in Volt on the normal hydrogen scale.

In Fig. 1 is also indicated what is to be expected when the corrosion potential approaches the reversible potential of the hydrogen electrode, E_R(H). The latter potential can certainly not be exceeded by the former in a completely de-aerated solution, and we have as a limit:

$$(E_c)_{lim} = E_o(H) - (2.303\ RT/F)pH \qquad (10)$$

At this limit, when considering (1a), 3a), (7), and (10), we also have

$$(d\log i_c/dpH)_{lim} = -1 \qquad (11)$$

In all the above calculations, the solutions have been assumed to be in equilibrium with hydrogen of standard atmospheric pressure, and no account has been made of a possible formation of solid corrosion products on the metal surface. Such a formation will certainly affect the corrosion by the resistance barrier it creates for at least some of the part reactions.

The points shown in Fig. 1, represent values experimentally found by the author [14] in HCl—KCl—($FeCl_2$) solutions. These points lie somewhat above the calculated lines because of a promoting effect of the iron dissolution reac-

tion on the hydrogen evolution reaction (see Ref.[14]). The dashed lines in Fig. 1 indicate what is to be expected for the corrosion rate and the corrosion potential when the solution contains dissolved oxygen of an amount giving a limiting oxygen reduction current of 10^{-6} A/cm^2. Also in this case, an upper pH-limit must be reached above which the corrosion potential will be equal to the reversible potential of the oxygen electrode, and the corrosion rate will vary according to (11). This is not shown in Fig. 1. A more detailed discussion of the effect of dissolved oxygen must await further data on the kinetics of the oxygen reduction reaction.

Solutions of appreciable ferrous ion content

Also in ferrous ion containing solutions, we must expect the corrosion rate and the corrosion potential to be in accordance with the above deductions as long as the requirement (6) is obeyed. However, with increasing pH (decreasing E_c) and increasing ferrous ion activity (decreasing pFe) this requirement must subsequently be broken. Under such conditions, we are not allowed to neglect the deposition reaction, and the corrosion rate must be represented by the complete equation (1b). Considering further the equations (2), (3c), (3d), and the obvious limiting condition

$$(E_c)_{lim} = E_o(Fe) - (2.303\, RT/2F)pFe \qquad (12)$$

we easily have:

$$(\log i_c(a))_{lim} = J(H) - pH + \tfrac{1}{4}\, pFe - (F/4.606\, RT)\,[E_o(Fe) - E_o(H)] \qquad (13a)$$

$$(\log i_c(b))_{lim} = J(OH) + \tfrac{1}{4}\, pFe - (F/4.606\, RT)\,[E_o(Fe) - E_o(OH)] \qquad (13b)$$

These deductions are presented graphically in Fig. 2, where they are represented by the curves extending into the dashed lines. These curves represent what is to be expected for the corrosion rate and the corrosion potential if there were no ferrous hydroxide precipitation, and if the solution were in equilibrium with hydrogen of sufficiently low pressure to satisfy the requirement

$$E_R(H) > E_c + (2.303\, RT/F) \qquad (14)$$

all over the pH-range considered.

The completely drawn curves in Fig. 2 represent what is to be expected at a hydrogen pressure of one atmosphere if there were no ferrous hydroxide precipitation. In actual cases, however, precipitation will occur when [15,16]

$$pH = 6.7 + 0.5\, pFe \qquad (15)$$

This equation also gives the minimum pFe (maximum ferrous ion activity) obtainable at any given pH, and it shows how pFe will vary with pH when precipitation occurs.

The curves in Fig. 2 have been crossed at those points at which, from (15), we have to expect the ferrous hydroxide precipitation to start. For any of these curves, that part lying to the right of such a point cannot be realized.

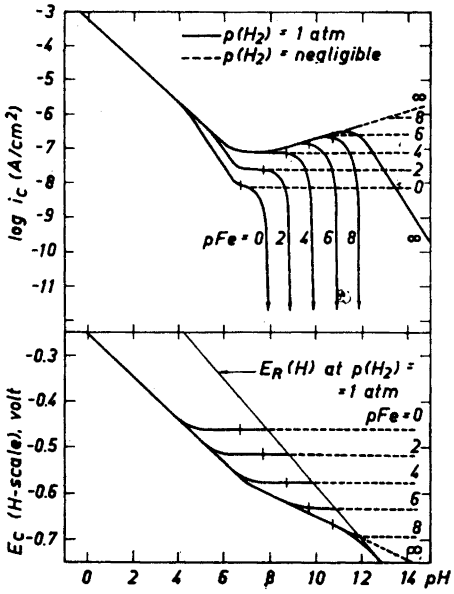

Fig. 2. Calculated effect of pH and ferrous ion activity on the corrosion potential and the corrosion rate of iron at a hydrogen pressure of 1 atm. (fully drawn lines) and at a negligibly small hydrogen pressure (stipulated lines) in the hypothetic absence of ferrous hydroxide precipitation (see the text).

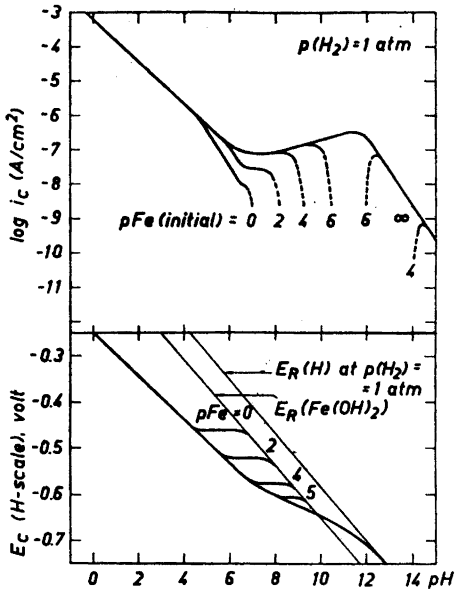

Fig. 3. Effect of pH and ferrous ion activity on the corrosion potential and the corrosion rate of iron at a hydrogen pressure of 1 atm. when regard is made of the ferrous hydroxide precipitation (see the text).

A prediction of how the corrosion potential will behave when precipitation occurs, is given in Fig. 3. It is much more difficult to predict what will happen to the corrosion rate. If the only effect of the precipitation were to decrease the ferrous ion activity, we should expect the corrosion rate to vary along a curve given by the precipitation points (crossed points in Fig. 2) for solutions of lower ferrous ion activity (higher pFe) than the one considered. It is likely, however, that a more marked effect of the precipitation is to give a protective film of ferrous hydroxide on the iron surface. The stability of such a film will probably increase with pH until the ferroate formation begins to destroy it. According to the data given by Pourbaix [15], we should expect that this starts at a pH of about 10.6, and that no precipitate should remain at pH-values above that given by:

$$\mathrm{pH} = 18.3 - \mathrm{pFe\ (initial)} \qquad (16)$$

From (15) and (16), it appears that precipitation should not occur at all in solutions of initial pFe-values above 7.7. In such solutions, therefore, the corrosion of iron is most likely not affected by the ferrous ions whereby the corrosion rate curves should follow the one applying to $\mathrm{pFe} = \infty$. Also in

solutions of initial pFe-values below 7.7, the corrosion must be expected to be independent of the ferrous and the ferroate ions at pH-values above that given by (16). The situation should then be somewhat as shown in Fig. 3.

In this treatment, the homogeneous hydrolysis of the ferrous ion has been ignored, and this seems justified on the basis of the low value ($10^{-9.5}$) found by Hedström [16] for the hydrolysis constant of this ion.

3.0 DISCUSSION

The above deductions have been made without considering the possible effect of impurities in the electrode material and of anions on the reactions of the $Fe/Fe^{++}aq$- and the $H_2(Fe)/H^+aq$-electrode. There are indications [14] that the impurities usually present in mild steel do not affect the iron electrode reations very much, whereas some of them strongly affect the hydrogen evolution reaction. Thereby, the corrosion behaviour will certainly also be affected. However, if the impurity effect is pH-independent, the relative relationship between corrosion and pH may still be as deduced above. There further are indications [14] that neither chloride ions nor sulphate ions do directly affect any of the above reactions. The deductions should therefore apply to both chloride and sulphate solutions. However, it may be a requirement that excess indifferent salt be present. The data used above are namely determined under such conditions, and it is further well known [6] that the effective potential drop at the electrode surface in dilute solutions may be affected by the salt content.

The literature is rich in experimental studies concerning the effect of pH on the corrosion of iron and steel (especially the latter), but only few of these seem to have been carried out under rigorous experimental conditions. Gatty and Spooner [1] have given a general summary of the data obtained up to 1938. They conclude that the variation of the corrosion potential with pH in acid solutions of several types is just that given by (9a) above. It has already been shown (Fig. 1) that this relationship also is in agreement with recent results of the author in acid chloride solutions. It is further in accordance with relatively recent results of Makrides, Komodromos, and Hackerman [17] in acid chloride solutions, of Hoar and Hurlen [18,19] in acid sulphate solutions, and of Bonhoeffer and Heusler [20,21] in acid sulphate and perchlorate solutions. Stern [22,23] and D'Ans and Breckheimer [24] report a variation more parallel to the reversible hydrogen potential.

The relationship (9b) for the corrosion potential in de-aerated alkaline solutions is also in relatively good agreement with the data gathered by Gatty and Spooner [1]. These data further show that the corrosion potential reaches the reversible hydrogen potential at a pH of about 12 and from there on follows this potential. This compares well with the deductions graphically presented in Fig. 1. As (9b) has been deduced partly on the basis of data obtained on the kinetics of the iron dissolution reaction in acid solutions, its good agreement with experimental data may be regarded a strong indication that the dissolution mechanism is the same in alkaline as in acid solutions (see Ref.[14]).

The deductions showing that the corrosion potential in ferrous ion containing solutions should be independent of the ferrous ion activity at low

pH-values and be nearly equal to the reversible potential of the $Fe/Fe^{++}aq$-electrode at somewhat higher pH-values (see eqn. (12) and Figs. 2 and 3) are excellently confirmed by the observations of D'Ans and Breckheimer [24].

The data available on the effect of pH on the corrosion rate of iron are somewhat conflicting. Thus, Stern [22,23] and Bonhoeffer and Heusler [20,21] in their recent work found a nearly pH-independent corrosion rate in solutions of low pH, whereas previous authors mostly have reported a logarithmic relationship to be obeyed under such conditions (see Refs.[1-4]). The recent work of Hoar and Hurlen [18,19] in acid sulphate solutions and of the present author [14] in acid chloride solutions (see Fig. 1) also gave a logarithmic relationship between corrosion rate and pH. Such a relationship is also reported by Novikov [25] and by Balezin and Krasovitskaya [26] as a result of comprehensive investigations on this subject with various types of iron and steel in various types of solutions. The results of the latter authors in acid sulphate solutions moreover agree with those of Hoar and Hurlen in such solutions and with those of the present author in acid chloride solutions in showing a pH-dependence quite near to that given by (9c) above.

The deductions predicting that the corrosion rate should go through a minimum in the vicinity of the neutral point and thereafter increase with pH according to (9d) until it again should fall when the corrosion potential approaches the reversible hydrogen potential (see Fig. 1), may be more difficult to test experimentally. In this pH-region, the measurements may easily be affected by dissolved oxygen (if not adequately removed) and by a possible formation of solid corrosion products on the metal surface (if the ferrous ion content in the solution is not kept low enough). In the vicinity of the neutral point, it is also difficult to have an adequate control of the pH. On this basis, the predicted corrosion-rate/pH relationship shown in Figs. 1 and 3 for iron in alkaline solutions is not in disagreement with the experimental results quoted in the well known corrosion monographs [1-4]. Some authors [27-29] have also experimentally found that the corrosion rate (especially in streaming solutions) goes through a minimum at a pH somewhat below the neutral point and through a maximum at a higher pH (*cf.* Figs. 1 and 3).

The electrode behaviour of corroding iron has been the subject of much study, thought, and speculation. This applies especially to the potential/pH-relationship in acid solutions, which long has been known [1] to be linear with a slope somewhat less than the 58 mV/pH of the reversible hydrogen electrode. Attempts have previously been made to explain this relationship on the assumption either of a hydride film formation on the iron surface [1,30,31] or of a formation of an ideal iron-hydrogen alloy in the surface [24,32-34]. Neither of these explanations have been accepted as satisfactory[20], however. More promising attempts have been made on the basis of the theory of mixed potentials [7-13], but also these have been unsatisfactory, mainly because of a poor knowledge of the kinetics of the iron dissolution reaction.

The present treatment represents a new attempt in solving this classical problem of corrosion science. Also this treatment is based on the theory of mixed potentials, and it applies the improved knowledge which recently has been gained on the iron dissolution reaction [14]. The reasonable fit of the theo-

retical deductions to many experimental data gives rise to the hope that we now are nearer to understand the corrosion behaviour of iron.

Heat of Activation in Electrode Kinetics

The $Fe/Fe^{++}\cdot aq$ Electrode

TOR HURLEN

Central Institute for Industrial Research, Blindern, Oslo, Norway

The treatment of data on the effect of temperature on the rate of electrode reactions is considered, and a way is shown in which the standard heat of activation (ΔH_o^*) of symmetric electrode reactions may be determined. The method is applied to the $Fe/Fe^{++}aq$ electrode reactions, for which the available data indicate:

ΔH_o^* (anodic) = 2 kcal(H-scale)

ΔH_o^* (cathodic) = 44 kcal(H-scale)

The accurary and the meaning of these values are somewhat discussed.

1.0 INTRODUCTION

There seems at present to be some confusion as to the determination of the energy or heat of activation of electrode reactions. The so far most commonly accepted ways of determining such an energy are based on the equations:

$$Q_V = -2.303\, R\, (\mathrm{d}\log i/\mathrm{d}(1/T))_V \qquad (1)$$

$$Q_o = -2.303\, R\, (\mathrm{d}\log i_o/\mathrm{d}(1/T)) \qquad (2)$$

where i_o is the exchange current of the electrode reaction considered, and Q_V and Q_o are called the Arrhenius energy of activation at the potential V and at the reversible potential, respectively.

Bockris [1] has clearly shown that these quantities are not »true» energies or heats of activation, but that they also include other terms, the main of which is proportional to the change in standard heat content for the overall electrode reaction. He therefore has suggested that Q_o be termed »the virtual heat of activation at the reversible potential». This quantity is common for two mutually reverse reactions. The application of (1) and (2) includes moreover the often inadequate assumption that the reactant activities are temperature independent. Eqn. (2) even implies that the activities of the reaction products also are independent of temperature.

Some investigators have improved (2) by putting i_o/T into it instead of merely i_o. This certainly brings the equation in better agreement with the absolute rate theory [2]. However, it does not alter the fact that the quantity determined is not a true heat of activation, and that it therefore is of minor use in revealing the properties of the activated state.

The quantity that would serve best in this respect, is the *standard heat* of activation, as this would give the best basis for comparison with other often well known standard energies connected with the reaction system (*e.g.* heat of reaction, heat of formation, heat of sublimation, *etc.*). Because of the apparent inaccessibility of single electrode potentials, the standard heat of activation of an electrode reaction may at present seem difficult to determine [1]. In the present paper, however, a way is suggested that should be applicable to symmetric reactions. The method is moreover applied to determine the standard heat of activation of the reactions of the $Fe/Fe^{++}aq$ electrode from experimental data previously obtained by Hoar and Hurlen [3].

2.0 THEORETICAL DEDUCTIONS

The standard heat of activation (ΔH_o^*) for any reaction is defined as the change in standard heat content of the reaction system when going from its initial to its activated state:

$$\Delta H_o^* = H_o^* - H_o^{(i)} \tag{3}$$

Quite analogous definitions apply to the standard energy and the standard entropy of activation. All these definitions, however, imply that the initial state should encompass just as many moles of the reactants as there are molecules (or atoms or ions) reacting for each act of the rate determining step. This is not necessarily equal to what is indicated by the equation for the overall reaction considered, but depends on the number of times(ν) the rate determining step occurs when the overall reaction occurs once. Thus, if we choose to define the initial state in the ordinary thermodynamic way (which certainly is the best in order to avoid confusion), (3) must be rewritten in the form:

$$\Delta H_o^* = H_o^* - \frac{1}{\nu} H_o^i \tag{4}$$

From (4), it is further seen that the standard heat of activation of a reaction should be related to that of its reverse reaction and to the ordinary standard heat of reaction by the following equation:

$$\Delta \vec{H}_o^* - \Delta \overleftarrow{H}_o^* = \frac{1}{\nu} \Delta \vec{H}_o \tag{5}$$

In the modern theory of electrode kinetics [1,4], the standard exhange current (J_o) of a reaction system is given by an Arrhenius equation of the following type:

$$\log (J_o/T) = C - \frac{\alpha n F \Delta \emptyset_o}{2.303 \nu RT} - \frac{\Delta H_o^*}{2.303 RT} \tag{6}$$

J_o is defined by

$$J_o = i_o \left[(\Pi a)_r^{1-\alpha} (\Pi a)_p^{\alpha}\right]^{-1/\nu} \tag{7}$$

where i_o is the exchange current at the activity products $(\Pi a)_r$ and $(\Pi a)_p$ of the reactants and the reaction products, respectively, (each activity counting as many times as given by the respective stoichiometric factors in the overall reaction). α is the apparent symmetry factor (equal to $\beta + \gamma$ in Refs.[1,4]) · n is the number of electrons *consumed* during one act of the overall reaction (positive for cathodic and negative for anodic reactions). $\Delta \phi_o$ is the Galvani potential difference between electrode and solution $(\phi_M - \phi_{sl})$ at the standard potential of the reaction system. C consists mainly of temperature independent constants and includes moreover the standard entropy of activation and the activity coefficient of the activated complex (both of which will here be assumed independent of temperature). The presumably small energy term δ introduced by Parsons [4] to represent the possible potential independent part of the electrical contribution to the standard free energy required to transform the system from the two end states (initial and final) to the two states nearest to the activated state (one on each side), may here be regarded either as neglected or as included in the standard heat of activation. It seems so far quite impossible to separate these two energy terms experimentally.

If $\Delta \phi_o$ and its temperature dependence were known, the standard heat of activation of a reaction could have been determined through the relationship (6), but it is well recognized that we so far are unable to determine the Galvani potential difference between two phases. In the case of symmetric reactions, however, we can easily manage without this knowledge. Such reactions are characterized by

$$\alpha = \tfrac{1}{2} \tag{8}$$

For two mutually reverse reactions of this type, the term containing $\Delta \phi_o$ in (6) will be equal in magnitude, but opposite in sign, whereby this term will cancel out in the sum of the heats of activation of these two reactions. We thus have from (6) and (8):

$$2 \log(J_o/T) = \vec{C} + \overleftarrow{C} - \frac{\Delta \vec{H}_o^* + \Delta \overleftarrow{H}_o^*}{2.303\, RT} \tag{9}$$

By differentiating (9) with respect to $1/T$ and combining with (5), we further have:

$$\Delta H_o^* = -2.303\, R \frac{\mathrm{d}\log(J_o/T)}{\mathrm{d}(1/T)} + \frac{1}{2\nu} \Delta H_o \tag{10}$$

From this relationship, we should be able to determine the standard heat of activation of any single electrode reaction for which (8) is valid. However, if hydrogen scale values of ΔH_o are used, ΔH_o^* will also be referred to this arbitrary scale.

3.0 APPLICATION TO THE Fe/Fe^{++}aq ELECTRODE

In a previous work[5], it has been shown that we for the Fe/Fe^{++}aq electrode reactions have:

$$\alpha = \tfrac{1}{2} \tag{11a}$$
$$\nu = \tfrac{1}{2} \tag{11b}$$
$$n_a = -2 \tag{11c}$$
$$n_c = +2 \tag{11d}$$
$$(\Pi a)_a = a_{OH^-}^{1/2} \tag{11e}$$
$$(\Pi a)_c = a_{Fe^{++}} \cdot a_{OH^-}^{1/2} \tag{11f}$$

where the indexes a and c refer to the anodic and the cathodic reaction, respectively. As (11a) is in accordance with (8), the heats of activation of these reactions should be in accordance with (10).

Values obtained by Hoar and Hurlen [3] for the exchange current (i_o) of the Fe/Fe^{++}aq electrode in a solution of 0.05 M $FeSO_4$ + 0.1 M $NaHSO_4$ at 0,25, and 50°C are quoted in Table 1. This table also gives data for the pH of the solutions, for the dissociation constant of water, and for the values thereby obtained for pOH at the three temperatures concerned.

There does not seem to be any direct data available on the effect of temperature on the ferrous ion activity. In this treatment, therefore, we shall assume this effect to be negligible and the ferrous ion activity coefficient to be the same as in a pure ferrous sulphate solution of the same ionic strength. The actual ionic strength is about 0.4 which corresponds to that of 0.1 M $FeSO_4$. From the activity coefficient data given by Robinson and Stokes [7] for similar divalent metal sulphates, we thus have $\gamma_{FeSO_4} = 0.15$. By further assuming the relationship $\gamma_{Fe^{++}} = \gamma_{SO_4^{--}} = \gamma_{FeSO_4}$ to be sufficiently valid, the ferrous ion activity should be as given in Table 1.

From the data in Table 1 and eqns. (11), values have been calculated for the quantity J_o defined by (7). These values are given in Table 2.

In Fig. 1, $\log(J_o/T)$ it plotted against $1/T$, and the line drawn in this diagram, corresponds to:

$$-2.303\,R\frac{d\log(J_o/T)}{d(1/T)} = 23.0 \text{ kcal} \tag{12}$$

Less attention is thereby paid to the data at 50°C than to those at 25 and 0°C. Both the potential measurements and the pH measurements by which the data have been obtained, have namely been carried out with quinhydrone electrodes, and it is well known that such a reference electrode is less reliable at higher temperatures. Strictly, it is not recommended [8] for use at temperatures above 38°C.

The accepted value for the standard heat of reaction of the iron electrode is [9]:

$$\Delta H_{o,a} = -\Delta H_{o,c} = -21.0 \text{ kcal (H-scale)} \tag{13}$$

Table 1. Data for $Fe/Fe^{++}aq$ and activities in 0.05 M $FeSO_4$ + 0.1 M $NaHSO_4$ at various temperatures

Temperature (°C)	0	25	50
Exchange current[3] (A/cm^2)	3.9×10^{-14}	2.5×10^{-11}	1.2×10^{-9}
pH (Ref.[3b])	1.317	1.474	1.615
pK_w (Ref.[6])	14.944	13.997	13.262
pOH (see text)	13.627	12.523	11.647
a_{Fe++} (see text)	(0.0075)	0.0075	(0.0075)

Table 2. Calculated values of J_o (defined by (7)) at various temperatures

T (°C)	0	25	50
log J_o (A/cm^2)	2.343	4.046	4.851
log (J_o/T)	−0.093	1.572	2.342

From (10), (11b), (12), and (13), we then have for the standard heats of activation of the iron electrode reactions:

$$\Delta H^*_{o,a} = 2 \text{ kcal (H-scale)} \tag{14a}$$

$$\Delta H^*_{o,c} = 44 \text{ kcal (H-scale)} \tag{14b}$$

As these values are based on measurements at three different temperatures only, and the data for one of these temperatures probably are less reliable, they cannot be regarded very much accurate. It is not likely, however, that they should be more than 1-2 kcal wrong in either direction. The data obtained at 50°C may further possibly indicate that they are rather too high than too low.

It has previously [5] been shown that the kinetic unit reactions (the reaction occurring for each act of the rate determining step) of the $Fe/Fe^{++}aq$ electrode are represented by:

$$2Fe + OH^- \rightleftharpoons 2Fe^{++} + OH^- + 4e^- \tag{15}$$

This means that the heats of activation refer to the transfer of two gram-atoms iron and one gramatom hydroxyl ions from the initial to the activated state. Thus, if one should like to express these heats as energy per gramatom iron, the values obtained must be divided by two.

Even though the present results are based on rather meager experimental data, it seems justified to conclude that the standard enthalpy of the activated state of the $Fe/Fe^{++}aq$ electrode is not much higher than that of the reduced

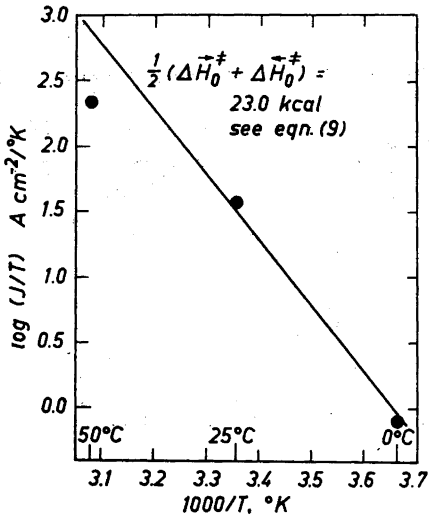

Fig. 1. Arrhenius plot for the standard exchange current of the $Fe/Fe^{++}aq$ electrode.

state (the initial state of the anodic reaction) of this electrode. It should have been interesting to compare the iron electrode with other metal/metal-ion electrodes in this respect. As far as we know, however, this is the very first determination of the standard heat of activation of any such electrode reaction, and further work is therefore needed before a comparison can be made.

4.0 DISCUSSION

In the well known monograph by Bockris [1] on electrode kinetics, it is stated that »little interest attaches to the evaluation of the standard heats of activation of electrode reactions because the potentials to which they refer cannot be experimentally determined». In this connection, Bockris also refers to a work of Temkin[10]. To the author, however, this statement seems rather strange. The standard heat of activation is namely a pure chemical term that is independent of the potential in just the same way as the standard heat of reaction. It should therefore be no more need of referring the one than the other of these quantities to any special potential.

Another problem is that the standard heat of activation may be difficult to determine because of the inaccessibility of single electrode potentials (see eqn. (6)). In the present paper, however, it has been shown that this problem is easily eliminated in the case of symmetric reactions ($\alpha = \frac{1}{2}$). As most electrode systems appear to be symmetric (or nearly symmetric), the way here suggested for the determination of standard heats of activation might have a rather wide applicability.

Studies in the Determination of Silica

III. Interference from Aluminum, Iron and Fluorine in the Spectrophotometric Determination of Silica

LARS HENRIK ANDERSSON

Dept. of Analytical Chemistry, Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Experiments with the effects of aluminum, ferric iron and sodium fluoride on the spectrophotometric silica determination are described. In the presence of aluminum the lower limit for the molybdate concentration is higher than that found for solutions containing only silica, sodium molybdate and acid. Sodium fluoride has qualitatively the same effect as aluminum. In connection with the work of Langmyhr and Graff [1] some experiments with solutions containing aluminum and sodium fluoride have also been made, which show that the pH must sometimes be chosen lower than recommended by them. In the case of iron only small amounts may be present. Iron interference has been eliminated by extraction of the iron-acetylacetone complex with carbon tetrachloride.

Ferric iron and aluminium react in water solutions with molybdate ions to form 2-heteropoly-12-molybdate ions and salts [2]. The presence of Fe(III) and Al(III) in solutions in which silica is to be determined spectrophotometrically as α-silicomolybdate may therefore have the effect of diminishing the amount of molybdate available for silicomolybdate formation. Another source of error which must be investigated is that an iron compound with molybdate may precipitate under certain conditions, removing some silicomolybdate from solution as a coprecipitate. Ferric molybdate solutions are also yellow in color at low pH values, causing high blanks. King *et al.*[3] found that small amounts of iron did not interfere with their molybdenum blue method.

When fluoride is present at least three specific effects should be considered: (1) glass vessels are attacked at low pH, (2) fluoride ions (hydrofluoric acid) may react with molybdate ions and/or (3) with silicic acid. Langmyhr and Graff [1] added aluminium to eliminate interference from fluoride in the determination of silica in hydrofluoric acid.

1. EXPERIMENTAL DETAILS

Extinction measurements were made as earlier described [4]. The temperature was 20.0° in all cases. The wavelength was 400 mμ.

pH measurements were in general carried out using a calomel reference electrode with asbestos fibre in the liquid junction. This electrode could not be used in solutions containing large amounts of aluminum chloride. An electrode with an open, bent up tip was used in such cases.

The chemicals used were of analytical grade. Acetylacetone was distilled once using a small Vigreux column.

Care must be taken that solutions containing fluoride do not remain in contact with glass long enough to dissolve measurable amounts of silica from the glass. At room temperature it is possible to handle solutions 0.1 M in NaF and 0.2 M in HCl in measuring flasks if dilution and mixing is done quickly.

If not otherwise stated, the following procedure was used in the experiments which are described later.

The silica solution was mixed with solutions of the interfering element in a polythene beaker, the pH was adjusted to the desired value and sodium molybdate solution having about the same pH was added. The pH was once more adjusted and the contents of the beaker transferred to a polythene bottle, which was placed on the steam bath. A longer heating time than that recommended earlier [4] was required with solutions containing fluoride or aluminum: 6 hours have always been sufficient. When equilibrium was reached the bottles were placed in a thermostat (20.0°C) and the solutions diluted to volume in measuring flasks before the extinction measurements

2. INTERFERENCE FROM SODIUM FLUORIDE

The ionic and molecular species that exist in aqueous solutions of sodium fluoride are determined by the following equilibria:

$$HF = H^+ + F^-$$
$$HF + F^- = HF_2^-$$

In 0.53 M KNO_3 solutions the equilibrium constants have been reported to be $10^{-2.91}$ and $10^{-0.56}$, respectively [5]. In the pH interval 1.0—4.0 the concentration of the undissociated hydrofluoric acid varies considerably with pH.

Preliminary experiments indicated that the presence of sodium fluoride increased the minimum concentration of molybdate required to obtain the full silicomolybdate color. This is shown in the following experiment, which is quite analogous to the one referred to on page 500, section 3.4 in the first paper in this series [4].

The standard procedure described in section 1 was applied. The final solutions were 0.114×10^{-3} M in Si * and 0.02 M in NaF: pH was adjusted with HCl to 3.5 and 1.5 in the solutions placed on the steam bath. The volume was then about 45 ml and the final volume was 50 ml.

In Fig. 1 the results are shown together with the curve from Fig. 5 in the previous paper [4]. The effect of decreasing the pH is to increase the effective molybdate concentration. If, however, a comparatively large excess of sodium molybdate is used, the pH interval for complete silico-molybdate formation is about the same as that obtained earlier when no fluoride was added. This is demonstrated in the following experiment.

* In the previous paper [4] sections 3.2, 3.3 and 3.4, the silica concentration is incorrectly given as 0.144×10^{-3} M in Si: the correct value is 0.114×10^{-3} M in Si.

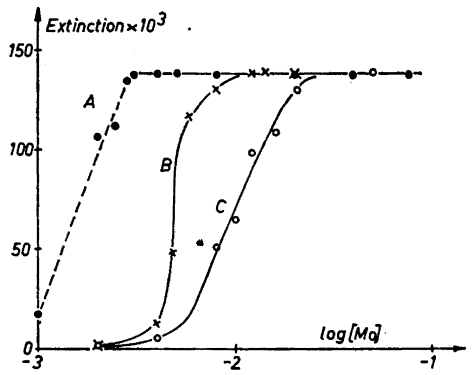

Fig. 1. Extinction as a function of the molybdate concentration for solutions containing sodium fluoride.
Curve A: 0.114×10^{-3} M Si, pH 2.0 with HCl.
Curve B: 0.114×10^{-3} M Si, 0.02 M NaF, pH 1.5 with HCl.
Curve C: » » » » » » » 3.5 » »

The standard procedure was applied. The final solutions were 0.117×10^{-3} M in Si, 0.02 M in NaF and 0.08 M in Na_2MoO_4. pH was varied between 1.0 and 4.0 by adding HCl.

The results of this experiment are given in Table 1. The extinction of blank solutions varies strongly at low pH values. Such a variation is not observed in solutions containing only silica, sodium molybdate and, *e.g.*, hydrochloric acid. Some experiments made at pH 1.0 resulted in the formation of a white precipitate: extinctions of such solutions were too low.

Langmyhr and Graff [1] have studied the behavior of solutions containing more fluoride than in the cases here treated. They show that the interfering action of fluoride can be eliminated if aluminium is added. Some experiments related to their paper are described in section 3.2.

Table 1. Extinction of silicomolybdate solutions containing sodium fluoride as a function of pH.

pH	Extinction of blank solution	Net extinction of silica solution
1.0	0.029	0.122 *
1.5	19	143
2.0	14	142
2.5	7	144
3.0	6	144
3.5	6	142
4.0	6	144

* Remark: Precipitate formed.

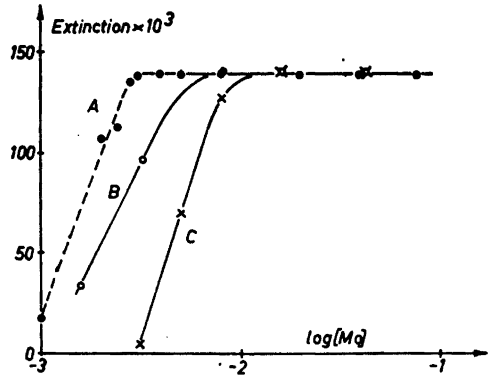

Fig. 2. Extintion as a function of the molybdate concentration for solutions containing aluminum chloride.
Curve A: 0.114 × 10^{-3} M Si, pH 2.0 with HCl.
Curve B: » » » 1.2 × 10^{-3} M Al.
Curve C: » » » 6.0 × 10^{-3} M Al.

3. INTERFERENCE FROM ALUMINUM

3.1. The effect of aluminum on the lower limit of sodium molybdate concentration.

Using the standard procedure solutions with two different aluminum concentrations were prepared. The final solutions were 0.114 × 10^{-3} M in Si, 0.0012 or 0.006 M in $AlCl_3$ and with varying sodium molybdate concentration. The pH was 2.0.

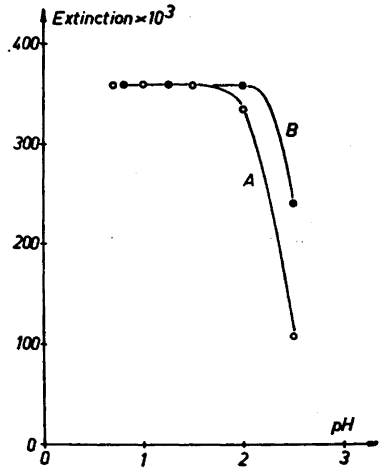

Fig. 3. Extinction as a function of pH for solutions containing aluminum chloride at two different sodium molybdate concentrations.
Curve A: 0.294 × 10^{-3} M Si, 0.1 M $AlCl_3$, 0.04 M Na_2MoO_4.
Curve B: » » » » » » 0.1 » »

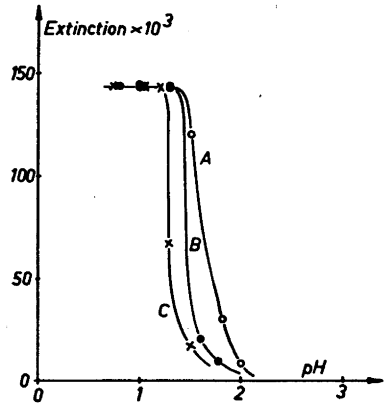

Fig. 4. Extinction as a function of pH for solutions containing sodium fluoride and large amounts of aluminum chloride.
Curve A: 0.114 × 10^{-3} M Si, 0.02 M NaF, 3.2 × 10^{-3} M Na_2MoO_4, 0.15 M Al.
Curve B: » » » » » » » » » 0.3 » »
Curve C: » » » » » » » » » 0.6 » »

Fig. 2 shows the resulting curves: the extinction has been plotted against log [Mo]. The lowest value of sodium molybdate necessary for a full development of the silicomolybdate color is higher than when no aluminum has been added.

3.2. Variation of pH in solutions of silica, sodium molybdate and aluminum chloride.

Using the standard procedure two series of solutions were prepared, which when measured in the spectrophotometer were 0.294 × 10^{-3} M in Si, 0.1 M in $AlCl_3$ and either 0.04 or 0.1 M in Na_2MoO_4. The pH was adjusted to different values with HCl.

In Fig. 3 the extinctions from the last experiments are plotted as functions of pH. The useful pH range is restricted and is a function of the molybdate concentration. It was found that a precipitate was formed when the pH was higher than about 2.5.

3.3. Experiments on the usefulness of aluminum chloride additions as a means of eliminating fluoride interference.

Langmyhr and Graff [1] were able to determine silica in hydrofluoric acid by the silicomolybdate method by adding aluminum chloride, which forms complexes with fluoride ions. They state that when their method is used the pH can be chosen anywhere in the interval 0.5—1.5. It is our experience however that the upper limit should be somewhat lower than 1.5. The following experiment is illuminating.

Using the standard procedure, series of solutions with varying pH were prepared. The aluminum concentration varied from series to series. The final solutions were 0.117 × 10^{-3} M in Si, 0.02 M in NaF and 3.2 × 10^{-3} M in Na_2MoO_4.

The curves from this experiment (Fig. 4) show that in the vicinity of pH 1.5 the extinction is a function of pH and of the aluminum concentration. It must therefore be concluded that a lower pH value than 1.5 must sometimes be chosen.

4. INTERFERENCE FROM FERRIC IRON

4.1. The presence of comparatively large amounts of iron.

If a sodium molybdate solution is mixed with a ferric chloride solution under suitable conditions, a white precipitate is formed. The possibility of determining silica spectrophotometrically in solutions in contact with such precipitates has been investigated.

The standard procedure was applied. pH was adjusted with HCl to 1.5. The final solutions were 0.3×10^{-3} M in Si, 0.05 M in Na_2MoO_4 and up to 12×10^{-3} M in $FeCl_3$. Heating on the steam bath was maintained for 3 h. The solutions were then placed in a thermostat (20.0°C) and the extinctions measured as soon as the supernatant liquids were clear. The extinction measurements were repeated several times during a period of 7 days.

The results of extinction measurements on solutions which have been allowed to stand 24 h in the thermostat are shown in Fig. 5. Measurements earlier and later indicate that the extinction of solutions in contact with precipitates is not constant but a function of time.

4.2. The presence of small amounts of iron. Variation of pH.

The investigations by Baker *et al.*[2] show that colorless complexes between ferric iron and molybdate are formed at pH values lower than about 4. It might therefore be possible to determine silica spectrophotometrically in the presence of small amounts of iron if the pH is chosen high enough.

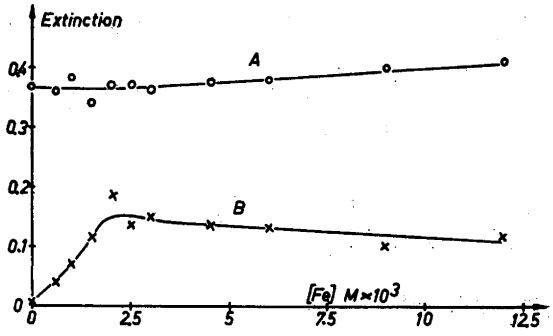

Fig. 5. Extinction in solutions containing large amounts of $FeCl_3$ as a function of the ferric iron concentration.

Clarke [6] gave the average percent composition with respect to silicon and iron of igneous rocks as 59 % SiO_2, 3 % Fe_2O_3 and 4 % FeO. This corresponds to a Si:Fe mole ratio of roughly 10:1. If silicon is to be determined spectrophotometrically in rock analysis an iron concentration of about 0.03 × 10^{-3} M

Table 2. Extinction of silicomolybdate solutions from which iron has been removed by extraction with acetylacetone-carbon tetrachloride.

Final silica concentration (molarity)	Extinction of fluoride-free solution	Extinction of fluoride-containing solution	Calculated extinction
0.396×10^{-4}	0.048	0.049	0.048
0.396×10^{-4}	0.047	0.049	0.048
0.396×10^{-4}	0.047	0.050	0.048
0.396×10^{-3}	0.482	0.478	0.482
0.396×10^{-3}	0.484	0.484	0.482
0.396×10^{-3}	0.485	0.483	0.482

is to be expected for a silica concentration chosen to give an extinction of about 0.35.

The standard procedure was used and the final solutions were 0.3×10^{-3} M in Si, 0.03 or 0.06 M in Na_2MoO_4 and 0.036×10^{-3}, 0.09×10^{-3}, 0.3×10^{-3} or 0.9×10^{-3} M in $FeCl_3$. The pH was adjusted with HCl.

The results are shown in Figs. 6 and 7. The blank solutions containing ferric iron show a marked increase in extinction measured against water when the pH sinks below about 2. They are then strongly pH-dependent. For higher pH values the blank extinctions are low and uninfluenced by small changes in pH and ferric iron concentration. However, iron concentrations higher than about 0.3×10^{-3} M should not be used, since the results are then usually too high, especially at high pH values. At low pH values, precipitates may also be formed.

4.3. The effect of anions other than Cl^-.

If the anions SO_4^{2-}, NO_3^- and ClO_4^- are substituted for Cl^- in the experiments described above, results are similar except that precipitates formed more easily in HNO_3 and $HClO_4$ solutions, and the interfering action of small iron concentrations was more pronounced in H_2SO_4 solutions. Attempts to use F^- ions for complexing ferric ions proved unsuccessful.

5. EXTRACTION OF FERRIC IRON PRIOR TO THE SPECTROPHOTOMETRIC SILICA DETERMINATION

Several methods to extract ferric iron from aqueous solutions into organic phases using complexing substances are described in the literature [7]. In connection with the work presented here, it was important that after the extraction had been made, it should be possible to determine accurately the amount of silica in the remaining water phase, and that the amount of silica present before extraction should be the same as that present after extraction. The possibility that fluoride may be present had also to be taken into account.

In the method finally adopted, acetylacetone was used as the complexing agent and carbon tetrachloride as the extracting solvent. If no fluoride was present, extraction was made at pH 4. The separatory funnels were conditioned before extraction by soaking overnight in dilute HCl (pH 4). In this way, interference from dissolved glass was considerably reduced. When fluoride was present the extractions were carried out in platinum dishes at pH 7.5; the phases were mixed by a motordriven aluminum stirring rod. The heavy organic phase was drawn off with pipettes with long capillary tips.

The composition of the solutions which were extracted was about 0.57×10^{-3} M in Si, 8.6×10^{-3} M in $FeCl_3$ and in cases where fluoride had been added 30×10^{-3} M in NaF. 2 ml acetylacetone was added to this solution, pH was adjusted with HCl to the appropriate value and the extractions carried out.

When the iron had been removed with three extractions of the water phase (about 35 ml) using 5 ml portions of CCl_4, 0.50 g sodium carbonate was added to the remaining water phase in a platinum dish. After evaporation to dryness on the steam bath, the remaining organic compounds were destroyed by heating the dish over a Meker burner until a clear melt was formed. The contents of the dish were then dissolved in water and the amount of silica left determined spectrophotometrically.

The results from these experiments are summarized in Table 2.

I wish to thank Dr F. Nydahl, Head of the department of Analytical chemistry, for his interest in this investigation and for the facilities put at my disposal.

Perjodatoxydation von Phenolen

VII *. 2,6-Dimethylphenol sowie 2,4,6- und 2,3,5-Trimethylphenol

ERICH ADLER, JOSEF DAHLÉN und GERTRUD WESTIN

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Schweden

2,6-Dimethylphenol und 2,4,6-Trimethylphenol liefern bei der Einwirkung von Perjodat die entsprechenden dimeren *o*-Chinole (VIII bzw. IV) neben 2,6-Dimethyl-*p*-chinon bzw. 2,4,6-Trimethyl-*p*-chinol, während 2,3,5-Trimethylphenol ein Gemisch von monomerem 2,3,5-Trimethyl-*o*-chinol (XI) und 2,3,5-Trimethyl-*p*-chinon gibt.

Die Dimeren VIII und IV lassen sich mit AcOAc–$HClO_4$ in die Diacetylderivate überführen, welche bei 180° Retrodienzerfall zu 2,6-Dimethyl-*o*-chinolacetat bzw. 2,4,6-Trimethyl-*o*-chinolacetat erleiden. Bei 120° geht 2,6-Dimethyl-*o*-chinolacetat wieder in sein Dimeres über. Bei alkalischer Verseifung wird aus dem Diacetat des Dimeren IV letzteres zurückgebildet, während aus dem Diacetat des Dimeren VIII teils das Dimere VIII, teils — unter Abspaltung von 1 Mol HOAc — ein phenolisches Anhydro-dimeres (XXIII) entsteht.

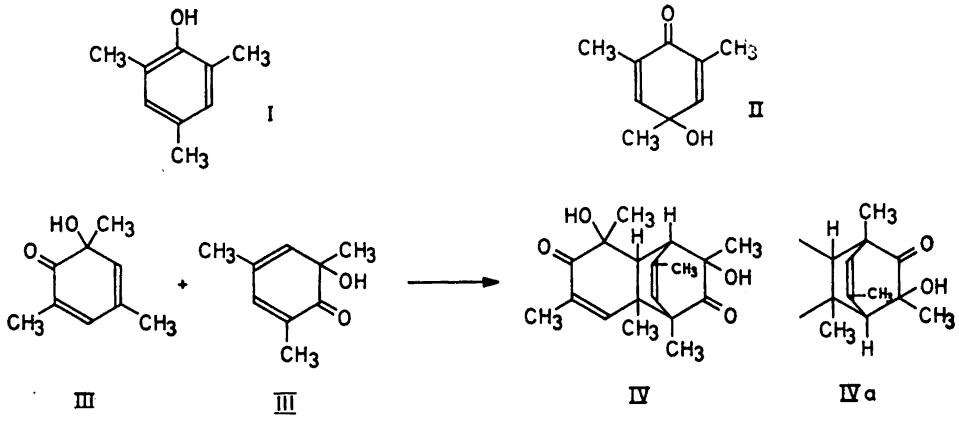
Diese Ergebnisse stehen in Einklang mit den Strukturen VIII bzw. IV für die beiden *o*-Chinoldimeren.

In einer früheren Mitteilung [1] wurde gezeigt, dass der rasch verlaufende Angriff von Natriumperjodat auf 2,4-Dimethylphenol hauptsächlich zu den beiden *ortho*-Oxydationsprodukten, dem 2,4-Dimethyl-*o*-chinol und dem 3,5-Dimethyl-*o*-chinon, führt. In geringem Ausmass entstand das *p*-Oxydationsprodukt, 2,4-Dimethyl-*p*-chinol. Das gebildete *o*-Chinol war in monomerer Form nicht existenzfähig, sondern stabilisierte sich sofort teils durch Dimerisierung, teils durch Addition an das 3,5-Dimethyl-*o*-chinon zu Derivaten des 1,4-Äthenonaphthalins. Beide Stabilisierungsreaktionen sind Diels-Alder-Additionen.

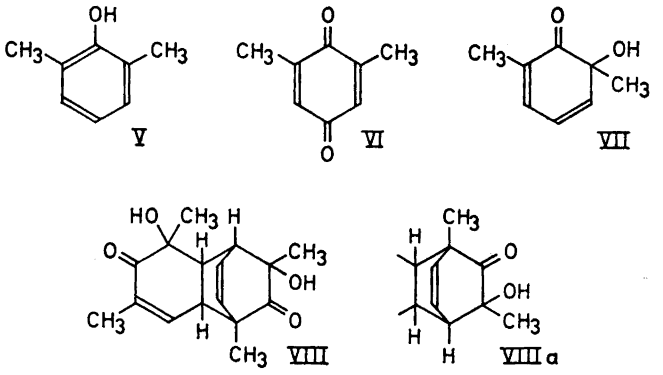
Erwartungsgemäss verbrauchte auch 2,4,6-Trimethylphenol (Mesitol, I) in wässriger Lösung sehr rasch 1 Mol Perjodat. In dem nach einer Oxydationsdauer von 5 Min. mittels Methylenchlorid extrahierbaren Gemisch der Reaktionsprodukte liess sich IR-spektroskopisch kein Mesitol mehr erkennen. Das

* VI. Mitt. (vorläufige Mitteilung zur vorliegenden Arbeit): Adler, E., Dahlén, J. und Westin, G. *Acta Chem. Scand.* **14** (1960) 512.

Rohprodukt konnte leicht aufgetrennt werden in 2,4,6-Trimethyl-*p*-chinol (II) [2] (Ausbeute 28 %) und eine Substanz vom Schmp. 182—183°, welcher nach Analyse und Molekulargewichtsbestimmung die Zusammensetzung $C_{18}H_{24}O_4$ zukam (Ausbeute 53 %). Es war naheliegend, in dieser Substanz ein durch Diels-Alder-Reaktion gebildetes Dimeres des primär zu erwartenden 2,4,6-Trimethyl-*o*-chinols (III) anzunehmen, und nach den beim 2,4-Dimethylphenol gemachten Erfahrungen kamen in erster Linie die Strukturen IV und IVa in Betracht (vorläufige Mitteilung, s. Zitat [3]).



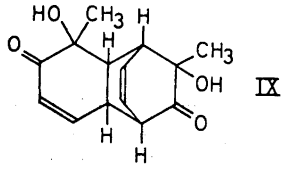
2,6-Dimethylphenol (V) reagierte ebenfalls rasch mit Natriumperjodat und lieferte nach Verbrauch von etwas mehr als 1 Mol des Oxydationsmittels ein Gemisch von 2,6-Dimethyl-*p*-chinon (VI) (Ausbeute 12 %) und einer farblosen, neutralen Substanz $C_{16}H_{20}O_4$ vom Schmp. 194—196° (Ausbeute 64%), in welcher ein Dimerisierungsprodukt des 2,6-Dimethyl-*o*-chinols (VII), und zwar in erster Linie ein Dimeres der Struktur VIII oder VIIIa, vermutet werden konnte.



Wenn wir die aus Mesitol bzw. 2,6-Dimethylphenol gewonnenen hochschmelzenden Produkte einstweilen als Dimere der Strukturen IV bzw. VIII betrachten — diese Strukturen werden weiter unten eingehend behandelt —, so finden wir, dass der Verlauf der Perjodatoxydation der beiden genannten Phenole dem früher [1] beim 2,4-Dimethylphenol beobachteten weitgehend ähnlich ist. (Zur Frage des Mechanismus vgl.[1]). In allen drei Fällen überwiegen die *o*-Oxydationsprodukte (hier die *o*-Chinole III bzw. VII) im Vergleich zu den *p*-Oxydationsprodukten (II bzw. VI), und die primär gebildeten *o*-Chinole sind nicht fassbar, da sie sich rasch durch Diels-Alder-Reaktion dimerisieren.

In der vorliegenden Arbeit richtet sich das Hauptinteresse auf die Struktur der aus Mesitol bzw. 2,6-Dimethylphenol erhaltenen Dimeren. Sie seien der Kürze halber im folgenden als "2,4,6-Dimeres" bzw. "2,6-Dimeres" bezeichnet.

Das 2,4,6-Dimere war von uns schon vor einigen Jahren als Dien-Philodienaddukt der Formel IV bzw. IVa aufgefasst worden [3]. Wie uns Herr Prof. F. Wessely, Wien, mitteilte, war man in seinem Arbeitskreis um etwa dieselbe Zeit zu der gleichen Auffassung gekommen. Das Dimere war im Wiener Institut bei der Hydrolyse von monomerem 2,4,6-Trimethyl-*o*-chinolacetat (X) erhalten worden; ein direkter Vergleich des so gebildeten Dimeren mit unserem bei der Perjodatoxydation gewonnenen Produkt vom Schmp. 182—183° bestätigte die Identität der beiden Substanzen (vgl. hierzu auch Zitat [4]). Später gelang es Metlesics und Wessely [5], das einfachste *o*-Chinolacetat, 2-Methyl-*o*-chinolacetat, in das dimere 2-Methyl-*o*-chinol überzuführen und für letzteres die Struktur



IX

IX eindeutig festzustellen. Dieses Ergebnis stützte auch die für das 2,4,6-Dimere angenommene Struktur (IV oder IVa) *.

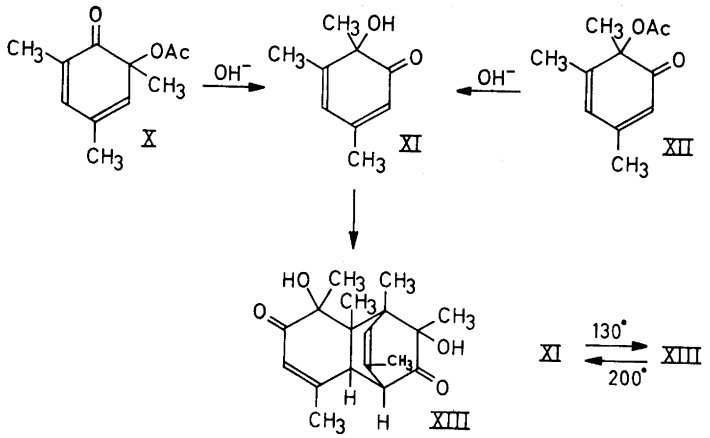
Kürzlich veröffentlichten aber Wessely und Mitarbeiter [6] ** Versuche, die sie zu einer Revision der Formel IV (bzw. IVa) veranlassten. Man hatte gefunden, dass kalte alkalische Verseifung von 2,4,6-Trimethyl-*o*-chinolacetat (X) neben dem Dimeren vom Schmp. 182—183° auch ein monomeres Trimethyl-*o*-chinol lieferte. Letzteres war jedoch nicht das erwartete 2,4,6-Trimethyl-*o*-chinol (III), sondern das isomere 2,3,5-Trimethyl-*o*-chinol (XI), das auch bei alkalischer Hydrolyse von 2,3,5-Trimethyl-*o*-chinolacetat (XII) entstand. Wurde das 2,3,5-Trimethyl-*o*-chinol XI auf 130° erhitzt, so ging es in das Dimere vom Schmp. 182—183° über, und letzteres zerfiel beim Erhitzen auf 200° teilweise unter Bildung des monomeren 2,3,5-substituierten *o*-Chinols (XI).

Diese Ergebnisse erklärten Wessely und Mitarbeiter [6] folgendermassen: Das bei der Verseifung von 2,4,6-Trimethyl-*o*-chinolacetat (X) freigelegte *o*-Chinol III unterlag unter der Einwirkung des Alkalis einer Acyloinumlagerung (vgl. Zitat [7]) zu 2,3,5-Trimethyl-*o*-chinol (XI), welches zum Teil dimerisierte. Dem Dimeren vom Schmp. 182—183° sollte demnach nicht die bis dahin angenommene Struktur des dimeren 2,4,6-Trimethyl-

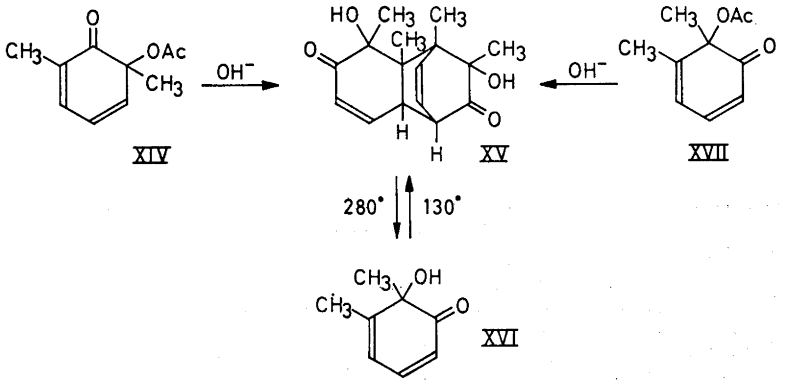
* Im folgenden wird der Einfachheit halber von den beiden möglichen Formeln IV und IVa für das 2,4,6-Dimere die dem Dimeren IX entsprechende Formel IV als die richtige angenommen. Für die übrigen in der vorliegenden Arbeit behandelten *o*-Chinoldimeren wird analog verfahren.

** Herr Professor Wessely machte uns diese Arbeit freundlicherweise vor ihrem Erscheinen als Korrekturabzug zugänglich.

o-chinols (IV), sondern die des dimeren 2,3,5-Trimethyl-*o*-chinols (XIII) zukommen. Damit schien auch die thermische Bildung des Dimeren aus dem Monomeren XI und die Regenerierung des letzteren beim Erhitzen des Dimeren verständlich zu sein.



Ähnliche Verhältnisse fanden Wessely und Mitarbeiter[6] beim 2,6-Dimethyl-*o*-chinolacetat (XIV). Dies ging beim alkalischen Verseifen direkt in ein Dimeres vom Schmp. 196° über, welches beim Erhitzen auf 280° 2,3-Dimethyl-*o*-chinol (XVI) lieferte. Diese Ergebnisse deuteten darauf hin, dass bei der alkalischen Verseifung von XIV unter Acyloinumlagerung Isomerisierung zu XVI eintrat, und dass letzteres sich sofort zum dimeren 2,3-Dimethyl-*o*-chinol (XV) stabilisierte. Das gleiche Dimere erhielt man auch bei alkalischer Verseifung von 2,3-Dimethyl-*o*-chinolacetat (XVII).



Wie bereits erwähnt, ist das von Wessely c.s.[6] aus 2,4,6- und aus 2,3,5-Trimethyl-*o*-chinolacetat (X, XII) (alkalische Verseifung) sowie aus 2,3,5-Trimethyl-*o*-chinol (bei 130°) erhaltene Dimere (Schmp. 182—183°) identisch mit dem von uns bei der Perjodatoxydation von Mesitol erhaltenen Produkt gleichen Schmelzpunkts. Neuerdings erwies sich auch das in Wien aus 2,6-

und aus 2,3-Dimethyl-*o*-chinolacetat (XIV, XVII) (alkalische Verseifung) erhaltene Dimere (Schmp. 196°) als identisch mit dem im hiesigen Laboratorium durch Perjodatoxydation von 2,6-Dimethylphenol (V) gewonnenen Produkt vom selben Schmelzpunkt *. Wären die von Wessely und Mitarb.[6] gezogenen Schlussfolgerungen richtig, müssten demnach auch den aus Mesitol bzw. 2,6-Dimethylphenol mittels Perjodat erhaltenen Dimeren anstelle der bisher angenommenen Formeln IV bzw. VIII die Formeln XIII (dimeres 2,3,5-Trimethyl-*o*-chinol) bzw. XV (dimeres 2,3-Dimethyl-*o*-chinol) zugeschrieben werden. Es wäre dann notwendig anzunehmen, dass bei der Perjodatoxydation der Phenole I bzw. V die primär zu erwartenden monomeren *o*-Chinole III (2,4,6-Trimethyl-*o*-chinol) bzw. VII (2,6-Dimethyl-*o*-chinol) sich durch Acyloinumlagerung rasch in die Isomeren XI (2,3,5-Trimethyl-*o*-chinol) bzw. XVI (2,3-Dimethyl-*o*-chinol) umwandelten, worauf die letzteren

[a] Maximum unscharf (Schulter) wegen Überlagung der K-Bande mit einer Bande mit Max. bei 210—212 mμ (gespannte Äthylenbrücke, vgl. S. 1586). In den übrigen Fällen war das K-Maximum von der kürzerwelligen Bande deutlich getrennt (s. Fig. 1).

dimerisierten. Unter den Bedingungen, wie sie von uns bei der Perjodatoxydation verwendet wurden — das pH der wässrigen $NaJO_4$-Lösung ist 4—5 — erschien indessen die Annahme einer Acyloinumlagerung, noch dazu einer rasch verlaufenden, recht unwahrscheinlich.

Im folgenden soll gezeigt werden, dass den beiden Dimeren die Strukturen des dimeren 2,4,6-Trimethyl-*o*-chinols (IV) bzw. des dimeren 2,6-Dimethyl-*o*-chinols (VIII) zukommen; die von Wessely und Mitarbeitern [6] vorgeschlage-

nen isomeren Strukturen XIII (2,3,5-Trimethylstruktur) und XV (2,3-Dimethylstruktur) (s.s. 1583) sind durch IV bzw. VIII zu ersetzen.*

Wertvolle Aufschlüsse lieferte zunächst ein Vergleich der UV-Absorptionsspektren verschiedener dimerer *o*-Chinole. Diese Substanzen zeigen die für α,β-ungesättigte Ketonsysteme charakteristischen Spektren mit einer kurzwelligen Bande hoher Extinktion (K-Bande) und einer längerwelligen Bande niedrigerer Extinktion (R-Bande) (Fig. 1). Die Lage des Maximums der K-Bande wird bekanntlich beeinflusst von der Anzahl und Stellung der Substituenten an der Äthylenbindung des konjugierten Enonsystems und lässt sich nach den von Woodward [8] angegebenen und von Fieser und Fieser [9] besonders in der Sterinreihe weiter geprüften Regeln berechnen. In Tabelle 1 sind die von uns bestimmten K-Maxima für fünf verschiedene Dimere und deren Diacetylderivate zusammengestellt. Es zeigt sich, dass die Werte für die Dimeren des 2-Methyl-[5], 2,4-[1] und 2,5-Dimethyl-*o*-chinols [10] sich gut an die berechneten Werte anschliessen. Was das Trimethylchinoldimere betrifft, lässt sich auf Grund der Lage der K-Bande keine Entscheidung zwischen den Isomeren IV (2,4,6-Struktur mit α,β-Substitution) und XIII (2,3,5-Struktur mit β,β-Substitution) treffen, da der Unterschied zwischen den für die beiden Isomeren berechneten Werten (2 $m\mu$) zu gering ist. Aufschlussreich ist dagegen das Spektrum des 2,6(2,3?)-Dimethyl-*o*-chinol-dimeren. Die Lage seines K-Maximums ist die für ein α,β-disubstituiertes Enon der Struktur VIII (dimeres 2,6-Dimethyl-*o*-chinol) zu erwartende und lässt sich nicht vereinbaren mit der von Wessely c.s.[6] angenommenen Struktur XV eines dimeren 2,3-Dimethyl-*o*-chinols (β-monosubstituiertes Enon).

Die in Fig. 1 wiedergegebenen Spektren der fünf verschiedenen *o*-Chinoldimeren und ihrer Acetate zeigen eine der K-Bande vorgelagerte, mehr oder weniger deutlich ausgeprägte Absorptionsbande im Bereich von 210—215 mμ. Es erscheint möglich, dass es sich hier um die Absorption der Äthylenbrücke handelt, die wegen der beträchtlichen Spannung des Bi*cyclo*octensystems gegenüber der normalen Äthylenabsorption bathochrom verschoben ist. Diese Annahme wird dadurch gestützt, dass die Bande verschwindet, d.h. vermutlich ihre normale Lage unterhalb 200 mμ annimmt, wenn die Ketolgruppierung des Bi*cyclo*octensystems durch Perjodat aufgespalten wird, wobei ein spannungsfreies Naphthalinsystem entsteht. Hierüber soll später berichtet werden.

Für die Richtigkeit der Strukturen IV bzw. VIII für die aus Mesitol bzw. 2,6-Dimethylphenol erhaltenen Dimeren (2,4,6-Dimeres bzw. 2,6-Dimeres) sprechen ferner folgende Ergebnisse:

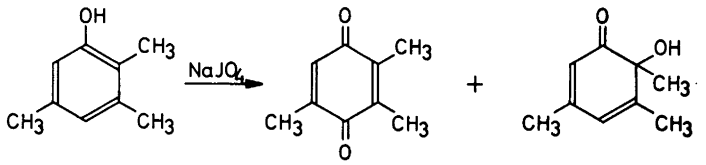
Das 2,4,6-Dimere lieferte beim kurzen Behandeln mit Essigsäureanhydrid in Äthylacetatlösung und in Gegenwart von Perchlorsäure als Katalysator (eine Methode [11], die sich für die Acetylierung des dimeren 2,4-Dimethyl-*o*-chinols bewährt hatte [1]) ein Diacetat (IV, OAc statt OH) vom Schmp. 162—163°. Sein UV-Spektrum (Fig. 1) zeigte an, dass das konjugierte Enonsystem

* Nach Fertigstellung des vorliegenden Manuskriptes übersandte uns Herr Prof. F. Wessely den Sonderdruck einer soeben erschienenen Arbeit von Zbiral, E., Wessely, F. und Lahrmann, E. *Monatsh.* **91** (1960) 92, in welcher die genannten Autoren gewisse Zweifel an der Richtigkeit der früher [6] angenommenen Dimerstrukturen XIII und XV äussern. Nach gleichzeitiger brieflicher Mitteilung von Herrn Prof. Wessely liegen nun in seinem Arbeitskreis weitere Ergebnisse vor, welche nicht mit Struktur XV sondern nur mit Struktur VIII für das dimere Dimethyl-*o*-chinol in Einklang gebracht werden können.

erhalten geblieben und demnach eine Acyloinumlagerung nicht eingetreten war. Durch milde alkalische Verseifung (äthanolische Kalilauge, Zimmertemp.) wurde aus dem Diacetat das 2,4,6-Dimere IV regeneriert. Auch unter dem Einfluss des Alkalis erfolgte also beim Dimeren keine Acyloinumlagerung. Wurde nun das Diacetat auf 180° erhitzt, so trat Retrodienzerfall unter Bildung von 2,4,6-Trimethyl-*o*-chinolacetat (X), Schmp. 82—84°, ein, das durch Vergleich mit einer nach Wessely und Sinwel [12] aus Mesitol und Bleitetraacetat dargestellten Probe identifiziert wurde.

Die einfachste Schlussfolgerung aus diesen Ergebnissen ist, dass das aus Mesitol mit Perjodat erhaltene Produkt das Dimere des 2,4,6-Trimethyl-*o*-chinols und nicht des 2,3,5-Trimethylisomeren ist. Folgende Versuche über die Perjodatoxydation des 2,3,5-Trimethylphenols (XVIII) bestätigen diese Auffassung.

2,3,5-Trimethylphenol (XVIII) verbrauchte unter den beim Mesitol bzw. 2,6-Dimethylphenol angewandten Bedingungen Perjodat erheblich langsamer als die beiden letztgenannten Phenole. Erst nach mehreren Stunden war XVIII nicht mehr nachweisbar. Aus dem Reaktionsgemisch liess sich in guter Ausbeute ein rotes Öl isolieren, das leicht im Vakuum destillierte. Das Destillat, ein gelbes, bei Temperaturen unter 12° kristallin erstarrendes Öl, erwies sich als ein Gemisch von 2,3,5-Trimethyl-*p*-chinon, Schmp. 34°, (XIX) [13], und monomerem 2,3,5-Trimethyl-*o*-chinol, Schmp. 42°, (XI) [6]. Ein dimeres Produkt war nicht zu entdecken.



XVIII XIX XI

Die Perjodatoxydation von 2,3,5-Trimethyl-phenol (XVIII) lieferte somit — neben dem *p*-Oxydationsprodukt XIX — monomeres 2,3,5-Trimethyl-*o*-chinol (XI), das unter den Versuchsbedingungen nicht in ein Dimeres überging. Dieses Ergebnis schliesst aus, dass das bei der analogen Oxydation des Mesitols erhaltene Produkt vom Schmp. 182—183° ein Dimeres des 2,3,5-Trimethyl-*o*-chinols (XIII) sein könne, wie von Wessely c.s.[6] angenommen wurde.

Über die unterschiedliche Geschwindigkeit der Perjodatoxydation verschiedener Typen von Alkylphenolen sowie über die verschiedene Neigung der entsprechenden Alkyl-*o*-chinole zur Dimerisierung soll später zusammenhängend berichtet werden.

Ähnliche, bisher nur orientierende, Versuche wurden mit 2,3-Dimethylphenol unternommen. Auch sie gaben kein dimeres Produkt. Dies spricht gegen die Auffassung, dass das aus 2,6-Dimethylphenol mit Perjodat sowie das von Wessely c.s.[6] auf andere Weise erhaltene, damit identische Produkt

vom Schmp. 194—196° ein dimeres 2,3-Dimethyl-*o*-chinol sei. Die Richtigkeit unserer Auffassung, dass dieses Produkt das 2,6-Dimere (VIII) ist, wurde durch die folgenden Versuche gestützt.

Das "2,6-Dimere" gab mit AcOAc—$HClO_4$ glatt ein Diacetat vom Schmp. 159—160° (Formel VIII, OAc statt OH). Sein UV-Spektrum (Fig. 1) zeigt wie das Ausgangsmaterial die für das α,β-substituierte konjugierte Enonsystem charakteristische K-Bande (s. Tab. 1) sowie die R-Bande um 300 mμ. Wurde das Diacetat auf 180° erhitzt, so gab es unter Retrodienzerfall 2,6-Dimethyl-*o*-chinolacetat (XIV), identifiziert mit einer nach Wessely und Mitarb.[6] erhaltenen Probe derselben Substanz. Umgekehrt liess sich das monomere Acetat XIV durch Erhitzen auf 120° wieder in das dimere Dimethyl-*o*-chinolacetat vom Schmp. 159—160° überführen. Diese Ergebnisse sind analog den von Metlesics und Wessely [5] für das Dimere des 2-Methyl-*o*-chinolacetats (IX, OAc statt OH) bzw. das entsprechende Monomere beschriebenen; sie sind im Einklang mit Formel VIII für das Dimethyl-*o*-chinoldimere.

Bei der thermischen Dimerisierung des 2,6-Dimethyl-*o*-chinolacetats (XIV) entstand neben dem acetylierten Dimeren vom Schmp. 159—160° noch ein isomeres Produkt vom Schmp. 182—84°. Es enthält ebenfalls das α,β-substituierte konjugierte Enonsystem (K-band bei 238 mμ, R-band bei 310 mμ) und könnte vielleicht das Diacetat des isomeren 2,6-Dimeren (VIIIa, OAc statt OH) sein.

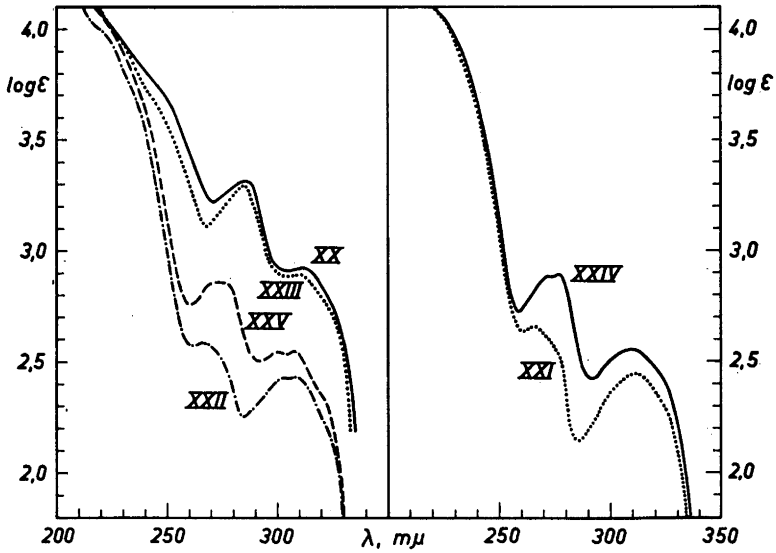


Fig. 2. Ultraviolett-Absorptionsspektren. Lösungsmittel: 96-proz. Äthanol.
2-Methyl-*o*-chinol-anhydrodimeres (XX), dessen
Monoacetat (XXI) und Diacetat (XXII).
2,6-Dimethyl-*o*-chinol-anhydrodimeres (XXIII),
dessen Monoacetat (XXIV) und Diacetat (XXV).

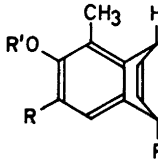
Im Gegensatz zum 2,6-Dimethyl-*o*-chinolacetat blieb das von Wessely und Mitarb.[14] beschriebene 2,3-Dimethyl-*o*-chinolacetat bei 120° unverändert.

Ein weiteres für das vorliegende Strukturproblem wichtiges Ergebnis lieferte die alkalische Hydrolyse des acetylierten 2,6-Dimeren (VIII, OAc statt OH). Es entstanden zwei Produkte in ungefähr gleicher Menge, nämlich ein in wässrigem Alkali unlösliches sowie ein alkalilösliches, das beim Neutralisieren der alkalischen Lösung mit CO_2 ausfiel. Das erstere war das erwartete Ausgangsdimere $C_{16}H_{20}O_4$ (VIII). Das zweite, vom Schmp. 172—174°, hatte die Zusammensetzung $C_{16}H_{18}O_3$, enthielt also 1 Mol. H_2O weniger als VIII; es sei als "Anhydro-2,6-dimeres" bezeichnet. Sein IR-Spektrum zeigte neben der für die dimeren *o*-Chinole typischen Hydroxylbande um 3 460 cm^{-1} eine längerwellige Hydroxylbande (bei 3 290 cm^{-1}). Von den beiden im Spektrum des Ausgangsdimeren VIII vorhandenen CO-Banden (1 672 cm^{-1} für die konjugierte, und 1 712 cm^{-1} für die isolierte Ketogruppe) war im Spektrum des Anhydrodimeren nur noch die Bande der isolierten Ketogruppe zu erkennen. Um 1 600 cm^{-1} gab sich eine, allerdings schwach ausgeprägte, "aromatische" Doppelbande (1 614 und 1 586 cm^{-1}) zu erkennen. Diese Daten legten nahe, dass es sich um ein Phenol handelte. Das UV-Spektrum der Substanz (Fig. 2) wies eine Bande mit Maximum bei 285 $m\mu$ ($\log \varepsilon = 3.29$) auf, sowie eine längerwellige Bande bei 311 $m\mu$ ($\log \varepsilon = 2.89$).

Durch Essigsäureanhydrid-Pyridin wurde die saure Hydroxylgruppe des Anhydrodimeren unter Bildung eines Monoacetats vom Schmp. 150—152° (UV-Spektrum, Fig. 2) verestert, während das tert. alkoholische Hydroxyl intakt blieb. Im IR-Spektrum liess sich das Phenolester-CO bei 1 755 cm^{-1}, das tert. OH bei 3 430 cm^{-1} erkennen. (Auch die tertiären Hydroxylgruppen des 2,6-Dimeren und anderer *o*-Chinoldimeren sind gegen AcOAc-Pyridin, selbst beim Kochen, resistent.) Einwirkung von AcOAc-$HClO_4$ auf das Anhydrodimere oder dessen Monoacetat lieferte dagegen erwartungsgemäss ein Diacetat, Schmp. 176—178°, (UV-Spektrum, Fig. 2), aus welchem durch milde alkalische Verseifung das Anhydro-2,6-dimere vom Schmp. 172—174° regeneriert wurde.

Die Struktur des Anhydro-2,6-dimeren ergab sich aus Vergleichsversuchen mit dem dimeren 2-Methyl-*o*-chinolacetat (IX, OAc statt OH) von Metlesics und Wessely[5]. Wurde die letztgenannte Substanz mit äthanolischer Kalilauge bei Zimmertemperatur behandelt, so entstand das Phenol XX, dessen Diacetat XXII Metlesics und Wessely[5] aus dem Dimeren IX oder seinem Diacetat durch Erhitzen mit Essigsäureanhydrid-Natriumacetat erhalten und zu XX verseift hatten. Die Struktur des Phenols XX ist von den genannten Autoren eindeutig festgelegt worden[5].

XX : R=H; R'=R''=H
XXI : R=H; R'=Ac; R''=H
XXII: R=H; R'=R''=Ac



XXIII: R=CH3; R'=R''=H
XXIV: R=CH3; R'=Ac; R''=H
XXV : R=CH3; R'=R''=Ac

Das Phenol XX zeigt weitgehende spektrale Ähnlichkeit mit dem oben beschriebenen Anhydro-2,6-dimeren; im IR-Spektrum des Phenols XX [5] sind die "aromatischen Banden" um 1 600 und 1 500 cm^{-1} jedoch deutlich ausgeprägt. Überzeugend für die strukturelle Analogie ist vor allem die Ähnlichkeit der charakteristischen UV-Spektren der beiden Phenole (Fig. 2). Wie das Anhydro-2,6-dimere gibt auch Phenol XX mit AcOAc-Pyridin ein Monoacetat, Schmp. 127—129° (XXI), und mit AcOAc-$HClO_4$ das bereits von Metlesics und Wessely [5] beschriebene Diacetat (XXII) (UV-Spektren, Fig. 2).

Auf Grund dieser klaren Analogien kann dem Anhydro-2,6-dimeren die Struktur XXIII, seinem Monoacetat Struktur XXIV und seinem Diacetat Struktur XXV zuerteilt werden.

Die Bildung des Phenols XXIII aus dem Acetat des Dimethyl-*o*-chinoldimeren lässt sich aber wieder nur mit der 2,6-Dimethylstruktur (VIII) für das letztere in Einklang bringen. In dieser Struktur sind — wie beim Acetat des dimeren 2-Methyl-*o*-chinols (IX) — die angulären Positionen mit Wasserstoff besetzt. Dies lässt die bei der alkalischen Verseifung eintretende Abspaltung von HOAc und die damit einhergehende Aromatisierung des brückenlosen Sechsrings verstehen. Ein solcher Reaktionsverlauf wäre nicht möglich, wenn dem ursprünglichen Dimeren die von Wessely c.s.[6] vorgeschlagene Struktur des dimeren 2,3-Dimethyl-*o*-chinols XV (mit einer angulären CH_3-Gruppe) zukäme.

Die Mono- und Diacetate der Phenolalkohole XX und XXIII zeigen wie diese selbst in ihren UV-Spektren zwei Banden oder Bandengruppen (Fig. 2). Von diesen ist die kürzerwellige sicher auf den phenolischen Ring zurückzuführen; die längerwellige ist möglicherweise einem Überschneiden der π-Orbitale des aromatischen Rings und der in β,γ-Stellung zu ihm stehenden Ketogruppe (und Äthylengruppe?) zuzuschreiben, wie es von Cookson und Wariyar[15] für β, γ-ungesättigte Ketone von geeignetem sterischem Bau angenommen wird. Für eine Verbindung verwandter Struktur (β-Naphthol-Maleinsäureanhydrid-Addukt, *exo*-Form) hat Wariyar [16] eine Absorptionskurve von recht ähnlichem Typus angegeben.

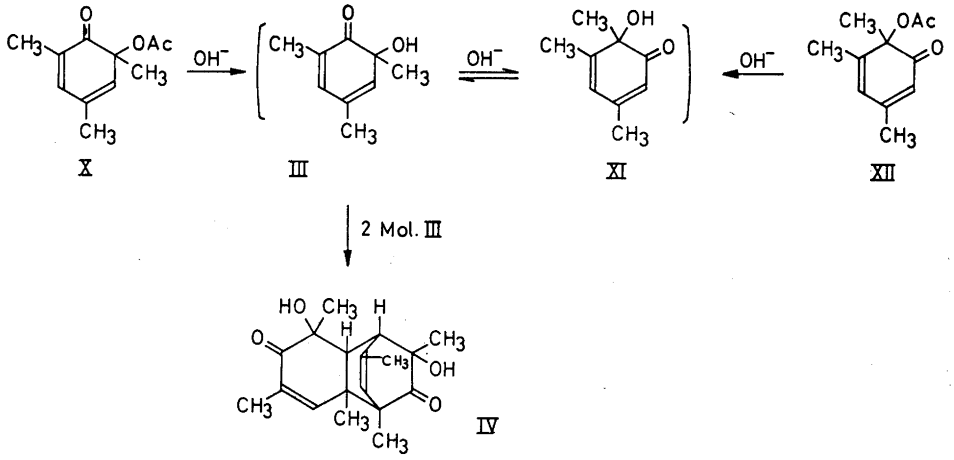
Wie bereits erwähnt, erhielten Metlesics und Wessely [5] das aromatische Diacetat XXII durch (2-stündiges) Erhitzen des dimeren 2-Methyl-*o*-chinols (IX) mit AcOAc-NaOAc. Auch bei solcher Behandlung verhielt sich das 2,6-Dimere (VIII) im Prinzip analog, denn aus dem Reaktionsgemisch konnte das Diacetat XXV des Anhydro-2,6-dimeren isoliert werden. Daneben entstand noch das Diacetat von VIII, und ausserdem war in beträchtlichem Ausmass Retrodienzerfall zum 2,6-Dimethyl-*o*-chinolacetat (XIV) eingetreten. Erwartungsgemäss lieferte auch das Diacetat von VIII beim Erhitzen mit AcOAc-NaOAc das Diacetat XXV neben monomerem 2,6-Dimethyl-*o*-chinolacetat (XIV).

DISKUSSION

Mit den voranstehenden Ergebnissen dürften die Strukturen des 2,4,6-Dimeren und des 2,6-Dimeren eindeutig im Sinne der Formeln IV bzw. VIII entschieden sein. Es erhebt sich dann die Frage, wie die eingangs kurz besprochenen Versuche von Wessely und Mitarbeitern [6] zu erklären sind, wonach dieselben Dimeren auch aus 2,3,5-Trimethyl-*o*-chinol bzw. 2,3-Dimethyl-*o*-

chinol in Gegenwart von Alkali oder beim Erhitzen auf 130° entstehen. Es seien zunächst die Verhältnisse bei den Trimethyl-*o*-chinolen betrachtet.

Wessely und Mitarb.[4,6] fanden, dass alkalische Verseifung von 2,4,6-Trimethyl-*o*-chinolacetat (X) zur gleichzeitigen Bildung von 2,3,5-Trimethyl-*o*-chinol (XI) und des Dimeren vom Schmp. 182—183° führt und nahmen an, dass letzteres durch Dimerisierung von XI entstand, das seinerseits aus dem eigentlich zu erwartenden 2,4,6-Trimethyl-*o*-chinol (III) durch Acyloinumlagerung gebildet worden war. Wir nehmen nun an, dass ein Teil des primär aus X freigelegten *o*-Chinols III sich zum Dimeren IV dimerisiert, während ein anderer Teil, in Konkurrenz mit der Dimerisierung, durch Acyloinumlagerung in das isomere *o*-Chinol XI übergeführt wird. Dem letzteren geht aber, wie oben gezeigt wurde, die Fähigkeit zur Dimerisierung ab und es kann deshalb als Monomeres isoliert werden.

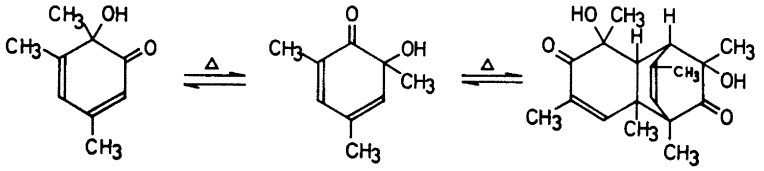


Es ist weiterhin anzunehmen, dass die Acyloinumlagerung III ⇌ XI reversibel ist (vgl. hierzu auch Derkosch und Kaltenegger [17]); man wird deshalb erwarten müssen, dass das 2,4,6-Dimere IV auch bei alkalischer Verseifung von 2,3,5-Trimethyl-*o*-chinolacetat (XII) — neben dem freien 2,3,5-Trimethylchinol XI — entsteht. Wessely c.s. geben allerdings nur die Bildung von XI an. Man würde ferner erwarten, dass aus dem Gleichgewicht III ⇌ XI allmählich alles *o*-Chinol in das Dimere IV übergeht. Dass bei der Verseifung von X die Produkte XI und IV nebeneinander gefunden wurden [4,6], ist wohl auf die Kürze der Versuchsdauer (10 Min.) zurückzuführen.

Bei der Oxydation des Mesitols mit Perjodat entsteht als *o*-Oxydationsprodukt zweifellos das 2,4,6-Trimethyl-*o*-chinol III. Es dimerisiert sich sehr rasch vollständig zum Dimeren IV. Unter den angewandten Versuchsbedingungen (wässerige Lösung, pH 4—5) erfolgt keine Acyloinumlagerung, denn im rohen Reaktionsprodukt liess sich infrarotspektroskopisch kein 2,3,5-Trimethyl-*o*-chinol nachweisen. Bei der Perjodatoxydation von 2,3,5-Trimethylphenol (XVIII) dagegen entstand als *o*-Oxydationsprodukt ausschliess-

lich 2,3,5-Trimethyl-*o*-chinol (XI) — welches nicht dimerisiert —, und da Acyloinumlagerung bei pH 4—5 offenbar nicht stattfindet, trat auch kein 2,4,6-Dimeres (IV) auf.

Die Ergebnisse der thermischen Versuche lassen sich auf ähnlicher Grundlage deuten. Nimmt man an, dass 2,3,5-Trimethyl-*o*-chinol (XI) bei höherer Temperatur einer reversiblen Acyloinumlagerung unterliegt, so versteht man, weshalb es — über 2,4,6-Trimethyl-*o*-chinol (III) — allmählich in das 2,4,6-Dimere (IV) übergeht [6]. Und man versteht auch, warum das Dimere IV beim thermischen Retrodienzerfall [6] — über 2,4,6-Trimethyl-*o*-chinol — das 2,3,5-Trimethyl-*o*-chinol (XI), neben unverändertem Dimeren IV, liefert:



XI III IV

Das Eintreten der Acyloinumlagerung nicht nur in alkalischer Lösung sondern auch bei höherer Temperatur, die Reversibilität dieser Umlagerungen, sowie die Tatsache, dass 2,4,6-Trimethyl-*o*-chinol unter allen bisher untersuchten Bedingungen rasch dimerisiert, während dem 2,3,5-Trimethyl-*o*-chinol die Dimerisierungstendenz abgeht, scheinen somit alle bisher bekannt gewordenen Befunde widerspruchsfrei zu erklären.

Bei den entsprechenden Acetaten liegen etwas andere Verhältnisse vor. Sowohl 2,3,5- wie 2,4,6-Trimethyl-*o*-chinolacetat, welche durch die Bleitetraacetatmethode von Wessely zugänglich sind, sind als Monomere haltbar. Ihre thermische Dimerisierung ist noch nicht untersucht. Bei der thermischen Spaltung des Acetates des Mesitoldimeren erhielten wir in normaler Weise das 2,4,6-Trimethyl-*o*-chinolacetat (X) (s.S. 1587). Im Gegensatz zum freien *o*-Chinol gibt das Acetat keine thermische Acyloinumlagerung, was im Hinblick auf den mutmasslichen Mechanismus dieser Umlagerungsreaktion ganz natürlich erscheint.

Was in der voranstehenden Diskussion am Beispiel des Isomerenpaares 2,4,6- und 2,3,5-Trimethyl-*o*-chinol gesagt wurde, gilt offensichtlich auch für das Paar 2,6- und 2,3-Dimethyl-*o*-chinol. Wir wollen hierauf zurückkommen, wenn begonnene Versuche, insbesondere über das Verhalten des 2,3-Dimethylphenols gegen Perjodat, abgeschlossen sind. Vorläufig lässt sich sagen, dass 2,3-Dimethylphenol — ganz ähnlich wie das 2,3,5-Homologe — verhältnismässig langsam oxydiert wird und dass dabei kein Dimeres entsteht. Dagegen reagiert 2,6-Dimethylphenol, wie oben gezeigt, rasch unter Bildung des dimeren 2,6-Dimethyl-*o*-chinols (VIII). Die von uns gemachte Beobachtung, dass 2,3-Dimethyl-*o*-chinolacetat beim zweistündigen Erhitzen auf 120° unverändert blieb, während das entsprechende 2,6-Isomere dimeri-

sierte (s. S. 1588-9), fügt sich gut in die hier angeführten Zusammenhänge ein. Dies gilt schliesslich auch für den Befund, dass das Diacetat des 2,6-Dimeren thermisch zum monomeren 2,6-Dimethyl-*o*-chinolacetat spaltbar ist (s. S. 1588).

EXPERIMENTELLES

Absorptionsspektren im ultravioletten und sichtbaren Gebiet wurden mit einem registrierenden Spektrophotometer (Perkin-Elmer Spectracord 4 000-A), IR-Spektren mit dem Perkin-Elmer-Instrument, Modell 21, aufgenommen. Die Elementaranalysen wurden im Laboratorium Alfred Bernhardt, Mülheim, ausgeführt.

Perjodatoxydation von Mesitol (I). Zu einer Lösung von 5 g Mesitol in 2.3 l Äthanol-Wasser (15:85) wurden 15.7 g Natriummetaperjodat ($NaJO_4$) (Molverhältnis 1:2), gelöst in 200 ml Wasser, unter Umschütteln zugegeben. Nach 5 Min. wurde unverbrauchtes Perjodat durch Zusatz von 4.55 g Äthylenglykol reduziert. Die schwach grünlichgelb gefärbte Lösung wurde sechsmal mit Methylenchlorid ausgeschüttelt, und die vereinigten Extrakte wurden nach Trocknen mit wasserfreiem Calciumsulfat im Vakuum zur Trockene gebracht. Der teilweise kristalline Rückstand wurde einige Male mit kaltem Hexan ausgezogen, und der ungelöst verbleibende kristalline Anteil aus Benzol umkristallisiert. Farblose Prismen von *dimerem 2,4,6-Trimethyl-o-chinol (IV)* *, Schmp. 182–183°; Ausbeute 53 %. (Gef.: C 71.00; H 7.97; aktiver H ** 0.64; Mol.-Gew., kryoskop. in HOAc **, 318. Ber. für $C_{18}H_{24}O_4$: C 71.03; H 7.95; aktiver H 0.66; Mol.-Gew. 304.37.) UV-Spektrum s. Tab. 1 und Fig. 1. IR-Banden (cm^{-1}): 3 490, 3 400 (aliph. OH), 1 710 (CO), 1 684 (konj. CO).

Aus dem oben erwähnten Hexanextrakt kristallisierte nach dem Einengen noch eine kleine Menge des Dimeren IV. Nach Entfernen des restlichen Lösungsmittels hinterblieb ein schwach gelbes Öl, das beim Abkühlen kristallisierte (Ausbeute 28 %). Umkristallisieren aus *Iso*propyläther gab farbloses *2,4,6-Trimethyl-p-chinol (II)*, Schmp. 45–46° (45.5–46° nach Bamberger und Rising [2]). Das UV-Spektrum der Substanz stimmte mit dem von Derkosch und Kaltenegger [18] angegebenen überein.

Dimeres 2,6-Dimethyl-o-chinol (VIII). Eine Lösung von 8.8 g 2,6-Dimethylphenol in 2.4 l Wasser wurde unter Rühren mit einer Lösung von 36 g $NaJO_4$ in 1.2 l Wasser (Molverhältnis Xylenol: $NaJO_4$ = 1 : 2.34) versetzt. Nach einer Reaktionsdauer von 30 Min. wurde überschüssiges Perjodat durch Zusatz von 8 ml Äthylenglykol entfernt, und die gelbe, etwas trübe Lösung portionsweise mit insgesamt 800 ml Methylenchlorid ausgeschüttelt. Aus dem Extrakt wurde nach Trocknen mit wasserfreiem Gips und Eindampfen i.V. ein uneinheitliches kristallines Rohprodukt erhalten. Letzteres wurde mit 30 ml Hexan ausgekocht, wobei 6.3 g rohes VIII vom Schmp. 187–192° zurückblieben. Ausbeute 64 %. Umkristallisieren aus Benzol-Hexan gab farblose Prismen, Schmp. 194–196°. (Gef.: C 69.33; H 7.27; O 23.15. Ber. für $C_{16}H_{20}O_4$: C 69.54; H 7.30; O 23.16.) UV-Spektrum s. Tab. 1 und Fig. 1. IR-Banden (cm^{-1}): 3 400 (aliph. OH), 1 712 (CO), 1 672 (konj. CO).

Aus dem Hexanextrakt (s. oben) kristallisierten 1.1 g (12 %) *2,6-Dimethyl-p-chinon (VI)*, Schmp. 73°.

Diacetat des dimeren 2,4,6-Trimethyl-o-chinols (IV, OAc statt OH). Dimeres 2,4,6-Trimethyl-*o*-chinol (IV) (1.2 g) wurde in 15 ml einer 2 M Lösung von Essigsäureanhydrid in Äthylacetat, die 1.15 % Perchlorsäure enthielt [11], gelöst. Nach 10 Min. wurde mit etwas Wasser zersetzt, die Äthylacetatschicht einige Male mit Wasser gewaschen, mit Na_2SO_4 getrocknet und i.V. eingedampft. Der feste Rückstand gab beim Umkristallisieren aus Äthanol farblose Prismen vom Schmp. 162–163° (69 %). (Gef.: C 67.87; H 7.31; $COCH_3$ 21.12. Ber. für $C_{22}H_{28}O_6$: C 68.02; H 7.27; $COCH_3$ 22.17.) UV-Spektrum s. Tab. 1 und Fig. 1. IR-Banden (cm^{-1}): 1 738 (Inflexion), 1 730 (Ester-CO und CO), 1 696 (konj. CO).

Verseifung des Diacetats mit 10-proz. äthanolischer Kalilauge (16 Std. bei Zimmertemp.) gab das Ausgangsdimere IV.

---

* Diplomarbeit L. Junghahn, 1954 [3].

** Diese Bestimmungen wurden von Herrn tekn.lic. R. Magnusson ausgeführt.

Thermische Spaltung des dimeren 2,4,6-Trimethyl-o-chinolacetats (IV, OAc statt OH). Das Acetat (650 mg) wurde in einem Knierohr, das an das Vakuum einer Wasserstrahlpumpe angeschlossen war, durch Eintauchen des Rohres in ein auf 180° erwärmtes Ölbad rasch erhitzt. Innerhalb weniger Minuten destillierte ein gelbliches, allmählich kristallin erstarrendes Öl in den gekühlten Teil des Röhrchens über. Umkristallisieren aus *Iso*propyläther gab gelblich-weisse Prismen von *2,4,6-Trimethyl-o-chinolacetat (III)*, (Ausbeute 73 %), Schmp. 82–84°, wie von Wessely und Sinwel [12] angegeben. UV- und IR-Spektrum stimmten mit den von Derkosch und Kaltenegger [17,18] veröffentlichten Spektren überein.

Perjodatoxydation von 2,3,5-Trimethylphenol (XVIII). Eine Lösung von 4 g des Phenols in 1.8 l Äthanol-Wasser (15:85) wurde mit einer Lösung von 18.95 g $NaJO_4$ (Molverhältnis 1:3) in 400 ml Wasser versetzt. Nach 16-stündigem Stehen bei Zimmertemperatur wurde das rote Reaktionsgemisch mit Methylenchlorid ausgeschüttelt. Eindampfen der mit wasserfreiem Na_2SO_4 getrockneten Methylenchloridlösung i.V. gab ein braunrotes Öl (4.3 g), das bei 2 mm Hg bei 70–80° destillierte. Das goldgelbe Destillat erstarrte unterhalb 12° kristallin. (Versuche mit 30- bzw. 45-stündiger Oxydationsdauer gaben dasselbe Resultat.) Das Absorptionsspektrum einer alkoholischen Lösung des Produktes (Max. bei 225, 255 und 313 mμ, Min. bei 213 und 284 mμ) war mit der Annahme eines Gemisches von 2,3,5-Trimethyl-*p*-chinon (XIX) (λ_{max} = 254 mμ) und 2,3,5-Trimethyl-*o*-chinol (XI) (λ_{max} = 312 mμ [18]) vereinbar. Das IR-Spektrum des Gemisches gab dieselbe Information. Versuche, die Komponenten durch fraktionierte Destillation zu trennen, waren erfolglos.

Die Hexanlösung einer Probe des gelben Gemisches wurde auf eine Säule von Aluminiumoxyd (Merck, stand., "sauer") gebracht. Beim Waschen mit Hexan-Benzol (90:10) wurde eine goldgelbe Zone eluiert, während eine heller gelbe Zone im oberen Teil der Säule adsorbiert blieb und auch mit anderen Lösungsmitteln nicht ausgewaschen werden konnte. Das Hexan-Benzol-Eluat hinterliess beim Eindunsten *2,3,5-Trimethyl-p-chinon (XIX)*, identifiziert durch Schmp., Misch-Schmp. und Spektren mit einem nach Teuber und Rau [13] dargestellten Vergleichspräparat.

Eine weitere Probe des gelben Gemisches wurde in 50-proz. Äthanol gelöst und durch 20 Min. langes Einleiten von SO_2 reduziert. Das Reaktionsgemisch färbte sich zunächst dunkel (Chinhydron) und nahm darauf eine blassgelbe Farbe an. Nach Verdünnen mit Wasser wurde mit Methylenchlorid ausgeschüttelt, und der nach dem Eindampfen der Methylenchloridphase verbleibende Rückstand mit Hexan ausgezogen. Aus der eingeengten Hexanlösung kristallisierten beim Abkühlen farblose Nadeln, die nach Umkristallisieren aus Wasser bei 96–97° schmolzen und mit *2,3,5-Trimethylphenol (XVIII)* keine Schmelzpunktsdepression gaben. Da im Gemisch vor der Reduktion UV- und IR-spektroskopisch kein Phenol nachweisbar war, muss dieses aus 2,3,5-Trimethyl-*o*-chinol (XI) bei der Reduktion mit SO_2 enstanden sein. Der in Hexan unlösliche Anteil des Reduktionsproduktes war 2,3,5-Trimethyl-hydrochinon, Schmp. 168-169°.

Diacetat des dimeren 2,6-Dimethyl-o-chinols (VIII, OAc statt OH). Das Dimere VIII (850 mg) wurde in 10 ml des AcOAc–$HClO_4$-Äthylacetat-Reagenses von Fritz und Schenk [11] gelöst. Nach 10 Min. wurde mit 2 ml Wasser zersetzt, die Äthylacetatschicht mit Wasser gewaschen, mit $CaSO_4$ getrocknet und i.V. eingedampft. Der kristalline Rückstand gab nach dem Umkristallisieren aus Äthanol Prismen vom Schmp. 159–160°. Ausbeute 74 %. (Gef.: C 66.88; H 6.79; CH_3CO 20.81. Ber. für $C_{20}H_{24}O_6$: C 66.65; H 6.71; CH_3CO 23.89.) UV-Spektrum s. Tab. 1 und Fig. 1. IR-Banden (cm^{-1}): 1 751, 1 736 (Ester-CO), 1 726 (CO), 1 702 (konj. CO), 1 658 (C=C).

Thermische Spaltung des dimeren 2,6-Dimethyl-o-chinolacetats (VIII, OAc statt OH). Das Dimeracetat (190 mg) wurde in einem Knierohr unter Wasserstrahlvakuum rasch auf 180° erhitzt. Nach etwa 10 Min. hatten sich im gekühlten Teil des Röhrchens 175 mg (92 %) eines hellgelben Öls angesammelt, das im Kühlschrank kristallisierte. Umkristallisieren aus *Iso*propyläther gab fast weisses *2,6-Dimethyl-o-chinolacetat (XIV)*, Schmp. 34–35°, keine Schmelzpunktsdepression mit einem nach Wessely und Mitarb.[6] hergestellten Vergleichspräparat gleichen Schmelzpunkts. Auch die UV- und IR-Spektren waren identisch. (Gef.: C 66.64; H 6.51; CH_3CO 25.86. Ber. für $C_{10}H_{12}O_3$: C 66.65; H 6.71; CH_3CO 23.89.)

Thermische Dimerisierung von 2,6-Dimethyl-o-chinolacetat (XIV). Das monomere Acetat XIV (3.125 g) wurde in einem Kölbchen während 2.5 Std. in N_2-Atmosphäre bei 120° gehalten. Das entstandene Öl wurde in 5 ml warmem Äthanol gelöst; beim Abkühlen

wurden 2.05 g (66 Gew.-%) eines farblosen, kristallinen Produkts vom Schmp. 130—155° erhalten. Durch fraktioniertes Kristallisieren aus Äthanol konnte die Hauptmenge dieses Produktes als reines *dimeres 2,6-Dimethyl-o-chinolacetat (VIII, OAc statt OH)*, Schmp. 159—160° (s.o.), erhalten werden. Identifizierung durch Mischschmelzp. und IR-Spektrum.

Als Nebenprodukt wurde aus den Mutterlaugen ein *isomeres Diacetat* vom Schmp. 182—184° in Form farbloser, zugespitzter Prismen isoliert (Gef.: C 66.70; H 6.84; $COCH_3$ 24.21; Ber. für $C_{20}H_{24}O_6$: C 66.65; H 6.71; $COCH_3$ 23.89). UV-Spektrum: Max. bei 238 mμ (log ε = 3.81) und 310 mμ (log ε = 2.18). Das IR-Spektrum zeigt eine zusammengesetzte Bande mit Max. bei 1 726, und Inflexionen bei ca. 1 748, 1 738 und 1 710 cm^{-1}.

Alkalische Verseifung des dimeren 2,6-Dimethyl-o-chinolacetats (VIII, OAc statt OH). Dimeracetat VIII (OAc statt OH) (2.8 g) wurde in 100 ml 10-proz. äthanolischer Kalilauge (die mittels 2-st. Durchleitens von N_2 von Luft befreit worden war) gelöst. Nach 16-stündigem Stehen unter N_2 bei Zimmertemperatur wurde die nunmehr schwach gelbliche Lösung mit Wasser verdünnt und der Hauptanteil des Alkohols i.V. entfernt. Beim Abkühlen kristallisierten 770 mg farbloser Plättchen, Schmp. 189—194°, nach Mischschmp. und IR-Spektrum identisch mit *dimerem 2,6-Dimethyl-o-chinol (VIII)* (Ausbeute 36 %).

Die Mutterlauge wurde mit CO_2 neutralisiert, worauf 725 mg farbloser Stäbchen vom Schmp. 167—72° ausfielen. Umkristallisieren aus Äthanol-Wasser erhöhte den Schmp. auf 172—174°: *Anhydroprodukt des dimeren 2,6-Dimethyl-o-chinols (XXIII)* (Ausbeute 36 %). (Gef.: C 74.51; H 7.14. Ber. für $C_{16}H_{18}O_3$: C 74.40; H 7.02.) UV-Spektrum s. Fig. 2. IR-Banden (cm^{-1}): 3 460 (aliph. OH), 3 290 (phenol. OH), 1 712 (CO), 1 615, 1 586 (schwach, arom. Ring).

Monoacetat (XXIV) des "Anhydro-2,6-dimethyldimeren". Phenol XXIII (200 mg) wurde in 20 ml eines Gemisches von AcOAc und Pyridin (1:1) gelöst. Nach 16-stündigem Stehen bei Zimmertemp. wurde in Eiswasser gegossen und das ausgefallene Öl in Methylenchlorid aufgenommen. Die Methylenchloridphase wurde mit wässrigem Bikarbonat und Wasser gewaschen, mit $CaSO_4$ getrocknet und i.V. eingedampft. Der feste Rückstand gab nach dem Umkristallisieren aus Benzol-Hexan das Monoacetat XXIV vom Schmp. 150—152°. Ausbeute 82 %. (Gef.: C 71.83; H 6.62. Ber. für $C_{18}H_{20}O_4$: C 71.98; H 6.71.) UV-Spektrum s. Fig. 2. IR-Banden (cm^{-1}): 3 475 (aliph. OH), 1 769 (Enolester-CO), 1 713 (CO), 1 617, 1 593 (schwach, aromat. Ring).

Diacetat (XXV) des "Anhydro-2,6-dimethyldimeren". a) Phenol XXIII (47 mg) wurde in 1 ml des AcOAc—$HClO_4$-Reagenses [11] gelöst. Nach 10 Min. wurde mit Wasser zersetzt und mit Äthylacetat ausgeschüttelt. Aus der Äthylacetatphase wurde das Diacetat XXV erhalten, das nach Umkristallisieren aus Äthanol bei 176—178° schmolz. (Ausbeute 79 %). (Gef.: C 70.13; H 6.48; $COCH_3$ 25.13. Ber. für $C_{20}H_{22}O_6$: C 69.98; H 6.39; $COCH_3$ 27.07.) UV-Spektrum s. Fig. 2. IR-Banden (cm^{-1}): 1 758 (Enolester-CO), 1 738 (Ester-CO), 1 730 (Inflexion, CO), 1 615 (schwach, arom. Ring).

b) Analoge Behandlung des Monoacetats XXIV lieferte ebenfalls das Diacetat XXV.

Verseifung mit 10-proz. alkoholischem KOH in der Kälte regenerierte aus dem Diacetat XXV den Phenolalkohol XXIII.

Alkalische Verseifung des dimeren 2-Methyl-o-chinolacetats (IX, OAc statt OH). Dimeracetat IX (OAc statt OH) [5] (135 mg) wurde in 4 ml luftfreier 10-proz. alkoholischer Kalilauge 16 Std. unter N_2 stehen gelassen. Nach Verdünnen mit Wasser und Neutralisieren mit HOAc wurde ein Teil des Alkohols i.V. entfernt, wobei ein Rohprodukt ausfiel (ca 50 %), das nach Umkristallisieren aus abs. Äthanol-Benzol das *phenolische Anhydroprodukt XX*, Schmp. 184—185°, gab. Es war nach Mischschmp. und Spektren identisch mit einer nach Metlesics und Wessely [5] dargestellten Probe gleichen Schmelzpunkts. UV-Spektrum s. Fig. 2. IR-Banden wie von Metlesics und Wessely [5] angegeben; zusätzlich sei das Vorkommen einer Bande bei 1 497 cm^{-1} (arom. Ring) vermerkt.

Monoacetat XXI. Acetylierung von XX mit AcOAc-Pyridin bei Zimmertemp. gab farblose Kristalle von XXI, Schmp. nach Umkristallisieren aus Benzol-Hexan 127—129°. (Gef.: C 70.42; H 5.66. Ber. für $C_{18}H_{16}O_4$: C 70.57; H 5.92.) UV-Spektrum s. Fig. 2. IR-Banden (cm^{-1}): 3 450 (aliph. OH), 1 754 (Enolester-CO), 1 716 (CO), 1 604 (schwach, arom. Ring).

Zu den bei den entsprechenden Verbindungen angegebenen IR-Daten der *o*-Chinoldimeren sowie der Anhydrodimeren und ihrer Acetylderivate sei hier folgendes bemerkt. Während bei den *o*-Chinoldimeren (vgl. IV und VIII) sowohl die isolierte wie die konju-

gierte CO-Gruppe durch Banden normaler Lage gekennzeichnet sind, liegen die entsprechenden Banden bei den Diacetaten (IV bzw. VIII, OAc statt OH) nach ungewöhnlich hoher Frequenz verschoben; die Banden für das konjugierte CO finden sich bei 1 696 bzw. 1 702 cm^{-1}, und diejenigen des isolierten CO werden teilweise von den Estercarbonylbanden überlagert. Ähnliche Verhältnisse werden bei den Anhydrodimeren beobachtet. Sowohl die freien Verbindungen (XXIII, XX [5]) wie deren Monoacetate (mit verestertem Phenolhydroxyl) geben eine CO-Absorption normaler Lage, während bei den Diacetaten (XXV bzw. dem Diacetat von XX [5]) die entsprechenden Banden bei 1 730 bzw. 1 732 als Inflexionen, überlagert von den Estercarbonylbanden, auftreten.

Erhitzen von dimerem 2,6-Dimethyl-o-chinol (VIII) mit AcOAc—AcONa. Das Dimere VIII (2.0 g) wurde mit 20 ml AcOAc und 2 g AcONa 2 Std. unter Rückfluss erhitzt. Die Hauptmenge des Essigsäureanhydrids wurde i.V abdestilliert, der Rückstand mit Wasser zersetzt und das ausfallende Produkt in Methylenchlorid übergeführt. Der ölige Abdampfrückstand der Methylenchloridlösung wurde in warmem Äthanol gelöst. In der Kälte kristallisierten 160 mg des Anhydrodimer-diacetats XXV, Schmp. 176—178° (s.o.), Ausbeute 6 %.

Die Mutterlauge wurde vom Lösungsmittel befreit und der ölige Rückstand bei 0.005 mm Hg und 60° Badtemp. destilliert. Das Destillat kristallisierte nach nochmaliger Destillation und gab nach Umkristallisieren aus *Iso*propyläther bei —80° 795 mg (31 %) des monomeren *2,6-Dimethyl-o-chinolacetats* (XIV), Schmp. 32—34° (s.o.).

Der feste Destillationsrückstand, der leicht sublimierte, gab beim Umkristallisieren aus wenig Äthanol das *dimere 2,6-Dimethyl-o-chinolacetat (VIII, OAc statt OH)*, Schmp. 157—159° (s.o.). Ausbeute 25 %.

Unter ähnlichen Bedingungen mit AcOAc—AcONa erhitzt, lieferte das Diacetat des 2,6-Dimeren (VIII, OAc statt OH) 57 % des monomeren 2,6-Dimethyl-o-chinolacetats (XIV) und ein Gemisch des Ausgangsmaterials mit dem Anhydrodimer-diacetat XXV.

Herrn Ing. Bo Skarstedt danken wir für wertvolle Hilfe bei der Aufnahme der UV- und IR-Spektren. *Statens Tekniska Forskningsråd* danken wir für die Gewährung eines Forschungsbeitrags.

ACTA CHEMICA SCANDINAVICA 14 (1960) 1597–1611

On the Thermodynamics of Hydrated Protons Activities, Activity Coefficients and the Average Degree of Hydration

ERIK HÖGFELDT

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Activities and activity coefficients for hydrated ions in mixtures of acids with water are derived and their properties investigated. It is shown that the activity product $a_{n+} \cdot a_{n-}$ of the ions $H^+(H_2O)_{n+}$ and $A^-(H_2O)_{n-}$ (A^- = anion of the strong acid HA) must have a maximum at $X = \frac{1}{1+n}$ where X is the stoichiometric mole fraction of HA and $n = n_+ + n_-$. The maximum is obtained independent of whether the ions in question predominate or even exist.

Various activity coefficients are studied and it is found that the molarity activity coefficient for $H^+(H_2O)_4$, ClO_4^- passes through a maximum near 8 M (moles · liter^{-1}) $HClO_4$ while the corresponding function for $H^+(H_2O)_4$,NO_3^- is practically constant in the range 9–16 M HNO_3. This difference in behavior can be primarily attributed to differences in dissociation of the two acids. Above 9.5 M $HClO_4$, there is not enough water present to keep all H^+ in the form $H^+(H_2O)_4$ while, on the other hand, there is sufficient water in the HNO_3 mixtures all the way up to 16 M.

By considering hydrated ions as mononuclear complexes, ordinary complex chemistry methods can be employed to derive a function $\bar{n}'$ closely related to the "true" average degree of hydration. It is found that $\bar{n}'$ is practically the same for H^+, ClO_4^- and H^+, HSO_4^- in a large part of the range of overlap while it is smaller for H^+, NO_3^- thus implying a smaller degree of hydration for NO_3^- than for ClO_4^- and HSO_4^-. For the ion pair H^+, HSO_4^- $\bar{n}'$ tends towards unity upon approaching pure acid. It is also shown that a maximum ionic concentration will appear at $X = \frac{1}{1+\bar{n}'}$. For H_2SO_4 and $HClO_4$, the maximum is located in the range $X = 0.4–0.5$ while HNO_3 has its maximum at about $X = 0.2–0.3$ consistent with the view that HNO_3 forms a compound $HNO_3 \cdot H_2O$ before it starts to dissociate.

In dealing with electrolyte solutions, Bjerrum [1] and Scatchard [2,3] made use of a simple model in which ions and molecules are considered to bind part of the solvent giving solvated species that are dissolved in the remaining free solvent. This distinction between two different kinds of water, free water and water bound as water of hydration, has been used in several instances

and recently by Stokes and Robinson [4a] as well as Glueckauf [5] and Miller [6] in their attempts to evaluate hydration numbers. All these treatments were restricted to dilute solutions where the average degree of hydration can be imagined to stay practically constant. However, upon decreasing the water content in the system by increasing the ionic concentration, the amount of water considered as bound as water of hydration must decrease. In case of the proton, it has been suggested that $H^+(H_2O)_4$ should be an especially stable complex in dilute solutions [5,7—10]. In concentrated solutions, most of this water is stripped off until H_3O^+ is finally obtained which seems to be the predominating proton species in these solutions [11a] and so stable that it may be recovered in the crystalline state [12].

In the following, the properties of the activities and activity coefficients of hydrated ions are investigated. Since $H^+(H_2O)_4$ and H_3O^+ seem to be so stable as to be experimentally observable, the thermodynamic functions for these two compositions of the hydrated proton will be evaluated and used as examples. We shall then construct a function approximating the average degree of hydration and investigate its bearing on the maxima in ionic concentration found in mixtures of strong acids with water.

Some of the results below have been given in a preliminary note [11b].

LIST OF SYMBOLS

a_{H^+}, a_{A^-}, a_{HA}	Activities of H^+, A^-, HA *etc.*
a_{n+}, a_{n-}	» » $H^+(H_2O)_{n+}$, $A^-(H_2O)_{n-}$
a_1, a_4	» » H_3O^+ and $H^+(H_2O)_4$
y_+, y_-	"True" molarity activity coefficients of various hydrated ions
y_{n+}, y_{n-}	Stoichiometric molarity activity coefficients of $H^+(H_2O)_{n+}$ and $A^-(H_2O)_{n-}$
y_1, y_4	Stoichiometric molarity activity coefficients of H_3O^+ and $H^+(H_2O)_4$
$y = [y_{H^+} \cdot y_{A^-}]^{\frac{1}{2}}$	Stoichiometric molarity mean activity coefficient of H^+, A^-
γ_{n+}, γ_{n-}	» molarity activity coefficients of $H^+(H_2O)_{n+}$ and $A^-(H_2O)_{n-}$
$\gamma = [\gamma_{H^+} \cdot \gamma_{A^-}]^{\frac{1}{2}}$	Stoichiometric molality mean activity coefficient of H^+, A^-
f_{n+}, f_{n-}	» mole fraction activity coefficients of $H^+(H_2O)_{n+}$ and $A^-(H_2O)_{n-}$
$f = [f_{H^+} \cdot f_{A^-}]^{\frac{1}{2}}$	Stoichiometric mole fraction mean activity coefficient of H^+, A^-
C_{H^+}, C_{A^-}	Molarities of H^+, A^-
C	Stoichiometric molarity of acid
m_{H^+}, m_{A^-}	Molalities of H^+, A^-
m	Stoichiometric molality of acid
X_{H^+}, X_{A^-}	Mole fraction of H^+, A^-
X	Stoichiometric mole fraction of acid
K, K_n	Equilibrium constants
N_{H_2O}, N_{HA}	Number of moles of H_2O and HA mixed together

n	Number of water molecules attached to an ion
$\bar{n}$	Average degree of hydration
$\bar{n}'$	Function approximating $\bar{n}$
S^+, S, S^-	$S = \Sigma K_n a_{H_2O}^n$ Function appearing in the treatment of complex equilibria
α	Degree of dissociation

SELECTION OF EXPERIMENTAL DATA

In the choice of experimental data for the computation of thermodynamic functions involving hydrated ions, the measurements that appear to be the most careful have been used wherever possible.

The data selected will now be discussed for each acid in turn.

a) *Hydrochloric acid.* Densities of HCl solutions at 25°C, necessary for the transformation from the molality to the molarity scale, were computed from the formulas given by Åkerlöf and Teare [13]. Stoichiometric mean activity coefficients were taken from Harned and Owen [14] for dilute solutions and from Robinson and Stokes for concentrated solutions [4b]. The activity coefficients of Harned and Owen are based on emf measurements by Harned and Ehlers [15]. The activities of Robinson and Stokes are calculated from their own isopiestic measurements [16,17] and agree well with those of Åkerlöf and Teare [18] obtained from emf measurements. Water activities were computed from osmotic coefficients given by Robinson and Stokes [4c].

b) *Perchloric acid.* Densities for $HClO_4$ solutions at 25°C have been taken from Markham [19] and water activities together with stoichiometric mean activity ceofficients from Robinson and Baker [20] who used the isopiestic method. These data seem to be accepted as being the best available at present [21]. For estimating the concentration of various species, the results from the NMR (nuclear magnetic resonance) measurements by Hood, Redlich and Reilly [21] have been used, which values show a better consistency than the Raman measurements by Redlich, Holt and Bigeleisen [22].

c) *Nitric acid.* Densities of HNO_3 solutions at 20°C have been taken from Landolt-Börnstein [23a]. Concerning water and nitric acid activities at this temperature, the agreement between different investigations is not as good as could be desired [23b, 24—26]. For this reason, it is difficult to make a choice between the various data. However, those by Potier [26] have been chosen because of the large concentration range studied and the reasonably good internal consistency.

The concentrations of the species present have been determined with the Raman technique by Redlich and Bigeleisen [27] and by Young and Krawetz [28,29a]. Concentrations determined from NMR measurements by Redlich *et al* [21]. are said to agree well with the Raman measurements by Krawetz [29a]. The precision of the NMR measurements is not quite so good as for the Raman method but the NMR data were the only data accessible to the present writer and they have been used in this paper.

d) *Sulfuric acid.* Densities of H_2SO_4 solutions at 25°C have been taken from the International Critical Tables [30]. When the present investigation

was begun, the best available thermodynamic data for sulfuric acid seemed to be the recent isopiestic measurements by Glueckauf and Kitt [31] which agree well with the vapor pressure measurements of Shankman and Gordon [32] and Hornung and Giauque [33]. The measurements of Glueckauf and Kitt stop around 16 M (moles · liter^{-1}). Now Deno and Taft [34] have given water activities up to nearly pure H_2SO_4 using a simple empirical relation between the water activity and the Hammett acidity function, H_0. Both sets of values agree well in the overlapping part of the range. The present writer has used Deno and Taft's water activities to compute the corresponding sulfuric acid activities by graphical integration with the aid of the Gibbs-Duhem equation. The value for pure sulfuric acid obtained by extrapolation, $\log a^2_{H^+} \cdot a_{SO_4^{--}} = 9.55$, differs considerably from the value 8.76 estimated by Abel [35] from literature data available at that time. However, thanks to the courtesy of Professor Giauque, a set of thermodynamic data, unpublished at that time, for sulfuric acid collected during the course of many years in Berkeley [36] were made available to the present writer. The value for pure sulfuric acid at 25°C is $\log a^2_{H^+} \cdot a_{SO_4^{--}} = 9.53$ which is so close to the value found from the data of Deno and Taft that their empirical method for correlating water activities with H_0 must be regarded as essentially correct. The water activity and the stoichiometric activity coefficient of H_2SO_4 obtained by Giauque *et al.* agree within a few per cent with those of Glueckauf and Kitt in the overlapping section of the range. This is such a good agreement that no recalculation using the data of Giauque *et al.* seemed necessary.

For the concentrations of the species present, Raman [29a,37] and NMR [38] measurements are available. The Raman measurements reported by Young *et al.*[29a] are believed to be more accurate than the early measurements reported by Young and Blatz [37,39]. Since the evaluation of the NMR data depends upon the Raman measurements, no decisive information about the correctness of the Raman data can be obtained from them. In the following, the more recent Raman data [29a] will be used.

ACTIVITIES

Definitions. In the Bjerrum treatment of solvation, ions are assumed to bind the solvent to form solvated ions. For the acid HA, we wish to consider the following reaction:

$$HA + n\ H_2O \rightleftharpoons H^+(H_2O)_{n_+} + A^-\ (H_2O)_{n_-} \tag{1}$$

where

$$n = n_+ + n_- \tag{2}$$

Application of the law of mass action to (1) gives:

$$a_{H^+(H_2O)_{n+}} \cdot a_{A^-(H_2O)_{n-}} = K_n \cdot a_{HA} \cdot a^n_{H_2O} \tag{3a}$$

For the sake of simplicity in notation, we write:

$$\begin{aligned} a_{n+} &= a_{H^+(H_2O)_{n+}} \\ a_{n-} &= a_{A^-(H_2O)_{n-}} \end{aligned} \tag{4a, b}$$

and thus

$$a_{n+} \cdot a_{n-} = K_n \cdot a_{HA} \cdot a^n_{H_2O} \tag{3b}$$

For the dissociation into unhydrated ions, we have

$$a_{H^+} \cdot a_{A^-} = K \cdot a_{HA} \tag{5}$$

where K is the thermodynamic dissociation constant of HA. The activities of H_+ and A^- are defined such that they approach the analytical concentrations of these ions in dilute solutions. From (3b) and (5) it is found:

$$a_{n+} \cdot a_{n-} = \frac{K_n}{K} \cdot a_{H^+} \cdot a_{A^-} \cdot a^n_{H_2O}$$

The simplest way of relating the activity scale of hydrated ions to that of the unhydrated ions is to define

$$K_n = K \qquad n = 1, 2 \ldots . \tag{6}$$

for all possible values of n. We thus obtain:

$$a_{n+} \cdot a_{n-} = a_{H^+} \cdot a_{A^-} \cdot a^n_{H_2O} \tag{7}$$

Since $a_{H_2O} \rightarrow 1$ when approaching infinite dilution, the reference state of the hydrated ions is the same as for the unhydrated ions, *i.e.* the activity tends towards the analytical concentration upon dilution. Since the activity product $a_{H^+} \cdot a_{A^-}$ can be obtained from the stoichiometric activity coefficients and water activities which are either tabulated directly or can be computed from osmotic coefficients reported in the literature, the activity products given by (7) can be evaluated for several strong acids and often over considerable concentration ranges.

The maximum. From eqn. (7), it is seen that the activity product of the hydrated ions is composed of two terms, one containing the activity product of the unhydrated ions and the other the activity of water. Since the first term increases monotonically and tends towards a finite limit and the second, the water activity, decreases monotonically towards zero with increasing concentration of acid, there must be a maximum for the activity product of the hydrated ions. In order to investigate this, (5) is substituted in (7), *i.e.*

$$a_{n+} \cdot a_{n-} = K \cdot a_{HA} \cdot a^n_{H_2O} \tag{8}$$

Logarithmic differentiation of (8) gives:

$$\mathrm{d}\ln a_{n+} + \mathrm{d}\ln a_{n-} = \mathrm{d}\ln a_{HA} + n\mathrm{d}\ln a_{H_2O} \tag{9}$$

Application of the Gibbs-Duhem equation to this system gives:

$$N_{HA}\, \mathrm{d}\ln a_{HA} = -N_{H_2O}\, \mathrm{d}\ln a_{H_2O} \tag{10}$$

N_{HA} and N_{H_2O} are the number of moles of HA and H_2O mixed together. By inserting (10) into (9) and using the condition that at the maximum $\mathrm{d}\ln a_{n+} + \mathrm{d}\ln a_{n-} = 0$ we find:

$$\mathrm{d}\ln a_{H_2O} \left(n - \frac{N_{H_2O}}{N_{HA}} \right) = 0$$

Since $\mathrm{d}\ln a_{H_2O} \neq 0$, the maximum must be located at the stoichiometric mole fraction of acid given by:

$$X = \frac{1}{1+n} \tag{11}$$

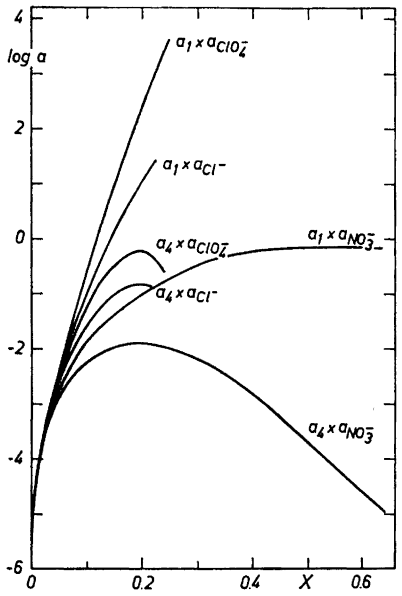

Fig. 1. The logarithms of the mole fraction activity products $a_1 \cdot a_A$- and $a_4 \cdot a_A$- plotted *versus* stoichiometric mole fraction, X, of acid for the three acids: HNO_3, HCl and $HClO_4$.

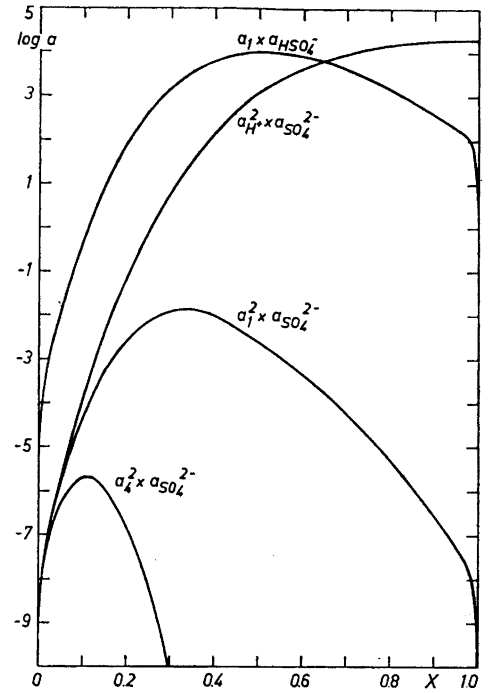

Fig. 2. The logarithms of the mole fraction activity products $(a_{H+})^2 \cdot a_{SO_4^{2-}}$, $a_1 \cdot a_{HSO_4^-}$, $a_1^2 \cdot a_{SO_4^{2-}}$ and $a_4^2 \cdot a_{SO_4^{2-}}$ plotted versus X.

This maximum is a purely thermodynamic consequence and shows that the activity product $a_{n+} \cdot a_{n-}$ has a maximum when the solution has the corresponding composition HA, n H_2O. The maximum is obtained independent of whether the ions in question exist or not.

Comparison of the activity products for two different n*-values.* Since many differently hydrated ions are possible, a large number of activity products $a_{n+} \cdot a_{n-}$ can be constructed. In order to study the properties of these activities, the following two special cases will be considered:

$$a_{H_3O+} \cdot a_{A^-} = a_1 \cdot a_{A^-} = a_{H+} \cdot a_{A^-} \cdot a_{H_2O} \quad (12a)$$

$$a_{H+(H_2O)_4} \cdot a_{A^-} = a_4 \cdot a_{A^-} = a_{H+} \cdot a_{A^-} \cdot a^4_{H_2O} \quad (12b)$$

where a_1 and a_4 are convenient notations. In Fig. 1, the activity products (12) on the mole fraction scale for the two acids HNO_3 and $HClO_4$ are plotted *versus* the stoichiometric mole fraction of acid. As is seen, the maximum of $a_4 \cdot a_{A^-}$ appears, for both acids, at $X = 0.2$. For HNO_3, the maximum for $a_1 \cdot a_{A^-}$ at $X = 0.5$ is hard to locate since the curve is very flat. For $HClO_4$, data are not available up to $X = 0.5$.

The only strong acid which has been studied over the whole concentration range from pure water to pure acid is sulfuric acid. In Fig. 2, the mole fraction activity products, $(a_{H^+})^2 \cdot a_{SO_4^{2-}}$, $a_1 \cdot a_{HSO_4^-}$ $a_1^2 \cdot a_{SO_4^{2-}}$ and $a_4^2 \cdot a_{SO_4^{2-}}$, are plotted on a logarithmic scale against stoichiometric mole fraction of H_2SO_4. The activity product $a_1 \cdot a_{HSO_4^-}$ can be computed from $(a_{H^+})^2 \cdot a_{SO_4^{2-}}$ and a_{H_2O} with knowledge of the second dissociation constant of sulfuric acid. The value $pK_{HSO_4^-} = 2.00$ for 25°C recently suggested by Hamer [29b] from considerations of available literature data has been accepted. This value agrees well with $pK_{HSO_4^-} = 2.01$ calculated by Kerker [40] from transference and conductance data. The activity product $a_1 \cdot a_{HSO_4^-}$ can now be computed from

$$\log a_1 \cdot a_{HSO_4^-} = \log (a_{H^+})^2 \cdot a_{SO_4^{2-}} \cdot a_{H_2O} \cdot K^{-1}_{HSO_4^-} =$$
$$= \log (a_{H^+})^2 \cdot a_{SO_4^{2-}} + \log a_{H_2O} + 2.00 \qquad (13)$$

As seen from Fig. 2, all functions have maxima as requested by (11). The function $(a_{H^+})^2 \cdot a_{SO_4^{2-}}$ can be considered as a special case with $n = 0$ for which (11) gives a maximum for the pure acid.

ACTIVITY COEFFICIENTS

For the acids, $HClO_4$, HNO_3 and H_2SO_4, Raman and NMR methods have been used to distinguish between the undissociated and dissociated parts of acids in concentrated solutions. It is thus possible to compute activity coefficients and study their properties.

a) *Definitions.* For the strong acid HA where the concentrations of the species present have been estimated using one of the methods mentioned above, the ionic activity coefficient products on the molarity scale for $H^+(H_2O)_{n+}$, $A^-(H_2O)_{n-}$ can be computed from

$$y_{n+} \cdot y_{n-} = \frac{a^c_{n+} \cdot a^c_{n-}}{(\alpha C)^2} \qquad (14a)$$

where the superscript c refers to the molarity scale, α is the degree of dissociation and C the stoichiometric molarity of HA.

The analogous expressions on the molality (m) and mole fraction (x) scales are:

$$\gamma_{n+} \cdot \gamma_{n-} = \frac{a^m_{n+} \cdot a^m_{n-}}{m_{H^+} \cdot m_{A^-}}; \quad f_{n+} \cdot f_{n-} = \frac{a^x_{n+} \cdot a^x_{n-}}{x_{H^+} \cdot x_{A^-}} \qquad (14b, c)$$

The activity coefficients in (14) have the same reference state as ordinary activity coefficients, *i.e.* they approach unity at infinite dilution. In the evaluation of these activity coefficients, the total ionic concentration is used because of the difficulty of making a distinction between differently hydrated ions. They are thus stoichiometric activity coefficients which approach the true ones at those concentrations where the corresponding ionic species may predominate.

b) *Properties.* The stoichiometric activity coefficients of the hydrated ions are related to the ordinary stoichiometric activity coefficients in the following way:

$$y_{n+} \cdot y_{n-} = \left(\frac{y}{a}\right)^2 \cdot a^n_{H_2O}$$

$$\gamma_{n+} \cdot \gamma_{n-} = \left(\frac{\gamma}{a}\right)^2 \cdot a^n_{H_2O} \, [1 - a\, n \cdot m \cdot (55.51)^{-1}]^2 \qquad (15a, b, c)$$

$$f_{n+} \cdot f_{n-} = \left(\frac{f}{a}\right)^2 \cdot a^n_{H_2O} \, [1 - a(n-1)X]^2$$

The term $(n\text{-}1)$ appearing in (15c) is due to the convention that, in the evaluation of the mole fractions, the ions of the dissociated acid are counted as separate entities. For $n = 0$, (15b) degenerates into the relation $\gamma_{H^+} \cdot \gamma_{A^-} = \left(\frac{\gamma}{a}\right)^2$ used by Robinson and Stokes [4]. From (15), it is seen that the activity coefficient product of the hydrated ions will always be smaller than that of the unhydrated ions because $a_{H_2O} \leq 1$.

It can be shown from (15) that the ratio of the activity coefficient product of any pair of hydrated ions to that of the unhydrated ions will in pure acid be the same for all three kinds of activity coefficients and equal to $a^n_{H_2O}$, where a_{H_2O} refers to the activity of water in pure acid.

c) *Comparison of activity coefficient products for some different* n*-values.* For the two cases H_3O^+, A^- and $H^+(H_2O)_4$, A^- considered in the discussion of the activities, the activity coefficients on the molarity scale take the form:

$$y_1 \cdot y_{A^-} = \left(\frac{y}{a}\right)^2 \cdot a_{H_2O} \qquad (16a)$$

$$y_4 \cdot y_{A^-} = \left(\frac{y}{a}\right)^2 \cdot a^4_{H_2O} \qquad (16b)$$

As seen from (15), the activity coefficients take the most simple form on the molarity scale because it is not necessary to distinguish between free and bound water when evaluating the molarities of the constituents present.

In Fig. 3, $\log y_1 \cdot y_{A^-}$ and $\log y_4 \cdot y_{A^-}$ are plotted against the stoichiometric molarity of the acid for HNO_3 and $HClO_4$. It is not suitable to plot the activity

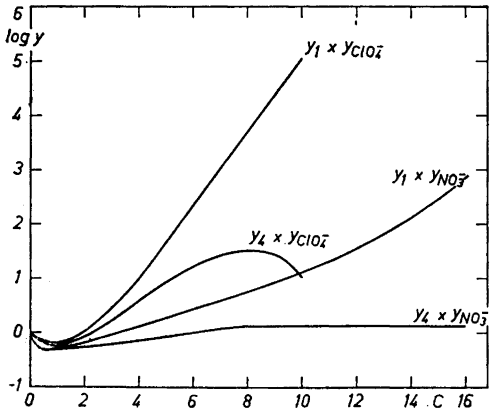

Fig. 3. The molarity activity coefficients $y_1 \cdot y_{A^-}$ and $y_4 \cdot y_{A^-}$ plotted on a logarithmic scale *versus* stoichiometric molarity of acid, C, for HNO_3 and $HClO_4$.

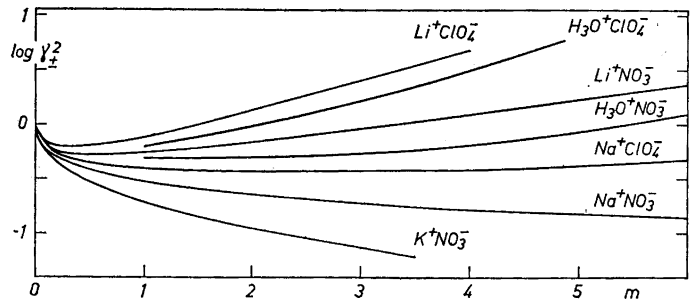

Fig. 4. The logarithms of the stoichiometric molality activity coefficients $\gamma_+ \cdot \gamma_-$ for $LiClO_4$, $LiNO_3$, $NaClO_4$, $NaNO_3$, KNO_3, H_3O^+, ClO_4^-, and H_3O^+, NO_3^- plotted *versus* the stoichiometric molality m.

coefficients *versus* the ionic strength or the total ionic concentration since these quantities go through a maximum and do not lead to single-valued activity coefficient functions.

It should be noted that, while $y_4 \cdot y_{ClO_4^-}$ goes through a maximum near 8 M $HClO_4$, $y_4 \cdot y_{NO_3^-}$ seems to be practically constant in the range 9—16 M HNO_3. On the other hand, both curves $y_1 \cdot y_{A^-}$ rise steeply. The maximum of $y_4 \cdot y_{ClO_4^-}$ can be imagined to be due to overcompensation caused by assuming too high a hydration number. From the data of Redlich *et al.*[21] near 9.5 M $HClO_4$, it appears that the amount of water present has decreased to four times that of H^+. Above this concentration, there is not enough water present to have all protons in the form of $H^+(H_2O)_4$. This may be the main reason for the maximum in $y_4 \cdot y_{ClO_4^-}$.

For HNO_3 on the other hand, the data by Redlich *et al.*[21] show that the amount of water present is at least six times that of H^+ even at 16 M HNO_3. For this acid, there is sufficient water to have a considerable fraction of the

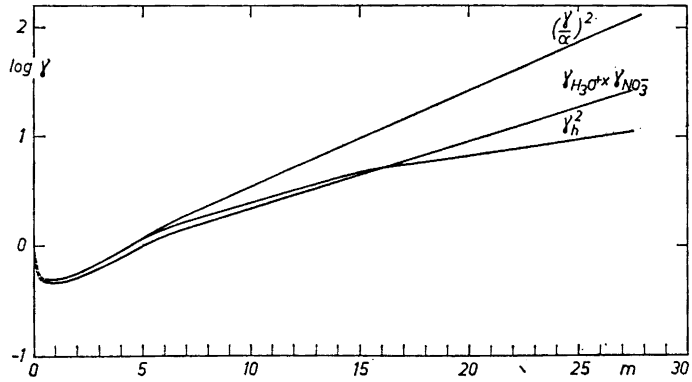

Fig. 5. log $\gamma_{H_3O^+} \cdot \gamma_{NO_3^-}$ compared with log $\left(\frac{\gamma}{a}\right)^2$ and log γ_h^2.

protons as $H^+(H_2O)_4$ or $H^+(H_2O)_3$. The nearly constant value of $y_4 \cdot y_{NO_3^-}$ between 9 and 16 M might thus be due to a practically negligible displacement of the proton equilibria towards less hydrated protons over almost the whole range of dissociation of HNO_3. On the other hand, for stronger acids like $HClO_4$, there is a change from something like $H^+(H_2O)_4$ in dilute solutions towards H_3O^+ in concentrated solutions.

Since free protons do not seem to exist in water solutions in measurable amounts, it is natural to consider H_3O^+ as the primary proton species which like any other ion upon dilution undergoes further hydration. Since H_3O^+ is a singly charged ion of a size comparable to K^+, it might be of interest to compare the molality activity coefficient products of H_3O^+, NO_3^- and H_3O^+, ClO_4^- with those of some related 1:1 electrolytes. This has been done in Fig. 4 where log $\gamma_{X^+} \cdot \gamma_{A^-}$ is plotted *versus* the stoichiometric molality for $LiClO_4$, $LiNO_3$, $NaNO_4$, KNO_3, N_3O^+, ClO_4^- and H_3O^+, NO_3^-. As seen, H_3O^+ falls between Li^+ and Na^+ for both NO_3^- and ClO_4^-. Upon considering only the size effect, one should have expected H_3O^+ to fall closer to K^+. The order of decreasing activity coefficients suggests that the degree of hydration decreases in the order $Li^+ > H_3O^+ > Na^+ > K^+$ in qualitative agreement with recent estimates[4a,5,6] although the different authors do not agree about the magnitude of the hydration numbers.

McKay[41] has recently evaluated an activity coefficient for the ionized part of HNO_3 where the tries to account formally for the influence of undissociated acid on the ions. In Fig. 5, this activity coefficient, γ_h, is compared with those of H^+, NO_3^- and H_3O^+, NO_3^-. Log γ_h^2 was computed from

$$\log(\gamma_h)^2 = \log\left(\frac{\gamma}{a}\right)^2 - 0.048\ (1-a) \cdot m$$

For the derivation of this expression, the reader is referred to the original paper. As seen in Fig. 5, γ_h^2 is close to $\left(\frac{\gamma}{a}\right)^2$ in dilute solutions while in concentrated solutions it falls below $\gamma_{H_3O^+} \cdot \gamma_{NO_3^-}$. Although the construction of γ_h contains an interesting attempt to correct for the influence of undissociated acid on the ionic activity coefficients, it suffers from the defect of referring to unhydrated protons and not to the actual species present.

A FUNCTION APPROXIMATING TO THE AVERAGE DEGREE OF HYDRATION

Considerations of only one kind of hydrated ionic species at a time must necessarily always be very crude. By considering the more realistic case of the simultaneous existence of several differently hydrated ionic constituents and by applying ordinary complex chemistry methods to the ion-water equilibria, a function closely related to the average degree of hydration can be derived as follows:

For the two types of reactions (n may have several values):

$$\left.\begin{aligned} H^+ + n\ H_2O &\rightleftharpoons H^+(H_2O)_n \\ A^- + n\ H_2O &\rightleftharpoons A^-(H_2O)_n \end{aligned}\right\} \qquad (17a, b)$$

the law of mass action gives:

$$\left.\begin{aligned} C_{H^+(aq)} &= \frac{K_n}{y_+} \cdot a_{H^+} \cdot a^n_{H_2O} \\ C_{A^-(aq)} &= \frac{K_n}{y_-}\, a_{A^-} \cdot a^n_{H_2O} \end{aligned}\right\} \qquad (18a, b)$$

We can now sum over all differently hydrated ionic constituents and get

$$\left.\begin{aligned} C_{H^+} = aC = \Sigma\, C_{H^+(aq)} &= \frac{a_{H^+}}{y_+} \Sigma\, K_{n+} \cdot a^n_{H_2O} = \frac{a_{H^+}}{y_+} \cdot S^+ \\ C_{A^-} = aC = \Sigma\, C_{A^-(aq)} &= \frac{a_{A^-}}{y_-} \Sigma\, K_{n-}\, a^n_{H_2O} = \frac{a_{A^-}}{y_-} \cdot S^- \end{aligned}\right\} \qquad (19a, b)$$

In the derivation of (19), it is assumed that the activity coefficients of the differently hydrated protons are the same ($= y_+$) and can be placed outside the summation sign and analogously for the anions.

The sums S^+ and S^- are functions appearing in the mathematical treatment of complex equilibria. They have the property:

$$\frac{\mathrm{d}\log S}{\mathrm{d}\log a_{H_2O}} = \frac{\Sigma\, n\, K_n\, a^n_{H_2O}}{\Sigma\, K_n\, a^n_{H_2O}} = \bar{n} \qquad (20)$$

where $\bar{n}$ is the average number of water molecules attached to the ion under consideration.

By multiplying (19a) with (19b) and inserting the stoichiometric activity coefficient $y = \left[\frac{a^c_{H^+} \cdot a^c_{H}}{C_{H^+} \cdot C_{A^-}}\right]^{\frac{1}{2}} = (y_{H^+} \cdot y_{A^-})^{\frac{1}{2}}$ we get after differentiation and use of equation (20):

$$\mathrm{d}\log(y_+ \cdot y_-)/\mathrm{d}\log a_{H_2O} - \mathrm{d}\log\left(\frac{y}{a}\right)^2 / \mathrm{d}\log a_{H_2O} = \bar{n}_+ + \bar{n}_- = \bar{n} \qquad (21)$$

In (21), all quantities except $y_+ \cdot y_-$ are known from experimental measurements. Various attempts to estimate related activity coefficient products have been made in recent papers on ionic hydration [4a,5,6]. However, these treatments employ the Debye-Hückel expression which is likely to break down in concentrated solutions. Because of our lack of knowledge of how to correct for electrostatic interactions in concentrated solutions of electrolytes, (21) cannot be employed for computing absolute $\bar{n}$-values. It can be used, however, for the computation of relative hydration numbers. When comparing the two acids HA and HB at the same water activity, we get from (21)

$$\mathrm{d}\log\left(\frac{y}{a}\right)^2_{HA} / \mathrm{d}\log a_{H_2O} - \mathrm{d}\log\left(\frac{y}{a}\right)^2_{HB} / \mathrm{d}\log a_{H_2O} = \bar{n}_{B^-} - \bar{n}_{A^-} \qquad (22)$$

if the assumption

$$\frac{\mathrm{d}\log y_{A^-}}{\mathrm{d}\log a_{H_2O}} = \frac{\mathrm{d}\log y_{B^-}}{\mathrm{d}\log a_{H_2O}} \qquad (23)$$

is correct. Even if not strictly valid, (23) might be a good first approximation and thus eqn. (22) may give reasonably good relative hydration numbers.

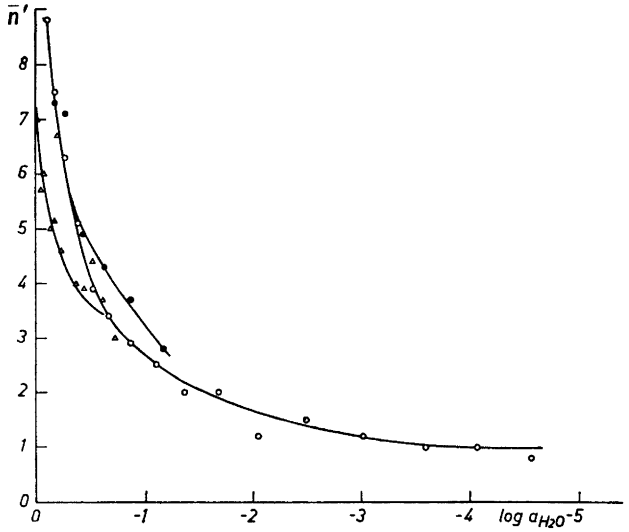

Fig. 6. The function $\bar{n}'$ for various ion pairs plotted *versus* log a_{H_2O}.
○ H^+, HSO_4^-
● H^+, ClO_4^-
△ H^+, NO_3^-

We can also use (21) to define an approximation to $\bar{n}$. From (21) we get

$$\bar{n}' = -\,\mathrm{d}\,\log\left(\frac{y}{a}\right)^2 / \,\mathrm{d}\,\log a_{H_2O} = \bar{n} - \mathrm{d}\log y_+ y_- / \mathrm{d}\log a_{H_2O} \qquad (24)$$

This approximation may be expected to be bad in dilute solutions because the activity coefficients vary very much while a_{H_2O} varies rather little. In concentrated solutions, on the other hand, activity coefficients seem to vary relatively little while the variation of a_{H_2O} is large and the function $\frac{\mathrm{d}\log y_+ \cdot y_-}{\mathrm{d}\log a_{H_2O}}$ therefore close to zero. One might thus expect $\bar{n}'$ to approach $\bar{n}$ in very concentrated solutions.

In order to study the behavior of $\bar{n}'$, this function, calculated according to (24), is plotted in Fig. 6 *versus* log a_{H_2O} for the three ion pairs: H^+, ClO_4^-, H^+, NO_3^- and H^+, HSO_4^-. As seen, the curves for H^+, ClO_4^- and H^+, HSO_4^- prachically coincide at high water activities. On the other hand, the curve for H^+, NO_3^- lies below the two others indicating a smaller degree of hydration for NO_3^- as compared with ClO_4^- and HSO_4^-. Unfortunately, there is a large scattering in the data for H^+, NO_3^- — it seems however that, in dilute solutions, ClO_4^- and HSO_4^- contain 2—3 more H_2O in the hydration shell as compared with NO_3^-. In more concentrated solutions, this difference decreases to ½—1 around log $a_{H_2O} = -0.5$. It should also be noted that, in the range $-0.3 >$ log $a_{H_2O} > -0.9$ corresponding to 9—16 M HMO_3^- $\bar{n}'$ varies rather little in agreement with previous considerations of $y_4 \cdot y_{NO_3^-}$

in the same concentration range. For the pair H^+, HSO_4^-, it is interesting to note that $\bar{n}' \rightarrow 1$ upon approaching pure H_2SO_4. This result seems reasonable since $H^+(H_2O)_n$ can be imagined to tend towards H_3O^+ and HSO_4^- to loose all its water of hydration with decreasing water activity. From the data presented here, it cannot be definitely concluded whether the remaining water molecule in the hydration shell belongs to H^+ or HSO_4^-. However, in a following paper, evidence is given that H^+ is likely to exist as H_3O^+ in concentrated solutions of H_2SO_4[11a]. The fact that $\bar{n}'$ tends towards a plausible limit lends support to the suggestion that $d \log y_+ \cdot y_-/d \log a_{H_2O} \approx 0$ in concentrated solutions and thus $\bar{n}' \approx \bar{n}$.

THE MAXIMUM IN IONIC CONCENTRATION

From Raman and NMR measurements in mixtures of strong acids with water, it has been found that each ionic constituent has a maximum concentration at a certain composition of the mixture. The location of this maximum can be correlated with the hydration of the ions in the following manner.

By multiplying (19a) and (19b) we get

$$C_{H^+} \cdot C_{A^-} = (C_{A^-})^2 = \frac{a^c_{H^+} \cdot a^c_{A^-}}{y_+ \cdot y_-} \cdot S^+ \cdot S^- = \frac{K \cdot a_{HA}}{y_+ \cdot y_-} \cdot S^+ \cdot S^- \qquad (25)$$

Differentiating (25) logarithmically, using the definition of $\bar{n}'$ given by (24) and the condition that at the maximum $d \log C_{A^-} = 0$ gives, after combining with the Gibbs-Duhem equation (10):

$$X = \frac{1}{1 + \bar{n}'} \qquad (26)$$

Eqn. (26) is obviously an extention of (11). In order to estimate which $\bar{n}'$-values correspond to the maxima found experimentally, the locations of the maximum ionic concentration for NO_3^-, ClO_4^- and HSO_4^- are compared with equation (26) in Table 1.

As seen from Table 1, the ions ClO_4^- and HSO_4^- have their maximum concentration in a range where $\bar{n}' \approx 1-2$ while NO_3^- has its maximum in a more

Table 1. Comparison of experimental material with eqn (26).

$\bar{n}'$	X Eqn. (26)	X Exptl. NO_3^-	ClO_4^-	HSO_4^-

4	0.20			

* Quoted from Ref[41].

dilute solution where $\bar{n}' \approx 3-4$. This might be due to the weaker dissociation of HNO_3. If we consider the reaction:

$$HA + H_2O \rightleftharpoons H_3O^+ + A^- \qquad (27a)$$

an infinitely strong acid will give one H_3O^+ and one A^- for every H_2O added. In such a case, the maximum will be at $X = 0.5$. Weaker acids on the other hand will have their maxima displaced towards lower concentrations. The maxima for $HClO_4$ and H_2SO_4 near $X = 0.5$ imply that these acids should be considered very strong and much stronger than HNO_3. It is surprising that such a difference is not more emphasized in the values of the thermodynamic dissociation constants of HNO_3 (22)[21] and $HClO_4$(38)[21]. If, on the other hand, HNO_3 first reacts with water to form a compound like $HNO_3.H_2O$ before it dissociates, then the reaction might be:

$$HNO_3 \cdot H_2O + H_2O \rightleftharpoons H^+ (H_2O)_{n_+} + NO_3^- (H_2O)_{n_-} \qquad n_+ + n_- = 2 \qquad (27b)$$

and the maximum in ionic concentration would be located somewhere below $X = 0.33$. The dissociation constant could nevertheless be of the same order of magnitude as that of $HClO_4$ in spite of the lower dissociation. Actually there is evidence that HNO_3 forms hydrates before it dissociates and also the Raman measurements show that the dissociation starts near the composition $HNO_3 \cdot H_2O$. These results support the dissociation reaction (27b) rather than (27a) for HNO_3.

For H_2SO_4, $X = 0.42$ gives $\bar{n}' = 1.40$ which implies that at the maximum concentration of HSO_4^- practically all of the free water has become bound as water of hydration. Now, the Raman measurements by Young et al show that measurable amounts of H_2SO_4 start to appear at about the same concentration. It thus seems that molecules of H_2SO_4 cannot appear until nearly all of the free water has been tied up as water of hydration.

The Crystal Structure of $Mo_{17}O_{47}$

LARS KIHLBORG

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

A crystal structure determination has been carried out on the $\varkappa$-molybdenum oxide, which has confirmed the proposed formula $Mo_{17}O_{47}$ and the orthorhombic space-group *Pba*2 for this phase.

The structure may be considered as built up from MoO_6 octahedra and pentagonal MoO_7 bipyramids. The Mo—O distances within the latter are rather unequal suggesting that the coordination is not so high as sevenfold. Fairly short O—O distances (mean value 2.32 Å) have been observed within the pentagonal rings of the oxygens in these bipyramids.

The polyhedra are connected in one dimension through common corners and in two dimensions by sharing corners and edges. A distance of 2.64 Å between two molybdenum atoms suggests a direct bond between them of the same kind as is known for example in several transition metal dioxides.

The structure is closely related to that of $W_{18}O_{49}$, previously determined by Magnéli, and this relationship is discussed.

The results of a phase analysis study of the MoO_2—MoO_3 region of the molybdenum — oxygen system were recently published in this journal [1]. In the course of these investigations a phase of composition near $MoO_{2.78}$ was observed formed below 560° ± 10°C and was designated the *$\varkappa$-oxide*. From its X-ray powder pattern, obtained with a Guinier focussing camera using Cu$K\alpha$ radiation, the following dimensions were derived for the orthorhombic unit cell:

$a = 21.61_5$ Å, $b = 19.63_2$ Å, $c = 3.951_5$ Å.

The observed density was found to be consistent with the formula $Mo_{17}O_{47}$, having 2 formula units in the unit cell.

A structure determination of this phase has now been carried out on the basis of single crystal data and is presented in this article.

EXPERIMENTAL

Details concerning the preparation of the oxide are given in Ref.[1] The single crystals obtainable were in the form of very thin, fragile needles which were too small to give reflexions with MoK radiation within reasonable time. The crystal investigated had a

length of 0.15 mm and a rectangular cross-section of 0.012 × 0.002 mm². The pronounced needle shape allowed the crystal to be rotated about the needle axis only, this being the *c*-axis of the unit cell. The layer lines *hk*0 to *hk*3 were registered in a Weissenberg camera with Cu*Ka* radiation using the multiple film technique. The intensities were estimated visually and the various layer lines were correlated by exposing parts of each of them on the same pack of films, using carefully controlled exposure times and radiation conditions [2].

A few photographs were also taken with a Buerger precession camera, which allowed 00*l* reflexions to be registered.

Lorentz-polarization corrections were applied by the method given by Löfgren [3]. The *hk*0 reflexions were corrected for the effect of absorption by means of a graphical method developed by Hesse [4]. In this way a set of relative structure amplitudes were obtained which were later brought to an absolute scale by comparison with the calculated structure factors.

Most of the calculations were carried out by means of the digital computers BESK and Facit EDB in Stockholm. A description of some of the programmes used with these machines has recently been published [5,6]. The atomic scattering curves of Thomas and Umeda [7] (for Mo) and Berghuis *et al.*[8] (for O) were used in the form of analytical representations given by Appel [9].

DETERMINATION OF THE STRUCTURE

The reflexions *h*0*l* and 0*kl* are absent for odd *h* and *k* which suggests the space groups *Pba*2 (No. 32) or *Pbam* (No. 55). In *Pbam* there are mirror planes perpendicular to the *c* axis and owing to the shortness of this axis it is unlikely that an atom could be in a general position relative to these symmetry elements. If the atoms were situated on the mirror planes, *i.e.* on one or both of the planes $z = 0$ and $z = \frac{1}{2}$, the observed relative intensities of the 00*l* reflexions could not be explained. It was therefore assumed that the space group is *Pba*2, which has been confirmed by the structure determination.

The projection on (001) is centro-symmetrical in contrast to the space group as a whole, and in the present case is the most important one as it contains the two long axes. The atomic *x* and *y* coordinates were derived exclusively from this projection on the basis of *hk*0 data, and when they had been established the *z* parameters were determined with use of full *hkl* data.

a. Determination of the *x* and *y* coordinates

In the space group *Pba*2 there are 2- and 4-fold positions. As the unit cell was supposed to contain 34 Mo atoms, two of these must be in one of the two 2-fold positions. Starting from this, it was possible to find an arrangement of the metal atoms that fully accounted for the Patterson projection $P(UV)$ shown in Fig. 1a. After two cycles of computation of structure factors $F_c(hk0)$ and electron density projections $\varrho(XY)$, correct signs could be assigned to all the observed structure amplitudes $|F(hk0)|$.

The electron density maps showed minor maxima, which could reasonably be interpreted as being due to 4 × 15 oxygen atoms (O_{10}—O_{24}, *cf.* Fig. 2). In a difference synthesis, where the contribution from all the Mo atoms had been subtracted, the remaining 2 × 1 + 4 × 8 oxygen atoms (O_1—O_9) were clearly revealed as rest maxima close to the positions of the Mo atoms. These maxima were about 20 % lower than the other oxygen peaks, even after the

refinement. Their heights are, however, very sensitive to the scattering factor used for molybdenum, and the fact that the calculated structure factors were based on the scattering curve of zero-valent molybdenum, can therefore explain the difference.

Structure factors were calculated with the coordinates of the strong peaks in $\varrho_o(XY)$ given to both $Mo_1—Mo_9$ and $O_1—O_9$ and the coordinates of the remaining oxygens obtained from the difference map. The corresponding $\varrho_c(XY)$ function was calculated and the back-shifts of the strong peaks were applied on the Mo positions. New parameters for all the oxygen atoms were obtained from a difference map, and these were used in a second back-shift of the Mo-coordinates. These last shifts did not exceed 0.007 Å. The final oxygen parameters were then derived from a new difference map.

An isotropic, over-all temperature factor with the value $B = 0.81$ Å^2 was used in the calculations. The reliability index obtained after this refinement is given in Table 1.

The x and y coordinates thus obtained are given in Table 2, together with standard deviations calculated according to Cruickshank [10]. For the oxygens $O_1—O_9$ no standard deviations are given, as the parameters derived for them may be systematically influenced by the presence of the Mo atoms. The coordinates of these latter atoms on the other hand are not likely to be seriously in error owing to the overlapping oxygen atoms.

Table 1. The reliability indices R of various layer lines. $R = \Sigma(|F_o|-|F_c|)/\Sigma|F_o|$ calculated from observed reflexions only.

Layer line	Number of independent reflexions	R
$hk0$	259	0.073
$hk1$	219	0.100
$hk2$	201	0.109
$hk3$	90	0.108

b. Determination of the z coordinates

From the appearance of some regions of the three-dimensional Patterson function, the conclusion could be drawn, that all the Mo atoms are situated near to two planes perpendicular to the c axis with a separation of $\Delta z \approx 0.16$. It was possible to distribute these atoms on two planes in such a way that the Patterson section $P(UV0)$ shown in Fig. 1b could be fully explained. The calculated phase angles were assigned to the observed structure factor amplitudes, and electron density sections were computed, from which the coordinates of $O_{10}-O_{24}$, as well as new parameters for Mo_1-Mo_9 were obtained. Maxima corresponding to the oxygens O_1-O_9 were observed around $z = 0$, but they were very broad and less well-shaped due to partly coinciding with the termination of series effects from the heavy atoms. In the calculations they were assigned the parameter values $z(O_n) = z(Mo_n) + \frac{1}{2}$, where $z(Mo_n)$ is the coordinate of the molybdenum atom with approximately the same x and y parameters.

After two more phase angle — electron density cycles a back-shift was performed, which yielded shifts within $\Delta z \leq 0.003$ for Mo and $\Delta z \leq 0.021$ for $O_{10}-O_{24}$. The coordinates thus obtained are listed in Table 2. The final z parameters of O_1-O_9 given in Table 2 have been obtained by consideration of interatomic distances. If these atoms were situated exactly halfway between the two molybdenum neighbours in the c-axis direction, they would in most cases have four oxygen atoms very close on one side and four others rather distant on the other side. The z coordinates have therefore been choosen so as to make the distances $O_{1-9}-O_{10-24}$ greater than 2.52 Å and approximately equal on both sides. This can be attained if Mo—O distances as short as 1.69 Å are allowed.

The reliability indices are given in Table 1.

The standard deviations calculated according to Cruickshank [10] (multiplied by 2 on behalf of the non-centrosymmetry) are $\sigma_{Mo}(z) = \pm 0.03$ ($= \pm 0.12$ Å) and $\sigma_O(z) = \pm 0.16$ ($= \pm 0.64$ Å). The low number of terms in the Fourier synthesis along the z axis and the fact that no absorption correction was applied to the reflexions hkl, $l \neq 0$, contributes to the large $\sigma(z)$ value. As the absorption coefficient is fairly constant for reflexions with the same values of h and k, this effect can not give rise to serious errors in the z parameters. For space reasons the value of $\sigma_O(z)$ seems much too high to have any real meaning. A deviation $\Delta z = 0.6$ Å for an oxygen atom decreases the distances to some

of its oxygen neighbours to generally below 2.30 Å. In Table 3, where interatomic distances *d* are listed, the standard deviations are given only for those distances where $\sigma(z)$ makes only a small contribution to $\sigma(d)$, and the more probable value $\sigma_O(z) = \pm 0.3$ Å was used in these cases.

Copies of a table of observed and calculated $|F(hkl)|$ values may be obtained on request.

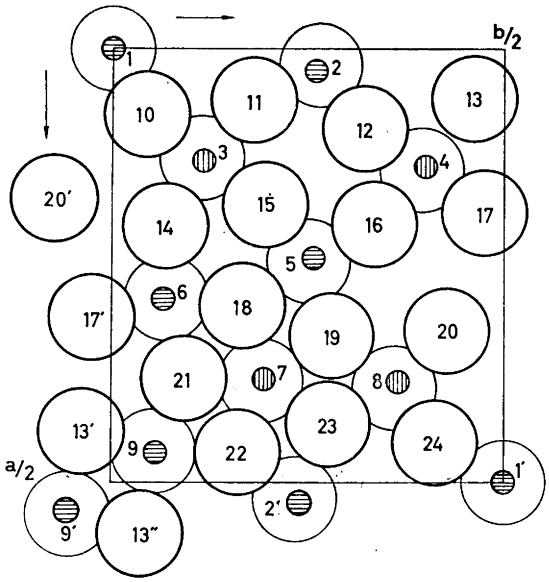

Fig. 2. Numbering of the atoms. Small circles = molybdenum. Large circles = oxygen. The numbers 1 to 9 refer to both molybdenum and oxygen.

DESCRIPTION OF THE STRUCTURE

The structural elements can, with one exception, be considered as distorted MoO_6 octahedra, coupled together by sharing corners or edges. The exception is the coordination polyhedron around Mo_7, which is fairly close to a pentagonal bipyramid.

Along the *c* axis, the extension of the polyhedra is one identity period. The coupling between them in this direction is brought about exclusively through common corners formed by the atoms O_1-O_9, which all lie at about the same height $z \approx 0$. The metal atoms are distorted from the centre of the polyhedra by an amount $\Delta z \approx \pm 0.08$, the distortion being in the same direction for Mo atoms with about the same x coordinates. The metal atoms thus form corrugated layers, as in Fig. 3.

Perpendicular to the *c* axis the polyhedra are linked together in a rather complicated way, which is best illustrated by Fig. 3. Only one fifth of the octahedra are of ReO_3 type, *i.e.* share all six corners with six neighbouring octahedra.

Mo_7 is the centre of an interesting arrangement, which has been found in $W_{18}O_{49}$ [11] (see below under Discussion) but has no counterpart among the other molybdenum oxides whose crystal structures are known at present. It has five Mo neighbours at the corners of a (puckered) pentagon, the projection of which along [001] is fairly regular. The distances to these corner atoms are 3.25—3.37 Å, which is normal for MoO_6 octahedra sharing edges [12]. The

distances from Mo_7 to the five oxygen neighbours O_{18}, O_{19}, O_{21}, O_{22}, and O_{23} range from 1.93 to 2.10 Å, with a mean value of 1.99 Å, which is somewhat greater than the mean 1.94 Å for the rest of the $Mo_{1-9}—O_{10-24}$ distances. As the distances to the two remaining oxygens, O_7 and $O_{7'}$, are very unequal,

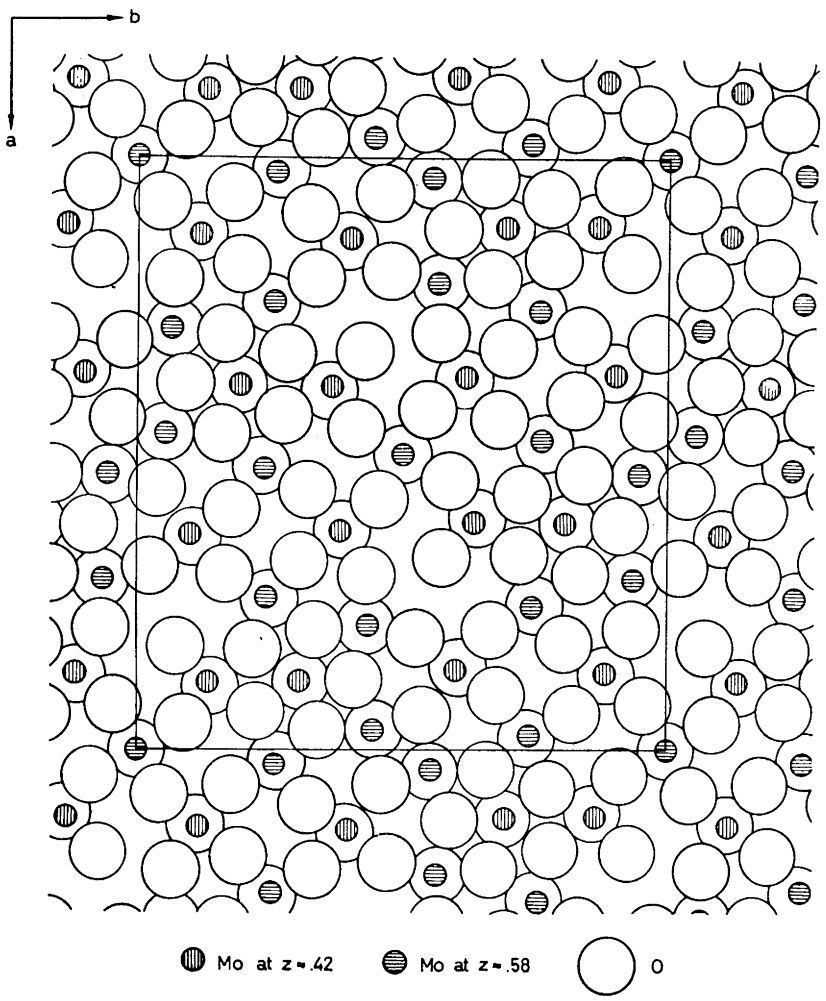

Fig. 3. The structure $Mo_{17}O_{47}$ viewed along [001]. The extension of one unit cell indicated. The oxygen atom above each molybdenum, in a position identical with that below it, has not been shown.

viz. 2.2 and 1.7 Å, the coordination can not be regarded as strictly sevenfold. The oxygens within the pentagon are very close together, the mean O—O distance being 2.32 Å, which is considerably shorter than has been observed for other molybdenum oxides.

The distance between Mo_9 and $Mo_{9'}$, which are related by a 2-fold axis, is only 2.639 Å. This indicates a bond between these atoms of the same kind that has been observed for example in MoO_2[13] and several other dioxides and dioxide systems [14] and recently also in low-Ti_3O_5[15]. In $W_{18}O_{49}$ the correspond-

Dots = W positions in $W_{18}O_{49}$; dotted lines = extension of the unit cell of $W_{18}O_{49}$; circles = corresponding Mo positions in $Mo_{17}O_{47}$. The arrangement in two pentagons is indicated and the rhombic unit building up the structure of $Mo_{17}O_{47}$ also shown.

ing distance is 2.60 Å [11]. A formal treatment, where each oxygen atom is assigned 2 valence electrons taken equally from its molybdenum neighbours [15], yields a number of $2\frac{2}{3}$ valence electrons available for the formation of this bond, which fits well into the diagram of metal-metal bond lengths *versus* available valence electrons given by Marinder and Magnéli [14].

The atom O_{20} is bonded to only one molybdenum *viz.* Mo_8. The distance between them is 1.76 Å, which is among the shortest of the Mo—O distances in this plane. Such singly bonded oxygens exist in MoO_3, where the corresponding bond length is 1.8 Å [16], but has not been found in any other molybdenum or tungsten oxide.

DISCUSSION

The molybdenum oxides, besides $Mo_{17}O_{47}$, whose crystal structures are known at present are: MoO_3 with a layer structure [16-18], Mo_9O_{26} (mon.)[2], Mo_8O_{23} [2] and Mo_4O_{11} (o.-rh.) [19] containing two-dimensionally infinite blocks of the ReO_3 type, MoO_2 of deformed rutile type [13], and the metallic oxide Mo_3O, probably of defective BiF_3 type [20]. Although MoO_6 octahedra can be distinguished as the main structural element in all but the last of these structures, these do not show any strong resemblance to the present structure. In the closely interrelated phases Mo_9O_{26} (mon.) and Mo_8O_{23} the metal atoms form layers which are puckered to about the same degree as in $Mo_{17}O_{47}$, but the arrangement within these layers is quite different.

There is, however, an extremely interesting and close relationship between the present structure and that of γ-tungsten oxide, $W_{18}O_{49}$, determined by Magnéli [11]. This structure is monoclinic with the space group $P2/m$. In Fig. 4 the black dots indicate the positions of the W atoms in a projection along the unique axis, and the extension of one unit cell is marked by dotted lines (the origin has been moved to $(\frac{1}{2}, 0, \frac{1}{2})$ compared with Magnéli's notation). If the 2-fold axis in the centre of this cell is brought into coincidence with the 2-fold axis at $(0, \frac{1}{2}, z)$ or $(\frac{1}{2}, 0, z)$ in $Mo_{17}O_{47}$, there is an almost complete accordance

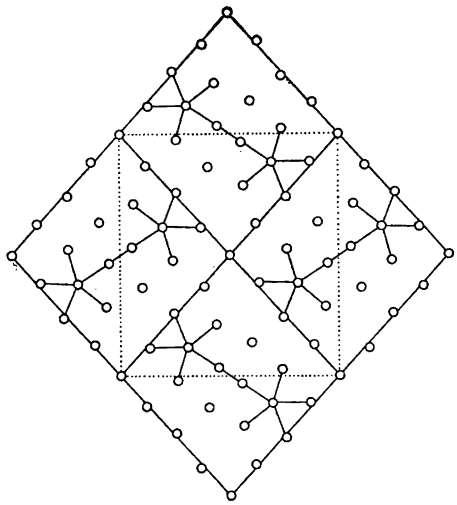

Fig. 5. The manner in which the $Mo_{17}O_{47}$ structure is built up from the rhombic unit of Fig. 4. Only metal atoms are indicated. Dotted lines show the extension of the unit cell.

between the metal atom patterns within an area containing 38 metal atoms. This can be seen in Fig. 4 where the positions of the Mo atoms within this area are marked by small circles. The pattern within the rhomb indicated by full lines builds up the $Mo_{17}O_{47}$ structure in the way shown in Fig. 5.

The oxygen positions in $W_{18}O_{49}$ were not revealed experimentally because of the unfavorable ratio between the scattering factors of oxygen and tungsten, but were derived by Magnéli from spatial considerations. Nevertheless they agree with those of $Mo_{17}O_{47}$ to about the same extent as do the metal positions. Oxygen-oxygen distances as short as 2.32 Å were quite naturally avoided, and this gave rise to a less symmetrical arrangement of oxygens around the tungsten atom equivalent to Mo_7, *i.e.* within the pentagons. It now seems most probable, however, that the arrangement is the same in $W_{18}O_{49}$ as in $Mo_{17}O_{47}$ in this respect too.

Both structures are thus built up from blocks, containing the two centered pentagons of metal atoms joined by a short metal-metal bond, and the essential difference between them is the way in which these blocks are mutually connected.

The wide, empty channels in $W_{18}O_{49}$, bordered by rings of six octahedra and running through the structure along the unique axis, have no counterpart in $Mo_{17}O_{47}$. Also in this structure, six octahedra are connected so as to form a ring, but in one of these octahedra the coupling is across a diagonal, leaving an oxygen atom (O_{20}) in the middle of the ring which fills up most of the available space. In spite of this, the oxygen packing is equally dense on the average in both structures, since the unit cell volume divided by the number of oxygen atoms has the same value 17.8 Å^3.

There is a further difference that becomes clear when the conditions in the third direction are examined. In $Mo_{17}O_{47}$ the metal atoms form layers

which are puckered with an amplitude of $\pm$ 0.3 Å, while in $W_{18}O_{49}$ all tungsten atoms are situated at the same height (on a mirror plane). This is partly reflected in the length of the corresponding axis, which is 3.951 Å in $Mo_{17}O_{47}$ and 3.775 Å in $W_{18}O_{49}$ [21]. The same difference between molybdenum and tungsten has been found in the closely interrelated structures of Mo_8O_{23} [2], Mo_9O_{26} (mon.)[2] and $W_{20}O_{58}$ [22], and has been discussed by Magnéli [23]. An analogous puckering of the layers in the $W_{18}O_{49}$ structure would imply doubling of the unit cell.

Although it can not be excluded that a molybdenum oxide of the $W_{18}O_{49}$ type or a tungsten oxide of the $Mo_{17}O_{47}$ type may form at conditions different from those hitherto used in the phase analysis of the Mo—O [1] and W—O [24] systems, there is no evidence for their existence at present. A study of the extent to which molybdenum and tungsten can replace each other in $Mo_{17}O_{47}$ and $W_{18}O_{49}$ would perhaps throw light on these problems.

Pd_9Se_8 and Rh_9S_8 with cubic crystal symmetry, have been studied by the X-ray powder method at temperatures in the range from 20 to 940°C. The average linear thermal expansion coefficient, β_a, is equal to 9.8×10^{-6} °C^{-1} for Pd_9Se_8 (20–625°C), 9.3×10^{-6} °C^{-1} for Rh_9S_8 (20–300°C) and 7.4×10^{-6} °C^{-1} for Rh_9S_8 (428–866°C). The volume expansion coefficient, a, is 29.5×10^{-6} °C^{-1} for Pd_9Se_8 (20–625°C), 27.8×10^{-6} °C^{-1} for Rh_9S_8 (20–300°C) and 22.2×10^{-6} °C^{-1} for Rh_9S_8 (428–866°C).

In a recent study of the thermal expansion of PtS_2, $PtSe_2$, $PtTe_2$ and $PdTe_2$, all with structures of the $Cd(OH)_2$-type, Kjekshus and Grønvold [1] found a general departure from linearity in the expansion perpendicular to the layers at higher temperatures. Since the reasons for the different modes of thermal expansion at higher temperatures are not fully explained by the existing theories for the perfect lattice, further experimental data might be desirable before a theoretical explanation is proposed.

The present paper is concerned with the thermal expansion of Pd_9Se_8 [2] and Rh_9S_8 [3], which have cubic symmetry and are probably isostructural. These compounds were also chosen in order to check the accuracy of the X-ray method for thermal expansion studies of compounds with relatively long cell edges of about 10 Å. The fact that the positions of the atoms in the unit cell are not known is of secondary importance, since the thermal expansion of the interatomic distances is equal to the expansion of the cell edges.

EXPERIMENTAL

Pd_9Se_8 was prepared [2] by heating a mixture of $PdSe_{1.00}$ and palladium, corresponding to the formula Pd_9Se_8, in an evacuated and sealed silica tube for 10 days at 650°C and 50 days at 450°C. Rh_9S_8 was prepared [3] by heating rhodium and sulfur in the right proportions in an evacuated, sealed silica tube for 14 days at 690°C and another 14 days at 350°C. Both samples were finally slowly cooled to room temperature.

Information about the purity of the elements is given elsewhere [2,3].

Table 1. Lattice constants and unit cell volumes for Pd_9Se_8 at different temperatures.

t(°C)	a(Å)	V(Å^3)
20	10.6060	1193.04
155	10.6200	1197.77
220	10.6268	1200.07
330	10.6382	1203.94
402	10.6457	1206.49
531	10.6595	1211.18
625	10.6694	1214.51
650	10.6725	1215.62

X-Ray powder photographs of the compounds were taken in a 190 mm Unicam high-temperature camera, with the samples sealed in thin-walled quartz capillaries. Pd_9Se_8 was studied at temperatures between 20 and 650°C. The highest temperature is close to the melting point of 665 ± 15°C. Rh_9S_8 was studied at temperatures between 20 and 940°C.

By means of a voltage regulator, the registered temperature of the furnace surrounding the specimen was kept constant within ± 5°C. The Pt/Pt-Rh thermocouples of the furnace had been calibrated with a standard couple located at the position of the specimen. Lattice constants are given i Ångström units ($\lambda_{CuK\alpha_1}$ = 1.54050 Å). Only the high-angle reflections of the diffraction pattern were used in the calculation of the lattice constants. The lattice constants were found by extrapolation according to the method given by Nelson and Riley [4]. The probable error in the lattice constant determinations at temperatures above room temperature was estimated to be about 0.01 %. This included a possible error due to variation in the composition of the sample with temperature. A much better reproducibility of about 0.003 % is found, however, between the results for two different expansion runs. Errors due to specimen contamination can be neglected, since the lattice constants at room temperature before and after the high temperature treatment were equal within the limits of the experimental error.

RESULTS

The results of the lattice constant measurements are listed in Tables 1 and 2. Here are also listed the unit cell volumes. The ratios $\frac{a_t - a_{20}}{a_{20}} = \frac{\Delta a}{a_{20}}$

Table 2. Lattice constants and unit cell volumes for Rh_9S_8 at different temperatures.

t(°C)	a(Å)	V(Å^3)
20	9.9116	973.71
120	9.9204	976.31
208	9.9289	978.82
300	9.9383	981.60
428	9.9495	984.93
538	9.9576	987.33
615	9.9632	989.00
681	9.9683	990.52
766	9.9744	992.34
866	9.9818	994.55
940	9.9894	996.52

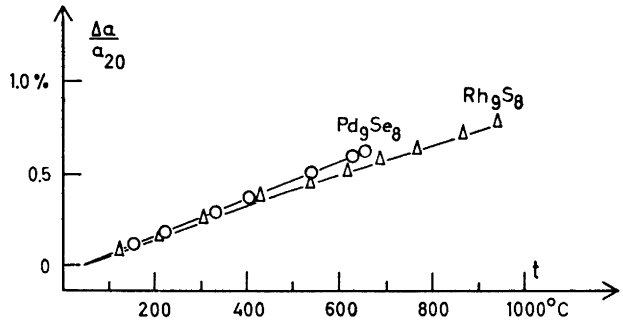

Fig. 1. Relative lattice constant variation as function of temperature.

and $\frac{V_t - V_{20}}{V_{20}} = \frac{\Delta V}{V_{20}}$ are calculated and plotted as $\frac{\Delta a}{a_{20}}$ *versus* t, and $\frac{\Delta V}{V_{20}}$ *versus* t, respectively. The calculations of the expansion coefficients were based upon these data.

The change in the length of the a-axis is similar below about 300°C for both Pd_9Se_8 and Rh_9S_8. As shown in Fig. 1, the a-axis increases linearly with increasing temperature. The expansion coefficient β_a is equal to 9.8×10^{-6} $°C^{-1}$ for Pd_9Se_8 (20—625°C) and 9.3×10^{-6} $°C^{-1}$ for Rh_9S_8 (20—300°C). At temperatures between 428 and 866°C the a-axis of Rh_9S_8 increases more slowly

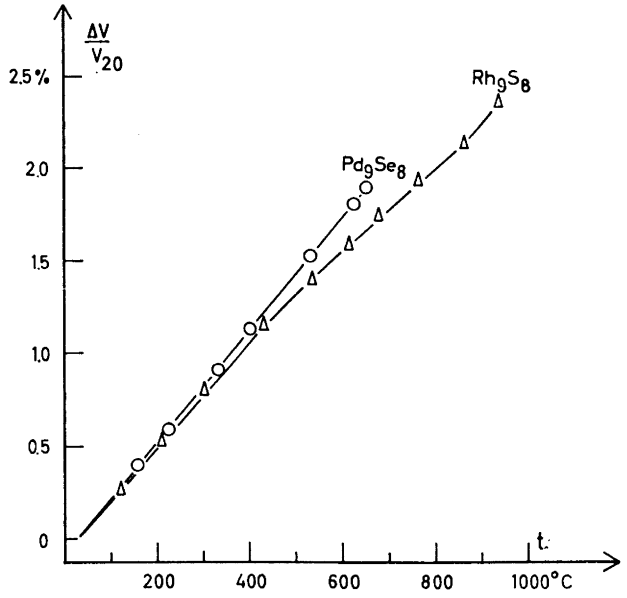

Fig. 2. Relative changes in volume with temperature.

than at lower temperatures. The thermal expansion is approximately linear, with expansion coefficient β_a equal to 7.4×10^{-6} °C^{-1} for Rh_9S_8 (428—866°C).

The volume expansion is plotted as function of the temperature in Fig. 2. For both compounds the volume expansion has a similar temperature dependence as the a-axis. Since β_a is of the order 10^{-5}, the average thermal volume expansion coefficient α is approximately $3\beta_a$. The numerical values for α are 29.5×10^{-6} °C^{-1} for Pd_9Se_8 (20—625°C), 27.8×10^{-6} °C^{-1} for Rh_9S_8 (20—300°C) and 22.2×10^{-6} °C^{-1} for Rh_9S_8 (428—866°C).

The intensities of the reflections on X-ray photographs taken at higher temperatures are almost equal to those of the corresponding photographs taken at room temperature. The parameters must thus be nearly the same. Because of the cubic symmetry the thermal expansion of the interatomic distances is approximately equal to the expansion of the a-axis (*cf.* Fig. 1).

The obtained expansion curves for Pd_9Se_9 deviate little from linearity. The assumed large increase [5,6] in the coefficient of thermal expansion in the temperature region just below melting does not occur. As the a-axis and the volume of Rh_9S_8 increase more slowly above 428°C than at lower temperatures, the relative expansion is still on the upper part of the sigmoidal curve. The values for the a-axis at 940°C (*cf.* Table 1) indicate that a more rapid increase might well take place above this temperature.

Acknowledgements. The author wishes to thank Professor Haakon Haraldsen and Dosent Fredrik Grønvold for their interest in this study. Thanks are due to Mr. Håkon Mohn for skillful technical assistance.

Relations between the Hammett Acidity Function, H_0, and Ion Activities in Mixtures of strong Acids and Water

ERIK HÖGFELDT

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

By combining of the Hammett acidity function, H_0, with activity data in mixtures of strong acids with water, functions $\varphi^{\nu} \cdot a_{X}{}^{\nu}$ can be constructed. ν is the ionic charge of species X and $\varphi = y_B / y_{BH}+$ *i.e.* the activity coefficient ratio of the basic and acid forms of the indicators used for the determination of H_0. The properties of these functions are investigated. It is found that the plot of log $\varphi \cdot a_{H_3O}+$ *versus* H_0 is the same for the acids, HCl, HBr, HNO_3, $HClO_4$ and H_2SO_4.

The functions $\varphi^{-1} \cdot a_{A^-}$ (A^- = anion of the acid HA) show a more individualistic behavior. The plots of log $\varphi^{-1} \cdot a_{ClO_4^-}$ and log $\varphi^{-1} \cdot a_{HSO_4^-}$ *versus* H_0 practically coincide in the range of overlap, those for Br^- and Cl^- form a different set of almost parallel curves but the curve for NO_3^- differs from all of the others.

From a plot of log $\varphi^{\nu} \cdot a_{X}{}^{\nu}$ *versus* H_0 for several species assumed to be present in H_2SO_4–H_2O mixtures, it is found that, from 10 M H_2SO_4 up to pure H_2SO_4, the curve for H_3O^+ runs parallel with that of HSO_4^-, that for SO_4^{2-} with log a_{H_2O} and the curve for $H_3SO_4^+$ with that of $HS_2O_7^-$. This behavior is found to be the result of the almost complete constancy of the activity coefficient expression $\varphi^2 \cdot y_{H_3O}+ / y_{HSO_4^-}$. Also, the following relation holds in the same concentration range:

$$-2H_0 - \log a_{H}^{2}+ \cdot a_{SO_4^{2-}} + \log a_{H_2O} = 3.95 \pm 0.03$$

A function closely related to the average degree of hydration of the various ions present is introduced. In concentrated solutions of H_2SO_4, this function tends towards unity for H^+ and towards zero for HSO_4^- implying the existence of H^+ as H_3O^+ in these concentrated solutions and that HSO_4^- is practically unhydrated.

From the slope of curves log $\varphi^{\nu} \cdot y_{X}{}^{\nu}$ *versus* H_0 where y symbolizes a kind of a stoichiometric activity coefficient, it is found that protons seem to be hydrated to the same extent in all strong acids when compared at the same water activity. The anions, ClO_4^- and HSO_4^-, seem to be hydrated to approximately the same extent up to about 7 M and much more so than NO_3^-, the slopes indicating a difference of 3 in hydration number.

In a preceding paper[1], activities and activity coefficients of hydrated ions were derived and their properties investigated. In addition a function closely related to the average degree of hydration of the ions was constructed and its bearing on the existence of maxima in ionic concentration demonstrated. Since individual ionic activities cannot be measured separately, the approximate hydration numbers evaluated referred to various combinations of positive and negative ions. In the following it will be shown, however, that for solutions of strong acids in water, combination of acidity function data with water and acid activities will give functions that depend mainly upon the activity of one of the ions.

LIST OF SYMBOLS

a_{X^ν}	Activity on the molarity scale of constituent X^ν
a_n	Activity of $H^+(H_2O)_n$
C	Stoichiometric molarity of acid
C_{X^ν}	Concentration of X^ν on the molarity scale
D	Spacing between the curves log $\varphi \cdot a_{H_3O^+}$ and log $\varphi^{-1} \cdot a_{HSO_4^-}$
d_o	Density of pure water
f_{X^ν}	Activity coefficient on the mole fraction scale of X^ν
K_1, K_n etc	Thermodynamic equilibrium constants
m	Stoichiometric molality of acid
M	Molar = moles · liter^{-1}
$\bar{n}$	Average hydration number
$\bar{n}'$, $\bar{n}''$	Functions closely related to $\bar{n}$, defined by eqns (38) and (40)
pK	$-\log K$
S	$S = \Sigma K_n a^n_{H_2O}$
X_{X^ν}	Mole fraction of X^ν
y_{X^ν}	Stoichiometric activity coefficient on the molarity scale of X^ν
$y = [y_{H^+} \cdot y_{A^-}]^{\frac{1}{2}}$	» mean activity coefficient of H^+, A^-
y_+, y_-	"True" activity coefficients on the molarity scale
$\varphi = y_B/y_{BH^+}$	Ratio of the activity coefficients on the molarity scale of the acid and base forms of the indicator B
α	Degree of dissociation of the strong acid HA
$\gamma = [\gamma_{H^+} \cdot \gamma_{A^-}]^{\frac{1}{2}}$	Stoichiometric mean activity coefficient of H^+, A^- on the molality scale
ν	Ionic charge.

THE IONIC ACTIVITY FUNCTIONS

For the acid-base equilibrium of an uncharged weak base indicator B, we can write:

$$BH^+ \rightleftharpoons B + H^+ \qquad (1)$$

The thermodynamic equilibrium constant of this reaction is defined by

$$K_{BH^+} = a_{H^+} \cdot a_B \cdot a^{-1}_{BH^+} \quad (2)$$

H^+ and a_{H^+} in (1) and (2) refer formally to the bare, unhydrated proton. a_{H^+} is so defined that it approaches C_{H^+} upon dilution.

By taking the logarithm of (2) and rearranging, we get:

$$pK_{BH^+} - \log(C_{BH^+} / C_B) = -\log a_{H^+} - \log(y_B / y_{BH^+}) \equiv H_0 \quad (3)$$

Eqn. (3) defines H_0. The left hand side indicates how it can be determined experimentally, *e.g.* by spectrophotometric measurements of the ratio C_{BH^+} / C_B The right hand side shows the relation of H_0 to the activity of free protons. Activities and concentrations are expressed on the molarity scale. When not otherwise stated this scale is used throughout the paper.

The quotient

$$\varphi = y_B / y_{BH^+} \quad (4)$$

is unknown although it has been suggested [2] that this term becomes nearly independent of electrolyte content over a wide range of concentration, *e.g.* for H_2SO_4 above 4—5 M. It is generally accepted that, at any given concentration of strong acid, φ is independent of indicator used as long as it belongs to the same charge type [3].

With the aid of (4), eqn. (3) rearranges to:

$$\log \varphi \cdot a_{H^+} = -H_0 \quad (5)$$

As stated by Guggenheim [4], single activities like a_{H^+} and activity coefficient ratios like y_B / y_{BH^+} can be neither experimentally determined nor satisfactorily defined within the framework of thermodynamics. Only by using some extra-thermodynamic assumption can ion activities be defined — as exemplified [5] by the definition of pH. As seen from (5), however, the quantity $y_B \cdot y^{-1}_{BH^+} \cdot a_{H^+}$ is experimentally available. It is obvious that H_0 is closely related to the activity of free protons although this activity cannot, of course, be evaluated because of the unknown function φ.

Since free protons do not exist in measurable amounts in water solutions but are known to be hydrated, it may be of interest now to consider the thermodynamic functions of these constituents.

For the reaction:

$$H^+ + n\ H_2O \rightleftharpoons H^+(H_2O)_n \quad (6)$$

the law of mass action yields:

$$K_n = \frac{a_n}{a_{H^+} \cdot a^n_{H_2O}} \quad (7)$$

where a_n is a convenient notation for the activity of $H^+(H_2O)_n$. The activity scale of the hydrated proton is conveniently fixed to that of H^+ by putting $K_n = 1$ as was done by Brönsted [6,7] for $n = 1$.

a_n is thus defined by:

$$a_n = a_{H^+} \cdot a^n_{H_2O} \quad (8)$$

By combining (5) and (8) we get

$$\log \varphi \cdot a_n = -H_o + n \log a_{H_2O} \tag{9}$$

In the following, we shall limit the discussion to H_3O^+, *i.e.*$n = 1$ in (9).

In order to derive the analogous function for A^- (anion of the strong acid HA), we make use of the reaction:

$$HA + H_2O \rightleftharpoons H_3O^+ + A^- \tag{10}$$

with the thermodynamic equilibrium constant, K, defined by:

$$K = \frac{a_{H_3O^+} \cdot a_{A^-}}{a_{H_2O} \cdot a_{HA}} \tag{11}$$

From (9) and (11):

$$\log \varphi^{-1} \cdot a_{A^-} = H_o + \log K \cdot a_{HA} \tag{12}$$

The quantity $K \cdot a_{HA}$ can be obtained from:

$$K \cdot a_{HA} = a_{H^+} \cdot a_{A^-} = (d^o \cdot \gamma \cdot m)^2 \tag{13}$$

Since our activities are given on the molarity scale, it is necessary to transform the activity on the molality scale to that on the molarity scale — this is done using d^o, the density of pure water. The stoichiometric mean molality activity coefficient, γ, is frequently tabulated in the literature together with a_{H_2O} or the osmotic coefficient. The ion activity functions (9) and (13) can thus be computed from such data, and often over considerable concentration ranges.

EXPERIMENTAL DATA SELECTED

In the following, a short survey of the experimental data employed in this investigation will be given. With the exception of HBr, they are more thoroughly discussed in Ref.[1]

a) *HCl.* Densities of HCl solutions at 25°C have been computed from formulas given by Åkerlöf and Teare [8]. Hydrochloric acid activities have been taken from Harned and Owen [9] for dilute solutions and from Robinson and Stokes for concentrated solutions [10a]. Water activities were computed from osmotic coefficients compiled by Robinson and Stokes.[10b].

b) *HBr.* Densities of HBr solutions at 20°C were taken from Landolt-Börnstein [11a]. Water and hydrobromic acid activities are also from the same source [11b] where Redlich has made a compilation of available freezing point, vapor pressure and emf data from several different investigations.

c) *HNO_3.* Densities of HNO_3 solutions at 20°C have been taken from Landolt-Börnstein [11a]. Water and nitric acid activities at the same temperature have been computed from vapor pressure measurements by Potier [12]. The concentrations of dissociated and undissociated acid have been taken from NMR measurements reported by Redlich et al [13].

d) *$HClO_4$.* Densities of $HClO_4$ solutions at 25°C have been taken from Markham [14] and water and perchloric acids activities from the isopiestic measurements of Robinson and Baker [15]. The concentrations of dissociated respectively undissociated acid are from Ref 13.

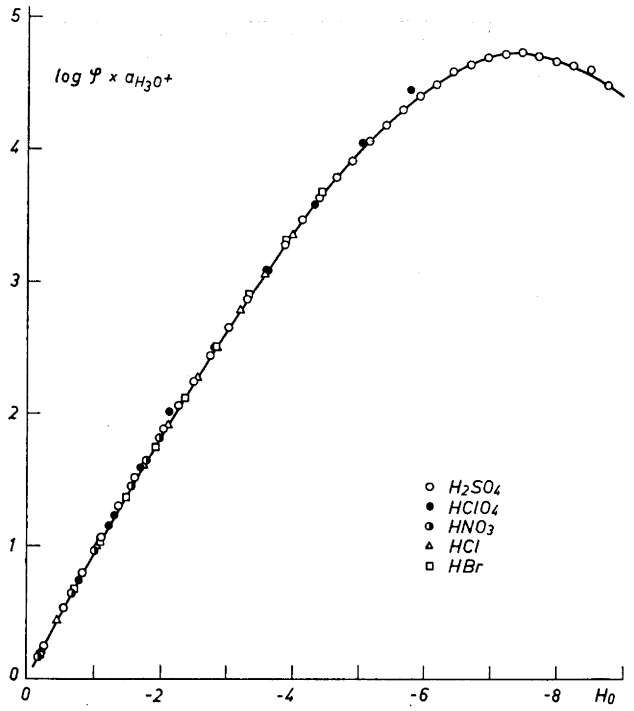

Fig. 1. The function log $\varphi \cdot a_{H_3O^+}$ *versus* H_0 for various strong acids: ○ H_2SO_4; ● $HClO_4$; ◑ HNO_3; △ HCl; □ HBr.

e) *H_2SO_4*. Densities of H_2SO_4 solutions at 25°C have been taken from International Critical Tables [16]. Water and sulfuric acid activities are the recent isopiestic measurements by Glueckauf and Kitt [17] which extended up to about 16 M. Above that concentration, water activities given by Deno and Taft [18] from an empirical relation between H_0 and a_{H_2O} were used and the corresponding water activities computed with the aid of the Gibbs—Duhem equation by the present writer. As discussed in Ref.1, the activities thus computed agree quite well with the vapor and freezing point measurements recently reported by Giauque *et al* [19]. Concentrations of species present have been taken from the Raman measurements reported by Young *et al.*[20a].

f) *H_0-data*. The H_0-data for dilute HCl solutions and H_2SO_4, solutions up to 12 M were taken from the author's own measurements [21] and in other cases from the review by Paul and Long [3]. Where the measurements of the present writer overlap those in the compilation of Paul and Long, the agreement was found to be good.

COMPARISON OF ION ACTIVITY FUNCTIONS IN SOME DIFFERENT ACIDS

Using the experimental data selected above, the ion activity functions $\varphi \cdot a_{H_2O^+}$ and $\varphi^{-1} \cdot a_{A^-}$ have been computed for the five acids in question.

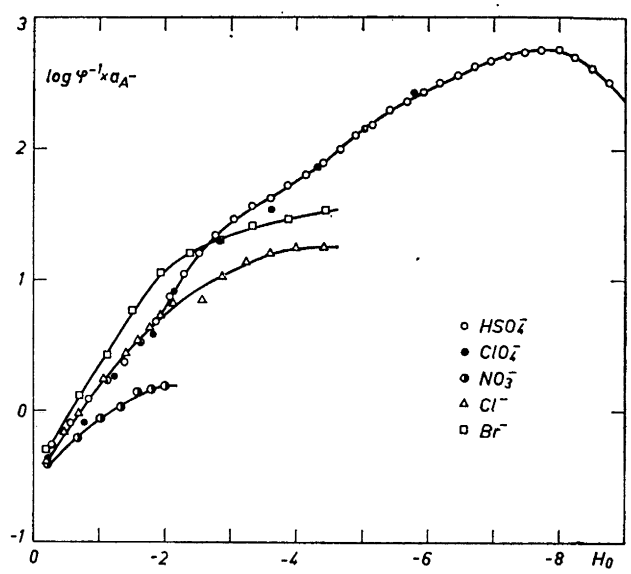

Fig. 2. The function log $\varphi^{-1} \cdot a_{A^-}$ *versus* H_0 for various anions: ○ HSO_4^-; ● ClO_4^-; ◑ NO_3^- △ Cl^-; □ Br^-.

In Fig. 1, log $\varphi \cdot a_{H_3O^+}$ is plotted *versus* H_0 and it can be noted that, within the limits of experimental error and within the range of overlap, they all fall on a single curve. This is equivalent to a finding by Wyatt [22] that, when H_0 was plotted against a_{H_2O} for several acids, all data fell on a single curve. From eqn. (9) it is seen that, if the curve H_0 *vs* a_{H_2O} is the same for all acids, $\varphi \cdot a_{H_3O^+}$ *vs* H_0 must also be the same. This behavior can be imagined to be due to the fact that the hydration equilibria:

$$H^+ + n\,H_2O \rightleftharpoons H^+(H_2O)_n \qquad n = 1,2,3\ldots$$

as well as the φ-values are the same in all acids when the comparison is made at the same water activity.

In Fig. 2, log $\varphi^{-1} \cdot a_{A^-}$ is plotted *versus* H_0 for the five anions: Cl^-, Br^-, NO_3^-, ClO_4^-, HSO_4^-. The anions behave more individually than the common cation, and no coinciding curves are obtained with the exception of the curves for the structurally similar ions HSO_4^- and ClO_4^- which lie quite close to each other. The curves for Br^- and Cl^- are nearly parallel and distinctly different from those for ClO_4^- and HSO_4^- and even more so from the curve for NO_3^- since the latter deviates markedly from all of the other anions already in dilute solutions. The significance of these differences is difficult to grasp with our present knowledge of concentrated electrolytes. That structural similarities should enter into the explanation seems plausible from the way into which the curves divide themselves into different groups with structurally similar ions.

THE PLOT $\log \varphi^{\nu} \cdot a_x{}^{\nu}$ FOR $H_2SO_4 - H_2O$

The only acid where H_0 and activity data are available over the whole concentration range from pure water up to pure acid is sulfuric acid. Since this acid is a dibasic acid, there are several species present and the relations between H_0 and the ionic activities take a slightly different form as compared with the monobasic acids. Consider the reactions:

$$H_2SO_4 + H_2O \rightleftharpoons H_3O^+ + HSO_4^-;\ K_{H_2SO_4} = \frac{a_{H_3O^+} \cdot a_{HSO_4^-}}{a_{H_2O} \cdot a_{H_2SO_4}} \qquad (14, 15)$$

$$HSO_4^- + H_2O \rightleftharpoons H_3O^+ + SO_4^{2-};\ K_{HSO_4^-} = \frac{a_{H_3O^+} \cdot a_{SO_4^{2-}}}{a_{H_2O} \cdot a_{HSO_4^-}} \qquad (16, 17)$$

$$2\ H_2SO_4 \rightleftharpoons H_3SO_4^+ + HSO_4^-;\ K_1 = \frac{a_{H_3SO_4^+} \cdot a_{HSO_4^-}}{a^2_{H_2SO_4}} \qquad (18, 19)$$

$$2\ H_2SO_4 \rightleftharpoons H_3O^+ + HS_2O_7^-;\ K_2 = \frac{a_{H_3O^+} \cdot a_{HS_2O_7^-}}{a^2_{H_2SO_4}} \qquad (20, 21)$$

$$a^2_{H^+} \cdot a_{SO_4^{2-}} = K_{H_2SO_4} \cdot K_{HSO_4^-} \cdot a_{H_2SO_4} \qquad (22)$$

For H_3O^+ we have eqn. (9) and for the other ions we find from (9), (15), (17), (19), (21) and (22)

$$\left.\begin{aligned}
&\log \varphi \cdot a_{H_2SO_4} = -H_0 + \log a_{H^+}{}^2 \cdot a_{SO_4^{2-}} + 2\ pK_{H_2SO_4} + \\
&+ pK_{HSO_4^-} - pK_1 \\
&\log \varphi^{-1} \cdot a_{HSO_4^-} = H_0 + \log a_{H^+}{}^2 \cdot a_{SO_4^{2-}} \cdot + pK_{HSO_4^-} \\
&\log \varphi^{-2} \cdot a_{SO_4^{2-}} = 2\ H_0 + \log a_{H^+}{}^2 \cdot a_{SO_4^{2-}} \\
&\log \varphi^{-1} \cdot a_{HS_2O_7^-} = H_0 + 2 \log a_{H^+}{}^2 \cdot a_{SO_4^{2-}} - \log a_{H_2O} + \\
&+ 2\ pK_{H_2SO_4} + 2\ pK_{HSO_4^-} - pK_2
\end{aligned}\right\} \qquad (23\ a—d)$$

All of the constants except $K_{H_2SO_4}$ are known with some certainty. For $K_{HSO_4^-}$, the recent value 1.00×10^{-2} given by Hamer [20a] from considerations of available literature data has been accepted. For K_1 and K_2, Kirkbride and Wyatt [23] report $K_1 = 3.45 \times 10^{-4}$ (moles per kg H_2SO_4)^2 and $K_2 = 1.8 \times 10^{-4}$ (moles per kg H_2SO_4)^2 in pure H_2SO_4. These values are fairly consistent with those reported by Gillespie and co-workers [24–26]. K_1 and K_2 are given with concentrations in moles per kg H_2SO_4 and with pure sulfuric acid as standard state for $a_{H_2SO_4}$. All other activities are referred to pure water and therefore K_2 and K_4 have to be transformed to the molarity scale and the standard state of H_2SO_4 changed to that in water. Using the density of pure sulfuric acid, 1.83, and the value [1] $\log a_{H^+}{}^2 \cdot a_{SO_4^{2-}} = 9.55$ in pure H_2SO_4, this transformation was performed with the aid of (22) giving:

$$pK_1 = 26.04 - 2\ pK_{H_2SO_4} \qquad (24\ a,b)$$

$$pK_2 = 26.31 - 2\ pK_{H_2SO_4}$$

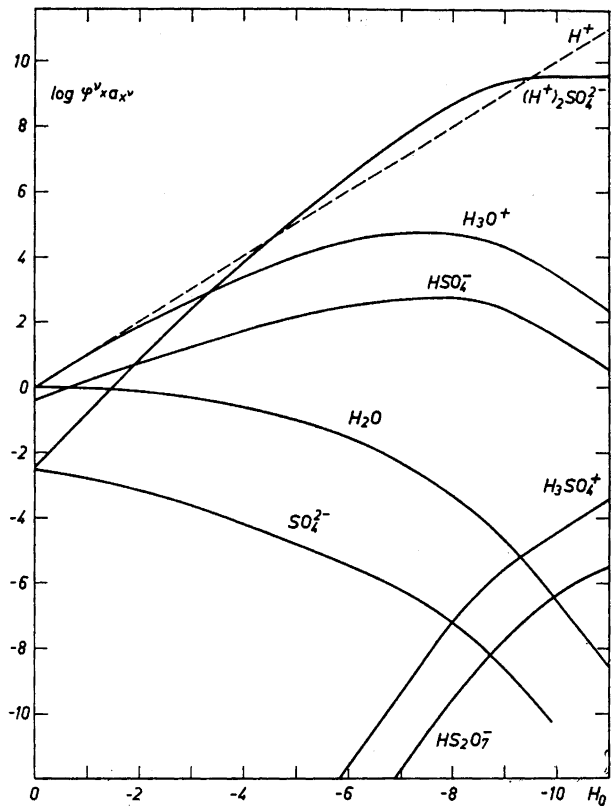

Fig. 3. The functions log $\varphi^{\nu} \cdot a_x{}^{\nu}$ *versus* H_0 for several species assumed to be present in mixtures of water and sulfuric acid.

Inserting the value for $pK_{HSO_4^-}$ and the expression for pK_1 and pK_2 from (24) into (23), we get:

$$\log \varphi \cdot a_{H_2SO_4} = -H_0 + \log a_{H^+}{}^2 \cdot a_{SO_4^{2-}} - 24.04$$

$$\log \varphi^{-1} \cdot a_{HSO_4^-} = H_0 + \log a_{H^+}{}^2 \cdot a_{SO_4^{2-}} + 2.00 \qquad (25\,a,b,c)$$

$$\log \varphi^{-1} \cdot a_{HS_2O_7^-} = H_0 + 2 \log a_{H^+}{}^2 \cdot a_{SO_4^{2-}} - \log a_{H_2O} - 22.31$$

In Fig. 3 the functions log $\varphi^{\nu} \cdot a_x{}^{\nu}$ for H^+, H_3O^+, $H_3SO_4^+$, H_2O, $(H^+)_2SO_4^{2-}$, HSO_4^-, $HS_2O_7^-$ and SO_4^{2-}, are plotted *versus* H_0.

For H_2SO_4 eqn. (22) has been used and the quantity log $a_{H^+}{}^2 \cdot a_{SO_4^{2-}}$, which differs from log $a_{H_2SO_4}$ by the constant log $K_{H_2SO_4} \cdot K_{HSO_4^-}$, is plotted in Fig. 3. Since $K_{H_2SO_4}$ is unknown, log $a_{H_2SO_4}$ itself cannot be evaluated.

The curve for H^+, is dashed because measurable amounts of hydrogen ions do not occur, a_{H^+} being only a formal quantity equal to $a_{H_3O^+}/a_{H_2O}$. It deserves also to be mentioned that there is still some uncertainty about the composition of the main species in concentrated sulfuric acid solutions [26].

SOME RELATIONS BETWEEN ACTIVITIES AND ACTIVITY COEFFICIENTS IN CONCENTRATED SOLUTIONS OF SULFURIC ACID

As seen from Fig. 3, all species with the exception of H_2SO_4 give curves that can be divided into three different sets of parallel or nearly parallel curves. The spacing between the curves for H_3O^+ and HSO_4^- will be denoted by $2\,D$, i.e.

$$\log \varphi \cdot a_{H_3O^+} - \log \varphi^{-1} \cdot a_{HSO_4^-} = 2\,D$$

which can be rearranged to give the following expression for

$$\varphi = \frac{y_B}{y_{BH^+}} = 10^D \left(\frac{a_{HSO_4^-}}{a_{H_3O^+}}\right)^{\frac{1}{2}} \tag{26}$$

Above 12 M, where the concentration of SO_4^{2-} can be neglected in comparison to HSO_4^-, $C_{H_3O^+} = C_{HSO_4^-}$ and we obtain from eqn. (26)

$$\varphi^2 \cdot \frac{y_{H_3O^+}}{y_{HSO_4^-}} = 10^{2D} \tag{27}$$

In order to test how constant D is, we make use of the expression

$$-2H_0 - \log a_{H^+}{}^3 \cdot a_{SO_4^{2-}} + \log a_{H_2O} = 2\,D + pK_{HSO_4^-} = 2(D + 1.00) \tag{28}$$

which can be obtained from (26), (9) and (25b). Since all three quantities, H_0, $a_{H^+}{}^2 \cdot a_{SO_4^{2-}}$ and a_{H_2O} have been measured, we can find the range of validity of a constant D value. In Table 1, values of H_0, $a_{H^+}{}^2 \cdot a_{SO_4^{2-}}$ and a_{H_2O} are listed together with the quantity $2(D + 1.00)$ computed from (28). It is seen that, above about 10 M H_2SO_4, $2(D + 1.00)$ is practically constant. For most of the data, the deviation from the average is less than $\pm$ 0.1. This is about the accurary with which H_0 can be determined in concentrated sulfuric acid [21]. Since the accurary of the water and sulfuric acid activities is higher [19], it can be concluded that, within the uncertainty in H_0, the relation (28) with a constant D-value is valid in the concentration range 10 — 18.61 M H_2SO_4.

Consequently the relation:

$$\varphi^2 \cdot \left(\frac{y_{H_3O^+}}{y_{HSO_4^-}}\right) = 10^{1.95 \pm 0.03} = 89 \pm 6 \tag{29}$$

will hold from 12 to 18.61 M H_2SO_4.

It is tempting to speculate about the physical significance of (29). In any such discussion must enter, however, a knowledge of the electrostatic interactions between the ions. Our lack of knowledge of the variation of the dielectric constant in these concentrated solutions does not permit a comparison with even very naive models for the ion-ion interactions. Until the necessary data and useful theories for concentrated solutions have been obtained, (29) must stand as a surprisingly simple empirical relation covering a large concentration range. Another consequence of the constant D-value is the parallelism of the three sets of curves: H_3O^+ and HSO_4^-, SO_4^{2-} and H_2O, and $H_3SO_4^+$ and $HS_2O_7^-$.

* From Giauque *et al.*[19]

Average : 3.95±0.03
in the range 10 — 18.61 M

Eqn. (19) can be used for defining single ion activities in the concentration range where D is found to be practically constant. The simplest choice is perhaps to define

$$y_{H_3O^+} = y_{HSO_4^-} \text{ for } 12 \leq C \leq 18.61 \quad (30)$$

Inserting (30) into (29) gives:

$$\varphi = 9.4 \pm 0.3 \text{ for } 12 \leq C \leq 18.61 \quad (31)$$

Expressions for the activities of the other ions are obtained by inserting the φ-value given in (31) into (9), (23 c) and (25). Especially the expression for the activity of SO_4^{2-} takes a very simple form:

$$\log a_{SO_4^{2-}} = \log a_{H_2O} - 2.00 \quad (32)$$

According to (32), the solubility of sulfates should be proportional to the water activity provided that the activity coefficient of the cation stays practically constant. No simultaneous solubility and water activity measurements seem to exist at present so the exact relation between solubility and water activity cannot be obtained. For the solubility of $BaSO_4$ in concentrated sulfuric acid solutions, Hammet and Deyrup [27] noted that the solubility decreased with increasing water content in qualitative agreement with (32).

Finally it may be mentioned that Brand [28] as well as Deno and Taft [18] have found empirical relations between H_0 and the concentrations of various species present in concentrated sulfuric acid solutions. Analogous expressions can be derived from (9), (25b) and (23) using the transformation from the molarity to the mole fraction scale. Using the Raman data of Young et al.[20a] it was found that

$$\log \frac{\varphi^{-1} \cdot f_{HSO_4^-}}{K_{H_2SO_4} \cdot f_{H_2SO_4}} \sim 8.51 = H_0 - \log \frac{X_{HSO_4^-}}{X_{H_2SO_4}} \quad (33)$$

above 16 M H_2SO_4 (90 % H_2SO_4), in excellent agreement with Brand's empirical constant 8.48 (corrected to the H_0-scale adopted by Paul and Long [3]).

Analogously, it was found that the same Raman data [20a] gave

$$\log \frac{f_{H_2O}}{\varphi \cdot f_{H_3O^+}} - 1.74 \sim 7.06 = H_0 - \log \frac{X_{H_2O}}{X_{H_3O^+}} \quad (34)$$

above 15 M H_2SO_4.

This differs by about 0.3 from the value 6.78 used by Deno and Taft (corrected to the H_0-scale adopted by Paul and Long [3]). The range of validity of (34) is the same as that found by Deno and Taft for their empirical relation. The Raman data thus confirm the validity of their equation although there is some uncertainty about the exact value of their empirical constant.

The relations (29), (33) and (34) show that the variations of several activity coefficients must practically cancel each other in concentrated solutions. Deno and Taft suggested that the individual activity coefficients may approach constancy in concentrated sulfuric acid. The ideal behavior of such solutions was suggested to be a result of the high dielectric constant [29]. The similarity to fused salts which are known to behave as practically ideal solutions [30] was also emphasized.

COMPARISON OF ION ACTIVITY COEFFICIENT FUNCTIONS IN SOME DIFFERENT ACIDS

In a preceding paper, stoichiometric activity coefficient products for hydrated ions were investigated [1]. With the aid of the functions (9), (12), (23c) and (25), analogous functions for the single ions can be defined. For H_3O^+ we can write:

$$\varphi \cdot y_{H_3O^+} = \frac{\varphi \cdot a_{H_3O^+}}{C_{H^+}} \tag{35}$$

where $\varphi \cdot a_{H_3O^+}$ is given by eqn. (9) with $n = 1$ and C_{H^+} is the total, *i.e.* the equilibrium concentration of solvated protons in the solution. In Fig. 4, $\log \varphi \cdot y_{H_3O^+}$ is plotted versus H_0 for the three acids, HNO_3, $HClO_4$ and H_2SO_4, for which Raman and NMR data have made possible a distinction between dissociated and undissociated acid. As seen, the three acids give practically parallel straight lines in the range of overlap. It does not seem unreasonable to suppose that, if no systematic experimental errors were present, all three curves would coincide as do the corresponding activities.

In analogy to (35) the function $\varphi^{-1} \cdot y_{A^-}$ is defined by:

$$\varphi^{-1} \cdot y_{A^-} = \frac{\varphi^{-1} \cdot a_{A^-}}{C_{A^-}} \tag{36}$$

where C_{A^-} is the equilibrium amount of A^-. For a monobasic acid HA, we have:

$$C_{H^+} = C_{A^-} = \alpha \cdot C \tag{37}$$

where α is the degree of dissociation of HA.

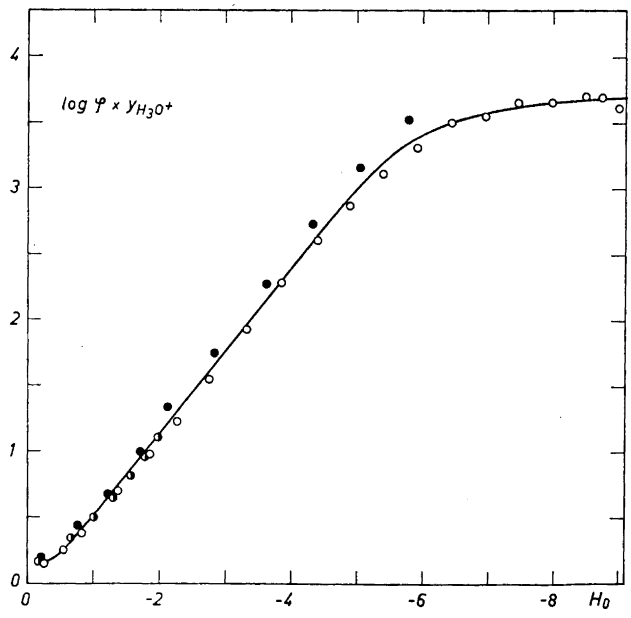

Fig. 4. The function $\log \varphi \cdot y_{H_3O^+}$ *versus* H_0 for the acids: ○ H_2SO_4; ● $HClO_4$; ◑ HNO_3

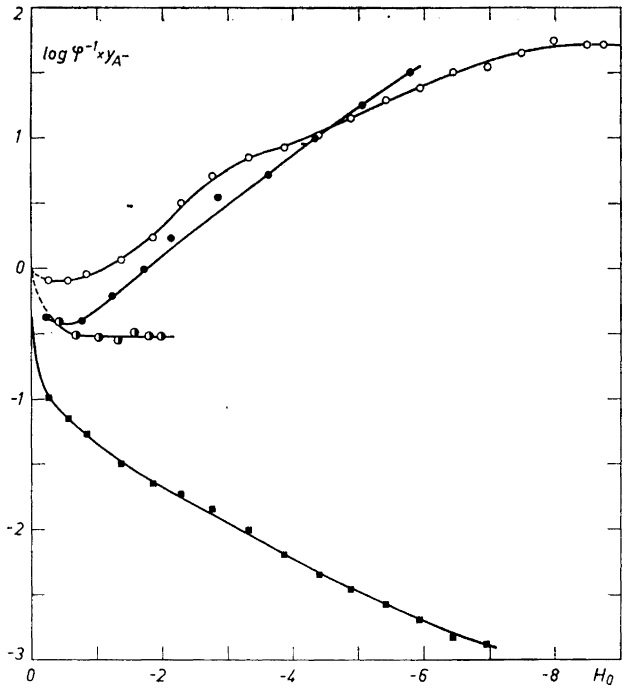

Fig. 5. The function log $\varphi^{-1} \cdot y_{A^-}$ *versus* H_0 for various anions: ○ HSO_4^-; ● ClO_4^- ◑ NO_3^-; ■ SO_4^{2-}.

In Fig. 5, log $\varphi^{-1} \cdot y_{A^-}$ is plotted against H_0 for the anions, NO_3^-, ClO_4^-, HSO_4^- and SO_4^{2-}. As seen, HSO_4^- and ClO_4^- give parallel curves for H_0 down to —3 while the curve for NO_3^- seems to be practically constant and the curve for SO_4^{2-} slopes in the other direction. In the following section, it will be shown how the slopes of the activity coefficient curves are related to the average degree of hydration.

THE AVERAGE DEGREE OF HYDRATION

In a preceding paper[1], it was shown that a function $\bar{n}'$ approximating to the average degree of hydration of the ions H^+, A^- could be computed from

$$\bar{n}' = -\operatorname{dlog}\left(\frac{y}{a}\right)^2 / \operatorname{dlog} a_{H_2O} = -\frac{\operatorname{dlog} y_{H^+} \cdot y_{A^-}}{\operatorname{dlog} a_{H_2O}} \tag{38}$$

where $\bar{n}'$ approaches the true hydration number $\bar{n}$ when

$$\frac{\operatorname{dlog} y_+ \cdot y_-}{\operatorname{dlog} a_{H_2O}} \sim 0 \tag{39}$$

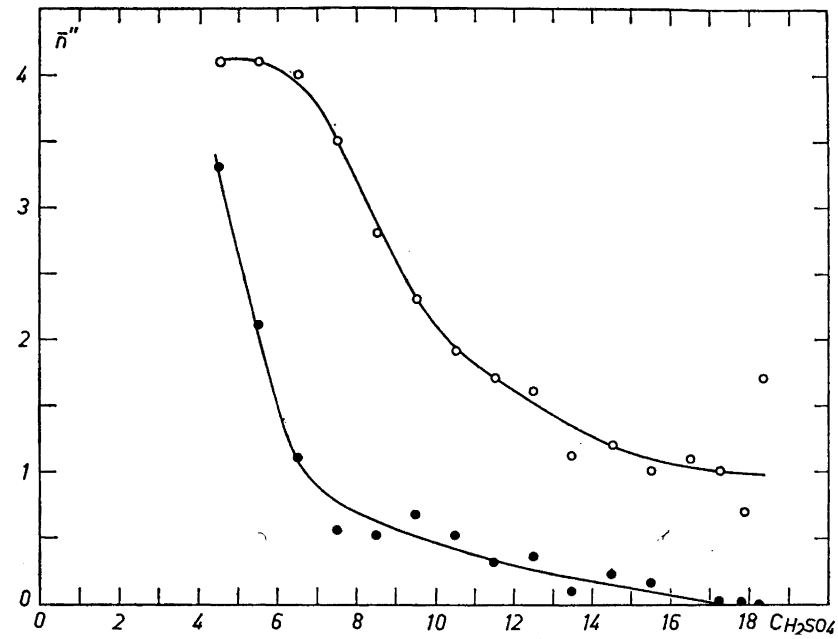

Fig. 6. The function $\bar{n}''$ for H^+ and HSO_4^- in H_2SO_4 *versus* the stoichiometric molarity, C, of the acid: ○ H^+; ● HSO_4^-.

y_+ and y_- are the »true» activity coefficients of the various hydrated ions with the simplifying assumption that y_+ is the same for all differently hydrated protons and y_- the same for all differently hydrated anions at each concentration.

From (38) we obtain by introducing the φ-function:

$$\bar{n}''_{H^+} = \frac{-\text{dlog } \varphi \cdot y_{H^+}}{\text{dlog } a_{H_2O}} \qquad \bar{n}''_{A^-} = \frac{-\text{dlog } \varphi^{-1} y_{A^-}}{\text{dlog } a_{H_2O}} \tag{40 a,b}$$

Using the definition of H_0 (eqn. 3) (40a) can be rearranged to

$$\bar{n}''_{H^+} = \frac{\delta \log C_{H^+} + \delta H_0}{\delta \log a_{H_2O}} \tag{41}$$

$\bar{n}''_{H^+}$ and $\bar{n}''_{A^-}$ approach the true hydration numbers if

$$\frac{\text{dlog } \varphi \cdot y_+}{\text{dlog } a_{H_2O}} \sim 0, \quad \frac{\text{dlog } \varphi^{-1} \cdot y_-}{\text{dlog } a_{H_2O}} \sim 0 \tag{42 a,b}$$

which may happen in concentrated solutions where, as seen in Fig. 3, a_{H_2O} decreases rapidly while the activity coefficients may approach constant values as indicated in Figs. 4 and 5 by the behavior of the stoichiometric coefficients. In Fig. 6, $\bar{n}''_{H^+}$ and $\bar{n}''_{HSO_4^-}$ are plotted versus C from 4 M to pure H_2SO_4. In this concentration range, $\bar{n}''_{H^+}$ decreases from about 4 in dilute solutions

to 1 in concentrated solutions while $\bar{n}''_{HSO_4^-}$ decreases from about 3 to 0. That $H^+(H_2O)_n$ tends towards H_3O^+, and $HSO_4^-(H_2O)_n$ towards HSO_4^- is quite reasonable. It thus seems that the conditions (42) may be valid in concentrated solutions and $\bar{n}''$ close to the real hydration number. Since the curve H_0 *versus* a_{H_2O} is the same for all strong acids, it is seen from eqn. (40) that the slopes of the curves log $\varphi^{\nu} \cdot y_X^{\nu}$ *versus* H_0 are proportional to $\bar{n}''$ and thus closely related to $\bar{n}$. In Fig. 4 the parallelism of the curves log $\varphi \cdot {}_{H_3O^+}$ for different acids implies that when compared at the same water activity (or H_0-value) the protons seem to be hydrated to the same extent in all strong acids.

In Fig. 5 it is seen that, in dilute and moderately concentrated solutions, ClO_4^- and HSO_4^- seem to be hydrated to the same extent. In more concentrated solutions, ClO_4^- seems to be more strongly hydrated than HSO_4^- as indicated by the steeper slope. On the other hand, the practically constant value for log $\varphi^{-1} \cdot y_{NO_3^-}$ implies a much smaller and nearly constant degree of hydration for NO_3^- as compared with ClO_4^- and HSO_4^- in the range of overlap. By adding 3·log a_{H_2O} to log $\varphi^{-1} \cdot y_{NO_3^-}$, a curve parallel to those for ClO_4^- and HSO_4^- is obtained. This implies a difference of 3 in hydration number in moderately concentrated solutions between NO_3^- on the one hand and ClO_4^- and HSO_4^- on the other.

For SO_4^{2-}, the slope of the curve log $\cdot \varphi^{-2} y_{SO_4^{2-}}$ is in the other direction compared with those for ClO_4^- and HSO_4^-. No explanation of this behavior has been found. Solvation by H_2SO_4 instead of H_2O might explain the different slope altough it is difficult to see how this might occur in solutions where SO_4^{2-} exists in measurable amounts only up to 12 M while measurable amount of H_2SO_4 do not seem to appear below 14 M.

Note added in proof. Recently, Young [26] and Wyatt [*Trans. Faraday Soc.* **56** (1960) 490] have suggested the existence of $H_3O^+ \cdot H_2SO_4$ in concentrated solutions of sulfuric acid. That $\bar{n}''_{H_3O^+}$ nevertheless tends towards unity suggssts that to a first approximation the interaction between H_3O^+ and H_2SO_4 can be neglected compared to the strong interaction between H^+ and H_2O.

Acknowledgements. The author wishes to express his sincere thanks to Professor Charles D. Coryell for stimulating discussions and encouraging interest when this work was in its infancy. Much helpful advice from Professor Lars Gunnar Sillén concerning the presentation of the material in this paper is gratefully acknowledged. Professor T. F. Young is thanked for comments on equilibria in concentrated solutions of sulfuric acid and Professor W. F. Giauque for giving access to thermodynamic data unpublished at that time for the system H_2SO_4—H_2O. Mr Don Gillam corrected the English text. Dr Åke Olin is also thanked for some helpful comments. Thanks are due to the *Swedish Atomic Energy Committee* and the *Swedish Natural Science Research Council* for financial support.

Reactions between Quinones and Carbonyl Compounds Catalysed by Aluminium Oxide

Part II *. The Addition of Acetone to *o*-Benzoquinones

RUNE MAGNUSSON

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

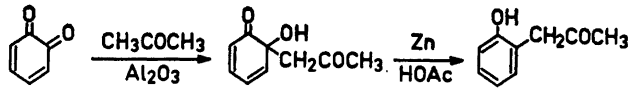
o-Benzoquinones react with acetone at room temperature in the presence of aluminium oxide to form 2-acetonyl-*o*-benzoquinols by the addition of one mole of acetone at one of the carbonyls by an aldol type condensation. An investigation was made of this reaction with unsubstituted *o*-benzoquinone and various alkyl and alkoxyl substituted *o*-benzoquinones. In most cases the *o*-benzoquinol could be isolated in a pure form but in two cases the crude *o*-quinol dimerised too rapidly for it to be purified.

In a preceding communication [1] it was briefly reported that 3,8-dimethoxy-1,2-naphthoquinone and 2,6-dimethoxy-1,4-benzoquinone reacted with acetone in the presence of aluminium oxide; one mole of acetone was added with the formation of an acetonyl-quinol. It has now been shown that similar aldol condensations occur with *o*-benzoquinones and the present paper is a report of an investigation of the addition of acetone to a number of *o*-benzoquinones in the presence of aluminium oxide.

The addition of ketones to tetrachloro-*o*-quinone has been investigated by Schenck *et al.*[2] Dry hydrogen chloride was used as a catalyst and the corresponding *o*-quinol was formed.

When an acetone solution of *o*-benzoquinone (I) is shaken with aluminium oxide, pyrocatechol is formed in 11 % yield. The formation of pyrocatechol also occurs spontaneously in an aqueous solution of *o*-benzoquinone and is probably the result of a complicated disproportionation [3]. The expected 2-acetonyl-*o*-benzoquinol (II) has not been isolated but its formation has been shown indirectly by the isolation of a small amount of 2-acetonyl-phenol (III) after treatment of the acetone solution with zinc and acetic acid.

* Part I, See Ref. [1]



I II III

In the experiments described below the reaction was applied to a number of alkyl and alkoxyl substituted *o*-benzoquinones (IV—XIII) which are more stable than *o*-benzoquinone. When a freshly prepared solution of the substituted *o*-benzoquinone in acetone was shaken with neutral aluminium oxide, the colour of the solution turned from red to yellow. Analysis of the reaction products showed that in all cases they were adducts of quinone and acetone in a 1:1 ratio.

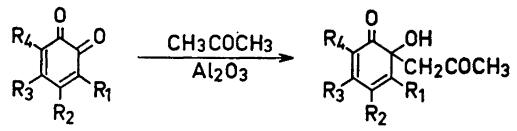
Under these conditions, the aldol condensation between *o*-quinone and acetone was accompanied by competing dimerisation and polymerisation reactions of the *o*-quinones [4-9]. These products however, unlike the acetone adduct, were strongly adsorbed on the aluminium oxide which usually acquired a dark colour. Dimeric *o*-benzoquinone for example was 95 % adsorbed on shaking with aluminium oxide in acetone. Thus the acetone adducts were purified automatically.

Reduction [10] of the *o*-quinone acetone adducts with zinc and acetic acid gave *o*-acetonylphenols, supporting the view that the adducts had an *o*-benzoquinol structure.

The addition of acetone to either of the carbonyl groups in the symmetrically substituted *o*-benzoquinone V would give only a single acetonyl-quinol, XV, but the unsymmetrically substituted *o*-quinones (IV and VI—XIII) could, formally, give two isomers. However in all cases only one isomer was obtained. To decide which was formed of two possible *o*-acetonyl-quinols in the case where one isomer had a free 4-position and the other a free 5-position the following method * was used. The phenol obtained by reduction of the quinol was treated with potassium nitrosodisulphonate[17]. The formation of a *p*-benzoquinone indicated that the phenol had a free *p*-position and therefore that the 4-position was free in the quinol. The quinones IV, VI, VIII, X, XI and XIII gave quinols which were shown in this way to have a free 4-position and could therefore be ascribed the structures XIV, XVI, XVIII, XX, XXI and XXIII, respectively. The quinone XII gave a quinol, the reduction product of which was slowly oxidised by potassium nitrosodisulphonate to an *o*-quinone with simultaneous loss of a tert-butyl group. The quinol must therefore be substituted in both the 4 and 6 positions, as in structure XXII. The quinones VII and IX gave quinols that were shown by spectrophotometric evidence (see below) to have the structures XVII and XIX.

The *o*-acetonylquinols XVI, XVII, XVIII, XIX, XX, XXI and XXII were crystalline while XIV was an oil and was purified by distillation. The *o*-quinols XV and XXIII were oils and could not be obtained in an analytically pure condition. Most of the *o*-quinols dimerised on keeping at room temperature and in the case of the latter two compounds, dimerisation was so

* Further details will be given in a following paper [10].



IV–XIII XIV–XXIII

IV, XIV $R_1=R_3=CH_3$; $R_2=R_4=H$
V, XV $R_1=R_4=H$; $R_2=R_3=CH_3$
VI, XVI $R_1=R_3=R_4=CH_3$; $R_2=H$
VII, XVII $R_1=OCH_3$; $R_2=R_3=R_4=H$
VIII, XVIII $R_1=OCH_3$; $R_2=R_4=H$; $R_3=CH_3$
IX, XIX $R_1=OCH_3$; $R_2=R_4=H$; $R_3=CH_2CH_2CH_3$
X, XX $R_1=R_2=R_4=H$; $R_3=OCH_3$
XI, XXI $R_1=R_2=R_4=H$; $R_3=OCH_2C_6H_5$
XII, XXII $R_1=R_3=C(CH_3)_3$; $R_2=R_4=H$
XIII, XXIII $R_1=R_2=R_4=H$; $R_3=C(CH_3)_3$

fast that it was impossible to purify the monomers. The dimeric products will be dealt with in a following paper [11].

The infrared spectra of the acetone adducts, some of which are shown in Fig. 1, were in full accord with the postulated *o*-benzoquinol structures. They showed a strong hydroxyl absorption with maxima varying between 3 194 and 3 472 cm^{-1}. The absorption bands between 1 705 and 1 721 cm^{-1} confirm the presence of the acetonyl groups and the bands between 1 667 and 1 686 cm^{-1} can be explained by the presence of an $\alpha,\beta,\gamma,\delta$-unsaturated carbonyl grouping. The lowest frequency for the conjugated carbonyl band was shown by the substances XVII, XVIII and XIX (1 667, 1 669 and 1 669 cm^{-1}) all of which have a 3-methoxyl substituent (see below). All compounds showed two bands in the intervals 1 616—1 647 and 1 538—1 582 cm^{-1}, which can be ascribed to the two double bonds in the *o*-quinol ring. These absorption bands of the dienone system in the acetone adducts are similar to those reported [12] for the first two *o*-benzoquinols known, 2,3-dimethyl-*o*-benzoquinol and 2,3,5-trimethyl-*o*-benzoquinol.

The ultraviolet spectra of the acetone adducts also confirmed the *o*-benzoquinol structure. This type of conjugated system has been investigated by Derkosch and Kaltenegger [13], who have determined the ultraviolet spectra of a number of 2-methyl-*o*-benzoquinol acetates and of 2,3,5-trimethyl-*o*-benzoquinol *. Ethanol solutions of these compounds give a relatively broad K-band with maxima in the region of 298—312 mμ and an R-band varying between 349 and 369 mμ. The K-band is present in all the spectra shown in Figs. 2 and 3 but the R-band can be seen only in the spectrum of 2-acetonyl-4,6-di-tert-butyl-*o*-benzoquinol (XXII). This band is present as an inflection at 373 mμ while the main absorption peak for this compound is at 313 mμ.

* In the quoted work the substance was erroneously assumed to be 2,4,6-trimethyl-*o*-benzoquinol (cf. Ref. [14]).

1. 2-Acetonyl-3,5-dimethyl-*o*-benzoquinol (XIV)
2. 2-Acetonyl-3,5,6-trimethyl-*o*-benzoquinol (XVI)
3. 2-Acetonyl-4,6-di-tert-butyl-*o*-benzoquinol (XXII)

Solvent: 95 % Ethanol.

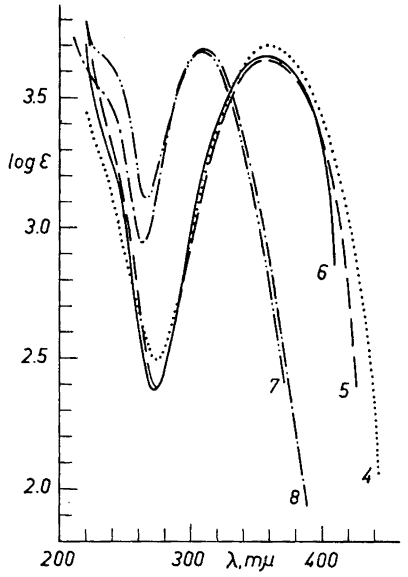

Fig. 3. Absorption spectra.
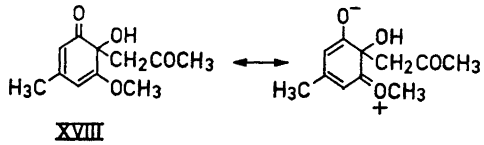
4. 2-Acetonyl-3-methoxy-*o*-benzoquinol (XVII)
5. 2-Acetonyl-3-methoxy-5-methyl-*o*-benzoquinol (XVIII)
6. 2-Acetonyl-3-methoxy-5-propyl-*o*-benzoquinol (XIX)
7. 2-Acetonyl-5-methoxy-*o*-benzoquinol (XX)
8. 2-Acetonyl-5-benzyloxy-*o*-benzoquinol (XXI)

Solvent: 95 % Ethanol.

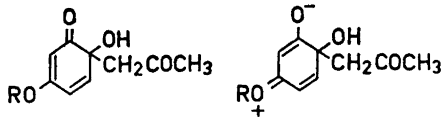
The two other alkyl-substituted quinols, 2-acetonyl-3,5-dimethyl- and 2-acetonyl-3,5,6-trimethyl-*o*-benzoquinol (XIV and XVI) have maxima at 321 and 327 mμ, respectively; the K-bands in these two *o*-quinols are thus at a relatively long wavelength and, since they are relatively wide, could possibly cover a smaller R-band.

2-Acetonyl-3-methoxy-5-methyl-*o*-benzoquinol (XVIII) has an ultraviolet spectrum (shown in Fig. 3) with an absorption maximum at a significantly longer wavelength, 356 mμ, than 2-acetonyl-3,5-dimethyl-*o*-benzoquinol (XIV), 321 mμ. This bathochromic shift can be explained by the mesomeric effect of the methoxyl group.



XVIII

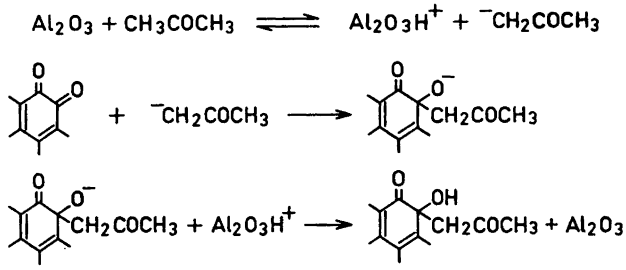
The ultraviolet spectra of XVII, XVIII and XIX are almost identical and since structural investigation [10] has shown that XVIII has a 3-methoxyl group it can be assumed that the same is also true for the other two compounds.



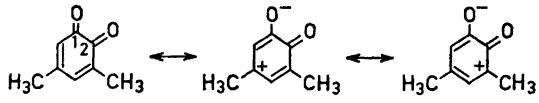
XX R = CH_3 XXI R = $CH_2C_6H_5$

In 2-acetonyl-5-methoxy-*o*-benzoquinol (XX) the methoxyl group makes possible a cross-conjugated resonance structure. This does not however give rise to any bathochromic displacement of the K-band. The spectra of this 5-methoxy-substituted quinol and of 2-acetonyl-5-tert-butyl-*o*-benzoquinol (XXIII) show absorption maxima at the same wavelength (305 mμ) and 2-acetonyl-5-benzyloxy-*o*-benzoquinol (XXI) with a maximum at 310 mμ shows only a very slight shift.

The aluminium oxide-catalysed addition of acetone to *o*-benzoquinones is of an aldol condensation type and therefore should be catalysed by alkali as well. Because of the instability of *o*-benzoquinones, alkali cannot be used as a catalyst in this case. The aluminium oxide may be assumed to act as a Lewis base, and the mechanism of the addition reaction may be presented as follows.

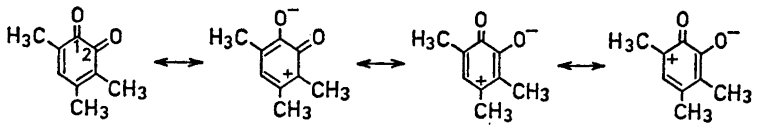


The acetonyl anion, when attacking the *o*-benzoquinone, would be expected to prefer the more positive of the two carbonyl carbon atoms. Which of carbon atoms 1 and 2 of the *o*-quinone ring will be the more strongly positive will depend on the inductive and mesomeric effects of the substituents in the ring. Thus the methyl groups in 3,5-dimethyl-*o*-benzoquinone (IV) by electron



IV a b

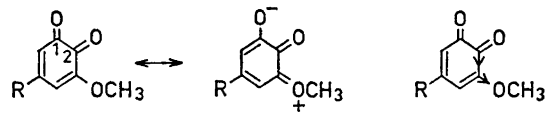
release should favour the resonance structures a and b. This will weaken the carbonyl character of the carbonyl group in position 1 and as a result carbon atom 2 will be comparatively more positive. Addition can therefore be expected to occur at 2, which is in agreement with the experimental result. Analogously favoured resonance structures can similarly be postulated for 3,5,6-trimethyl-*o*-benzoquinone (VI). In this case one of the methyl groups (that in the three



VI

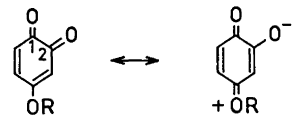
position) will favour reaction at carbonyl group 2 while the two others (in positions 4 and 6) will favour reaction at carbonyl group 1. The product of the reaction of 3,4,6-trimethyl-*o*-benzoquinone was 2-acetonyl-3,5,6-trimethyl-*o*-benzoquinole (XVI) which shows that the two methyl groups acting together exerted the dominant effect.

In 3-methoxy-*o*-benzoquinone (VII), 3-methoxy-5-methyl-*o*-benzoquinone (VIII) and 3-methoxy-5-propyl-*o*-benzoquinone (IX), the methoxyl group



VII R=H, VIII R=CH_3, IX R=$CH_2CH_2CH_3$

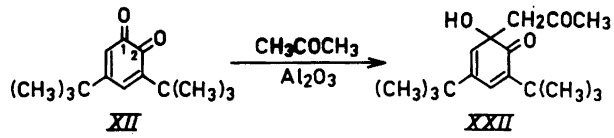
weakens the carbonyl character of carbonyl group 1 by a resonance effect and the acetonyl anion will therefore be accepted by carbon atom 2. Electron attraction by the methoxyl group may also contribute to make carbon atom 2 more positive than carbon atom 1. In VIII and IX, the alkyl group will co-operate with the methoxyl group to make carbonyl group 1 less reactive towards acetone than carbonyl group 2.



X R=CH_3, XI R=$CH_2C_6H_5$

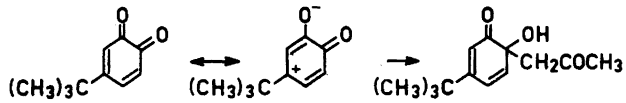
For both 4-methoxy-*o*-benzoquinone (X) and for 4-benzyloxy-*o*-benzoquinone (XI) *p*-quinonoid resonance structures are possible and as a result carbonyl group 2 will be less receptive to attack than carbonyl group 1.

An exception to the rule that acetone addition will take place at the carbonyl group that can be regarded as having the more strongly positive C-atom was found in the addition of acetone to 3,5-di-tert-butyl-*o*-benzoquinone (XII). This gave 2-acetonyl-4,6-di-tert-butyl-*o*-benzoquinol (XXII), probably



XII XXII

because carbonyl group 2 which should have the more strongly positive C-atom was hindered by the bulky butyl group in the 3-position. A tert-butyl group not present in a sterically hindering position directs the addition in the same way as methyl groups. 4-tert-Butyl-*o*-benzoquinone (XIII) gave 2-acetonyl-5-tert-butyl-*o*-benzoquinol (XXIII) which is in harmony with the expected electron displacement shown in the formula below.



XIII XXIII

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were recorded on a Perkin Elmer model 21 spectrophotometer using KBr discs in the case of solid substances and films between salt plates in the case of oils. Ultraviolet spectra were measured with a Beckman DU spectrophotometer. Microanalyses were done by Alfred Bernhardt, Mülheim (Ruhr).

Materials. *o*-Benzoquinone and 3-methoxy-*o*-benzoquinone were prepared by dehydrogenation of pyrocatechol and pyrogallol-1-methyl ether, respectively, with tetrachloro-*o*-quinone * according to Horner and Dürckheimer [15]. 3,5-Di-tert-butyl-*o*-benzoquinone was prepared according to Flaig *et al.*[16] and the other quinones with the exception of 4-tert-butyl-*o*-benzoquinone (see below) were prepared according to Teuber and Staiger [17]. Neutral aluminium oxide "Woelm" of activity 1 and acetone purum or p.a. were used. No differences were observed between the two grades.

4-tert-Butyl-o-benzoquinone (XIII). This *o*-quinone was prepared by dehydrogenation of the corresponding pyrocatechol by periodate according to the procedure described by Adler and Magnusson [18]. A solution of 1,2-dihydroxy-4-tert-butylbenzene (7.0 g) in water (1 l) was mixed with sodium metaperiodate (10 g) dissolved in water (150 ml). The red reaction mixture was extracted immediately with methylene chloride. The extract was dried with sodium sulphate and evaporated. The residue was recrystallised from a mixture of ether and light petroleum, giving red needles of 4-tert-butyl-*o*-benzoquinone, m.p. 66—67° [17] (3.8 g, 54 %).

Addition of acetone to *o*-benzoquinones

General procedure. A solution of the *o*-benzoquinone in acetone was shaken with aluminium oxide at room temperature. The end of the reaction was indicated by a colour change from red or red-brown to yellow. The quantities of reactants used and the time of shaking are given below. The solution was decanted and the aluminium oxide, which usually was strongly discoloured, was washed several times with acetone. The combined solutions were centrifuged to remove traces of alumina. The acetone solution was then evaporated in a rotary vacuum evaporator and the reaction product obtained purified as described below.

* *o*-Benzoquinone as well as 3-methoxy-*o*-benzoquinone when prepared in this way on keeping sometimes suddenly decomposed. However if the crude substance was recrystallised immediately from ether it was usually stable.

o-*Benzoquinone* (I) a) *o*-Benzoquinone (0.82 g) in acetone (15 ml) was shaken with aluminium oxide (12.5 g) for 30 min. The reaction solution on evaporation (see above) gave a partially crystalline residue. It was extracted with boiling hexane. On cooling, the extract gave *pyrocatechol* (89 mg, 11 %), identified by m.p. and mixed m.p.

b) *o*-Benzoquinone (8.0 g) in acetone (300 ml) was shaken with aluminium oxide (200 g) for 30 min. The solution was decanted and shaken with zinc dust (20 g) and acetic acid (20 ml) until colourless. The aluminium oxide was washed with acetone and the washings were treated in the same way. The combined solutions were filtered and neutralised with sodium bicarbonate solution. The acetone was distilled off under reduced pressure and the aqueous solution remaining was extracted with ether. The ether solution, which contained 2.0 g of product, was extracted with 20 % aqueous sodium bisulphite (10 × 50 ml). The bisulphite solution was neutralised with sodium bicarbonate and extracted with ether. The ether solution was dried and evaporated giving an oil (0.55 g) which crystallised after a day. Recrystallisation from hexane gave colourless plates of *2-acetonylphenol* (*III*), m.p. 62—64° (0.20 g, 2 %). After sublimation (0.05 mm Hg, bath temperature 70°) and further recrystallisation from hexane it had m.p. 63—64°. (Found: C 71.99; H 6.82. Calc. for $C_9H_{10}O_2$: C 71.98; H 6.71). Infrared bands (cm^{-1}): 3408 (OH), 1712 (C=O), 1616, 1597 and 1504—1513 (benzene ring); ultraviolet maximum at 276 mμ, log ε, 3.12. The substance could be converted into 3-methylcoumarone by boiling with ethanolic hydrochloric acid.

Since this experiment was carried out, the preparation of the compound in another way has been reported [20].

3,5-Dimethyl-o-*benzoquinone* (*IV*) (2.30 g) in acetone (125 ml) was shaken (15 min) with aluminium oxide (50 g). The reaction mixture when worked up gave a yellow oil (1.26 g). Distillation at 10^{-3} mm Hg (bath temp. 110°) gave *2-acetonyl-3,5-dimethyl*-o-*benzoquinol* (*XIV*) as a yellow viscous oil. (Found: C 68.45; H 7.66. Calc. for $C_{11}H_{14}O_3$: C 68.02; H 7.26). Infrared bands (cm^{-1}): 3 401 (OH), 1 715 (C=O), 1 671 (conj. C=O), 1 645 (C=C) and 1 580 (C=C); ultraviolet spectrum, see Fig. 2. The yield was low since a part of the substance decomposed on distillation giving a black tarry residue. The substance dimerises [11] at room temperature but can be stored at —20° for some weeks without change.

4,5-Dimethyl-o-*benzoquinone* (*V*) (3.80 g) in acetone (150 ml) was shaken with aluminium oxide (100 g) for 5 min and the mixture was then cooled to —80°. It was worked up rapidly at low temperature (*ca.* 0°) giving *2-acetonyl-4,5-dimethyl*-o-*benzoquinol* (*XV*) as a yellow viscous oil (1.45 g). Infrared bands (cm^{-1}): 3 448 (OH), 1 712 (C=O), 1 686 (conj. C=O) and 1 647 (C=C). On warming to room temperature the product dimerised rapidly and after 30 min the dimer was crystalline. Recrystallisation twice from acetone gave colurless prisms (0.91 g) of *2-acetonyl-4,5-dimethyl*-o-*benzoquinol dimer* which turned dark at 186° and decomposed at 205° [Found: C 67.89; H 7.16; MW 388 (cryoscopic in acetic acid). Calc. for $C_{22}H_{28}O_6$: C 68.02; H 7.26; MW 388.44].

3,4,6-Trimethyl-o-*benzoquinone* (*VI*) (1.58 g) in acetone (50 ml) was shaken with aluminium oxide (30 g) for 30 min. The reaction solution on evaporation gave a yellow oil (1.22 g) which was distilled at 10^{-3} mm Hg (bath temperature 90°) and after one day crystallised. The product was recrystallised from ethanol giving *2-acetonyl-3,5,6-trimethyl*-o-*benzoquinol* (*XVI*), yellow prisms, m.p. 57—59° (0.28 g) (Found: C 68.91; H 7.64. Calc. for $C_{12}H_{16}O_3$: C 69.20; H 7.55). Infrared spectrum, see Fig 1; ultraviolet spectrum, see Fig. 2. In another experiment the crude undistilled *o*-quinol was seeded with crystalline material. The solid obtained was recrystallised giving 53 % of XVI. The substance is stable at room temperature.

3-Methoxy-o-*benzoquinone* (*VII*) (6.58 g) in acetone (400 ml) was shaken with aluminium oxide (200 g) for 15 min. The reaction mixture when worked up gave a yellow oil (2.61 g) which crystallised on standing for some days. The product was dissolved in ethanol at room temperature and cooled to —20° giving *2-acetonyl-3-methoxy*-o-*benzoquinol* (*XVII*) as a yellow crystalline conglomerate, m.p. 68—69° (2.10 g, 23 %) (Found: C 61.37; H 6.30; OCH_3 16.04. Calc. for $C_{10}H_{12}O_4$: C 61.21; H 6.18; OCH_3 15.81). Infrared spectrum, see Fig. 1; ultraviolet spectrum, see Fig. 3. The substance is stable at room temperature.

3-Methoxy-5-methyl-o-*benzoquinone* (*VIII*) (1.78 g) in acetone (100 ml) was shaken (1 h) with aluminium oxide (50 g). The reaction solution when evaporated gave a yellow oil (1.04 g) which crystallised after some hours. The product was recrystallised from

ethanol giving *2-acetonyl-3-methoxy-5-methyl*-o-*benzoquinol (XVIII)* as a yellow crystalline conglomerate, m.p. 109° (0.64 g, 26 %) (Found: C 62.72; H 7.01; OCH_3 14.74. Calc. for $C_{11}H_{14}O_4$: C 62.84; H 6.71; OCH_3 14.76). Infrared bands (cm^{-1}) 3 344 (OH), 1 718 (C=O), 1 669 (conj. C=O), 1 629 (C=C), 1 558 (C=C); ultraviolet spectrum, see Fig. 3. The substance is stable at room temperature.

3-Methoxy-5-propyl-o-*benzoquinone*[19] *(IX)* (1.67 g) in acetone (30 ml) was shaken with aluminium oxide (25 g) for 1 h. On evaporation the reaction solution gave a yellow oil (0.90 g) which crystallised after several days. The product was recrystallised from ethanol giving *2-acetonyl-3-methoxy-5-propyl*-o-*benzoquinol (XIX)* as a yellow crystalline conglomerate, m.p. 56° (0.65 g, 30 %) (Found: C 65.08; H 7.36; OCH_3 13.17. Calc. for $C_{13}H_{18}O_4$ C 65.43; H 7.61; OCH_3 13.02). Infrared bands (cm^{-1}): 3 425 (OH), 1 718 (C=O), 1 669 (conj. C=O), 1 629 (C=C), 1 553 (C=C); ultraviolet spectrum, see Fig. 3. The substance is stable at room temperature.

4-Methoxy-o-*benzoquinone (X)* (3.0 g) in acetone (200 ml) was shaken with aluminium oxide (90 g) for 20 min and the mixture was then cooled rapidly (*ca.* 0°) and worked up fairly quickly (30 min). The product was an orange-coloured oil (1.06 g) which was kept at −80° and crystallised after some days. It was dissolved in ether at room temperature and cooled to −20° giving *2-acetonyl-5-methoxy*-o-*benzoquinol (XX)* as pale yellow needles, m.p. 66−67° (0.48 g, 11 %) (Found: C 61.52; H 6.12; OCH_3 15.93. Calc. for $C_{10}H_{12}O_4$: C 61.21; H 6.17; OCH_3 15.82). Infrared spectrum, see Fig. 1; ultraviolet spectrum, see Fig. 3. The substance can be kept at −20° without changing but dimerises at room temperature.

4-Benzyloxy-o-*benzoquinone (XI)* (4.40 g) in acetone (220 ml) was shaken with aluminium oxide (110 g) for 20 min. On evaporation the reaction solution gave a yellow oil (1.05 g) which crystallised after several hours. After treatment with charcoal and recrystallisation from ethanol it gave *2-acetonyl-5-benzyloxy*-o-*benzoquinol (XXI)* as almost colourless needles, m.p. 108° (0.77 g, 14 %) (Found: C 70.65; H 6.01. Calc. for $C_{16}H_{16}O_4$: C 70.57; H 5.92). Infrared bands (cm^{-1}): 3 356 (OH), 1 721 (C=O), 1 670 (conj. C=O), 1 634 (C=C), 1 577 (broad, C=C and phenyl ring) and 1 504 (phenyl ring); ultraviolet spectrum, see Fig. 3. This compound could be kept at room temperature for several days. Changes occurring after that have not been investigated.

3,5-Di-tert-butyl-o-*benzoquinone (XII)* (20.0 g) in acetone (600 ml) was shaken with aluminium oxide (400 g) for 1 h. The product obtained on working up was a brown oil which crystallised from light petroleum giving *2-acetonyl-4,6-di-tert-butyl*-o-*benzoquinol (XXII)* as yellow needles, m.p. 64−65° (11.8 g, 47 %) (Found: C 73.53; H 9.26. Calc. for $C_{17}H_{26}O_3$: C 73.34; H 9.42). Infrared spectrum, see Fig. 1; ultraviolet spectrum, see Fig. 2. The substance has been kept for several months at room temperature without change.

4-tert-Butyl-o-*benzoquinone (XIII)* (3.14 g) in acetone (100 ml) was shaken with aluminium oxide (50 g) for 30 min and the mixture was then cooled to −80°. It was worked up rapidly at low temperature (*ca.* 0°) and gave *2-acetonyl-5-tert-butyl*-o-*benzoquinol (XXIII)* as a viscous yellow oil (2.22 g); infrared bands at 3 449 (OH), 1 712 (C=O), 1 670 (conj. C=O), 1 645 (C=C) and 1 577 (C=C) cm^{-1}; ultraviolet maximum at 305 mμ (log ε, 3.50). On warming to room temperature the substance dimerised rapidly and after 30 min the dimer began to crystallise. Recrystallisation from ethanol gave colourless prisms, m.p. 173−175° (Found: C 70.60; H 8.02; MW 472 (cryoscopic in acetic acid). Calc. for $C_{26}H_{36}O_6$: C 70.24; H 8.10; MW 444.52).

The Kinetics of Calcium Oxalate Precipitation

ARNE E. NIELSEN

Universitetets fysisk-kemiske institut, Copenhagen, Denmark.

At concentrations below 1 mM the rate determining step in the precipitation of calcium oxalate is a reaction in the surface of the crystals. It is apparently of an order between 3.0 and 3.5. It is shown that when the incompleteness of the dissociation of calcium oxalate is taken into account the »true» order of the reaction is 4, when the rate is expressed by the ionic concentrations, and 2, when expressed by the concentration of the undissociated calcium oxalate.

At concentrations above 1 mM the rate is determined by diffusion.

In a previous work [1] the kinetics of calcium oxalate precipitation was investigated by means of experiments with the initial concentration c_0 = 0.75 and 0.50 mM. It was found that the rate of formation of the precipitate — measured by the electric conductance of the aqueous solution — was proportional to the total surface area of the precipitate and to a power of the concentration of the unprecipitated calcium oxalate close to 3.5. The power was clearly larger than 3 and less than 4.

The data found in the present work where c_0 = 1 and 5 mM, are treated in the way described in a previous work [2] on barium sulfate and the logarithm of the growth rate, dl/dt, where l is the length of a cube of the same volume as one of the growing crystals, and t is time, is plotted as a function of the logarithm of the concentration of the calcium oxalate in the solution at that time; see Fig. 1. In the region where $c < 1$ mM the points lie close to a straight line of slope 3.3, which means that the rate is proportional to the 3.3-rd power of c. At $c > 1$ mM the rate is proportional to c. Later on we shall see that in this part of the curve the rate is diffusion controlled. But first we shall consider the steeper part of the curve.

THE ORDER OF THE SURFACE REACTION

In interpreting the power or order of the reaction it must be remembered that calcium oxalate may be incompletely dissociated at the concentrations used. When this is taken into account it turns out that the precipitation (or crystal growth) rate follows

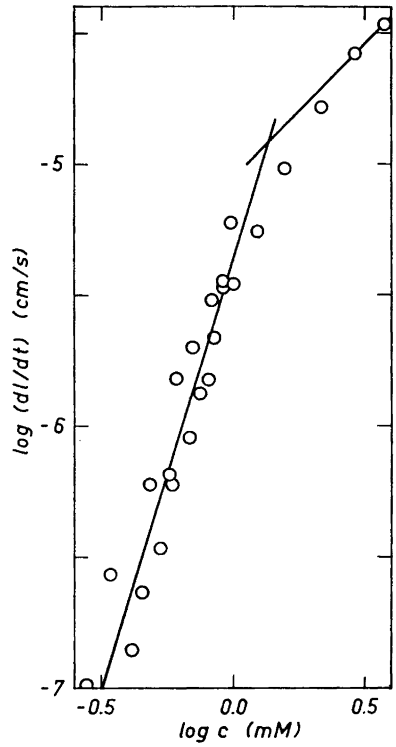

Fig. 1. The linear rate of crystal growth as function of (CaOx) in a logarithmic diagram. Below 1 mM the rate is proportional to the 3.3rd power of the concentration. Above 1 mM the rate is proportional to the concentration.

$$J_1 = k_1\,(\mathrm{CaOx})^2$$
$$J_2 = k_2\,(\mathrm{Ca^{++}})^2\,(\mathrm{Ox^{--}})^2$$
$$J = J_1 + J_2 = k_1\,(\mathrm{CaOx})^2 + k_2\,(\mathrm{Ca^{++}})^2\,(\mathrm{Ox^{--}})^2$$

where J is the total rate of depositing matter per unit area of the crystal surfaces.
From the law of mass action

$$(\mathrm{Ca^{++}})\,(\mathrm{Ox^{--}}) = K \cdot (\mathrm{CaOx})$$

it follows that

$$J = k_{\mathrm{I}}(\mathrm{CaOx})^{\,2} = k_{\mathrm{II}}(\mathrm{Ca^{++}})^{\,2}(\mathrm{Ox^{--}})^{\,2}$$

where $k_{\mathrm{I}} = k_1 + k_2K$

$$k_{\mathrm{II}} = k_1/K + k_2$$

When the ionic species Ca^{++} and Ox^{--} are present in equivalent concentrations we define $c = (\mathrm{CaOx}) + (\mathrm{Ca^{++}}) = (\mathrm{CaOx}) + (\mathrm{Ox^{--}})$.

At *low* concentrations we have $(\mathrm{CaOx}) \ll (\mathrm{Ca^{++}}) = (\mathrm{Ox^{--}})$

$$(\mathrm{Ca^{++}}) = (\mathrm{Ox^{++}}) = c$$

$\therefore J = k_{II}c^4$

At *high* concentrations $(CaOx) \gg (Ca^{++}) = (Ox^{++})$

$c = (CaOx)$

$\therefore J = k_I c^2$

If however (CaOx), (Ca^{++}) and (Ox^{--}) are of the same order of magnitude none of the above mentioned approximations is valid and if one writes

$J = kc^p$

p is only apparently a constant, $2 < p < 4$, in limited concentration ranges. To be more precise we may define p by

$p = d\ln J/d\ln c.$

Putting $(CaOx) = x$, $(Ca^{++}) = (Ox^{--}) = c - x$ we find

$(c - x)^2 = Kx$

$$\therefore \frac{dx}{dc} = \frac{1}{1 + (K/2(c - x))}$$

$J = k_1 x^2$

$$p = \frac{d\ln J}{d\ln c} = \frac{c}{J}\frac{dJ}{dc} = \frac{2c}{x[1 + (K/2(c - x))]}$$

Solving the mass action law with respect to x we find

$$x = c - \frac{K}{2}\left(\sqrt{1 + \frac{4c}{K}} - 1\right)$$

$$\therefore p = \frac{2c}{[c - (K/2)(\sqrt{1 + (4c/K)} - 1)][1 + (1/(\sqrt{1 + (4c/K)} - 1))]}$$

$$= \frac{2}{[1 - (1/2q)(\sqrt{1 + 4q} - 1)][1 + (1/(\sqrt{1 + 4q} - 1))]}$$

Table 1.

q	p
0.001	3.989
0.01	3.961
0.05	3.826
0.1	3.690
0.2	3.491
0.5	3.155
1	2.895
2	2.667
5	2.437
10	2.312
100	2.100
1 000	2.041

where $q = c/K$. Values of p calculated by this formula are in Table 1. It is easily seen that $p \to 2$ for $q \to \infty$ and $p \to 4$ for $q \to 0$.

DETERMINATION OF THE DISSOCIATION CONSTANT

The calibration measurements were performed on solutions of $CaCl_2$, Na_2Ox and NaCl having the same compositions as the reaction mixture at different degrees of advancement during a kinetic run. From these measurements the dissociation constant may be estimated neglecting the dependence of the molar conductivities on the concentration. This is only permissible when the range of ionic strengths used is small. We write

$$10^3 \varkappa = c_0(\Lambda_{CaOx}(1 - \alpha)\delta + 2\Lambda_{NaCl})$$

$$10^3 \varkappa_1 = 2c_0\Lambda_{NaCl}$$

$$K = (Ca^{++})(Ox^{--})/(CaOx) = c_0(1 - \alpha)\delta^2/(1 - \delta)$$

where

$\varkappa$ = specific electric conductance
c_0 = initial concentration of CaOx
Λ_{CaOx} and Λ_{NaCl} = molar conductivities
α = degree of reaction
δ = degree of dissociation of CaOx.

Eliminating δ and Λ_{NaCl} we obtain

$$\frac{c_0(1 - \alpha)}{\varkappa - \varkappa_1} = \frac{\varkappa - \varkappa_1}{K\Lambda_{CaOx}^2} + \frac{1}{\Lambda_{CaOx}}$$

A diagram of $c_0(1 - \alpha)/(\varkappa - \varkappa_1)$ as function of $\varkappa - \varkappa_1$ should thus yield a straigth line intersecting the ordinate axis at $1/\Lambda_{CaOx}$ and having the slope $1/K\Lambda_{CaOx}^2$. From Fig. 2 we see that a straigth line is really found in this way, and that

$$\Lambda_{CaOx} = 192; \quad K = 0.00162 \text{ M}.$$

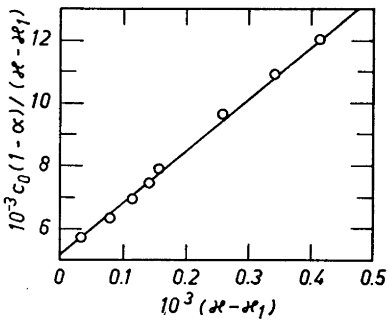

Fig. 2. A plot of $c_0(1 - \alpha)/(\varkappa - \varkappa_1)$ as function of $\varkappa - \varkappa_1$. From the slope of the straight line the dissociation constant of calcium oxalate can be determined (Units: mM, Ω and cm).

This number is, within the uncertainties and errors of approximations, the concentration dissociation constant. The activity dissociation constant K_a (or, the former extrapolated to ionic strength zero) can be estimated in the following way. The ionic strength is

$$I = \frac{1}{2}\Sigma c_i z_i^2 = 2c_0(1 + 2(1 - \alpha)\delta)$$

Assuming values of K, c_0 and α, δ can be calculated from

$$\delta^2/(1 - \delta) = K/c_0(1 - \alpha)$$

With $K = 0.001$ M, $c_0 = 0.001$ M, $\alpha = 0.8$, we find the lowest ionic strength used: $I_{min} = 0.0027$ M; with the same K, $c_0 = 0.005$ M and $\alpha = 0$ we find the highest ionic strenth $I_{max} = 0.017$. Using furthermore the Debye-Hückel equation in the Güntelberg formulation [3]

$$\log f_z = -0.5\, z^2 \sqrt{I}/(1 + \sqrt{I})$$

we find that f_2, the activity coefficient of a doubly charged ion lies between 0.59 and 0.80; now $K_a = Kf_2^2$. Since the mean value of 0.59^2 and 0.80^2 is near to 0.50 we may estimate

$$K_a = 0.0008 \text{ M}$$

This may be compared with the value 0.0010 M reported by Davies [4].

DISCUSSION OF THE KINETICS

In Fig. 1 the range of concentrations corresponding to the steeper part of the curve is $0.0003 < c < 0.001$ M. Since $q = c/K$ where $K = 0.0016$ we have $0.2 < q < 0.6$ and consequently (see Table 1) $3.5 > p > 3.1$. We may therefore conclude from the experimental slope 3.3 that the surface reaction controlling the rate of growth of the calcium oxalate crystals is of the fourth order in the ionic concentration or, which is equivalent, of the second order in the concentration of the undissociated calcium oxalate.

This is similar to the result obtained in experiments on the precipitation of barium sulfate [2,5]. For $BaSO_4$ it has been shown [5] that $K > 0.004$ M, and most probably K is about 0.008 M. The surface reaction is rate determining for the precipitation of barium sulfate when $c < 0.4$ mM. When $q = c/K < 0.05$ Table 1 shows that $3.8 < p < 4.0$ which is just what has been found.

In the high concentration end of the curve on Fig. 1 the slope approaches 1. This is easily explained since at these high concentrations the diffusion of the matter from the bulk of the solution to the surface becomes rate determining — as explained in greater detail in the papers on barium sulfate [4]. From the electric mobilities $l_+ = 5.9 \times 10^{-4}$ and $l_+ = 7.4 \times 10^{-4}$ cm²/s·V we calculate the diffusion coefficient

$$D = 2kTl_+l_-/(l_+ + l_-)q = 8.5 \times 10^{-6} \text{ cm}^2/\text{s}$$

and the diffusional growth rate should consequently follow, in CGS-units:

$$dl/dt = 2.60\ vDc/l = 0.00147\ c/l$$

With the value of l in the highest point on Fig. 1, $l = 3.12 \times 10^{-4}$, cm we find $dl/dt = 4.7\ c$; the experiments give $(dl/dt) = 8.9\ c$. The reason why the growth rate is larger than calculated, is probably that the particles are not — as assumed in the calculations — spheres or cubes, but show the shape of small »stars» when viewed in a microscope. The rate of growth depends — in case of diffusion — rather on the largest corner to corner dimensions of the particles than of the volume. There is no doubt, therefore, that the rate is mainly controlled by diffusion at $c > 1$ mM.

Physical Properties of Isotopic Forms of Some Inorganic Acid-Water Azeotropes

KARL ERIK HOLMBERG

Division of Chemistry, Section for Nuclear Chemistry, AB Atomenergi, Stockholm, Sweden

The azeotropes of DCl, DBr or DNO_3 with D_2O are more volatile than the corresponding azeotropes containing H. In the $HCl-H_2O$ and $HBr-H_2O$ azeotropes, the difference in volatility of ^{16}O and ^{18}O is larger than in water. Other isotope enrichment effects are small or imperceptible. Differences in other physical properties, such as density, viscosity and refractive index, are similar to those between H_2O and D_2O though less pronounced.

In the maximum boiling point azeotropes formed by various inorganic acids and water, there is a considerable interaction between the components in the liquid phase but not in the vapour phase. Different isotopic forms of the azeotropes may therefore differ with respect to volatility and composition (mole ratio acid : water).

The azeotropes of HCl, HBr or HNO_3 with H_2O and the corresponding fully deuterated azeotropes have been prepared and compared with each other with respect to composition, boiling point and some other physical properties. Separation factors for the various isotopes have been determined by Rayleigh distillation at atmospheric pressure and, in some cases, at reduced pressure. The results are summarized in Tables 1—5. For convenience, the following abbreviations will be used for the azeotropes:
$HClH_2O$, $DClD_2O$, $HBrH_2O$, $DBrD_2O$, HNO_3H_2O and DNO_3D_2O although, of course, they are not composed of equimolecular amounts of acid and water.

Physical properties. The H and D forms of the azeotropes do not differ much in composition and the difference with respect to physical properties between them is a reflection of the difference between the two forms of water. Thus, the D azeotropes have a higher density and viscosity and a lower refractive index and the relative differences are approximately proportional to the water content of the azeotrope.

Volatilities. The D forms of the azeotropes are the more volatile while, for pure water, the opposite holds true. This phenomenon is no doubt the same as what was found by Combs and Smith [1] who investigated the volatility of light and heavy water from salt solutions. They found that the relative vola-

tility of D_2O increases with the salt concentration and that the effect is more pronounced at higher temperatures.

The ratios of the vapour pressures of the H and D forms of the azeotropes have been calculated from the boiling point differences. The separation factors for H/D have been determined by Rayleigh distillation using $HClH_2O$ and HNO_3H_2O containing a fair amount of D.

Distillation of $HClH_2O$, containing 18.5 % D, gave a separation factor $\alpha = 1.0043$ with an estimated error of ± 0.0014 in close agreement with the

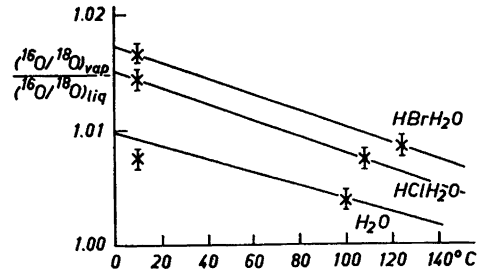

Fig. 1. Separation factors for $^{16}O/^{18}O$ from Rayleigh distillations. The line for H_2O is drawn according to a compilation by Dostrovsky[6].

ratio of the vapour pressures of the D and H systems. In fact, the separation factor α would be expected to be the square root of the vapour pressure ratio (or even smaller) just as the separation factor upon distillation of water is the square root of $p(H_2O)/p(D_2O)$. The reason for the different behaviour may be that the H and D forms of the azeotrope have somewhat different compositions, or it may be partly due to experimental errors.

The ratio of the vapour pressures of the H and D forms of HNO_3H_2O was found to be 1.100. The separation factor upon distillation of a mixture may be predicted tentatively. If differences in the forces between the water molecules are chiefly responsible it may be expected to be $1.100^{1.65/(1+2\times1.65)} = 1.037$ while, if it is due to the differences in the forces between HNO_3 and H_2O, we would get $1.100^{1/(1+2\times1.65)} = 1.022$.

From a Rayleigh distillation of a HNO_3H_2O azeotrope with about 4.5 % D abundance, the separation factor α was found to be 1.052 calculated on the first distillate and 1.037 calculated on the residue. A weighted average was 1.044. This is probably not too large considering the tendency of the Rayleigh distillations to give low values [2].

From boiling point measurements at various pressures (Table 4), it is evident that the separation factor will not be much better at other pressures than atmospheric. In this connection, it may be observed that Dawber and Wyatt [3] have found that at 0°C the vapour pressure of pure DNO_3 is more than 7 % larger than that of HNO_3.

The behaviour of the oxygen isotopes is very interesting. In the $HClH_2O$ and $HBrH_2O$ azeotropes, ^{16}O is enriched in the vapour, just as for water, but with a considerably larger factor, *cf.* Fig. 1. Further, the enrichment increases when the temperature decreases. This is quite in contrast to the H isotopes which are enriched in different directions in water and in the azeotropes.

In the HNO_3H_2O system, there is almost no enrichment of oxygen isotopes possibly because there is an exchange of O between H_2O and HNO_3 [4,5] and because the tendency of ^{18}O enrichment in the H_2O and HNO_3 vapours from the azeotrope may be in opposite directions.

Heavy isotopes of oxygen have been enriched, *e.g.* by Dostrovsky [6], on a rather large scale by the distillation of water. From the point of view of column volume and heat consumption, the $HClH_2O$ and $HBrH_2O$ azeotropes should be more favourable but the corrosion problems will probably be so serious as to offset the advantages.

The possibility of an enrichment of Cl isotopes by distillation of azeotropic hydrochloric acid has been pointed out by London [7]. The actual separation is, however, very small and therefore difficult to ascertain. By Rayleigh distillation, it has now been found that the separation factor is probably less than 1.001, ^{37}Cl enriching in the vapour. According to a column distillation experiment, described below, it is probably about 1.0003. This is a little surprising. It has been found by Johnston and Hutchison [8] that, upon electrolysis of a NaCl solution, ^{37}Cl enriches in the liquid by a factor of 1.0060. If this is an equilibrium process, the separation factor for the exchange between $Cl^-(aq)$ and $Cl_2(gas)$ will be the same ($\alpha = 1.0060$). It has been calculated by Urey [9] that, upon exchange between gaseous HCl and Cl_2, ^{37}Cl will enrich in the Cl_2 by the factor 1.003. From this, it is expected that, on exchange between $Cl^-(aq)$ and HCl (gas), which must occur between the liquid and gaseous $HClH_2O$ azeotrope, ^{37}Cl should be enriched in the liquid by a factor of 1.009 (at 25°C).

The present experimental results, however, agree with those of Urey *et al.*[10] who found a rather small enrichment of ^{37}Cl in the gas upon exchange between HCl (gas) and HCl (aq) at ambient temperature.

Similarly, for $HBrH_2O$, no separation of Br isotopes could be observed.

Considerable difficulties are met with when very small separation factors are to be determined. Ordinary mass spectrometric measurements seldom give the isotope ratio with a better accuracy than 0.1 %. To obtain a better accuracy, the elementary factor must be multiplied. By means of Rayleigh distillation, it is possible to have conveniently an enrichment corresponding to four single steps.

Column distillation would be an excellent multiplication method if the actual number of theoretical plates at equilibrium were known. A given column operates with a different number of theoretical plates for different systems. Therefore, it is not possible to evaluate a column with a known system and then use it to investigate unknown systems (if any accuracy is desired).

It may be thought that an internal comparison of different separation factors within the same system by column distillation would be possible with a good accuracy. It is, however, probable that even in this case the theoretical plate height (H.E.T.P.) may be different for different separations. On the other hand, the results could be expected to be much better than for a comparison of quite different systems by means of separate distillations.

A method of distillation where the number of theoretical plates may be predicted has been suggested by Kuhn *et al.*[11] but it requires an accurate regulation of the reflux ratio.

To have a check on the results of the Rayleigh distillations, a column distillation has been performed with the $HClH_2O$ azeotrope containing about 10 % D. In the top reservoir of the column, the various isotopes were enriched by the factors Q given in Table 5. A certain separation factor, determined above, is assumed to be correct and from it the number of theoretical plates is calculated and from this number the separation factors for the other isotopes are found. The discrepancy between the different calculations may be due to errors in the values from the Rayleigh distillations or, perhaps, to a different efficiency of the column towards the different isotope pairs in the system.

EXPERIMENTAL

Preparations. $HClH_2O$ was prepared by dilution of hydrochloric acid to the proper concentration and distillation at atmospheric pressure through a 1 meter column, with glass helices, to obtain an azeotrope with a narrow boiling point range (0.1°C).

SO_2Cl_2 was reacted with an excess of D_2O and distilled. The distillate was fractionated to give the azeotrope $DClD_2O$ with a narrow b.p. range.

$HBrH_2O$ was prepared by distillation from $KBr + H_2O + H_2SO_4$ and fractionation of the product with the 1 meter column [12].

$DBrD_2O$ was prepared in the same way from $KBr + D_2O + D_2SO_4$. D_2SO_4 had been obtained in the reaction above of $SO_2Cl_2 + D_2O$ or by reaction of SO_3 with D_2O.

HNO_3H_2O azeotrope was obtained by fractionation of common nitric acid.

DNO_3D_2O was prepared by distillation from $KNO_3 + D_2O + D_2SO_4$ and fractionation of the product.

Analyses. Analyses were made by titration with standard alkali.

Physical properties. The measurement of boiling points, densities and viscosities has been described earlier [2].

Rayleigh distillations. The apparatus for Rayleigh distillation at atmospheric pressure has been described earlier [2]. Rayleigh distillations at reduced pressure were performed from one flask to another, the first being heated by the surrounding air or a water bath and the second being cooled to 0°C or lower with alcohol and solid CO_2. The distillation temperature was adjusted to be about 10°C.

Test distillations with water followed by oxygen isotope analyses showed that the Rayleigh distillation gave slightly too low values for the separation factors, just as had been found earlier with H_2O—D_2O mixtures [2].

Column distillations. Azeotropic $HClH_2O$ with about 10 % D abundance was distilled in a column of 1.5 meter length packed with glass helices and with a reservoir at the top. It was refluxed for 9 days which was much more than was estimated to be necessary to reach equilibrium. Samples from the top and the still pot were analysed for the abundance of H, O and Cl isotopes.

Preparations for isotopic analyses

D analysis. The acid sample was neutralized with anhydrous Na_2CO_3 and the water was distilled off quantitatively under vacuum. It was purified by redistillation in vacuum and its density was measured.

^{18}O analysis. The acid sample together with a small amount of CO_2 was sealed in a glass tube and equilibrated at room temperature for a few days. The CO_2 was separated from the sample by freezing out. The dilution error was about 1 %.

Cl isotope analysis. Cl was precipitated as AgCl which was reacted with CH_3I in a sealed tube to give CH_3Cl [13].

Br isotope analysis. $HBrH_2O$ and CH_3OH were heated in a sealed tube to give CH_3Br which was separated and analysed [14].

^{15}N analysis. HNO_3 was reduced to NH_3 with Arnd's alloy [15] and then handled as usual for a N isotope analysis.

Errors

The errors in the ratios of the vapour pressures of the H and D forms of the azetropes are calculated from the estimated errors of the b.p. differences. The errors in the H/D separation factors correspond to the scattering of the experimental values. The other errors given correspond to the estimated errors of the mass spectrometric measurements and do not include accidental or systematic experimental errors.

Acknowledgement. Thanks are due to Mr. R. Cedenholt for assistance with the experimental work and to AB Atomenergi for permission to publish the results. The isotope abundance measurements were performed by the Mass Spectrometer Laboratory, Karolinska Institutet, Stockholm.

Short Communications

The Acid Soluble Nucleotides of *Vicia Faba* II

M. F. ABDEL-WAHAB and S. A. EL-KINAWI

Radioisotope Centre, A.E.E., Dokki, Cairo, U.A.R.

In a previous work from this department the acid soluble nucleotides, obtained by perchloric acid (PCA) extraction, of *Vicia Faba* plant just before fruiting, were studied [1]. The yield was found to be low at that stage of growth; this urged us to estimate the acid soluble nucleotides in the plant at different stages of germination.

In the last few years some important papers have been published about the metabolism of the acid soluble nucleotides in some plants and yeast [2-4]. Some difficulties arising in the separation from interfering substances of the nucleotides in plants in the pure form were overcome [5]. Previous methods developed primarily for the isolation of nucleotides from animal tissue proved to be unsatisfactory for the isolation of these compounds from plants. An improved method for the isolation of the acid soluble nucleotides from plant tissue has been described by Bergkvist [2]. The application of this method to *Vicia Faba*, seeds, pods, and seedling, has established the occurrence of ten nucleotides, *viz.* cytidine monophosphate, diphosphopyridine nucleotide, adenosine monophosphate, guanosine monophosphate, uridine monophosphate, adenosine diphosphate, a sugar derivative of uridine diphosphate, adenosine triphosphate, uridine triphosphate, and guanosine triphosphate.

Extracts prepared by directly homogenising plant material from any source in ice-cold perchloric acid demonstrated complex ultraviolet absorption spectra and hardly any separation of the acid soluble nucleotides from impurities [2]. Chromatography or ionophoresis at this stage proved also to be impracticable. Bergkvist overcame this difficulty by adsorbing the nucleotides quantitatively on Norite, and recovered them by repeated elution with 25 % aqueous ethanol containing 0.5 % ammonia. Spectrophotometric analysis of the combined eluates showed that the nucleotides were mixed with large quantities of non-nucleotides material [5].

In our laboratories a similar method was used where the whole organ was homogenised in 10 % PCA and reextracted with 5 % PCA in a Waring Blender. The nucleotides were isolated from the acid extract by the method used before [1]. After extraction and purification from the non-nucleotide fractions, the nucleotides were adsorbed on a strong base anion exchanger in the formate form. The individual nucleotides were eluted with formic acid solutions containing increasing concentrations of sodium formate. Elution of the nucleotides was followed by measuring the optical densities of the effluent fractions at 260 mμ and 270 mμ. The optical densities were plotted against the effluent volume. The extinction obtained from the eluate was plotted for the seeds, pods and seedlings, one, two, three and four weeks old. An example is shown in Fig. 1. The investigation was carried out on plants grown out of doors. The radioactivity of the effluent fractions was also determined. At all stages of germination the peaks of the extinction curves and the radioactivity curves coincided. This confirms the previous results that no reduced nucleotides are found in *Vicia Faba* [1]. The fact that in the course of germination ten distinct peaks

Table 1.

Compound	μmoles of nucleotides at different stages					
	seeds	1st week	2nd week	3rd week	4th week	Pods
CMP	2.00	1.00	1.50	1.00	0.32	0.08
DPN	0.30	0.20	0.60	0.20	0.28	0.07
AMP	0.28	0.30	0.50	0.21	0.50	0.10
GMP	0.20	0.22	0.20	0.24	0.26	0.08
UMP	0.32	0.32	0.30	0.22	0.30	0.07
ADP	0.21	0.20	0.20	0.23	0.28	0.08
UDPx	0.08	0.22	0.50	0.24	0.24	0.12
ATP	0.22	0.44	0.72	0.26	0.24	0.08
UTP	0.12	0.45	0.98	0.23	0.08	0.20

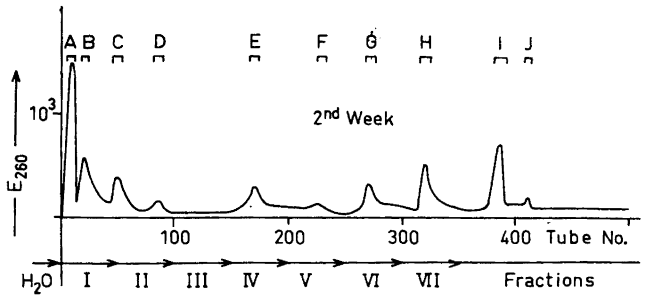

Fig. 1.

were observed, confirmed that no other nucleotides could exist.

Characterisation of the nucleotides was obtained by the following procedures:

1. Paper chromatography identification of the nucleotides and their bases after hydrolysis.
2. The position of the phosphate group on the different nucleotides was confirmed by oxidation with periodate [6].
3. Estimation of phosphorus for the different nucleotides [7].

Table 1 summarises the results obtained by plotting the extinction of the nucleotides at 260 mμ against the effluent fractions at different stages of germination.

Fig. 1 shows the absorption chromatogram at 260 mμ of the effluent fractions, collected by an automatic fraction collector, against the tube number. The material was obtained from 150 g of whole fresh *Vicia Faba* plants (2nd week seedlings) grown out of doors. Extraction by PCA as described above. Adsorption on Dowex 1, X-10, 200—400 mesh, 1 × 20 cm, formate form, flow rate 1 ml per min. The extinction was measured by means of a spectrophometer, Zeiss type PMQ II.

The peaks are identified as follows: A:CMP; B:DPN; C:AMP; D:GMP; E:UMP; F:ADP; G:UDPx; H:ATP; I:UTP; J:GTP. UDPx is a sugar derivative of uridine diphosphate.

The present work establishes the occurrence, in the beans, of all the four ribonucleotides in the form of the acid soluble 5′-nucleotides at different levels of phosphorylation. Nearly 30 % of the acid soluble nucleotides consists of cytidine and adenosine derivatives, the cytidine derivatives predominating. The acid extract of the seeds showed that CMP corresponds to the highest peak in the whole spectrum, next to CMP come UMP, DNP, AMP and ATP. The other five nucleotides are present to lesser extents. The same picture is found in the seedlings which are one week old with the exception that CMP is half its amount in the seeds. Another slightly different picture was observed in the second week but still CMP is present in the highest amount. Next in abundance are UTP, ATP, DNP, UDPx and UMP. GMP, GTP and ADP are present at levels which are nearly equal for the three nucleotides. At the end of the third week the acid extract showed another picture where almost all the nucleotides are present in more or less equal quantities with the exception that the amount of CMP is still high.

In the fourth week chromatogram, before fruiting, the picture was exactly the same as that previously obtained [1]. Experiments carried out with pods revealed a very low nucleotide yield.

From the preceding discussion one can conclude that the best material for obtaining good yield of the different nucleotides is the second week seedlings, see Fig. 1. Not only are the nucleotides present in good amounts, but they can also be well separated.

Thiamine Phosphatases in Liver, Kidney, and Brain of the Rat

KARL-HEINZ KIESSLING

Institute of Zoophysiology, University of Uppsala, Sweden

In previous papers [1,2] it has been shown that thiamine diphosphate * is hydrolyzed by liver fractions to TMP and TMP to thiamine with different optimal rates, *viz.* at pH 9.3 and 6.0, respectively. This fact together with the findings that the TDP splitting capacity could be separated from that of TMP at the extraction of a liver homogenate in a special way, indicates that the two steps are catalyzed by different enzymes.

In the present communication the occurrence of the enzymes hydrolyzing TDP to TMP (TDPase) and TMP to thiamine (TMPase) are studied for liver, kidney, and brain.

Experimental. Whistar rats were decapitated, brain, liver, and kidneys rapidly removed, and put in icecold 0.02 M $KHCO_3$, cut in pieces with a pair of scissors, washed, and homogenized in a Waring blendor for 2 min in acetone at −15°C. After filtration on a Büchner funnel the powder was suspended in cold acetone, rehomogenized, collected by filtration, weighed, and suspended in 20 vol. of 0.02 M $KHCO_3$ at 0°C. After 25 min. extraction at 0°C with continuous stirring the sample was centrifuged, and the clear supernatant used as source of enzyme.

0.25−0.5 ml of the supernatants was used for incubation together with 1 ml 0.1 M Tris-maleate buffer (pH 5−7.5) or 0.1 M Tris-buffer (pH 7.5−10), 0.2 ml 0.1 M $MgCl_2$, 0.5 $TD^{32}P$, containing 1 μmole TDP and giving about 2×10^3 counts/min, and water to 2.5 ml. To find out if the Tris-maleate and the Tris-buffer acted differently on the enzymes, an incubation at pH 7.5 was made with either of the two buffers. No significant difference was found. After 20 min incubation at 37°C with continuous shaking, the samples were cooled to 0°C, 5 M H_2SO_4 added to a final concentration of 0.5 M, proteins removed by centrifugation, and 1 ml samples taken for determination of inorganic and organic radioactive phosphate according to Ernster *et al.*[3]

$TD^{32}P$ and $TM^{32}P$ were prepared according to Viscontini *et al.*[4] with the addition that radioactive inorganic phosphate was also present during the synthesis. The compounds were then separated by paper chromatography [5].

Results and discussion. A comparison of the TDPase and TMPase activities in the different rat organs at pH 6, 7 and 9 gave the following proportions between liver, brain, and kidney. The figures are mean values of four experiments.

TDPase	pH 7	1.5 : 1 : 3
	pH 9	2.2 : 1 : 4.7
TMPase	pH 6	2.2 : 1 : 1.9
	pH 7	1.6 : 1 : 3.3

Figs. 1 and 2 show the activities of TDPase and TMPase at different pH values. There, the percentages of hydrolyzed TDP are not comparable from one tissue to the other, the tissues being taken from different individuals and also different amounts of enzyme having been used.

Of the tissues investigated kidney is most active in hydrolyzing TDP to TMP. From Fig. 2 it is seen, however, that kidney and brain, but not liver, have two optima for hydrolyzing TMP, one at pH 6 and another at pH about 9, while liver shows one only at pH 6. The figures for TDPase activity in kidney at pH 9, given above, could therefore be expected not only to show TDPase activity but also TMPase activity as the TMP formed by the first enzyme might be further hydrolyzed to thiamine by the second enzyme. This might also be the case with enzymes prepared from brain, although to a smaller extent. Paper chromatographic analysis of the samples after finished incubations, however, shows that a surprisingly small amount of the TMP formed has been further hydrolyzed. This may very truly be ascribed to the short incubation times (20 min) used in these experiments.

In none of the tissues examined TDPase and TMPase are dependent in the same manner upon pH. With the liver enzymes the two substrates TDP and TMP are hydrolyzed with optimal rate at distinctly different pH, with the kidney enzyme one peak is common to the two substrates, while the brain enzyme gives two common

* Abbreviations: TDP: thiamine diphosphate, TMP: thiamine monophosphate, TDPase: Thiamine diphosphatase, TMPase: thiamine monophosphatase.

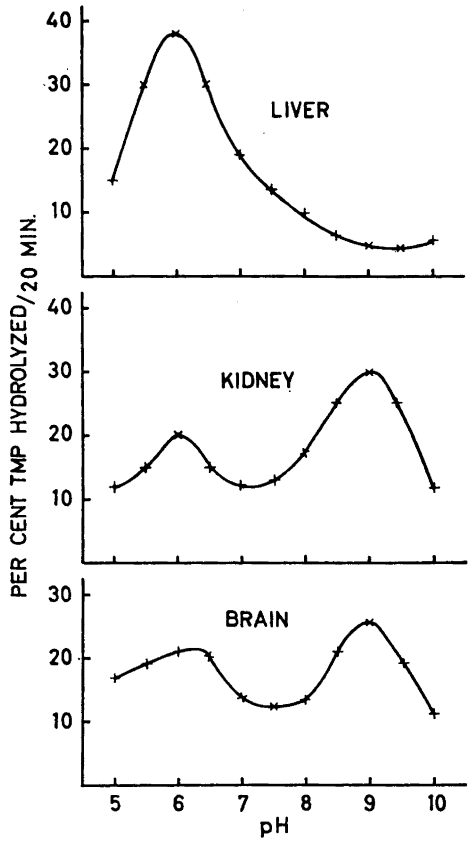

Fig. 2. Enzymatic hydrolysis of thiamine monophosphate to thiamine. Incubations were performed as described in Experimental.

peaks. With the last enzyme the peaks with TDP as a substrate are not very distinct, that is, TDP is hydrolyzed at moderate speed over a broad pH range. This is in agreement with findings by Naidoo and Pratt [6] in their histochemical investigation of a thiamine pyrophosphatase in nervous tissue from chicken.

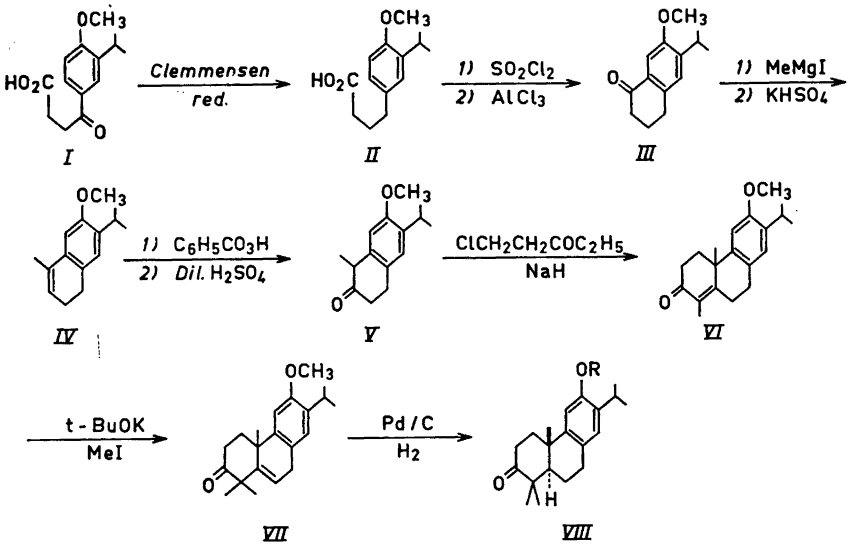
The Synthesis of DL-Hinokione Methyl Ether

YUAN-LANG CHOW

Kungl. Tekniska Högskolan, Organisk-kemiska Institutionen, Stockholm, Sweden

Hinokione has been isolated from the heartwood of several conifers [1] and its structure has recently been shown to be VIII (R = H) [1]. A synthesis of the DL-form of hinokione methyl ether (R = CH_3) has been carried out as indicated in the following scheme:



Succinoylation of 2-*iso*propylphenol methyl ether gave the keto-acid I, m.p. 133—135°, which furnished a deep red 2,4-dinitrophenylhydrazone, m.p. 85—88°. The keto-acid was reduced by Clemmensen's method to the acid II, m.p. 31—34°. The corresponding acid chloride when treated with aluminium chloride furnished the α-tetralone III, b.p. 136—138°/1 mm, λ_{max} 263 mμ (ε, 12 700) and 225 (19 700), ν_{CO} 1 675 cm^{-1} (film), further characterised as the deep red dinitrophenylhydrazone, m.p. 198—200°. The α-tetralone III reacted with methyl magnesium iodide giving a product that on treatment with potassium hydrogen sulphate underwent dehydration to yield the dihydronaphthalene IV, b.p. 101—104°/0.3 mm. IV was epoxidised with perbenzoic acid and the product isomerised [2] with dilute sulphuric acid to the β-tetralone V, b.p. 111—116°/0.1 mm, ν_{CO} 1 715 cm^{-1} (film) which gave a crystalline semicarbazone, m.p. 184—187°.

The β-tetralone V was condensed with β-chlorodiethyl ketone in the presence of sodium hydride [2] to give the α,β-unsaturated ketone VI, m.p. 92—94°, ν_{CO} 1 665 and $\nu_{C:C}$ 1 623 cm^{-1}, λ_{max} 287 mμ (ε 4 160), 279 (4 720), 230 (16 000) and 247 (17 100), giving a red 2,4-dinitrophenylhydrazone, m.p. 225—228°. Methylation of VI with methyl iodide and potassium *t*-butoxide led to the ketone VII, m.p. 92—94°, ν_{CO} 1 712 and $\nu_{C:C}$ 1 668 cm^{-1}, (2,4-dinitrophenylhydrazone, m.p. 212—214°), which was hydrogenated in ethanol in the presence of Pd/C to DL-hinokione methyl ether VIII (R = CH_3), m.p. 119—121°, (2,4-dinitrophenylhydrazone, m.p. 215—218°). The I.R. spectra of the synthetic and the natural hinokione methyl ether (in carbon tetrachloride) were superimposable.

The U.V. spectra were taken in 95 % ethanol solution and the I.R. spectra in carbon tetrachloride unless otherwise specified. Satisfactory analyses were obtained for all the compounds described.

The details of this investigation will be published elsewhere. This research was sponsored in part by the *Office of Research and Development, U.S. Department of Army*, through its European Office. The author is indebted to Professor H. Erdtman for his interest in this work.

ACTA CHEMICA SCANDINAVICA 14 (1960) 1673–1676

Chemistry Department of Karolinska Mediko-kirurgiska Institutet in Stockholm 1810—1960

J. ERIK JORPES

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

Karolinska Institutet, the State Medical School in Stockholm, this year celebrates its 150th Anniversary. With its forty-five professors, twenty-two associate professors, 250 assistant teachers and about 1 000 undergraduates it is at present about twice as large as any of the other medical faculties of Sweden. It is an independent medical school with otherwise the same academic status as the medical faculties of the universities at Uppsala, Lund, Gothenburg and Umeå. Its activities, however, have in the past and in recent times as well extended considerably beyond the grounds of the purely medical sciences, particularly in the field of chemistry.

It is unique among the medical schools of Europe in that, from the beginning, chemistry was taught to the medical students by a full time professor. Furthermore, this professor happened to be *Jöns Jacob Berzelius* (1779—1848). In 1802 he began lecturing on chemistry to the medical profession of Stockholm. In 1807 he was appointed professor of medicine and pharmacy at the Surgical School of the Medical Board and from 1813 professor of chemistry and pharmacy at the new Medical School, Karolinska Institutet, erected in 1810 in Stockholm.

In one respect the teaching system of the medical faculties in Sweden including Karolinska Institutet differs from that prevailing outside of Scandinavia. *Complete medical education is as a rule a prerequisite for an appointment as teacher at a medical school*, a system introduced already in Berzelius' days. He himself, Olof Hammarsten and Torsten Thunberg were physicians like all the present members of the teachers' staff with only one exception amongst 200 chairs, including the chairs of chemistry, physiology, pharmacology, bacteriology, anatomy and histology.

On this occasion it may not be out of place to review shortly the main scientific achievements reached at the Chemistry Department of Karolinska Institutet. It is quite remarkable that before the time of spectral analysis no less than 9 new elements were discovered within a short space of time at one and the same institute.

Few chemists have been as successful in their work as Berzelius. His influence upon events in the field of chemistry rivalled that of Linnaeus in botany. In 1813 he introduced the chemical nomenclature in use today, applying the first letter or letters of the Latin name of the elements as their symbols. He determined the combining weights of 45 of the 49 elements then known. He himself discovered cerium, selenium and thorium, and his pupils *Arfwedson* and *Sefström* lithium and vanadium, respectively. His co-worker and successor, *C. G. Mosander*, discovered lanthanum, didymium, erbium and terbium, the two latter from the famous yttria earth — named after the small village Ytterby in the archipelago of Stockholm. The concepts of *isomerism* and *catalysis* were created by him. His textbook in chemistry was a standard work of its time, the fifth German edition of which appeared in 5 volumes between 1843 and 1848, with no fewer than 4650 pages. His animal chemistry of 1806 and 1830 and his annual reviews of the progress of chemistry, physics and mineralogy for the years 1821—1848 were highly appreciated by the contemporary scientific world. Here only a short reference is made to the literature dealing with Berzelius *. His successor Mosander is presented in a separate paper.

Count Karl Axel Hampus Mörner, professor of chemistry and pharmacy between 1884 and 1917, was a prominent personality. In 1897 he discovered myoglobin, a substance which *Hugo Theorell* crystallized in 1932 in Mörner's old laboratory at Karolinska Institutet. In 1899 Mörner demonstrated that cystine, found by Wollaston in 1810 in a urinary calculus, is an ordinary amino acid, occurring in most proteins, and very abundantly in keratin. As Dean of the faculty 1897—1917 he helped to draw up the Articles of the Nobel Foundation and was head of the Nobel Committee for Physiology and Medicine from 1901 to 1917.

The research activities of the Chemistry Department were greatly expanded under the leadership of *Einar Hammarsten* (associate professor of chemistry and pharmacy 1918—1928; professor 1928—1957). About 1920 he showed that not only guanylic acid but also pyrimidine pentose nucleotides do occur in the pancreas. In his doctor's dissertation of 1924 he demonstrated that the laws of the osmotic pressure do not apply to the salts of thymonucleic acid and similar high molecular acids, the cations being devoid of osmotic effects. This phenomenon enables thymonucleic acid to be stored in high concentration in

Arne Fredga: *Jöns Jacob Berzelius.* Minnesteckning föredragen vid minnesfesten över Berzelius i Stockholms Stadshus den 20 september 1948. *Levnadsteckningar över K. Sv. Vetenskapsakademiens ledamöter*, No. 134. Almqvist & Wiksell, 1948.

the cell nuclei, as also the heparin in the granules of the mast cells, without osmotic breakdown of the nuclear or granular membranes due to uptake of water. Hammarsten's institute was at that time one of the few research centres devoted to the study of nucleic acid chemistry. With the advent in later years of the isotope technique for the study of the metabolism of purines and pyrimidines his institute was well equipped to enter the new field.

In the course of the years, under Hammarsten's leadership, several independent research institutes were erected closely connected to his own department: the Biochemistry Department of the Nobel Institute of Medicine under *Hugo Theorell* (professor of biochemistry 1937 —), the Institute of Cell Research under *Torbjörn Caspersson* (professor of cell research 1944—), and the Institute of Medical Physics under Arne Engström (professor of medical physics 1952—).

Theorell's work from 1934 on the isolation of Warburg's yellow respiratory enzyme by means of an electrophoresis apparatus, designed by Theorell himself, his demonstration of phosphoric acid in its prosthetic group and the separation of the co-enzyme and apo-enzyme and their reunion into an active enzyme, and the crystallization of the enzyme, aroused great attention. In 1934 Caspersson introduced ultra-violet microscopy into histology, thus enabling the morphological processes to be studied without fixation or destruction of the tissues.

In the 1930's Hammarsten and *Gunnar Ågren*, in collaboration with *Henrik Lagerlöf* and *Hilding Berglund*, made fundamental studies on the intestinal hormone secretin. A secretin test for the pancreatic function was elaborated.

In 1935 *Erik Jorpes* (associate professor of chemistry and pharmacy 1919—1947; professor of medical chemistry 1947—) found heparin to be a highly esterified sulfo-mucopolysaccharide. A number of Swedish clinicians headed by *Clarence Crafoord* and *Gunnar Bauer* then started to use heparin as a remedy against thrombosis, simultaneously with Charles Best, Gordon Murray and their co-workers of the University of Toronto. In 1937 *Jorpes* and *Olof Wilander* in collaboration with the histologist *Hjalmar Holmgren* discovered that the metachromatic granules of the tissue mast cells of Ehrlich consist of heparin. An overwhelming literature is now dealing with the mast cells as well as with the therapeutic and prophylactic use of anticoagulants against thrombosis.

In recent years *Jorpes* and *Viktor Mutt* purified cholecystokinin and secretin. The latter was found to have an extremely high biological activity.

The extended study of heparin and of its interference in the coagulation mechanism resulted in new findings in the coagulation field. Thus, *Margareta* and *Birger Blombäck* succeeded in 1956 in elaborating a new technique of preparing fibrinogen which made this plasma protein more easily accessible for use in surgery and obstetrics. With the same technique a preparation can be obtained, containing the antihemophilic globilin, coagulation factor VIII, now in use as a specific therapeutic agent in hemophilia A.

Per Edman initiated his studies on proteins at the Chemistry Department with his thesis of 1945 on the purification of hypertensin. During his subsequent stay at the University of Lund they were followed up with his invention of a new ingenious technique for the determination of N-terminal amino acids in proteins and peptides and for the determination of the sequence of the amino acids in a peptide chain.

Likewise *Torsten Teorell*, professor of physiology, Uppsala, got his education under Hammarsten.

Robin Fåhraeus, later professor of pathology at Uppsala, performed at the Chemsistry Department around 1920 the experimental work in connection with his discovery of the erythrocyte suspension stability test, which later became an extremely important diagnostic tool in medicine.

As previously pointed out complete medical education is as a rule a prerequisite for an appointment as teacher at a medical school in Sweden. Along the same line *the chemical laboratories for clinical pathology* are run by medical men, trained in biochemistry at the medical faculties; thus *Greta Hammarsten*, *Kjell Agner*, *Bertil Josephson*, *Bo Norberg*, *Bertil Swedin* and *Ingemar Jungner* in Stockholm, *Olof Wilander* in Örebro, *Carl-Olof Oldfeldt* in Linköping and *Gunnar Jungner* in Gothenburg got their postgraduate training at the Chemistry Department of Karolinska Institutet. During the last 30 years 37 such laboratories attached to larger clinical centres have been erected in Sweden, not less than 7 in the City of Stockholm, a trend in the recent development of our hospital system which pays due attention to the importance of biochemistry for medicine. The head of a clinical laboratory attached to a university clinic has teaching obligations as well. This system enables the doctors to have in their vicinity laboratory people speaking their own language, helping them in interpreting the chemical tests and discussing diagnostic and therapeutic problems.

ACTA CHEMICA SCANDINAVICA 14 (1960) 1677–1680

On Dry Distilled Racemic Acid

J. J. BERZELIUS*

Communication of the Swedish Academy of Sciences 1835 p. 142.

INTRODUCTION

The products resulting from the dry distillation of organic substances have recently been the object of particularly thorough study. Mention may be made of Faraday's investigation of the several forms of carbon-bound nitrogen obtained in this way, Bussy and Lecanu's of the distillation products of fatty oils, Riechenbach's of the products obtained from beech-wood and Pelouze's of the distillates of tannins, pyrogallic acid and malic acid. Despite the fairly important findings that have then been made, it is evident that this subject is still in its cradle, and that the so-called dry distillation of organic substances opens up an entirely new field in chemistry.

It is namely not only by means of the distillation of various substances, or of a mixture of several organic substances, that different products are formed, but the same substances — or mixtures of substances — may give rise to different products, according to temperature and the admixture of different inorganic substances.

It is easily realized that if one would undertake to study the dry distillation of a certain substance — for example, cane sugar — under all these varying conditions, a number of different compounds would be formed, among them perhaps many as yet unknown. If one then undertook the similar treatment of one unmixed substance after the other, it is impossible to predict the number of substances that would be produced in this way. It is nevertheless evident that if one would first study the special distillation of each organic substance, it would then be all the easier to analyze the products of their mixtures, *e.g.* woods, seeds, leaves, *etc.*, that are distilled.

* The Editor presents here a translation of the handwritten original of Berzelius' communication to the Swedish Academy of Science in 1835 concerning his discovery of pyruvic acid and its preparation and properties. The paramount interest taken in this compound by the biochemists of today may justify a reproduction of Berzelius' paper. It may also be of interest to note that he, when he in 1835 created the concept of catalysis, metal catalysis in chemistry and enzyme catalysis in biology, claimed that "the catalytic force ... functions largely in the same manner as heat". Here his experimental skill allowed him to produce at 200°C and to isolate the same labile compound, which much later was shown to be produced by enzymes when sugar and similar substances are burnt at ordinary temperature in the living organisms.

Published by permission of the Swedish Academy of Sciences, Stockholm.

The excellent investigations for which we are indebted to Pelouze, of the dry distillation of pyrogallic acid and malic acid, prompted me to resume an interrupted study of the distillation products of tartaric acid and racemic acid, in particular of the latter. Since, in the course of this work, I found myself forestalled by the same distinguished chemist, I can only hope that the ears I have plucked on the field left by him are not entirely without value.

ON PYRUVIC ACID AND THE CHANGES WHICH OCCUR WHEN RACEMIC ACID IS SUBMITTED TO DRY DISTILLATION AT A TEMPERATURE NOT EXCEEDING + 250°C.

In the report of my investigation of the composition of tartaric acid and racemic acid, which I had the honour to present to the Royal Swedish Academy of Sciences in 1832, I pointed out that racemic acid on dry distillation produces an acid different from the pyrotartaric acid arising from tartaric acid, which has been well known for a long time.

This pyrotartaric acid was intensively studied first by Gruner and then by Pelouze, who showed that the distillation products of tartaric and racemic acids are the same, mainly pyrotartaric acid and acetic acid, the latter in such a high concentration that it almost crystallizes out. Although I have confirmed the findings of Pelouze that tartaric acid and racemic acid give the same distillation products, I did not reach the same conclusion that he did concerning the nature of the main part of the distillate, which he considered, because of its smell, to consist of acetic acid. This acid is the same as that which I orginally thought to be formed from racemic acid alone, which I called pyruvic acid and described as a volatile acid.

I will go on using the name pyruvic acid, *acidum pyruvicum*, as an indication of its origin from the grape. The same acid is also found in the acidic fluid which is formed when solid potassium tartrate is submitted to dry distillation; it consequently occurs in an ancient remedy, *mixtura diatrion* or *m. pyrotartarica* and deserves to be known for this reason as well.

I distilled a sample of tartaric acid in a tubulated glass retort on a sand bath, the temperature of which could be kept almost constant by increasing or reducing the draught. The mass started to give off a water clear distillate of a sharp taste, smelling of acetic acid, whereupon it melted, turned grayish, and began to foam.

When the material showed a tendency to boil over, the cork was removed from the tubular extension and a rigid platinum wire was introduced to break the foaming, which was easily accomplished. It was sometimes necessary to repeat this procedure. Without this precaution the distillation proceeds extremely slowly and the entire foaming mass collects in the upper part of the retort leaving the lower part empty. During the operation carbon dioxide is developed in a continuous stream, necessitating tubulation of the receiver, the end of the tube being submerged in water.

The content of the retort gets very sticky before the end of the operation, mostly due to condensed pyruvic acid. Later on in the operation the distillate gets more and more concentrated, and becomes yellow in colour, but even at the end is no more than pale yellow if the temperature does not exceed + 220°

(Celcius). The residue in the retort becomes more and more sticky, finally changing to a fluid which boils without foaming; the temperature is then about + 200°, and when the boiling is finished and nothing more distils at + 200° the operation is finished. There is then left in the retort a mass which is soft while still hot but after cooling behaves like carbon.

The distilled acid contains no oil although the last fraction becomes slightly cloudy on dilution with water. It has an acetic acid like smell although slightly burned, a burning sharp acid taste, a consistency like sulfuric acid, and a yellow colour. If it is distilled over a water bath, which proceeds very slowly, one gets at first a colourless acid smelling strongly of acetic acid but also slightly of formic acid. The distillate usually turns yellow and assumes a thick consistency. In the last viscous fraction I found a specific gravity of 1.2792 or even slightly more. During the procedure carbon dioxide gas develops continuously, although no gas bubbles can be seen in the liquor, and the carbon dioxide must be given a possibility to escape; the fluid in the retort darkens more and more, finally turns dark brown and leaves a residue of a resinous mass at the end of the distillation. *Sometimes in my experiments the syrupy distillate, on cooling, was completely filled with crystals of pyruvic acid*, but this happened only half the number of times that I repeated the process. Before the distillation this pyrotartaric acid (?) was dissolved in the fluid together with part of the brown sticky material, most of which is formed during the redistillation; new quantities of this material are formed each time the distillation is repeated.

I have tried to redistil the acid in an apparatus from which I had removed the air in order to find out whether the air exerted any influence on its formation; the result, however, was the same, the only difference was that the distillation proceeded much more slowly. When the apparatus was opened carbon dioxide gas escaped with an explosion and showed that an increased pressure of carbon dioxide gas was the reason for slowing up the distillation. A considerable quantity of the resinous mass remains after distillation indicating that the acid after a few redistillations would soon be destroyed. The test with silver carbonate (carbonated silver oxide) indicated that formic acid could be present in the distillate. However, the salts prepared with sodium hydroxide and lead oxide always indicated the presence of acetic acid through their solubility in alcohol in which the lead salt of formic acid is almost insoluble. Also the acid does not become opalescent on boiling.

Since an attempt to obtain *the free acid* from its sodium salt, through distillation with sulfuric acid, failed, while the acid was almost completely destroyed, I had to find another way to obtain pure acid in a fairly strong concentration. This can be achieved in the following way. Freshly precipitated lead carbonate is dissolved in the redistilled acid to full saturation; at first the oxide dissolves but later on it is precipitated as a granular powder increasing in amount during 48 hrs, particularly in the cold. It is collected on a filter paper and washed.

The lead salt is suspended in a minute quantity of water, treated with hydrogen sulphide and strained through cloth. The lead sulphide is pressed and the mother liquor evaporated over sulfuric acid *in vacuo*. A thick syrup results which finally ..... (unreadable). No gas is evolved during this

concentration. A certain amount of the acid disappears, however, because of its volatility.

The properties of the acid are as follows: thick syrup which can be drawn out in threads, weak but sticky acid smell, strongly acid, later bitter taste. Turns fluid in the air. Soluble in alcohol and ether. On heating it partly evaporates and partly disintegrates, as previously described. The composition and the degree of saturation of this acid were elucidated through the analyses of its silver and sodium salts. The analyses were as follows: 0.31546 g acid produced with copper oxide 0.5225 g carbonic acid and 0.0145 g water It gave in per cent:

	Found	Atoms	Calculated
Carbon	45.80	6—458.628	46.042
Hydrogen	3.68	6— 37.488	3.463
Oxygen	50.52	5—500.000	50.195
	100.00	999.116	100.00

Its formula is consequently $C_6H_6O_5$. Upon comparison of this formula with that of tartaric acid and racemic acid, which is $C_4H_4O_5$, one finds that *this acid can be considered to be a lower degree of oxidation of the same radical.* On the same quantity of oxygen it contains one and a half times as much of the radical as do the tartaric and racemic acids, giving a formula for the latter acids 2 CH + 5 O, while the formula for the pyruvic acid is 3 CH + 5 O.

One could say that formic acid, tartaric acid, pyrogallic acid and pyruvic acid are derived from the same radical giving them the following composition:

Pyrogallic	acid	3 CH + 3 O
Pyruvic	»	3 CH + 5 O
Racemic and tartaric	»	2 CH + 5 O
Citric	»	2 CH + 4 O
Formic	»	CH + 3 O

Berzelius goes on to describe in six large pages no less than *20 different metal salts of the new acid,* all prepared and analyzed by himself. It is very typical of this tremendously diligent and ambitious chemist that he did not feel satisfied until he had prepared the potassium, sodium, silver, ammonium, barium, strontium, calcium, aluminium, beryllium, ytterbium, thorium, manganese, iron, cobalt, mercury, lead, basic lead, uranium, copper, platinum, and gold salts of his new acid.

As is evident, Berzelius interpreted the structure of the pyruvic acid in accordance with the ruling concepts of those days. He considered the acid to be an oxide of an organic radical, the ethine radical C_2H_2, here written as CH, assumed to be common to a series of well known organic acids. In spite of the improvement Berzelius made of the quantitative organic analysis by introducing the use of the calcium chloride tube for the collection of the water of combustion, his technique of analysis was by far not so accurate in the organic field as it was in the inorganic. Hence the misleading figures, which allowed him to drawn the wrong conclusions. On another occasion the theory about organic radicals influenced Berzelius' thinking, namely when in 1838 he suggested the name "protein" for a new radical, that the Dutch chemist Mulder claimed that he had found in all kinds of animal and plant material.

Carl Gustaf Mosander

J. ERIK JORPES

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

Mosander became through his discoveries of the new elements lanthanum (1839), didymium (1842), erbium and terbium (1842) a worthy successor of Berzelius. In 1831 Berzelius decided to withdraw from the professorship of chemistry and pharmacy at the Karolinska Medico-Chirurgical Institute in Stockholm, partly because of his desire as secretary of the Academy of Science to devote himself exclusively to his research work and partly in order to give his co-worker Mosander an opportunity to get a position as full term professor, which the latter then held for 26 years until his death in 1858.

Mosander was born in 1797 in the city of Kalmar. Like Scheele he started his career as a pharmacist. At the age of 15 he enlisted as an apprentice at the Owl's Apothecary in Stockholm and at 22 took up medical studies. In 1824 he was appointed as teacher in chemistry at Karolinska Institutet, the medical school in Stockholm under Berzelius and in 1832 he succeded him as professor of chemistry and pharmacy.

Although Mosander took over Berzelius' teaching at the medical school he did not share his teacher's devotion to physiological chemistry in its broadest sense. Mosander restricted his work mainly to the field of inorganic chemistry and mineralogy. In these fields he became the master's equal. He spent much of his time organizing the Collection of Minerals at the State Museum of Natural History.

Here follows an English translation of the history of Mosander's discoveries, written for the Swedish Academy of Science by A. Erdman in 1873.

"In 1803 Berzelius and Hisinger discovered a new metal in a mineral that had recently been found in the Bastnäs copper mine in the Skinnskatteberg district of the province of Västmanland. They called it *cerium*. The methods of reduction known at that time were not, however, sufficiently effective to enable them to obtain their new substance in a pure metallic state. — After a long interval of time this substance was examined again by Mosander and the success of his efforts is described in a paper in the proceedings of the Swedish Academy of Science for 1826. This paper describes a number of new or previously little known compounds of the metal cerium with other elements.

A few years later in 1829 Mosander made an important contribution to the knowledge of the composition of titanium compounds.

Previous experiments made at the end of the eighteen-twenties had led Mosander to suspect that cerium oxide contained some other substance but

he was unable to separate it. After he had obtained sufficient material, he took up the investigation again in the middle of the eighteen-thirties and in 1839 had the satisfaction of being able to announce to the scientific world that the number of known elements had been increased by one more to which he had given the name *lanthanum* from the Greek work *λανθανειν*, to conceal, because the presence of this substance in cerium oxide had long remained a secret.

Mosander's next task was a study of the properties of the new element or rather of the two separated elements, lanthanum and cerium. These investigations, which he pursued with all the perspicacity and clearsightedness that always marked his scientific activities, took up all the time left over from his official duties for several years. Some of the results he obtained led him to suspect that there was also a third element present, that in some experiments followed the lanthanum oxide and in others was distributed between the lanthanum and cerium oxides. This third substance he called *didymium* from the Greek *διδυμοι*, twins, since it followed cerium or lanthanum in cerium-containing minerals like a twin brother. It took a large number of experiments over a long period before Mosander finally ventured to announce the discovery of the oxide of another previously unknown metal at the second Scandinavian Scientific Meeting in Stockholm in 1842. This was nearly three years after he had first succeeded in separating it from lanthanum oxide — a striking instance of the praiseworthy care and reticence which Mosander always showed in such cases.

The very complex reactions characterizing the recently discovered lanthanum and didymium and the difficulties that arose in trying to prepare them in a completely pure state caused Mosander to make similar studies on the oxide yttria which often accompanies cerium in nature. These experiments soon led to a result that was just as unexpected as it was gratifying. As a consequence at the same time as he announced the discovery of didymium at the 1842 meeting, Mosander was also able to inform the meeting that the earth that hitherto had been named yttria, "ytterjord" in Swedish, was not a pure earth but was mixed with another of previously unknown properties. Continued investigations soon showed that Mosander had in no way allowed himself to announce any hasty conclusions to his scientific audience but was fully able to confirm his statement. He was able to announce before the end of the year that the old *yttria* which is one of the main components of the mineral gadolinite from the Ytterby feldspar works near Vaxholm in the Stockholm archipelago was *a mixture of three different earths*, two of which were new to science. He called the elements from which the two new ones derived *erbium* and *terbium* from parts of the name Ytterby. The element in the third earth was left with the old name *yttrium*.

The inscription on a medal struck by the Swedish Academy of Science in 1869 in honour of Mosander, 'Coacta disjungit semina terrarum' referred to all of these discoveries."

New findings were later added to those of Mosander. Thus Auer von Welsbach resolved in 1885 the earth didymia into two different oxides, *praseodymia* and *neodymia*. The names of the earths erbia and terbia were later interchanged. In 1878 Marignac dissolved the erbia from the gadolinite into *erbia* and

ytterbia, and from the latter Nilsson separated in 1879 a new element, *scandium*, the second newly discovered element which fitted into Mendelejev's periodic system on the place of ekabor. After removal of ytterbia and scandia from the erbia Cleve in Uppsala found in the same year another two new oxides *thulia* and *holmia*. As to the names of these two elements, the last ones in a series of 22 elements discovered between 1730 and 1879 in Sweden, Cleve suggested *thulium*, deriving from Thule, the ancient name of Scandinavia, and *holmium*, from the latinized name of Stockholm in whose vicinity occur so many minerals rich in yttria.

Properties and Structure of the Compounds Formed between Cytochrome c and Nitric Oxide *

ANDERS EHRENBERG and TADEUSZ W. SZCZEPKOWSKI**

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The compound formed between ferricytochrome c and nitric oxide has been found to be diamagnetic. It is proposed to be a ferrocytochrome c nitrosyl compound from which the ferrocytochrome c nitric oxide compound can be obtained by alkalinization. Other haemoproteins behave similarly. The relationship between the optical absorption spectra of the nitrosyl, nitric oxide and carbon monoxide compounds of some ferrohaemoproteins is discussed. The haemlinked group of cytochrome c that is replaced by nitric oxide cannot be detected as a normal histidine imidazole by acid base titration. The possibility of a sterically hindered imidazole group has to be considered.

It is well known that nitric oxide, NO, has the power of combining with iron-porphyrin compounds containing either ferrous or ferric iron [1–3]. Reactions take place with iron-porphyrin bound to proteins [1,2] as well as in haemi- or haemochromogens [2] or with free haem or haematin under certain conditions [3]. While ferricytochrome c combines easily with NO, the reduced form, ferrocytochrome c, seems to be very inert to NO, and attempts to produce a distinct compound have so far failed.

The ferrous NO compounds which are all stable exhibit typical haemochrome spectra not very different from those of the corresponding CO compounds. Magnetic measurements on the NO derivative of haemoglobin have shown that this complex holds only one unpaired electron [4] which means that the ferrous iron here is surrounded by six octahedral d^2sp^3 bonds and has all its d-electrons paired. The odd electron detected, originates from the NO molecule and is supposed still to belong to the same atomic grouping in the complex. A similar state of affairs is very probably valid for the other ferrous NO compounds.

The ferric NO compounds also show two-banded absorption spectra in the visible but the bands are more distinct and shifted 5 to 10 mμ towards shorter wavelengths, as compared with the corresponding reduced form. Most of the ferric compounds are unstable, *e.g.* ferri HbNO[1] and ferri MbNO which are

* Most of the experimental work was made during the stay of T. S. in Stockholm, 1956—57, Fellowship of the Polish Academy of Sciences.

** Present address: Zakad Chemii Fizjologiczbej, ul. Kopernika 7, Krakow, Poland.

gradually autoreduced. In contradistinction to these compounds ferricytochrome-c-NO is stable for a long period of time.

A discussion of the properties of these ferric NO-compounds in terms of the bonds involved in the iron porphyrin complex has not yet been possible, mainly because of lack of magnetic data for the compounds considered. In the present paper it will be shown that these compounds are diamagnetic and contain ferrous iron. The formation of ferrocytochrome-c-NO as a spectroscopically well characterized compound will also be demonstrated.

EXPERIMENTAL

Materials

Nitric oxide was generated from sodium nitrite mixed with ferrous sulphate by addition of dilute sulphuric acid. The gas was passed through two traps filled with dilute potassium hydroxide and collected in a glass gasometer over dilute hydroxide with phenolphthaleine added as an indicator.

Commercial *nitrogen* from a gas tank was made oxygen free by passing through two traps with vanadyl sulphate dissolved in dilute sulphuric acid and in contact with amalgated zinc.

Cytochrome c was prepared from beef heart according to Paléus and Neilands [5] and contained 0.43 % iron. The haemopeptide was purified after degradation of the cytochrome c by pepsin [6]. These preparations were put at our disposal by Dr. S. Paléus.

Myoglobin, prepared from horse muscle was kindly given to us by Mr. Å. Åkeson. We are indebted to Dr. K. G. Paul for a sample of *horseradish-peroxidase*.

Methods

The magnetic measurements were performed in the instrument constructed by Theorell and Ehrenberg [7] and later modified to allow for better temperature control and give better reproducibility in the readings [8]. Since the nitric oxide compound of cytochrome c is more stable at lower temperatures all the measurements were made at + 7°C, the lowest temperature at which it was feasible to operate the instrument.

A weighed amount (about 30 mg) of lyophilized cytochrome c was placed in a small Thunberg tube. Since part of the cytochrome was present in the reduced form the sample was first dissolved in 0.25 ml 0.2 N HCl and left in this solution until a spectroscopic test revealed that all the reduced cytochrome c had been autoxidized. The sample was thereafter adjusted to the desired pH and concentration, either by 6 N NaOH and M/15 phosphate buffer to a final volume of 1 ml and pH 7.2, or by water to a final volume of 0.5 ml containing 0.1 N HCl, which together with the protein, gave a pH of about 3. In every case two more Thunberg tubes were filled in an identical way, except that the cytochrome c was omitted. These solutions served as blanks in the magnetic determinations, one being measured before and the other after the sample. The magnetic susceptibility was determined prior to and after treatment with NO. This treatment and the measurement on the NO–derivative were made as follows.

The three Thunberg tubes were placed in an ice bath in order to minimize evaporation when the tubes were evacuated. They were connected to a common three way outlet through which they could be quickly evacuated and subsequently filled with nitrogen. This procedure was repeated seven times. The connection leading to the NO-gasometer was also flushed with nitrogen. The Thunberg tubes were then filled twice with NO and left after the last filling for at least 10 min in order to assure a complete reaction, a condition that had been spectrophotometrically controlled for similar samples. The tubes were again quickly evacuated and thereafter placed in a jacket connected to the magnet thermostat and allowed to equilibrate for 20 min to the desired temperature of 7°C. Immediately before the measurement nitrogen was let in and care was also taken to flush with nitrogen the magnet tube and the glass pipet used for transferring the liquid.

The results were corrected for the diamagnetism of the protein by means of data obtained by measuring in the magnet the reduced form of similar samples of cytochrome c.

The acid-base titrations were made on 3 ml samples in a small glass beaker with ground neck and a tightly fitting perspex stopper. Holes were drilled in the stopper for one glass and one calomel electrode, two micrometer burets (Agla syringes), and two tubes for inlet and outlet of the gas. A rubber collar was placed in each hole and sealed to the perspex and the inserted glass tube by paraffin. To ensure complete tightness the perspex stopper was provided with a collar and covered with a one cm thick layer of mercury. As an extra precaution the outlet tube was immersed in a vessel filled with mercury to give a constant overpressure in the vessel. Before entering this the gas was freed from traces of acid by passing through a trap filled with dilute potassium hydroxide. Temperature was kept constant by streaming thermostated water in an outer water jacket and stirring was achieved by a magnetic stirrer. 15 to 30 mg cytochrome c was dissolved in 3 ml 0.2 M sodium chloride. 50 μl of this solution was taken for spectrophotometric determination of the concentration after dilution and reduction. The sample was brought to a pH below 3 by addition of 0.4 N HCl and left there in contact with air and with slow stirring for about 1 h to ensure complete autoxidation. A stream of nitrogen was started and the ferricytochrome c was titrated with 0.4 N NaOH up to pH 10 and then titrated back with 0.4 N HCl to a pH just below 5. Nitric oxide was now introduced until the colour of the sample had changed. Most of the nitric oxide was replaced by nitrogen and the titration of the NO-compound was made with just enough nitrogen streaming to maintain the small overpressure.

For the amounts of cytochrome c used in the experiments 2 to 4 μl of the 0.4 N acid or base corresponded to 1 equivalent. The volumes could be read to every 0.2 μl. The pH was measured by a Radiometer pH-meter, model PHM3. The glass electrode was standardised with phthalate and borate buffers before and after each run. In every case the change was less than 0.01 pH unit.

The spectrophotometric absorption curves were made with a Beckman DK 2 recording spectrophotometer. Cuvettes with a side bulb, ground stoppers and stopcocks were used. They could be evacuated and washed with nitrogen or argon before NO was let in and later on reaction with the contents in the side bulb could be started. When desired the excess of NO could be removed by evacuation and flushing with argon. All spectrophotometric analyses were made with a Beckman DU spectrophotometer.

RESULTS AND DISCUSSION

The magnetic susceptibility of the NO-derivative was found to be 490×10^{-6} emu at pH 7.2 and 220×10^{-6} emu at pH 3. In both cases the error of the determination was estimated to be $\pm 100 \times 10^{-6}$ emu. These data prove that the complex is diamagnetic. The small positive susceptibility values obtained can be explained by some dissociation of the NO-compound, a process that gives two paramagnetic molecules out of one diamagnetic. The experimental value at pH 3 is lower than that at pH 7.2 in spite of the increased susceptibility of cytochrome c at the lower pH [9]. This indicates that the NO-compound is stabilized in the more acid solution. Since the compound is thus found to be diamagnetic as compared with another diamagnetic derivative, ferrocytochrome c, and we are here interested in the "spin susceptibility" there was no reason to correct our data for the "orbital susceptibility" estimated by Griffith for this type of complex [10].

The diamagnetism of the compound immediately leads to the conclusion that there must be an odd number of NO molecules that combine with the ferric iron, so that the total number of electrons becomes even and the spins can pair out. Earlier equilibrium data support the view that there is only one NO molecule reacting with each cytochrome c molecule [2]. If NO in this

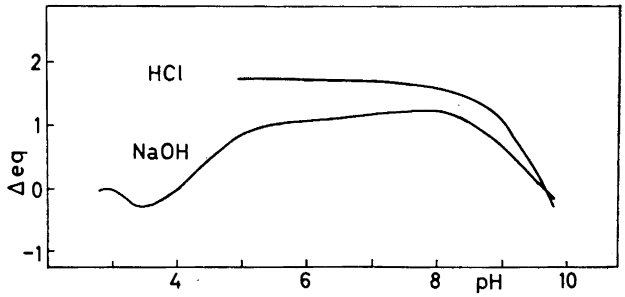

Fig. 1. Difference titration curve of ferricytochrome c after and before reaction with NO.

reaction replaces one of the nonporphyrin ligands and this ligand is a histidine residue it might be possible to identify it by a difference titration. When NO reacts the pH of the solution would rise if the pK of the replaced ligand is equal or higher than the pH of the solution. The pH would be unaffected if the pK of the ligand is low enough. In all the experiments a drop in pH was instead observed upon reaction with NO and in the different experiments a number of equivalents that varied from slightly less than one to more than four were titrated in the range pH 3 to 5 as seen from the difference curve between the titrations of NO-cytochrome c and ferricytochrome c. A typical curve is given in Fig. 1. Apparently the removal of oxygen had not been complete and some nitrous acid with pK = 3.4 had been formed. 4 to 8 μl of oxygen of normal temperature and pressure corresponds to 1 equivalent of cytochrome c in the present experiment. The amount of oxygen dissolved in the standard acid and base used can be neglected, since the solutions were stored under vaccum for some time before the burets were filled. The difference curve also reveals that some groups that are titratable above pH 8 in ferricytochrome c have disappeared in the NO-compound. It is quite reasonable that some of the free amino groups in the protein could react with the nitrous acid and thus be transformed into alcoholic hydroxyls.

In no case more than fractions of one equivalent were titrated in the range between pH 5 and 8. All the equivalents titrated below pH 5 are not necessarily artefacts due to nitrous acid and our experiments are compatible with a pK somewhere between 3 and 5 for the released haemlinked group. This low pK might either correspond to a carboxyl group or a histidine residue with its pK shifted from the normal range. Such a shift might be caused by the histidine being embedded between the protein helices as suggested in the proposed structure of cytochrome c [11]. Also surrounding positively charged groups will operate in the same direction by decreasing the local concentration of the hydrogen ions. The possibility that no haemlinked group is replaced and that the NO is capable of joining to the iron through a new seventh bond of considerable strength must be considered highly improbable, *e.g.* because of the symmetry properties of the bonding orbitals of the porphyrin iron.

When NO reacts with ferricytochrome c to form a diamagnetic compound iron might either donate one electron to NO or accept one electron that is given off by the ligand. In the former case the iron would be oxidized to the

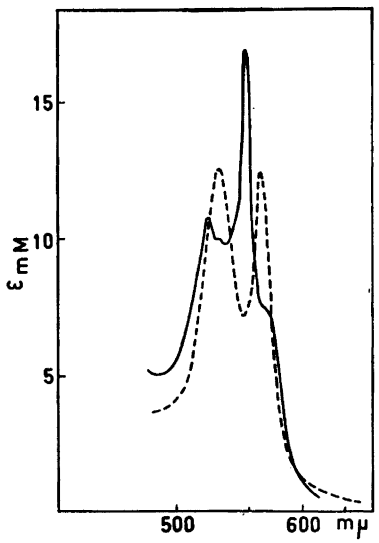

Fig. 2. Broken curve: Spectrum of ferrocytochrome c nitrosyl compound formed in acid or neutral solution from ferricytochrome and nitric oxide. Full drawn curve: Spectrum of the same solution after removal of excess nitric oxide and addition of alkali to obtain pH 12.

ferryl state and NO reduced to a negative ion that would be isoelectronic with molecular oxygen. A compound of this type is, however, unlikely to be diamagnetic since the third 3 d orbital of the iron would be left empty. The theory predicts electronic configurations of ferryl iron with four unpaired electrons in the high spin state and two, but not zero, unpaired electrons in the low spin state [12]. The secondary peroxide complexes of catalase or horseradish peroxidase and the peroxide compounds of myoglobin are thought to be of this ferryl type [13]. They might be considered to be compounds formed between ferric iron and a free radical representing the rest of the peroxide and have indeed two odd electrons [14,15]. In the second case the iron is reduced to the ferrous state and NO is oxidized to the positive nitrosyl ion, NO^+, that is isoelectronic with carbon monoxide and by analogy is likely to form a stable compound with the reduced haem iron. The compound formed in the reaction between ferricytochrome c and NO would thus be a ferrocytochrome c nitrosyl compound as schematically shown in reaction (1).

$$Fe^{+++} + NO \rightleftharpoons [Fe^{+++} - NO] \rightleftharpoons \underset{I}{Fe^{++} - NO^+} \qquad (1)$$

The intermediary complex put within brackets has not been demonstrated and it must be very shortlived if it exists. The spectrophotometric experiments to

be reported below have supplied considerable support for the correctness of the proposed formation of the ferro-nitrosyl compound (I) to the right in formula (1).

When ferricytochrome c reacts with NO at a neutral or acid pH, compound I is rapidly formed. The spectrum, part of which is shown in Fig. 2, has absorption maxima at 417, 530, and 564 mμ. The dissociation constant for the back reaction is so very small that practically all the excess NO gas can be removed and the compound is still stable at these low pH values. If the formulation of I as a ferro-nitrosyl compound is correct it would, however, be possible for this compound also to dissociate into ferrocytochrome c and the nitrosyl ion:

$$Fe^{++} - NO^{+} \rightleftharpoons Fe^{++} + NO^{+} \quad (2)$$

The nitrosyl ions are in equilibrium with the hydroxyl ions, nitrous acid and nitrite ions:

$$NO^{+} + OH^{-} \rightleftharpoons HNO_2 \quad (3)$$

$$HNO_2 + OH^{-} \rightleftharpoons NO_2^{-} + H_2O \quad (4)$$

A high pH would thus force reaction (2) to the right. Indeed, if the excess NO gas was removed from an acid solution of I, and this solution was brought under anaerobic conditions to pH 12, a new and stable spectrum quickly appeared. As can be seen from Fig. 2 this spectrum is complicated but the main bands in the visible are situated at 520 and 550 mμ thus confirming the formation of reduced cytochrome c in a high yield. Less intense bands are situated at 530, 540 and 567 mμ.

If the alkalinization of I is made in the presence of excess NO-gas the complicated spectrum just described is first rapidly formed. However, it gradually changes into a simpler spectrum with absorption bands in the visible at 540 and 567 mμ, as shown in Fig. 3, and the Soret band at 411 mμ. Very similar intermediary spectra are observed and an identical end product is formed when oxidized or reduced cytochrome c or a mixture of the two is reacted with NO at pH 12. The compound formed in all these reactions has to be formulated as a complex with nitric oxide bound to the iron of ferrocytochrome c, and is here labeled II:

$$Fe^{++} + NO \rightleftharpoons Fe^{++} - NO \quad (5)$$

II

Compound II has also been shown to be stable at lower pH-values. It was first formed from ferrocytochrome c and NO at pH 12 and then in the presence of NO brought to pH 7.5 by addition of a measured amount of primary phosphate. No marked change in the spectrum was observed after 30 min. At still lower pH-values and in the presence of nitrite compound I is formed by reversal of reactions (2)—(5). Enough nitrite for this reaction sequence is easily formed by incomplete anaerobiosis during exposure to NO, especially if compound II has originally been obtained from I, in which reaction one equivalent of nitrite is formed.

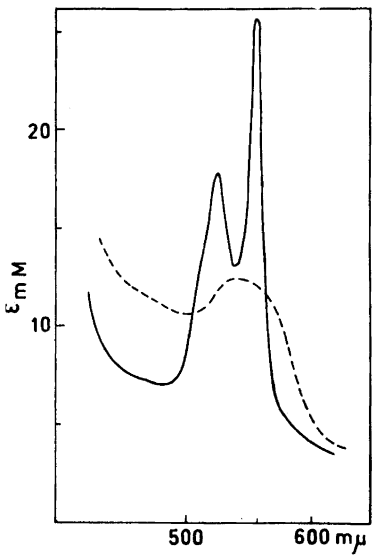

Fig. 4. Spectrum of ferrohaemopeptide at pH 7, full drawn curve, and the products after reaction with NO, broken curve.

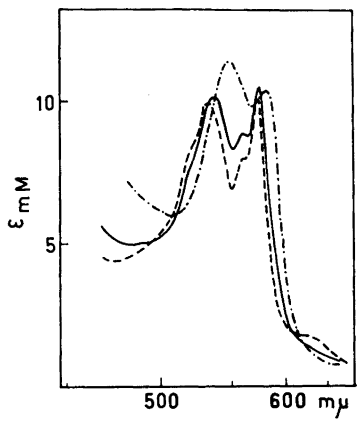

Fig. 5. Transient spectrum of ferrimyoglobin immediately after reaction with NO at pH 7 (— — — —) and the stable spectrum of the ferronitrosyl compound measured 3 hrs later (————). At pH 10 the later spectrum is immediately formed, and with excess NO the stable spectrum of the ferromyoglobin NO-compound could be measured after 2 hrs (— . — .).

From formula (3) it can be seen that the nitrosyl ion concentration would be expected to increase with the concentration of nitric acid and the concentration of hydrogen ions. This dependence is illustrated by the spectral changes of reduced cytochrome c in 10 mM nitrite solutions of different pH. At pH 2 and 4.2 the reduced cytochrome c was immediately transformed into compound I. At pH 5.3 the transformation is slower and at pH 7 or higher no reaction at all takes place.

At pH-values below 2 oxidized cytochrome c is also quantitatively transformed into I by the action of nitrous acid. This shows that NO must be formed from nitrous acid under these conditions, probably by disproportion into nitric acid and nitric oxide. At pH 5.3 the spectrum of oxidized cytochrome c is not affected by added nitrite.

The inability of ferrocytochrome c to react with NO in neutral solution parallells its behaviour towards CO and O_2. These molecules are all small and uncharged but can nevertheless not reach and react with the iron. A very close and tight structure is thus necessary around the haem of cytochrome c. This structure is opened slightly when the cytochrome is oxidized, and the NO molecule can now penetrate and react with the iron. Molecules of similar size but with an electrical charge, *e.g.* CN^-, can still not reach the iron because

Table 1. Comparison of the absorption band positions of some ferrohaemoprotein derivatives. Data on the CO compounds of cytochrome c and catalase are taken from Refs.[17,18], respectively.

Haemoprotein	Derivative	Wavelength of absorption maximum in mμ		
Cytochrome c	NO+	563	530	417
	CO	563	530	—
	NO	567	540	411
Myoglobin	NO+	575	537	420
	CO	578	542	423
	NO	580	548	421
Haemoglobin	NO+	568	532	—
	CO	568	538	419
	NO	576	542	—
Horseradishperoxidase	NO+	570	539.5	423
	CO	573	542	423
	NO	575	545	423.5
Catalase	NO+	576	540	—
	CO	580	545	—
	NO	—	—	—

of a potential barrier due to charge groups in the protein moiety. The same potential barrier helps to stabilize the ferro-nitrosyl complex formed, by protecting the positively charged nitrosyl ion from "leaking" out. This protection is strongest in acid solutions, when positive charges dominate on the protein surface, and will decrease with increasing pH, thus explaining the observed pH dependence of the stability of the ferrocytochrome c nitrosyl complex. The compact structure itself will also be opened at higher pH-values. Ferrocytochrome c can now combine with NO or CO or it can be oxidized by O_2. The stability of the ferro-NO compound when neutralised also demonstrates that an uncharged molecule can be captured inside the closed structure surrounding the haem.

The spectra and reactions of some compounds related to cytochrome c have also been explored. Thus the ferrihaemopeptide gives with NO a compound with α-and β-bands that are indistinguishable from those of I. This is to be expected, since there is the same configuration around the iron whether NO reacts with the ferrihaemopeptide from the opposite side to the single histidine imidazole present, or with ferricytochrome c by replacement of one of the coordinated histidines. As distinct from ferrocytochrome c the ferrohaemopeptide that has no closed structure reacts with NO in neutral solution as is seen in Fig. 4. The spectrum is poorly defined and probably represents a mixture of compounds. Possibly more than one NO molecule could be coordinated.

When NO reacts with ferrimyoglobin at pH 7 a distinct but rather complicated spectrum is immediately formed, see Fig. 5. This spectrum is not stable but in a couple of hours changes into one where the main absorption maxima are at slightly longer wavelengths. The concomitant disappearance of a weak

absorption at 630 mμ indicates that some ferrimyoglobin is slowly transformed into the ferronitrosyl compound, which itself is stable for many hours in the neutral solution. At pH 10 the ferro-nitrosyl compound is formed immediately. but in the presence of excess NO it is completely transformed into the ferro-myoglobin NO-compound in less than two hours. The latter can be formed directly from ferromyoglobin and NO at pH 10 and also at pH 7. All the main features of these reactions of myoglobin are compatible with a structure where the haem is more exposed than in cytochrome c.

It is very interesting to compare the absorption maxima of the compounds listed in Table 1. Changing the ligand to the reduced haem iron from NO^+ to CO and then to NO the general trend is that the wavelengths of the α- and β-bands increase slightly, while the γ-band remains constant or is somewhat shifted towards shorter wavelengths. Both NO^+ and CO have empty orbitals and are capable of forming a weak double bond with the iron, thus pulling electrons away from the iron. The effect of the positively charged NO^+ will be more pronounced than for the neutral CO. NO is not capable of forming a double bond, because there is no empty orbital, and its effect will be even smaller. The pull on the electrons will be transmitted from the iron out through the conjugated bond system of the porphyrin. The excitations corresponding to the α- and β-bands are believed to be associated with a charge-redistribution resulting in a shift of the electrons towards the perifery of the porphyrin disc [16]. The pull on the electrons exerted by a ligand at the iron will make these excitations more difficult and hence will shift the bands towards shorter wavelengths, as observed. The γ-excitation is associated with less pronounced charge-redistribution [16], the direction of which cannot be settled with certainty from the data of the γ-bands in Table 1.

The Isolation of Prostaglandin F from Sheep Prostate Glands

SUNE BERGSTRÖM and JAN SJÖVALL

Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

A smooth muscle stimulating factor present in vacuum-dried sheep prostate glands has been isolated in crystalline form. The formula $C_{20}H_{36}O_5$ has been suggested.

Goldblatt [1] and U. S. von Euler [2,3] described the presence of a smooth muscle stimulating and blood pressure reducing activity in sperm and in extracts of the prostate glands of certain species. The activity was ascribed to a factor named "Prostaglandin" by von Euler, who made studies on the distribution of this type of activity in various organs and species. He also made extensive physiological studies on a concentrate prepared from sheep prostate glands [4–6].

This raw material was used by Bergström [7] for further concentration of the factor. We have continued this work and have succeeded in isolating a crystalline compound, PGF, from vacuum-dried sheep prostate glands. This compound has a stimulating effect on smooth muscles of rabbit intestinal strips but does not show any effect on the blood pressure of rabbits. This paper describes the isolation procedure and some of the properties of the compound. The isolation of a second factor from frozen sheep prostate glands is described in a following paper.

EXPERIMENTAL AND RESULTS

Starting material. The glands (*glandula vesicalis*) located in the area where the urethra leaves the bladder, were removed at slaughter, immediately frozen in dry ice and stored at —20°C. They were then ground through a quarter-inch plate in a semifrozen condition and promptly dried in a vacuum mixer. The dehydrated material was then shipped to our laboratory and stored at —20°C for several years before being processed. Only this type of starting material was used for the work described in this paper.

We are greatly indebted to Dr. Walter Lundberg of the Hormel Institute, to Mr. Murphy, and Hormel & Co., Austin, Minn. U.S.A., for the collection of the sheep prostate glands used in this investigation.

Extraction procedure. During the various stages of the isolation procedure, the physiological activity was determined on duodenal intestinal strips of rabbits in a bath of 30 ml (*cf.* Ref.[5]).

The dried glands were suspended with a mechanical stirrer in 4 liters of tap water per kg of dried glands and 15 min later 12 liters of 95 % ethanol were added. The suspension was stirred mechanically for about one hour and then left to sediment overnight. The supernatant, clear, ethanol solution was siphoned off and the insoluble residue strained through cheese cloth and filtered. The combined extracts were evaporated *in vacuo* to about one twentieth of their original volume.

This crude extract was first extracted once with its own volume of ether. The aqueous phase was then acidified to about pH 3.5 with 6 N hydrochloric acid and extracted once with its own volume and then twice with half the volume of ether. The aqueous phase was discarded and the combined ether extracts were extracted 6 times with half the volume of 0.2 M sodium phosphate buffer of pH 8. During the first extraction, the pH of the buffer had to be adjusted back to pH 8 with 2 M sodium carbonate. The ether phase was discarded and the combined buffer phases were acidified to pH 3 with hydrochloric acid. They were extracted once with one volume of ether and then twice with half the volume of ether. The aqueous phase was discarded. The combined ether extracts were washed until free of chloride ions with small portions of water, each of which passed a second ether phase. The combined ether phases were then evaporated to dryness *in vacuo* leaving a dark, brown paste.

Preliminary purification. The residue obtained as described in the previous section was subjected to a five or ten-stage counter-current distribution between equal volumes (200 ml per 5 g of extract) of ether and 0.5 M sodium phosphate buffer pH 6.4. The buffer phases were acidified and extracted three times with ether. All the phases were evaporated and weighed and the physiological activity of each phase was determined. An example of a five-stage, counter-current distribution is given in Table 1, though a ten-stage procedure is more efficient and has more often been used.

Table 1.

Phase number	Weight (g)	Physiological activity Relative units per phase	per mg
Ether 1	6.40	7 200	1
» 2	0.80	2 200	3
» 3	0.25	1 300	5
» 4	0.15	1 000	7
» 5	0.10	1 200	12
Buffer 5	0.06	1 700	28

» 3	0.05	2 400	48
» 2	0.06	2 200	37
» 1	0.80	2 100	3

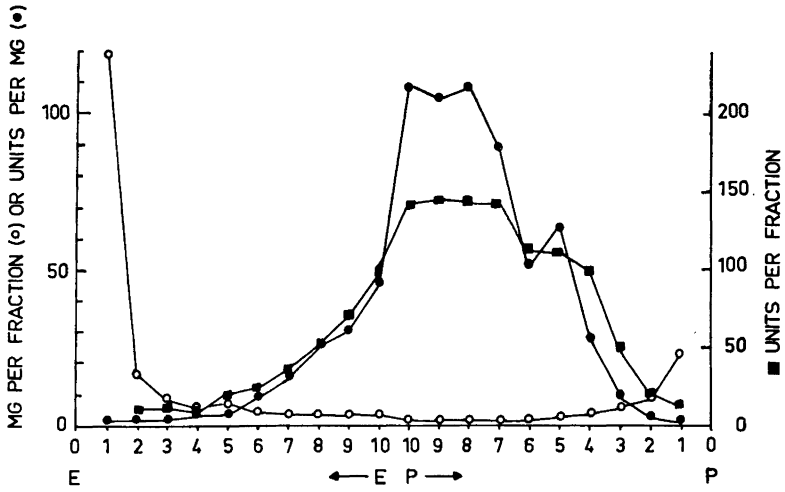

Fig. 1. Purification of PGF with a ten-stage, counter-current distribution of the crude extract of prostate glands. E = ether phases, P = buffer phases.

The material corresponding to that contained in ether 4 to buffer 2 was combined and used for the further purification of PGF. Different lots of prostate glands gave somewhat different distributions of physiological activity in the counter-current distribution procedure. The activity in the earlier ether phases only occurred in certain batches of dried glands apparently due to the handling during collection and drying. In Fig. 1 a ten-stage distribution of material that did not contain any activity in the first ether phases is

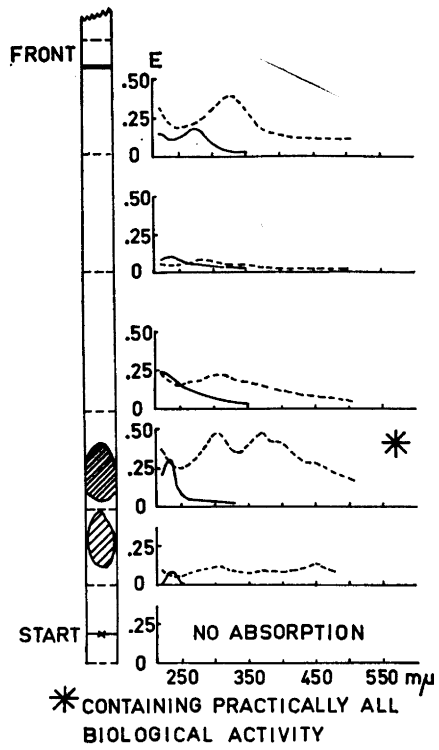

Fig. 3. Paper chromatographic analysis of the active material obtained after the purification with reversed-phase chromatography. For explanations see text.

shown. A study of the more lipophilic factor will be described in a following paper.

First partition chromatography. The material from the phases ether 4 to buffer 2 in a five-stage, counter-current distribution, or the corresponding phases in a ten-stage procedure, was subjected to reversed phase partition chromatography. 300 ml of 50 % (v/v) methanol/water was equilibrated with 30 ml of 50 % (v/v) *iso*octanol/chloroform in a separatory funnel. 4 ml of the less polar phase were supported on 4.5 g of hydrophobic Supercel (silane treated kieselguhr) which was then slurried in the aqueous phase, poured into a chromatography tube and allowed to settle. A one cm layer of sand was put on the top of the column. About 100 mg of the material was then dissolved in the smallest possible amount of moving phase and added onto the top of the column. When larger amounts of material were run, the size of the column was correspondingly increased and it was found that columns with 90 g of Supercel gave good results with 2—3 g of material.

A typical result of a chromatographic separation with an 18 g column is shown in Fig. 2. Besides the distribution of physiological activity (determined in every third fraction) and weight, the light absorption at 270 and 230 mμ of diluted aliquots of the fractions are shown.

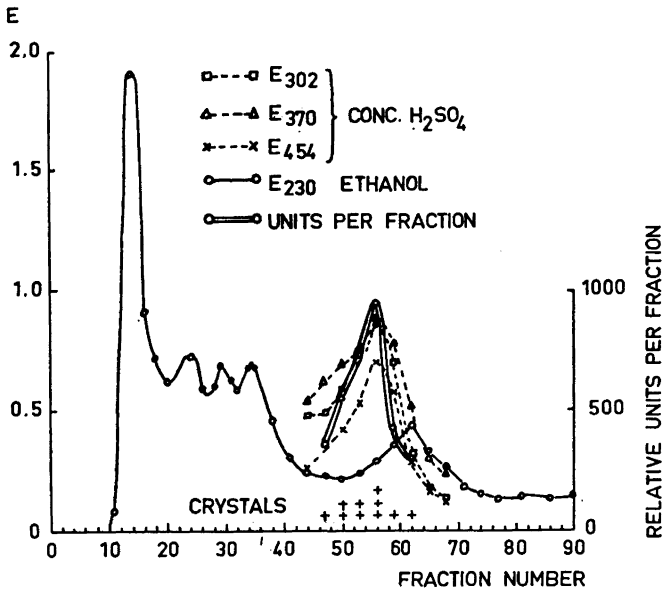

Fig. 4. Chromatography with the acid solvent system of the active material (purified PG) obtained after reversed-phase chromatography. For explanations see text.

Paper chromatography. The phase system used for the paper chromatography of prostaglandin concentrates has been utilized before for the separation of bile acids [8,9]. Ethylene chloride/heptane 50/50 was used as moving phase after equilibration with an equal volume of 70 % (v/v) acetic acid/water. A suitable aliquot of the fractions (usually about 50 μg of material) was put on the starting line of the filter paper (Whatman 3 MM). After equilibration overnight in the chromatographic tank in the vapors of both phases, the papers were brought into contact with the moving phase and developed for 6 h using the ascending technique. After drying, the papers were sprayed with a 15 % ethanolic solution of phosphomolybdic acid. Heating for a few minutes at 80°C revealed blue spots on the chromatograms. Ethanol elution of zones on unsprayed papers, corresponding to these spots, revealed that practically all of the physiological activity was confined to the zone of one of the spots. The results of paper chromatographic analyses of fractions from the chromatography shown in Fig. 2 are shown in the same figure below the chromatogram. The R_F values of the spots varied in different runs, but the relative position of the spots and the physiological activity was unchanged.

The fractions from the reversed-phase partition chromatography that contained the physiological activity were combined. Aliquots of this material were used for a spectrophotometric analysis after paper chromatography, according to the method described by Sjövall [9]. Paper chromatography, with the phase system described above, was performed on washed filter paper strips with purified solvents. After the development of the chromatograms, unsprayed

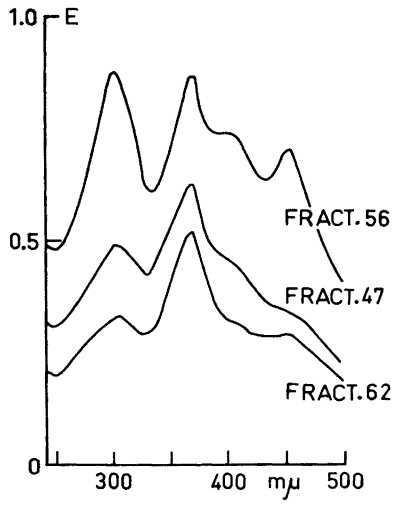

Fig. 5. Sulphuric acid spectra of active material (fractions from K 25) from the chromatography shown in Fig. 4. The fraction numbers refer to this figure.

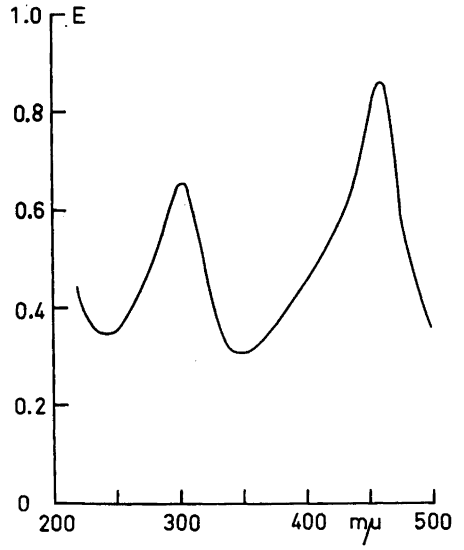

Fig. 6. Sulphuric acid spectrum of crystalline PGF, (31.2 μg after 2 h at room temperature in 1 ml conc. H_2SO_4).

strips were cut into pieces with the guidance of the spots on the sprayed strip. These pieces were eluted with ethanol and the eluates evaporated to dryness *in vacuo*. Light absorption spectra were then recorded in ethanol solution and in 96 % sulphuric acid after 2—3 h at room temperature. An automatic spectrophotometer (Perkin-Elmer, Spectracord 4 000) was used. The physiological activity of the eluates was also determined; the results of a typical analysis are shown in Fig. 3. The area containing the physiological activity had a typical sulphuric acid spectrum, and corresponded to a blue spot obtained with phosphomolybdic acid.

Second partition chromatography. It was evident (Fig. 3) that the material from the reversed-phase partition chromatography was inhomogeneous. A column chromatography with an acid solvent system was therefore developed. Ethylene chloride/heptane 50/50, after equilibration with 1/3 of its volume of acetic acid/water 60/40 was found to be a suitable moving phase. 4 ml of the acetic acid/water phase were supported on 4.5 g of Hyflo Supercel and served as stationary phase. The column was prepared as described for the reversed phase column. 50 mg of the material from the reversed-phase partition chromatography were run on a column of this size. With larger amounts, the column was correspondingly increased. The material was transferred onto the top of the column dissolved in the smallest possible amount of moving phase.

Fig. 4 illustrates a run of about 200 mg of material on a column with 18 g of Supercel. The peak of physiological activity appeared at approximately 280 ml effluent. Suitable aliquots of every third fraction were evaporated to

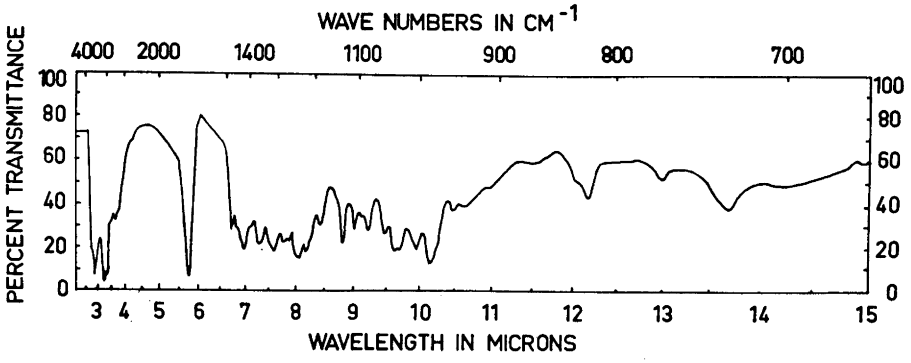

Fig. 7. Infrared spectrum of the methyl ester of PGF (KBr disc).

dryness *in vacuo* and were dissolved in one ml of ethanol. The U.V. spectra were recorded and it was found that most fractions had an absorption maximum at 230 mμ. The extinction of the different fractions at this wavelength is shown in Fig. 4. It is evident that there is no correlation to the physiological activity. One-thirtieth of each of these fractions was then evaporated to dryness and dissolved in 1 ml of 96 % sulphuric acid. After 2—3 h at room temperature, the U.V. spectra were recorded. The spectra of fractions at the beginning, middle and end of the band of physiological activity are shown in Fig. 5. Three absorption maxima are found at 302, 370 and 454 mμ, respectively, and the extinctions at these wavelengths are recorded in Fig. 4. As seen from Fig. 5, the band of physiological activity does not consist of a pure compound since the ratios between the extinctions at the three maxima are different in the beginning, middle and end of the band. The best correlation between activity and light absorption was found for the maxima at 320 and 454 mμ.

Paper chromatography of aliquots of the fractions showed just one spot with the phosphomolybdic acid reagent and physiological activity was confined to the same zone as this spot. By making spot tests with approximately 20 μl of the effluent from the acetic acid columns, the material containing the physiological activity could be detected. This method was sometimes used instead of testing on intestinal strips.

Crystallization. After evaporation in a vacuum oven at 50°C, the fractions containing the main part of the physiological activity crystallized partly in needle-shaped crystals. The relative distribution of crystals is shown in Fig. 3. The amount of crystals in each tube was less than 1 mg in this run.

The crystals were found to be relatively insoluble in ether. Trituration of each fraction with a few drops of ether at 0° dissolved the oily substance, leaving most of the crystals. After pipetting off the ether, the crystalline residues were combined and recrystallized several times from ethyl acetate/light petroleum until a constant m.p. of 102—103°C was reached. The crystals were small, colourless needles. In all, we have had about 20 mg of this material. The sulphuric acid spectrum of pure PGF is shown in Fig. 6.

Elementaly analysis yielded the following results:

		C	H	O	N
Found:		67.2	10.0	22.6	0.0
Calc. for	$C_{20}H_{32}O_5$ (352.45)	68.2	9.2	22.7	
	$C_{20}H_{34}O_5$ (354.47)	67.8	9.7	22.6	
	$C_{20}H_{36}O_5$ (356.49)	67.4	10.2	22.4	

CHN-analysis was done with an ultramicro gasometric technic by Dr. W. Kirsten, Uppsala, and oxygen determinations by Dr. K. J. Karrman, Lund.

A titration of 2.50 mg in 50 % ethanol yielded a curve indicating a pK of 6.3 and an equivalent weight of 357 ($\pm$ 20).

A titration of cholic acid under the same conditions yielded the half equivalent point at 6.3 and an equivalent weight of 412 (calc. 409).

A microhydrogenation in ethanol-acetic acid and Adams-Shriner platinum catalyst at room temperature resulted in the uptake of slightly more than one mole of hydrogen per an assumed molecular weight of 356.

The infrared spectrum of the methylester is shown in Fig. 7.

Dr. Sixten Abrahamsson, Uppsala, has kindly determined the interplanar spacings by X-ray diffraction of crystalline PGF. The values obtained were as follows (Ångström units; intensities put in brackets with the scale *v*ery *s*trong, *s*trong, *m*edium, *w*eak, *v*ery *w*eak): 16.44 (s), 9.46 (w), 8.16 (w), 6.19 (m), 5.46 (m), 5.05 (m), 4.71 (vw), 4.63 (vs), 4.54 (m), 4.46 (m), 4.08 (m), 4.02 (s), 3.74 (w), 3.56 (w), 3.45 (vw), 3.07 (vw), 2.93 (w), 2.80 (w), 2.67 (vw), 2.56 (vw), 2.48 (vw), 2.39 (vw), 2.34 (vw) 2.02 (w), 1.48 (w).

One mg of the compound was treated with diazomethane and the resulting methyl ester subjected to cracking in a mass spectrometer (Dr. R. Ryhage, Stockholm). The masspectrum indicated a molecular weight of 356 for PGF. The details will be discussed in a forthcoming publication.

The results obtained would thus suggest the compound to be an unsaturated acid with the formula $C_{20}H_{36}O_5$.

Acknowledgements. The technical assistance of Mr. L. Krabisch, Miss Anita Ivarsson and Miss Berit Persson is gratefully acknowledged.

The Isolation of Prostaglandin E from Sheep Prostate Glands

SUNE BERGSTRÖM and JAN SJÖVALL

Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

A smooth muscle stimulating and blood pressure depressing factor present in sheep prostate glands — Prostaglandin E — has been isolated in crystalline form. The most likely formula is $C_{20}H_{34}O_5$.

We have described the isolation of prostaglandin F from vacuum dried sheep prostate glands in the preceding paper [1].

In that work it was noticed that a more lipid soluble factor was sometimes present which showed activity both on intestinal strips and on rabbit blood pressure. It has been found that this fraction is responsible for most of the activity of the fresh or frozen glands.

The isolation of this factor, prostaglandin E (PGE) in crystalline form, will be described in this paper.

EXPERIMENTAL AND RESULTS

Starting material. Frozen sheep prostate glands were obtained from various slaughter houses.

Extraction procedure. The frozen glands were minced in a meat grinder. After addition of 4 liters of 95 % ethanol per kg, the suspension was stirred mechanically for one hour and then left to sediment over night. The extract was separated and concentrated as described in the preceding paper [1]. The crude concentrate was then extracted into ether and transferred into phosphate buffer as described in the same paper.

Partition chromatography. In this work, we left out the counter-current distribution procedure for the preliminary purification of the crude extract. Instead, this extract was directly subjected to reversed-phase chromatography with 50 % methanol/water as moving phase and 50 % *iso*octanol/chloroform as stationary phase, supported on Hostalen (Hoechst). In most cases the extract from 12.5 kg of prostate glands weighed 5—7 g and this material was put on a column with 67 ml of stationary phase on 100 g of Hostalen. The result of such a chromatography is shown in Fig. 1. The peak of physiological activity appeared at about 1.5 l effluent. This position varied somewhat depending

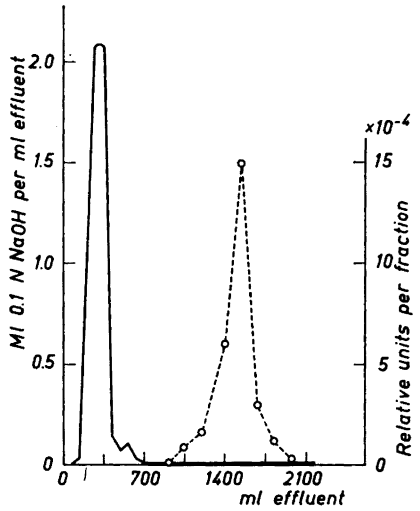

Fig. 1. Reversed phase partition chromatography of the crude extract of prostate glands.

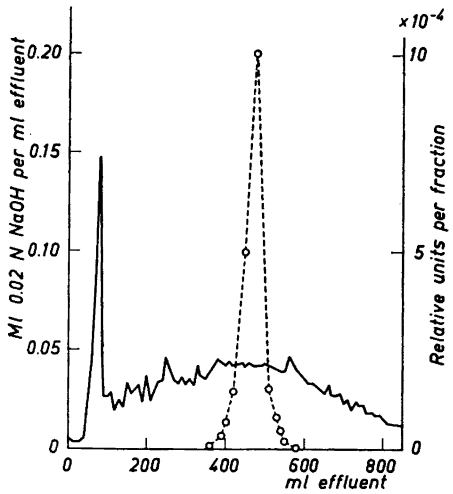

Fig. 2. Reversed phase chromatography of the active material obtained from the chromatography shown in Fig. 1.

upon the amount of material put on the column. Good separations have been obtained with 24 g of extract put on a column with 200 g of Hostalen. A 10 to 30-fold purification of the active material was obtained with the reversed phase chromatography.

The material obtained was found to lower rabbit blood pressure. This effect is not obtained with previously isolated PGF. It was found, however, that PGE, although being eluted somewhat later than PGF, was not separated from this compound. Therefore, a second reversed-phase chromatography was run using 35 % (v/v) methanol/water saturated with 1/10 of its volume of 40 % (v/v) *iso*amyl acetate/chloroform as moving phase. The hydrophobic phase was used as stationary phase, 4 ml being supported on each 4.5 g of silane treated kieselguhr. With this system, PGF is eluted just after the front, separated from PGE which is eluted at about 50 ml effluent from a 4.5 g column. For preparative purposes, 250—500 mg of material from the first chromatography were usually run on a column with 45 g of hydrophobic kieselguhr. Columns with up to 200 g of kieselguhr have been used for separation of larger amounts of material (3 g). Fig. 2 shows the chromatogram of the active material obtained from the chromatography shown in Fig. 1. No activity was found at the place of PGF in this case and an approximate 4-fold purification was obtained.

Paper chromatography. During the chromatographic purifications, paper chromatography was used to test the purity of the fractions eluted from the columns. This method was described in the preceding paper [1]. PGE was found to move somewhat faster than PGF on the chromatograms and clearly separated from this compound. However, attempts to use the column chroma-

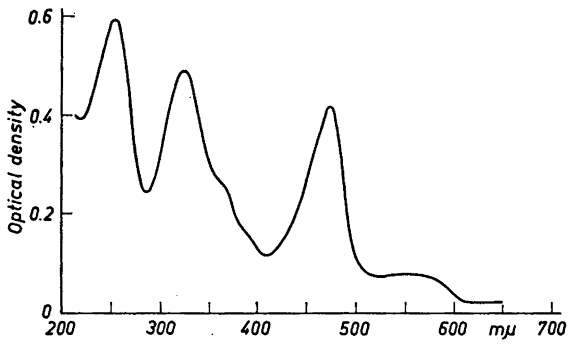

Fig. 3. Absorption spectrum of 40 μg of PGE after 85 min in 96 % sulphuric acid.

tography with acid solvent systems [1] for the preparative separation of PGF and PGE failed; the compounds being eluted together in one peak with a displacement of only a few fractions. Paper chromatograms of the fractions from the second reversed-phase chromatography showed the highest purity of PGE in the last part of the peak of activity. Besides PGE, the first part of the active peak contained a compound giving a spot on the chromatograms between the positions of PGE and PGF.

Crystallization of prostaglandin E. The fractions from the second reversed phase chromatography, containing the last half of the active band, were combined as also were those containing the first half. After evaporation to dryness *in vacuo*, the residues were dissolved in a few ml of ethyl acetate and allowed to stand overnight at room temperature. Needle-shaped crystals were usually obtained from the material contained in the last half of the active band in contrast to the material from the first half of this band. The latter material, from several chromatograms, was therefore again subjected to reversed phase chromatography with 35 % methanol as moving phase and 40 % *iso*amyl acetate/chloroform as stationary phase and crystallization procedure repeated. In some cases, the noncrystalline material was subjected to chromatography with the acid solvent system [1] prior to the second reversed phase chromatography.

The crystalline material was recrystallized several times from ethyl acetate and ethyl acetate/heptane until a constant m.p. of 115—117°C was reached. The sulphuric acid spectrum [1] of the crystalline compound is shown in Fig. 3.

Ultramicro C, H analysis and oxygen determinations yielded the following results:

Found	C 68.0	H 9.7	O 22.9
Calc. for $C_{20}H_{34}O_5$:	67.8	9.7	22.6

C, H analysis was done with an ultramicro gasometric technique by Dr. W. Kirsten, Uppsala, and oxygen determinations by Dr. K. J. Karrman, Lund.

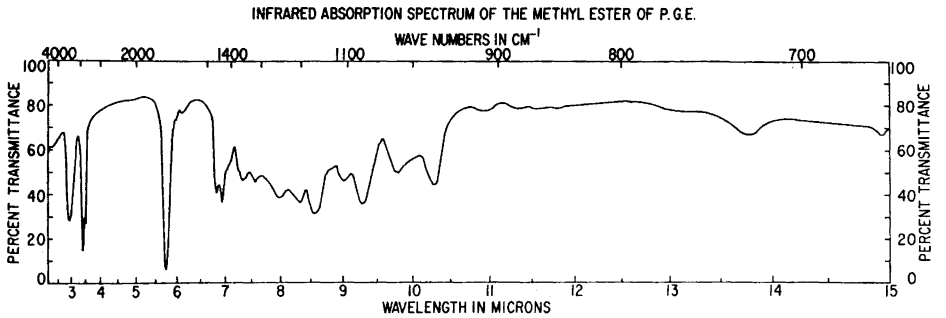

Fig. 4. Infrared spectrum of the methyl ester of PGE (KBr disc).

A microtitration curve obtained in 50 % ethanol indicated a pK of 6.5 and a molecular weight of 350 ± 20.

The methyl ester was prepared from one mg of the compound and subjected to cracking in a mass spectrometer (Dr. R. Ryhage, Stockholm). The results indicated a molecular weight of 354.

In a single crystal X-ray study done for us by Dr. S. Abrahamsson, Uppsala, it was found that there were eight molecules per unit cell. The unit cell dimensions were: $a = 8.23 \pm 0.04$; $b = 19.4 \pm 0.1$; and $c = 25.9 \pm 0.1$ Å. The specific gravity, as determined by flotation in potassium bromide solution, was 1.135 g/cm^3. These results give a molecular weight of 353 ± 5.

The interplanar spacings in Ångström units obtained by X-ray diffraction of crystalline PGE (Dr. S. Abrahamsson, Uppsala), were as follows (the intensities are denoted with *v*ery *s*trong, *s*trong, *m*edium, *w*eak, *v*ery *w*eak): 13.00 (s), 6.45 (vw), 6.13 (vw), 5.80 (w), 5.75 (m), 5.01 (m), 4.26 (vw), 4.20 (vw), 4.14 (vs), 3.97 (s), 3.91 (m), 3.75 (vw), 3.48 (w), 3.25 (w), 3.18 (w), 3.06 (w), 2.87 (vw), 2.75 (w), 2.65 (vw), 2.59 (vw), 2.50 (w), 2.44 (vw), 2.39 (vw), 2.38 (vw), 2.35 (vw).

The infrared spectrum of the methyl ester of PGE is shown in Fig. 4.

In a microhydrogenation of PGE in ethanol-acetic acid and Adams-Shriner platinum catalyst at room temperature, hydrogen was taken up corresponding to approximately one mole of hydrogen per molecule of 354.

The results, taken together, strongly indicate a C_{20} formula. The elementary analysis, the mass spectrometer data, and the X-ray data together support the formula $C_{20}H_{34}O_5$ (354.5). The C values obtained are a little low, but ultramicro analysis of cholic acid also yielded carbon values that were about 0.5 % low.

The mass spectrometer data indicate that the peaks at 332 and 350, differing by 18 units, correspond to fragments of the methyl ester that have lost two and one molecule of water, respectively. The whole ester molecule would then have the weight 368 and the corresponding free acid a molecular weight of 354. This is also made very likely by the mass spectra of the ethyl ester.

Results of investigations of the physiological activity of PGE have been published separately [2,3].

Smooth Muscle Stimulating Factors in Ram Semen

SUNE BERGSTRÖM, LENNART KRABISCH and JAN SJÖVALL

Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

Extraction and chromatographic separation of lipid soluble, acidic material in ram seminal plasma has shown the presence of at least two different factors with smooth muscle stimulating and blood pressure lowering effects. One of the factors shows certain properties similar to those of the PGE previously isolated from sheep prostate glands.

The pharmacodynamic effects of extracts of seminal fluid and male accessory glands of humans and some animal species were observed independently by Goldblatt [1] and U.S. von Euler [2,3]. The active principle was called prostaglandin.

We have recently described the isolation of two factors, PGE and PGF, from the prostate glands of sheep in crystalline form [4,5]. The compound PGE predominates in the extracts of frozen glands, while roughly equal amounts of the two compounds were found in vacuum-dried glands.

In order to ascertain the nature of the active compounds present in the seminal plasma, we have made a preliminary study of the chemical properties of the physiologically active factors normally present in ram semen plasma.

EXPERIMENTAL AND RESULTS

Ram seminal plasma was obtained through the courtesy of Dr. T. Mann, Molteno Institute, Cambridge, to whom we are greatly indebted for his help. The ram semen had been collected at the A.R.C. Unit of reproductive Physiology and Biochemistry, Cambridge. The seminal plasma was obtained by centrifugation of 23 ejaculates (30 ml). The supernatant seminal plasma (24 ml) was precipitated with two volumes of 96 % ethanol and was sent by air mail to our laboratory.

Extraction and chromatography. The ethanolic solution was filtered and the precipitate washed several times with 96 % ethanol. About 150 ml of clear solution was obtained and evaporated *in vacuo* to a volume of a few ml After dilution to about 10 ml with water, the solution was acidified with hydrochloric acid to pH 3 and extracted three times with equal volumes of ether.

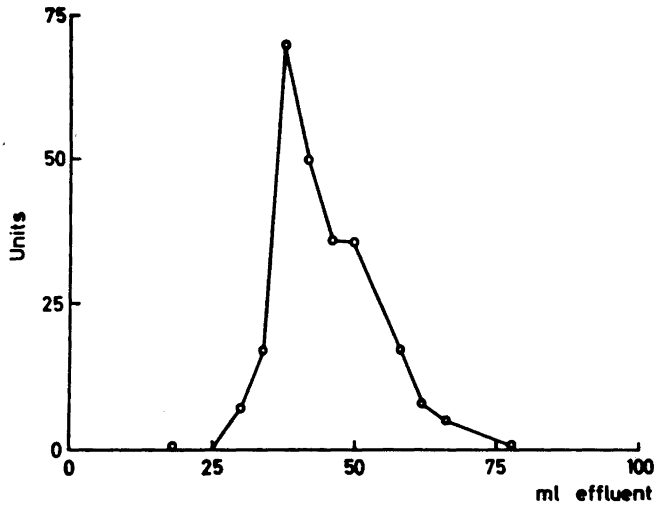

Fig. 1. First chromatography of the physiologically active material in ram seminal plasma.

The combined ether extracts were extracted twice with half the volume of 0.2 M sodium phosphate pH 8, the pH having been corrected to 8 with sodium carbonate during the first extraction.

The buffer solution was acidified to pH 3 with hydrochloric acid and extracted twice with equal volumes of ether. After washing with small portions of water, each of which was passed through a second ether phase, evaporation of the combined ether extracts left about one mg of residue.

This material was subjected to reversed-phase chromatography. 150 ml methanol, 150 ml water, 15 ml chloroform and 15 ml *iso*octanol were shaken in a separatory funnel and left to separate at 23°C. The less polar phase was used as the stationary phase; 3 ml were supported on 4.5 g of Hostalen (Hoechst) that had been purified by continuous ethanol extraction in a Soxhlet apparatus for two days. The column was prepared as described earlier [4]. The residue was dissolved in a few ml of the moving phase and transferred onto the top of the column. 100 ml of the moving phase were allowed to pass through the column and 2 ml fractions were collected. The activity of every third fraction was determined on duodenal intestinal strips; results are shown in Fig. 1. The activity appeared at the same place in the chromatogram as PGE and PGF which move together in this system. The testing was done against a standard of pure PGE, *1 μg being defined as one PGE rabbit intestinal unit.* The total activity corresponded to approximately 500 μg of PGE. The effect of the fractions at 34 and 58 ml effluent was tested on rabbit blood pressure and it was found that 2—4 intestinal units produced a distinct lowering of blood pressure.

The fractions between 25 and 75 ml effluent were combined and subjected to reversed-phase chromatography, using methanol/water/*iso*amylacetate/chlo-

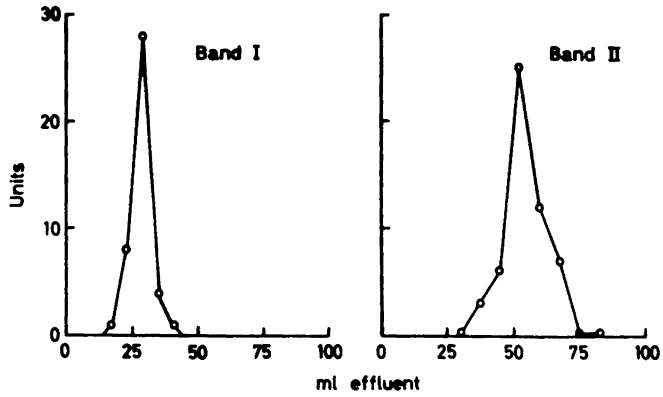

Fig. 2. Chromatography of the two active bands separated by chromatography of the active band shown in Fig. 1. See text.

roform (70/130/8/12/ (v/v)). Four ml of the less polar phase were supported on 4.5 g of silane treated hydrophobic Supercel. On testing the fractions on the intestinal strip, it was found that the activity had been separated into two bands. The peak of the first band appeared at 27 ml effluent and that of the second band at 56 ml effluent. Both bands contained material with a depressing effect on rabbit blood pressure.

The peak fractions of both the bands were used for paper chromatography with ethylene chloride/heptane 5:5 as moving phase and acetic acid/water 7:3 as stationary phase at a constant temperature of 23°C. After the developed chromatograms were sprayed and heated at 80° for a few minutes, one blue spot was revealed which had moved as PGE in the case of the second band and slightly slower in the case of the first one.

The fractions of each peak from the reversed-phase chromatography were then combined and rechromatographed with the same solvent system as that used for their separation (Fig. 2).

Spectroscopic properties. The peak fractions of the chromatograms shown in Fig. 2 were used for a study of the spectroscopic behaviour of the compounds in alkaline and acid solution. After evaporation of the solvents, the residues were dissolved in spectroscopically pure absolute ethanol and the U.V. spectra were recorded with an automatic spectrophotometer (Perkin-Elmer, Spectracord 4 000). The ethanol was then evaporated and the fractions dissolved in 0.01 N sodium hydroxide in 50 % ethanol and heated from 2 h at 100°C in sealed tubes. The U.V. spectra were again recorded against an appropriate solvent blank. After the addition of 50 μl of 0.1 N sodium hydroxide and having been heated for one hour at 100°C in sealed tubes, a third recording of the spectra was made. After addition of 0.5 ml of 4 N hydrochloric acid to each sample and having been heated at 100°C for one hour in sealed tubes, a final recording of the spectra was made.

The results with the peak fraction of band II (Fig. 2) are shown in Fig. 3. The original ethanolic solution of the substance showed a low, noncharacteristic

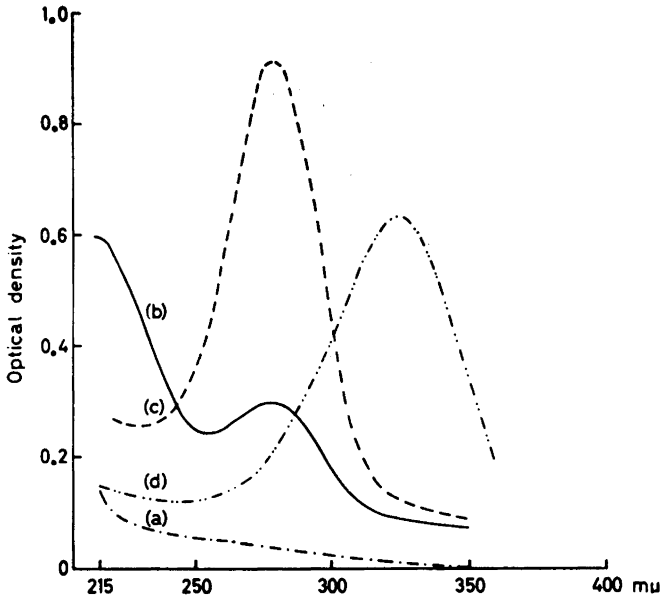

Fig. 3. Absorption spectra of the peak fraction of band II, Fig. 2: (a) in ethanol, (b) after 2 h at 100°C in 0.01 N NaOH, (c) after another hour at 100°C after addition of 50 μl of 0.1 N NaOH, (d) after another hour at 100°C after the addition of 0.5 ml of 4 N HCl. For further explanations see text.

increase of the extinction towards shorter wavelengths (Fig. 3a). After it was heated in 0.01 N sodium hydroxide, a large increase in the absorption at 215 mμ was observed and a lower maximum was present at 280 mμ (Fig. 3b). The latter band increased several times on reheating with more alkali, whereas the absorption at 215 mμ decreased (Fig. 3c). After heating in hydrochloric acid, the maximum at 280 mμ had disappeared and a new maximum at 325 mμ was found (Fig. 3d). All the changes observed are typical for PGE.

In the case of the peak fraction of band I (Fig. 2), no such typical changes in the spectra were found. There was only a noncharacteristic, continuous increase in extinction values towards lower wave-lengths, and heating in alkali and acid increased these values only slightly.

DISCUSSION

The extraction and the chromatographic separation of the lipid soluble, acidic material present in ram seminal plasma has shown that at least two different factors are present in comparable amounts, judging from the activity on intestinal strips from rabbits.

One of these behaves in the column chromatographic separations as well as on paper chromatograms, as the PGE isolated from sheep prostate glands. The purified fractions also show the same typical U.V. spectra on heating with

alkali and acid. The extinctions observed are in rough agreement with those expected from the biological activity.

The observed activity corresponds to a content of about 10 μg of PGE per ml of seminal plasma, *i.e.* the avarage content of prostaglandin E per ejaculate would be slightly higher.

The second active compound is likewise active, both on the intestinal strip on rabbit blood pressure, *i.e.* it is not identical with PGF which shows no activity on the blood pressure. It is furthermore differentiated from PGF by the absence of a maximum at about 225 mμ after being heated with acid. Possibly minor amounts of PGE may be present, but if so, the third physiologically active compound observed in this paper predominates.

A Specific Depression of the Reactivity of Peroxidase Complex II towards Donor Molecules by Substitutions in the Haem Group

BRITTON CHANCE and KARL-GUSTAV PAUL

Johnson Research Foundation, University of Pennsylvania, Philadelphia, Penn., U.S.A., and Biokemiska institutionen, Medicinska Nobelinstitutet and Karolinska institutet, Stockholm, Sweden

The substitution of the vinyl groups in the horse radish peroxidase protohaematin by acetyl groups has previously [1] been found to give decreased overall peroxidase activity. It is now demonstrated that the substitution affects the reaction between peroxidase-peroxide complex II and donor (k_4) whereas the rate of formation of complex I remains constant. The substitution has a greater effect upon the reactivity with uric acid than with ascorbic acid. The reason for the change in the complex II-donor reaction is briefly discussed. The experiment suggests a specific control of enzyme reactivity by side chain substitutions in the haematin.

For several reasons it has become of interest to determine the way in which the enzymic activity of horse radish peroxidase is affected by changes in the structure of its haem group. The initial studies of Theorell, Bergström and Åkeson [2] showed that successful recombinations with meso- or deutero-haematins and peroxidase apoprotein can be achieved. The activity with these haematins was found to be about half of that of the intact enzyme; a considerably higher activity with mesohaematin was, however, also reported [3]. Somewhat later monoazahaematin peroxidase was found to be one fifth as active as the intact enzyme [4]. Recently the activities of some of the previously studied artificial peroxidases were redetermined and in some cases also compared with the activities obtained with isomers of the haematins [1]. It is now well established that the propionic acid residues at the positions 6 and 7 are needed for the formation of an enzymatically active peroxidase [1,2,5]. Some 2,4-substitutions cause parallel shifts in peroxidase activity and pyridine haemochromogen spectrum [1]. Deuterohaematin is an exception, but its two free pyrrolic 2-positions may influence the activity. The homologue with three free 2-positions gave one tenth of the activity obtained with deuterohaematin itself [6].

Further studies of the artificial peroxidases are of interest also in view of the knowledge of haemoprotein structures now available through X-ray crystallography [7,8] and of the effect of haematin substitutions on the reactivity of myoglobin [9,10]. The fact that meso-, haemato-, and deuterohaematins but not diacetyldeuterohaematin can be utilized as growth factors by a haem-requiring *Staphylococcus* mutant [11] also will draw attention to the mechanism by which the artificial peroxidases differ.

In most determinations of the activity of reconstituted peroxidases, the purpurogallin test was used. A study of this reaction indicated the possibility of a rate-limiting step between the completion of the enzyme activity and the formation of coloured products [12]. Whereas such a slow step will not necessarily be of great consequence in determinations of protoperoxidase purity the situation may not be identical with substituted peroxidases. The mesidine test, used in some activity determinations, is at present being studied in the same way (B.C. *et al.*). A further complication is introduced by the fact that the over-all assays may measure either k_1 or k_4 according to the following equation [12]:

$$\frac{dx}{dt} = \frac{e}{(1/k_4 a) \times (1/k_1 x)} \qquad (1)$$

where k_1 and k_4 are defined below, a and x are the donor and peroxide concentrations and dx/dt is the rate of disappearance of x.

It is the purpose of this paper to study a reconstituted peroxidase of an activity sufficiently different from that of the protohaematin enzyme to permit the assigning of the decrease in activity to one or more steps in the following reaction mechanism (*cf.* Ref.[13]):

$$HRP + H_2O_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} HRP - I + H_2O \qquad (2)$$

$$HRP - I + AH_2 \xrightarrow{k_7} HRP - II + AH^\circ \qquad (3)$$

$$HRP - II + AH_2 \xrightarrow{k_4} HRP + AH^\circ \qquad (4)$$

Diacetyldeuterohaematin peroxidase is such an enzyme [1].

MATERIAL AND METHODS

Horse radish peroxidase was prepared as previously described [14], and Fraction C was crystallized twice from ammonium sulfate solution. The preparation of the apoprotein and the coupling was performed as usual [5], ethanol being added to stabilize the haematin solutions in alkali [15]. After the chromatography on Dowex — 2 the concentrations of the reconstituted enzymes were determined by pyridine haemochromogen measurements [5].

The methyl peroxide solution was standardized by UV absorption as previously described [16]. Tenth molar acetate buffer of pH 4.6 and 26° were used in all experiments.

The stopped-flow apparatus [17] (optical path length 1 cm) was used to record the cycle of formation and disappearance of the enzymesubstrate intermediates. With this, a double-beam spectrophotometer [18] was used to record the absorbancy changes of the reactants, the wavelengths being set to the peak and trough values for the difference between the free enzyme and the secondary peroxidase complex, II. For protoperoxidase the appro-

priate wavelengths were 427 and 395 mμ, and for diacetyldeuteroperoxidase 415 and 388 mμ. The initial rate of the absorbancy change was measured from a mirror oscillograph recording and the full cycle of appearance and disappearance of the intermediate was recorded on a slower time scale (Fig. 1).

The peroxide was added to a solution containing the enzyme and the donor in the stopped-flow apparatus. This procedure was desirable since any trace of peroxide formed by autoxidation of the donor would be removed prior to testing the activity. The final concentration of haematin was 0.5 μM.

The molecular extinction coefficient of the protohaematin peroxidase was $\varepsilon = 108$ cm^{-1} mM^{-1} and that of the diacetyldeuterohaematin peroxidase was 71 cm^{-1} mM^{-1} at 403 and 405 mμ, respectively. The reconstituted protohaematin peroxidase gave this value whereas the unsplit material [14] gave 98 cm^{-1} mM^{-1}, both on the basis of pyridine haemochromogen measurements. $\varepsilon = 108$ has been used for the present calculations.

According to determinations in the split-beam recording spectrophotometer [19] the extinction coefficient of the secondary complex as measured at the pairs of wavelengths 427—395 mμ and 415—388 for proto- and diacetyldeuterhaemin peroxidases, respectively, were 84 and 59 cm^{-1} mM^{-1}. In the flow apparatus, however, where the absorbancy change is measured immediately after the reaction of peroxidase with donor and peroxide, the values were higher, 106 and 74 cm^{-1} mM^{-1}. These were used in calculating k_4 from the cycles of the intermediate compounds.

RESULTS

Typical experimental results are shown on the superimposed tracings of Fig. 1 which represents the formation and disappearance of complex II of protohaematin peroxidase (upper trace) in the presence of 7 μM uric acid and 1.5 μM methyl peroxide. Time proceeds from left to right and illustrates the reaction kinetics which ensue upon mixing peroxide with enzyme plus donor. The upward deflections of the traces indicate increases of absorbancy at 427 and 415 mμ, measured with respect to 395 and 388 mμ, respectively. The intermediate forms abruptly in both cases. In the case of protohaemin peroxidase the concentration of the intermediate falls to zero in a few seconds, the value of $t_{\frac{1}{2}\ off}$ being 4.8 sec. In the case of diacetyldeuterohaemin peroxidase $t_{\frac{1}{2}\ off}$ is 8 times larger (40 sec.).

A quantitative determination of the values of k_4 can be obtained from the formula [20,21]:

$$k_4 = \frac{x_o}{p_{max}\ t_{\frac{1}{2}\ off}\ [AH_2]} \qquad (5)$$

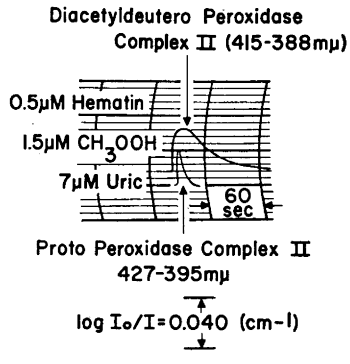

Fig. 1. Superimposed spectrophotometric records showing the kinetics of formation and disappearance of protohemin peroxidase and deuterohemin peroxidase, measured at the appropriate wavelengths indicated on the diagram. Time moves from left to right; an upward deflection of the trace corresponds to increased absorbancy at the longer wavelengths. 0.5 μM peroxidase, 0.1 M acetate buffer, pH 4.6, 26°C. Other conditions indicated on the diagram (Expts. 132 b—6,7).

Table 1. Comparison of the kinetics of proto- and diacetyldeuterohematin peroxidase (Expt. 132 b).

Hematin	Proto-	Diacetyl-deutero-	Proto-	Diacetyl-deutero-
λ(mμ)	427–395	415–388	427–395	415–388
(x_o) CH_3OOH (μM) Donor	1.5 Ascorbic acid	1.5 Ascorbic acid	1.5 Uric acid	1.5 Uric acid
(a_o) Donor concentration (μM)	10	10	7	7
p_{max} (μM)	0.31	0.28	0.26	0.43
$t_{\frac{1}{2}\ off}$ (sec)	5.0	20	5.0	40
$k_4 \times 10^4$ ($M^{-1} \times sec^{-1}$)	0.97	0.26	2.0	0.13
Rate of formation (μM/sec)	0.49	0.42	0.63	0.51

The values of k_4 calculated in Table 1 by eqn. 5 show that the ratio of the activities for proto- and diacetyldeuteroperoxidases is 15 with uric acid as the donor. Experiments carried out with ascorbic acid as the donor give a ratio of 3.7. It should be noted that the values of k_4 for protoperoxidase obtained in the presence of ascorbic acid are significantly less than those obtained with previous preparations [22]. No explanation is put forward for this difference at the present time.

The data of Fig. 1 show qualitatively the cause of the low reactivity of diacetyldeuteroperoxidase, namely that there is a higher steady-state concentration of complex II in this substituted peroxidase than in the natural one. This suggests that the formation of the intermediate is not a ratelimiting factor and that its decomposition is the rate-limiting factor.

Support for the idea that the rate of formation of the intermediates is not greatly affected by the substitution of the haematin is afforded by kinetic data obtained with the stopped flow method. The last row of Table 1 gives the rates of formation of the intermediates in μmoles per liter per second (μM/sec) in the four experiments. It can be seen that the values for diacetyldeuterohaematin peroxidase are between 80 and 85 % of those for the protohaematin enzyme.

Table 2. Values of k_4 as determined in open cuvettes.

	Ascorbic acid	Uric acid
	$k_4 \times 10^{-4}$ M^{-1} s^{-1} (S.D.,n)	
Protohaematin-HRP	0.62 ± 0.04 (6)	1.88 ± 0.52 (5)
Diacetyldeutero-haematin-HRP	0.12 ± 0.02 (3)	0.21 ± 0.01 (7)

In another series of experiments varying amounts of peroxide were added to a solution of peroxidase and donor in an open cuvette (Table 2). In this series the ratio of activities in the presence of ascorbic acid was 5 and in the presence of uric acid 9. Measurements of the overall reaction in terms of the formation of "tetraguaiacol" from guaiacol were also studied. When performed as previously described [23] the guaiacol test gave the values 2.86 and 2.56×10^4 M^{-1} sec^{-1}. Under these conditions the test gives mainly k_1 with some contribution from k_4.

DISCUSSION

In these experiments it has for the first time been possible to assign to a substitution of groups in the haematin of the peroxidase a depression of one of the three reaction velocity constants for the action of this enzyme (see eqns. 2—4). That this is a specific effect is clear from a comparison of the lifetime of complex II of the proto- and diacetyldeuterohaematin enzymes in the presence of equal concentrations of donor and peroxide, as shown by Fig. 1. When suitable corrections have been made for the actual amount of complex II present, these curves show a 15-fold decrease in the rate of reaction with uric acid and an approximately fourfold decrease in the reaction with ascorbic acid.

Several causes for the reduction in reactivity of complex II can be discussed. The possibility that the splitting procedure somehow altered the apoprotein is ruled out by previous investigations [1,2,4] as well as by the present experiments, in which both peroxidases were recombined from the same batch of apoprotein. An alternative explanation is presented by a comparison with kinetic studies on catalase [24] which suggested a limited accessability of complex I to donor molecules of increasing chain length. At that time related effects had not yet been observed with horse radish peroxidase. A consideration of the crystallographic data on metmyoglobin [8] indicates that its haematin might be of limited accessability and, of most importance, that the vinyl groups of the haematin could be a factor in determining the accessibility of the iron porphyrin group to large molecules [10]. Although no noticeable limitation to the accessibility of peroxidase haematin is observed with the native enzyme, the haematin configuration in the diacetyldeuteroperoxidase may represent a less favourable steric situation. However, dipropionyldeuterohaematin peroxidase showed approximately the same activity as the diacetyl enzyme in the quaiacol test. If steric effects account for the decrease in the rate of reaction one would expect an inhibition of the reaction of complex I with the donor molecule to form complex II, provided that the same reactive site is involved in this transformation. Further, an inhibition of the reactivity of the peroxidase to alkyl hydrogen peroxides of increasing chain length to form complex I would also be expected. Experiments on this point will be taken up.

The Binding of DPNH by Liver Alcohol Dehydrogenase

ALBERT WITTER*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

1. Pure horse liver alcohol dehydrogenase (LADH) contains 28 —SH groups/mole enzyme as determined spectrophotometrically with PCMB. There is no decrease in —SH groups after addition of DPNH or of DPNH and *n*-butyramide, the reaction with PCMB, however, being somewhat retarded in the latter case.

2. Incubation of LADH and LADH—DPNH with sulfhydryl reagents leads to a protection against inactivation in case of the enzyme-coenzyme complex as compared with enzyme alone.

The number of reacted —SH groups seems to be the same in both cases, however.

3. With PCMB as the sulfhydryl reagent the decrease in enzymatic activity and the decrease in bound coenzyme is about linear with increasing PCMB concentrations.

Only after complete reaction of the LADH with PCMB, the enzymatic activity and the coenzyme binding capacity become zero.

4. The role of the —SH groups in the working mechanism of LADH is discussed. The role of helping in maintaining the requisite ternary structure seems more likely than one of direct binding of coenzyme alone, but a combination of these roles is possible.

5. N(-4-Dimethylamino-3,5-dinitrophenyl)maleimide reacts with only about 30 % of the —SH groups, leading to a corresponding decrease in activity. The partly reacted LADH is precipitated by *iso*propanol (*ca.* 5 % v/v) as a deeply coloured product.

6. The inhibitory effect upon activity of *iso*propanol in higher concentration is probably due to oxidation of *iso*propanol by LADH and DPN.

7. Inactivation of LADH by Cd^{2+} is to a great extent prevented by DPNH and Zn^{2+}. This leads to the conclusion that: a) DPNH is bound directly via Zn to LADH, and b) the inactivation by Cd^{2+} is primarily caused by replacement of Zn by Cd, leading to a less active enzyme and secondarily to reaction with —SH groups.

In 1951 Theorell and Bonnichsen [1] considered the possibility of direct interaction between the —SH groups of LADH ** and its coenzyme. The absorb-

* Present address: Organisch Chemisch Laboratorium der Rijks-Universiteit, Bloemsingel 10, Groningen, Netherlands.

** The following abbreviations will be used: LADH = Horse liver alcohol dehydrogenase; DPN respectively DPNH = oxidized and reduced form, respectively, of diphosphopyridine-nucleotide; PCMB = *p*-chloromercuribenzoic acid; YADH = yeast alcohol dehydrogenase; NEM = N-ethyl maleimide; DDPM = N(-4-dimethylamino-3,5-dinitrophenyl)maleimide; μ = ionic strength.

tion maximum of DPNH at 340 mμ is replaced by a new absorbtion maximum at 325 mμ when LADH was added, because of the formation of an enzyme-coenzyme complex. Addition of PCMB, which inhibits the enzyme, immediately caused the absorbtion maximum to shift back to 340 mμ, the maximum of free DPNH.

This, together with the fact that a dissociable group with $pK' = 10$ was found to be involved in the binding of DPNH by the enzyme, lead to the aforementioned possibility.

Although the —SH groups in LADH definitely play a very important role in the working mechanism of this enzyme, there is no further evidence for its role being one of direct coenzyme binding. The finding that 2 Zn atoms are firmly bound by LADH and the fact that LADH is inhibited by metal binding agents such as 1,10-phenanthroline [2] indicate that Zn has a possible role in coenzyme binding [3]. This was stressed by the fact that both DPN and DPNH compete with 1,10-phenanthroline [4].

Other parts of the protein molecule cannot *a priori* be excluded as possible binding sites for the coenzyme, but the known inhibition of LADH by PCMB and 1,10-phenanthroline draws attention first of all to —SH groups and to Zn atoms.

Regarding the coenzyme, nearly all of the groups present in the coenzyme molecule (the carbonamide group, the pyridine nitrogen, the phosphate group, the adenine part) have been considered, as possible sites for binding to the protein molecule, especially in those papers dealing with speculative mechanisms for the action of the related enzyme YADH [3,8,15].

In this paper some experiments with LADH will be described which show the protective effect of coenzyme against some inhibitory —SH reagents.

EXPERIMENTAL

The LADH was prepared as described by Dalziel [5], and was stored at −15°C as a crystalline suspension in 30 % ethanol. After centrifugation, the crystals were dissolved in pH = 9 buffer [5] and dialysed against phosphate buffer pH = 7.05, $\mu = 0.1$, and a solution about 4.5×10^{-5} M in this buffer was obtained. This solution, when stored at about 4°C, keeps its original activity for a few days. If not stated otherwise the purity of the preparation was about 65−70 % based on enzymatic activity [6] and absorbtion at 280 mμ, assuming that all the material absorbing at this wavelength has the same extinction coefficient as LADH.

The DPNH and DPN used were preparations from Sigma Chemical Company. The purities were 90 % and 92 % for DPN and DPNH, respectively. Fresh solutions containing 1 mg/ml were used.

NEM was a Theodor Schuchardt (Munich) product.

$CuSO_4 \cdot 5H_2O$ and $Zn(OOCCH_3)_2 \cdot 2H_2O$ were p.a. Merck products.

$3CdSO_4 \cdot 8H_2O$ was a Baker Analyzed Reagent, lot no. 3363.

PCMB c.p. was a product from the Amend Drug and Chemical Co., New York.

n-Butyramide was purchased from Eastman Kodak, while the *iso*propanol was an Analar product.

The —SH groups were titrated spectrophotometrically with PCMB at 255 mμ [7]. Usually 20 μl quantities of a 10^{-3} M PCMB solution were added to a 2 to 2.5 μM solution of LADH in phosphate buffer pH = 7.05, $\mu = 0.1$, at 23.5°C.

In the presence of DPNH or DPN, however, smaller concentrations of LADH were used to permit the formation of the enzyme-coenzyme complex without having to add too much DPN(H).

Absorbance was measured with a Beckman DU Spectrophotometer and the end point was estimated graphically. A Beckman Energy Recording Adapter in connection with a Philips Recorder was used to follow the reactions kinetically.

RESULTS

The number of sulfhydryl reagents which also inhibit LADH is rather limited. Compounds such as iodoacetic acid or chloroacetophenone do not inhibit the enzyme and NEM reacts only very slowly. Heavy metal ions inhibit readily [8], but their specificity is questionable. Amperometric titrations have not been carried out, but might give additional information.

I. Interactions with PCMB

98 % pure LADH has 28 SH groups/mole enzyme (mol.wt. 84 000) as was found independently at the Nobel Medical Institute [9] and by the author at the State University's Laboratory for Organic Chemistry in Groningen. The enzyme preparation used in this investigation contained 25.5 ± 0.5 SH groups/mole of active enzyme. Active enzyme means that the enzyme concentration is calculated from the enzymatic activity test. In the case of pure LADH in the presence of enzymatic inactive, no —SH groups containing material, the number of —SH groups/mole of active enzyme, should be 28. The presence of enzymatic inactive, but —SH groups containing material should give a higher value, whereas enzymatic active, but no —SH groups containing material should give a lower value.

In the presence of DPNH or DPN the same number of —SH groups were found [9]. The dissociation constant for LADH-DPN at pH = 7.0 is

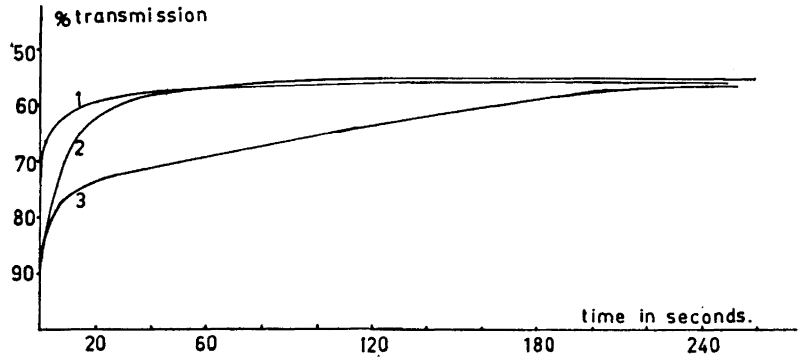

Fig. 1. The reaction of PCMB with LADH, LADH—DPNH—*n*-butyramide and LADH + imidazole *versus* time.
1: [LADH] * = 1 μM, alone, or with [DPNH] = 20 μM or [DPN] = 40 μM.
2: [LADH] = 1 μM, [DPNH] = 20 μM, [*n*-butyramide] = 1 M.
3: [LADH] = 1 μM, [imidazole] = 0.1 M.
In 3.0 ml μ = 0.1 phosphate buffer pH = 7.05. Temperature 23.5°C. In all cases PCMB was added at zero time to a final concentration of 30 μM. λ = 255 mμ.

* Concentrations of LADH in this article are given as molarities of active enzyme.

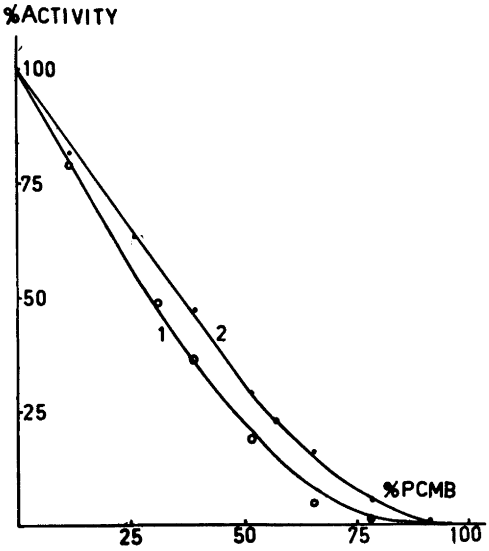

Fig. 2. The decrease in activity of LADH and LADH—DPNH, when increasing amounts of PCMB are added.

1: [LADH] = 2.03 μM.
2: [LADH] = 2.03 μM, [DPNH] = 40 μM.

Total volume = 1.50 ml, μ = 0.1, phosphate buffer p_H = 7.05. Room temperature was used. All the enzyme or coenzyme solutions were incubated 15 min and 10^{-3} M PCMB was added, then, in increasing amounts and after 15 min the activities were measured. 100 % PCMB means conversion of all the —SH groups in LADH.

160×10^{-6} M;* the dissociation constant for LADH—DPNH at pH = 7.0 is 0.31×10^{-6} M [10]. This makes it possible to have at least 95 % association in the case of DPNH, whereas in the case of DPN, under the experimental conditions used, it is difficult to get more than about 40 % association, without causing interference in the PCMB titration because of high absorbtion at 255 mμ. In this case, a difference of 1 or 2 SH groups would be difficult to detect. When the reaction is followed with a recorder there is no detectable difference in the reaction velocities of the two complexes, but, in as much as the reaction is fast, a refinement in the measuring methods might possibly reveal differences (Fig. 1).

Recently Winer and Theorell [11] described very stable ternary complexes of the type LADH—DPNH—fatty acid-amide and LADH—DPN—fatty acid*. The ternary complex LADH—DPNH—*n*-butyramide was further investigated, but showed no difference from LADH alone in —SH groups titrable with PCMB. The —SH groups of the complex, however, react more slowly with PCMB (Fig. 1). There is no evidence from this figure, that some special —SH groups are involved in this retardation of the reaction. In this laboratory it was also found [9] that imidazole forms a complex with LADH—DPNH; in this case the reaction with PCMB was strongly retarded (Fig. 1).

Bovine serum albumin (a commercial sample, titrating 0.42 SH/mole) reacted immediately with PCMB either with or without the presence of imidazole. In both cases the same amount of —SH groups was found, but, when plotting the $\Delta E_{255\ m\mu}$ against the amount of PCMB added, in the case when imidazole was present, it was found that the second part of the curve, representing the addition of PCMB to fully reacted serum albumin, was not straight, but bent downwards. This thus resulted in a smaller $\Delta E_{255\ m\mu}$ when excess

* See the following paper.

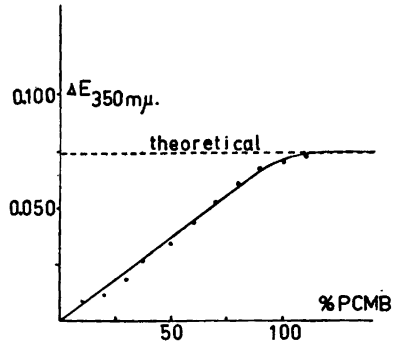

Fig. 3. The liberation of DPNH from LADH—DPNH by PCMB. [LADH] = 16.3 μM, [DPNH] = 50 μM in μ = 0.1 phosphate buffer pH = 7.05. Temperature 23.5°C.
PCMB added every 2 min and measurements made 1 min after each PCMB addition. Corrected for protein absorbtion and oxidation of DPNH in the presence of LADH.

PCMB was added to serum albumin. The same was also found to occur in the case of LADH. Furthermore, it was found that when PCMB was added to imidazole, a small absorption maximum occurred at around 245 mμ.

When the activity of LADH is plotted against increasing amounts of PCMB, a curve as in Fig. 2 is obtained, as was found in this laboratory [9].

The first part of the curves is practically straight and only towards the end is the fall in activity somewhat less than observed at the beginning. An incubation time of 15 min with PCMB ensures practically complete reaction at a temperature of 23°C. It can be seen that with or without DPNH all the —SH groups are necessary for activity. I am much indebted to Dr. J. S. McKinley McKee for letting me know the results of these experiments.

Another interesting feature is the small, but consistent protective effect of DPNH against PCMB inactivation. Although the titration curve is the same with or without DPNH, the inactivation curve is clearly distinct in the two cases.

In order to get somewhat more information about the breakdown of the LADH—DPNH complex by PCMB, it seemed useful to add the PCMB stepwise and to measure the breakdown at 350 mμ [1]. Accurate titration of the LADH—DPNH complex with PCMB was rather difficult, however.

Rather high concentrations of LADH and DPNH must be used in order to follow the breakdown of the complex spectrophotometrically, and at these high concentrations, there is an as yet unexplained oxidation of DPNH, which can be easily followed by the decrease of absorption at 340 mμ with time. This effect had earlier been observed with water purified on ion exchangers and was then explained by the presence of aldehyde which had dissolved from the resin [10]. Here, however, ordinary distilled water was used.

As was described by Theorell and Bonnichsen [1], the greatest difference in extinction between free and enzyme bound DPNH occurs at 350 mμ. The increase in extinction at 350 mμ *versus* added PCMB, corrected for protein absorbtion and DPNH oxidation, and thus representing the breakdown of the complex by PCMB, is shown in Fig. 3.

The curve obtained resembles that of Fig. 2. Again, complete breakdown of the complex seems to be reached only after complete reaction of LADH with PCMB. This breakdown is at first directly proportional to the amount

of PCMB added and deviates from linearity, at higher PCMB concentrations. The most likely conclusion is that most, if not all, of the —SH groups are important for the coenzyme binding.

II. Interactions with NEM

Direct titration of the —SH groups of LADH or LADH—DPNH with NEM at 300 mμ [12] is practically made impossible by turbidity and even the formation of a precipitate after about 8 h incubation. Furthermore, the reaction is very slow. It was observed, however, that in the case of LADH—DPNH the turbidity was much less pronounced than in the case of LADH alone.

LADH and LADH—DPNH were incubated with NEM, and the decrease in activity and —SH groups was followed. The determination of remaining —SH groups was carried out by titrating back with excess PCMB as follows. The incubation mixtures were centrifuged, and 3.0 ml of the supernatant solution was immediately pipetted out, the extinction at 255 mμ measured, and a small excess of PCMB added. The increase in extinction at $\lambda = 255$ mμ was measured after 1, 10, 20 and 30 min and the solution was again centrifuged. The $\Delta E_{255\ m\mu}$ was measured immediately and the percentage of remaining —SH groups was calculated from the last values. The discrepancies between the percentages obtained at the different time intervals indicated that the SH titration was only approximate. The results are given in Fig. 4.

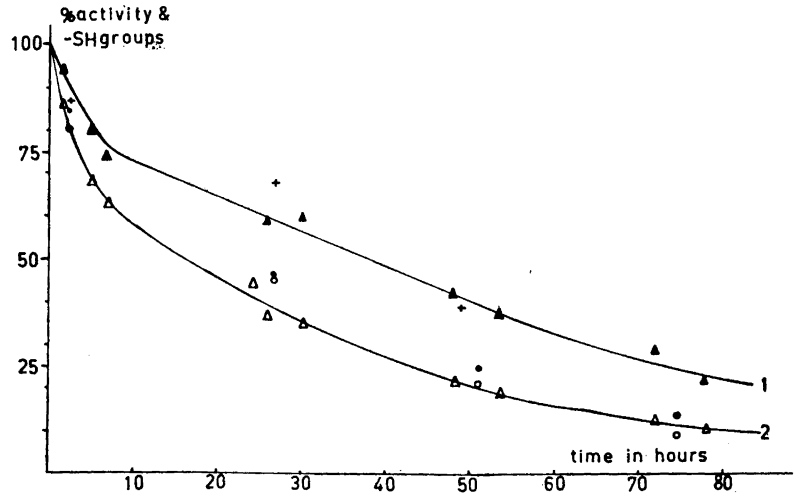

Fig. 4. The effect of excess NEM on activity and —SH titer of LADH and LADH—DPNH with time.
1: [LADH] = 1.00 μM, [DPNH] = 40 μM, [NEM] = 267 μM (▲).
2: [LADH] = 1.00 μM, [NEM] = 267 μM (△).
Total volume 15.0 ml in $\mu = 0.1$ phosphate buffer pH = 7.05. Room temperature.
● = percentage of —SH groups for 1, O = *idem* for 2.
\+ = *idem* for LADH—DPNH without NEM.
Determined by addition of 200 μl 5.15×10^{-4} M PCMB to 3.0 ml solutions, after centrifugation, at 255 mμ.

The activity decreases of LADH and LADH—DPNH without the addition of NEM were comparable.

The loss in activity of the LADH—DPNH without added NEM is similar to that for curve 1. However, in this case the decrease in free —SH groups runs parallel with the decrease in activity. There is a very strong protective effect of DPNH against inactivation, but there seems to be no protection against the decrease in free —SH groups. There is, however, a small difference in —SH groups titrated between LADH—DPNH and LADH at the end of the experiment, where it is most difficult to get clear-cut results with PCMB. Whether this difference is real or not has yet to be ascertained.

In the presence of DPN, a protection against inactivation is also present; no —SH determinations were carried out as relatively high DPN concentrations were used. On the other hand, in the case of the ternary complex LADH—DPNH—*n*-butyramide no activities could be measured because *n*-butyramide completely inhibits the enzyme. The decrease in —SH titre, however, was rather slow, about 60 % of the —SH groups still being present after 75 h.

III. Interaction with DDPM

DDPM, a coloured maleimide derivative used for the identification of cysteinyl peptides (Witter and Tuppy, unpublished results), behaves somewhat differently from NEM. Because of its rather poor solubility in water, the reaction was performed in alcohol-water mixtures.

Reaction in isopropanol. Solutions were made up in the following way: in a total volume of 3.0 ml (phosphate, $\mu = 0.1$, pH = 7.05) containing [LADH] = 0.71 μM, the concentrations of *iso*propanol were, respectively, 0.22 M, 0.44 M, 0.66 M, 0.88 M, 1.10 M, 2.20 M, and the corresponding concentrations of DDPM were, respectively, 4 μM, 8 μM, 12 μM, 16 μM, 20 μM, 40 μM, made by the addition of a 2.42×10^{-4} M solution of DDPM in *iso*propanol. The enzymatic activities of these solutions, and of the corresponding solutions with only

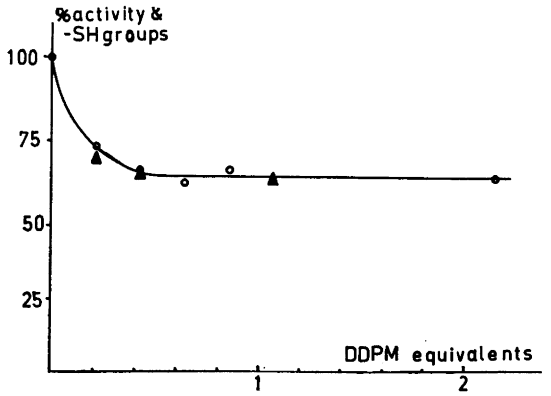

Fig. 5. The effect of DDPM on activity and — SH titer of LADH, corrected for the influence of the solvent, *iso*propanol.
○ = % activity, ▲ = % free —SH groups.

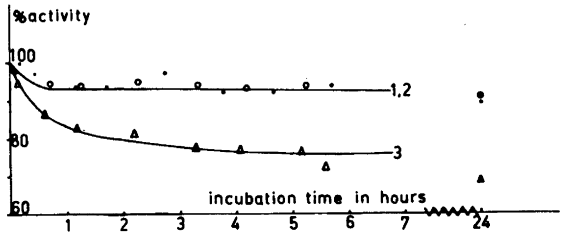

Fig. 6. The effect of excess DDPM on activity of LADH and LADH—DPNH with time.

1: [LADH] = 0.9 μM, [DPNH] = 14 μM, [DDPM] = 52.5 μM (O).
2: [LADH] = 0.9 μM (●).
3: [LADH] = 0.9 μM, [DDPM] = 52.5 μM (△).

All solutions in μ = 0.1 phosphate buffer p_H = 7.05, containing 1 % ethanol, which gives the optimal ethanol concentration in the test, as 150 μl of the incubation mixture was used for activity tests. Incubation at room temperature.

*iso*propanol (and thus no DDPM) were tested after 5 h incubation; after 7 h of incubation, the —SH groups were titrated with PCMB, after centrifugation. The differences in activities and —SH groups for the solutions containing DDPM and those containing only *iso*propanol (*vide infra*) are shown in Fig. 5.

As can be seen from this figure the decrease in activity and —SH titer are about parallel and seem to reach a constant value after about a 30 % decrease.

As in the case of NEM, an excess of DDPM is necessary to get complete reaction of the —SH groups, but a further increase in reagent concentration than used here will lead to difficulties. The enzyme will precipitate at high *iso*propanol concentrations, the absorbtion of DDPM at 255 mμ will make the —SH titrations doubtful, and also the DDPM itself may precipitate. However, as the decrease is constant from about 0.5 to 2 equivalents DDPM, it seems that with the rather weak reagent DDPM, only about 30 % of the —SH groups can react. Also in the case of NEM (Fig. 4), and to a lesser extent in the case of PCMB (Figs. 1 and 2), there seem to be faster and slower-reacting —SH groups.

Two other interesting observations were made. In the solutions containing DDPM, the reacted LADH forms a deep-yellow precipitate (from the solution containing 12 μM DDPM and 0.66 M *iso*propanol onward), which can be easily removed by centrifugation. In the solution containing only *iso*propanol, a small precipitate was observed in the test tube containing 2.20 M *iso*propanol (that is about 13 %), but in all the other solutions no precipitate was formed during the time the experiment lasted.

The second point is the effect of *iso*propanol. This secondary alcohol is reported not to be oxidized [13,14]. However, an inhibitory effect of *iso*propanol on LADH activity was found under the conditions described here (in the case of the solution containing 2.20 M *iso*propanol, there is present in the test solution 73 mM *iso*propanol and 8 mM ethanol). The inhibition might be due to impurities in the *iso*propanol used, but as other secondary alcohols (second-

ary butanol for example) are reported to be oxidized [14], the oxidation of *iso*-propanol itself cannot be excluded.

In a separate experiment the K_m for this *iso*propanol at pH = 10.05 and 23.5°C was found to be 9.2 mM, using [LADH] = 13.3 μg/ml, [DPN] = 0.42 mM and [*iso*propanol] = 1.75 to 44.0 mM.

Acetone (Analar) in a concentration of 900 mM with [DPNH] = 0.2 mM and [LADH] = 13.3 μg/ml at pH = 7.05 (μ = 0.1, phosphate) was found to be very slowly reduced.

It thus seems possible that *iso*propanol also is a substrate for LADH, but highly purified material will be necessary to ascertain this.

The effect of *iso*propanol on the —SH titer is very small, so that the corrections for the solvent made in Fig. 5 are mainly those caused by the reduced enzymatic activity, being about 10, 15 and 45 % for *iso*propanol concentrations of, respectively, 0.88, 1.10 and 2.20 M.

Reaction in ethanol. In this case an excess of DDPM in ethanol was added to LADH and LADH—DPNH and the fall in activity was measured with time. No —SH titrations were carried out. The addition of DDPM (5.25×10^{-3} M, dissolved by heating) is best carried out with the help of a stirring rod, as otherwise the DDPM will precipitate. In the enzymatic activity test, minor corrections were made for the absorbance of the DDPM at 340 mμ. The results and the experimental conditions can be seen in Fig. 6.

Because of the low alcohol concentration (1 %), all solutions remained clear throughout the experiment. Again a decrease of about 30 % in activity was observed. In the presence of DPNH, there was complete protection against this fall in activity.

IV. Interaction with heavy-metal ions

Heavy metals inhibit LADH and this was explained by their interaction with the —SH groups of the enzyme [8]. In order to get more information about the interaction of LADH with heavy metals, the fall in activity of LADH and LADH—DPNH upon incubation with heavy metals was followed, as was the —SH titer. The addition of Ag^+ ions results in a rapid precipitation and inactivation of both LADH and LADH—DPNH. In the case of Cu^{2+}, precipitation started after complete inactivation had occurred, and increased gradually with time. LADH was completely inactivated within 3 min, whereas LADH—DPNH was completely inactivated after 45 min. With Zn^{2+} on the other hand, a very slow inactivation occurred, the enzyme still having about 50 % of its original activity after 48 h. There was a definite protective effect against inactivation in the case of LADH—DPNH. In both cases no precipitation occurs.

The most interesting effects were obtained with Cd^{2+}, and were studied in more detail. The concentrations, which were the same as used for the experiments with Ag^+, Cu^{2+} and Zn^{2+}, were: [LADH] = 2.0 μM, [DPNH] = 40 μM, [$CdSO_4$] = 80 μM. All solutions were made up in μ = 0.1 phosphate buffer pH = 7.05, and incubated at room temperature. The result can be seen in Fig. 7. The protective effect of DPNH against inactivation of LADH

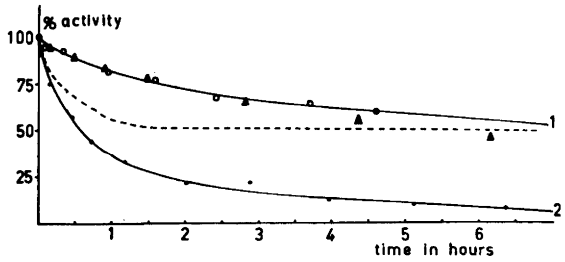

Fig. 7. Inactivation of LADH (2) and LADH—DPNH (1) by Cd^{2+} ions. ▲ represents the fall in activity in the case: [LADH] = 2 μM + [Zn acetate] = 80 μM + after 10 min [$CdSO_4$] = 80 μM. ----- = (1) + 100 % − (2), (see text).

by Cd^{2+} is very large. The same effect was observed when LADH alone was pre-incubated with Zn^{2+} before the addition of Cd^{2+}.

Addition of Zn^{2+} to LADH + Cd^{2+} after 15 min incubation does not lead to reactivation, but the slope of the inactivation curve decreases to become similar to that of the LADH—DPNH + Cd^{2+} curve. The concentration of the added Zn was 400 μM. The results show that the inactivation of LADH by Cd^{2+} is not primarily due to a reaction with —SH groups, but probably to replacement of the Zn by Cd in the active centre, leading to a less active enzyme. As DPNH has the same effect as Zn^{2+}, the coenzyme seems to be bound via Zn^{2+} to the enzyme, thus protecting the Zn atom against the replacement reaction. The very slow inactivation by Zn^{2+} could thus be due entirely to reaction with —SH groups. In the latter case, the DPNH has a smaller protective effect.

Assuming that in the case of LADH—DPNH the inactivation by Cd^{2+} is due entirely to interaction with —SH groups, the sum of curve 1 and 100 % minus curve 2 in Fig. 7 should roughly give the effect due to replacement alone. Equilibrium is reached within 2 h and remains constant for the 6 h of the experiment; the inactivation due to replacement is thus roughly 50 %.

Once replaced by Cd in the concentration used, Zn is unable to replace the Cd again, but can prevent further replacement when added in excess. Further evidence that not the reaction of —SH groups, but rather the replacement of Zn^{2+} plays the primary role in inactivation was obtained by titrating the —SH groups. Solutions containing [LADH] = 2.3 μM with or without [DPNH] = 45 μM were incubated with [$CdSO_4$] = 150 μM at room temperature and in μ = 0.1 phosphate buffer pH 7.05. Three ml samples, immediately after centrifugation, were titrated with excess PCMB (50 μl of a 5×10^{-4} M solution), the $\Delta E_{255\ m\mu}$ measured after 1 min and 30 min and the percentage of titrable —SH groups (which were within 2 % for the two time intervals) calculated. The decrease in —SH titer was roughly parallel to the inactivation curve of LADH—DPNH (curve 1 in Fig. 7), but was about 5—10 % lower, indicating that in the case of LADH—DPNH, the replacement reaction takes place to a very small extent. The decrease of —SH groups was the same for both LADH and for LADH—DPNH, but as in the case of NEM, at the end of the incubation time, the fall was somewhat less in the case of LADH—DPNH.

DISCUSSION

These results, together with the previous results of other investigators, mainly Vallee, Hoch and coworkers [2,4], make it seem highly probable that DPNH is bound to LADH by way of Zn atoms. The way this binding takes place is as yet unknown; the carbonamide group [3], the phosphate groups [15] and the adenine part [8] have all been proposed. Also the mode of binding of the Zn to the enzyme is unknown; it has not been possible to demonstrate the role of sulfhydryl groups in this respect.

It is difficult to understand what role the —SH groups play in the working mechanism. The following possibilities seem to be the most likely ones:

1) *Help in maintaining a requisite ternary structure.* From the experiments, specially those with PCMB, it can be concluded that both activity and DPNH binding depend on the presence of all the —SH groups, about equally for the first 70 % and to a lesser extent for the last 30 % of the —SH groups. To this comes the fact that the protective effect of DPNH against inactivation is very marked, and in the first period of inactivation with NEM or Cd^{2+} or Zn^{2+} this protective effect is not caused by a protection of —SH groups. In the case of Cd^{2+}, this is very probably due to prevention of the Zn-Cd replacement, but this is not so in the case of NEM or Zn^{2+}, nor in the case of PCMB, where the protective effect is small, but the amount of reacted —SH groups the same throughout the PCMB concentration range used. The necessity of all —SH groups for both activity and DPNH binding, and the lack of a convincing demonstration of direct coenzyme binding through —SH groups, could thus indicate that the role of the —SH groups lies in their help in maintaining a requisite ternary structure. This would explain the necessity for all the —SH groups, and the fact that the last remaining —SH groups have a smaller effect. In the case of LADH—DPNH it is possible that bound DPNH, to a certain extenct, takes over the role of the —SH groups in the maintenance of the ternary structure, leading to a partial protection against inactivation by sulfhydryl reagents.

2) *Binding of coenzyme.* When some —SH groups are involved in coenzyme binding, the explanation of the experiments would not be that both activity and DPNH binding depend on the presence of all the —SH groups, but that all —SH groups have the same reactivity towards the sulfhydryl reagents used and that the binding of coenzyme, as far as —SH groups are involved, is rather weak.

Because of the equal reactivity of the —SH groups towards sulfhydryl reagents, the decrease in activity with increasing concentration of sulfhydryl reagent will be linear, independent of the value of the coenzyme and not coenzyme binding —SH groups for enzymatic activity.

Because of the weak bond between coenzyme and binding —SH groups, the relative reactivity of these —SH groups towards sulfhydryl reagents will only be somewhat reduced, the degree depending upon the efficiency of the sulfhydryl reagent.

With an effective reagent for sulfhydryl groups, as for example PCMB, the effect of bound coenzyme will be small. The same number of —SH groups will be found, and only the somewhat higher enzymatic activity of the enzyme-

coenzyme complex as compared with enzyme alone (Fig. 2) results from the bound DPNH because of the suppressed possibility of reaction of the coenzyme binding —SH groups with PCMB.

With NEM, which only reacts very slowly with the —SH groups of LADH, the effect of DPNH in preventing the reaction of the coenzyme binding —SH groups with the sulfhydryl reagent will be more efficient and the resulting protection against enzymatic inactivation is much larger.

When the reaction of these essential —SH groups with NEM would be prevented completely, a difference in remaining —SH groups between LADH and LADH—DPNH after complete reaction with NEM would be found. This was indeed the case, but as outlined, these results were rather unreliable and the reaction with NEM was not complete at the end of the experiment (Fig. 4). It would also implicate that the —SH groups, which don't play a role in coenzyme binding do play a role in enzymatic activity.

It is of course possible that the role of the —SH groups involves both possibilities, but further work will be necessary to ascertain the role of —SH groups in LADH.

Acknowledgments. The author wishes to thank Professor H. Theorell for his generous hospitality and for his interest in this work. Thanks are also due to Dr. J. S. McKinley McKee for helpful discussions, and to Mr. L. G. Falksveden for skilled technical assistance. The stay was made possible by a grant from the *H. J. Backer Fonds.*

Dissociation Constants of Ternary Complexes of Fatty Acids and Fatty Acid Amides with Horse Liver Alcohol Dehydrogenase-Coenzyme Complexes

ALFRED D. WINER* and HUGO THEORELL

Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

1. Fatty acids form dissociable binary compounds with liver alcohol dehydrogenase (ADH), and ternary compounds with DPN—ADH, but not with DPNH—ADH. The fatty acids compete with alcohols for the same binding site.

2. The amides of fatty acids form binary compounds with ADH, and ternary complexes with DPN—HADH, but not with DPN · ADH. They compete with aldehyde for the same binding site.

3. Spectrophotofluorometric methods were elaborated for determining all the dissociation constants involved: $K_{E,I}$; $K_{E.O}$; $K_{EO,I}$; and $K_{EI,O}$ in the case of fatty acids, $K_{E,I}$; $K_{E,R}$; $K_{ER,I}$; and $K_{EI,R}$ in the case of amides.

4. With increasing C-chain length the complex forming power increases for both acids and amides, in some of the combinations many thousand-fold. For the fatty acids this increase continues up to C_{15}. From C_{16} and upwards the complexing ability practically disappears.

5. In these ternary complexes coenzyme and substrate analog mutually stabilize one another's binding to the enzyme.

6. The high affinity of the long-chain fatty acids and amides for ADH—DPN or ADH—DPNH is parallelled by the high reaction velocities observed with higher alcohols and aldehydes in comparison with ethanol.

7. The significance of these results is discussed.

In 1955 Theorell *et al.*[1] presented data on the effects of anions on the liver-ADH ** system as determined from reaction velocity measurements. Strong effects with anions such as chloride, bromide, nitrate and sulfate were reported as had been previously observed from work on the old yellow enzyme [2]. Surprisingly, however, it was found that formate and acetate, which were inactive

* This investigation was carried out during the tenure of a Postdoctoral Fellowship from the National Institute of Neurological Diseases and Blindness, United States Public Health Service. Present address: Department of Biochemistry, University of Kentucky Medical Center, Lexington, Kentucky.

** Abbreviations, see p. 1730.

in the O.Y.E. system, had strong effects on the liver-ADH system. Formate was found to effect only two of the six velocity constants, *i. e.* DPN · ADH $\xrightarrow{k_2'}$ DPN + ADH and DPN · ADH + alcohol $\xrightarrow{k'}$ DPNH · ADH + + aldehyde + H^+. On this basis it was suggested that formate reacts with the DPN · ADH complex, but not with the reduced complex, DPNH·ADH. Since formate inhibited competitively with alcohol it was presumed that formate enters into the binding site for ethanol in DPN.ADH. The effect of acetate appeared to be weaker than for formate.

More recent work by Theorell and Winer [3] using the fluorometric technique to measure dissociation constants showed that while formate has a small apparent effect on $K_{E,R}$ it exerts a very strong apparent effect on $K_{E,O}$. This again suggested that the effect of formate depends on the formation of a ternary ADH · DPN · formate complex. Since the fluorometric method offers a rapid procedure for the determination of dissociation constants, it was decided to investigate the effects of other saturated fatty acids on the ADH-coenzyme system. The effects of fatty acid amides were also investigated in line with recent substrate specificity studies on liver ADH by one of us (A.D.W.) [4] which indicated that long chain aldehydes were, in some cases, better substrates than acetaldehyde.

It was found that all the fatty acids studied (C_1—C_{20}) form ternary complexes with ADH · DPN and compete with the ethanol binding site while all of the fatty acid amides studied (C_1—C_6) form ternary complexes with ADH · DPNH and compete with the aldehyde binding site. In this way fatty acids and amides act as inhibitors. Remarkably strong effects were found with increasing chain length for both acids and amides. From a suitable choice of experimental conditions it is possible to calculate the dissociation constants describing the effect of the inhibitor on ADH ($K_{E,I}$), on the ADH · coenzyme complex ($K_{ER,I}$ and $K_{EO,I}$) and of the coenzyme on the ADH · inhibitor complex ($K_{EI,O}$ and $K_{EI,R}$). It is suggested that the ADH · DPNH · amide and

R_t = Total conc. of reduced diphosphopyridinenucleotide (DPNH)
R = Conc. of free » » (»)
O_t = Total conc. of oxidized » (DPN)
O = Conc. of free » » (»)
I_t = Total conc. of fatty acid or amide
I = Conc. of free » » » »

$$K_{E,R} = \frac{E \times R}{ER}$$

$K_{E,R,app}$ = apparent dissociation constant of ADH · DPNH in presence of I

$$K_{E,O} = \frac{E \times O}{EO}; \qquad K_{EI,R} = \frac{EI \times R}{ERI}$$

$$K_{E,I} = \frac{E \times I}{EI}; \qquad K_{EO,I} = \frac{EO \times I}{EOI}$$

$$K_{ER,I} = \frac{ER \times I}{ERI}; \qquad K_{EI,O} = \frac{EI \times O}{EOI}$$

ADH · DPN · fatty acid complexes, just like the fluorescent lactic dehydrogenase · DPNH · anion complexes recently described by Winer and Schwert [5], are similar in structure to activated complexes formed between ADH, DPNH, aldehyde and ADH, DPN, alcohol.

EXPERIMENTAL

Fluorometric measurements of emission spectra, the calculation of the dissociation constants $K_{E,R}$ and $K_{E,O}$, the buffer salts used and the purity of DPN and DPNH (Sigma) have been previously described [3]. Fatty acids, C_1-C_9, were reagent grade chemicals further purified by distillation under suitable pressures; $C_{10}-C_{20}$ acids were gifts of Professor E. Stenhagen, Uppsala, and had the following melting points in °C: C_{10} 31.2—32.0; C_{11} 28.0—28.5; C_{12} 43.7—43.9; C_{13} 41.5—41.7; C_{14} 54.5—54.9; C_{15} 59.5—59.8; C_{16} 62.5——62.9; C_{17} 61.3—61.4; C_{18} 69.6—69.8; C_{19} 68.4—68.5; C_{20} 75.2—75.3. These acids were solubilized after lyophilization of the potassium salts. The amides were products of the Eastman Kodak Company and recrystallized twice from water prior to use. Heart muscle lactic dehydrogenase and beef liver glutamic dehydrogenase were commercial preparations from C. F. Boehringer and Son, Mannheim.

Enzyme preparation. Crystalline ADH as prepared by the method of Bonnichsen and Brink [6] and treated with DPN to remove traces of endogenous ethanol as previously described [3] was used for all experiments. Liver ADH prepared in this manner is surprisingly stable for long periods of time (2—3 weeks at 2°). The concentration of the enzyme * in the fatty acid experiments was determined by calculations from $C\left(\frac{a''}{b''}-\frac{a'}{b'}\right)Z^2-(a''-a')\,Z+(b''+b')=0$ ** using $Q_{E,R}$*** = 13.5 as determined previously. Calculated values for enzyme concentration were 10—20 % lower than those determined from activity measurements at pH 10 using the assay method of Dalziel [7].

In the amide experiments the concentration of ADH was determined by titration with DPNH in the presence of excess *iso*butyramide. This method of determining enzyme concentration has been found very much superior to activity measurements because of the high Q and the low dissociation constant $K_{EI,R}$ (= 0.02 μM).

The enzyme concentration as determined by the amide procedure was also 10—20 % lower than that determined by activity measurements. The Q for different amides was determined by two methods:

1. Addition of a small amount of DPNH to an excess of ADH and amide (»direct» method).

2. Titration of ~1 μN ADH with 6—10 steps of ~0.5 μM DPNH, and in experiments where appreciable dissociation occurred (for instance with acetamide) calculation of Z ($= Q-1$) from [3]

$$C\left(\frac{a''}{b''}-\frac{a'}{b'}\right)Z^2-(a''-a')\,Z+(b''+b')=0$$

and extrapolation to $I=\infty$ by the aid of eqn. (14) ("calculated" method).

METHODS OF CALCULATION OF DISSOCIATION CONSTANTS

1. I = Fatty Acids

The experimental results were found to agree with the assumption that fatty acids form binary complexes EI with ADH, but not ternary ERI complexes. Thus

* By ADH concentrations the number of binding sites is meant (2 sites/mole from pH 6—9).

** See the previous publication [3] for derivation of this equation.

*** Q is the deflection ratio DPNH · ADH/DPNH as measured with our apparatus at 410 mμ when activated at 325—330 mμ.

$$K_{E,R} = \frac{(E_t - ER - EI)(R_t - ER)}{ER} \quad (1)$$

From the experiments in presence of I we obtain:

$$K_{E,R\ app} = \frac{(E_t - ER)(R_t - ER)}{ER} \quad (2)$$

Only EI is unknown. Therefore

$$EI = (1 - K_{E,R} / K_{E,R\ app})\ (E_t - ER), \text{ and} \quad (3)$$

$$K_{E,I} = \frac{(E_t - ER - EI)(I_t - EI)}{EI} \quad (4)$$

When mixtures of ADH, I and DPN were titrated with DPNH, the experimental results were found to agree with the assumption that besides EI and ER also EO and EOI were formed.

$$K_{E,R} = \frac{(E_t - ER - EO - EI - EOI)(R_t - ER)}{ER} \quad (5)$$

$$K_{E,O} = \frac{(E_t - ER - EO - EI - EOI)(O_t - EO - EOI)}{EO} \quad (6)$$

$$K_{E,I} = \frac{(E_t - ER - EO - EI - EOI)(I_t - EI - EOI)}{EI} \quad (7)$$

ER is determined experimentally, EO, EI and EOI are unknown.

$K_{E,R}$ and $K_{E,O}$ are determined separately in experiments without I [3], $K_{E,I}$ from eqns 3 and 4.

Since O in these experiments was always much larger than EO and EOI, from eqns 5 and 6:

$$EO = \frac{K_{E,R} \times ER \times O}{K_{E,O}\ (R - ER)} \quad (8)$$

From eqns 6 and 7 when $I \gg EI + EOI$, $O \gg EO + EOI$:

$$EI = \frac{EO \times K_{E,O} \times I}{O \times K_{E,I}} \quad (9)$$

$$EOI = E_t - ER - EO - EI - \frac{ER \times K_{E,R}}{R_t - ER} \text{ (where the last term} = E) \quad (10)$$

$$K_{EO,I} = \frac{EO(I_t - EI - EOI)}{EOI} \quad (11)$$

$$K_{EI,O} = \frac{EI(O_t - EO - EOI)}{EOI} \quad (12)$$

2. I = Fatty acid amides

Fatty acid amides, unlike the free acids, were found to form ternary complexes ERI, as indicated by changes in fluorescence intensity (See Table 4)

and by decreased values for the apparent $K_{E,R}$. Binary complexes EI (and ER) are also formed. The mode of calculation is somewhat different in cases where Q_{ERI} differs markedly from Q_{ER}, and in cases where Q_{ERI} is $\approx Q_{ER}$.

$$Q_{ERI} \neq Q_{ER}.$$

In the presence of large excess of I, E and ER are negligible. Titration with R therefore gives the value of $K_{EI,R}$. In addition one obtains the Q-values for ERI (Q_{ERI}) which varies for different amides (See Table 4). In the cases where Q_{ERI} is sufficiently different from Q_{ER} (≈ 13.5), as for example with *iso*butyramide, this offers a possibility of determining the ratio ER/ERI experimentally at intermediate I. When $I >> EI + ERI$, which is mostly the case

$$K_{ER,I} = \frac{ER \times I}{ERI} \tag{13}$$

and the ratio ER/ERI is independent of R and remains constant through the titration, just as the fluorescence increase factor Q_{ER+ERI} for the mixture of ER + ERI. Therefore

$$\frac{ER}{ERI} = \frac{Q_{ERI} - Q_{(ERI+ER)}}{Q_{(ERI+ER)} - Q_{ER}} \tag{14}$$

On the other hand, ER + ERI can be calculated using Q_{ER+ERI} for any point of the titration curve. These values of ER/ERI and ER + ERI give ER and ERI which if inserted in either of the equations

$$K_{EI,R} = \frac{EI(R_t - ER - ERI)}{ERI} \tag{15}$$

or

$$K_{E,R} = \frac{(E_t - EI - ER - ERI)(R_t - ER - ERI)}{ER} \tag{16}$$

give EI, and allow the calculation of $K_{E,I}$.

If now another titration with R is carried out on a solution containing the same amounts of E and I, but in addition a suitable amount of O ($[DPN] \approx K_{E,O}$) it is found that the calculated values of EI, ER and ERI when introduced into (16) give a higher value than $K_{E,R}$ ($= K_{E,R,app}$). This was to be expected since some of the free E is bound to O, but it could not be predicted whether this occurs both as EO and EOI. It was found, however, that under the assumption that *only* EO is formed, the values for EO, calculated from

$$K_{E,R} = \frac{(E_t - EI - ER - ERI - EO)(R_t - ER - ERI)}{ER} \tag{17}$$

and inserted into

$$K_{E,O} = \frac{(E_t - EI - ER - ERI - EO)(O - EO)}{EO} \tag{18}$$

gave values for $K_{E,O}$ which agreed as well as could be expected with the values for $K_{E,O}$ obtained in titrations without inhibitors; see Table 5. *The conclusion is that EO, unlike ER, does not form ternary complexes with fatty acid amides.*

$$Q_{ERI} \approx Q_{ER}.$$

In this case the experiments give values only for $ER' = ER + ERI$. $K_{EI,R}$ is determined directly in experiments with large excess of I. Then from experiments with intermediate I the ratio EI/ERI is obtained from

$$\frac{EI}{ERI} = \frac{K_{EI,R}}{R_t - ER'} \tag{19}$$

which together with the equations

$$ER' = ER + ERI \text{ and} \tag{20}$$

$$K_{ER} = \frac{(E_t - EI - ER')(R_t - ER')}{ER} \tag{21}$$

allows the calculation of the three unknown ER, EI and ERI, and the corresponding dissociation constants. Experiments in the presence of DPN are evaluated as described above.

In the case of high affinity of the inhibitors for the binary complexes, sometimes such small concentrations of I had to be used that corrections for the amount of bound I had to be introduced.

As is easily derived from the above formulae the dissociation constants for the binary and ternary complexes are related by

$$\frac{K_{EI,R}}{K_{E,R}} = \frac{K_{ER,I}}{K_{E,I}} = \frac{EI \times ER}{ERI \times E}, \tag{22}$$

and *vice versa* for the complexes with DPN. When the constants are calculated as described above, eqn. 22 serves as an excellent check on the correctness of the calculations. The data given in Tables 1, 2, 3 and 5 have all been found to fulfil condition (22) within the limits of error.

RESULTS

The dissociation constants $K_{E,I}$, $K_{EI,O}$ and $K_{EO,I}$ (I = Fatty acid)

It is seen from Table 1 that fatty acids exhibit strong ternary complex formation with ADH · DPN complex and that the affinity on the whole increases strongly with the length of the carbon chain of the acid up to C_{15}. The dissociation constant for the ternary complex ADH · DPN · fatty acid, $K_{EO,I}$, decreases from 2 900 μM for formate and 9 500 for acetate to 0.7 μM for C_{15} acid, while the dissociation constant for fatty acid and ADH, $K_{E,I}$, decreases from 47 000 μM for formate and 100 000 for acetate to 6 μM for C_{15} fatty acid. The dissociation constant reflecting the effect of DPN on the ADH · fatty acid complex, $K_{EI,O}$, is rather constant at about 5 μM to the C_{11} acid, and then increases from 2—7 times this value from C_{11}—C_{15}. The ability of the fatty acids to form complexes and the dissociation constant reflecting the formation of a ternary complex between EO and I, $K_{EO,I}$, increasing to a constant level of about 25 μM for the acids C_{16} to C_{20}.

Table 2. Dissociation constants (K) for complexes of liver ADH (E) with DPN (O), DPNH (R) and capric acid (I). 23.5° C, phosphate μ = 0.1.

	pH 6	pH 7	pH 8
$K_{E,R}$	0.26 μM	0.38 μM	0.45 μM
$K_{E,O}$	107 »	84 »	28 »
$K_{E,I}$	31 »	200 »	290 »
$K_{EO,I}$	1.1 »	3.8 »	11.4 »
$K_{EI,O}$	3.7 »	1.6 »	1.1 »

Table 2 shows the effects of capric acid (C_{10}) at different pH-values. The dissociation constants $K_{E,R}$ and $K_{E,O}$ were taken from independent determinations with the same enzyme solution and used to calculate the other constants. It can be seen that both $K_{E,I}$ and $K_{EO,I}$, the constants reflecting the effect on inhibitor on free ADH and on ADH · DPN complex, increase with increasing pH while the constant reflecting the effect of DPN on ADH · inhibitor complex decreases as the pH increases. The presence of fatty acid stabilizes the binding of DPN in the ternary complex, ADH · DPN · fatty acid, particularly at pH 6, and *vice versa*, DPN stabilizes the fatty acid in the ternary complex.

The dissociation constants $K_{I,E}$, $K_{EI,R}$ and $K_{ER,I}$ of fatty acid amide complexes.

Table 3 shows the effects of amides as indicated by the various dissociation constants. The presence of inhibitor lowers the dissociation constant $K_{EI,R}$ from 0.31 to 0.02 μM for the amides C_4—C_6 whereas it is slightly higher for the lower amides. The lowering of the constants, reflecting the effects of inhibitor on free ADH and on ADH · DPNH complex is about 10 000 times from acetamide to hexamide. Column 6 in Table 3 is the calculated $K_{E,O}$ as determined

Table 3. The effect of straight chain amides on the dissociation constants at pH 7, 23.5°C ($K_{E,R} = 0.31$).

Chain Length	$K_{EI,R}$	in μM $K_{ER,I}$	$K_{E,I}$	[DPN]	$K_{E,O}$ (calc.)

C_6	0.020	11	165	218	95

from eqn. 15. The amount of DPN used to determine the constants is listed in column 5 of the table. As stated in the experimental section, the determination of the Q_{ERI}-values for the various amides used to determine the constants was made by one of two methods. Table 4 states the values of Q_{ERI} for the amides tested together with the concentration used and the method of determination. The Q_{ERI}-values increase from formamide to propionamide and then decrease from butyramide to hexamide. The value for *iso*butyramide is specially high, about 3 times the value obtained in the absence of inhibitor. Q is independent of pH from 6—9. The fluorescence changes observed with acetamide are shown in Fig. 1. As previously noted [7,8], the shift of wavelength observed when DPNH combines with ADH is about 20 mμ from 472 mμ to 450 mμ (uncorr.). The further shift to 435 mμ is observed in the presence of nearly saturating amounts of acetamide. A similar shift to wave length when the ADH · DPNH ·

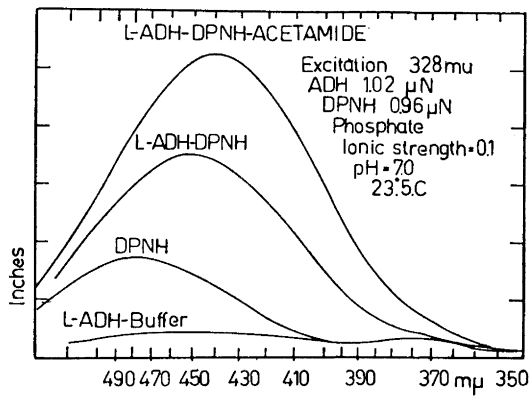

Fig. 1. The effect of adding acetamide to a partly dissociated L-ADH-DPNH complex; the fluorescence increases both because a much less dissociated ternary complex is formed and because the ternary complex has a somewhat higher Q-value than for ER.

amide complex was formed is seen with all amides tested, independent of the fact noted in Table 4 that some amides actually quench, others increase, to varying extents, the fluorescence of ADH · DPNH. Ternary complex formation with ADH—DPNH is specific for carbon chain amides and is not observed with glutamine, nicotinamide or succinimide. Benzamide, if analogous to benzaldehyde (which is a good substrate for liver ADH [4]), would form a ternary complex with ADH—DPNH, but such a complex, if formed, is obscured by the non-specific quenching of this amide. Partly dissociated complexes of lactic and glutamic acid dehydrogenase of the type ER show no observable fluorescence changes at either the protein or DPNH wave lengths upon the addition of acetamide.

Table 5 indicates the changes in the dissociation constants with pH. The constant $K_{E,R}$ was determined from independent experiments without amides, and $K_{E,O}$ was calculated using eqn. 15 from titrations of ADH + DPN + ami-

Table 5. Dissociation constants (K) in μM for complexes of liver ADH (E) with DPN (O); DPNH (R) and *iso*butyramide (I) at 23.5°C.

	pH 6	pH 7	pH 8	pH 9
$K_{E,R}$	0.25	0.31	0.45	0.95
$K_{E,O}$	125	88	22	15
$K_{E,I}$	270	5 750	930	540
$K_{ER,I}$	180	450	210	120
$K_{EI,R}$	0.17	0.02	0.10	0.20

des with DPNH. The agreement of these values for $K_{E,O}$ with the earlier values[3] give strong support to the assumption that ternary complexes between ADH, DPN and amides are not formed.

Competition of amides and fatty acids for the aldehyde and alcohol binding sites respectively.

As noted in the introduction formate was earlier found from reaction velocity constant measurements to compete with ethanol. Fig. 2 shows a typical Lineweaver-Burk plot of the competitiveness of *iso*butyramide with acetaldehyde.

Fluorescence emission data of amide and fatty acid complexes when excited with 289 mμ light.

As Velick [10] has reported with glyceraldehyde phosphate and heart muscle lactic dehydrogenase, the protein fluorescence at 350 mμ when activated at 289 mμ is quenched by either DPN or DPNH. Fig. 3 shows a typical spectrum of the effects observed at 350 mμ when DPNH in a final concentration of 0.70 μM is added to an 0.59 μN ADH solution in phosphate buffer, pH 7. The fluorescence of ADH is quenched somewhat but there is no shift in the wave length when ADH · DPNH complex is formed. The addition of 2.6×10^{-2} M acetamide quenches the fluorescence and shifts the wave length about 10 mμ to 360 mμ. The emission bands in the visible wave lengths when ADH · DPNH and ADH · DPNH · acetamide complexes are formed are similar to those

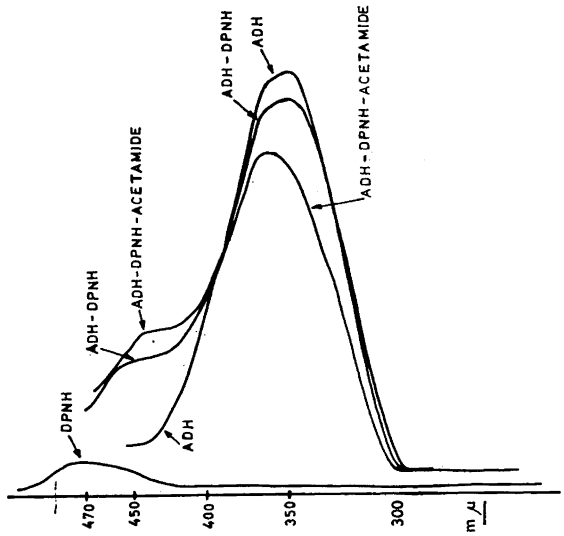

Fig. 3. Emission spectra of ADH, ADH—DPNH and ADH—DPNH-acetamide, when activated by 289 mμ. Complex formation with DPNH causes slight quenching and shift of maximum emission from 350 to 360 mμ. The emission of the complexes in the visible light is presumably caused by energy transfer from the protein moiety to the coenzyme.

shown in Fig. 1. No effect is seen when fatty acids are added to the ADH·DPNH complex nor is any effect observable when an amide is added to the ADH · DPN complex. The latter observations support the conclusion that ternary complexes are not formed in these cases.

DISCUSSION

While the measurements of dissociation constants by the fluorometric technique indicates the existence of complexes of the type ADH · DPNH · fatty acid and ADH · DPNH · amide, it is not immediately apparent that these complexes bear any relation to the enzymatically active complexes. However, the following lines of evidence suggest that such complexes are indeed similar in structure to the activated complexes involved in the interconversion of ADH, DPNH, aldehyde and ADH, DPN, alcohol:

1. The fluorometric results can be fitted to a mathematical treatment which is based upon the postulate that in the case of amides no EOI or OI and in the case of fatty acids no ERI or RI is formed.

2. Fatty acids show competitive behaviour with ethanol, and fatty acid amides with acetaldehyde.

3. The spectroscopic emission data of the amide complexes both at the pyridine nucleotide fluorescence band and at the protein fluorescence band and of the fatty acid complexes at the protein fluorescence band indicate the analogy with true enzyme-coenzyme-substrate complexes.

4. The inhibition effect of acids and amides increase with the length of the C-chain just like the enzymatic activity on alcohols and aldehydes, as indicated from substrate specificity studies.

5. Neither amides nor fatty acids show any observable effects with other pyridine-coenzyme dehydrogenase complexes studied, such as lactic acid dehydrogenase-DPNH and glutamic acid dehydrogenase-DPNH.

6. The observation of ternary complex formation of lactic dehydrogenase · DPNH with anions such as oxamate and oxalate has recently been reported by Winer and Schwert [5]. The values of the dissociation constant of oxamate from the LDH · DPNH · oxamate complex were found to be of the same order of magnitude, and to vary in the same way with pH, irrespective of whether the values were estimated from kinetic inhibition or from quenching experiments.

The effect of saturated fatty acids and fatty acid amides in lowering the dissociation constants indicates that the substrate analogs stabilize the binding of the coenzyme with ADH. *Vice versa*, the coenzyme stabilizes the binding of I on the ternary complexes. In the case of the acids the relative magnitudes of $K_{EI,O}$ and $K_{EO,I}$ indicate that from C_1 to C_{10} I dissociates easier than O from EOI, whereas the reverse is true from C_{11} to C_{15}. The *preferred* * order of the dissociation reaction of EOI is thus from C_1 to C_{10} the same as that assumed for ADH—DPN-alcohol by Theorell and Chance [13], but is reversed for C_{11} to C_{15}. In the case of acetate and formate it appears, as had been indicated earlier from kinetic data [1], that acetate dissociates easier from ADH and from ADH—DPN than does formate. It should be pointed out that the apparently irregular variations in the dissociation constants with stepwise increasing chain length may be largely due to experimental errors. The general trend is, however, very obvious.

The low solubility in water of the potassium salts of the acids from C_{16} upwards prevented the use of higher concentrations, but it is clear from the results that complexes of the type EI for C_{16} to C_{20}, if existent, are much more dissociated than C_{11} to C_{15}, see Table 1. The sudden change between C_{15} and C_{16} may reasonably be attributed to difference in micelle formation, and would in such case be expected to be temperature dependent. Further investigations are needed to solve this problem.

It is evident from Table 2 that changes in pH can invoke changes in the preferred order of reaction, as seen from a comparison between the values for $K_{EO,I}$ and $K_{EI,O}$. At pH 8 I is much more easily dissociated from EOI than is O, as postulated by Theorell and Chance [13] for a ternary ADH · DPN · ethanol complex. But at pH 6 the order is reversed, so that O is more easily dissociated from EOI than is I. This could explain the discrepancies between the values for $K_{E,O}$ found in equilibrium and kinetic measurements [3]. The kinetic values would then be calculated on the basis of a wrong assumption. The differences were by far the greatest in acid solutions, as we indeed would expect if a qualitative analogy can be drawn between the EOI and EO-ethanol complexes. Too high values for $K_{E,O}$ would be found in kinetic experiments in case the presence

* We consider *"preferred"* order rather than *"compulsory"* order more appropriate when speaking of enzyme-coenzyme complexes since the order may change depending on the experimental conditions employed. This has already been pointed out by one of us (H.T.) [12].

of ethanol in the ternary complex would loosen the attachment of DPN, thus increasing the "off" velocity rate constant *.

In the case of *iso*butyramide (see Table 5), $K_{ER,I}$ is $\gg K_{EI,R}$ at all pH values. This indicates that the dissociation of the ADH · DPNH · amide complex preferably leads to ER + I, whereupon the dissociation of ER goes much easier. If we assume, by analogy, that $K_{ER,S}$ is $\gg K_{ES,R}$, where S means acetaldehyde, the dissociation velocity constant (k_2) of ER would most probably be rate limiting in the reaction between ADH and an excess of DPN and alcohol, since the large difference between $K_{ER,S}$ and $K_{ES,R}$ could scarcely depend only on differences between the association velocity constants of ER to S and ES to R. The kinetic experiments should therefore be expected to give the true values of $k_2 \cdot K_{E,R}$ as determined either in equilibrium or in kinetic measurements agreed at all pH values [3], that is $K_{E,R} = k_2/k_1$ (where k_2 is the dissociation, k_1 the association velocity constant). Since $K_{E,R}$ and k_2 are most probably essentially correct we may draw the conclusion that the value found for k_1 in kinetic experiments must be near the true one too. Why is this so? $K_{E,I}$ for *iso*butyramide is certainly much larger than $K_{E,R}$ (See Table 5), which could depend in part on the association velocity constant of E + R being larger than that of E + I. If, by analogy, the same holds true for E + R *versus* E + S (aldehyde) this would imply preferred formation of ER in a mixture E + R + S. However, in the kinetic experiments k_1 becomes rate-limiting only at low [R] and high [S], so that E will nevertheless perhaps combine with S before it combines with R. If this is the case, the kinetic experiments can give true values for k_1, only if the association velocity constants of E + R and of ES + R are about the same.

The formation of ternary complexes with long-chain acids and amides is in line with the substrate specificity studies on the liver ADH system with different aldehydes and alcohols recently reported by one of us (A.D.W.) [4] **. Higher alcohols such as octanol and decanol are good substrates whereas cetyl- and stearyl-alcohols are very poor substrates, and both of the latter alcohols show about the same initial reaction velocities under identical experimental conditions ***. The failure of the fatty acids from C_{16} upwards to form complexes of the type EI may reflect the orientation of the fatty acid on the substrate site. If it is considered, therefore, that aldehydes and amides on one side, and alcohol and acids on the other side function as structural analogs, there is strong suggestion that the ADH · DPNH · amide and ADH · DPN · fatty acid complexes, in which no net reaction occurs, represent complexes analogous with those formed between ADH, DPNH, aldehyde and ADH, DPN · alcohol.

---

* An example of ternary complex formation leading to $K_{EI,R}$ being $> K_{E,R}$ has recently been observed by H. Theorell and J. S. McKinleyMcKee (unpublished) in the highly fluorescent complex ADH · DPNH · imidazole.

** With yeast ADH, ternary complexes of the type ERI with amides and EOI with fatty acids are also formed. However, in this case increasing chain length does not seem to increase the stability of the complexes appreciably (unpublished observations of Thomas Langan Jr.). This is in accord with the very different specificity requirements of the yeast enzyme.

*** A manuscript describing the specificity of higher alcohols on the liver alcohol dehydrogenase system is in preparation.

Thus, from these inhibition studies of substrate analogs, it seems that not only is the coenzyme important for the binding of substrate but also the substrate is important for the binding of coenzyme. One should perhaps speak of enzyme-coenzyme specificity rather than enzyme specificity. In the natural enzymatic reaction involving a simultaneous change of one form of the coenzyme to another and a corresponding change in the substrate, it would appear that the change from one to another requires a coordinated change in molecular shape of both coenzyme and substrate. The fact that the substrate analogs were found to form ternary complexes with ADH and either, but not both, DPN or DPNH, suggests that the reactive ADH · DPN · alcohol and ADH · DPNH · aldehyde complexes can be formed, but not the non-reacting ADH · DPN · aldehyde or ADH · DPNH · alcohol complexes. Such complexes would involve a corresponding inhibition of enzyme activity and Nature has, it seems, found stereochemical means of preventing their formation at least to any disturbing extent.

Remark by H.T., February 10, 1960. The experimental work described here was finished in June 1959. Refinement of the fluorometric technique has afterwards revealed that DPN to some extent lowers the Q-values of ER. As a consequence hereof the values for $K_{E,O}$ given in this paper and in Ref.[14] (84—125 μM) are somewhat too low. A more probable value is 160 μM. This discrepancy does not affect the general conclusions, but the absolute values of the dissociation constants $K_{EO,I}$ and $K_{EI,O}$ may have to be somewhat revised.

Preparation of Crystalline Cytochrome c from Beef Heart Muscle

SVEN PALÉUS

Medicinska Nobelinstitutet, Biokemiska avdelningen, Karolinska Institutet, Stockholm, Sweden

A simple method for the crystallization of beef heart cytochrome c is described. Amino acid analysis together with a number of physico-chemical characteristics of the preparation are reported. An explanation for previous discrepancies in the sulphur content of cytochrome c is given.

For some years we have been concerned with the development of a simple, reproducible method [1] of preparing crystalline mammalian cytochrome c *. As early as 1950 we introduced a new chromatographic procedure [2] in the preparation of cytochrome c. This involved the use of the ion-exchange resin Amberlite IRC-50 and much of the procedure to be described is based on the use of this carboxylic acid type resin. Japanese biochemists [3–6] who have recently carried out a great deal of work with cytochrome c from a variety of sources have taken advantage of this ion exchange treatment during the purification and concentration procedure. The acid extraction of cytochrome c was introduced by Theorell [7] and was also employed in the classical modifications by Keilin and Hartree [8,9]. The latter workers, however, used trichloroacetic acid both for the extraction and the final precipitation of the pigment. There has been some question, however, as to the effect of TCA on cyt.c and as we [10] had already found H_2SO_4 to give a better yield in the extraction of salmon heart cyt.c this acid was accordingly used for the extraction of beef heart cyt.c.

EXPERIMENTAL

Assay method. The concentration of cyt.c was determined spectrophotometrically after reduction with sodium dithionite in 0.065 M phosphate buffer, pH 6.8 using $E_1^{1\ \mathrm{cm}}_{\%}$ 550 mμ = 22.7, corresponding to cytochrome c of 0.435 % iron content.

* The following abbreviations will be used: cyt.c = cytochrome c, TCA = trichloroacetic acid.

Preparation of resin

(*A*) *Amberlite.* 1/2 kg Amberlite XE-64 was suspended in 1 l 2 N NaOH and allowed to stand in a water-bath (50°) for 6 h with occasional stirring. The supernatant was discarded and the resin washed with distilled water until neutral. 5 l of 5 % H_2SO_4 were then added and the mixture after stirring allowed to stand for 1/2 h. The resin was next washed with distilled water until neutral and then suspended in 5 l of 5 % ammonium hydroxide and allowed to stand for 1 h with occasional stirring. Finally the resin was washed with redistilled water until neutral and filtered on a Büchner funnel until nearly dry (20 % moisture content). The resin was stored in this state.

(*B*) *Duolite.* 10 g of Duolite CS-101 was ground by hand using a pestle and mortar and suspended in 200 ml 2.5 % H_2SO_4. It was then washed with distilled water until neutral; at the same time the finest particles were removed by decantation. The ammonium salt of the resin was formed by standing for 1/2 h with occasional stirring in 250 ml of 5 % ammonium hydroxide. It was then washed with distilled water until neutral. The regeneration procedure was repeated once, using redistilled water instead of distilled water as formerly. It was filtered and stored damp as for the Amberlite.

Preparation and purification of cytochrome c

Step 1. 6 kg fresh cow hearts were minced, 15 l of cold distilled water added and the pH adjusted to 4.1 with 1 N H_2SO_4. This and the subsequent steps were carried out at 4°. The mixture was allowed to stand for about 1 h with occasional stirring. After filtration through cheese cloth the mince was extracted further with 6 l of water. The total extract was brought to pH 7 with 4 N ammonia, allowed to stand for 1 ½ h, then centrifuged (2 000 *g*) and the supernatant filtered through Whatman No. 1 paper. This resulted in a volume of 20.7 l, which contained 132 g total protein determined by the biuret reaction as modified by Gornall *et al.*[11]

Step 2. 198 g of Amberlite XE-64 were added and the mixture stirred occasionally over 2 h. The resin which by then had taken up the cyt.c was washed with about 50 l distilled water on a Büchner funnel. The cyt.c. was eluted in a total volume of 3 400 ml 0.15 M phosphate buffer, pH 7. It was then dialyzed against 65 l of 0.002 M ammonium hydroxide and centrifuged. The final volume was 3 425 ml with a total protein content of 6.2 g and a cyt.c. content of 925 mg as determined by spectrophotometric assay.

Step 3. The preparation was next concentrated by adsorption on 10 g of Amberlite XE-64. The resin was washed with about 400 ml 0.002 M ammonium hydroxide and the cyt.c eluted in 475 ml 0.09 M phosphate buffer, pH 7.5.

Step 4. Am_2SO_4 was now added in a concentration of 0.6 g/ml, the preparation allowed to stand overnight and filtered through a Whatman No. 1 filter paper (14 cm diam.). The volume at this stage was 600 ml. The preparation was dialyzed against approx. 50 l 0.002 M ammonium hydroxide, and finally against 18 l of 0.05 M ammonium phosphate buffer, pH 7.

Step 5. The preparation (volume 850 ml) was next concentrated on a column (2 × 20 cm) of Duolite CS-101 and washed with 150 ml 0.05 M ammonium phosphate buffer pH 7 and eluted in 28 ml 0.4 M ammonium phosphate buffer pH 7. The total yield of cyt.c was 436 mg.

Crystallization

346 mg of the above material was dialyzed against a total of 6 l of 0.002 M ammonium hydroxide in 3 changes. Part of this preparation was used for an iron content determination and other analyses; the remainder was dialyzed against 50 % saturated Am_2SO_4, pH 7, and finally against 98 % saturated Am_2SO_4, pH 7. The starting volume for crystallization was 12.5 ml and the concentration of cyt.c was 23.9 mg/ml. 200 µl ammonium hydroxide (25 %) and 10 mg ascorbic acid were added; the pH as measured with the glass electrode was 8.5. After 12 h at room temperature there was a precipitate of rod-like crystals, which after several days were transformed into ball-like aggregates which have earlier been described by Hagihara *et al.*[3] The crystals which were collected by centrifuga-

tion were in the reduced state. The supernatant (10 ml) was also completely reduced, and contained 4.26 mg cyt. c/ml. The yield of crystals was therefore 86 %. The crystals were dissolved in 0.8 ml distilled water, 5 mg ascorbic acid and, 150 µl ammonium hydroxide (25 %) were added, and Am_2SO_4 was then added in solid form to 93 % saturation. Similar crystals were again obtained on standing; in this case the supernatant contained 20 mg cyt. c and the crystal yield here was 92 %. For a third crystallization the crystals were again collected by centrifugation. They were then washed with 5 ml 98 % saturated Am_2SO_4-solution (pH 8) and dissolved to 5 ml with distilled water. 250 µl ammonium hydroxide (25 %) and 5 mg ascorbic acid were added (pH 9.5) and then solid Am_2SO_4 to 80 % saturation whereupon precipitation occurred. Crystals (Fig. 1) formed after 1 ½ days. There was again a tendency of the crystals, especially at first, to come together in ball-like aggregates. On standing, a partial transformation of the crystals into plates occurred as was described by Hagihara *et al.*[4] The crystals were collected by centrifugation (87 % yield), dissolved in the minimum volume of water and dialyzed against distilled water until sulphate free.

Analytical results obtained on thrice crystallized cytochrome c

The iron content as determined by the modified Lorber method [12] was 0.43 %.

The homogeneity of the pigment was tested by electrophoresis in the Spinco model H instrument. The preparation was dissolved in phosphate buffer pH 7.08, ionic strength 0.1, and completely oxidized by careful addition of $K_3Fe(CN)_6$. Only one symmetrical peak was obtained after 4 h running.

The extinction ratios $\frac{E_{550\ m\mu\ red}}{E_{280\ m\mu\ ox}} = 1.20$, $\frac{E_{590\ m\mu\ ox}}{E_{590\ m\mu\ red}} = 5.85$ and $E^{1\ \%}_{1\ cm}$ 550 mμ = 22.6 were obtained.

The nitrogen content (Dumas) was 14.83 %. The sulphur content of the preparation at this stage was determined to be 1.42 %. However, after passage through a column (10 × 2 cm) of Lewatite MIH (a weakly basic anion exchange resin from Farbenfabriken

Table 1. Amino acid composition of crystalline beef cytochrome c (0.43 % Fe; Mol. wt = 12 900; 14.83 % N — Dumas method). 2.5—5.5 mg of cyt.c hydrolyzed 20 and 70 h at 110 °C with 0.5 ml 5.7 N HCl in a sealed, evacuated tube. For a small (< 1 %) residue of black humin substance, correction was made in the 70 h sample.

* Starting weight of minced beef heart —6 kg.

Bayer, Leverkusen) this value was reduced to 1.05 %. An amino acid analysis according to Moore *et al.*[13] is given in Table 1. A portion of the sample dissolved in 0.065 M phosphate buffer, pH 6.8, and reduced with a small excess of ascorbic acid in a loosely capped cuvette was still in the fully reduced state over a period of three days.

DISCUSSION

As already reported [1] the early method of preparing crystalline beef heart cyt.c by Hagihara *et al.*[3] did not give a homogeneous preparation. The homogeneity of the preparation described here was indicted by the electrophoretical result and the yield of crystals calculated on the weight of the starting material has been nearly doubled over that obtained by the above workers. In Table 2 a summary has been given of the purification method. It should be noted how well the iron-content increases up to the value of 0.43 % in the last step and also how the $E^{1\,\%}_{1\,cm}$ 550 mμ-values conform with the iron-values. It was very difficult to obtain the high ratios of $\frac{E_{550\ m\mu\ red}}{E_{280\ m\mu\ ox}}$ as reported by Hagihara *et al.*[3] The values were variable without apparent reason within the range 1.15—1.30. On the other hand the value of 5.85 for the ratio $\frac{E_{590\ m\mu\ ox}}{E_{590\ m\mu\ red}}$ was close to but slightly higher than the values reported by Henderson and Rawlinson [14] and also Margoliash *et al.*[15] for resin-purified but not crystallized material.

The amino acid analysis (Table 1) revealed values which agreed well in most cases with the results of Ehrenberg and Theorell [16]. There is a difference of one amino acid residue in the case of aspartic acid, arginine and phenylalanine; the difference in the case of glycine, serine and threonine is insignificant. Compared with the results of Takahashi *et al.*[17] there are some further small differences, especially in the case of glutamic acid, serine and threonine, tyrosine and α-alanine. On the other hand the phenylalanine content is the

Fig. 1. Crystalline beef cytochrome c (× 430), Crystal size, 2 × 10 μ. Reduced form.

same in both preparations. It should be noted that the three above-mentioned analyses were carried out on samples of cyt.c prepared by different methods.

The nitrogen content (14.83 %) of the crystals was rather low and corresponded to 137 N-atoms per iron atom. This result was in conformity with other analyses carried out by the author on different preparations of cyt.c [10]. On adding the nitrogen-atoms of all the amino acids present (using the highest value from the 20 and 70 h hydrolyses) together with the four porphyrin-nitrogen atoms, 139 nitrogen-atoms (15.08 % N) are obtained. Earlier, Theorell and Åkeson [18] had found 143 and Paul [19] 145 nitrogen atoms per iron atom, but their preparations had been obtained by different methods.

The iron content of 0.43 % corresponds to a minimal molecular weight of 12 900, which value was used in the calculation of the amino acid content of the preparation.

Åkeson [20] showed that two methionine residues were present in cyt. c. Confirmation of this was obtained by the author [21] but at the same time four sulphur atoms only were found to be present. The remaining two S-atoms were accounted for as the two cysteine residues shown by Theorell [22] to be concerned in the prosthetic group linkage. There still remained, however, the discrepancy between the 5—6 sulphur atoms observed by Theorell and Åkeson [18] and Åkeson [20]. This appears now to be explained by the finding that the sulphur content is reduced from 6 to 4 atoms per cyt.c molecule by passage through an anionic resin. As no other significant change in the cytochrome c molecule has been observed by this treatment and as the author's former value

of 4 sulphur atoms per molecule was obtained after exhaustive dialysis it would seem likely that two salt linked sulphate ions are removed by the anionic resin.

Addendum: The sedimentation constant of this thrice crystallized material was $S^\circ_{20} = 1.62 \times 10^{-13}$ *s*, very close to the value found in this laboratory for previous preparations [23]. Determination of the molecular weight of crystalline beef cyt.c by Ehrenberg [24] has given a value of 13 300, which is in agreement with the value obtained above from the iron content (12 900).

Acknowledgements. The author wants to express his sincere gratitude to Professor H. Theorell and Dr. R. W. Henderson for kind criticism in connection with the work.

The work was supported by grants from *Statens naturvetenskapliga forskningsråd* and *Magn. Bergvalls Stiftelse.* It is a pleasure to thank Misses A.-M. Fridén and G. Tietgen for technical assistance.

Application of Edman's Phenyl*iso*thiocyanate Method in the Determination of C-terminal Amino Acids and Peptides after Hydrazinolysis *

PER WALLÉN and INGVAR SJÖHOLM**

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

Edman's phenyl*iso*thiocyanate method has been used for identification and quantitative determination of the C-terminal amino acids released in hydrazinolysis of fibrinopeptides A and B and of insulin. The method is found to be particularly suitable in cases where relatively large amounts of C-terminal peptides are formed, since it can also be used for sequence determinations of these peptides. For more detailed studies of complicated hydrazinolysates, Edman's method can be preceded by electrophoretic separation. The C-terminal sequences of fibrinopeptides A and B and of insulin as found in the present work are in accordance with the known structure of these substances.

Certain peptide bonds are found to be highly resistant to hydrazine under the conditions used (100°C for 10 h). In hydrazinolysis of fibrinopeptide A, only an inappreciable quantity (5 %) of ornithine is obtained from the C-terminal amino acid arginine, whereas a good yield (about 70 %) is obtained from the di- and tripeptides val-orn and gly-val-orn, respectively, deriving from the C-terminal end. Thus, the peptide bond val-orn (val-arg) seems to be only inappreciably split in hydrazinolysis. The C-terminal peptide bond in fibrinopeptide B, ala-orn (ala-arg), also seems to be relatively resistant, as is the penultimate peptide bond in the B-chain of insulin, pro-lys.

The phenylthiohydantoin (PTH) derivative of ornithine has been synthesized. A solvent system is described for separation of the phenylthiohydantoin derivatives of lysine and ornithine.

After the introduction by Akabori *et al.*[1] of the hydrazinolysis method for determination of C-terminal amino acids in peptides and proteins, this technique has been applied in many investigations. The method elaborated by Ohno [2] for identification and determination of the amino acids obtained after hydrazinolysis as the dinitrophenyl derivatives has subsequently been

* This work has been supported by Research Grant No. H—4295 (R 1) to Professor E. Jorpes from the *National Heart Institute, National Institutes of Health, United States Public Health Service*, and by grants from *Karolinska Institutets Reservationsanslag, Svenska Sällskapet för Medicinsk Forskning* and *Svenska Nationalföreningen mot tuberkulos och andra folksjukdomar.*

adopted by many workers, particularly in the modification of Niu and Fraenkel-Conrat [3]. In view of the finding of Ohno [2,4] and of Niu and Fraenkel-Conrat [3] that C-terminal peptides are formed both on partial hydrazinolysis and when the C-terminally situated peptide bonds are resistant to hydrazine, the question arose of whether the phenyl*iso*thiocyanate method of Edman [5] could be applied in the analysis of amino acids and peptides obtained on hydrazinolysis. In the determination of the amino acid sequence of peptides, this method is more advantageous than the dinitrophenyl (DNP) method most often used hitherto.

An account is given in the present paper of the application of Edman's method in C-terminal analyses of fibrinopeptides A and B and of insulin by the hydrazinolysis method, as well as of some observations on the resistance of certain peptide bonds to hydrazine. The phenyl*iso*thiocyanate method as modified by Sjöquist [6-8,22] was used.

EXPERIMENTAL

Materials

*Fibrinopeptide A**.

*Fibrinopeptide B**.

Insulin, recrystallized 7 times **.

Hydrazine, anhydrous. Prepared according to Kusama [10]***. 50 g of 99 % $N_2H_4 \cdot H_2O$, 500 g of crushed CaO and 500 g of toluene were allowed to stand overnight. The mixture was then refluxed for 3 h and distilled. An azeotropic mixture was obtained, consisting of toluene and hydrazine, b.p. 89—92°C. The hydrazine content was determined with KIO_3, using the method of Kolthoff [11]. Content: 98.2—99.5 %. Fresh hydrazine was prepared for each hydrazinolysis.

n-*Heptaldehyde*, technical, Hopkin & Williams. Distilled *in vacuo*.

n-*Heptane*, Eastman-Kodak. Distilled, b.p. 98°C.

5-[3-(β-Phenylthioureido)-propyl]-3-phenyl-2-thiohydantoin (Ornithine-PTH). Prepared according to Edman's method for preparation of lysine-PTH [12]. The extinction curve showed a maximum at $\lambda = 268$ mμ ($\varepsilon = 27\,650$). $E^{245}/E^{269} = 0.71$. M.p. 196-7°C (decomp.). (Found: N 14.45 %. Calc. 14.57).

n-*Pentane*, A. R., Kebo, Stockholm.

1,2-Dichloroethane, Hopkin & Williams. Distilled, b.p. 83—84°C.

Ethyl acetate, Hopkin & Williams. Distilled, b.p. 77°C.

Formic acid, A. R., Merck.

Methods

Hydrazinolysis. Before hydrazinolysis, the peptide material was dried *in vacuo* for 8—10 h in a desiccator over phosphorus pentoxide. 100 μl of N_2H_4 were used for 3 mg of peptide, 200 μl for 12 mg, and 500 μl for 55 mg. Four-ml test tubes with groundglass stoppers were used for hydrazinolysis, which was carried out for 10 h at 100°C. The excess N_2H_4 was evaporated *in vacuo* over concentrated sulphuric acid for 2—3 h. After this time, no smell of hydrazine was present.

Aldehyde treatment. The hydrazides formed were removed by shaking with *n*-heptaldehyde, as recommended by Kusama [10]. The preparations were dissolved in 0.5 ml

* Prepared according to Ref.[9] and kindly placed at our disposal by Dr. B. Blombäck, Karolinska Institutet, Stockholm.

** Kindly placed at our disposal by Mr. G. Lindén, Apoteksvarucentralen Vitrum, Stockholm.

*** Hydrazine prepared according to Ståhler [13] or Locker [14] had no advantages, both the relative quantity of C-terminal amino acids obtained and the total yield were smaller.

of water, shaken three times with 0.75 ml of *n*-heptane + *n*-heptaldehyde (1 : 1) for 5, 30 and 30 min, after which the aqueous phase was freed from heptaldehyde by shaking twice with 0.5 ml of heptane. Finally, it was shaken twice with 0.5 ml of *n*-pentane. The aqueous phase was evaporated *in vacuo* over P_2O_5. The dried preparations were kept at −15°C.

The addition of heptane during the aldehyde treatment results in a larger yield of amino acids and peptides in the aqueous phase. In order to minimize the risk of the hydrazides being hydrolyzed, the first treatment with heptane-heptaldehyde should be carried out quickly.

Sequence determination. The amino acid sequence in the peptides was determined with the phenyl*iso*thiocyanate method of Edman, as modified by Sjöquist [6-8,22]. The peptide material was treated with phenyl*iso*thiocyanate in a buffer solution of pH 10 for 1 h at 40°C, resulting in formation of the phenylthiocarbamyl (PTC) derivatives of the peptides. The samples were washed with heptane and dried *in vacuo* (< 0.01 mm Hg). The phenyl*iso*thiocyanate treatment was repeated once. The phenylthiohydantoin (PTH) derivatives of the N-terminal amino acids were obtained from the PTC peptides by treating them with a mixture of acetic acid saturated with hydrogen chloride and water (2 : 1) at 40°C for 2 1/2 h. The samples were then re-dried *in vacuo*.

A mixture of dichloroethane, ethyl acetate and *n*-heptane (2 : 2 : 1.5) with a density slightly lower than that of water, was washed 3 times with an equal volume of water. The last washing water (aqueous phase) was used to dissolve the vacuum-dried samples, after which the PTH derivatives were extracted twice with 0.75 ml and three times with 0.5 ml of the solvent mixture. The organic phase was evaporated by a stream of air, and the aqueous phase *in vacuo* over P_2O_5.

The dried aqueous phase, which contained the remaining part of the peptide, could then be re-treated with phenyl*iso*thiocyanate, after which the procedure already described was repeated. All operations, from hydrazinolysis to extraction of the PTH derivatives inclusively, were performed in the same test tube.

The PTH derivatives were identified and determined quantitatively by paper chromatography, according to Sjöquist [8]. On hydrazinolysis arginine is converted to ornithine. In Sjöquist's system, ornithine-PTH migrates with lysine-PTH and glycine-PTH in solvent II, and with lysine-PTH and alanine-PTH in solvent III. Consequently, ornithine cannot be determined separately from lysine. In order to permit concurrent determination of the two basic amino acids separately in a mixture, we used a solvent system consisting of *n*-heptane, dichloroethane and 75 % formic acid (1 : 1 : 2). The organic phase was used as eluent, and was also sprayed over the strips of filter paper on the short ends of a chromatography tank of the kind described by Sjöquist [8]. The formic acid phase (stationary phase) was sprayed over the strips of filter paper hanging in the tank. Each time the tank was used, the old stationary phase was replaced by a fresh one. One hour was required for equilibration. With this system, the PTH-derivatives of glycine, ornithine, lysine and alanine could be completely separated (see Fig. 1).

Paper electrophoresis. Electrophoresis of the peptide material obtained after hydrazinolysis and heptaldehyde treatment was performed with a water-cooled high-voltage apparatus of Perspex. A buffer consisting of 6 ml of glacial acetic acid and 8 ml of pyridine in 1 liter of water (pH 4.9) was used throughout. Whatman No. 3 MM paper was used for preparative electrophoresis. A potential of 25 V/cm was applied across the paper, resulting in a current intensity of approximately 30 mA. Adequate separation was obtained after about 1 1/2 h.

The preparation was placed on a 5 cm wide strip. In order to identify the fractions, a small quantity of the preparation was applied as a spot beside the main part of it. After electrophoresis and drying at 100°C, a strip corresponding to this spot was cut out, and developed with a ninhydrin reagent (0.25 % ninhydrin + 0.5 % collidine in 95 % ethanol). The fluorescence of the substances in ultraviolet light was also used for identification purposes. The fractions were eluted with water, and the eluates evaporated *in vacuo* over P_2O_5.

Hydrolysis. Hydrolysis of the peptides was carried out in constantly boiling hydrochloric acid at 105°C for 23 h, using evacuated sealed glass tubes.

Two-dimensional paper chromatography. Two-dimensional paper chromatography, performed on both unhydrolyzed and hydrolyzed electrophoretic fractions, was done on Whatman No. 1 paper. Development of the chromatograms took place in the first direc-

tion (descending) with the upper phase of a mixture of acetic acid, *n*-butanol and water (1 : 4 : 5), and in the second direction (ascending) with 80 % pyridine in water.

Quantitative amino acid analysis. Quantitative analysis of the amino acids in hydrolyzed material was performed according to Sjöquist [8].

RESULTS

Fibrinopeptide A. Hydrazinolysis according to the standard procedure described in the aforegoing was performed on about 1 μmole (1.89 mg) of fibrinopeptide A. After removal of the hydrazides, sequence determination was made on the C-terminal fraction, without previous separation by electrophoresis or paper chromatography. The results are shown in Table 1. In the first step, glycine and valine were obtained as the main components. On the other hand, ornithine — which on hydrazinolysis is formed from arginine — appeared only in extremely small quantities, and was completely lacking in some experiments. This is remarkable, since it has recently been demonstrated that the C-terminal sequence in fibrinopeptide A is gly-val-arg [15,16]. In the second and third steps, on the contrary, ornithine appeared in considerably larger quantities, amounting to 70—80 % of the valine in the preceding step. The valine in the second step corresponded fairly well to the glycine in the first step. In the fourth step, no PTH amino acids could be demonstrated. These experiments seemed to afford definite evidence that hydrazinolysis results in formation chiefly of the C-terminal residues gly-val-orn and val-orn, whereas only extremely small quantities of the C-terminal amino acid are present.

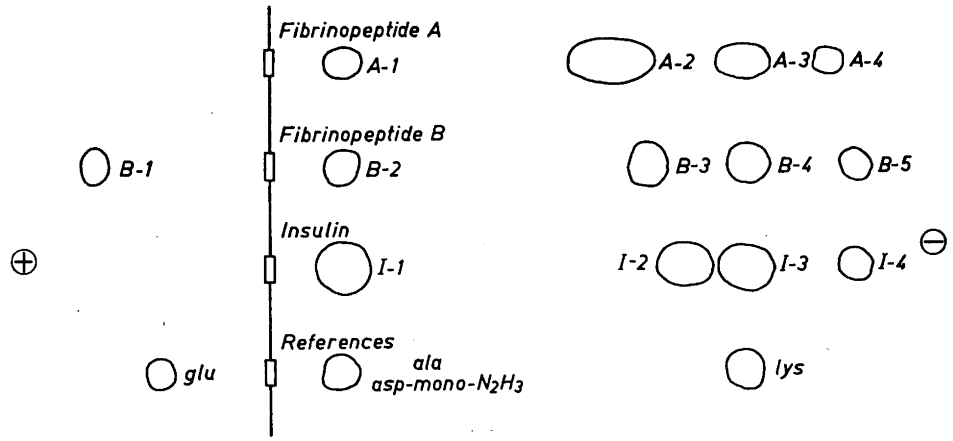

Fig. 2. Electropherograms of hydrazinolyzed and heptaldehyde-treated fibrinopeptides A and B and insulin (pH = 4.9, μ = 0.1 and length of runs 90 min at 25 V/cm in all figures).

For additional verification of these results, attempts were made to separate the components of the hydrazinolysate freed from the hydrazides, by means of electrophoresis and paper chromatography. About 8 μmoles (15 mg) of fibrinopeptide A were hydrazinolyzed with 0.2 ml of hydrazine. The excess hydrazine and the hydrazides were removed as described earlier. In electrophoresis, four fractions could be identified (Fig. 2); they all migrated to the cathode. In the following, they are denoted as A-1, A-2, A-3, and A-4.

A-1, which migrated at the same rate as the neutral amino acids, and A-2, which migrated somewhat more slowly than lysine, were consistently present. A-3, at the site of lysine and ornithine, and A-4, which was strongly basic and could be identified only by its UV fluorescence, were weak and were sometimes lacking altogether.

The fractions were eluted from the paper, divided into two equal parts, and dried. One part of each electrophoretic fraction was used for two-dimensional paper chromatography and for sequence determination (Fig. 3 and Table 2). The other part was hydrolyzed, after which the component amino acids were identified by means of two-dimensional paper chromatography.

In two-dimensional paper chromatography, fraction A-1 showed only two weak components, one of which was probably glycine (Fig. 3). After hydrolysis, on the other hand, several amino acids appeared, *i.e.* proline, as well as traces of serine, aspartic acid, glutamic acid and glycine. Sequence analysis of the unhydrolyzed part of the fraction disclosed that all these amino acids already appeared in the first step, and serine and aspartic acid in the second step as well (Table 2).

Fraction A-2 was shown by two-dimensional paper chromatography to consist of two strong components, which were partly confluent (Fig. 3). Owing to lack of material, no attempt was made to separate and analyze these components individually. After hydrolysis of this fraction, large quan-

tities of glycine, valine and ornithine could be demonstrated. In sequence determination, only glycine and valine appeared in the first step (Table 2). In the second step, valine and ornithine appeared in quantities corresponding approximately to the glycine and valine, respectively, in the first step. No glycine appeared in this step. In the third step, ornithine appeared in quantities corresponding to the valine in the second step. No other amino acids could be identified in this step. Fraction A-2 thus seemed to consist of two peptides, val-orn and gly-val-orn.

In paper chromatography of fraction A-3, only one spot at the site of lysine and ornithine was obtained before hydrolysis (Fig. 3). The result was the same after hydrolysis. Sequence determination gave ornithine alone in the first step, and no amino acids in the two subsequent steps. This fraction thus consisted only of ornithine. Quantitatively, however, it amounted to only a small proportion (6—7 %) of the ornithine in the C-terminal fragments of A-2.

Fraction A-4 gave no ninhydrin-positive spot in direct paper chromatography. After hydrolysis, one weak spot at the site of lysine and ornithine was obtained in two-dimensional chromatography. No PTH derivatives of these amino acids were, however, obtained in determination with Sjöquist's method.

Fibrinopeptide B. Fibrinopeptide B was studied in largely the same way as fibrinopeptide A. Sequence determinations were made on the hydrazinolysate remaining after heptaldehyde treatment. The results of one such test are shown in Table 3. In the first step, ornithine, was obtained which agrees with arginine being the C-terminal amino acid. In addition, alanine and aspartic acid appeared in quantities that could not be neglected. The presence of alanine might indicate that the C-terminal dipeptide was present in the sample. As has been shown recently, the C-terminal sequence in fibrinopeptide B is gly-ala-arg [15,16]. In the second step, it was chiefly ornithine that appeared. This may agree with the sequence ala-arg. However, in view of the high aspartic acid value in the first step, the ornithine might equally well have derived from an asp-arg sequence.

In order to obtain further information, paper electrophoresis was performed on the heptaldehyde-treated hydrazinolysate. The appearance of the electropherograms is shown in Fig. 2. Five fractions were identified; they are denoted in the following as B-1, B-2, B-3, B-4, and B-5. B-1 had a negative charge, and all the other fractions a positive charge.

The fractions were eluted with water. Two-dimensional paper chromatography was performed on a small part of each fraction (Fig. 4). Except for traces of glycine in fraction B-2, and spots corresponding to ornithine or lysine in B-3 and B-4, no spots indicative of free amino acids were present. The spots in fraction B-5 could not have been free amino acids, since in electrophoresis

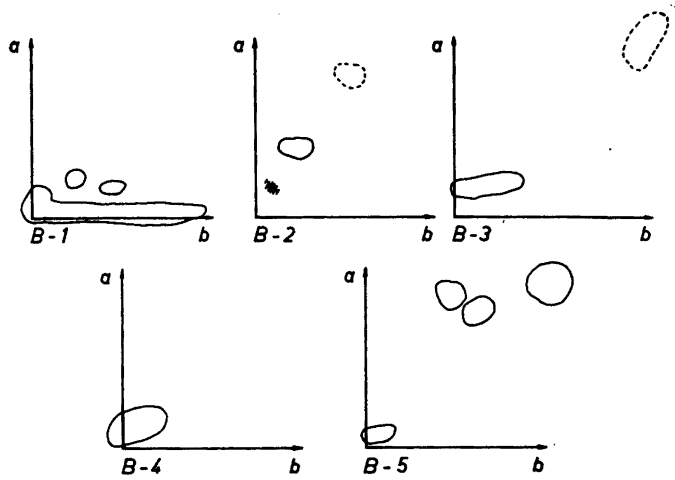

Fig. 4. Two-dimensional paper chromatograms of the electrophoretic fractions B-1, B-2, B-3, B-4, and B-5, obtained from hydrazinolyzed and heptaldehyde-treated fibrinopeptide B. (The solvent system is the same as in Fig. 3.) Faint spots are indicated by dotted lines, traces by shaded areas.

this fraction migrated further than the amino acids conceivably present in the sample.

Part of each electrophoretic fraction was removed and hydrolyzed. Quantitative amino acid analysis according to Sjöquist was then done on the hydrolysate. The results are listed in Table 4. In fractions B-1 and B-2, glutamic acid and aspartic acid predominated. Traces of ornithine and glycine were also demonstrable. Fraction B-3 was found to consist mainly of equally large quantities of alanine and ornithine, in addition to extremely small quantities of lysine, glutamic acid and aspartic acid.

In sequence analysis of the unhydrolyzed fraction B-3, alanine alone appeared in the first step, and ornithine in the second step. It is evident that this fraction consisted chiefly of the dipeptide ala-orn, which must have derived from the C-terminal dipeptide ala-arg. Both before and after hydrolysis, frac-

tion B-4 yielded only large quantities of ornithine, in addition to traces of alanine and lysine. This fraction thus consisted mainly of the ornithine derived from the C-terminal amino acid arginine. After hydrolysis of fraction B-5, ornithine appeared, probably derived from the ornithine hydrazide.

In some experiments with fibrinopeptide B, PTH proline appeared in fairly large quantities in the first step of sequence determination of the unfractionated hydrazinolysate. In these cases, approximately equimolar amounts of the PTH derivatives of lysine and valine were obtained in the second and third step, respectively. In the fourth step, glycine could also be traced, but was not determined quantitatively. In qualitative amino acid determinations of the electrophoretic fractions after hydrolysis, fraction B-4 was found to contain proline, lysine, valine and glycine, in addition to the ornithine normally present. Fraction B-3 also contained these amino acids, although in smaller amounts, which made the quantitative determinations unreliable.

In determination of the sequences in these two fractions, proline, lysine, valine, and glycine appeared in the first, second, third, and fourth step, respectively. It is possible that, in these experiments, a peptide hydrazide was formed with the sequence pro-lys-val-gly, which was present in the electrophoretic fraction B-4. In this event, the hydrazide would have been partly hydrolyzed during the procedure, resulting in formation of the corresponding peptide, present in fraction B-3. The reason why this hydrazide was not removed by aldehyde treatment is uncertain. A possible explanation is that, because of its size and charge, this hydrazide had become so hydrophilic that it remained in the aqueous phase on treatment with aldehyde. We did, in fact, also obtain small quantities of ornithine and lysine hydrazides in the electrophoretic fractions B-5 and I-4 (see the following), which indicates that the basic hydrazides are not, as a rule, completely removed by aldehyde treatment.

Insulin. Sequence determination with the procedure described earlier was performed on the heptaldehyde-treated hydrazinolysate from about 2μmoles (11.5 mg) of insulin. The results are summarized in Table 5. Each value is the mean of the values obtained in 14 hydrazinolyses with only small differences between them. As could be expected, alanine appeared in relatively large quantities in step 1, but measurable amounts of proline, lysine and ornithine could also be identified, as well as traces of glycine, glutamic acid and aspartic acid. Since the B-chain of insulin ends with pro-lys-ala [17], it seemed likely that the lysine and proline demonstrable in step 1 comprised the N-terminals of the C-terminal peptides formed in hydrazinolysis. The subsequent analysis did not verify this assumption, since the amount of alanine in steps 2 and 3 by no means corresponded to the quantity of lysine obtained in the preceding step. The results of the sequence determination indicated instead that the hydrazinolysate contained — in addition to small quantities of C-terminal peptides, lys-ala and pro-lys-ala — free lysine and possibly some proline, as well as the peptide pro-lys.

For further elucidation, electrophoretic separation of the heptaldehyde-treated hydrazinolysate was performed, as well as subsequent analysis of the various fractions. In electrophoresis, we obtained four fractions — in one case a fifth as well (Fig. 2); they are denoted in the following as I-1, I-2, I-3, I-4, and I-5. All fractions migrated to the cathode. I-5, which was not invariably

present, moved further than lysine, and probably consisted of strongly basic hydrazides, which had not been completely removed by aldehyde treatment. No analysis was therefore made of this fraction.

The various electrophoretic fractions were chromatographed both before (Fig. 5) and after hydrolysis in the two-dimensional chromatography system described.

In electrophoresis, fraction I-1 migrated as far as the neutral amino acids and the glutamic and aspartic acid monohydrazides. Chromatographically, it consisted of two fractions. One of them migrated at the site of alanine, and one at the site of glycine. No proline — which, if it had been present in free form, should have appeared in this fraction — was, however, observed. After hydrolysis, a fairly complicated pattern was obtained. In addition to alanine, which gave a strong spot, small quantities of aspartic acid, glycine, serine, lysine and/or ornithine were present, as well as traces of valine, proline and threonine. Thus, in I-1, alanine and possibly glycine migrated, whereas the other amino acids obtained on hydrolysis derived from small quantities of peptide hydrazides with one free carboxyl group, as well as aspartic and glutamic monohydrazides.

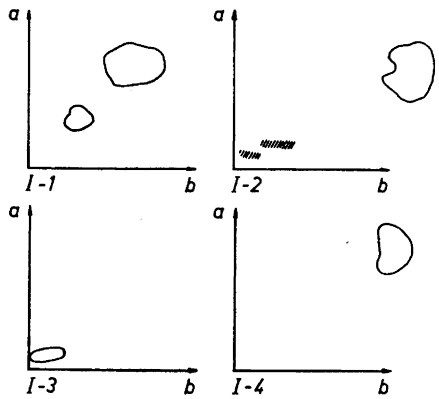

Fig. 5. Two-dimensional paper chromatograms of the electrophoretic fractions I-1, I-2, I-3, and I-4, obtained from hydrazinolyzed and heptaldehyde-treated insulin. (The solvent system is the same as in Fig. 3.) Traces are indicated by shaded areas.

Electrophoretically, fraction I-2 migrated somewhat more slowly than lysine and ornithine. In chromatography of the fraction, we obtained a component which moved like alanine in the butanol direction, but somewhat more slowly than alanine in the pyridine direction. This component reacted strongly to ninhydrin. Two additional fractions, which reacted very weakly to ninhydrin, were present. They migrated close to the site of lysine. After hydrolysis, relatively large quantities of proline and lysine were obtained, as well as extremely small amounts of aspartic acid, glycine and alanine. This fraction thus seemed to consist chiefly of a peptide containing proline and lysine.

Fraction I-3 moved as rapidly in electrophoresis as lysine and ornithine. In our system, the fraction was found chromatographically uniform with a single spot at the site of lysine and ornithine. After hydrolysis, lysine and/or ornithine were demonstrable, as well as traces of aspartic acid and glycine. This fraction thus consisted of free lysine and/or ornithine.

In chromatography, fraction I-4 which yielded a yellow spot in the ninhydrin reaction, moved slightly more rapidly than alanine. After hydrolysis, it proved to consist of lysine and/or ornithine.

The analysis therefore showed that the hydrazinolysate consisted principally of alanine and pro-lys, as well as small amounts of lys-ala, lysine and ornithine. In addition to these peptides and amino acids, it contained small quantities of hydrazides of amino acids and peptides, which had not been removed completely through the aldehyde treatment. The presence of amino acids and peptides that were not C-terminal might imply that undesirable hydrolysis of hydrazides to free amino acids and peptides had occurred in the course of analysis. Previous investigations have, however, shown that if removal of the hydrazides is done rapidly, such hydrolysis takes place only to an inappreciable extent [18]. Another possible explanation is that in preparation of the insulin, it might have been partially split by the traces of trypsin present. Since the action of trypsin has been found to be strictly confined to peptide bonds in which the carboxyl groups of basic amino acids are included, such splitting could have taken place only in the B-chain, between the amino acids 22—23 (arg-gly) and 29—30 (lys-ala) [19]. It is probable that the large fragments thus formed follow the unaltered insulin during the preparation. Those amino acids and peptides obtained in the analysis that can not have been released from the C-terminal sequence in the complete insulin molecule can all have derived from the C-terminal sequence in the fragments formed by the action of trypsin, *i.e.*, glu-arg, which yields orn, and thr-pro-lys, which yields both pro-lys and lys. Evidently the recrystallized insulin used in this work was prepared with a technique in which a certain enzymatic destruction is unavoidable. That such an interaction of trypsin on insulin can occur in the process of manufacturing has since then been demonstrated by Jorpes and Lindén [20]. However heating of the crude alcoholic extract of the pancreatic gland at pH 2.0—4.5 at a temperature of 70°—75°C for 10 min will destroy the trypsin and considerably increase the yield in the large scale manufacture of insulin. The recrystallized insulin used in this work was in fact prepared with a technique in which a certain enzymatic destruction of insulin is unavoidable.

DISCUSSION

When Edman's phenyl*iso*thiocyanate method is applied to a hydrazinolysate of a peptide, the C-terminal amino acid released is determined, as well as the N-terminal amino acids of the C-terminal peptides formed in hydrazinolysis. By utilizing the possibility of sequence determination given by this method, the C-terminal sequence can, in favourable cases, be determined directly on the heptaldehyde-treated hydrazinolysate, without further separation. About 1—2 μmoles of peptide material are required for such an analysis.

A direct sequence determination according to the aforegoing should give sufficiently reliable results in a relatively pure hydrazinolysate from peptides consisting of a single chain. In certain cases, however, it is not possible to obtain a clear picture of the C-terminal constitution of the peptide without further separation of the components of the hydrazinolysate. This applies, for example, in studies of peptides with more than one chain, and those whose structure disposes to the formation of acid peptide hydrazides, which are difficult to remove completely from the hydrazinolysate. By using high-voltage electrophoresis and two-dimensional paper chromatography, we were able to separate from the hydrazinolysate several fractions, which were subsequently analyzed.

Of the analyses performed in the present investigation, those on fibrinopeptide A and insulin gave results that are in agreement with the C-terminal sequence of the peptides. In application of Edman's method to the hydrazinolysate of these peptides, we obtained exceedingly small — in certain cases not measurable — amounts of PTH derivatives, particularly from glycine, aspartic acid and glutamic acid, that could not have been released from the C-terminal parts. The quantities of these amino acids were about as large as those reported by Bradbury [21] in his studies on insulin, *i.e.*, as a rule < 0.05 mole per mole of peptide. After electrophoresis and two-dimensional paper chromatography of the hydrazinolysate it could, in fact, be shown that — with the possible exception of glycine — they did not derive from free amino acids. After hydrolysis of the less basic electrophoretic fractions, we nevertheless obtained small quantities of glutamic and aspartic acid. In view of the rate of migration of the electrophoretic fractions they should have derived from hydrazides. Glutamic and aspartic acid can occur inside a peptide chain with free carboxyl groups. In hydrazinolysis, the free carboxyl group remains intact, whereas a hydrazide group is obtained from the carboxyl group in the peptide bond. It is probable that, at the pH applied in heptaldehyde treatment, the free carboxyl group makes the hydrazone formed slightly hydrophilic, so that in certain cases it is not completely extracted with the organic heptane-heptaldehyde phase. In an attempt to produce more effective removal of the hydrazides, we substituted benzaldehyde for heptaldehyde in some experiments, but this did not prove to have any advantage.

The results obtained in hydrazinolysis of fibrinopeptide B were less clear. The analyses indicated that the hydrazinolysate contained — in addition to ornithine and ala-orn, which may have derived from the C-terminal sequence — aspartic acid and glutamic acid hydrazides and, in some cases, also a tetrapeptide hydrazide with the sequence pro-lys-val-gly. The same sequence has been demonstrated in sequence studies of fibrinopeptide B [22].

Since some of the hydrazides formed in hydrazinolysis contain one or several free carboxyl groups, which make them extremely difficult to remove from the water phase, the value of this method for C-terminal analyses is presumably reduced in some cases. This is because certain difficulties may arise in studies of *e.g.* peptides and proteins containing large quantities of aspartic and glutamic acid. It is, however, possible that the use of solid polyaldehydes — *e.g.* polyacrolein as introduced by Kauffmann and Boettcher [23] — would result in more effective removal of the hydrazides, and thus in a still more reliable method for C-terminal studies.

Our experiments were made on peptides containing basic amino acids in their C-terminal part. After 10 hours' treatment with hydrazine, we were able to demonstrate relatively large quantities of peptides. This might indicate that the peptide bonds in which basic amino acids are present are fairly resistant to hydrazine. Thus, we found, for example, in hydrazinolysis of fibrinopeptide B that the peptide ala-orn was obtained in almost as large a quantity as ornithine (Table 3). The lys-ala bond in the intact insulin molecule seems, on the contrary, to be fairly easily split, since only small amounts of lys-ala were demonstrable. On the other hand, large quantities of the dipeptide pro-lys were present, and small quantities of lys. This implies that the peptide bond pro-lys is also relatively resistant in hydrazinolysis. The resistance of the val-arg (orn) bond, which occurs C-terminally in peptide A, is still more marked. In analysis of fibrinopeptide A we obtained, in fact, in the first step of sequence determination 0.36 mole of gly (from gly-val-orn) and 0.34 mole of val (from val-orn), but only 0.05 mole of orn per mole of peptide A. In this case, the amount of peptide is 14 times the amount of C-terminal amino acid. Our results seem to show that the gly-val bond is also relatively stable.

The number of hydrazinolysis studies is still too small to permit any definite conclusions regarding which peptide bonds are difficult to split, or the reason underlying the difference between the sensitivity of the bonds to hydrazine. No complete investigation has yet been made of the kinetics in hydrazinolysis of peptides, although Bradbury [21] has studied the rate of hydrazinolysis in certain tri- and dipeptides as catalyzed by hydrazonium sulphate. He was able to demonstrate considerable differences between the stability of the peptides. For example, the peptide leu-val was much more stable than leu-gly which, in turn, showed greater stability than gly-gly. Judging by the material hitherto available for analysis, a peptide bond whose amino group derives from a basic amino acid is relatively stable, as are bonds containing amino acids with longer and branched carbon chains.

Our results indicate the existence of certain peptide bonds that are considerably more resistant to hydrazine than was formerly believed. If a peptide or a protein has resistant peptide bonds in its C-terminal part, the hydrazinolysate from them will contain a varying proportion of peptides even after relatively lengthy hydrazine treatment. If the C-terminal peptide bond is almost completely resistant — as, *e.g.* val-arg in fibrinopeptide A — the yield of the free C-terminal amino acid will be extremely small. Naturally, in such cases it is not possible to apply the criteria suggested by Akabori *et al.*[18] for evaluation of whether or not the amino acid is situated C-terminally. According to these criteria, the yield should be at least 20 % of a certain amino acid

for it to be regarded as C-terminal. The value often falls below this figure, and the yield may even be so low that it is difficult to determine exactly. For example, Dixon, Kauffmann and Neurath [24] recently described a peptide obtained by tryptic hydrolysis of oxidized di-*iso*propyl-phosphoryl-trypsin, and denoted as O-Tr-1, in which no C-terminal amino acid could be determined by hydrazinolysis in the modification of Niu and Fraenkel-Conrat. They were, however, able to show by partial hydrolysis that the C-terminal sequence was gly-lys. Like ala-orn (arg) in fibrinopeptide B, this peptide bond is probably relatively stable in hydrazinolysis.

Our knowledge of which amino acids or combinations of them determine the resistance of the peptide bonds to hydrazine is still incomplete. Consequently, a full analysis must be made of the hydrazinolysate obtained in order to get an accurate picture of the C-terminal structure of an unknown peptide. A suitable tool for such an analysis is Edman's phenyl*iso*thiocyanate method, possibly preceded by electrophoretic separation of peptides and amino acids in the aldehyde-treated hydrazinolysate. Edman's method seems to have certain advantages over other techniques hitherto available. This is because it gives a good quantitative picture of the composition of the hydrazinolysate, and also permits a stepwise breakdown of the existing peptides.

Metabolism of Chenodeoxycholic Acid in the Rabbit

Bile Acids and Steroids 104

KJELL HELLSTRÖM and JAN SJÖVALL

Department of Medicine, Serafimerlasarettet, and
Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

Two rabbits, one with a permanent duodenal fistula and the other with a permanent stomach fistula, were given chenodeoxycholic acid-24-^{14}C intravenously. Bile samples were taken intermittently for three days through the fistulas which were closed except during the sampling periods. Unchanged chenodeoxycholic acid could not be positively identified. Lithocholic acid was the main metabolite in the feces and bile of one rabbit. In addition to lithocholic acid, ursodeoxycholic acid and small amounts of 7-ketolithocholic acid were found in both the bile and feces of the other animal. The excretion of isotope in feces indicated a slow turnover of the acids.

Cholic and deoxycholic acids are the main bile acids in rabbit bile (for references see Ref.[1]). Cholic acid is formed from cholesterol in the liver whereas deoxycholic acid is secondarily formed from cholic acid by intestinal microorganisms [1]. Chenodeoxycholic acid has not been found in rabbit bile but lithocholic acid, which can be formed from this acid in the rat intestine [2], has been isolated in minor amounts [3]. The rabbit has been extensively used for studies of atherosclerosis and in connection with an investigation of bile acid production in this animal we found it necessary to acquire more information on the qualitative metabolism of chenodeoxycholic acid in the rabbit. Results obtained with the aid of labelled chenodeoxychclic acid are presented in this paper.

EXPERIMENTAL

Chenodeoxycholic acid-24-^{14}C was synthesized according to Bergström, Rottenberg and Voltz [4]. The specific activity was about 10 μC per mg. Ursodeoxycholic acid (m.p. 202–203°) was prepared according to Samuelsson [5].

Animal experiments. Two rabbits weighing about 2.5 kg were used. One of these was provided with a permanent fistula between the duodenum and the abdominal wall (rabbit DK), the other one was provided with a similar fistula between the distal part of the stomach and the abdominal wall (rabbit VK). The fistula consisted of a plexi-glas tube (length 5 cm) that could be closed with a plexi-glas stopper occupying the whole

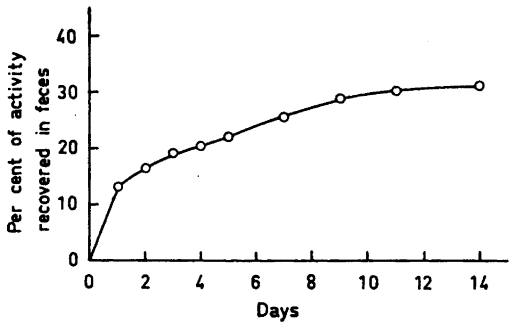

Fig. 1. Cumulative excretion in the feces of rabbit VK of activity not removed through the fistula.

volume of the tube up to the level of the mucosa [6]. Bile samples were taken directly *via* the duodenal fistula by removing the stopper, or by introducing a rubber tube through the stomach fistula into the duodenum. Except when samples were being taken, the plexiglas tubes were stoppered and the animals were allowed to move freely in their cages. This technique was adopted in order to follow specific activities of bile acids *in vivo* and details will be described later. The experiments were started about one month after the operation. The animals had free access to cabbage and carrots, were apparently healthy and increased in weight. Rabbit VK is still in good health 10 months after the operation.

2.8 mg of the sodium salt of the labelled chenodeoxycholic acid was given intravenously in 4 ml of saline. 24 h later duodenal contents was collected after i.v. injection of cholecystokinin-pancreozymin (kindly supplied by Prof. E. Jorpes). Collection was continued for 6 h and the procedure repeated on the following two days. Feces were collected every day.

Extraction and chromatography. About 10 volumes of ethanol was added to the duodenal contents. After filtration, most of the solvent was evaporated on the water bath and the bile acids were extracted with butanol from the acidified aqueous solution. The homogenized daily portions of feces were extracted 4—5 times with ethanol by refluxing for 2 h. Complete extraction of the isotope was ascertained by radioactivity measurements on each extract. After concentration of the combined extracts, the bile acids were extracted with ether from an acidified aqueous solution. Reversed phase chromatography was performed as previously described [7,8]. The following phase systems were used:

Phase system	Moving phase (ml)	Stationary phase (ml)
C 1	Methanol-water 150:150	Chloroform-*iso*octanol 15:15
F 1	Methanol-water 165:135	Chloroform-heptane 45:5
F 2	Methanol-water 180:120	Chloroform-heptane 45:5
F 3	Methanol-water 180:120	Chloroform-heptane 40:10

4.5 g of hydrophobic Supercel or Hostalen (Hoechst) [9] was used to support 4 and 3 ml, respectively, of the stationary phase. When larger columns were needed these amounts were proportionally increased. Radioactivity was determined by the counting of an infinitely thin layer in a Frieseke-Hoepfner (FH 51) methane gas-flow counter.

RESULTS

A total of about 15 % of the isotope injected was recovered by collection of duodenal contents for 6 h during each of the 3 days following the injection of chenodeoxycholic acid-24-^{14}C. The fecal excretion of isotope was extremely

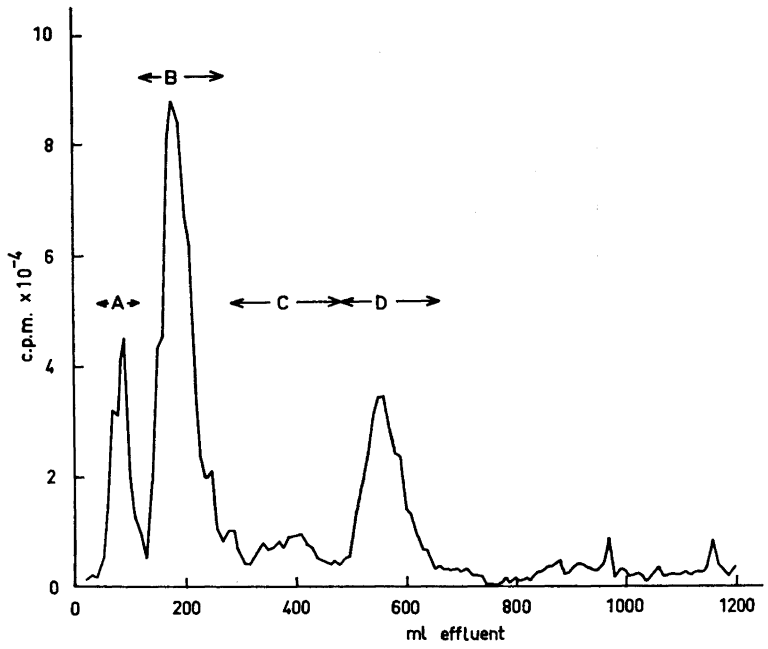

Fig. 2. Chromatogram of labelled compounds in the bile of rabbit VK. Column: 36 g Hostalen, phase system F 1.

slow. Only 22 % of the activity not recovered from the duodenum was excreted during the first 4 days in rabbit DK. Rabbit VK was therefore studied for 14 days and the same result was obtained as shown in Fig. 1.

Radioactive compounds in duodenum. The radioactive compounds extracted from the bile obtained from the duodenum were separated on Hostalen columns with phase system F 1. The result for rabbit VK is shown in Fig. 2. Conjugated bile acids appear with the front in this phase system but, as seen in the figure, only a minor part of the activity is eluted with the front (A, Fig. 2). The main part of the isotope is present in two peaks (B and D, Fig. 2) which appear at places corresponding to ursodeoxycholic and lithocholic acids, respectively. Only about 2 % of the total activity remained in the stationary phase. The active bands A, B, C, D (Fig. 2) were further purified by rechromatography on hydrophobic Supercel.

When peak A was chromatographed with phase system C 1, one main peak was found (Fig. 3, left curve). Chromatography, with inactive cholic acid added as carrier, showed that no radioactive cholic acid was present. The nature of the compounds separated with phase system C 1 has not been further investigated.

The rechromatography of peak B (Fig. 2) on Supercel columns with phase system F 1 is shown in Fig. 3 (middle curve). The isotope appears just before the large titration peak of the deoxycholic acid normally found conjugated in

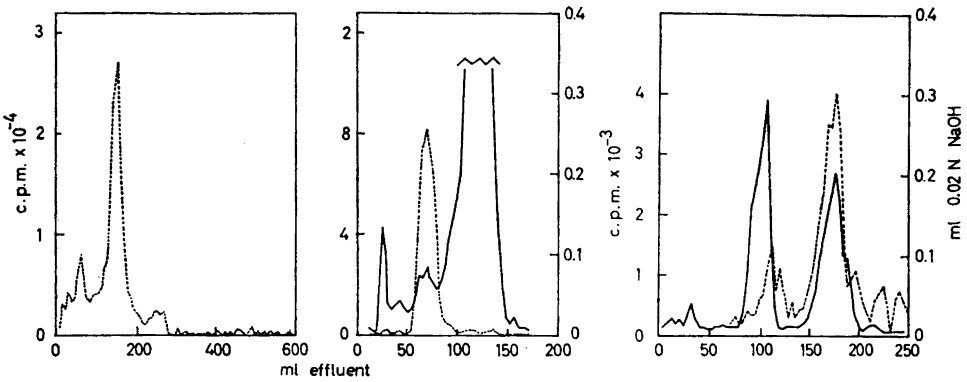

Fig. 3. Left curve: Rechromatography of peak A (Fig. 2) on a 18 g Hostalen column with phase system C 1. Middle curve: Rechromatography of peak B (Fig. 2) on a 9 g Supercel column with phase system F 1. Right curve: Rechromatography of band C (Fig. 2) together with unlabelled 7-ketolithocholic acid. 9 g Supercel, phase system F 1. Solid line: Titration. Broken line: Radioactivity.

rabbit bile. There is a small but definite titration peak coinciding with the radioactive one. No isotope is seen at the place of chenodeoxycholic acid. The radioactive fractions were re-run together with inactive ursodeoxycholic acid and the activity coincided with the titration peak of the added carrier (Fig. 4, left curve). The small titration peak which can be seen after the main peak is due to incomplete removal of the deoxycholic acid originally present in the bile. The identity of the labelled compound with ursodeoxycholic acid was further established by isotope dilution.

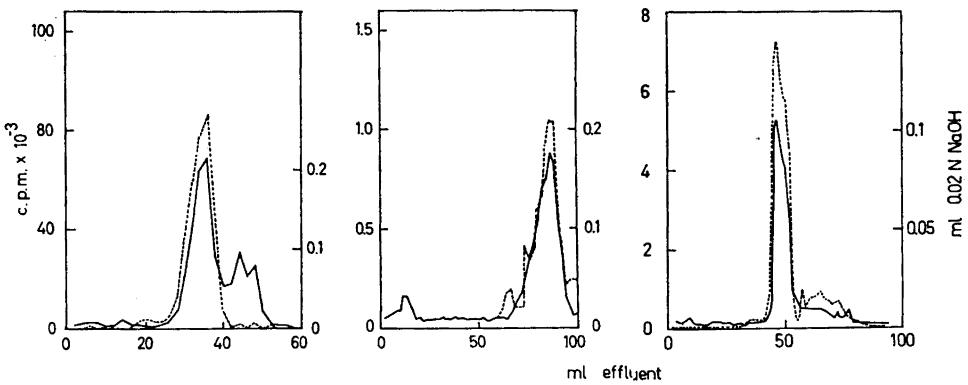

Fig. 4. Left curve: Rechromatography of peak B (Fig. 2) together with inactive ursodeoxycholic acid. 4.5 g Supercel, phase system F 1. Middle curve: Rechromatography of peak C from feces (Fig. 5) together with inactive 7-ketolithocholic acid. 4.5 g Supercel, phase system F 1. Right curve: Rechromatography of part of the "lithocholic acid band" from feces of rabbit DK together with inactive lithocholic acid. Solid line: Titration. Broken line: Radioactivity.

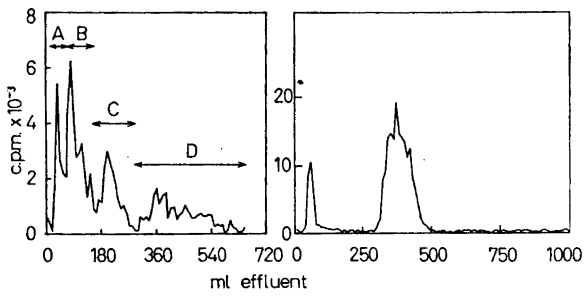

Fig. 5. Chromatograms of labelled fecal acids obtained from rabbit VK (left curve, 18 g Hostalen) and from rabbit DK (right curve, 27 g Hostalen). Phase system F 1 was used in both cases.

After one rechromatography with phase system F 1, band C (Fig. 2) was re-run with unlabelled 7-ketolithocholic acid. Most of the isotope appeared together with the carrier (Fig. 3, right curve) and the identity was established by isotope dilution. As was the case with the rechromatography of ursodeoxycholic acid, not all of the very large amounts of inactive deoxycholic acid had been removed. Therefore, a titration peak of this acid is still seen in Fig. 3 at 100 ml effluent.

The last radioactive band seen in Fig. 2 (peak D,) was rechromatographed with phase system F 2 and a titration peak coincided with the isotope peak. Chromatography with carrier lithocholic acid and determinations of specific activity upon recrystallization with lithocholic acid, showed that the labelled compound (Fig. 2, D) was identical with this acid.

Analysis of the duodenal bile from rabbit DK gave essentially the same result as above but, in this animal, lithocholic acid was by far the dominating metabolite (74 %) whereas only about 10 % of the total activity appeared in the ursodeoxycholic acid band. Furthermore, 7-ketolithocholic acid could not be found but this acid also accounted for only 5—10 % of the total metabolites in rabbit VK.

Radioactive compounds in feces. The analysis of the metabolites in feces was carried out in the same way as described for the duodenal bile. The main bands of radioactivity present in the chromatograms of feces were the same as those of the duodenal bile. The first chromatographies of a fecal sample from both rabbit VK and rabbit DK on Hostalen columns with phase system F 1 are shown in Fig. 5 (left and right curves resp.). Lithocholic acid was even more dominating in the feces of rabbit DK than in the duodenal contents of this animal (Fig. 5, right curve). It was identified by rechromatography with carrier lithocholic acid (Fig. 4, right curve) and by isotope dilution. Chromatograms of fecal extracts from the first, second and third days after the injection of the labelled chenodeoxycholic acid were very similar.

The labelled bands B, C, and D from rabbit VK shown in Fig. 5 (left curve) were rechromatographed with inactive ursodeoxycholic, 7-ketolithocholic and lithocholic acids, respectively. In all cases most of the isotope appeared

together with the reference compounds. This is shown for 7-ketolithocholic acid in Fig. 4 (middle curve). No isotope dilution experiments were made. The small amount of isotope appearing with the front (A, Fig. 5) was not studied further.

DISCUSSION

A striking finding is the very slow excretion of isotope in the feces of both the rabbits. This indicates a much longer half-life time of the chenodeoxycholic acid in the rabbit than in the rat. In this connection it is interesting to note that the amount of bile acids taking part in the enterohepatic circulation seemed to be very large in the rabbits previously studied (about 550 mg) [1]. In view of the sensitivity of the rabbit for hypercholesteremia, these quantitative aspects of the bile acid metabolism are now being studied.

Another finding differing from that found in rat and man is the occurrence of large amounts of unconjugated bile acids in the duodenal contents. In the bile all bile acids are conjugated [1]. This indicates a bacterial hydrolysis of bile acids already in the duodenum. In order to find out whether this was due to the presence of a fistula, four normal rabbits were killed and the duodenal contents was analyzed with paper chromatography. Large but variable amounts of free bile acids were found.

Unpublished findings by S. Lindstedt indicate that minute amounts of chenodeoxycholic acid are formed from cholesterol in bile fistula rabbits. We have now shown that chenodeoxycholic acid is rapidly and almost completely metabolized mainly to lithocholic and ursodeoxycholic acids. It is therefore probable that any chenodeoxycholic acid formed will be transformed and escape detection in normal bile. Lithocholic acid has been isolated from rabbit bile [3] and we have seen titration peaks in the chromatograms coinciding with both the labelled lithocholic acid and the labelled ursodeoxycholic acid.

Although we have not determined whether the transformation of chenodeoxycholic acid takes place in the liver or in the intestine, or in both, it seems most probable that lithocholic acid is formed by microorganisms, as is the case in the rat [3]. The transformation of chenodeoxycholic acid during the enterohepatic circulation is very extensive in the rabbit, which is also true for cholic acid in this animal [1]. The ursodeoxycholic acid found is probably formed *via* the 7-ketolithocholic acid also found. Whether the 7-ketolithocholic acid has been formed both by liver enzymes [10] and in the intestine by the action of *E. coli* [11] is not known.

Acknowledgments. We are greatly indebted to Dr. Lars Olbe for help and advice with the fistula operations. The technical assistance of Miss A. Björkman and Miss M. Frankesten is gratefully acknowledged.

This work is part of investigations supported by *Statens Medicinska Forskningsråd* and the *National Heart Institute (H 2842) U.S. Public Health Service*, Bethesda, Maryland.

Hämine verschiedener Strukturen als Bakterienwuchsstoffe

K. G. PAUL und E. THOFERN

Biokemiska institutionen, Karolinska institutet, Stockholm, Schweden; Hygiene-Institut der Universität Göttingen, Bundesrepublik Deutschland

Eine früher beschriebene häminheterotrophe, streptomycinresistente Mutante von *Micrococcus pyogenes* var. *aureus* SG 511 kann statt Protohämin IX Hämato- und Mesohämin IX, dagegen nicht Mesohämin I und Diacetyldeuterohämin IX, für ihre Hämoproteidesynthese ausnützen.

Jensen und Thofern haben eine streptomycinresistente häminheterotrophe Mutante des *Micrococcus pyogenes* var. *aureus* S. G. 511 isoliert [1,2], die imstande ist, die Apoproteine ihrer Hämoproteide aufzubauen und mit Häminen zu kuppeln. Die Synthese der Holohämoproteide ist aber nur nach der Zugabe von Hämin möglich.

Es ist mit einigen Hämoproteiden gelungen die reversible Spaltung in Hämin und Eiweiss durchzuführen [3–5]. Nicht nur Protohämin sondern auch gewisse andere Hämine können die spezifische Wirkung wiederherstellen [6,7], aber nur solche, die Propionsäuren an den Stellungen 6 und 7 (»Reihe IX») besitzen [8]. Die 6,8-Isomeren (»Reihe I») dagegen geben inaktive, auf Anionenaustauschern spaltbare Verbindungen [9]. Aber nicht alle dikarboxyligen Hämine der Reihe IX geben aktive Verbindungen. Bei Meerettichperoxydase scheint eine Beziehung zwischen Aktivität und Spektrum vorzuliegen, indem die Aktivität geringer wird je langwelliger die α-Bande im Hämochromogenspektrum liegt. Diacetyldeuterohämin IX, z.B., ruft keine Peroxydaseaktivität hervor obwohl es eine feste Verbindung, ein wahres Holohämoproteid, mit Apo-Meerrettichperoxydase bildet [9].

Es war nun von Interesse herauszufinden, ob auch die Mutante eine Isomeriespezifizität aufwiese und ob auch eine Beziehung zwischen Häminspektrum und den Lebensäusserungen der Mutante bestände.

MATERIALIEN UND METHODEN

Die wachsende Mutante gibt auf Nähragar (2 % Agar in 1.5 % Caseinpepton — 1 % Glukose — Na-Phosphatpuffer 67 mM, pH 7.6) einen hauchdünnen Rasen, der ringsum ein Stanzloch mit der zu prüfenden Lösung einen Wachstumshof, einen Hemmhof oder

keine Veränderung zeigt. Von der Häminlösungen (0,05—0,10 mM in 0,1 M Natriumkarbonat) wurden 0,05 ml pro Loch abgemessen. Die Platten wurden nach 20 Std bei 37°C abgelesen.

Die ruhende Mutante, in der obigen Bouillon ohne Agar anaerob vorgezüchtet und mit Kochsalzlösung und Puffer gewaschen, zeigt in Manometerversuchen eine mässige Sauerstoffaufnahme. Sie wurde während 30 min verfolgt ehe die Häminlösung eingekippt wurde. Bei dem Kippen erschien meistens eine CO_2-Freisetzung (siehe z. B. Abb. 3). Für die Messungen wurden verwendet 5 mg von Bakterien, als Trockengewicht

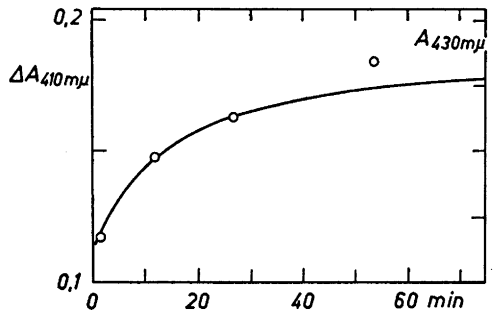

Abb. 5. Lichtabsorption- und Aktivitätszunahme während der Reaktion zwischen Apomeerrettichperoxydase und Hämatohämin. Probeküvette: 0,02 μ Mole Protein + 0,03 μ Mole Hämatohämin in 3,7 ml 0,1 M Na – Phosphat, pH 7,1. Referenzküvette: Dasselbe ohne Protein. Lichtabsorption: Ordinate links und Kurve. In den Aktivitätsmessungen wurden 0,15 ml des Küvetteninhaltes für die Purpurogallinreaktion verwendet, 250 ml Äther. Ordinate rechts und Cirkel (Zusammen mit Y. Avi-Dor, 1952).

berechnet, 67 mM Na-Phosphat von pH 7,6, 100 mM Glukose, Luft als Gasphase, 37°C und 110 Oscillationen pro Minute. Anschliessend an die Atmungsversuche wurde die Katalaseaktivität bei 0–2°C titrimetrisch bestimmt [10] und als ml 10 mN Wasserstoffperoxyd ausgedrückt, die in 12 min zerlegt werden.

Sämtliche Hämine ausser Hämatohämin waren als Porphyrinester chromatographiert, nach Verseifung mittels Äther – HCl gereinigt und in Hämine mittels Ferroacetat in Eisessig überführt.

Die Kuppelung in Abb. 5 geschah wie früher beschrieben [9].

ERGEBNISSE

Die Ergebnisse sind in Abb. 1—5 und in Tabelle 1 gesammelt.

Tabelle 1. Katalaseaktivitäten der Gefässinhalte in Abb. 2–4.

Abbildung	Kurve	Hämine	Katalaseaktivität ml 10 mN H_2O_2/12 min

DISKUSSION

Die Beobachtungen in den Agar-Stanzlochtesten und in den Manometerversuchen mit den anschliessenden Katalasebestimmungen stimmen insofern gut überein, dass von den geprüften Häminen nur Proto-, Meso- und Hämatohämin IX positive Reaktionen hervorrufen, Mesohämin I und Diacetyldeuterohämin IX aber nicht. In Vorversuchen zeigte sich auch Deuterohämin IX als wirksam. Es ist unwahrscheinlich, dass die Mutante Enzyme für die Umwandlung der Meso-, Deutero- und Hämatohämine — nicht aber Diacetyldeuterohämin — in Protohämin parat hat. Man könnte deshalb vermuten, dass die zugesetzten Hämine unverändert eingebaut werden. Solche artifizielle Hämoproteide sind in der Natur früher nicht gefunden worden. Hämin a kann aus den Bakterien nach Protohäminzugabe isoliert werden [11], ob die zugegebenen Protohäminmoleküle in Hämin a übergehen ist aber nicht eindeutig beantwortet. Für die Identifizierung der prosthetischen Gruppen müssen die gebildeten Hämoproteide von dem Überschuss an zugesetztem Hämin isoliert werden. Solche Versuche mit Verwendung von $^{14}C/^{59}Fe$-Hämin sind im Gange.

Genau jene Hämine sind für die Mutante nutzbar, die mit Apo-Meerrettichperoxydase aktive Verbindungen geben [8]. Dies ist um so bemerkenswerter da nach Protohäminzugabe mehrere Hämoproteide zu finden sind [12]. Unter den verwendeten Bedingungen wird die steigernde Wirkung des Protohämins auf die Sauerstoffaufnahme durch Diacetyldeuterohämin reduziert, zu 78 und 56 % in Doppelbestimmungen in Abb. 4; die Katalasebestimmungen gaben 72 und 47 %. In Abb. 1 sieht man zwischen den Löchern 6 und 7 eine gerade Begrenzung. Diese Befunde deuten eine Konkurrenz zwischen den beiden Häminen an. In dieser ist es wegen der Spektra zu erwarten, dass Protohämin fester als Diacetyldeuterohämin gebunden wird. Die Hemmung in Abb. 4 wurde mittels einem fünffachen Überschuss an Diacetyldeuterohämin erhalten. Da weiter Mesohämin I die Bakterien gegen die IX-Isomeren vollständig blockiert, muss man das Vorkommen von spezifischen Haftstellen, reaktiven Gruppen, in den Bakterien annehmen. Es ist an sich nicht überraschend, dass Mesohämin I als Wuchsstoff oder Co-Faktor nicht verwendbar ist, da bisher alle in der Natur gefundenen Hämoproteide Hämine der Reihe IX enthalten.

Die Zunahme des Sauerstoffverbrauchs der ruhenden Mutante nach Häminzugabe (Abb. 2) kommt schnell, noch schneller als die Aktivitätszunahme nach dem Vermischen von Hämin mit Apoperoxydase (Abb. 5). Dies könnte mit einer unspezifischen Redoxwirkung vom Hämin erklärt werden. Der Unterschied zwischen den vier untersuchten Häminen der Reihe IX wäre dadurch zu verstehen, nicht aber die Unfähigkeit Mesohämins I Sauerstoffaufnahme und Wachstum zu fördern, auch nicht die oben erwähnte Konkurrenz.

Bei den auf Agar aerob wachsenden Bakterien begrenzt die Diffusion des Hämins den Wachstum, daher werden die Zeitverhältnisse unklarer. In den inneren Teilen des Wachstumshofs verschwand mit allen drei Häminen der Wachstum mehr oder weniger. Da aber diese leere Zone bei Mesohämin am breitesten war, kann Mangel an CoA, das für den bakteriellen Einbau von Protohämin in die Katalase notwendig sein soll [13], oder an anderen Co-Faktoren

kaum die Ursache sein. Von den drei Häminen zeigt Hämatohämin in Wasserlösungen eine hohe Polymerisierung, Mesohämin eine niedrigere. Dementsprechend diffundiert Mesohämin weiter als die beiden anderen, und die Ausdehnung der leeren Zone mag damit verbunden sein. In Stanzlochversuchen mit Kobaltporphyrinen und *Lactobacillus lactis* Dorner bewirkten die Hämato- und Protoverbindungen Wachstum, Meso dagegen Hemmung [14].

Alle bisherigen Ergebnisse wären durch die Annahme, dass die Bakterien spezifische Apoeiweissmoleküle besitzen, die ihre Haftgruppen oberflächlich tragen, erklärt. Sie schliessen aber auch beinahe aus, dass die Zunahme der Sauerstoffaufnahme nach Häminzugabe durch eine Kette von Hämin-Redoxkatalysatoren stattfindet, fastmehr scheint es sich um nur ein Hämoproteid zu handeln. Die Peroxydasewirkung der Katalase könnte hier die Funktion einer terminalen Oxydase einnehmen.

In den hier beschriebenen Versuchen (Abb. 2—4) wurden die Bakterien während der Phase ihres schnellsten Wachstums geerntet. Zu dieser Zeit sollten sie also, nachdem was oben gesagt wurde, Apokatalase enthalten. Aus der Literatur ist zu entnehmen, dass eine Beziehung zwischen Wachstum und Peroxydase- bzw. Katalaseaktivität vorliegen könnte. Es ist schon längst bekannt, dass Kürbiskotyledone an Katalase sehr reich sind [15]; eine nähere Untersuchung [16] ergab das Katalasemaximum zwischen den 6. und 8. Tag bei 15°C in Erbsenpflanzen. Auch in tierischen Geweben sind ähnliche Beobachtungen gemacht worden. Während der Oestradiol-induzierten Uterushyperplasie steigt bei Mäusen die Peroxydaseaktivität stark an [17,18]. Ein eingehender Vergleich zwischen den durch Peroxydase und Zytochrome bedingten Sauerstoffaufnahmen während der verschiedenen Phasen des Wachstums wäre von Interesse. Aus der allgemeinen Verbreitung und der hohen Katalaseaktivität in den Erythrozyten geht aber hervor, dass die Wirkung der Hydroperoxydasen nicht nur mit Wachstum verknüpft sein können.

Die Untersuchung wurde von *Statens naturvetenskapliga forskningsråd*, Schweden (K. G. P.) und die *Deutsche Forschungsgemainschaft* (E. Th.) unterstützt.

A New Principle for Large Scale Production of Insulin

ERIK JORPES, VIKTOR MUTT and SELAHADDIN RASTGELDI

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

The conventional method for large scale manufacture of insulin starts with an extraction of the pancreatic glands with acidified ethyl alcohol and subsequent evaporation of the alcohol *in vacuo* at low temperature. The authors present a technique of adsorbing the insulin from the alcoholic extract at pH about 3 on an ion exchanger, alginic acid, with subsequent elution of the insulin by means of 0.2 N HCl. The use of a cumbersome and expensive distilling equipment is thereby made superfluous. Fats are not adsorbed. An increased yield of insulin is obtained if the traces of tryptic enzymes still present in the extract are destroyed by heating the alcoholic extract at pH 3.2 to 70°C before adsorbtion.

Since the very first beginning, when insulin in 1921—1922 became available for clinical use through the endeavours of the University of Toronto group, the manufacturing process has included extraction of the pancreatic glands with alcohol, acidified with hydrochloric or sulphuric acid, evaporation of the alcohol *in vacuo* at low temperature, removal of fats from the aqueous residue and precipitation of proteins with sodium chloride followed by isoelectric precipitation of the insulin from water at pH 5.2 and subsequent crystallization. During all these years, no major changes have been made in this procedure.

Since no information was available on the successful use of ion exchangers for recovery of the insulin from the alcoholic extract, we in 1954 took up experiments along such a line. As a result the Swedish manufacturer of insulin, Vitrum AB, Stockholm, could in 1956 start to apply a new technique, which now has been in use for the last three years. Since no distillation at low temperature is necessary, the large-scale production has been greatly facilitated.

Historical. The technique of adsorbing bases on inorganic ion-exchangers was introduced in biochemistry in 1917 by Otto Folin, who adsorbed ammonia on Permutite. The same reagent was later used extensively for the adsorption of organic bases, basic proteins of low molecular weight and peptides [1].

From 1950 on, the carboxylic acid ion-exchange resin Amberlite IRC-50 was used by different authors to study the homogeneity of basic proteins of low molecular weight, such as cytochrome c [2], ribonuclease [3], lysozyme [4] and chymotrypsinogen [5]. Up to 1953, the ion-exchange resins had been used only

for chromatographic analysis of small quantities of purified proteins, the applicability being limited to low-molecular basic proteins.

When Peterson and Sober [6] in 1956 recommended cellulose ion-exchangers for the chromatography of proteins, they stated that "the application of chromatography to the separation of proteins has not met with the general success obtained with smaller, simpler molecules. The large size of the protein molecule prevents its penetration into the adsorbent particle, therefore only the adsorbing sites located on the exterior can be utilized."

Boardman [7] tried in 1955 to increase the surface of a sulphonated polystyrene ion-exchanger by precipitating the resin on the surface of kieselguhr (Celite 545), and used the product for the study of the purity of crystalline insulin.

The only successful attempt at using ion-exchangers on a technical scale for the reversible adsorption of proteins was that of Astwood, Raben, Payne and Grady [8] of 1951. They adsorbed the basic peptide hormone, corticotropin, on oxycellulose from dilute aqueous acetic acid.

No attempts seem to have been made to take up the insulin from the acidic alcoholic extract on ion-exchangers. As an illustration, it can be mentioned that as late as June 1956, Samsonov and Faddajeva [9] published a study of the possibility of adsorbing insulin on an ion-exchange resin, SBS-1, having a particularly suitable porosity. Elution was performed with 1 **N** ammonia. They applied their technique to the residual aqueous extract after distilling off the alcohol.

Own work. Since the previous discussion dealt with ion-exchange chromatography in aqueous solution and, furthermore, was confined to more or less basic proteins of low molecular weight, removal of the acidic protein insulin from a crude alcoholic extract offered new aspects. The use of ordinary cation-exchangers of the Dowex-50 type was excluded because of the size of the insulin molecule, which does not allow a diffusion into the inner spaces of the resin. Moreover, if adsorption is to be carried out at an acidic reaction, pH below 4, making the insulin a cation, the most commonly used adsorbent, Amberlite, IRC-50, is only sparingly ionized and less efficient as an adsorbent. An ion-exchanger with easily accessible ionizable groups is necessary.

We found alginic acid to be a highly suitable ion exchanger for this purpose *. Insulin is taken up quantitatively by the alginic acid from a 65 % ethanolic solution having an acidity of pH 2.8—3.4. The bulk of fats remains in the alcoholic extract from which the alcohol is recovered in an ordinary rectifying column. The insulin is eluted from the alginic acid with 0.2—0.3 N aqueous hydrochloric acid. The stability of the molecule of the alginic acid, its chain-like structure [19] and the strong ionization of the carboxylic groups of this polyhydroxyacid at pH 3.4 [11] could explain its usefulness in this respect.

Since the previous technique of manufacturing insulin required an elaborate distillation plant with evaporators, condensers, vacuum pumps and a heavy cooling machinery, demanding both manpower, steam and electricity

* Jorpes, J. E., Mutt, V. and Rastgeldi, S. Swedish patent 157, 387 Oct. 18, 1956. Priority date Feb. 9, 1955, Swed. patent 162, 669 Jan. 23, 1958, Britt. patent 797, 959 Oct. 29, 1958, U.S. patent 2, 878, 159 March 17, 1958.

to run it, the possibility of taking up the insulin directly on an ion-exchanger completely altered the large-scale manufacturing process.

EXPERIMENTAL

The minced frozen glands are extracted with the ordinary amount of ethyl alcohol, acidified with oxalic acid (30 g per kg pancreas, dissolved in water), citric acid (70 g per kg) or preferably phosphoric acid (15—20 ml conc. per kg).

In this procedure as in the old one ammonia is added to pH 8.0 and the proteins precipitated are removed. The ammonium ions present would prevent the adsorption on the alginic acid and are therefore to be removed. This is achieved by means of Dowex-50 in the hydrogen form, added step-wise until pH 3.2 is reached. The ion-exchanger is collected for regeneration with acid.

Before use the alginic acid is washed free of metallic ions with 0.3 N hydrochloric acid and then with water. It is usually stored slightly moistened at —15°C. If dry it must be moistened with water before adding it to the alcoholic extract. *The capacity of new lots of alginic acid to adsorb insulin was constantly low, about 50 % of normal, and increased to an optimum level after 2 regenerations.* Per kg pancreas 30 g of alginic acid is taken, to be left in contact with the extract during 4 h at room temperature under constant stirring. The acid is collected through filtration or centrifugation and washed with 95 % and absolute ethanol in order to remove fats, and the alcohol is removed by aeration. Elution of the insulin is performed with 0.2—0.3 N hydrochloric acid at room temperature. The alginic acid is washed with water and used again for at least 10, possibly 15 times.

Elimination of proteolytic enzymes. In using calf pancreas the procedure worked excellently. When it was applied to ordinary frozen ox pancreas the yield of insulin slowly dropped, until on the sixth to eighth time the alginic acid was in use, no insulin at all precipitated on adding sodium chloride to the eluate. The different behaviour of the calf and the ox pancreas could hardly be due to anything else than a destruction of the insulin through enzymes still present in the extract and accumulated on the alginic acid during its repeated use. As most clearly demonstrated by Birgitta Werner [12] in 1948, the enzyme-producing apparatus of the pancreas is, in man, not yet fully developed in the newborn.

We therefore together with Mr Gunnar Lindén of Vitrum AB after removal of the Dowex-50 heated the alcoholic extract of the ox pancreas at pH 3.2 before addition of the alginic acid. The yield of insulin then even exceeded the expected level and the product crystallized readily. This also applies to the hog pancreas. After introducing this procedure of raising the temperature of the alcoholic extract up to 70—75°C in the course of 30 min, and cooling it to 30°C during a further 30 min — a procedure which destroys the proteolytic enzymes — the manufacturing process ran smoothly.

The yield of insulin depends not only upon the manufacturing process, but also upon the gland material available. Old dairy cows, an important source of glands in some countries, may have as low an insulin level in the pancreas as 400—500 units per pound, whereas the corresponding figure for young cattle is about 2 000 units. The collection and the storage of the glands also influence the yield. The heaviest losses are of course made during the concentration of the alcoholic extract, particularly if the distilling equipment is less efficient. The new procedure eliminates this risk, thereby increasing the yield of insulin with at least 20—30 %. The simultaneous gain through the saving of laboratory space, equipment, power consumption and labour add further to the value of the technique.

The Action of Intestinal Microorganisms on Bile Acids

Bile Acids and Steroids 101

ARNE NORMAN* and SVEN BERGMAN

Department of Physiological Chemistry and Department of Bacteriology, University of Lund, Lund, Sweden

The transformation of cholic-24-^{14}C acid by intestinal microorganisms of the rat in aerobic and anaerobic cultures has been studied. 7-Ketodeoxycholic, deoxycholic, 12-ketolithocholic and 3,12-diketocholanic acids were isolated from the cultures and identified. 7-Ketodeoxycholic acid was the main metabolite formed in the aerobic cultures. The removal of the hydroxyl group at C-7 in cholic acid was mainly effected by anaerobic microorganisms. The ability of different intestinal miroorganisms to transform cholic acid was also tested. Certain strains of *Escherichia coli* and *Clostridium perfringens* oxidize cholic acid to 7-ketodeoxycholic acid.

Numerous bacteria and fungi are known to transform bile acids and related steroids into a variety of metabolites both *in vivo* and *in vitro* (see, *e.g.*, the reviews by Haslewood [1] and Talalay [2]). When labelled bile acids are given to rats, their radioactive metabolites occur as a complicated mixture of unconjugated compounds in the feces [3,4]. The products of purely microbial transformation of cholic acid have been isolated from the feces of rats with biliary fistula following the injection of cholic-24-^{14}C acid into the caeca. The main metabolites have been identified as 3α, 12α-dihydroxy-7-ketocholanic, deoxycholic and 3α-hydroxy-12-ketocholanic acids [5,6]. Small amounts of at least four unidentified labelled products were also isolated from the feces specimens.

In the present investigation we have studied the microbial transformation of cholic acid *in vitro*. The metabolites of the acid formed in cultures of both aerobic and anaerobic intestinal microorganisms were isolated and the major metabolites were identified. Also different bacterial strains isolated from the caecum of the rat were tested for their ability to transform cholic acid.

* Present address: Department of Chemistry, Karolinska Institutet, Stockholm, Sweden.

EXPERIMENTAL

Bile acids. 24-^{14}C-Labelled cholic, deoxycholic and chenodeoxycholic acids were prepared by the procedure of Bergström, Rottenberg and Voltz [7].

Taurocholic-24-^{14}C and glycocholic-24-^{14}C acids were synthesized as described by Bergström and Norman [24]. The conjugated bile acids were isolated from the products of the reactions by reversed-phase partition chromatography [8].

7-Ketodeoxycholic acid (3α,12α-dihydroxy-7-ketocholanic acid) was obtained by oxidizing cholic acid with N-bromosuccinimide [9] and was crystallized in the form of its methyl ester from ethyl acetate-light petroleum. The melting point of the methyl ester was 153—155°C.

7-Ketolithocholic acid (3α-hydroxy-7-ketocholanic acid) was synthesized as described by Samuelsson [10] and was kindly supplied by him.

12-Ketolithocholic acid (3α-hydroxy-12-ketocholanic acid) was prepared according to Bergström and Haslewood [11]. Its melting point was 160—161°C.

3,12-Diketocholanic acid was synthesized by chromic acid oxidation of deoxycholic acid. It melted at 183—185°C.

Column chromatography. The technique of reversed-phase partition chromatography developed by Bergström, Sjövall and Norman [12-14] was employed using the following phase systems:

Phase system	Moving phase (ml)	Stationary phase (ml)
C 1	methanol-water 150—150	chloroform-*iso*octanol 15—15
C 2	methanol-water 144—156	chloroform-*iso*octanol 15—15
C 4	methanol-water 165—135	chloroform-*iso*octanol 15—15
F 1	methanol-water 165—135	chloroform-heptane 45— 5
F 3	methanol-water 180—120	chloroform-heptane 45— 5.

Four ml of the stationary phase was supported on 4.5 g of hydrophobic Super Cel.

Paper chromatography. The routine method employed to isolate the metabolites of cholic acid-24-^{14}C produced by different microorganisms was the paper chromatographic method developed by Sjövall [15,16]. Specimens of broth culture media, 0.05 ml in volume, were run on strips of Whatmann 3 MM paper 1.5 cm wide. Cholic acid and 7-ketodeoxycholic acid were separated by descending paper chromatography with *iso*propyl ether-heptane (50:50 v/v) as the moving phase. The more hydrophobic metabolites, including deoxycholic acid, were separated from unchanged cholic acid by ascending paper chromatography with 70 % acetic acid as the stationary phase and *iso*propyl ether-heptane (85:15 v/v) as the moving phase.

Radioassays. ^{14}C was determined with a Tracerlab end-window or a gas-flow counter. The radioactivity on the paper chromatograms was measured with an automatic scanning device with a G.M. tube.

Bacteriological procedures. The culture medium employed was a placenta digest broth prepared according to Erlansson [17] to which 10 μg of labelled bile acid had been added per ml. After autoclaving, the broth media were inoculated with different strains of intestinal microorganisms or fecal suspensions and incubated at 37°C under aerobic or anaerobic conditions. The anaerobic cultures were incubated in an anaerobic jar of the Fildes-McIntosh type.

RESULTS

Transformation of cholic acid by intestinal microorganisms in vitro. A loopful of the caecal content from rats was transferred to broth containing cholic-24-^{14}C acid. After either aerobic or anaerobic incubation for seven days, the labelled compounds in the broth were separated by column chromatography.

Fig. 1 shows chromatograms of the metabolites formed in anaerobic cultures of caecal microorganisms. Chromatographic analysis of the ether extract

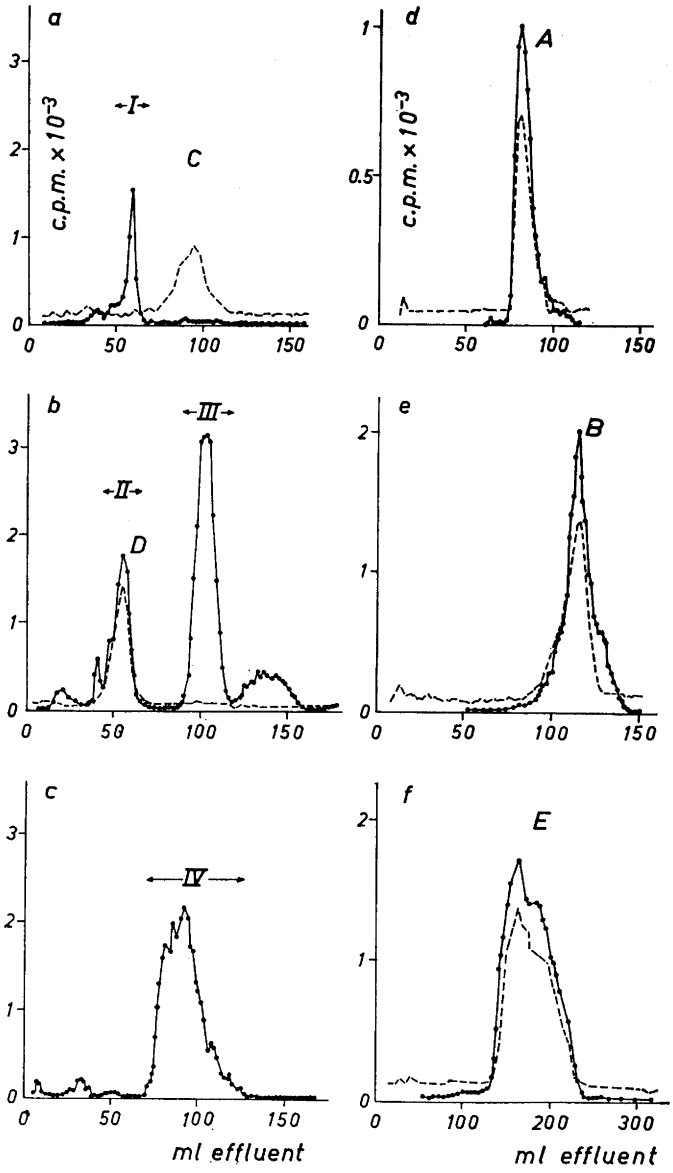

Fig. 1. Separation of metabolites of cholic acid formed in anaerobic cultures of caecal microorganisms. The following fractions were subjected to chromatography. *a*: Ether extract of the broth. Phase system C 1. *b*: Labelled compounds remaining in the stationary phase after the preceding chromatographic elution. Phase system F 1. *c*: Labelled compounds remaining in the stationary phase after the preceding chromatographic elution. Phase system F 3. *d*: Radioactive band I. Phase system C 2. *e*: Radioactive band III. Phase system F 1 *f*: Radioactive band IV. Phase system C 4. Reference substances: cholic (C), deoxycholic (D), 7-ketodeoxycholic (A), 12-ketolithocholic (B), 3, 13-diketocholanic (E) acids. ●—●—●, radioactivity; ————, titration.

of the broth medium with phase system C 1 yielded the chromatogram shown in Fig. 1 a. A separation of 3,12-dihydroxy-7-ketocholanic acid (in effluent fraction 60—70 ml), 3-hydroxy-7,12-diketocholanic acid (80—110 ml) and 3,7,12-triketocholanic acid (110—150 ml) is effected by this phase system. The only labelled compound (I) was found in the effluent fraction where 7-ketodeoxycholic acid is eluted. Most of the radioactive compounds were retained in the stationary phase. When the chromatographic analysis of these metabolites was continued with phase system F 1 (Fig. 1 b) three radioactive bands were eluted; the first two emerged in the effluent fractions where a dihydroxycholanic acid (II) and a monoketomonohydroxycholanic acid (III) were expected. The remaining labelled material in the stationary phase was eluted at 70—100 ml (IV) when phase system F 3 was employed (Fig. 1 c). Lithocholic and 3,12-diketocholanic acids are eluted at about the same rate (70—100 ml) by phase system F 3. To separate these we employ *iso*octanol-chloroform instead of heptane-chloroform as the stationary phase because *iso*octanol retains hydroxy derivatives of cholanic acid more effectively than it retains the keto derivatives of the acid. When phase system C 4 is employed, 3,12-diketocholanic acid is eluted in the effluent fraction 100—210 ml, whereas lithocholic acid stays in the stationary phase. Rechromatography of compound IV with phase system C 4 showed that it behave like 3,12-diketocholanic acid (Fig. 1 f).

The analyses thus showed that no unchanged cholic acid was left in the anaerobic cultures of caecal microorganisms, but instead five metabolites had been formed. Radioactive bands appeared in the effluent fractions where 7-ketodeoxycholic acid (I), 3,12-diketocholanic acid (IV), a dihydroxycholanic acid (II) and a monoketomonohydroxycholanic acid (III) appear. These radioactive metabolites were rechromatographed together with appropriate inactive carriers: fraction I with 7-ketodeoxycholic acid, fraction II with deoxycholic acid, fraction III with 12-ketolithocholic acid, and fraction IV with 3,12-diketocholanic acid. As seen from Fig. 1, the titration peaks coincided with the radioactive peaks. The identities of the metabolites were also confirmed by determining the specific activities after they had been recrystallized together with the inactive reference compounds. The identity of the fifth metabolite (effluent fraction 120—160 ml, Fig. 1 b) was not established.

Chromatographic separations of metabolites formed in aerobic cultures of caecal microorganisms showed that a complete transformation of cholic acid had occurred also in these cultures. The separated metabolites appeared in the same places in the chromatograms as the metabolites produced in the anaerobic cultures. The quantitative distribution, however, was different. More than 80 % of the cholic acid was transformed into deoxycholic, 12-ketolithocholic and 3,12-diketocholanic acids in the anaerobic cultures, whereas only 10 % was transformed into these metabolites in aerobic cultures of the same inocula. It is thus obvious that anaerobic microorganisms are responsible for the removal of the 7α-hydroxyl group. The main metabolite formed in the aerobic cultures was 7-ketodeoxycholic acid. Oxidation of cholic acid to 3-hydroxy-7,12-diketocholanic or 3,7,12-trihydroxycholanic acid was not found to occur.

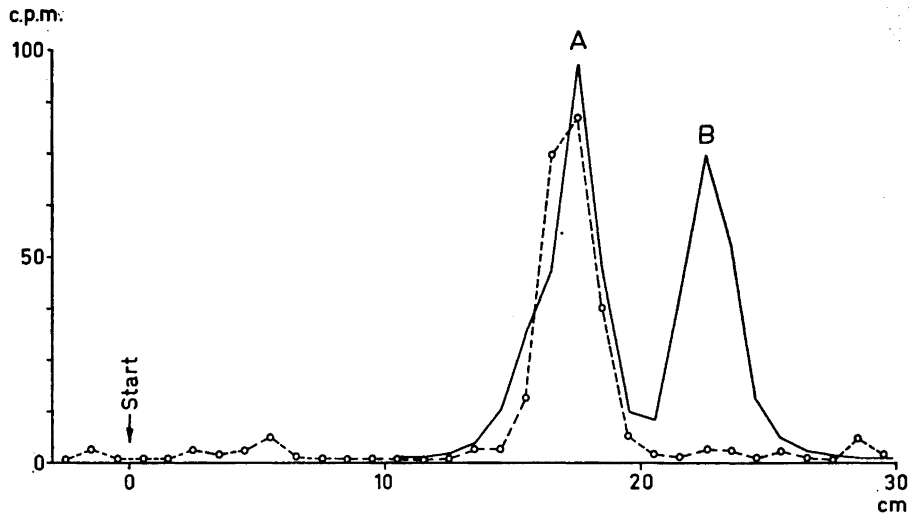

Fig. 2. Descending paper chromatography with *iso*propyl ether-heptane (50—50) as moving phase. ————, 24-^{14}C-labelled 7-ketodeoxycholic (A) and cholic (B) acids. O—O—O, 0.05 ml of a broth originally containing cholic acid-24-^{14}C incubated seven days after inoculation with *E. coli*.

Transformation of cholic acid by microorganisms isolated from the rat caecum. A number of aerobic and anaerobic intestinal microorganisms were isolated from the rat caecum. A loopful or organisms from a blood agar plate was inoculated into the broth and incubated for seven days. The ability of the organisms to transform cholic acid was determined by paper-chromatographic analysis. Of the isolated strains the following were found to be inactive: various strains of aerobic and anaerobic streptococci, *B. proteus*, *Pseudomonas pyocyanea*, *Aerobacter aerogenes*, *Staphylococcus aureus* and *albus*, *B. subtilis*, *diphtheroids* and some *candida* and *streptomyces* strains.

Different strains of *E. coli* transformed cholic acid completely into a labelled compound that appeared in the chromatogram in the same place as 7-ketodeoxycholic acid (Fig. 2). The same transformation was effected by strains of *Clostridium perfringens*. No intestinal microorganisms have yet been isolated that are capable of removing the 7α-hydroxyl group from cholic acid.

Oxidations of bile acids by E. coli and Clostridia. Fig. 3 shows chromatograms of broth specimens containing cholic acid that had been incubated 24 and 72 h after inoculation with *E. coli*. After three days the cholic acid had been completely transformed into a compound with the same chromatographic behaviour as 7-ketodeoxycholic acid (Fig. 4 a). An aliquot of the labelled metabolite was treated with chromic acid under conditions known to oxidize 7-ketodeoxycholic acid to dehydrocholic acid. After rechromatography the radioactivity then moved with dehydrocholic acid added as carrier. After its reduction with sodium borohydride the labelled compound exhibited the same

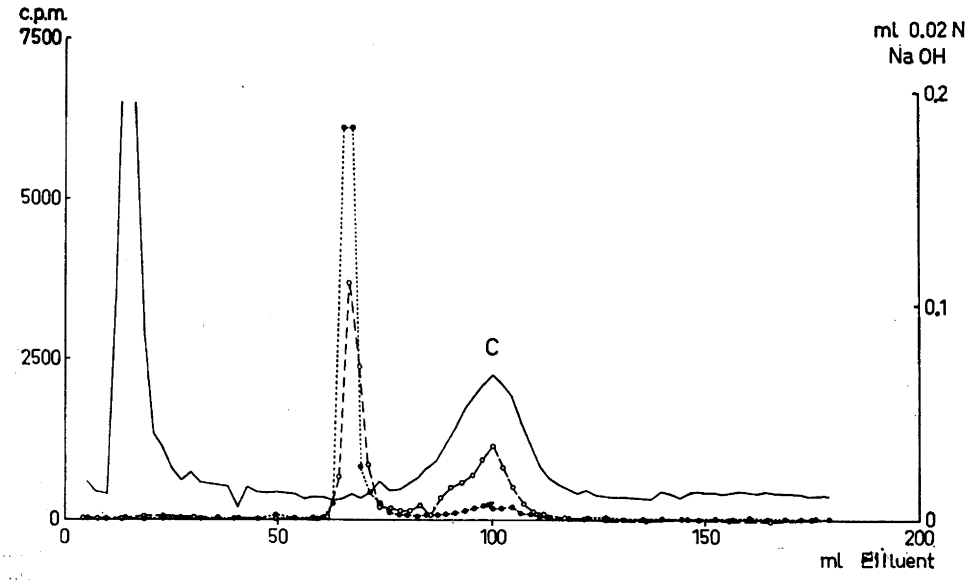

Fig. 3. Separation of labelled products formed in a broth originally containing cholic acid-24-^{14}C and inoculated with a strain of *E. coli* after 24 (O—O—O) and 72 (●—●—●), hours incubation. Phase system C 1. Reference substance: cholic acid (C). ———— titration.

Fig. 4. b: Chromagraphy of metabolites of cholic acid-24-^{14}C formed by *Clostridium perfringens* type E during seven days' incubation. Phase system C 1. Reference substance: 7-ketodeoxycholic acid (A). ————, radioactivity; — — — — —, titration.

Table 1. Transformation of cholic acid into 3,12-dihydroxy-7-ketocholanic acid by different strains of *E.coli* isolated from human feces. 5 ml of inoculated placenta broth containing 0.1 mg of cholic acid-24-^{14}C were cultured one and seven days. The quantitative estimates were based on paper-chromatographic analyses.

All the *E.coli* strains produced acid from arabinose, glucose, maltose and mannitol (also gas) and also produced indole.

chromatographic behaviour as cholic acid. The identity of the metabolite was confirmed further by recrystallizing it together with unlabelled 7-ketodeoxycholic acid. The specific activity remained constant through five recrystallizations.

E. coli strains are capable of oxidizing only the hydroxyl group at C-7 as no oxidation to 3-hydroxy-7,12-diketocholanic or 3,7,12-trihydroxycholanic acid was established. Chenodeoxycholic acid was transformed in cultures of *E. coli* into a compound that behaved like 12-ketolithocholic acid (Fig. 5 a) in chromatography and which was further identified by cocrystallization with unlabelled 12-ketolithocholic acid. No oxidation of deoxycholic acid occurred (Fig. 5 b) in similar tests. Experiments with 24-^{14}C-labelled glycocholic and taurocholic acids have shown that these conjugates undergo a similar oxidation by *E. coli*. No splitting of peptide bonds was observed.

Sixteen strains of *E. coli* isolated from human feces were tested for their ability to oxidize cholic acid to 7-ketodeoxycholic acid (Table 1). All the strains except one effected a rapid and complete oxidation of the cholic acid.

In a previous study [18] it was found that different strains of *Clostridium perfringens* quickly hydrolyze conjugated bile acids and transform a minor part of cholic acid into a more polar compound. Fig. 4 b shows a chromatogram of a broth culture of *Clostridium perfringens* type E originally containing cholic-24-^{14}C acid. The metabolite formed was eluted at the same rate as 7-ketodeoxycholic acid. It was identified as 7-ketodeoxycholic acid in the manner described above.

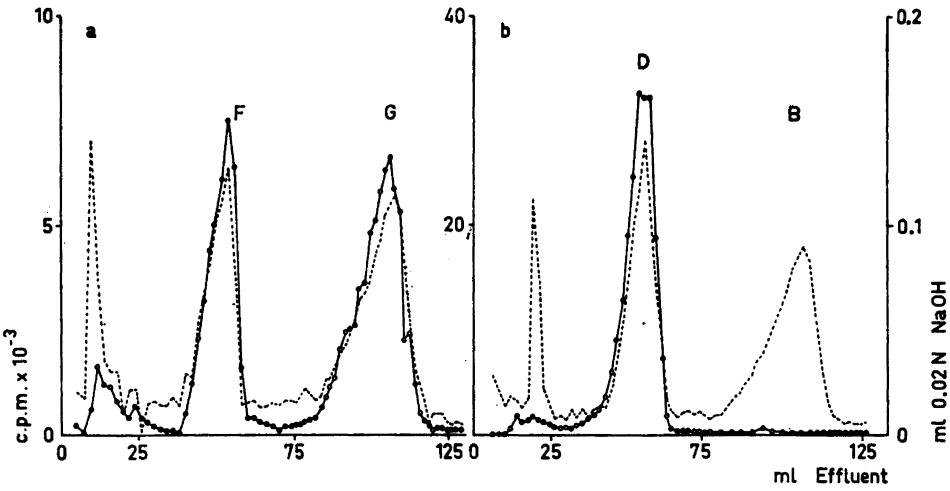

Fig. 5. Chromatographic analyses of three-day-old broth cultures of *E. coli*. *a*: broth originally contained chenodeoxycholic acid 24-^{14}C. *b*: broth originally contained deoxycholic acid-24-^{14}C. Phase system F 1. Reference substances: deoxycholic (D), chenodeoxycholic (F), 12-ketolithocholic (B) and 7-ketolithocholic (G) acids. ————, radioactivity; — — — — —, titration.

DISCUSSION

A transformation of cholic acid similar to that taking place *in vivo* is effected by anaerobic caecal microorganisms *in vitro*. The 7*α*-hydroxyl group is removed for the most part. Whereas the greater part of deoxycholic acid is excreted unchanged by the rat, the acid is for the most part oxidized by caecal microorganisms in vitro to 12-keto-3-hydroxycholanic and 3,12-diketocholanic acids. However, the caecal microorganisms more quickly remove the 7*α*-hydroxyl group than oxidize the hydroxyl groups at C-3 and C-12.

Schmidt and Hughes [19,20] demonstrated that a rapid and extensive decomposition of cholic acid occurs in the caecum of the guinea pig. They assumed this to be mainly due to an oxidative breakdown of the acid by strains of *Alcaligenes faecalis via* 7-keto-3,12-dihydroxycholanic and 7,12-diketo-3-hydroxycholanic acids to 3,7,12-triketocholanic acid. We have found that a rapid oxidation of cholic acid to 7-ketodeoxycholic acid occurs in aerobic cultures of microorganisms isolated from the rat caecum where the removal of the 7-*α*-hydroxyl group takes place only in minor degree. No further oxidation of the hydroxyl groups at C-3 and C-12 in cholic acid has been demonstrated. Neither 7,12-diketo-3-hydroxycholanic nor 3,7,12-triketocholanic acids has been isolated from the rat feces.

Turfitt [21] and Hayakawa *et al.*[22] have reported that the bile acid side chain is degraded by *Proactionomyces* and *Streptomyces gelatinus* 1164, respectively. Our experiments with 24-^{14}C-labelled cholic acid did not provide any evidence showing that a degradation of the bile acid side chain occurs in cultures of

microorganisms isolated from the rat caecum. Several investigators [22,23] have shown that cholic acid is oxidized to derivates of 3-keto-Δ^4-cholanic acid by different microorganisms. The formation of such compounds by intestinal microorganisms of the rat seems to be of minor degree.

Isolation of Seromucoids from Human Serum

JOHN GOA

Department of Medical Biochemistry, University of Gothenburg, Sweden *

A mixture of seromucoids has been prepared by means of fractional precipitation with perchloric acid and phosphotungstic acid. The seromucoids were separated into three fractions by means of chromatography on DEAE-cellulose. Each fraction was separated into subfractions by preparative paper electrophoresis, a total of seven fractions being obtained. One fraction was shown to be identical with MP-1 of Winzler or α_1-acid glycoprotein of Schmid. With the unfractionated seromucoid mixture six to eight precipitation lines were obtained immunologically by gel precipitation technique. Some chemical data of the proteins are given, — they are all rich in carbohydrate.

According to Winzler [1] seromucoids means a heterogeneous group of serum proteins left in solution by perchloric acid and precipitated by phosphotungstic acid. These proteins are rich in carbohydrate, which can be split from the protein only by very drastic treatment, and differ from other glycoproteins by their higher solubility.

Zanetti [2], Bywaters [3] and Rimington [4] prepared proteins of this type from the filtrate after heat coagulation of the bulk of the serum proteins. Winzler *et al.*[5] prepared them by ammonium sulphate precipitation of the perchloric acid filtrate of serum, and by means of electrophoresis found three components. The largest component moved like α_1-globulin at pH 8.4, the two other and smaller components moved slower [6]. The first component was subsequently prepared in pure state by ammonium sulphate precipitation of serum [7], and the chemical composition was studied. It was called M-1 or MP-1.

From Cohn-fraction VI, Schmid [8,9] isolated an α_1-acid glycoprotein which was shown to be identical with Winzlers MP-1. Later on Schmid isolated another carbohydrate-rich protein [10,11] which moved like α_2-globulin at pH 8.6. This protein, however, was heterogeneous in acetate buffer at pH 3.5 where it showed three components.

* Present address: Central Laboratory, Rikshospitalet, Oslo, Norway.

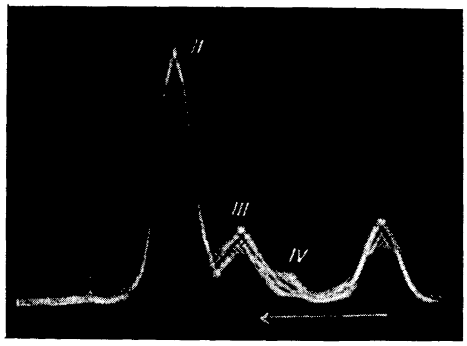

Fig. 1. Moving boundary electrophoresis of seromucoids. Barbital buffer pH 8.6, $\mu = 0.1$. Temp. + 1.5°C. Potential: 7.60 V/cm. Time:115 min. descending.
Mobility: I -8.2×10^{-5} cm²/V sec.
II -5.7×10^{-5} cm²/V sec.
III -3.5×10^{-5} cm²/V sec.
IV -1.9×10^{-5} cm²/V sec.

Of the seromucoids mentioned here, only Winzlers MP-1 or Schmids α_1-acid glycoprotein has been characterized. This protein has also been called orosomucoid [1].

During recent years chromatography on different ion exchangers has been used for isolation and purification of many proteins. Peterson and Sober [12] introduced several derivatives of cellulose, of which diethylaminoethyl-(DEAE)-cellulose has been especially useful. In the present study a combination of fractional precipitation, chromatograhy on DEAE-cellulose and preparative paper electrophoresis has been used for isolation of some carbohydrate-rich serum proteins which are not precipitated by perchloric acid.

METHODS OF PREPARATION

Fractional precipitation

One volume of serum or plasma was diluted with one volume of 0.9 % sodium chloride and precipitated by addition of two volumes of 1 M perchloric acid (final concentration 0.5 M). The precipitate was immediately centrifuged off or filtered. To the filtrate was added 1/20 volume of 2 % phosphotungstic acid in 2 N hydrochloric acid, the precipitated

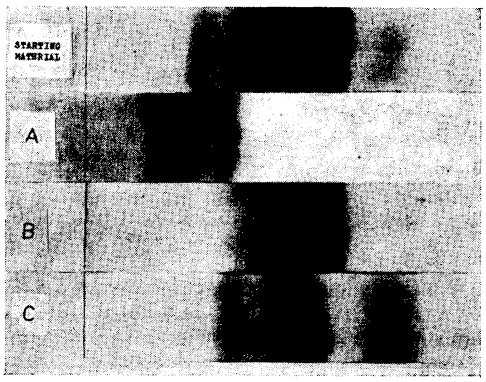

Fig. 2. Paper electrophoresis of seromucoids in barbital buffer pH 8.6. Starting material is the serum proteins left in solution by perchloric acid. A, B, and C are the fractions obtained by chromatography on DEAE-cellulose. The fractions are concentrated before electrophoresis and there is no quantitative relation between the amount of protein on the papers and the proportions in which they are present in the starting material.

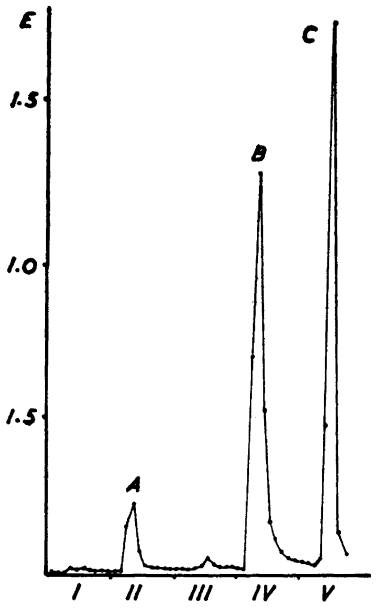

Fig. 3. Elution curve of 110 mg seromucoids. The Roman figures indicate the eluting buffers. I = 0.005 M phosphate, II = 0.005 M phosphate + 0.08 N sodium chloride, III = 0.05 M phosphate, IV = 0.05 M phosphate + 0.1 N sodium chloride and V = 1 N sodium chloride + 0.1 N sodium hydroxide. In all phosphate buffers pH was 6.8–6.9.

seromucoids were centrifuged off and dissolved by dropwise addition of 0.1 N sodium hydroxide to pH 6–7. To the solution obtained was added three times its volume of 95 % ethanol, and centrifuged. The precipitate was dissolved in distilled water and dialyzed. At pH 8.6 it consists electrophoretically of four fractions as shown in Figs. 1 and 2.

Chromatography

DEAE-cellulose was prepared exactly according to Sober *et al.*[13] The nitrogen content of the dried powder was 1.3 %. The cellulose ion exchanger was equilibrated with 0.005 M phosphate buffer pH 6.9 and packed in chromatographic columns (25 × 200 mm, fitted with a G2 sintered glass disk). The length of the cellulose columns were 6–7 cm. The proteins were eluted stepwise by increasing the ionic strength of the eluting buffer.

Step I. About 200 mg seromucoids were applied on each column at room temperature. All the protein was adsorbed to the cellulose, and an addition of 100 ml 0.005 M phosphate buffer resulted in no elution of protein.

Step II. The composition of the eluting buffer was changed to 0.005 M phosphate + 0.08 N sodium chloride, pH 6.9. The protein eluted with this buffer was called fraction A, and a paper electrophoresis strip of this fraction is shown in Fig. 2.

Step III. When no more protein was eluted in step II, some 100 ml 0.05 M phosphate buffer, pH 6.8 was allowed to pass the column, only traces of protein being eluted.

Step IV. The eluting buffer was now changed to 0.05 M phosphate + 0.1 N sodium chloride. The protein eluted was called fraction B and showed electrophoretically one large fraction (about 90 %), followed by a small one (Fig. 2).

Step V. After elution of fraction B about 40 % of the applied protein was left on the column. This protein was eluted with 1 N sodium chloride + 0.1 N sodium hydroxide and called fraction C. Electrophoretically it consists of three components (Fig. 2).

The effluent was collected in 10 ml samples and read in a Beckman DU spectrophotometer at 278 mμ. An elution curve is shown in Fig. 3.

Table 1. The table shows the approximate amounts of the different seromucoids isolated from 1 litre human serum. It also shows the percentage of hexose and hexosamine and the glucosamine/galactosamine ratio in the preparations.

Fraction	mg per litre serum	Hexose in per cent of protein	Hexosamine in per cent of protein	Glucosamine/ galactosamine ratio
A-1	20	6.6	7.1	1 : 0.12
A-2	20	5.1	5.6	1 : 0
B-1	250	16.2	11.3	1 : 0
B-2	25	10.6	10.6	1 : 0.28
C-1	25	7.2	3.5	1 : 1.10
C-2	100	9.3	10.4	1 : 0.35
C-3	75	7.8	8.3	1 : 0.50

Preparative paper electrophoresis

The fractions eluted from the column were dialyzed and concentrated by pervaporation to a concentration of 4—5 % protein. About 0.5 ml of the concentrated solution was placed evenly along a line transversely on 10 × 40 cm Munktell No. 150/20 filter paper strips, and run for 6—7 h with a voltage of 300 V as described previously [14]. The buffer used was barbital pH 8.6, ionic strength 0.05. When the electrophoresis was completed the paper was dried in the air and a strip cut out longitudinally and stained with bromophenol blue. With this strip as reference the protein fractions were cut out, eluted from the paper in 0.9 % sodium chloride, dialyzed and lyophilyzed.

RESULTS

Each of the fractions from the chromatographic column could be separated into subfractions by means of preparative paper electrophoresis. Fraction A was separated into two subfractions, the fastest called A-1, the slowest A-2. Fraction B was also separated into two subfractions, the fastest called B-1, the slowest B-2. Fraction C was separated into three subfractions, which were called C-1, C-2, and C-3, according to their mobilities.

All the isolated subfractions were homogeneous in paper electrophoresis at pH 8.6. The amounts prepared from one litre human serum are given in Table 1.

Table 2. Comparison between analytical data of fraction B-1 and "acid glycoprotein" of Schmid [9].

	Nitrogen per cent of protein	*Hexose* per cent of protein	*Hexosamine* per cent of protein	*Glucosamine/ galactosamine* ratio
Fraction B-1	10.6	16.2	11.3	1 : 0
Acid glycoprotein (own preparation)	11.3	16.4	11.3	1 : 0
Acid glycoprotein (values given by Schmid)	10.7	17.2	11.5	

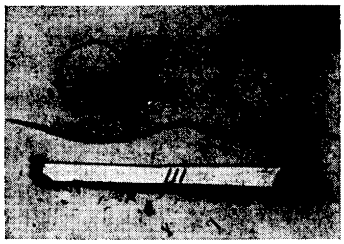

Fig. 4. Immunological identification test of fraction B-1 and "acid glycoprotein". In I 15 µl 5 % fraction B-1, in II 15 µl 5 % "acid glycoprotein" and in III 20 µl antihuman serum from rabbit (Behringwerke). The precipitation lines are stained with Amidoblack.

One of these fractions is well known beforehand, *viz.* fraction B-1, which is also present in largest amount in serum. It is identical with α_1-acid glycoprotein of Schmid or MP-1 of Winzler. To show the identity, α_1-acid glycoprotein was prepared according to the description of Schmid [9]. The protein thus prepared and fraction B-1 were analyzed for nitrogen (micro Kjeldahl), hexose [14], hexosamine [15] and the glucosamine/galactosamine ratio [16]. The values are given in Table 2 together with values given by Schmid [9].

In paper electrophoresis fraction B-1 had the same mobility as α_1-acid glycoprotein, and by moving boundary electrophoresis it moved like α_1-globulin with the mobility -5.7×10^{-5} cm^2/V sec. in barbital buffer pH 8.6 and ionic strength 0.1. In acetate buffer pH 4.5 and ionic strength 0.1 it moved with the mobility -3.2×10^{-5} cm^2/V sec.

Immunological experiments with gel precipitation technique according to the principle of double diffusion as worked out by Ouchterlony [17,18], were carried out with fraction B-1 and α_1-acid glycoprotein. With anti-human serum from rabbit and 2 % agar as diffusion medium, the two preparations gave a common precipitation line indicating identity (Fig. 4).

Fig. 5. The seromucoid preparation (15 µl, 5 %) precipitated in agar against antihuman serum from rabbit (Behringwerke). Four precipitation lines are seen (stained with Amidoblack).

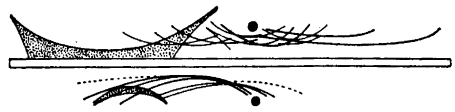

Fig. 6. Immune electrophoresis of normal serum (upper part) and a 10 % solution of the unfractionated seromucoid mixture (lower part).

Of other seromucoids described earlier, *e.g.* MP-2 and MP-3 of Winzler *et al.*[5] or α_2-glycoprotein of Schmid [11] there are no chemical data for comparison.

The content of hexose, hexosamine and the glycosamine/galactosamine ratio for all the fractions are given in Table 1. The values are not corrected for ash and water content except for fraction B-1. It will be seen that they are all rich in carbohydrate.

The possibility exists that some of the fractions described are artefacts or in some way modified proteins. Thus de Vaux St-Cyr *et al.*[19] found a lower mobility of orosomucoid prepared by perchloric acid than with trichloroacetic acid precipitation. However, with the immunological double diffusion gel technique the unfractionated seromucoid mixture showed four precipitation lines (Fig. 5), and by immunoelectrophoresis according to Grabar [20] it showed five distinct lines, one diffuse and two week lines (Fig. 6). When run simultaneously with normal serum the precipitation lines were found in the region of α-globulins (Fig. 6). In a similar preparation de Vaux St-Cyr *et al.*[19] found six precipitation lines.

In a previous paper [21] it has been reported that fraction C-2 and C-3 have antitryptic effect. Work is in progress on preparation and purification of the fractions in a preparative scale.

The author is greatly indebted to Miss Anita Boman for skilful technical assistance.

"Substrate Inhibition" of Intestinal Glycosidases

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The influence of *substrate concentration* on the initial rate of hydrolysis of different glycosides by hog intestinal glycosidases has been studied.

In some cases marked "substrate inhibition" was observed at 0.139 M substrate concentration, which is the concentration previously used as a standard concentration for the determination of intestinal glycosidase activities. *Transglycosylation* plays an important role in the "substrate inhibition" but it is not the only factor involved.

The use of 0.028 M substrate concentration as a standard concentration for the determination of intestinal glycosidase activities, rather than 0.139 M, is recommended. The influence of this lower substrate concentration on the absolute and relative activities of some purified hog intestinal glycosidases, and of crude hog intestinal glycosidase preparations, on different substrates has been determined.

Methods for determination of intestinal glycosidase activities are described, and units for expressing intestinal glycosidase activities are defined.

For studies of glycosidases, 0.139 M substrate is commonly used as a standard concentration [1], and so was done by the present author in a recent investigation of hog intestinal α-glucosidases [2]. During this investigation it was observed, however, that some intestinal α-glucosidases show marked "substrate inhibition" at 0.139 M substrate concentration and that lowering the concentration of substrate resulted in an *increase* of glycosidase activity with these enzymes [3].

A similiar observation has recently been made with invertase from sheep rumen protozoa [4,5]. In that case the authors found 0.025 M sucrose to give maximal invertase activity.

In the present paper a detailed study on the influence of substrate concentration on hog intestinal glycosidase (α-glucosidase, β-galactosidase and β-glucosidase) activities will be reported and procedures for the quantitative determination of intestinal glycosidase activities will be described. Since the standard substrate concentration now recommended is lower than the concentration used earlier, the absolute and relative activities of crude and purified intestinal glycosidase preparations on different substrates have been determined at this new substrate concentration.

RESULTS AND DISCUSSION

Influence of substrate concentration on the activities of isolated intestinal glycosidases

A) α-Glucosidases

The different α-glucosidase activities exerted by extracts from hog intestinal mucosa are caused by a mixture of at least five separate enzymes with varying specificity [2]. Three of these enzymes have been isolated, namely *invertase* (= maltase I), *maltase III* and *trehalase.** The "substrate inhibition" has been studied with each of these enzymes separately.

1) *Invertase.* Purified hog intestinal invertase hydrolyzes *sucrose*, *maltose* and *turanose* [6]. The influence of substrate concentration upon these activities of purified invertase is seen in Fig. 1. V_{max} in the figure has been calculated from the v_{obs} (observed initial velocity of hydrolysis) at *low* substrate concentrations (below 0.06 M) by the graphical method of Lineweaver and Burk [7] as modified by Dixon [8].

When the substrate concentration exceeded 0.1 M, the initial velocity of hydrolysis of all three substrates was *lower* than could be predicted from the Michaelis-Menten equation [9]. The "substrate inhibition" was more marked with *turanose* than with the other two substrates. At 0.28 M substrate concentration the initial velocity of hydrolysis of turanose was 30 % lower than the value calculated from the Michaelis-Menten equation. With sucrose or maltose as substrates the initial velocity at 0.28 M substrate concentration was 10—

* Maltase II has been isolated too, but only in small amounts [3].

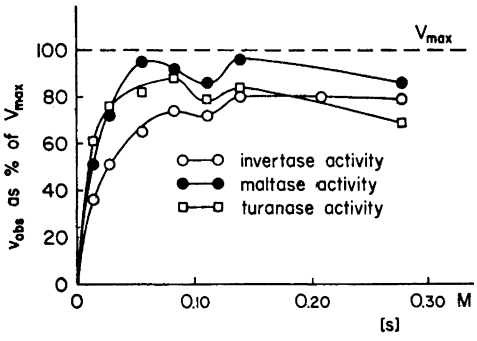

Fig. 1. Influence of substrate concentration, [s], on the invertase, maltase and turanase activities of purified intestinal invertase. Temp. 37°C, pH 6.5 (0.05 M maleate buffer). The observed initial rate of hydrolysis (v_{obs}) is expressed as per cent of V_{max} (calculated from the v_{obs} at low substrate concentrations as described in the text).

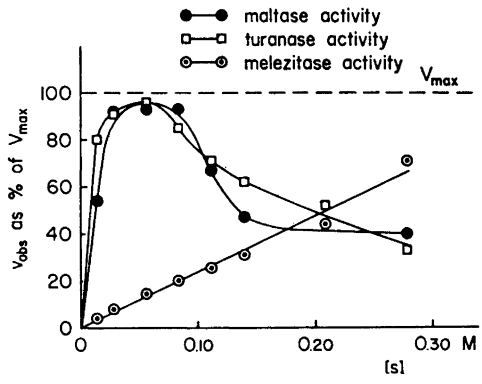

Fig. 2. Influence of substrate concentration on the maltase, turanase and melezitase activities of purified intestinal maltase III. Experimental conditions, see Fig. 1.

15 % too low. These findings suggest that *transglycosylation* may be the cause of the "substrate inhibition", since the invertase and maltase activities were measured with reducing sugar methods, which measure both the glycon and the aglycon liberated, while the turanase activity was measured with a glucose oxidase reagent, which measures only the glycon liberated. If transglycosylation is the cause of the "substrate inhibition" the amount of glycon liberated will be lower than the amount of aglycon liberated.

To elucidate whether transglycosylation was the cause of the "substrate inhibition" the amounts of glucose (glycon) and fructose (aglycon) liberated during the hydrolysis of turanose were measured separately by quantitative paper chromatography [10]. The amount of glucose liberated at 0.28 M substrate concentration was 31 % lower than the amount of fructose liberated. This indicates that transglycosylation is the main factor responsible for the "substrate inhibition" of this enzyme.

An irregularity of the shape of the curve between 0.08 and 0.15 M substrate concentration was observed with all three activities (Fig. 1). The cause of the irregularity is not known. It may indicate that more than one factor is involved in the "substrate inhibition" of intestinal invertase.

2) *Maltase III.* Purified hog intestinal maltase III hydrolyses *maltose, isomaltose, turanose, phenyl-α-D-glucopyranoside* and *melezitose* [2,3,11]. The influence of substrate concentration upon the maltase, turanase and melezitase activities of this enzyme is seen in Fig. 2.

With this enzyme the "substrate inhibition" of the maltase and turanase activities was considerably more marked than with the activities exerted by invertase (= maltase I) (Fig. 1). When the substrate concentration exceeded 0.05 M, the initial velocity of hydrolysis of these substrates was lower than calculated from the Michaelis-Menten equation and at 0.28 M substrate concentration the initial velocity was about 60 % lower.

With the melezitase activity no "substrate inhibition" could be demonstrated. This fact is, however, readily explained by the low affinity of the enzyme for melezitose (see Fig. 2) [11,13].

As was done in the experiments with purified invertase described above, the amounts of glucose and fructose liberated from turanose by maltase III were measured separately. At 0.28 M substrate concentration the amount of glucose liberated was 35 % lower than the amount of fructose liberated. This indicates that the transglycosylase reaction also with maltase III plays an important role in the "substrate inhibition", although it can explain only a part of the inhibition.

3) *Trehalase.* Purified hog intestinal trehalase differs from the two enzymes described above by that it hydrolyzes only one single substrate, namely *α,α-trehalose* [12]. The influence of substrate concentration upon trehalase activity is seen in Fig. 3. No "substrate inhibition" could be demonstrated with this enzyme. In other experiments substrate concentrations as high as 0.8 M (= 30 % trehalose) were used without any decrease of trehalase activity. It is known that intestinal trehalase, in contrast to other intestinal glycosidases, has no transglycosylase activity [12].

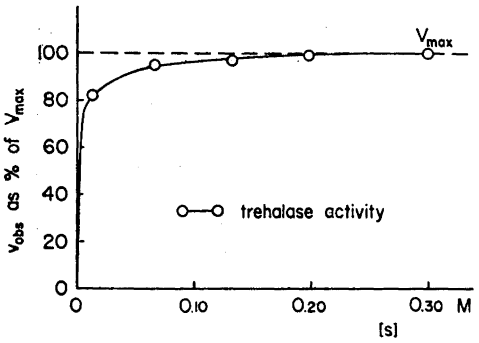

Fig. 3. Influence of substrate concentration on the activity of purified intestinal trehalase. Temp. 37°C, pH 6.0 (0.05 M maleate buffer).

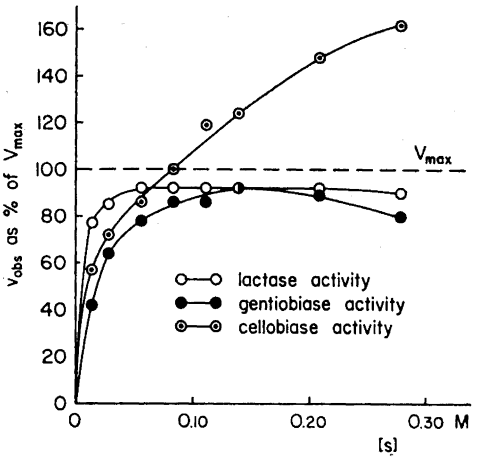

Fig. 4. Influence of substrate concentration on the lactase, cellobiase and gentiobiase activities of a crude hog intestinal glycosidase preparation. Temp. 37°C, pH 6.0 (0.05 M maleate buffer). When the substrate concentration exceeds 0.10 M, the observed initial rate of hydrolysis (v_{obs}) of cellobiose exceeds the V_{max} calculated from the v_{obs} at substrate concentrations below 0.06 M.

B) β-Galactosidase and β-Glucosidase

Hog intestinal mucosa preparations hydrolyze *lactose*, which is a β-galactoside, and a number of β-glucosides as *cellobiose*, *gentiobiose* and *phenyl-β-D-glucopyranoside*. The relation between these activities is under current investigation, but preliminary results indicate that the β-galactosidase and β-glucosidase activities of hog intestinal mucosa are caused by one single enzyme, intestinal lactase. The activities on these substrates therefore were studied with crude hog intestinal glycosidase preparations, obtained as described earlier [2].

The influence of substrate concentration upon the *lactase*, *cellobiase* and *gentiobiase* activities of a crude hog intestinal glycosidase preparation is seen in Fig. 4. The "substrate inhibition" of the lactase and gentiobiase activities is relatively weak. Up to 0.1 M substrate concentration these activities followed the Michaelis-Menten relationship. At 0.28 M substrate concentration the lactase activity was 10 % and the gentiobiase activity 15 % lower than calculated. The velocity of hydrolysis of these substrates was measured with the glucose oxidase reagent, and therefore with lactose as substrate only the *aglycon* (glucose) liberated was measured. The *glycon* (galactose) does not react with this reagent. This means that even if the transglycosylase reaction may contribute to the "substrate inhibition" of lactase, it is not the only factor

involved, for in that case the rate of liberation of the aglycon would not have decreased.

The *cellobiase* activity shows a behaviour quite different from that of the other activities studied in the present paper. It shows "substrate *activation*" rather than "substrate innibition". At low substrate concentration (0.01—0.06 M) the cellobiase activity seemed to follow the Michaelis-Menten equation, but when the substrate concentration was further increased, the velocity of hydrolysis became considerably greater than the V_{max} calculated from the values obtained at low substrate concentrations (Fig. 4). This phenomenon appeared in repeated experiments. At present no explanation can be given for this behaviour of the cellobiase activity.

The choice of a standard substrate concentration

As was pointed out in the introduction of the present paper, 0.139 M is commonly used as a standard substrate concentration for glycosidase activity determinations. From the results described above it appears, however, that some of the intestinal glycosidases show marked "substrate inhibition" at that concentration. In studies of intestinal glycosidases it seems preferable therefore, to use 0.028 M substrate as a standard concentration. At that substrate concentration all the activities hitherto studied (with the exception of melezitase, which has an extremely high K_s value [11]) will yield a velocity of hydrolysis which is more than 50 % of V_{max}.

There is one additional advantage in using the more dilute substrate as a standard concentration. The low solubilities of heteroglycosides (*e.g.* phenylglycosides) make it difficult to prepare reaction mixtures with 0.139 M concentration of these substrates [3]. The preparation of a reaction mixture with 0.028 M substrate will, however, not be difficult in these cases.

If 0.028 M substrate is selected as a standard concentration for the determination of intestinal glycosidase activities, the figures earlier reported [2,3] for the relative activities on different substrates of crude intestinal glycosidase preparations and of purified intestinal glycosidases will have to be recalculated. A comparison therefore was made of the relative activities of intestinal glycosidases on different substrates at 0.139 M and at 0.028 M substrate concentration.

Relative activities at 0.139 M and at 0.028 M substrate concentration

The lowering of the standard substrate concentration for determination of intestinal glycosidase activities to 0.028 M will result in the following alterations of the absolute and relative rates of hydrolysis of different substrates.

A. Isolated enzymes

1) *Invertase* (= *Maltase I*). The *invertase* activity will *decrease* by 40 %, the *maltase* activity by 30 % and the *turanase* activity by about 10 % (Table 1). The *maltase/invertase activity quotient* of purified invertase (maltase I)

Table 1. Relative activity of purified hog intestinal invertase (= maltase I) on different substrates at 0.139 M and 0.028 M substrate concentration in the presence of 0.05 M maleate buffer pH 6.5 and at temperature 37°C. The maltase activity of the enzyme at 0.139 M substrate concentration has been arbitrarily set at 100.

Substrate	Relative activity at 0.139 M substrate concentration	Relative activity at 0.028 M substrate concentration
Maltose	100	75
Sucrose	170	110
Turanose	7.5	7.0

thus will increase from 0.6 to 0.7, and the *turanase/invertase activity quotient* from 0.04 to 0.06.

2) *Maltase II.* The influence of the substrate concentration upon the activities of purified maltase II has not been studied, but from the similiarity of this enzyme with maltase III may be expected that the dilution of the substrate will *increase* the rate of hydrolysis of the different substrates hydrolyzed by maltase II. This theory was confirmed by the alteration of the total maltase activity of a *crude* hog intestinal glycosidase preparation (Table 4).

3) *Maltase III.* The *maltase* activity of this enzyme will increase by 100 % (Table 2). Also the *isomaltase* and *turanase* activities of this enzyme will increase. The *phenyl-α-D-glucopyranosidase* activity will not be measurably affected. The *melezitase* activity, due to the low affinity of the enzyme for this substrate, will be lowered by 75 %.

The *isomaltase/maltase activity quotient* will decrease from 0.05 to 0.04, the *turanase/maltase activity quotient* from 0.06 to 0.05, the *phenyl-α-D-glucopyranosidase/maltase activity quotient* from 0.05 to 0.03 and the *melezitase/maltase activity quotient* from 0.0040 to 0.0005.

4) *Trehalase.* The *trehalse* activity will be lowered by about 10 %.

Table 2. Relative activity of purified hog intestinal maltase III on different substrates at 0.139 M and at 0.028 M substrate concentration in the presence of 0.05 M maleate buffer pH 6.5 and at temperature 37°C. The maltase activity of the enzyme at 0.139 M substrate concentration has been arbitrarily set at 100.

Substrate	Relative activity at 0.139 M substrate concentration	Relative activity at 0.028 M substrate concentration
Maltose	100	200
Isomaltose	5	7
Turanose	6	9
Phenyl-α-D-glucopyranoside	5	5
Melezitose	0.4	0.1

Table 3. Relative activity of intestinal lactase (?) on lactose and some β-glucosides at 0.139 M and at 0.028 M substrate concentration in the presence of 0.05 m maleate buffer pH 6.0 and at temperature 37°C. The lactase activity at 0.139 M substrate concentration has been arbitrarily set at 100.

Substrate	Relative activity at 0.139 M substrate concentration	Relative activity at 0.028 M substrate concentration
Lactose	100	90
Cellobiose	50	30
Gentiobiose	1.5	1
Phenyl-β-D-glucopyranoside	5.0	4.5

5) *"Specific" isomaltase and "specific" phenyl-α-D-glucopyranosidase* *. These enzymes have not been isolated, and the influence of the substrate concentration on their activities is not known.

6) *β-Galactosidase and β-glucosidase.* The *lactase* activity will decrease by 10 % and the *cellobiase* activity by 40 % (Table 3). The *cellobiase/lactase activity quotient* consequently will decrease from 0.5 to 0.3. The absolute and relative rates of hydrolysis of *gentiobiose* and *phenyl-β-D-glucopyranoside* will undergo only small alterations.

B. Crude intestinal glycosidase preparations

The relative activities on different substrates by a crude hog intestinal glycosidase preparation will of course be dependent on the relative amounts of the different intestinal glycosidases present in the preparation. Since many substrates are hydrolyzed by two or three different enzymes in the preparation, the relative activity on each of these substrates at 0.139 M and at 0.028 M substrate concentration will also vary with the composition of the enzyme mixture.

The variations in the relative amounts of the different glycosidases present in hog intestinal glycosidase preparations, obtained on different occasions, are, however, usually not great. It has been reported earlier that the *maltase/invertase activity quotient* of such preparations when measured at *0.139 M* substrate concentration usually is about 2, the *trehalase/invertase activity quotient* 0.5 (provided the preparation is obtained from the *upper* part of the small intestine [12]) and the *lactase/invertase activity quotient* 0.2 [15]. At this substrate concentration the three different maltases present (maltase I—III) account for about *one third each* of the total maltase activity [2,3].

The activities on different substrates at *0.028 M* substrate concentration by a preparation which the composition described above has been investigated, and the results are seen in Table 4. At 0.028 M substrate concentration the *maltase/invertase activity quotient* was 5, the *trehalase/invertase activity quotient*

* "Specific" isomaltase and "specific" phenyl-α-D-glucopyranosidase may be identical [8].

Table 4. Relative activities of a crude hog intestinal glycosidase preparation * on different substrates, measured in the presence of 0.05 M maleate buffer, at pH 6.0 for trehalase, β-galactosidase and β-glucosidase activities, and at pH 6.5 for the other activities, at temperature 37°C. The maltase activity at 0.139 M substrate concentration has been arbitrarily set at 100.

Substrate	Enzymes acting upon each substrate	Relative activity at 0.139 M substrate concentration	Relative activity at 0.028 M substrate concentration
Maltose	{Invertase (= Maltase I) Maltase II Maltase III}	100	150
Sucrose	Invertase (= Maltase I)	50	30
Trehalose	Trehalase	25 **	23 **
Isomaltose	{"Specific" isomaltase? † Maltase II Maltase III}	8—10	8—10
Turanose	{Invertase (= Maltase I) Maltase II Maltase III}	7—8	7—8
Phenyl-α-D-glucopyranoside	{"Specific" phenyl-α-D-glucopyranosidase? † Maltase II Maltase III}	5—6	6—7
Melezitose	{Maltase II Maltase III}	0.20***	0.05***
Lactose	{Lactase?}	10	9
Cellobiose		5	3
Gentiobiose		0.20	0.15
Phenyl-β-D-glucopyranoside		0.50	0.45

* Prepared as described earlier. [2]

** Provided ethanol precipitation (which inactivates trehalase) has been omitted, and that the preparation has been obtained from the upper part of the jejunum. [2,12]

*** Calculated as complete hydrolysis of the trisaccharide. [13]

† "Specific" isomaltase and "specific" phenyl-α-D-glucopyranosidase may be identical.[14]

0.8 and the *lactase/invertase activity quotient* 0.3. Maltase I accounted for 15 % only of the total maltase activity, the remaining 85 % of the total maltase activity was exerted by maltase II and maltase III.

METHODS FOR DETERMINATION OF INTESTINAL GLYCOSIDASE ACTIVITIES

Substrates

Maltose (4-(α-D-glucopyranosyl)-D-glucose) monohydrate was obtained from Merck A.G. (Germany), *sucrose* (2-(α-D-glucopyranosyl)-β-D-fructofuranoside) and *lactose* (4-(β-D-galactopyranosyl)-D-glucose) monohydrate from Baker Co. (U.S.A.), *trehalose* (1-(α-D-glucopyranosyl)-α-D-glucopyranoside) dihydrate, *melezitose* (α-D-glucopyranosyl-

(1→3)-β-D-fructofuranosyl-(2→1)-α-D-glucopyranoside) dihydrate. and *cellobiose* (4-(β-glucopyranosyl)-D-glucose) from Pfanstiehl Chemical Co (U.S.A.), *turanose* (3-(α-D-glucopyranosyl)-D-fructose), *gentiobiose* (6-(β-D-glucopyranosyl)-D-glucose) and *phenyl-β-D-glucopyranoside* dihydrate from Nutritional Biochemicals Co. (U.S.A.). *Isomaltose* (6-(α-D-glucopyranosyl)-D-glucose) and *phenyl-α-D-glucopyranoside* were prepared as described earlier [14,12].

Incubation conditions and units

The *standard conditions* for determination of intestinal glycosidase activities are as follows. The enzyme acts in a 0.028 M solution of substrate in the presence of 0.05 M maleate buffer [16] at optimum pH (*i.e.* pH 6.5 for all α-glucosidase activities except trehalase, pH 6.0 for trehalase, β-galactosidase and β-glucosidase activities) at 37°C. Toluene is used as a preservative. The degree of hydrolysis is not allowed to exceed 15 % (within this limit the reaction follows zero order kinetics and the (initial) velocity of hydrolysis is proportional to the amount of enzyme present).

One unit of glycosidase activity is the activity which causes 5 % of hydrolysis in 2.0 ml of reaction mixture in 60 min under these conditions. 5 % of hydrolysis in 2.0 ml of reaction mixture at 0.028 M substrate concentration is equal to the formation of *1 mg of glucose* with maltose, isomaltose, trehalose, cellobiose or gentiobiose as substrate, *1 mg of invert sugar* (= 0.5 mg of glucose) with sucrose or turanose as substrate, and *0.5 mg of glucose* with phenyl-α-D-glucopyranoside, phenyl-β-D-glucopyranoside or lactose as substrate.

Preparation of the substrate solutions

The reaction mixture is generally obtained by mixing equal volumes of substrate solution and a suitably diluted enzyme solution. Since the reaction mixture shall contain 0.028 M substrate and 0.05 M maleate buffer, the substrate solution shall contain 0.056 M substrate and 0.10 M buffer. The substrate solutions are prepared (according to Table 5) by dissolving the substrates in 0.10 M maleate buffer [16] of suitable pH.

Table 5. Composition of substrate solutions. The solutions also contain 1 ml of toluene per 100 ml and should be stored in a refrigerator.

Substrate	Gram of substrate per 100 ml of substrate solution	pH of maleate buffer
Maltose monohydrate	2.00	6.5
Sucrose	1.90	6.5
Trehalose dihydrate	2.10	6.0
Isomaltose	1.90	6.5
Turanose	1.90	6.5
Phenyl-α-D-glucopyranoside monohydrate	1.52	6.5
Phenyl-α-D-glucopyranoside anhydric	1.42	6.5
Phenyl-β-D-glucopyranoside dihydrate	1.62	6.0
Melezitose dihydrate	3.00	6.5
Lactose monohydrate	2.00	6.0
Cellobiose	1.90	6.0
Gentiobiose	1.90	6.0

Determination of the degree of hydrolysis

The method which is most suitable for the determination of the degree of hydrolysis of the substrate, will vary with the properties of the substrates.

A) *3,5-Dinitrosalicylic acid.* The 3,5-dinitrosalicylate reagent, introduced by Sumner [17] for the determination of reducing sugars, is very suitable for the determination of the degree of hydrolysis of nonreducing substrates as sucrose, trehalose or melezitose. (It is, however, not suited for phenyl-glycosidase activity determinations [2]). The method has the advantage that the presence of proteins does not interfere, and therefore protein precipitation is not necessary.

For glycosidase activity determinations 1.0 ml of substrate solution is mixed with 1.0 ml of enzyme solution (diluted to contain 0.5—3.0 units of glycosidase activity per ml) in a test tube immersed in a water bath at 37°C. After 60 min the reaction is interrupted by the addition of 2.0 ml of 3,5-dinitrosalicylate reagent (most readily prepared as described by Hostettler *et al.*[18]) A blank with the same composition is prepared, in which the 3,5-dinitrosalicylate reagent is added *before* the mixing of the substrate and enzyme solutions. The tubes are then heated in a boiling water bath for 10 min, chilled for a few min in running tap water, and diluted with 20.0 ml of distilled water. The red colour produced is measured in a Beckman B spectrophotometer at 530 mμ using 1 cm cuvettes. The colour is stable for at least 24 h.

The amount of monohexoses produced in each sample is calculated from a standard curve made with known amounts of glucose (0.5—3.0 mg). Glucose and fructose have the same extinction coefficient with the 3,5-dinitrosalicylate reagent.

If the enzyme solution contains 1 unit/ml of *invertase* or *trehalase*, 1 mg of monohexoses will be formed during the procedure described above. If more than 3 mg are formed, the determination has to be repeated with a more dilute enzyme solution.

The amount of reducing sugars produced from a trisaccharide as *melezitose* will depend on whether one or both of the glycosidic links are hydrolyzed.

The 3,5-dinitrosalicylic acid method is not sensitive enough when only a small amount of the substrate or the enzyme is available, or when it is desired to use very dilute substrate solutions. In these cases the amount of monohexoses produced from a non-reducing substrate may be determined with Somogyi-Nelson's copper reduction method [19,20], after the precipitation of the proteins with Somogyi's Zn-Ba-reagents [21].

B) *Glucose oxidase.* When the substrate is a *reducing* disaccharide, the 3,5-dinitrosalicylic acid method is not applicable. The amount of glucose liberated in those cases may be determined specifically with a reagent containing glucose oxidase. This reagent does not react with fructose or galactose. It does, however, react with maltose and isomaltose,[2] and cannot, therefore, be used for the determination of the degree of hydrolysis of these substrates.

The glucose oxidase reagent is used for the determination of turanase, lactase, cellobiase and gentiobiase activity. It cannot be used for phenyl-glucosidase activity determinations, since free phenol interferes with the production of the colour.

The determination of glycosidase activity is performed in the following way. The enzyme solution is diluted with water to contain 0.2—1.0 units/ml of cellobiase or gentiobiase activity or 0.5—2.0 units/ml of any of the other activities. In a 7 × 120 mm test tube 0.1 ml of the diluted enzyme solution is mixed with 0.1 ml of the substrate solution, and the tube is immersed in a water bath at 37°C for 60 min. Then 0.8 ml of water is added, and the enzymatic reaction is interrupted by immersing the tube in a boiling water bath for 2 min. A blank is prepared with the same composition, which immediately after the mixing of enzyme and substrate is immersed in a boiling water bath for 2 min.

When turanose is used as substrate, the water added after incubation is replaced by 0.8 ml of 0.1 M acetate buffer pH 5.0. (Turanose will undergo partial alkaline hydrolysis when boiled at a pH higher than 6.0.) This is not necessary with the other substrates. The addition of acetate buffer does not interfere with the subsequent enzymatic determination of the amount of glucose liberated.

After chilling the tubes, 0.5 ml of the contents of each tube is transferred to a 17 × 180 mm tube, added 3.0 ml of the glucose oxidase reagent (prepared as described by Huggett and Nixon [22]), mixed and placed in a water bath at 37°C for 1 h for development of the colour. After that time the colour produced is measured in a Beckman B spectrophotometer at 420 mμ using 1 cm cuvettes.

A standard curve is made with known solutions of glucose, containing 10, 30 and 50 μg of glucose/0.5 ml (0.5 ml of the standard solution is mixed with 3.0 ml of the glucose oxidase reagent and placed at 37°C for 1 h).

If the enzyme solution contains 1 unit/ml of glycosidase activity, 50 μg of glucose will be formed under these conditions with cellobiose or gentiobiose as substrates, and 25 μg with turanose or lactose as substrates.

C) *Acid copper reagent.* For the determination of the degree of hydrolysis of maltose and isomaltose is used an acid copper reagent, which is reduced to a much smaller extent by reducing disaccharides than by monosaccharides [2].

The enzyme solution is diluted with water to contain 1.0—3.0 units/ml of glycosidase activity. In a 7 × 120 mm test tube 0.1 ml of enzyme solution and 0.1 ml of substrate solution are mixed, and the tube is immersed in a water bath at 37°C for 60 min. Then 1.0 ml of a 0.3 N $Ba(OH)_2$-solution, 1.0 ml of a 0.15 M $ZnSO_4$-solution and 1.8 ml of water are added (the $Ba(OH)_2$- and $ZnSO_4$-solutions are previously titrated against each other and adjusted so as to give an ion-free supernatant [21]) which precipitate the proteins and interrupt the enzymatic reaction. A blank is prepared with the same composition, which is precipitated immediately after mixing the enzyme and the substrate. The content of each tube is transferred to a centrifuge tube and centrifuged for 5 min.

Then 2.0 ml of the clear supernatant is transferred to a Folin tube for sugar determination (with a narrow part to prevent oxidation of the cuprous oxide by air, and graduated at 12.5 and 25.0 ml) and 2.0 ml of acid copper reagent is added (prepared as described by Tauber and Kleiner [22]). The tubes are immersed in a boiling water bath for exactly 10 min, and chilled with tap water for 2 min. 2.0 ml of Benedict's molybdate reagent [23] is added and after a further 2 min water to the 25 ml mark. The blue colour is immediately measured in a Beckman B spectrophotometer at 660 mμ, using 1 cm cuvettes.

When the determination is performed in this way, the Folin tube will contain 0.1 ml of reaction mixture. Even when more dilute substrate solutions are used (*e.g.* for K_s determinations) it is impossible to use a greater amount of the reaction mixture for the sugar determination, since the maleate buffer then will interfere with the reaction [2]. For maltase activity determinations the reagents in such experiments may be replaced by the modified reagents described by Caputto *et al.*[24] which are less sensitive to the interference by the buffer. These reagents are not suitable for isomaltase activity determinations [2].

The degree of hydrolysis is calculated from a series of tubes containing mixtures of maltose (isomaltose) and glucose corresponding to 0, 5, 10 and 15 % hydrolysis of the substrate. One unit of maltase (isomaltase) activity per ml in the enzyme solution used will cause 5 % of hydrolysis of the substrate. If the degree of hydrolysis exceeds 15 %, the determination should be repeated with a more dilute enzyme solution.

In determinations with this reagent it is necessary to include a new standard series in each set of tubes that is boiled.

Maltase III (heat-stable maltase) in the presence of maltase I and maltase II is determined by the same method, but after heating the enzyme solution in 0.01 M phosphate buffer pH 6.0 at 60°C for 45 min as described earlier [25].

D) *Phenol determination reagent.* For the determination of the degree of hydrolysis of phenyl-α-D-glucopyranoside and phenyl-β-D-glucopyranoside the amount of phenol liberated is determined with the commercial Folin-Ciocalteau reagent [26] (obtained from G.T.Gurr Ltd., England).

The procedure is as follows. 0.5 ml of diluted enzyme solution (containing 0.5—2.0 units/ml of glycosidase activity) is mixed with 0.5 ml of substrate solution at 37°C. After 60 min the proteins are precipitated by the addition of 1.0 ml of 0.3 N $Ba(OH)_2$, 1.0 ml of 0.15 M $ZnSO_4$ and 1.0 ml of water (see above). A blank is prepared with the same composition, which is precipitated immediately after mixing the enzyme and the substrate.

After centrifugation for 5 min, 1.0 ml of the clear supernatant is transferred to another test tube. To this tube is added 2.0 ml of Folin-Ciocalteau reagent (the commercial reagent diluted with four volumes of distilled water) and 6.0 ml of 1 N Na_2CO_3. The tube is immersed in a water bath at 37°C for 20 min, and then the blue colour produced is measured in a Beckman B spectrophotometer at 675 mμ using 1 cm cuvettes.

A standard curve is made with solutions of phenol in water (32.5 and 65.0 μg of phenol/ml), treated in the same way as the supernatants of the precipitated reaction mixture.

If the enzyme solution contains 1 unit of glycosidase activity/ml, 32.5 μg of phenol will be formed during these conditions.

The Sialic Acids of Bovine and Equine Submaxillary Mucins

GUNNAR BLIX and EWERT LINDBERG

Institute of Medical Chemistry, University of Uppsala, Sweden

The sialic acids of bovine submaxillary mucin (BSM) were separated and isolated by the aid of paper column chromatography. The predominant sialic acids in BSM are an N,O-diacetylneuraminic acid (with the O-acetyl in C-7 position) and an N-acetyl-di-O-acetylneuraminic acid (with one of the O-acetyls at C-7 and the other at C-8 or C-9). Small quantities of N-glycollylneuraminic acid and N-acetylneuraminic acid were also found, the latter possibly formed from the diacetylneuraminic acid during the isolation procedure. In addition there appeared small amounts of a fifth sialic acid which contained O-acetyl and was possibly a labile isomer of the N-acetyl-7-O-acetylneuraminic acid.

The sialic acid of equine submaxillary mucin was isolated in pure crystalline form. It was identified as N-acetyl-4-O-acetylneuraminic acid.

In an earlier investigation [1] it was found that, on paper chromatography, several-times-recrystallized *bovine* submaxillary mucin (BSM) regularly yielded four spots as indicated by the orcinol or Ehrlich reagents. Numbering the fractions I—IV with increasing R_F-values, fraction II was the predominant one. The amounts of fraction II isolated at that time were too small to allow closer analysis. It could hardly be doubted, however, that this fraction was an O,N-diacetylneuraminic acid, the O-acetyl of which, according to the result of periodate oxidation, was at the C-7 position. The R_F of fraction I tallied with that of N-acetylneuraminic acid. The nature of the faint fraction III and of fraction IV remained unelucidated.

The heterogeneity of sialic acid preparations of BSM was also brought out by work of Klenk and Uhlenbruck [2]. Applying a micro-method for the quantitative determination of the glycollyl group they obtained values corresponding to the presence of 21—25 % N-glycollylneuraminic acid in their preparations. We have arrived [3] at somewhat lower values (13—17 %), the difference probably depending on somewhat differing methods of preparation.

The ratio between the different kinds of sialic acid may well be different in the mucin (BSM) from that in the several-times-recrystallized preparation of sialic acid obtained from it. The sialic acids differ in solubility, and the

O-acetyl groups are very easily split off [3]. The preparation method has therefore been modified in the endeavour to minimize the risk of losses in the mother liquors and by decomposition. In preparations obtained by the modified method fractions II and IV clearly predominate, and seem to be present in about equal amounts, perhaps with some preponderance of the latter. Both were isolated and analysed. It was confirmed that fraction II was an O,N-diacetylneuraminic acid. It appeared chromatographically uniform, but contained about 1—2 % glycollyl. Fraction IV proved to be an N-acetyl-di-O-acetylneuraminic acid. It was also found uniform on rechromatographing, and contained no glycollyl.

In the new preparations fraction I could be resolved chromatographically into two spots, one with the same R_F as N-glycollylneuraminic acid, the other moving as N-acetylneuraminic acid. Crystalline matter obtained from total fraction I gave the X-ray powder pattern of N-acetylneuraminic acid, indicating that this substance was the main component of the crystals (concerning mixed sialic acid crystals see Abrahamsson and Svennerholm [6]). Glycollyl determinations of total fraction I gave values corresponding to a content of 7—12 % of N-glycollylneuraminic acid. The N-glycollylneuraminic acid is probably, at least in the main, preformed, since fractions III and IV do not contain any glycollyl and fraction II contains little of it. The N-acetylneuraminic acid present may be preformed, or it may have been formed from the di- and triacetylneuraminic acids during the isolation procedure.

The di- and triacetylneuraminic acids are not stable in aqueous solutions at + 37°. When pure aqueous solutions of the diacetylneuraminic acid are kept for various lengths of time at + 37° and the ensuing changes followed with paper chromatography, there arises at first a new spot which moves with the R_F of fraction III. With longer times a spot with the R_F of N-acetylneuraminic acid appears which increases in size as the two others diminish. Attempts to obtain fraction III in crystalline form were unsuccessful. This fraction gives a positive ester reaction with the $FeCl_3$-hydroxylamine test. It is probably a labile isomerization product of the diacetylneuraminic acid (formed by acetyl migration?). In similar experiments with the triacetylneuraminic acid the product which first formed had the R_F of the bovine diacetylneuraminic acid. Later spots appeared with the R_F-values of fraction III and N-acetylneuraminic acid, respectively. This result seems to indicate that one of the O-acetyl groups of the triacetylneuraminic acid has the same position as the O-acetyl of the bovine diacetylneuraminic acid, that is at C-7. Since the triacetylneuraminic acid is not oxidized by periodate, the second O-acetyl must be at C-8 or C-9.

In the earlier investigation [1] sialic acid from *equine* submaxillary mucin (ESM) was not obtained in a pure state. The analyses of the impure preparations suggested that this substance was an isomer to the bovine diacetylneuraminic acid. The purification procedure has now been improved and the nicely crystallizing substance obtained was chromatographically uniform.

Analysis of the substance has fully confirmed that it is an O,N-diacetylneuraminic acid. Contrary to the bovine diacetylneuraminic acid it consumes two molecules of periodate per molecule. Since the C-2 position is excluded, because this group is bound to hexosamine in the mucin, the result of the

periodate oxidation indicates that the equine sialic acid is N-acetyl-4-O-acetylneuraminic acid.

EXPERIMENTAL

1. Preparation of submaxillary mucins

The method is in principle the same as that used in earlier works from this laboratory [1]. The procedure is now described in more detail, to facilitate its reproduction.

Fresh glands are freed from adherent lymph glands, fat, and connective tissue, and are then frozen. Batches of 3 kg of frozen glands are cut into cubes of about 2 cm^3. The cut glands are then barely covered with distilled water, and kept at + 4° for 24 h, with occasional stirring. The cubes are removed by pouring the mixture through a stainless steel cone perforated with holes about 4 mm in diameter. The "filtrate" is freed from coarse particles by centrifuging. The first extract is usually strongly tinged by haemoglobin, and contains in addition much protein other than mucin, which may disturb the precipitation of the latter. It is therefore best discarded. The glands may be extracted at least 5—7 times in this way.

Dilute hydrochloric acid is added to the extract until the mucin just dissolves on the acid side of its isoelectric zone. The amount of HCl required may vary, and is conveniently determined in a preliminary test on a few ml of the extract. The mucin is precipitated by dilution with a few volumes of water. If the solution is vigorously stirred during and after the process of dilution, the mucin precipitate as a rule coalesces and adheres as an elastic clot to the spatula or rod used for stirring. The mucin is then dehydrated by alcohol, and torn into small pieces during the procedure. It is then ground to a powder, and freed from fatty impurities by extraction with ether.

2. Isolation of the BSM sialic acids

40 g of mucin is placed in a 2-litre flask. Small portions of water are added, and the whole vigorously shaken until a viscid suspension is obtained. The suspension is then made up to 400—500 ml water with gentle warming and constant shaking. The suspension, which has a pH of 3.3—3.4, is heated for 1 h in the boiling water bath. After cooling to room temperature the mixture is centrifuged, and the undissolved residue washed with 200 ml water. The supernatants are combined and freeze-dried.

The residue is repeatedly (6 times) extracted with methanol for 4—5 h at + 4°. Since the tri- and di-acetylneuraminic acids dissolve much more readily in methanol than do the N-acetyl- and N-glycollylneuraminic acids, the first extracts of the residue contain the main part of the two former kinds of sialic acid and nothing or very little of the two latter, which predominate in the last extracts (Fig. 1). In order to minimize methyl ester formation each extract is evaporated below 0° in the freeze-drying apparatus. The residues are dissolved in small quantities of methanol, and the solutions then combined and brought to dryness below 0°. The final residue thus obtained is dissolved in a minimum of water (about 2 ml); 30 ml of methanol is added, followed by 90 ml of ether. An amorphous precipitate formed is immediately filtered off. The filtrate is evaporated in the freeze-drying apparatus. The residue is dissolved in 5 ml of water-*n*-butanol-acetic acid (5:4:1), and then chromatographed on a paper roll (75 × 6 cm) in the same solvent. The LKB Chromax pressurized paper column system * was used. The eluate is collected in fractions of about 20 ml. Of each or each second fraction 0.5 ml is taken for sialic acid analysis (with the Ehrlich reagent). Fractions II, III, and IV are not completely separated in this procedure, but the separation is sufficient for the preparation of fractions II and IV in pure or almost pure state.

The fractions containing the di- and triacetylneuraminic acid are pooled separately, and evaporated to dryness in the freeze-dryer. In order to remove the last traces of butanol the residues are dissolved in about 100 ml of methanol, and the solution evaporated to dryness in the same manner.

* May be obtained from AB LKB-Produkter, Stockholm, Sweden.

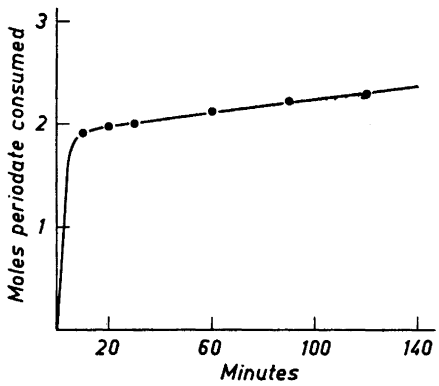

Fig. 2. Periodate oxidation of the sialic acid of equine submaxillary mucin in acetate buffer of pH 4.4 at + 8—10°. Moles periodate consumed per mole of substance oxidized.

For crystallization fraction II is dissolved in 1—2 ml water, fraction IV in at most 1 ml water; 30 ml of methanol is added, followed by 90 ml of ether. Light petroleum is then added drop by drop to the filtrate until faint turbidity appears. Crystallization takes place at room temperature or in the refrigerator. More substance crystallizes on each addition of a few drops of light petroleum during the next few days. The formation of crystals may continue for a week or more. (If too much light petroleum is added at one time the sialic acid comes out as an oil.) Recrystallization is performed in the same way. The yield of the once-recrystallized substances is 150—200 mg of diacetylneuraminic acid and about 500 mg of triacetylneuraminic acid.

3. Analysis of the BSM sialic acids

The *diacetylneuraminic acid* crystallizes with 1 molecule crystal water in rectangular plates, just as the crude substance obtained in the earlier investigation [1]. The substance decomposed with browning at 138—140°. $[\alpha]_D^{22}$ (H_2O) + 6 ± 2°. These values differ slightly from those originally given for this substance [1].

The nitrogen determinations were carried out by Dumas' method, the total acetyl as described by Friedrich and Rapaport [4], and the O-acetyl by Hestrin's method [5]. Two

Nitrogen analyses,			
$C_{13}H_{21}NO_{10}$(351)	Calc.	N	3.99
(dried at 100° *in vacuo*)	Found 1.		3.98
			3.98
	2.		3.84
			3.82
$C_{13}H_{21}NO_{10} \cdot H_2O$(369)	Calc.	N	3.79
(dried in desiccator)	Found		3.74
			3.77
Total acetyl,			
$C_{13}H_{21}NO_{10} \cdot H_2O$	Calc.		23.3
	Found		21.2
			21.4
			22.0
O-acetyl,			
$C_{13}H_{21}NO_{10} \cdot H_2O$	Calc.		11.6
	Found		10.7

glycollyl determinations (method of Klenk and Uhlenbruck [2]) gave values between 1.3 and 2.2 %. The X-ray powder pattern was identical with that of the crude product earlier investigated [1].

The *triacetylneuraminic acid* crystallized in needles or prisms with one molecule of crystal methanol, which did not disappear on heating at + 70° for several hours. It was driven off by heating *in vacuo* at 100° for 10 h. Methoxyl determination on the substance dried at 70° gave 7.4 % (calc. for $C_{15}H_{23}NO_{11} \cdot CH_3OH$ 7.4 %), whereas the substance dried at 100° gave no methoxyl value. It does not consume any periodate at pH 4.4 and + 10°.

The substance is more easily soluble in methanol than the other sialic acids. It melts with gas evolution but without discoloration at 130—131°. $[\alpha]_D^{22}$ (H_2O) + 9 ± 2°. The elementary and acetyl analyses agreed reasonably with the formula $C_{15}H_{23}NO_{11} \cdot CH_3OH$.

$C_{15}H_{23}NO_{11} \cdot CH_3OH$ (425)	Calc.	C	45.17	H 6.40	N 3.29
	Found 1.		44.83	6.53	—

	2.		44.60	6.45	3.41
			44.58	6.43	3.42
	3.		44.77	6.43	3.30
			44.66	6.46	3.31

Total acetyl,	Calc. (three acetyls)		30.35
	Found		29.8
			32.9
O-acetyl,	Calc. (two acetyls)		20.21
	Found		20.6
			20.9

3. Isolation of the *equine diacetylneuraminic acid*

40 g of mucin is suspended in 400—500 ml water as described above for BSM. The pH is then adjusted to 2.5, and the suspension heated for 1 h in the boiling water bath with occasional shaking. The pH tends to rise, and should therefore be adjusted to pH 2.5 two or three times during the heating. After cooling to room temperature the mixture is centrifuged, and the undissolved residue washed with 200 ml water. The supernatants are combined and neutralized to pH 3.5 with dilute barium hydroxide. The new mixture is then freeze-dried without previous filtration.

The residue is repeatedly (5—6 times) extracted with methanol for 4—5 h at + 4°. In order to minimize methyl ester formation each extract is evaporated below 0° in the freeze-dryer.

The residues are dissolved in small quantities of methanol. The solutions are combined and brought to dryness in the freeze-dryer. The final residue thus obtained is dissolved in a minimum of water (4—5 ml), 30 ml methanol is added, followed by ether and light petroleum in the same manner as described for the BSM sialic acid. On recrystallization the addition of light petroleum is superfluous. The pure substance may be recrystallized from methanol without addition of ether. They equine sialic acid crystallizes in long needles. 40 g mucin yields 0.4—0.5 g of recrystallized substance.

4. Analyses of the *equine diacetylneuraminic acid*

The substance decomposes with browning at about + 200°. $[\alpha]_D^{22}$ (H_2O) −62 ± 1°. These values are slightly higher than those reported for the impure substance [1].

$C_{13}H_{21}NO_{10}$ (351),			Calc.	C 44.44	H 6.03	N 3.99
			Found	44.34	6.26	4.04
				44.18	6.17	4.07
Total acetyl,	Calc.	(two acetyls)		24.5		
	Found			21.0		
O-acetyl,	Calc.	(one acetyl)		21.5		
	Found			11.6		

The substance contained no appreciable amounts of methoxyl or glycollyl groups. The X-ray powder diagram was identical with that of the impure product given in the earlier report [1]. Periodate oxidation was carried out at pH 4.4 and + 8—10°, as earlier [1] described. The result of one such experiment is given in Fig. 2: 2 moles of periodate are evidently consumed per mole sialic acid.

Formation of Lithocholic Acid from Chenodeoxycholic Acid in the Rat

Bile Acids and Steroids 103

ARNE NORMAN and JAN SJÖVALL

Department of Chemistry, Karolinska Institutet, Stockholm 60, Sweden

Chenodeoxycholic acid-24-^{14}C has been injected into the cecum of bile fistula rats. 50–60 % of the isotope was absorbed. Lithocholic acid comprised more than 50 % of the labelled fecal acids but only traces were found in the bile. At least eight other microbial transformation products were present. One of these was probably 3-ketocholanic acid.

Cholic and chenodeoxycholic acids are the primary bile acids formed from cholesterol in the rat liver (*cf.* Ref.[1]). Chenodeoxycholic acid is further tranformed by liver enzymes into 3α, 6β, 7α- and 3α, 6β, 7β-trihydroxycholanic acids and to a small extent into 7-ketolithocholic and ursodeoxycholic (3α, 7β-diol) acids [2–4].

During the enterohepatic circulation, the bile acids are attacked by microbial enzymes in the cecum and colon and the metabolites formed are partly absorbed [5]. By this mechanism deoxycholic acid is formed from cholic acid. The aim of the present investigation was to find out whether a similar removal of the 7-α-hydroxyl group from chenodeoxycholic acid takes place during the enterohepatic circulation. If this were so, labelled lithocholic acid would be found in the bile and feces of rats which had received chenodeoxycholic acid-24-^{14}C. The presence of lithocholic acid in the bile of different animals has been repeatedly shown (*cf.* Sobotka [6]).

EXPERIMENTAL

Chenodeoxycholic acid-24-^{14}C (10 μC per mg) was prepared according to Bergström *et al.*[7]

Animal experiments. Bile duct-cannulated white rats weighing 200–300 g were used [8]. 0.5 mg of labelled sodium chenodeoxycholate in 0.2 ml of saline was injected into the cecal content [5]. Bile and feces were collected for two days.

Analysis of bile and feces. Bile acids were extracted from feces by refluxing three times for 2 h with 80 % aqueous ethanol. After evaporation to dryness the bile acids were extracted with ether from an acidified water solution. The bile was hydrolyzed with N NaOH in a closed steel tube for 6 h at 120° and the bile acids were extracted as described above.

The bile acids were separated with reversed phase column chromatography [9,10] using the following solvent systems:

Phase system	Moving phase (ml)	Stationary phase (ml)
C 1	Methanol-water 150:150	Chloroform-*iso*octanol 15:15
F 1	Methanol-water 165:135	Chloroform-heptane 45:5
F 2	Methanol-water 180:120	Chloroform-heptane 45:5
F 3	Methanol-water 195:105	Chloroform-heptane 25:25

4 ml of stationary phase were supported on 4.5 g of hydrophobic Supercel. The fractions collected from the columns were titrated and isotope determined on aliquots. For the sake of comparison, the effluent volumes of the figures have been corrected to correspond to a 4.5 g column.

RESULTS

After intracecal injection of labelled sodium chenodeoxycholate 40—50 % of the isotope was excreted in the feces. The remaining labelled products were absorbed and excreted in the bile.

Separation of labelled bile acids in feces. The ether extract of the feces was first chromatographed with phase system F 2. The labelled products appearing before lithocholic acid and those remaining in the stationary phase were rechromatographed with phase systems F 1 and F 3, respectively. The front band from the chromatography with phase system F 1 was re-run with phase system C 1.

As shown in Fig. 1 only a few per cent of the chenodeoxycholic acid was unchanged (Fig. 1., Phase system F 1, 45—65 ml). At least nine different metabolites were separated. Most of these were more hydrophobic than chenodeoxycholic acid. More than half of the isotope appeared at the site of lithocholic acid added as carrier (Fig. 1., Phase system F 1, 70 — 100 ml). The identity of the radioactive compound with lithocholic acid was established by isotope dilution. Rechromatography of the metabolites more hydrophobic than lithocholic acid (Fig. 1., Phase system F 3), together with 3-ketocholanic acid, showed that the radioactivity of the fourth band (100—150 ml) coincided with the titration peak of the carrier.

Since *E. coli* oxidizes chenodeoxycholic acid to 7-ketolithocholic acid *in vitro* we expected to find this acid in the feces [11]. A radioactive peak was present in the chromatogram very close to 7-ketolithocholic acid added as carrier (Fig. 1., Phase system F 1, A). Rechromatography showed that only a small fraction of isotope was eluted together with the carrier acid while the main peak appeared immediately afterwards.

The small amount of metabolites more hydrophilic than chenodeoxycholic acid was separated with phase system C 1 (Fig. 1). One band of activity appeared before, and another one just after, cholic acid added as carrier.

Separation of labelled bile acids in bile. As shown in Fig. 2 chromatographic analysis of the bile revealed the presence of at least eight radioactive com-

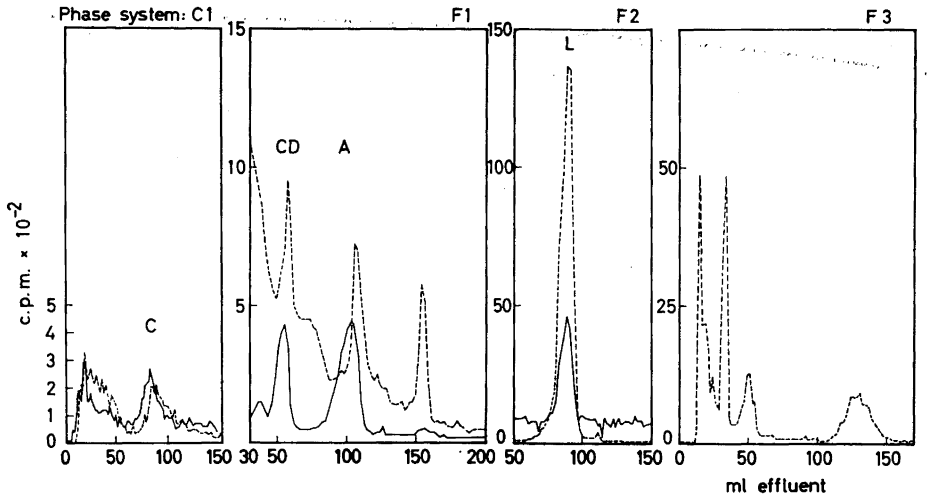

Fig. 1. Chromatographic separations of labelled products in feces after the injection of chenodeoxycholic acid-24-^{14}C into the cecum of a bile fistula rat. Reference substances: cholic (C), chenodeoxycholic (CD), 7-ketolithocholic (A), and lithocholic (L) acids. Solid line: Titration. Broken line: Radioactivity.

pounds. Apart from unchanged chenodeoxycholic acid (Fig. 2., Phase system F 1, 40—60 ml) radioactive peaks appeared at the sites of 3α, 6β, 7α- and 3α, 6β, 7β- trihydrocycholanic acids (Fig. 2., Phase system C 1, 60—80 ml and 100—140 ml, respectively). The metabolite eluted before chenodeoxycholic

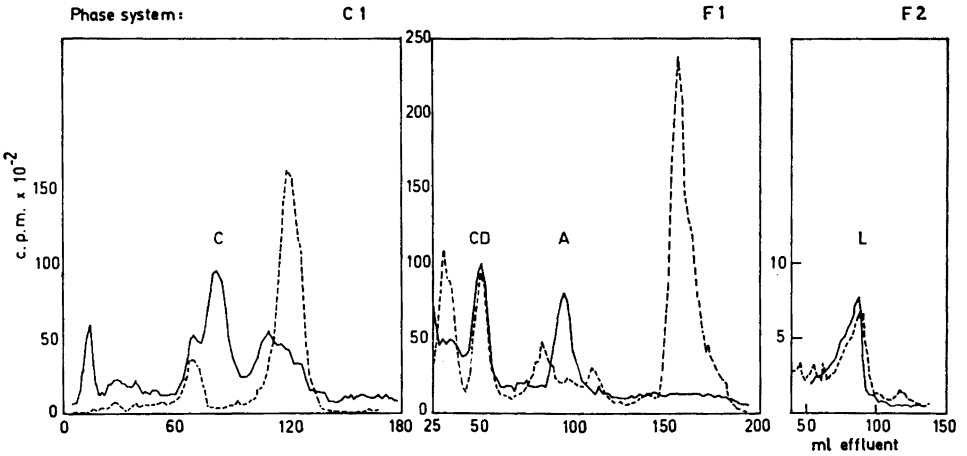

Fig. 2. Chromatographic separations of the labelled products in the bile of the same rat as used for the experiment shown in Fig. 1. The extract was first chromatographed with phase system F 1. The activity in the front band and that remaining in the stationary phase were rechromatographed with phase systems C 1 and F 2, respectively. For reference substances see Fig. 1.

acid (Fig. 2., Phase system F 1, 25—40 ml) was rechromatographed with ursodeoxycholic acid and the radioactivity and the titration peak coincided.

The metabolites described above are also present in the bile after intraperitoneal injection of chenodeoxycholic acid. The other compounds separated are thus microbial transformation products and/or liver metabolites of these substances. Except for lithocholic acid present in very small amounts, the nature of these compounds is unknown.

DISCUSSION

According to Siperstein *et al.*[12] lithocholic acid might be an intermediate in the formation of cholic and chenodeoxycholic acids from cholesterol. This would explain the presence of lithocholic acid in the bile. Their hypothesis has not been generally accepted (*cf.* Ref.[1]). In the present study we have shown that the 7α-hydroxylgroup of chenodeoxycholic acid can be removed by microorganisms in the large intestine. The lithocholic acid thus formed can be absorbed and appears in the bile. At the present time the microbial biogenesis seems to us to be the most plausible mechanism for the formation of lithocholic acid.

The technical assistance of Miss Margret Månsson and Miss Margaretha Persson is gratefully acknowledged. This work has been supported by grants from *Statens Medicinska Forskningsråd* and the *National Heart Institute* (H 2842), U.S. Public Health Service, Bethesda, Maryland, U.S.A.

Crystalline Leghemoglobin

II. The Molecular Weights and Shapes of the two Main Components

NILS ELLFOLK*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The molecular weights of the two main components of leghemoglobin have been determined, on the basis of sedimentation and diffusion studies, to be 16 800 for the electrophoretically faster component, and 15 400 for the slower one. The sedimentation constants, extrapolated to infinite dilution, were 2.01 S for the electrophoretically faster component, and 2.04 S for the slower one, whereas the diffusion constant was 11.18 F for the faster component and 12.35 F for the slower one. The partial specific volume of the unresolved material was 0.740 ml/g. The molar frictional ratio was 1.118 for the electrophoretically faster component and 1.043 for the slower one. The results of this study show that the two main components of leghemoglobin differ slightly from each other in molecular size and shape.

Studies on the molecular weight of leghemoglobin (Lhb) have not been made until quite recently. In 1952 Ellfolk and Virtanen [1], on the basis of their osmotic and sedimentation and diffusion studies, reported that the unresolved chromoprotein had an average molecular weight of 20 000. Difficulties in resolving the chromoprotein into its components in good yield limited the studies of the individual components. The electrophoretically faster component was found to have an iron content of 0.34 % [1]. This caused the authors to assume that the electrophoretically faster component represented pure Lhb and that the electrophoretically slower component was an inhomogeneous protein. After the recent development of a procedure for preparing the two main components in good yield in a crystalline state [2], it was decided to reinvestigate the molecular sizes and shapes of the two individual main components.

EXPERIMENTAL

Material. Pure fractions of the electrophoretically faster and slower components of Lhb were prepared by a chromatographic procedure that was published earlier [2]. For the sedimentation and diffusion measurements, the protein solutions were dialyzed for

* Permanent address: Research laboratories of the State Alcohol Monopoly, Helsinki, Finland

48 h at + 3°C against a 0.283 μ buffer of pH 7 that contained 0.05 M sodium phosphate and 0.171 M sodium chloride.

Sedimentation. The sedimentation analyses were made in a Spinco analytical ultracentrifuge model E. All analyses were performed at 59 780 r.p.m. Because of the low molecular weight of the two chromoproteins studied, only the synthetic boundary cell was used. Inasmuch as the distances moved by the boundaries were rather small, ten photographs of the sedimenting boundary position were obtained in each experiment. The sedimentation coefficients were evaluated from enlarged images of the photographs projected onto millimeter graph paper. By inserting a scale into the rotor in place of the cell, a reference plate, which can be used to combine the magnification of the camera and enlarger into one, is obtained. The sedimentation constants were reduced to pure water at 20°C by applying the usual corrections for the density and viscosity of the medium [3]. The results are given in Svedberg units (1 S = 10^{-13} cm sec^{-1} $dyne^{-1}$).

Diffusion. The diffusion experiments were conducted in a Spinco diffusion and electrophoresis instrument at a temperature of 0.6°C. Boundary sharpening was obtained by withdrawing a small amount of solution from the vicinity of the boundary with a long hypodermic needle, and then allowing the diffusion to occur. By repeating this procedure, a sharp boundary was obtained. The optics were adjusted for studying the Rayleigh-Calvet-Philpot interferogram at 644 mμ. The number of fringes, and the position of the maxima and minima were measured visually by means of the optical system of a Hilger densitometer. The cell magnification was 1.0105. The diffusion constants were evaluated according to the "height-area" method described by Svensson [4].

$$D_A = \frac{(n_1 - n_2)^2}{4\,\pi\,t\,n'^2_{max\,(x)}}$$

where n_1 and n_2 are the refractive indices of the two solutions, t is the time, and $n'_{max(x)}$ is the maximum value for the derivative of the refractive index function with respect to position in the cell. Some exposures were evaluated according to the "moment" method using the equation by Svensson [5] as slightly modified by Ehrenberg and Agner [6]

$$D_m = \frac{\int_{n_o}^{n_c} x^2\,dn}{2(t-t_o)\,(n_c-n_o)} = \frac{a}{t-t_o}$$

where n denotes the refractive index increment measured at a particular fringe number, x is the fringe coordinate measured from the center of the boundary, and t is the length of time of diffusion. The diffusion constants were reduced to pure water at 20°C by applying corrections for the density and viscosity of the medium. The results are given in Fick's units (F = 10^{-7} cm^2 sec^{-1}).

Partial specific volume. The partial specific volume was determined for solutions of Lhb that were extensively dialyzed against distilled water. The densities of the solutions and of the solvent were measured at 24.45°C using a pycnometer of the Sprengel-Ostwald type having a capacity of about 10 ml.

RESULTS

Sedimentation coefficients. The two main components of Lhb, as far as could be judged from the photographs obtained in the ultracentifuge experiments, appeared to be homogeneous throughout the concentration ratios studied (Fig. 1). All the sedimentation patterns consisted of single, symmetrical peaks showing no indications of more than one component. The sedimentation constants for the two components were concentration dependent, increasing in value with dilution. Values of the sedimentation constants at different

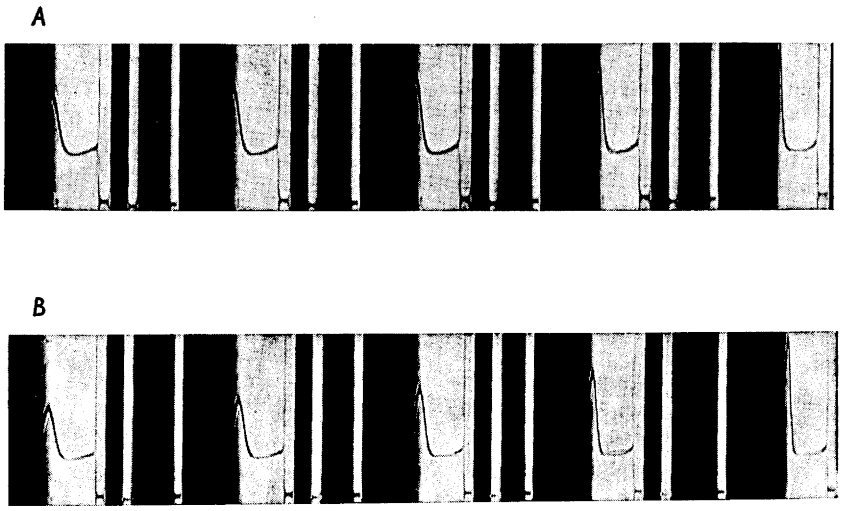

Fig. 1. Representative photographs obtained during the sedimentation analyses of the two main components of leghemoglobin. The pictures at the right represent the beginning of the runs.

A) The electrophoretically faster component at a protein concentration of 8.23 mg/ml (in sodium phosphate-NaCl buffer as described in the text) measured at an average temperature of 19.83°C and at a rotor speed of 59 780 rpm. Photographs were taken at intervals of 8 min. The five first photographs are reproduced.

B) The electrophoretically slower component at a concentration of 6.40 mg/ml measured at an average temperature of 18.78°C. The other conditions are the same as in A.

protein concentrations are shown in Fig. 2. The lines drawn through these data were calculated by the method of least squares, and fit the equation

$$S^{\circ}_{20} = S_{\infty} - \beta a$$

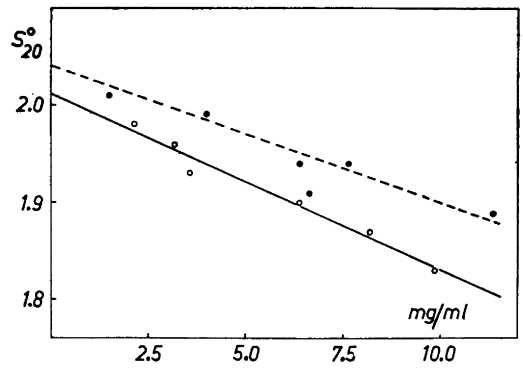

Fig. 2. Concentration dependence of the sedimentation constants of the electrophoretically faster (O) and slower (●) components of leghemoglobin in sodium phosphate-NaCl buffer (pH 7.0, ionic strength 0.283).

where S_∞ is the sedimentation coefficient extrapolated to infinite dilution, and a is the concentration of protein in mg/ml. S_∞ was found to be 2.012 S for the faster component and 2.041 S for the slower one. The equations for the sedimentation coefficients of the two components were:

$$S^\circ_{20} = 2.012 - 0.0180\ a \quad \text{(fast component)}$$
$$S^\circ_{20} = 2.041 - 0.0138\ a \quad \text{(slow component)}$$

The close similarity in the sedimentation data for the two components indicates that these proteins cannot be distinguished from each other by their behavior in the ultracentrifuge.

Diffusion coefficient. Several experiments were performed on each of the two components prepared from different batches. The experiments usually were performed in the standard cell. The protein concentrations for the two

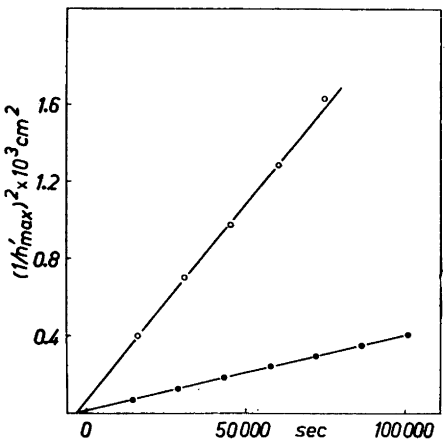

Fig. 3. A plot of inverted squares of the maximum fringe densities *versus* the length of time of diffusion. This plot was used for the calculation of the diffusion constants for the electrophoretically faster component according to the "height-area" method. Protein concentrations were 1.35 mg/ml (O) and 3.20 mg/ml (●) in sodium phosphate-NalC buffer (pH 7.0, ionic strength 0.283).

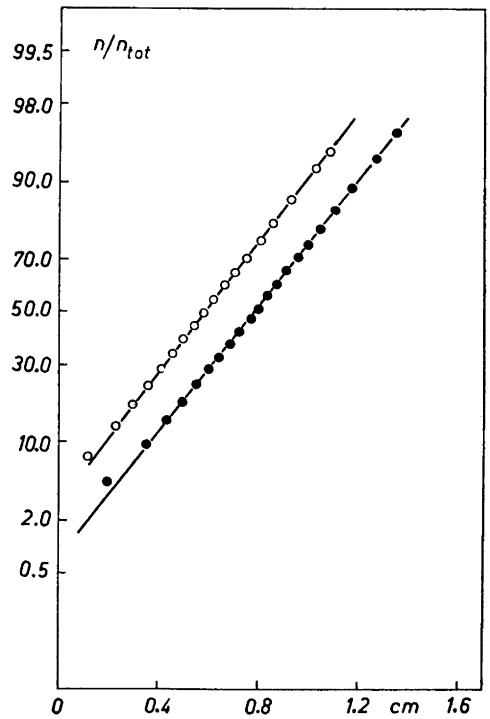

Fig. 4. Plots of relative fringe numbers *versus* fringe coordinates on a normal distribution graph in order to test the fit of the experimental diffusion curve of the electrophoretically faster component. The exposures are for protein concentratoins of 1.35 mg/ml (after 73 980 sec. of diffusion) (O), and for 3.20 mg/ml (after 86 400 sec.) (●).

Table 1. Diffusion data for the two main components of leghemoglobin obtained by the "height-area" method.

Component	Conc. mg/ml	t_o sec.	$D_{0.6}$ F	D^o_{20} F
Fast	1.35	−3 769	5.787	11.29
»	3.20	−3 874	5.620	10.96
		Average value		11.13
Slow	2.40	−3 111	6.174	12.04
»	7.40	−1 491	6.143	11.98
		Average value		12.01

experiments with the faster component were 1.35 mg/ml and 3.20 mg/ml, and the total fringe numbers were 19.10 and 42.62 respectively. Fringe intervals, Δn, of 4 and 9, respectively, were chosen for the calculation of the maximum fringe density, n'_{max}[4]. When applying the "height-area" method, the rate of increase of $(1/n'_{max})^2$ with time was determined. Five and seven exposures were evaluated in the first and second experiments, respectively. The corresponding plots of the data for the two experiments are shown in Fig. 3. The equations of the lines drawn through the points obtained in the two experiments have been calculated by the least squares method. The numerical data are given in Table 1. Four exposures from the higher concentration were evaluated according to the "moment method", and the results are given in Table 2. The zero-time correction, as determined by the "height-area" method, has been used.

The diffusion curve of a homogeneous, ideal-diffusing substance has the form of the normal probability curve, and for such a substance D_A and D_m should have the same value. Curves of mixtures have sharper peaks than the normal curve, and hence $D_m > D_A$. The close agreement between the values obtained

Table 2. Diffusion data for the two main components of leghemoglobin obtained by the "moment" method.

Component	Conc. mg/ml	t sec.	$t-t_o$ sec.	$D_{0.6}$ F	D^o_{20} F
Fast	3.20	43 200	47 074	5.784	11.28
		57 600	61 474	5.769	11.25
		86 400	90 274	5.746	11.20
		100 800	104 674	5.720	11.15
			Average value		11.22
Slow	7.40	66 600	68 091	6.575	12.82
		81 000	82 491	6.488	12.65
		95 400	96 891	6.464	12.61
			Average value		12.69

by the two different methods for the faster component is an indication of the essentially homogeneous character of the protein.

A more sensitive test of the diffusion behaviour, however, is to compare the experimental curve with a normal probability curve drawn on graph paper [6]. In Fig. 4, the relative fringe numbers, n/n_{tot}, have been plotted against the fringe coordinates determined from two exposures, one for each concentration. The line drawn for the lower concentration (19.10 fringes) corresponds to $D^{\circ}_{20} = 11.29$ F, whereas the line for the higher concentration (42.62 fringes) corresponds to $D^{\circ}_{20} = 10.98$ F. The zero-time correction obtained by the "height-area" method was applied in these calculations.

A value of 11.18 F is obtained as an average value for the two methods of calculation in the concentration range studied. This value has been used for the calculations of the molecular weight and the asymmetry of the faster component.

In a preliminary study, a diffusion constant equal to 8.5 F was reported for the slower component [2]. In more recent studies, this value has not been confirmed. If precaution were taken to avoid all possibility of denaturation during

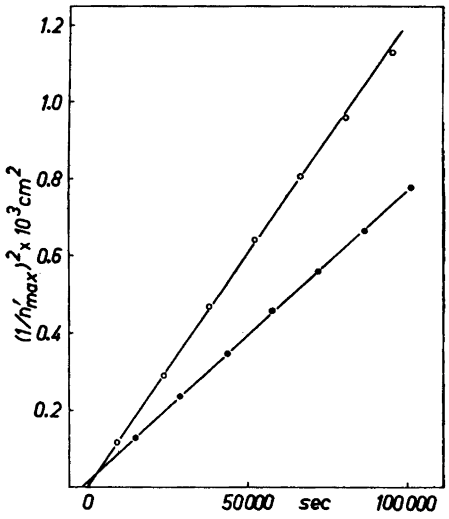

Fig. 5. A plot of inverted squares of the maximum fringe densities *versus* the length of time of diffusion. This plot was used for the calculation of the diffusion constants for the electrophoretically slower component according to the "height-area" method. Protein concentrations were 2.40 mg/ml (O) and 7.40 mg/ml (●) in sodium phosphate-NaCl buffer (pH 7.0, ionic strength 0.283).

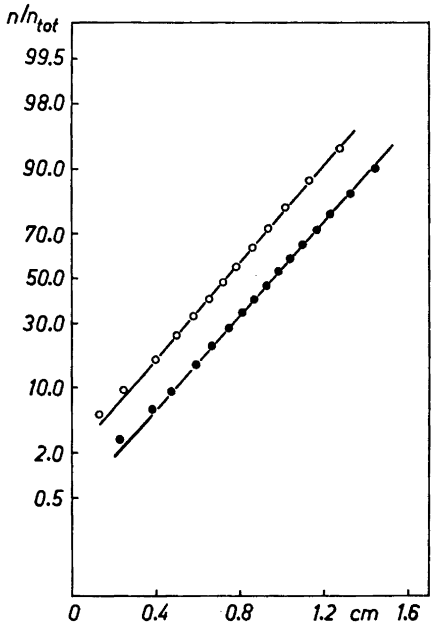

Fig. 6. Plots of relative fringe numbers *versus* fringe coordinates on a normal distribution graph in order to test the fit of the experimental diffusion curve of the electrophoretically slower component. The exposures are for protein concentrations of 2.40 mg/ml (after 95 400 sec. of diffusion) (O) and for 7.40 mg/ml (after 100 800 sec.) (●).

preparation, the value obtained was higher. Several experiments were run, two of which are reported here. One experiment in which the protein concentration was 2.40 mg/ml was conducted in the standard cell, whereas another experiment in which the protein concentration was 7.40 mg/ml was conducted in the micro cell. (The optical path in the micro cell is 1/4 of that in the standard cell). The total fringe numbers were 32.20 for the lower concentration and 25.60 for the higher one. A fringe interval, Δn, of 5 and 7 was used in the calculation of the maximum fringe density, n'_{max}, with 7 exposures evaluated at both concentrations. The corresponding plots of the data for the two experiments as calculated by the "height-area" method are given in Fig. 5, whereas the numerical data are recorded in Table 1.

Three exposures from the higher concentration were evaluated according to the "moment method", and the results are recorded in Table 2. The zero-time correction from the "height-area" method was used.

The closeness of fit to the requirements of ideal diffusion was checked by plotting the data from the two experiments on a normal distribution graph (Fig. 6). The line drawn for the lower concentration (32.60 fringes) corresponds to $D^{\circ}_{20} = 12.21$ F, whereas for the higher concentration, the line corresponds to 12.35 F.

An average value of 12.35 F was obtained by the two methods of calculation. This value has been used for the calculation of the molecular weight and asymmetry of the slower component.

Partial specific volume. The partial specific volume was determined in three experiments. The unresolved material was used because as high a protein concentration as possible was desired. A solution of 5 mg/ml gave the following values: 0.740, 0.740 and 0.739 ml/g. A value of 0.740 ml/g was used for the calculations that follow.

Molecular weight. The values of the molecular weights of the two components were calculated by means of Svedberg's formula [3]

$$M = \frac{RTs}{D(1-V\varrho)}.$$

From the determined values of s, D and V, the electrophoretically faster component was found to have a molecular weight of 16 800, and the electrophoretically slower one a molecular weight of 15 400.

Molecular shape. The molecular frictional ratio f/f was calculated according to the following formula [3]:

$$f/f_o = \left[\frac{1-V}{D^2_{20}s_{20}V}\right]^{1/6} 10^{-8}$$

The molar frictional ratio was found to be 1.118 for the faster component and 1.043 for the slower one. Following the procedure of Oncley [3], f/f_o can be represented as a product of two factors, f/f_e and f_e/f_o. The first factor, f/f_e, represents the effect of hydration, while the second factor, f_e/f_o, represents the influence of the asymmetry of the molecule. Kramer [3] has shown that the hydration factor is related to the grams of water per gram of protein, w, by the formula

$$f/f_e = \left[1 + \frac{w}{V\varrho}\right]^{1/3}$$

in which ϱ is the density of the water solvating one gram of pure solute of the partial specific bolume V. The maximum possible degree of hydration for the electrophoretically faster component would make f/f_e equal to 1.118 and would lead to a value of 0.29 for w. On the other hand, if the entire molar frictional ratio is due to asymmetry, f_e/f_o would be equal to 1.118. In the equations of Perrin [3], this value would represent axial ratios of 3.1 and 3.2 for prolate and oblate ellipsoids, respectively. Assuming an elongated ellipsoid and zero hydration, the faster component would have a minor axis of 23 Å and major axis of 72 Å.

If the molecular frictional ratio, $f/f_o = 1.043$, of the slower component is due entirely to hydration, the value for w would be 0.032. If the frictional ratio is due only to asymmetry, the axial ratios would be equal to 2.0 for both prolate and oblate ellipoids. An unhydrated ellipsoid of the slower component would have a minor axis of 26 Å and a major axis of 52 Å.

DISCUSSION

Both of the main components of leghemoglobin appear to be single, homogeneous proteins in the ultracentrifuge. Earlier ultracentrifugal studies [1] distinguished two components of unequal concentration. The predominant component was slowly sedimenting (1.9 S), whereas the lesser component was a rapidly sedimenting fragment (5 to 6 S). The rapidly sedimenting fraction seemed to form a part of the electrophoretically slower component. The presence of such a small, heavy component could not be confirmed in the present studies of the individual components.

The molecular weight of 20 000 found earlier for the unresolved material [1] deviates considerably from the new molecular weights of 16 800 and 15 400 presently determined for the electrophoretically faster and slower components, respectively. This discrepancy is essentially due to differences in the diffusion constants of the different preparations investigated. The latter difference probably occurs because of the introduction of chromatography in the purification of the individual components [2]. The chromatographic procedure fractionates the unresolved material into at least four different components and removes some denaturated material which was not removed by ammonium sulphate fractionation [2]. The heavy component observed earlier in the unresolved material might consist of this denaturated material. Hence, the former assumption [1] that the electrophoretically slower component is an artefact of a heavy, iron-free protein surrounded by leghemoglobin molecules has no experimental basis.

The two main components are highly symmetrical in shape. The values for the frictional ratios calculated for both of the components are among the lowest that have been described. Our knowledge of the hydration of proteins is not in an advanced state, but undoubtedly water is immobilized on the surfaces of protein molecules. A value of 0.3 g of water per g of dry protein would

seem to be a reasonable figure and would lead to a value of 1.120 for the frictional ratio. This is evidently an upper limit of the possible contribution of hydration to the frictional ratio. If the frictional ratios of the two components were explained only on the basis of hydration a great difference in hydration would exist between the two components. This may be explained as being caused by differences in the amino-acid content of the components.

Leghemoglobin shows similarities to other hemin proteins in respect to molecular weights. The molecular weight of 16 800 for the faster component closely resembles the unit molecular weight of animal hemin proteins. Such a molecular weight has also been found for the hemoglobin of *Lampetra fluviatilis* [3]. The electrophoretically slower component, with its molecular weight of 15 400, falls in a class between the molecular weight of *Lampetra* hemoglobin and that of animal cytochrome c.

Acknowledgements. The author wishes to express his thanks to Professor Hugo Theorell and to Dr Anders Ehrenberg for valuable discussions and advice during the course of this work. Able technical assistance has been given by Miss Bodild von Sobeck in running the ultracentrifuge. The investigation has been supported by a grant from *Finlands State Commission of Natural Sciences* (*Statens Naturvetenskapliga Kommission*) which is gratefully acknowledged.

Extraction of Mucopolysaccharides from Connective Tissue

ANUND HALLÉN

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

Human *nucleus pulposus* and umbilical cords were extracted with water, and the extracts and residues obtained on centrifugation were analyzed for mucopolysaccharides. It was found that, in the extract of *nucleus pulposus*, the yield of keratosulphate was smaller than that of chondroitin sulphate. In the umbilical cord extract, the yield of chondroitin sulphate was smaller than that of hyaluronate.

It is a general experience that the chondroitin sulphate of cartilage is so firmly bound that a good yield can be obtained only with the use of drastic methods for preparation, such as extraction with strong alkali [1–4], or disintegration of the tissue by proteolytic digestion [5–7], by autodigestion [8] or by vigorous mechanical treatment [9]. With neutral salt solutions, only small amounts of mucopolysaccharides are extracted [10,4]. Even such a strong solution as 10 % calcium chloride [11] is ineffective [10], whereas 1 % potassium carbonate in 30 % potassium chloride [8] is moderately effective in extracting the chondroitin sulphate of cartilage.

Differences are, however, present between various tissues with respect to the ease with which their mucopolysaccharides can be extracted. For instance, a large part of the hyaluronate can be extracted from umbilical cords with such a mild agent as distilled water [12].

It was considered of interest to investigate in some detail differences in the extractability of individual mucopolysaccharides. An account is given in the following of experiments with adult human *nucleus pulposus*, and with human umbilical cords, freed from vessels. It seems to be well established [13–17] that chondroitin sulphate and keratosulphate are the main polysaccharides in the *nucleus pulposus*. As indicated by the results of infrared spectrum [18] and alcohol fractionation studies [17], the chondroitin sulphate is the 6-isomer. The mucopolysaccharides of the umbilical cord are less well characterized, although hyaluronate is known to be the main polysaccharide [12,19,16]. According to results of Meyer *et al.*[12,19,20] and of Mathews [21], chondroitin-6-sulphate is also present.

EXPERIMENTAL

Prparation of the tissues. Healthy intervertebral discs were taken at autopsy from a 59-year-old man, one day after death. The *nucleus pulposus*, the central part of the disc, was dissected free from the surrounding *annulus fibrosus*.

Human umbilical cords were obtained not more than one day after delivery, and were freed from blood vessels. It was found that the most suitable procedure was to cut the cord into 2 cm pieces, thread a peg through the vein, fix the peg on a stand and dissect out the stroma with a razor-blade. The arteries were then removed by blunt dissection.

The tissues were homogenized by grating and grinding. The doughy material was stored for some weeks at −15°C, and thawed immediately before use.

Extraction of the mucopolysaccharides. About 4 g each of wet *nucleus pulposus* and umbilical cord tissues were extracted with 250 ml of distilled water overnight at 0°C, under gentle stirring. Centrifugation for 20 min at about 15,000 *g* yielded a clear extract and a residue from both tissues. After evaporation of the extract *in vacuo* to a small volume, the material was freeze-dried.

Analysis of the freeze-dried extracts and residues. Hexosamines and disaccharides were analyzed with the chromatographic method described earlier [16], glucosamine and galactosamine after hydrolysis for 8 h in 6 M hydrochloric acid, chondrosin and hyalobiuronic acid after hydrolysis for 2.5 h in 0.6 M hydrochloric acid. Sulphate sulphur was determined gravimetrically as barium sulphate, after hydrolysis for 4 h with 4 M hydrochloric acid. Nitrogen was determined by a micro-Kjeldahl procedure. Collagen was determined by means of hydroxyproline analysis [22,23]. The collagen content was obtained by multiplying the hydroxyproline value by the factor 7.5.

The ratio of galactose/glucuronic acid in the *nucleus pulposus* extract and residue was determined colorimetrically after partial purification of the mucopolysaccharides. Samples of the extract and residue were boiled with water for 30 min, and submitted to digestion with glycerol extracts of pig pancreas and intestinal mucosa [6,13] for 2 months. To ensure complete hydrolysis of the proteins, a second digestion with papain [7] was carried out overnight, after preliminary heat denaturation in a boiling water bath for 15 min. The mucopolysaccharides, together with some impurities, were precipitated by the addition of one volume of 10 % calcium chloride in glacial acetic acid and four volumes of 10 % calcium chloride in ethanol. The mucopolysaccharides were then extracted from the precipitate by stirring vigorously with distilled water. The galactose content of the clear and colourless solutions obtained on centrifugation was determined with the anthrone method of Scott and Melvin [24], and the glucuronic acid content with the carbazole method of Dische [25]. The interference, amounting to some 10 %, of glucuronic acid in the anthrone reaction, and of galactose in the carbazole reaction was neglected. This approximation is possible provided that the galactose/glucuronic acid ratio does not differ greatly from 1. The presence of interfering sugars other than galactose and glucuronic acid is not probable, but has not yet been experimentally excluded.

Table 1. Analyses of freeze-dried extracts and residues of *nucleus pulposus* and umbilical cord *.

Material analyzed	Moisture %	Ash %	Collagen %	Nitrogen %	Sulphur %	Hexosamine %	Hexosamine % of total	Hexosamine / Sulphur molar ratio
Nucleus pulposus								
Extract: 0.42 g	10.1	15.4	0.1	5.9	2.73	9.2	52	0.6
Residue: 1.32 g	9.2	3.2	40.2	14.3	0.52	2.7	48	0.9
Umbilical cord								
Extract: 0.36 g	5.9	22.1	0.1	8.5	0.20	2.0	66	1.8
Residue: 0.93 g	11.3	2.7	50.3	14.8	0.10	0.4	34	0.7

* Hexosamine content of freeze-dried tissues: *nucleus pulposus* 6.5 %; umbilical cord 1.3 %.

RESULTS AND DISCUSSION

Behaviour of nucleus pulposus. As shown in Table 1, the hexosamines, *i.e.* glucosamine + galactosamine, were obtained in about 50 % yield in the extract. The molar ratio of hexosamine/sulphate was close to 1 in the residue, but somewhat less in the extract, probably depending on the presence of sulphate ions. The collagen remained, as expected, quantitatively in the residue. The high nitrogen contents indicate the presence of protein other than collagen. Nitrogen values higher than expected from the collagen and hexosamine contents have proved to be a constant finding, even after careful exclusion of blood contamination and dialysis.

For a more detailed study of the hexosamines in the extract, another water extract was prepared from 13 g of a pooled *nucleus pulposus* sample. The molar ratio of hexosamine/sulphate was found to be 0.79, but after dialysis it rose to 1.04. The ratio of glucosamine/galactosamine was 0.65 before dialysis, and 0.62 after, thus practically the same. The hexosamine losses during dialysis were negligible. These results are well compatible with the presence of keratosulphate and chondroitin sulphate.

Table 2. Molar ratios of sugar components in freeze-dried tissue specimens, extracts and residues of *nucleus pulposus* and umbilical cord *.

Material analyzed	*Nucleus pulposus*			*Umbilical cord*	
	glucosamine / galactosamine	glucosamine / chondrosin	galactose / glucuronate	glucosamine / galactosamine	mucosin / chondrosin
Untreated tissue	0.97	1.05	—	3.5	1.8
Extract	0.82	0.44	0.79	9.5	12.6
Residue	1.68	1.91	1.23	1.5	0.8

* Mucosin synonymous with hyalobiuronic acid. The glucosamine/galactosamine ratio in annulus fibrosus surrounding the *nucleus pulposus* was 0.89.

As shown in Table 2, the ratio of glucosamine/galactosamine was lower in the extract than in the residue. This implies that the ratio of keratosulphate/chondroitin sulphate was lower in the extract than in the residue. Further evidence is afforded by the fact that the ratio of glucosamine/chondrosin was lower in the mild acid hydrolysate of the extract than of the residue, as was the ratio of galactose/glucuronic acid.

In order to study the influence of salt on the extraction, 5—6 g of pooled *nucleus pulposus* were extracted with 500 ml of 1 % sodium chloride. The residue was then extracted twice with 250 ml of 1 % sodium chloride. The ratio of glucosamine/galactosamine, which was 0.89 in the original sample, was 0.57 in the first extract and 0.91 in the second. The third extraction yielded practically no material, the ratio in the residue being 2.00. In another experiment, 10 % calcium chloride was used; the ratio of glucosamine/galactosamine was 0.75 in the first extract, 1.03 in the second, 1.03 in the small amount of material obtained in the third extract, and 1.26 in the residue. In this experiment, as in that with 1 % sodium chloride, all the material had been dialyzed before

freeze-drying. The results indicate that salts do not influence the differences in extractability.

In the experiments with 1 % sodium chloride and 10 % calcium chloride, only some 1—2 %, and 2—3 %, respectively, of the collagen was obtained in the extracts. This is in accordance with findings of Davidson and Woodhall [17]. The yield of hexosamines in the extracts was the same as when distilled water was used, or slightly greater, in conformity with the results of Hass and Garthwaite [10] in the case of cartilage.

Behaviour of umbilical cord. It is evident from Table 1 that the hexosamine/sulphate ratio was fairly high in the extract, as could be expected in view of the predominance of hyaluronate, whereas the very approximate value of this ratio in the residue was lower. As seen in Table 2, the ratio of glucosamine/galactosamine was much higher in the extract than in the residue. These results are in good agreement with those of Meyer and Palmer [12], and indicate a higher hyaluronate/chondroitin sulphate ratio in the extract than in the residue. This is also borne out by the higher ratio of hyalobiuronic acid/chondrosin in mild acid hydrolysates of the extract than of the residue.

Interpretation of the results. The results of this study indicate that differences are present between the mucopolysaccharides with respect to their extractability. Thus, in *nucleus pulposus* keratosulphate is more difficult to extract than chondroitin sulphate, whereas in umbilical cord chondroitin sulphate is more difficult to extract than hyaluronate. Since the experiments were performed with homogeneous tissues, the conditions of extraction of the individual mucopolysaccharides thus being comparable, these differences may reflect differences in the properties of the mucopolysaccharides themselves, of their complexes with non-collagenous protein [26,27], or their attachment to the collagen fibers. Unfortunately, a detailed interpretation is, as yet, difficult, in view of our incomplete knowledge of the mucopolysaccharides and of the proteins in the connective tissue.

It is possible that the extractability of the mucopolysaccharide fraction may influence the physical and morphological properties of the tissue. For instance, the *nucleus pulposus* of a young subject is a viscous fluid, whereas in the old it is somewhat dry and firm and — in the highest age groups — is easily torn. This might be explained, to some degree, by an increase in the ratio of keratosulphate/chondroitin sulphate with age [15,16], which — according to the results of the present investigation — would imply a shift to a less easily extractable mucopolysaccharide component. There are reasons to believe that the deposition of other materials that are difficult to extract, such as collagen and "lipofuscin", may also be of importance for the change in the nature of the tissue with age.

Acknowledgements. I am greatly indebted to Docent Lennart Rodén and Docent Sven Gardell for valuable discussions, as well as to Mrs. Ruth Flagell for skilful technical assistance.

Effect of Arsenate on Oxidative Phosphorylation and Related Reactions

G. F. Azzone* and L. Ernster

Wenner-Grens Institute, University of Stockholm, Stockholm, Sweden

Crane and Lipmann [1] have shown in 1953 that arsenate causes uncoupling of respiration from phosphorylation in washed particles from rat liver, accompanied by a depression of the respiration in the presence of various substrates. The uncoupling occurred in a gradual manner, increasing in extent with the duration of the incubation. We have now been able to confirm these findings using intact rat liver mitochondria and a variety of substrates including glutamate, succinate and β-hydroxybutyrate. We have found, furthermore, that arsenate also induces an adenosine triphosphatase activity in the mitochondria, as well as a release of endogenous inorganic and high-energy phosphates, and that these effects take place prior to the uncoupling of the electron transport coupled phosphorylation. These findings are illustrated in Tables 1 and 2.

Table 1 shows that the arsenate-induced ATP-ase (which has recently also been observed by Azzone *et al.*[2] and by Wadkins [3]) reached a maximal activity at 3 mM arsenate, and that this activity was about 8 times higher than that found in the absence of arsenate; this maximum was about 2-3-fold lower than the ATPase activity induced by 10^{-4} M 2,4-dinitrophenol. Addition of succinate (or other substrates) resulted in an apparent depression of the ATPase activity, due to the phosphate uptake accompanying the oxidation of these substrates which, as could be ascertained in parallel tests, was not seriously impaired by low concentrations of arsenate in these short-term experiments. As expected, this effect of added substrates could be abolished by inhibiting the respiration with antimycin A (and, in the case of DPN-linked substrates, also with amytal).

The depleting effect of arsenate on mitochondrial endogenous phosphates is illustrated in Table 2. For these studies, so-called "^{32}P-labelled mitochondria" were prepared according to Beyer *et al.*[4], *i. e.*, preparations of mitochondria obtained from liver to which a suitable quantity of ^{32}P-orthophosphate was added during the homogenization procedure. These mitochondria, as demonstrated by Beyer *et al.*[4], contain most of the bound ^{32}P in the form of orthophosphate and high-energy phosphates, the ratio of the former to the latter varying between 7:3 and 5:5. When such mitochondria were suspended in a sucrose-KCl medium and incubated at 30°C in the presence of 1—3 mM arsenate, a rapid release of the bound ^{32}P took place, reaching nearly completeness within 5 min. 2 mM amytal, which caused a slight release by itself, greatly protected the mitochondria against the arsenate-induced release; antimycin A and cyanide, in contrast, gave only a weak protection. Of interest is also that 2,4-dinitrophenol, which has earlier been shown by Teply [5] to release the so-called "gel-phosphate" from "cyclophorase" preparations, had only a partial releasing effect under the present

10	1.88	0.77	2.07

Each tube contained: 100 μmoles KCl, 50 μmoles TRIS buffer pH 7.5, 10 μmoles ATP, 125 μmoles sucrose, mitochondria from 100 mg rat liver (wet weight) and, when indicated, 10 μmoles succinate and 1 μg antimycin A; final volume 2.0 ml. Temp. 30°C. Time of incubation 20 min.

conditions. However this effect could be markedly enhanced by adenosine-5′-phosphate, presumably due to a conversion of intramitochondrial ATP into extramitochondrial (*cf.*Ref.[6]). Finally, succinate greatly inhibited the releasing effect of arsenate, at the same time as it promoted the effect of dinitrophenol. These effects, the possible mechanisms of which will be discussed in some detail, have recently been of great importance as a basis for demonstrating a requirement of high-energy phosphate for the aerobic oxidation of succinate by intact rat liver mitochondria [7].

The above findings will be discussed in relation to the hypothesis that the arsenate-induced ATPase and release of mitochondrial endogenous phosphate are primary manifestations of the general, gradual uncoupling effect of arsenate, observed by Crane and Lipmann [1]. It is visualized that these primary effects reflect an active uptake of arsenate by the mitochondria, this process possibly involving an electron transport via the amytal-sensitive step of the respiratory chain, accompanied by an oxidative arsenylation.

The Presence of a Phosphodeoxyribomutase Activator in Deoxyribose 1-Phosphate Preparations

E. Christiansen, J. Jonsen, S. Laland and J. McKinley McKee

Department of Biochemistry, University of Oslo, Blindern, Norway

The presence of an enzyme in calf thymus converting deoxyribose 1-phosphate to the 5-phosphate was originally described by Manson and Lampen [1]. In studying this reaction, we have prepared the substrate deoxyribose 1-phosphate enzymatically from thymidine and phosphate using horse liver phosphorylase [2]. The sugar phosphate was isolated as the crystalline di*cyclo*hexylamine salt. When chromatographed in *n*-propanol-conc. NH_3 (6:4) and developed with the diphenylamine spray it was homogeneous and had R_F value different from that of deoxyribose 5-phosphate. Paper electrophoresis in phosphate buffer pH 7.5 gave one band only. Its phosphorus/deoxyribose ratio was 1.01.

The phosphodeoxyribomutase used was extracted from calf thymus with 1 % KCl and purified by ammonium sulphate fractionation, phosphate gel adsorption and gradient elution with Tris-hydrochloric acid, pH 7.4, on a DEAE cellulose column. A fifty-fold purification was usually achieved.

The presence of an activator in the substrate was demonstrated in the following way. 3 μmoles of the di*cyclo*hexylamine salt of deoxyribose 1-phosphate were run electrophoretically in phosphate buffer pH 7.5. Ribose 1-phosphate and ribose 1,5-diphosphate were used as reference substances. Deoxyribose 1-phosphate was located by the diphenylamine test whereas the ribose phosphates were detected by the aniline phthalate spray. In one experiment deoxyribose 1-phosphate and ribose 1-phosphate had a mobility of 9.5 cm compared with 12.5 cm for ribose 1,5-diphosphate. Activation was demonstrated with material eluted from an area of the deoxyribose 1-phosphate run corresponding to the mobility of ribose 1,5-diphosphate. The activating material (A) and the deoxyribose 1-phosphate band (purified deoxyribose 1-phosphate) were freeze-dried after elution from the paper.

The enzymatic test system was set up in 0.004 M Tris-hydrochloric acid buffer, pH 7.4, and contained 0.34 μmoles deoxyribose 1-phosphate, 9.6 μg purified enzyme (60 × purification) in a total volume of 0.85 ml. The mixture was incubated for 30 min at 23°C. The amount of deoxyribose 5-phosphate formed was estimated by a novel procedure [3] utilizing the difference in the diphenylamine colour before and after reduction with sodium borohydride.

It is apparent from the table that purification of the substrate by electrophoresis substantially reduces the enzymic activity. The activity is not restored by the addition of 8-hydroxyquinoline whereas the addition of ribose 1,5-diphosphate in the presence of 8-hydroxyquinoline restores the activity. Addition of part of the material present in area A also restores the activity. Furthermore it was shown that the eluate of a similar blank area of the paper did not restore the activity. Since the mobility of the activating substance is equal to that of ribose 1,5-diphosphate, the presence of a sugar diphosphate in the deoxyribose 1-phosphate employed is suggested. Analysis of the material in area A showed that only traces (<0.4 %) of a deoxyribose 1,5-diphosphate could be present.

[a] The material obtained from 3 μmoles of deoxyribose 1-phosphate was dissolved in 1 ml water.
[b] Activity of enzyme in the presence of not purified deoxyribose 1-phosphate: 100 %.

In connection with the present finding it is interesting to note that biosynthetically prepared ribose 1-phosphate contains an activator, for the phosphoribose mutase reaction. This activator is removed by ion exchange chromatography of the substrate [4].

Enzymic Properties of Human Skeletal Muscle Mitochondria

O. Eeg-Olofsson*, G. F. Azzone**, R. Luft and L. Ernster

Wenner-Gren Institute, University of Stockholm, and Department of Endocrinology, Karolinska Sjukhuset, Stockholm, Sweden

Certain enzymic properties of isolated human skeletal muscle mitochondria have been investigated on the basis of knowledge from, and in comparison with, known properties of mitochondria from animal tissues, in the first place skeletal muscle, heart muscle, and liver. Human skeletal muscle mitochondria catalyze a rapid aerobic oxidation of pyruvate (in the presence of malate) and of α-ketoglutarate, whereas other Krebs-cycle metabolites are oxidized at relatively low rates. However, the oxidation of succinate can be greatly enhanced if the accumulation of oxaloacetate is prevented by the addition of either amytal or cysteine sulfinic acid. Glutamate is oxidized usually at high rate, whereas other amino acids as well as fatty acids give rise only to low rates of respiration. Glycerol-1-phosphate was oxidized at low rate under the experimental conditions used.

The respiration with all substrates was accompanied by a phosphate uptake, and the P/O ratios approached the values generally accepted for intact mitochondria, *i. e.* 3 in the case of DPN-linked substrates, and 2 in the case of succinate. The mitochondria exhibited a high extent of respiratory control, as revealed by a severe lowering of the respiratory rate when the terminal phosphate acceptor system, *i. e.* ATP, hexokinase and glucose, was omitted from the incubating medium. Catalytic amounts of ATP enhanced this "resting" respiration, and this enhancement was a function of the concentration of Mg^{++} present in the medium. This function parallelled the resting ATPase activity of the mitochondria, both reaching maximum at a Mg^{++} concentration of 0.5—1 mM. A relatively high Mg^{++}-activated ATPase activity seems to be a common attribute of intact muscle mitochondria from different sources, which, as will be pointed out, must be taken into account when desiring to obtain an adequate estimate of the respiratory control capacity of these mitochondria; addition of catalytic amounts of ATP to the resting respiratory system may obscure the true extent of respiratory control. It is postulated that this ATPase differs in mechanism from that found in structurally damaged rat liver mitochondria in that it does not involve the primary high-energy intermediate(s) of electron transport coupled phosphorylation.

2,4-Dinitrophenol uncouples respiration from phosphorylation in human skeletal muscle mitochondria and gives rise to an increased ATPase activity, both effects reaching maximal extent at a dinitrophenol concentration of 10^{-4} M. On the other hand a concentration of dinitrophenol as low as 10^{-5} M, which affects phosphorylation and ATPase activity only slightly, completely abolishes respiratory control, *i. e.* gives rise to maximal respiration even in the absence of terminal phosphate acceptor. Possible interpretations of this phenomenon will be discussed. 10^{-4} M dinitriphenol also inhibits to some extent the respiration of human skeletal muscle mitochondria when this is supported by glutamate, but not when it is supported by α-ketoglutarate. Bovine serum albumin partially protects against all effects of dinitrophenol, as well as of other uncouplers such as dicoumarol and gramicidine.

The data will be discussed in relation to some earlier findings [1] made with skeletal muscle mitochondria from patients with elevated basal metabolic rates.

Selective Extraction of DT Diaphorase from Mitochondria and Microsomes

L. Danielson, L. Ernster and M. Ljunggren

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

We recently reported the purification from the soluble fraction of rat liver cytoplasm of a diaphorase oxidizing DPNH and TPNH at equal rates, and reacting with a number of dyestuffs and quinones as electron acceptors [1]. The enzyme, called DT diaphorase, was characterized by a requirement for an activator, in the form of a dispersing agent such as serum-albumin or Tween-20, to exhibit maximal activity, as well as by a high sensitivity to dicoumarol. Although the bulk of the enzyme was found in the soluble fraction of the cytoplasm, portions of the enzyme were consistently recovered in the mitochondrial and microsomal pellets, and could not be removed from these by repeated washing with 0.25 M sucrose. However, when these pellets were suspended in 0.003 M phosphate-buffer, pH 7.5, and the suspensions treated in the cold with a Super-Thurrax blendor for 2 min, the clear supernatant obtained upon recentrifugation of the suspensions at high speed contained DT diaphorase. Moreover, the solutions so obtained were practically free from other diaphorase elements present in the mitochondria and microsomes. Illustrative data are summarized in Tables 1 and 2.

Table 1 shows an experiment with mitochondria. The blendorizing procedure employed here was adapted from that previously used by Kielley and Kielley [2] for the preparation of mitochondrial adenosine triphosphatase. It consisted of a treatment of the mitochondrial suspension with the Super-Thurrax blendor as described above, followed by a centrifugation of the treated suspension at 20 000 *g* for 10 min. The sediment was resuspended in 0.003 M phosphate buffer and the suspension was blendorized once again and recentrifuged as above. The two supernatants were combined and centrifuged at 105 000 *g* for 30 min. Three fractions were thus obtained: a "low-speed pellet", a "high-speed pellet", and a final supernatant. As shown in Table 1, only the final supernatant exhibited an appreciable TPNH diaphorase activity, and this was accompanied by an equally high DPNH diaphorase activity. Moreover, these activities were enhanced by 0.3 % Tween-20 and strongly inhibited by 10^{-6} M dicoumarol. By contrast, the DPNH diaphorase activities found in the low- and high-speed pellets were not stimulated (and even slightly inhibited) by 0.3 % Tween-20, and were completely insensitive to 10^{-6} M dicoumarol. When the supernatant solution was subjected to chromatography on DEAE-cellulose column, the TPNH and

Table 1. Diaphorase activities of mitochondrial subfractions. For fractionation procedure, see text. The test system contained: 0.04 mM 2,6-dichlorophenolindophenol (DCPIP), 0.1 mM DPNH or TPNH, 0.33 mM KCN and 0.05 M potassium phosphate, pH 7.5.

	TPNH	0.15	0.27	0.16
Recovery	DPNH	1.33		
	TPNH	0.34		

DPNH diaphorase activities were recovered in the same fraction.

An experiment with microsomes is shown in Table 2. Here, the treatment with the Super-Thurrax blendor was followed directly by centrifugation at 105 000 *g* for 60 min, after which the pellet was resuspended in 0.003 M phosphate-buffer, retreated with the blendor, and recentrifuged. The procedure was repeated three times altogether, thus resulting in three supernatant fractions and one final pellet. As seen in Table 2, the first supernatant exhibited equally high DPNH and TPNH diaphorase activities, and these were stimulated by 0.3 % Tween-20 and strongly inhibited by 10^{-6} M dicoumarol. The second and third supernatants exhibited only low TPNH diaphorase activities, and definitely higher, though still low, DPNH diaphorase activities. The final pellet revealed a high DPNH diaphorase activity, which was partially inhibited by 0.3 % Tween-20, and completely insensitive to 10^{-6} M dicoumarol. This fraction contained furthermore a definite portion, about half, of the TPNH diaphorase activity of the original microsomes. This TPNH diaphorase was, like the one found in the first supernatant, markedly enhanced by 0.3 % Tween-20, but in contrast, it was completely insensitive to 10^{-6} M dicoumarol.

The data presented above are consistent with the conclusion that DT diaphorase occurs both in mitochondria and microsomes, and can be selectively released from these elements after disruption of their structure by suitable means. Mitochondria seem to contain only one major enzyme with TPNH diaphorase activity and this is entirely accounted for by DT diaphorase. This conclusion is consistent with the previous finding of Stein and Kaplan [3] that column-chromatography of extracts of sonicated mitochondria yielded only one fraction with TPNH diaphorase activity, and that this fraction coincided with one of the two DPNH diaphorase fractions found by these authors. Microsomes, on the other hand, seem according to the present data to contain two types of TPNH diaphorase activity. One of these is accounted for by DT diaphorase, whereas the other seems to be independent of this enzyme as indicated by its resistance to dicoumarol and its firm association with the microsomal structure. The possible relation between this enzyme and the TPNH-neotetrazolium reductase recently found in microsomes by Williams *et al.*[4] is presently being investigated.

A Liver-Microsomal Enzyme System Liberating Orthophosphate from Nucleoside Di- and Triphosphates

Lois C. Jones and Lars Ernster

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

Freshly prepared microsomes from 0.25 M sucrose homogenates of rat liver exhibit a high "ATPase" activity. This activity resembles the "latent" ATPase activity [1] appearing in liver mitochondria upon structural damage in the following respects: 1) it requires added Mg^{++} [1]; 2) it is stimulated by $Na_2S_2O_4$ [2,3]; 3) it is inhibited by atebrin [3], chlorpromazine [4], azide [5,6]; 4) the enzyme is not strictly specific (like the dinitrophenol-induced ATPase of intact mitochondria) for ATP, but reacts, in a non-additive manner, with the five nucleoside triphosphates, ATP, GTP, UTP, CTP and ITP [7].

In the course of attempts to more closely characterize this enzyme it was observed that the activities with the different nucleoside triphosphates responded in different ways to the presence of sodium deoxycholate (DOC) in the test system. Thus, at 0.05 % DOC, the GTPase and UTPase activities became markedly stimulated, whereas the activities with the other three triphosphates either decreased or remained unchanged; at higher DOC concentrations, all five activities were strongly inhibited. Simultaneously it was also found that a nucleoside diphosphatase activity, which was relatively low in the absence of DOC, revealed a strong increase at both 0.05 and 0.1 % DOC in the case of GDP, UDP or IDP as substrates, whereas it remained unchanged or became inhibited with ADP or CDP as substrates.

Treatment of microsomes with 0.26 % DOC in the cold, and subsequent centrifugation at 105 000 *g* for 2 h, resulted in a clear supernatant fraction, which exhibited a high activity toward GDP, UDP and IDP as compared with the two remaining diphosphates and the five triphosphates. Table 1 illustrates the nucleoside di- and triphosphatase activities of this fraction as compared with those found in the original microsomes. The activities of the three active diphosphatases recovered in this fraction corresponded to about 90 % of the total activities found in the DOC-treated microsomes. The five triphosphatase activities were concentrated, 2—8 fold on the protein basis, in a loose pellet appearing in this fractionation [8] on the top of the tightly packed ribonucleoprotein particles. This loose pellet has recently been found [9] to contain the microsomal DPNH-cytochrome c reductase and glucose-6-phosphatase activities in a concentrated form. The ribonucleoprotein particle fraction exhibited only marginal di- and triphosphatase activities.

When the clear DOC supernatant was tested with the three active diphosphates in combination the resulting activity did not exceed the maximum found with the individual diphosphates; addition of the two remaining diphosphates lowered this activity slightly. The di-

Table 1. Nucleoside di- and triphosphatase activities of rat liver microsomes, as determined in fresh preparations and in deoxycholate-extracts. The test system contained microsomes or microsomal extract from 40 mg wet weight liver, 2.5 μmoles substrate, 2 μmoles $MgCl_2$, and 25 μmoles TRIS buffer, pH 7.5, in a final volume of 0.5 ml. Incubation at 30°C. The values are expressed in terms of μmoles orthophosphate liberated in 10 min. per gram microsomal protein.

Substrate	Microsomes	Deoxycholate-extract
ATP	846	158
GTP	865	525
UTP	702	420
CTP	747	281
ITP	1 026	368

UDP	576	2 012
CDP	207	123
IDP	640	1 595

phosphatase activities required added Mg++ and were inhibited by atebrine, chlorpromazine and azide to about the same extent as the triphosphatases.

The above findings seem to indicate that freshly prepared rat liver microsomes exhibit a nucleoside triphosphatase activity which resembles that of structurally damaged rat liver mitochondria in regards to behavior toward certain activators and inhibitors, lacking nucleoside specificity, and firm association with the membrane structure. In addition, microsomes seem to contain a "latent" nucleoside diphosphatase activity, which can be rendered manifest by disruption of the microsomal membranes. This enzyme resembles the nucleoside triphosphatase in its behavior toward certain activators and inhibitors, but differs from the latter in possessing a more restricted array of nucleoside specificity, as well as in being more loosely associated with the microsomes.

An enzyme with a similar array of specificity has been known for some time [10-13], but its association with microsomes and its latent character have not been reported.

By-Pass of the Amytal-Sensitive Site of the Respiratory Chain in Mitochondria by Means of Vitamin K_3

T. E. Conover* and L. Ernster

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

A soluble diaphorase (DT diaphorase) from liver has been isolated which can couple the oxidation of extramitochondrial reduced pyridine nucleotide through vitamin K_3 to the respiratory chain of mitochondria [1]. The cellular distribution of this enzyme has been shown[2], and significant amounts can be extracted from isolated mitochondria [3].

The presence of this enzyme in intact mitochondria and its interaction with intramitochondrially-generated reduced pyridine nucleotide is demonstrated in this paper by the bypassing of the point of amytal inhibition in the respiratory chain with the addition of vitamin K_3.

Mitochondria freshly prepared from rat liver as previously described [4] were incubated in a isotonic, buffered medium containing substrate, phosphate, Mg++, adenosine triphosphate, hexokinase and glucose. In these conditions the pyridine nucleotide-linked oxidation of substrates showed the usual high rates and strong sensitivity to amytal as is shown for glutamate in Table 1. The addition of low concentrations of vitamin K_3 (5×10^{-6} M) to the amytal-inhibited system gave a complete recovery of the maximal respiration. It can also be seen from Table 1 that this respiration was highly sensitive to antimycin A, KCN, and dicumarol. The high degree of inhibition obtained by low concentrations of dicumarol strongly implies the role of DT diaphorase, as the high sensitivity of this enzyme to dicumarol is considered to be very characteristic[2].

It was found that the concentration the of vitamin K_3 was important in this reaction as concentrations under 5×10^{-6} M were limiting in the oxidation of glutamate in these conditions, while higher concentrations were often inhibitory. This inhibition seemed to be related to a loss of pyridine nucleotide and could be protected at least partially by added nucleotide or nicotinamide.

Table 1. Effect of vitamin K_3 and various inhibitors on the respiration of mitochondria in the presence of amytal.

Additions	μatoms oxygen
none	5.49
vitamin K_3	5.57
dicumarol	5.32
amytal	0.22
amytal + vitamin K_3	5.25
amytal + vitamin K_3 + antimycin A	1.57
amytal + vitamin K_3 + KCN	1.18
amytal + vitamin K_3 + dicumarol	1.13

The complete system contained per Warburg vessel: 10 μmoles glutamate, 20 μmoles Tris buffer (pH 7.4), 20 μmoles orthophosphate (pH 7.4), 4 μmoles $MgCl_2$, 2 μmoles adenosine triphosphate, 24 μmoles glucose, an excess of yeast hexokinase, 50 μmoles sucrose, and mitochondria from 200 mg rat liver. The amounts of the additions were as follows: 5×10^{-3} μmoles vitamin K_3, 10^{-2} μmoles dicumarol, 1.0 μmoles amytal, 1 μg antimycin A, and 1.0 μmoles KCN. Final volume, 1.0 ml. Temperature, 30°C. Reading begun after 6 min. thermoequilibration. Time measured, 20 min.

» + 10^{-5} M coenzyme Q_0			0.72

Conditions were the same as Table 1. Quinones were added in 10 μl ethanol. Time measured, 20 min.

It was of great interest to observe also that there was a very high degree of specificity with regards to the structure of the quinone. As can be observed in Table 2, not only did other common electron carriers such as DPN, FAD, cytochrome c, and ascorbate fail to give the bypass of the amytal inhibition, but likewise closely related benzoquinones and naphthoquinones were considerably less active. Since it has been shown that these quinones may accept electrons from the DT diaphorase [2] the specificity must be in the interaction of the reduced quinone with the respiratory chain.

This amytal-insensitive system shows the ability to couple respiration to the esterification of phosphate. The P/O ratios observed vary depending upon the substrate used from approximately 0.9 with β-hydroxybutyrate to 1.3 with glutamate. It is difficult to determine from these values whether one or two sites of respiratory chain phosphorylation are involved. However, the low values may be partly due to a slight uncoupling activity of the vitamin K_3 as determined with succinate as substrate. The phosphorylation was completely sensitive to 10^{-4} M DNP.

The question of the antimycin A sensitivity of this respiration has been further investigated. It is felt that it must be due to an unavailability of the cytochromes of the respiratory chain on the oxidizing side of the antimycin A-sensitive site, such as, for instance, cytochrome c, which has been shown [2] to be rapidly reduced in isolated systems by reduced pyridine nucleotide in the presence of DT diaphorase and vitamin K_3. The addition of purified cytochrome c to the mitochondrial system gives a several fold stimulation of the antimycin A-insensitive respiration. This respiration is also sensitive to KCN and dicumarol.

Oxidative Phosphorylation with Endogenous Mitochondrial Substrates

Eugene C. Weinbach*

National Institutes of Health, Bethesda, Maryland, U.S.A.

During recent studies of oxidative phosphorylation [1,2], we observed that carefully isolated rat liver mitochondria, when incubated in media containing the usual cofactors of oxidative phosphorylation, catalyzed a substantial uptake of inorganic orthophosphate in the absence of any added exogenous substrate. In Table 1 are shown representative data that illustrate the magnitude of this activity as well as the excellent stoichiometry that was obtained when the endogenous values were subtracted from those observed with added substrate. Independent experiments revealed that the internal substrates were not readily exhausted in short term incubations at 30°. In view of the large endogenous activity found with these preparations, in contrast to what has been observed previously [3-5], it was necessary to establish by anion exchange chromatography, and other tests, that the endogenous phosphate uptake was not an artefact of the assay procedure and that it led to an aerobic synthesis of ATP.

Experiments with inhibitors indicated the following: a) the endogenous phosphate uptake is associated with an *oxidative* phosphorylation since it was completely abolished by anaerobiosis, cyanide, azide, antimycin A, dinitrophenol and other uncoupling agents; b) tricarboxcylic acid cycle intermediates are not sole contributors to the endogenous activity since only partial inhibition was obtained with malonate and fluoroacetate; c) the internal substrates are oxidized *via* pyridine nucleotides. This was demonstrated by the finding that amytal completely prevented the endogenous phosphate uptake (*cf.* Ref.[6]).

Previously we had observed [2] that a high rate of endogenous activity was characteristic of mitochondria which were stable to prolonged storage at 4°. Indeed, when mitochondria from tissues other than liver were assessed both for their endogenous activity and for their stability of oxidative phosphorylation with added substrate, a positive correlation was found; *i. e.* those preparations which exhibited the

Particulate and Soluble D-Lactic Cytochrome c Reductase of Yeast

Agnar P. Nygaard

Johan Throne Holst's Institutt for Ernæringsforskning, Blindern, Oslo, Norway

The main fraction of the D-lactic cytochrome c reductase activity (D-LDH) of aerobic yeast was associated with respiratory particles. By means of the extraction of lipids with *n*-butanol, acetone, and ether, 40 % of the enzyme was solubilized. The solubilized enzyme has been purified one thousand fold. The difference spectrum of oxidized/reduced enzyme had absorption maximum at 450 mμ. At pH 3, flavin fluorescence appeared. The flavin concentration, calculated from the spectral difference, agreed well with that obtained from fluorescence intensity. In contrast to the flavohaemoprotein L-lactic cytochrome c reductase (L-LDH), there was no haem associated with the D-enzyme, and the D-enzyme did not reduce the haem of L-LDH. The turnover number of D-LDH was 20 000 min^{-1} $mole^{-1}$, compared with 15 000 for L-LDH.

Particulate as well as solubilized D-LDH were absolutely specific for D-lactate. A preparation of D-LDH, which was obtained directly in a soluble form in the cell homogenate[1], has erroneously been determined to have relative stereospecificity [2]. The apparent Michaelis constant of D-lactate for D-LDH was under certain conditions one thousand fold lower than that of L-lactate for L-LDH.

The oxidation of D-lactate to pyruvate went to completion with excess of cytochrome c. At a relatively high buffer concentration (μ 0.08), the initial rate of reaction has been determined for a series of cytochrome c concentrations, each with a series of D-lactate concentrations. The results can be summarized as follows: The apparent Michaelis constant of D-lactate was proportional to the cytochrome c concentration, and the rate, obtained with excess of lactate, was proportional to the cytochrome c concentration. These criteria, which were the same for soluble and particulate enzyme, are fullfilled in the following reaction scheme (where E = enzyme, SH_2 = lactate, and A = cytochrome c):

$$SH_2 + E \rightleftharpoons SH_2 \cdot E \xrightarrow{k_3} S + EH_2$$

$$EH_2 + A \xrightarrow{k_4} E + AH_2$$

In this scheme, $k_3 \gg k_4 \times A$

$$SH_2 + E \rightleftharpoons SH_2 \cdot E \xrightarrow{k_3} S + EH_2$$

$$EH_2 + A \xrightarrow{k_4} E + AH_2$$

In this scheme, $k_3 \gg k_4 \times A$

The fresh preparations of soluble D-LDH reduced ferricyanide at a rate which was 5 % of that with cytochrome c. On storage, the ferricyanide reduction was lost more rapidly than the cytochrome c reductase activity. This could either be ascribed to a modification of D-LDH, or to the presence of another enzyme. The aerobic "D-lactic ferricyanide reductase" had reaction properties strikingly different from those of the corresponding anaerobic enzyme.

Purification of Yeast Hexokinase by Cellulose Ion Exchanger Chromatography

Gunnar Ågren, Lorentz Engström and Sten Eklund

Institute of Medical Chemistry, University of Uppsala, Sweden

In an earlier communication from this laboratory, it was reported that radioactive phosphorylserine could be isolated from a hydrolysate of a crude yeast hexokinase preparation which had been incubated with its radioactive substrate, AT^{32}P or glucose-6-^{32}P[1]. It seemed necessary to perform further studies with a more purified enzyme. Yeast hexokinase was isolated in a crystalline form several years ago [2,3]. By using cellulose ion exchanger chromatography, it now appears possible to obtain a more active preparation than the crystalline enzyme in an easy way.

As starting material, a commercial preparation (Sigma hexokinase, Type III) was used having a specific activity of 100–150 units per mg of preparation (estimated according to Kunitz *et al.*[3]). The activity was raised by two consecutive chromatographic separations using carboxymethyl cellulose columns (Serva Entwicklungslab., Germany) to between 1 200 and 1 900 units/mg protein, respectively. The elution was performed at pH 5 with a gradient increase in the concentration of the acetate buffer (0.02 N → 0.30 N with regard to sodium acetate). The enzyme was then chromatographed on a column of diethylaminoethyl cellulose (Eastman Org. Chem., U.S.A.). It was eluted with a potassium phosphate buffer of pH 7.0, increasing gradually from 0.05 M to 0.30 M. The enzyme was eluted as a main peak with nearly constant specific activity from fraction to fraction. No inactive protein could be separated from the enzyme activity by similar rechromatography of the main part of the enzyme peak. The specific activity was about 3 000 units/mg protein (as compared to about 1 400 units/mg protein found by Kunitz *et al.*[3]). The average yield in the three step purification was about 10 %.

When a sedimentation analysis was carried out in a Spinco ultracentrifuge, Model E, only one boundary was obtained. A single determination of the molecular weight was performed according to Archibald [4], and it was found to be about 50 000.

On Electron Transport and Phosphorylation in Plant and Bacterial Light-Induced Phosphorylation

Herrick Baltscheffsky, Margareta Baltscheffsky and Barbro Arwidsson

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

The following findings from experiments on light-induced phosphorylation (aerobic conditions, saturating light-intensities) will be discussed:

(1) Coenzyme Q_0 stimulates light-induced phosphorylation in isolated spinach chloroplasts. It is, however, less efficient as stimulatory agent than menadione. At 10^{-4} M concentration, for example, coenzyme Q_0 gives only 70 % of the stimulation obtained with the same concentration of menadione.

(2) Valinomycin, which completely uncouples oxidative phosphorylation in animal mitochondria at low concentrations [1], inhibits light-induced phosphorylation in isolated chromatophores of the photosynthetic bacterium *Rhodospirillum rubrum* to approximately 50 %. This may indicate that two phos-

phorylation sites are involved, one of which is affected, whereas the other one remains unaffected. When the rate of light-induced phosphorylation is stimulated several fold by phenazine methosulfate, only a small part of the phosphorylation, which is about equivalent to the sensitive part of the unstimulated system, is inhibited by valinomycin. This supports the conclusion that one of two sites, the "valinomycin-insensitive" one, is activated by addition of phenazine methosulfate. "Cyclic" light-induced phosphorylation in spinach chloroplasts remains unaffected by valinomycin, which may indicate that only a site corresponding to the "valinomycin-insensitive" site in bacterial chromatophores is participating in light-induced phosphorylation of the isolated spinach chloroplasts.

(3) When a preparation of bacterial chromatophores has been aged at 55–57°C, the initially very low stimulation obtained by menadione increases with the aging time, up to 15–25 minutes of preaging, after which a very rapid decrease occurs. In contrast to the stimulation obtained by phenazine methosulfate, that obtained by menadione is very sensitive to low concentrations of the inhibitors antimycin A and 2-*n*-heptyl-4-hydroxyquinoline-N-oxide. Thus a difference has been found between the modes of action of the two stimulatory agents on light-induced phosphorylation.

Glycolysis in Human Erythrocytes Studied with ^{14}C-labelled Glucose

C.-H. de Verdier

Department of Clinical Chemistry, University Hospital, Uppsala, Sweden

The energy required for the maintenance of viability of the erythrocytes is obtained through breakdown of glucose mainly to lactate. Some hemolytic anemias and the aging of erythrocytes *in vitro* or *in vivo* have been shown to be accompanied by disorders in the glycolytic system [1-4].

In order to study these disorders more closely a test system has been worked out. The erythrocytes are washed at 4°C and finally suspended in an inorganic buffered salt solution with the following composition: NaCl 108 mM; KCl 3.9 mM; $MgCl_2$ 5 mM; Na-phosphate (pH 7.4) 20 mM. 2 ml of the suspension (holding 15 % hemoglobin) are incubated at 37° in the two media described in Table 1. After 60 min the glycolysis is stopped by adding perchloric acid. Different perchloric acid soluble substances are then separated using stepwise elution through a Dowex 1 column according to Bartlett [4]. Methylene blue stimulates breakdown along the pentose phosphate shunt [5] and the CO_2 formed during incubation is absorbed to NaOH moistened filter paper strips in the center well of the Erlenmeyer

Dilatometry in the Study of Acyl Shift in Peptides and Proteins

Lars Josefsson

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The dilatometer technique as described by Linderstrøm-Lang [1] has been introduced in our studies on the formic acid induced reversible inactivation of protein enzymes [2-4] in order to elucidate the mechanism of the reactivation process.

From our previous studies three reactions were thought possible in this process, namely 1. an O,N-acyl shift, 2. deformylation of the formylated amino groups, or 3. deformylation of the formylated hydroxyl groups of the hydroxyamino acid residues.

Therefore the volume changes accompanying some proton transfers as well as the O,N-acyl shift in some model substances have been determined in addition to those accompanying the reactivation of formic acid inactivated protein enzymes.

The volume change accompanying the reactivation of ribonuclease when performed in phosphate buffer, *i. e.* 15.3 ml per equivalent base consumed, is in good agreement with that accompanying the proton transfers in the neutralisation of formic acid with secondary phosphate ions, *i. e.* 15.7 ml. In contrast, the value found for an O,N-acyl shift is 21.1 ml. Thus the data strongly suggest that the reactivation is based on a deformylation process.

Dilatometer experiments on formic acid treated glycyl-DL-serine as well as glycyl-O-formyl-DL-serine further suggest that the deformylating process is a splitting of the formamid bond in the O-acyl formed structure.

The Mechanism of the Vitamin K_3 Induced Glutathione Instability in Human Red Blood Cells. The Possible Intermediary Role of Methemoglobin

Andrew Sass-Kortsak*, Bertil Thalme, and Lars Ernster

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

It has been known for some time that administration of vitamin K_3 to premature newborn infants may lead to the development of kernicterus. The kernicterus is probably the result of an increased rate of destruction of red blood cells, which in turn is brought about by a precipitous drop in the GSH ** content of the erythrocytes, as Zinkham has shown in *in vitro* studies [1]. The exact mechanism whereby vitamin K_3 produces this effect is not known.

It has been noted by others, and recently shown at this laboratory [2] that vitamin K_3, when incubated with red blood cells, hemolysates, or a solution of crystalline Hb, induces a rapid formation of MeHb. Vitamin K_1 does not share this effect of K_3, nor does vitamin K_1 lead to hemolytic disease in the newborn.

* On study leave from the Research Institute of the Hospital for Sick Children, Toronto, Canada.

** Abbreviations: GSH, reduced glutathione; Hb, hemoglobin; MeHb, methemoglobin; TPNH, reduced triphosphopyridine nucleotide.

Table 1. Oxidation of GSH by MeHb. Incubation at 37°C with constant shaking in tubes open to air. Final concentrations: NaCl 0.077 M; phosphate buffer, pH 7.4, 0.05 M, MeHb and GSH indicated. Total volume, 2 ml/tube.

Series No.		Initial concentration mM	MeHb reduced or GSH oxidized, μmoles/2 ml incubate 0 h	1 h	2 h	3 h
1	MeHb	2.0	0	0.40	0.88	1.0
	GSH	1.0	0	1.07	1.62	1.63
2	MeHb	2.0	0	1.32	1.68	—
	GSH	2.0	0	2.23	3.55	—
3	MeHb	2.0	0	1.96	2.72	2.50
	GSH	5.0	0	3.00	4.48	5.76

With this information on hand it seemed of interest to investigate whether MeHb may play an intermediary role in the loss of erythrocyte GHS, brought about by vitamin K_3.

In the first series of experiments red blood cells from freshly obtained and defibrinated adult human blood were used. The red cells were washed three times and incubated in Krebs-Ringer-phosphate solution (approx. 40 % hematocrit) at 37°C in open tubes with constant shaking. At periodic intervals aliquots were removed for the simultaneous determination of GSH and MeHb contents. GSH was determined by the method of Grunert and Phillips [3]. The relative amounts of MeHb were assessed in samples diluted with distilled water, by measuring the optical density at 630 and 700 mμ, before and after

Table 2. Interaction between GSH, Hb and vitamin K_3-bisulfite. Incubation at 37°C with constant shaking in tubes open to air. Final concentrations: NaCl, 0.077 M; phosphate buffer, pH 7.4, 0.05 M; GSH, 1 mM; and when indicated: Hb 3.6 mM = 6.2 gm %, K_3bisulfite, 0.33 mM. Total volume, 2 ml/tube.

Additions	0 h MeHb	0 h GSH	1 h MeHb	1 h GSH	2 h MeHb	2 h GSH	3 h MeHb	3 h GSH
	μmoles/2 ml incubation mixture							
GSH	—	2.0	—	2.0	—	1.6	—	1.4
GSH + Hb	0	1.8	0	1.9	0	1.5	0	1.6
GSH + K_3bisulfite	—	1.8	—	1.8	—	1.5	—	1.4
GSH + Hb + K_3bisulfite	0	1.8	2.9	1.2	4.6	0.8	5.5	0.6

the addition of an excess of potassium ferricyanide.

During 4 h of incubation of the washed cells, without addition of substrate, the GSH levels in the cells remained constant and formation of MeHb was not observed. When vitamin K_3bisulfite (final concentration 0.33 mM) was added, considerable amounts of MeHb were formed and the level of GSH fell to 30 % of the original. Addition of glucose in 6 mM final concentration prevented the fall of GSH level, and lessened, but did not entirely abolish, the formation of MeHb. These findings confirm some of the observations made by Zinkham [1]; moreover they prove that, in addition to its detrimental effect on GSH, vitamin K_3 bisulfite induces the formation of MeHb as well.

It has been found by others that GSH can be oxidized by simple chemical interaction with MeHb [4]. It seemed that this reaction could be one way by which vitamin K_3 could bring about loss of GSH. Experiments were carried out to explore this possibility. These consisted of incubating vitamin K_3bisulfite, GSH, Hb and MeHb in various combinations and concentrations under the conditions specified in Tables 1 and 2. The Hb solution used in these experiments was prepared according to Beutler [5], but the use of toluene was avoided, and hemolysis without undue dilution was effected by rapid freezing and thawing of the washed cells three times. MeHb was prepared by adding to the Hb solution twice the equivalent amount of solid potassium ferricyanide, followed by dialysis against large volumes of distilled water. GSH and MeHb were determined as specified above.

When GSH, in 1 mM concentration, was incubated without any addition, during 3 h the GSH concentration declined only slightly, probably due to oxidation by atmospheric oxygen. The addition of 0.33 or 3.3 mM vitamin K_3bisulfite did not lead to an acceleration of the slow autooxidation of GSH. When MeHb in 2 mM (3.4 mg %) concentration was incubated with three different concentrations of GSH, and without addition of vitamin K_3bisulfite, GSH was rapidly oxidized and MeHb was reduced (Table 1). The expected stoichiometric relation of 2 moles of GSH oxidized by 1 mole of MeHb is supported by these data. The rate of the reaction was found to depend on the concentration of both MeHb and GSH, according to first order kinetics.

Further experiments were carried out to observe the interaction between vitamin K_3bisulfite, Hb and GSH. In Table 2 it can be seen that the addition of either one of Hb or vitamin K_3bisulfite to GSH did not accelerate the slow rate of autoxidation of GSH. Furthermore, when Hb was incubated in the presence of GSH, no MeHb was formed. However, when GSH was incubated in the presence of both Hb and vitamin K_3bisulfite, MeHb formation occurred and simultaneously the rate of oxidation of GSH was definitely increased. During 3 h of incubation, 76 % of the added Hb was oxidized and 66 % of the GSH was lost.

Another possible route by which formation of MeHb induced by vitamin K_3 may lead to glutathione instability in the red blood cell was also investigated. One may suppose that the accumulation of MeHb may lead to drainage of the existing stores of TPNH *via* the TPNH dependent MeHb reductase. Under these conditions it may be difficult for the exclusively TPNH dependent glutathione reductase to maintain glutathione in the reduced state and the GSH levels may decrease as a consequence. To explore this possibility experimental conditions were chosen to observe the effect of active intracellular MeHb reduction on the ability to maintain high levels of GSH in the erythrocyte. By exposing washed adult red blood cells to trace amounts of amylnitrite according to the method of Gibson [6], 40–50 % of the total Hb was oxidized to MeHb. When these cells, after washing, were suspended in physiological saline containing 0.01 M phosphate buffer (pH 7.4) and incubated without the addition of substrate, the amount of preformed MeHb remained constant. The GSH levels, which were reduced somewhat by the pretreatment with amylnitrite, remained also constant during the subsequent 4 h of incubation. Addition of glucose (final concentration 10 mM) led to a gradual reduction of the preformed MeHb in the cells, disposing of about 50 % of the MeHb in 4 h. This process was markedly enhanced by further addition of catalytic amounts of methylene blue (final concentration 0.01 mM), the MeHb virtually disappearing from the cells at the end of merely 1 h of incubation. Under the latter two conditions, however, and especially when glucose and methylene blue were added together, and when there was an extremely rapid reduction of MeHb, the GSH levels did not decrease but remained stable. This suggests that at least under these experimental conditions the drainage of the TPNH stores by the MeHb reductase did not influence the maintenance of the reduced state of glutathione.

The results of these studies suggest that the formation of MeHb may play an intermediary role in the oxidation of GSH in erythrocytes exposed to vitamin K_3bisulfite.

It seems likely that this mechanism consists of direct chemical interaction between MeHb and GSH. In order to reconcile the present tentative conclusions with the often emphasized fact that methemoglobinemia and glutathione instability are not necessarily correlated *in vivo* [7], it will be necessary to investigate more closely the mechanisms which, in the intact cell, may protect GSH from the oxidizing effect of MeHb, or may be able to replenish the losses of GSH effectively. It may well be that ultimately it will depend on the effectiveness or failure of these mechanisms whether an increased rate of formation of MeHb will lead to actual loss of GSH.

Isolation of β-Fructofuranosidase from Yeast by Ion Exchange Chromatography on Diethylaminoethylcellulose

Bjørn Andersen

Universitetets fysisk-kemiske Institut, Copenhagen, Denmark

The mechanism of the splitting of sucrose into α-D-glucopyranose and β-D-fructofuranose by invertase from yeast has been investigated by numerous workers. This has given rise to a great number of papers describing purification procedures of the enzyme. One of the most successful is that of Fischer and Kohtes [1], which using precipitation with picric acid and acetone, followed by adsorption to $Al(OH)_3$ obtained a preparation containing 4–5 % N with an activity of 4 000 units/mg N.

The development of cellulose derivatives for separation of proteins by ion exchange chromatography [2,3] has opened new possibilities for a further purification of the enzyme.

In the present work the β-fructofuranosidase from yeast has been separated on a N,N-diethylaminoethylcellulose (DEAE) column. The starting material was »Invertan.K.B.» (commercial invertase preparation, manufactured by De forenede Bryggerier, Copenhagen.) After dialysis against distilled water at 4°C for 24 h the solution was added to the column, previously equilibrated with 0.005 M phosphate buffer, pH 6.5. Eluation was made with increasing concentrations of sodium chloride (0–0.25 M). A sharp separation was obtained between the active component and the other proteins in the solution. After freeze-drying the nitrogen content was determined to give a value of 11.02 %. The enzyme activity was determined according to a method described in a previous publication [4]. Converted to the units of Fisher and Kohtes the activity was 22 000 units/mg N to be compared with the 4 000 units/mg N obtained by these authors. Electrophoresis, which at the present time has only been carried out at one pH, indicates one single protein component. Determination of the molecular weight at the optimal pH (4.75), using the osmometer designed by Christiansen and Jensen [5] gave the value 116 000. Calculation of the enzyme activity as number of substrate molecules reacting per min per molecule of enzyme gives a value of 260 000.

A more detailed description of the isolation will be given.

A Study of the Effect of Amytal on the Respiration of Rat Liver Slices

B. Kadenbach*, T. E. Conover** and L. Ernster

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

It has been reported [1] that rat liver slices, incubated for 1 h in a Krebs-Ringer solution containing glucose, exhibit an oxygen uptake which is resistant to amytal (5-ethyl-5-*iso*amyl-barbituric acid) to an extent of about 40 %. Closer examination of this amytal-resistant respiration has now revealed that it is characterized by a declining initial phase, lasting about 20—30 min., during which its rate drops from about 60 to 20 % of the control rate, followed by a second stationary phase where the respiration remains constant at about 20 % of the control rate over a period of at least 1 h. Omission of glucose and/or addition of α-ketoglutarate, malate, glutamate, lactate and glycerol-1-phosphate increased the respiration with and without amytal (Table 1). Addition of the glycolytic inhibitors, iodoacetate or fluoride, both of which strongly depressed the control rate, had little effect on the level of the amytal-resistant respiration. Addition of succinate caused, in agreement with earlier literature [2], about a ten fold increase of the respiratory rate, and this respiration was entirely amytal-insensitive. This finding is consistent with the concept [3] that succinate is oxidized by an amytal-insensitive oxidase.

Added DPN or TPN caused about an equal, 50—100 % stimulation of the control respiratory rate both in the absence of added substrate and in the presence of added glucose or the previously mentioned pyridine nucleotide-linked substrates. The two pyridine nucleotides differed, however, with respect to their effect on the amytal-resistant respiration, this being stimulated more by TPN than by DPN. Moreover DPN and TPN added together stimulated the amytal-resistant respiration by more than the sum of the individual stimulations. These effects were apparent only on the stationary, and not the initial, phase of the amytal-resistant respiration. It would therefore seem that while the initial phase of the amytal resistant respiration probably originates from some endogenous substrate which is not continuously formed during incubation, the constant respiration phase is due to substrates which are continuously available, and part of which, at least, appear to be oxidized by way of TPN. The glucose-6-phosphate dehydrogenase shunt would seem to be a likely reaction of this type. That added DPN, in combination with TPN, further increases the amytal-resistant respiratory rate, may be due to the stimulation of a pyridine nucleotide transhydrogenase mechanism, conceivably through the mediation of lactic dehydrogenase [4].

It has been of interest also to establish whether the recently described DT diaphorase [5] is involved in the amytal-resistant respiration. This enzyme can mediate electron transport between both intra- and extramitochondrial [6] DPNH and TPNH and the cytochrome system

Table 1. Effect of added substrates and pyridine nucleotides on the amytal-resistant respiration of rat liver slices. 80 to 120 mg of liver slices (20 mg with succinate) were incubated for 1 h at 37.5°C in Krebs-Ringer-phosphate solution (half Ca^{++} conc.) with 100 % O_2 as gas phase. Final volume, 1 ml; final concentrations of the additions were: glucose, α-ketoglutarate and malate, 0.025 M; glycerol-1-phosphate, lactate, glutamate and succinate, 0.05 M; amytal, 0.002 M.

Expt. No.	Additions	μatoms oxygen/60 min./100 mg wet weight without amytal	with amytal
1	none	4.57	2.39
	glucose	4.11	1.84
2	none	4.51	1.82
	α-ketoglutarate	6.12	4.30
	malate	5.36	2.49
3	none	4.21	1.53
	glutamate	7.15	2.28
	succinate	55.4	60.5

Table 2. Dicoumarol-sensitive respiration of rat liver slices. Conditions as in Table 1. Final concentrations of the additions were: glucose, 0.05 M; iodoacetate, 0.2 mM; amytal 2 mM; vitamin K_3-bisulfite, 0.005 mM; citrate, 0.025 M; TPN, 0.001 M; dicoumarol, 0.005 mM. The system was preincubated for 20 min in the presence of all additions except amytal. The values give the respiration obtained during 48 min following the addition of amytal.

Additions	μatoms oxygen/100 mg wet weight without dicoumarol	with dicoumarol	% inhibition
none	1.79	2.43	−39
vitamin K_3-bisulfite	1.31	1.53	−19
citrate	2.46	1.72	30
citrate + vit. K_3-bis.	4.06	2.46	39
citrate + vit. K_3-bis. + TPN	7.88	4.61	41

of isolated mitochondria in an amytal-insensitive way provided that a catalytic amount of vitamin K_3 is added. To investigate this possibility, the sensitivity of the respiration to dicoumarol was tested, since it has been shown that DT diaphorase is highly sensitive to this agent [7]. It was found that 5×10^{-6}M dicoumarol, which completely inhibits DT diaphorase, had no effect on the respiration under any of the above conditions, either in the absence or in the presence of added vitamin K_3, and occasionally it even caused a slight stimulation probably due to release of the respiratory control. It was found (Table 2), however, that preincubation of the slices for 20 min. in the presence of iodoacetate in order to exhaust glycolytic intermediates, and subsequent incubation with added citrate, resulted in an increased amytal-resistant respiration which now was inhibited by 5×10^{-6}M dicoumarol to about 30 %. Moreover, addition of vitamin K_3 or of vitamin K_3 and TPN both of which further increased the amytal-resistant respiratory rate, also increased its dicoumarol sensitivity in an absolute as well as relative fashion. These findings are preliminarily interpreted to indicate that the DT diaphorase apparently takes no major part in the normal respiration of the liver cell, but may act as an alternative pathway of TPNH (and DPNH) oxidation, which can be made manifest experimentally by suppressing more efficient pathways. The main interest of these findings may lie in the fact that a dicoumarol-sensitive respiration, *i.e.* a DT diaphorase reaction, has been demonstrated in these conditions to function in the intact liver cell even without supplementation with vitamin K_3.

Short Communications

Totarolone, a New Diterpene Ketophenol from *Tetraclinis articulata* *

YUAN-LANG CHOW and HOLGER ERDTMAN

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

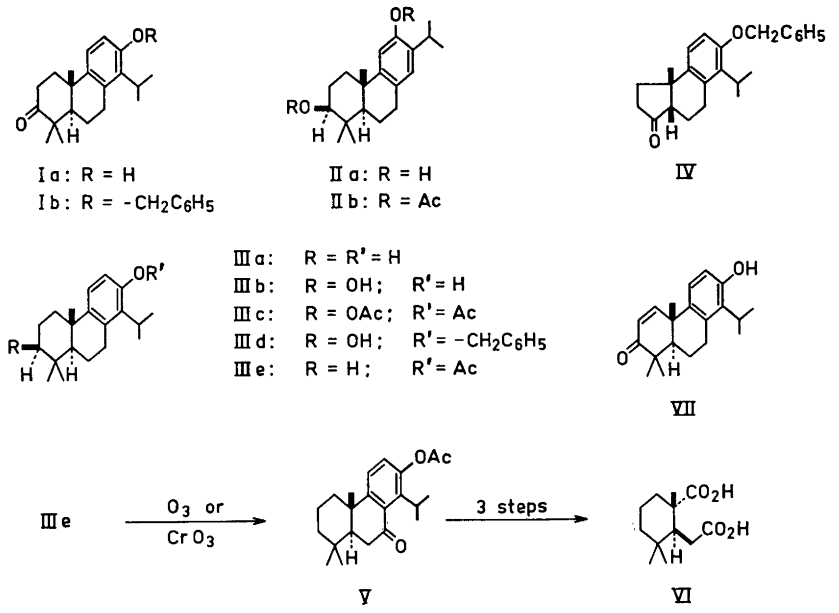
A mixture of two new ketones, totarolone and totarolenone, has recently been isolated from the heartwood extract of *Tetraclinis articulata* (Vahl, Masters).[1] Hydrogenation of the mixture over Pd/C in ethanol gave pure totarolone, $C_{20}H_{28}O_2$, m.p. 188–189°, $[\alpha]_D$ + 102°. The empirical composition, the U.V. absorption of totarolone [λ_{max}] 208 mμ (ε 37 700), 281 (1 900), and 286 (1 900)] and the I.R. absorption [3 380, 1 685 (1 705 in CCl_4), 1 590, and 810 cm^{-1}] suggests that totarolone is a new diterpene ketophenol containing a keto group that is not conjugated with the aromatic ring. This is supported by the physical properties of totarolone acetate, $C_{22}H_{30}O_3$, m.p. 113–115°, $[\alpha]_D$ + 96.6° ν_{max} at 1 755, 1 704 and 1 210 cm^{-1}, λ_{max} 207 mμ (ε 5 600), 266 (470).

Totarolone, now shown to be Ia, gave on Clemmensen reduction a good yield of totarol [2] (IIIa). Reduction of totarolone with potassium borohydride gave a diol, totaradiol (IIIb), $C_{20}H_{30}O_2$, m.p. 100–102°, $[\alpha]_D$ + 38.5°, ν_{max} 3 610, 1 002 and 3 380 cm^{-1}. Acetylation (pyridine-acetic anhydride) furnished a diacetate (IIIc): $C_{24}H_{34}O_4$, $[\alpha]_D$ + 41°, ν_{max} 1 766 and 1 725 cm^{-1}. The molecular rotation shift between totaradiol and its diacetate, m.p. 120–122°, $\Delta[M]_D$ + 43° is very similar to that between hinokiol (IIa) and its diacetate (IIb) $\Delta[M]_D$ + 47° [3] suggesting that the environments of the assymetric centres are similar in both cases. Confirmation of structure Ia for totarolcne was obtained as follows.

Totarolone benzyl ether, m.p. 169–171°, (Ib) was reduced with lithium aluminium hydride to totaradiol benzyl ether, (IIId) m.p. $C_{27}H_{36}O_2$, 192–193°, ν_{max} 3 420, 1 032, and 1 264 cm^{-1}. The ether (IIId) was treated successively with phosphorus pentachloride, osmium tetroxide and lead tetraacetate as recently described for hinokiol [3]; acetone and the trisnor-ketone (IV), ν_{max} (in CCl_4) at 1 740 and 1 260 cm^{-1}, [2,4-dinitrophenylhydrazone (amorphous), $C_{30}H_{32}O_5N_4$, λ_{max} 363 mμ (ε 20 200)] were obtained. The optical rotatory dispersion curve of IV was very similar to that of a 5β-A-norsteroid [4] indicating that inversion had occurred at C_5 during the reactions [5].

Furthermore the large positive Cotton effect shown by totarolone (and also by hinokione) is similar to that shown by lanost-8-en-3-one [6]. The A/B ring junction in totarolone, and consequently that in totarol, must therefore possess the conventional steroid absolute configuration, namely 5α,10β. The correctness of this assignment was also demonstrated by a direct correlation of totarol with dehydroabietic acid *etc.* in the following manner. Ozonisation, or better chromic acid oxidation, of totarol acetate (IIIe) gave 7-keto-totarol acetate (V), $C_{22}H_{30}O_3$, m.p. 169–170°, λ_{max} at 213 mμ (ε 23 900), 252 (8 100), and 297 (2 600), ν_{max} at 1 758 and 1 676 cm^{-1}, $[\alpha]_D$ + 43.3° (in $CHCl_3$). Successive treatment of V with trifluoroperacetic acid, ozone and alkaline hydrogen peroxide afforded the dicarboxylic acid VI [7], m.p. 160–163° (identified by mixed

* This research was sponsored in part by the *Office of Research and Development, U.S. Army Department*, through its European Office. Part of this investigation was first presented during "Svenska kemistdagarna", Stockholm, June 9–11, 1960. (*Svensk Kem. Tidskr.* **72** (1960) 602).



melting point and its I.R. spectrum). A racemic totarolone methyl ether having the structure I (R = CH_3) has recently been synthesised by Taylor [8] and its I.R. spectrum was shown to be identical with that of the methyl ether of the natural product (m.p. 98—100°).

Since the original mixture of totarolone and totarolenone has a U.V. absorption at 223 mμ and an I.R. band at 1 652 cm^{-1} in addition to those of totarolone, it follows that the unisolated totarolenone must be 1,2-di-dehydrototarolone (VII).

Infrared spectra were taken in KBr discs and optical rotations in ethanol unless otherwise specified. All ultraviolet spectra were taken in ethanol solution. Satisfactory analyses were obtained for all the compounds described. We thank Dr. W. Klyne for the rotatory dispersion data and valuable discussions and Professor O. Jeger for an authentic specimen of the dicarboxylic acid VI.

Studies on Peroxy Compounds

IX *. The Introduction of Alkoxy Groups into Tetrahydrofuran

SVEN-OLOW LAWESSON and
CURT BERGLUND

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Uppsala, Sweden

When *t*-butyl perbenzoate is decomposed in the presence of various types of substrates such as olefins [1,2], benzyl ethers [3], benzyl sulphides [4], simple ethers and sulphides [5] (catalytic amounts of cuprous salt being present) according to a method first described by Kharasch and Sosnovsky [1], the benzoyloxy group is introduced without rearrangement, fragmentation, dimerization or isomerisation of the substrate. No oxidation occurs when the substrate is a sulphide. In the case of tetrahydrofuran, tetrahydropyran and di-*n*-butyl ether, however, the *α*-*t*-butoxy compounds [6,7] are obtained. It is most probable that the benzoyloxy compounds are first formed, which revert to the *t*-butoxy compound, since we have found [5] that when the benzoyloxy compound I is heated under mild conditions with *t*-butanol, the *t*-butoxy compound II is formed.

The sulphur analogue III, however, gives an *α*,*β*-unsaturated sulphide IV [5] when heated with or without *t*-butanol.

* by a mistake the boiling point was said to be 127°/760 mm Hg in an earlier paper [7].

In further studies of the reaction between *t*-butyl perbenzoate and cyclic ethers and sulphides, we found, that if an alcohol (R—OH) is added to the substrate (tetrahydrofuran) before carrying out the reaction with *t*-butyl perbenzoate in the usual way, the alkoxy compound V is formed.

Yields cited are based on one series of experiment only and are not considered to be the maximum obtainable. A more detailed paper [8] on this subject will be published in the near future.

Analysis of Oxide Films on Copper by Coulometric Reduction

A. RÖNNQUIST

Institute of Chemistry, University of Uppsala, Sweden

Several methods have been used for analysing oxide films on copper [1]. The most attractive features of the coulometric method, originally developed by Evans and Bannister [2] and by Miley [3,4], are its high sensitivity and the possibility of determining both cuprous and cupric oxide in the same run. When determining the two oxides the choice of a suitable electrolyte is important. Campbell and Thomas [5] pointed out that since copper oxide will dissolve in ammonium chloride, there is a possibility of error in earlier determinations made with NH_4Cl as electrolyte. KCl does not have this disadvantage, but it usually fails to give separation of the two oxides. Later Mills [6] suggested a phosphate buffer of pH 6.9 as a suitable electrolyte for separate determinations of the two oxides. To improve the coulometric method Lambert and Trevoy [7] recently demonstrated the importance of the complete elimination of dissolved oxygen and also of plateable cations from the electrolyte. This can be achieved by pre-electrolysis. The present paper demonstrates the possibility of using KOH (0.1 M) as electrolyte in the analysis

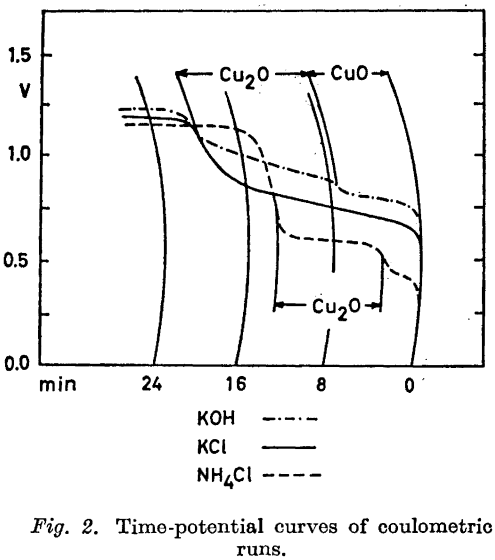

Fig. 2. Time-potential curves of coulometric runs.

In further studies of the reaction between *t*-butyl perbenzoate and cyclic ethers and sulphides, we found, that if an alcohol (R—OH) is added to the substrate (tetrahydrofuran) before carrying out the reaction with *t*-butyl perbenzoate in the usual way, the alkoxy compound V is formed.

Yields cited are based on one series of experiment only and are not considered to be the maximum obtainable. A more detailed paper [8] on this subject will be published in the near future.

Analysis of Oxide Films on Copper by Coulometric Reduction

A. RÖNNQUIST

Institute of Chemistry, University of Uppsala, Sweden

Several methods have been used for analysing oxide films on copper [1]. The most attractive features of the coulometric method, originally developed by Evans and Bannister [2] and by Miley [3,4], are its high sensitivity and the possibility of determining both cuprous and cupric oxide in the same run. When determining the two oxides the choice of a suitable electrolyte is important. Campbell and Thomas [5] pointed out that since copper oxide will dissolve in ammonium chloride, there is a possibility of error in earlier determinations made with NH_4Cl as electrolyte. KCl does not have this disadvantage, but it usually fails to give separation of the two oxides. Later Mills [6] suggested a phosphate buffer of pH 6.9 as a suitable electrolyte for separate determinations of the two oxides. To improve the coulometric method Lambert and Trevoy [7] recently demonstrated the importance of the complete elimination of dissolved oxygen and also of plateable cations from the electrolyte. This can be achieved by pre-electrolysis. The present paper demonstrates the possibility of using KOH (0.1 M) as electrolyte in the analysis

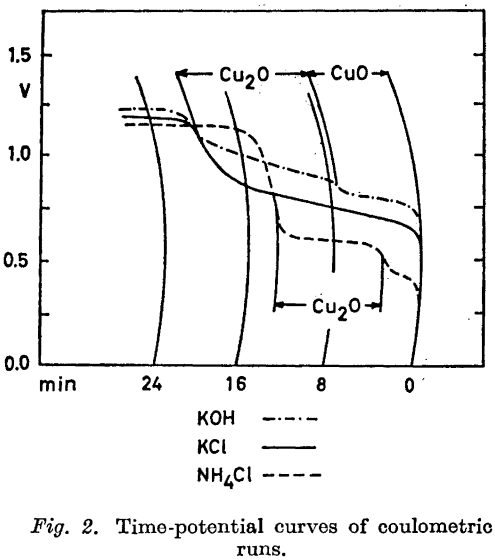

Fig. 2. Time-potential curves of coulometric runs.

Table 1.

Electrolyte	Cu_2O $\mu g/cm^2$	CuO $\mu g/cm^2$	Cu_2O+CuO $\mu g/cm^2$
KCl	—	—	51
NH_4Cl	29	10	39
KOH	37	15	52

of oxide films on copper. The use of this electrolyte has been developed during studies of morphological and kinetic phenomena in the oxidation of copper.

When KCl is used as the electrolyte, the difference between the potentials at which CuO and Cu_2O are reduced is very small and varies with the density of the reducing current. Because of this small difference potassium chloride usually fails to give separation of the two oxides. When KOH is used, the potential difference is independent of the current density and large enough to give separation in a coulometric run. Fig. 1 shows the potential at which the two oxides are reduced in KOH, measured against an Ag—AgCl electrode, as a function of the current density.

To demonstrate the possibility of using KOH as the electrolyte, the following experiment was carried out. A copper wire was mechanically polished and oxidized for one minute at 560°. The wire was then cut into three equal lengths. The amount of oxide on each part was coulometrically determined using NH_4Cl, KCl and KOH, respectively, as the electrolytes. The current density was the same in all three cases (670 $\mu A/cm^2$). The electrolytes were all cleaned by bubbling oxygen-free nitrogen through them. Oxygen was removed from the nitrogen in the usual manner with pyrogallol and a solution of chrome (II) ions. The time-potential curves for the three runs are given in Fig 2.

With KCl only one potential plateau appeared. With KOH and NH_4Cl two plateaus were obtained, indicating the presence of the two oxides. The time for complete reduction is equal in the cases of KCl and KOH, but when using NH_4Cl it becomes shorter because of dissolution of the two oxides. Table 1 gives the amount of oxide determined in the different electrolytes.

A special examination of the dissolution of the two oxides in KOH has been made. Samples of cuprous and cupric oxide powders (supplied by May and Baker Co. Ltd) were left in contact for one month with KOH of molarities 0.05, 0.1, 0.3, and 0.5. A determination of dissolved copper was then made by complexometric titration [8]. The result of the titrations showed that CuO does not dissolve. No dissolution of Cu_2O could be observed in KOH of molarities 0.05 and 0.1. In solutions of molarities 0.3 and 0.5 the amounts of dissolved cuprous oxide were determined to be less than 2.4 and 7.2 mg/100 ml, respectively. It is seen that within the normal duration of a coulometric analysis, no dissolution is to be expected.

Conclusions. The solubility of cuprous and cupric oxide in 0.1 M KOH is small enough to be neglected in this instance. The difference between the potentials at which the two oxides are reduced is nearly constant and independent of the current density. These properties make KOH (0.1 M) a possible electrolyte in the analysis of oxide films on copper.

Acknowledgements. I wish to thank Professor G. Hägg for his interest in this work and for the facilities placed at my disposal. Thanks are also due to Dr. L. H. Andersson for suggesting the method of titration and to Dr. H. Fischmeister and Dr. J. Drott for stimulating discussions. Sorption of Organic Vapours in Organic Ion Exchanging Substances

TORBJÖRN WESTERMARK

Division of Physical Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

When it was shown that the transmission properties of beta particles through layers of matter possessing sorption properties (*e.g.* towards vapours) could be used to study these processes [1] (kinetics, equilibria), the author tried to find illustrative examples of how the method might be applied. Some of these examples have been published [1] but some others have not. Some of them concern the sorption properties of ion exchangers. The observations made were not pursued systematically but, as nothing similar has apparently been given in the literature, two short notes will be given. The present note concerns the sorption of organic vapours in ion exchanging materials. Another note will deal with water sorption kinetics.

Ion exchanging substances containing typical functional groups, *e.g.* SO_3^-, COOH, NH_2, *etc.*, can to our present knowledge be considered to react within their whole volume at least for small ions (*cf.* Kunin and Myers [2]) in the liquid phase. It was therefore judged likely that they would have a very high "inner surface" (in about the same sense as is used for, *e.g.*, activated charcoal) and consequently be able to sorb polar molecules to a great extent, for example, when exposed to gases.

Simple experiments to test this idea were made by bubbling dry nitrogen from a tank tube through wash-bottles containing some organic liquids at room temperature. The gas stream (a few ml/sec) thereby becomes saturated (or very nearly so) and thus the sorption figures given correspond to the vapour pressure at room temperature under these conditions. Table 1 summarizes the observed percentage weight increase of the material when apparent equilibrium was reached.

Table 1. Equilbrium sorption of some organic vapours in ion exchangers at 21°C. The ion exchange material was present in a glass tube in grain form (50—100 Mesh) and was nearly dry at the beginning of the experiment.

Ion exchanger	Vapour	Percent weight increase referred to dry material
Wofatite KS—Na	Diethylether	15
» »	Methanol	21
Dowex 50-H	*n*-Butanol	43.1
» »	Benzene	4.7

From these few observations, it is indicated that the hydrophilic substances (*e.g.* the alcohols) are sorbed to a greater extent than a less hydrophilic one (*e.g.* benzene). It might from this evidence be assumed that ion-dipole interaction plays a role in the sorption process.

The sorption rate was interpreted in terms of spherical diffusion which gives as is well known [3]:

$$F = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-\frac{n^2 \pi^2 D}{\gamma_0^2} t\right)$$

where D is the diffusion coefficient of the organic molecule within the ion exchanger grains, t time, γ_0 grain radius and F fractional attainment of equilibrium.

The results are in rough accordance with this formula which is valid if the diffusion is rate-determining. The diffusion coefficient for benzene is about 12×10^{-10} cm²/sec and, for n—C_4H_9OH, 6×10^{-10} cm²/sec according to these estimates in Dowex 50-H. It was demonstrated that the sorption processes mentioned could be easily followed by beta ray transmission.

It might be added that it has been found in this laboratory that molecular iodine (as fission product ^{131}I) is readily sorbed [4] from the gas phase on an anion exchanger Dowex 2.

Obviously it would be of interest to study sorption equilibria and kinetics systematically for different types of ion exchangers. The sorption properties of ion exchangers normally used in liquid systems might find applications in certain cases. It might well be possible to use these pro-

perties for some vapour chromatographic purposes.

Note on the Sorption Rate of Water Vapour in Almost Dry Ion Exchangers

TORBJÖRN WESTERMARK

Division of Physical Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

This note will draw attention to some aspects of the sorption rate of water vapour in organic cation exchangers. The results were obtained when the beta ray transmission technique was used to follow (*in situ*) the sorption properties of various solids towards vapours [1]. Another note describes the sorption of organic vapours by organic cation exchangers [2]. It was shown that the sorption rate and attainment of equilibrium could be easily followed by measuring the transmission of a pencil of ^{32}P beta rays through a flat cell of the type described (in Ref.[1]) filled with the grainy ion exchange material. Such studies are nowadays facilitated by stable vibration-reed-electrometers and rapid recorders. The data presented below, however, have been obtained using ordinary weighing procedures.

The experiments were performed using several organic cation exchangers but the main efforts were concentrated on Dowex 50, 50–100 mesh grain size. The material was treated according to standard practice with 3 N HCl until every trace of three-valent iron had been eluted. The resin was then transferred to the forms required by eluting with an excess of simple inorganic electrolytes in a pure form and containing the cation wanted, *e.g.* $Ca(NO_3)_2$, $RbNO_3$, *etc.* After complete expulsion of the acidic ions, the resin was treated with distilled water, transferred to weighed glass vessels and then carefully dried by successively heating until constant weight was obtained (highest temperature 105°C). A similar procedure was used with other cations to yield Dowex 50 in the following ionic forms: H^+, Rb^+, Cs^+, H_4N^+, $(CH_3)_4N^+$, Be^{2+}, Mg^{2+}, Sr^{2+}, Ba^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Ce^{3+}, Fe^{2+}, Fe^{3+} and UO_2^{2+}.

Vessels containing a certain cation form of Dowex 50 were placed in air of a definite humidity. This was accomplished by using standard electrolytic solutions giving, after equilibrium, well-known relative humidities [3].

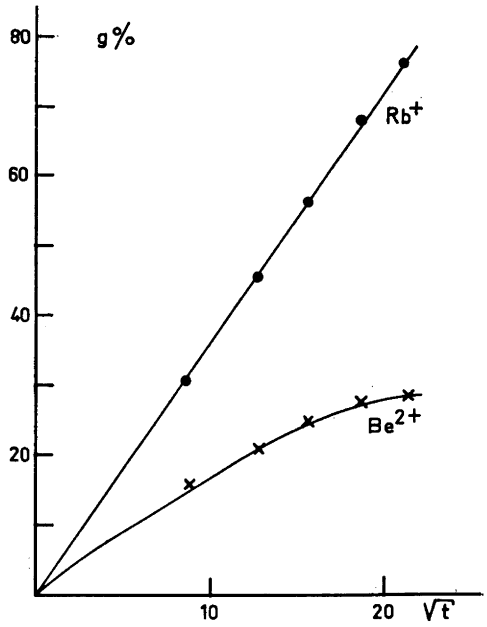

Fig. 1. Fractional attainment of equilibrium (g, in %) for water sorption on Dowex 50-Me as a function of $\sqrt{t}$ (t in min). The two cases of Me = Rb^+ and Be^{2+} are seen to behave somewhat differently.

Note on the Sorption Rate of Water Vapour in Almost Dry Ion Exchangers

TORBJÖRN WESTERMARK

Division of Physical Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

This note will draw attention to some aspects of the sorption rate of water vapour in organic cation exchangers. The results were obtained when the beta ray transmission technique was used to follow (*in situ*) the sorption properties of various solids towards vapours [1]. Another note describes the sorption of organic vapours by organic cation exchangers [2]. It was shown that the sorption rate and attainment of equilibrium could be easily followed by measuring the transmission of a pencil of ^{32}P beta rays through a flat cell of the type described (in Ref.[1]) filled with the grainy ion exchange material. Such studies are nowadays facilitated by stable vibration-reed-electrometers and rapid recorders. The data presented below, however, have been obtained using ordinary weighing procedures.

The experiments were performed using several organic cation exchangers but the main efforts were concentrated on Dowex 50, 50–100 mesh grain size. The material was treated according to standard practice with 3 N HCl until every trace of three-valent iron had been eluted. The resin was then transferred to the forms required by eluting with an excess of simple inorganic electrolytes in a pure form and containing the cation wanted, *e.g.* $Ca(NO_3)_2$, $RbNO_3$, *etc.* After complete expulsion of the acidic ions, the resin was treated with distilled water, transferred to weighed glass vessels and then carefully dried by successively heating until constant weight was obtained (highest temperature 105°C). A similar procedure was used with other cations to yield Dowex 50 in the following ionic forms: H^+, Rb^+, Cs^+, H_4N^+, $(CH_3)_4N^+$, Be^{2+}, Mg^{2+}, Sr^{2+}, Ba^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Ce^{3+}, Fe^{2+}, Fe^{3+} and UO_2^{2+}.

Vessels containing a certain cation form of Dowex 50 were placed in air of a definite humidity. This was accomplished by using standard electrolytic solutions giving, after equilibrium, well-known relative humidities [3].

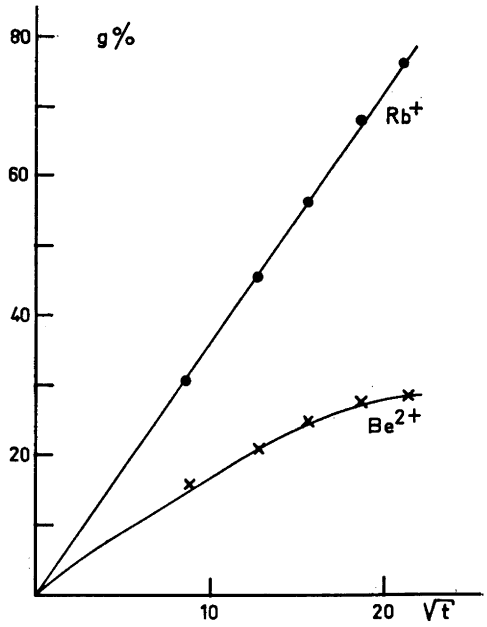

Fig. 1. Fractional attainment of equilibrium (g, in %) for water sorption on Dowex 50-Me as a function of $\sqrt{t}$ (t in min). The two cases of Me = Rb^+ and Be^{2+} are seen to behave somewhat differently.

The increase in weight was found as a function of time at a single temperature (23° ± 1) until apparent equilibrium was reached at a certain relative humidity (RH). Then a new step to a higher RH was taken and the resulting kinetics and equilibrium were studied. RH up to 90 % were studied. Especially at these high RH, equilibrium took a long time — up to two weeks — to become established.

The weight increase at a certain RH was divided by the final equilibrium weight increase under the same conditions in order to yield the "fractional attainment of equilibrium", g[4]. The g-value did not follow any definite function of time. In some cases (especially for the alkali cations) it followed the wellknown $\sqrt{t}$-behaviour. Fig. 1 illustrates this behaviour for Dowex 50—Rb^+. In the same figure, another extreme is represented by Dowex 50—Be^{2+}. The best (but not exact) description was given by the known relation:

$$g = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-\frac{D\pi^2 n^2 t}{r_0^2}\right) \quad (1)$$

This equation was theoretically derived [5] for the case of diffusion controlled sorption into spherical grains of radius, r_0. (D is the diffusion coefficient of water in the material). Various factors seem to cause deviations from the conditions for which (1) was derived. One is certainly that the grain radius, r_0, increases during sorption. Microscopic examination revealed a very rapid increase of r_0 at the beginning of the exposure to water vapour followed by a slower one. (The grain diameter was found to increase with the ionic volume of the cation.) Some of the originally almost spherical grains became cracked (probably during drying) and thus many were only hemispheres.

For the above reasons, the evaluation of a diffusion coefficient from (1) for all the materials investigated would not correspond to reality. Therefore we simply take the g-value after a certain time for all the materials and represent this as a function of some cation property.

The most interesting behaviour is got by studying the kinetics of the step from the dry state to the state corresponding to RH 8.7 %. The sorption of water at equilibrium at this RH does not correspond to more than 10 % (for H^+) of the weight of the ion exchanger material. Usually about 5 % is obtained and so the regain at

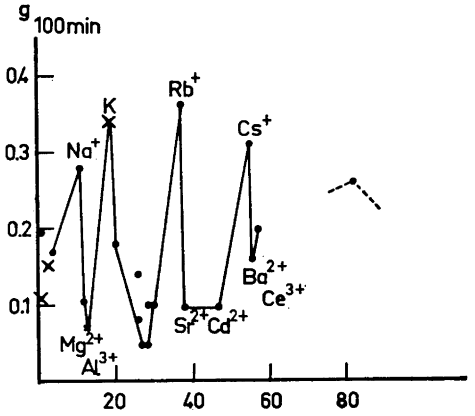

Fig. 2. g-Value for 100 min sorption of water at 8.7 % relative humidity starting from dry material. The g-value, as given as a function of the atomic number of the cation of the Dowex 50, exhibits a periodical character. (Points not explained are H^+ and Li^+ at the left end, and then after K^+, Ca^{2+}, Fe^{3+} (highest), Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}. Points to the right are Pb^{2+} and UO_2^{2+}).

equilibrium corresponds to a state of less than one water molecule per monomer unit (assumed to be (—CH_2-CH-  $SO_3Me)_n$.

Thus we are justified in expecting the individuality of the different cations to appear under these conditions.

Fig. 2 shows the fractional attainment (g) figures (for 100 min sorption from the dry state) as a function of the atomic number of the counter ions of the ion exchanger. It is seen that a periodic function is obtained which to some extent resembles the behaviour of, *e.g.*, the atomic volume [6]. If similar studies are made for the steps involving higher RH's, the individuality of the cations disappears almost completely and the kinetics are nearly identical for all materials studied. Adsorption isoterms were obtained for the materials (and for other types of cation exchangers) but resemble those published by Gluechauf [7] and others and will therefore not be presented here.

Although too little systematic material is available, we feel justified in suggesting that the initial hydration is a dipole-ion interaction involving the cation of the ion

exchanger (and also the sulphonic acid anion).

A complete description of the sorption rate might necessarily involve the interaction energy for the process considered as an activation energy for the diffusion coefficient. If so, a larger ion would exhibit a smaller activation energy and hence a larger sorption rate (or diffusion coefficient). The results of Fig. 2 could then be reasonably connected with the periodicity of the atomic volumes. As for the latter, the ion charge must also be taken into account. Among the alkalis, the sorption rate increases with increasing (crystallographic) ion volume in accordance with the above picture. Unfortunately, the result for $Z > 45$, was obtained with a different batch of Dowex 50 and so no conclusions can be drawn from the result for cesium. The complete description might also contain entropy factors. These are apparently not known for the systems studied here. Following the picture given above it is reasonable that, under wetter conditions, the sorbing water molecules would mainly interact with water already sorbed, thus roughly explaining why the individuality of the counter ions disappears in such a case.

A more complete study of these phenomena would seem to be of interest. The temperature dependence of the sorption rate might give a clue for the interpretation of the interaction mechanism suggested.

Sheet Ion Exchangers as Resistance Gauges for Moisture in Gases

TORBJÖRN WESTERMARK

Division of Physical Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

The sulphonation of sheets, rods, tubes or any shape of solid polystyrene yields a thin layer of polystyrene sulphonic acid [1], a well-known cation exchange material. Many other ways of forming a sheet ion exchanger are possible [1] or conceivable.

It has been found that the electrical resistance of this material is a good measure of the relative humidity in air. The ion exchange groups may be saturated by Na^+-ions for instance, so that the moisture detector is less likely to be affected by materials sorbed from the gas which may cause precipitation *etc.* The ion exchange layer of course is a hydrophilic substance, the moisture content of which is a function of the water partial pressure in the surrounding gas if equilibrium prevails. The conductance of the sheet ion exchanger will increase with increasing moisture content and so the resistance of an exchanger unit will be an appropriate measure of the moisture content. At constant temperature, it will after calibration with standard salt solutions [2] be a good moisture detector. Changing the temperature of course changes both the equilibrium conditions and conductance and must be corrected for by recalibration.

Practical exchanger units can be made by simply clamping two platinum electrodes on a sulphonated piece of polystyrene or better by winding a double spiral on a sulphonated (sodium ion-saturated) rod or hole cylinder using two wires of platinum (stainless steel was found to corrode in the long run), the wires being separated by about 0.5 mm or so. The wires should be long in order to reduce the resistance.

A typical calibration curve is given in Fig. 1. At decreasing humidities, the resistance increases steadily; at very low figures, the resistance may be impractically high. The resistance is preferably measured at 1 000 Hz to avoid polarization phenomena at the electrodes. Such effects were often obtained when DC was used. Any of the common electrical circuits can be used

exchanger (and also the sulphonic acid anion).

A complete description of the sorption rate might necessarily involve the interaction energy for the process considered as an activation energy for the diffusion coefficient. Sheet Ion Exchangers as Resistance Gauges for Moisture in Gases

TORBJÖRN WESTERMARK

Division of Physical Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

The sulphonation of sheets, rods, tubes or any shape of solid polystyrene yields a thin layer of polystyrene sulphonic acid [1], a well-known cation exchange material. Many other ways of forming a sheet ion exchanger are possible [1] or conceivable.

It has been found that the electrical resistance of this material is a good measure of the relative humidity in air. The ion exchange groups may be saturated by Na^+-ions for instance, so that the moisture detector is less likely to be affected by materials sorbed from the gas which may cause precipitation *etc.* The ion exchange layer of course is a hydrophilic substance, the moisture content of which is a function of the water partial pressure in the surrounding gas if equilibrium prevails. The conductance of the sheet ion exchanger will increase with increasing moisture content and so the resistance of an exchanger unit will be an appropriate measure of the moisture content. At constant temperature, it will after calibration with standard salt solutions [2] be a good moisture detector. Changing the temperature of course changes both the equilibrium conditions and conductance and must be corrected for by recalibration.

Practical exchanger units can be made by simply clamping two platinum electrodes on a sulphonated piece of polystyrene or better by winding a double spiral on a sulphonated (sodium ion-saturated) rod or hole cylinder using two wires of platinum (stainless steel was found to corrode in the long run), the wires being separated by about 0.5 mm or so. The wires should be long in order to reduce the resistance.

A typical calibration curve is given in Fig. 1. At decreasing humidities, the resistance increases steadily; at very low figures, the resistance may be impractically high. The resistance is preferably measured at 1 000 Hz to avoid polarization phenomena at the electrodes. Such effects were often obtained when DC was used. Any of the common electrical circuits can be used

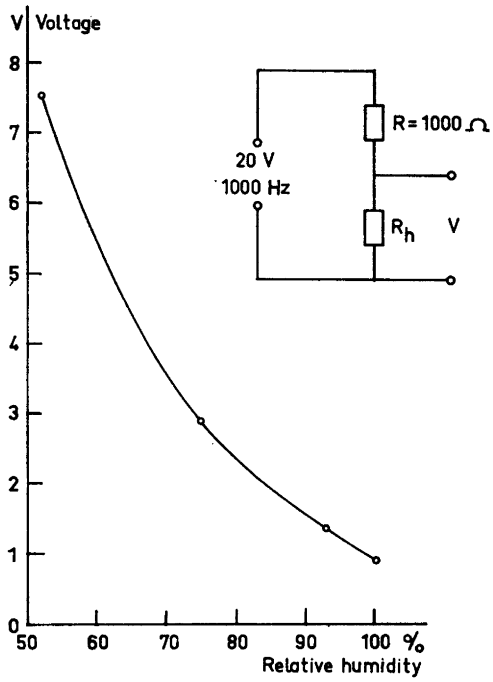

Fig. 1. Typical calibration curve of sheet ion exchanger resistance hygrometer. The voltage, V, is measured (at equilibrium) across the variable hygrometer resistance, R_h, with an electronic voltmeter in the circuit as indicated. The hygrometer is placed in a closed glass vessel, the relative humidity of which is varied by using standard salt solutions. The temperatur was 25° ± 0.1.

including AC bridges, simple volt-ampère coupling, or cross-coil instruments.

The unit responds quickly to changes in humidity. The rate is probably governed by the diffusion of water in the layer and thus the latter should be thin (a few microns). Units responding in a few seconds can be produced.

A special point for the possible use of this method for meteorological purposes is that pure water can be condensed or poured on the unit and the calibration will still be valid after evaporation and subsequent equilibration. This property is hardly provided by such hygrometers that are based on the impregnation of glass with lithium salts or phosphoric acid.

The units can be made very small and might be applicable in cavities difficult to reach with other hygrometers.

Obviously, the calibration curve will change if another cation is used. The study of the resistance properties and water diffusion kinetics would themselves be an interesting field of study.

A draw-back of the method is that some hysteresis effects have been detected when travelling along a resistance-humidity curve. The effect was not found to exceed what corresponds to 2 % RH. Another draw-back is that, if thicker layers of sheet ion exchangers are wanted, they are difficult to prepare from commercial polystyrene apparently due to the very low, or quite absent, cross-linkage and to mechanical cracking of the hydrophilic material formed on the polymer blocks or sheets. ¡It seems that this disadvantage could now be overcome by a moderate dose of ionizing radiation (*e.g.* by ^{60}Co γ-rays) which is known to introduce cross-linking [3]. This would be expected to improve the mechanical stability but might at the same time decrease the swelling of the ion-exchanger and hence somewhat decrease the sensitivity of the hygrometer.

This hygrometer is an example of the application of ion exchangers for quite a different use than the usual one. There is a commercial unit which has properties very similar to the present unit (which has been used since 1953 in this laboratory) but, from the pamphlets [4] supplied, it was not possible to see whether the ideas and the materials are the same or not. The applications should comprise a lot of cases of interest in the laboratory and elsewhere. A special case is the dry-boxes used for radioactive or moisture-sensitive materials. We have not attempted any extended systematic studies of the design of this hygrometer. It is therefore likely that anyone interested can find useful modifications and improvements of the description given above.

Valuable discussions and encouragement of Eng. S. Almberg of AB Billmanregulator, Stockholm, is greatly acknowledged. Eng. L.E. Lundh assisted in taking the data of Fig. 1.

The Structure of Arsenobenzene

SVEND ERIK RASMUSSEN and JACOB DANIELSEN

Department of Inorganic Chemistry, University of Aarhus, Aarhus, Denmark

Arsenobenzene is generally formulated as:  . Double bonds, however, are rarely formed between atoms heavier than oxygen.

Lyon and Mann [1] have previously cast some doubt upon the validity of the classical formula on the basis of molecular weight determinations but no satisfactory structure of the molecule has so far been proposed.

In order to obtain a satisfactory molecular formula we are investigating the crystal structure of arsenobenzene. The compound was obtained by the reduction of phenyl arsonic acid. Two different kinds of crystals can be recognised under the polarizing microscope. One kind forms transparent needle shaped crystals which exhibit parallel extinction and are optically biaxial. The other kind of crystals are a little opaque and show oblique extinction. The transparent ones become opaque between 182°C and 192°C and melt at 196°C. The opaque crystals melt at 196°C. We have not yet proved that the transparent crystals are changed to the opaque form by heating but it appears to be likely. Chemical analysis on the mixture give the following results: C 47.60; H 3.37; calc. for $(AsC_6H_5)_n$: C 47.40; H 3.32.

Weissenberg and precession photographs proved the transparent crystals to be monoclinic. Filtered Cu-radiation was employed. The unit cell has the following dimensions, unique axis *b*, the needle axis:

$$a = 24.04 \text{ Å}$$
$$b = 6.20 \text{ Å}$$
$$c = 12.22 \text{ Å}$$
$$\beta = 111.2°$$

The following extinctions were found: $h0l$ for $h = 2n + 1$ and $0k0$ for $k = 2n + 1$. Hence the space group is $P2_1/a$. The density of the crystal is 1.73. Consequently there are 12 $As-C_6H_5$ groups in the unit cell. As the general point is four fold the $As-C_6H_5$ groups must be linked together in groups of three or of six.

The Patterson projection along the *b*-axis indicated very strongly that the molecular unit contains six arsenic atoms forming a non planar ring with a centre of symmetry. A Fourier projection based upon the As-coordinates reveals the whereabouts of the benzene rings.

On this basis we propose that arsenobenzene is $(AsC_6H_5)_6$. Each As-atom forms two single As—As bonds (approximately 2.4 Å) with its neighbours in the ring and a third As—C bond. Isomers of different conformations are possible. The opaque crystals are triclinic. They will be investigated in more detail later.

A refinement of the structure of the monolinic crystals is in progress.

Note on the Development of Methods for Studying the Polymerisation of Styrene and Acrylonitrile by Positive Gaseous Ions

T. WESTERMARK, L. WESTFELT, H. LINDROTH and N. GHANEM

Division of Physical Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

It has been argued that positive gaseous ions, due to their very high electron affinity, act radiation-like and are thereby capable of breaking covalent chemical bonds. Accordingly these ions might be assumed to be precursors to reactive entities characteristic for radiation chemistry, *e.g.* free radicals. Thus, upon bringing positive gaseous ions into contact with liquids containing monomers, one would expect polymerisation to occur. It is thought that the polymerisation produced by ionizing radiations proceed in some cases *via* free radicals and in other cases (often at low temperatures) *via* ionic species [2,3].

We have developed methods for studying the polymerisation of styrene and acrylonitrile by positive gaseous ions. For styrene, some postive evidence has been found. It seems, however, that emphasis has to be placed primarily on the design of the apparatuses and the methods by which basic studies can be made. We shall discuss such points by referring to Fig. 1 which shows a modification of an apparatus developed for studies on aqueous solutions [4].

One of the main methodological problems is that the liquid phase has to be sufficiently conductive to allow the passage of unipolar charges through the system. For this purpose, one has to select solutions which contain some electrolyte, but the latter should be chosen so as not to inhibit the polymerisation too much. For styrene it was found possible, after performing the conventional extraction of inhibitors by means of a dilute NaOH solution, to add alcohol (about 25 %), water (about 1.3 %) and $CaCl_2$ (less than 0.1 %) to give a solution of sufficient conductivity. Due to these additions, the radiation chemical G-value is reduced — this can be elucidated by means of γ-ray induced polymerisations of samples of the solution. Using this solution in the apparatus of Fig. 1, it was found possible to achieve corona currents of some μA with helium flushing through the space over the section 1 of the apparatus. It was found possible to maintain stable conditions over a period of many days. The formation of polystyrene was detected by precipitating with methanol after cooling with ice.

For acrylonitrile the conductivity problem is easier since it is soluble in water. A distillation of the monomer under oxygen-free conditions served to remove inhibitors. Samples of the monomer were dissolved in distilled water which had been previously redistilled twice in a quartz apparatus. The solution was made 5 % in acrylonitrile and then 0.1 % in $CaCl_2$ in order to increase the conductivity sufficiently so as to allow currents of the order of some μA to be used. In addition, a radiation polymerisation by means of gamma rays was performed in the same way as that described by Dainton [5].

The helium gas used was 99.99 % pure, the possible impurities stated being N_2 0.01 %, O_2 0.0005 %, H_2 0.0005 %. The gas was purified using a 1 m tube containing granular copper * at 175°C. This removed traces of oxygen from the gas but not nitrogen. It is therefore possible that some charge transfer from helium to nitrogen may have taken place.

Positive evidence has been obtained with styrene but the yield was small. A clear turbidity in the contents from cell 1 was observed upon methanol treatment but nothing occurred in the samples from cells 2, 3 and 4. The yield was 0.2 mg and the total number of μAh was 34 as found by a recorder. The voltage used was $\sim$ 5kV and the current a few μA. The helium flow-rate was about 15 ml/min. The anode light was confined to the tungsten wire and no sparking was detected. Some difficulties due to alcohol evaporation were encountered in the experiments. This caused a

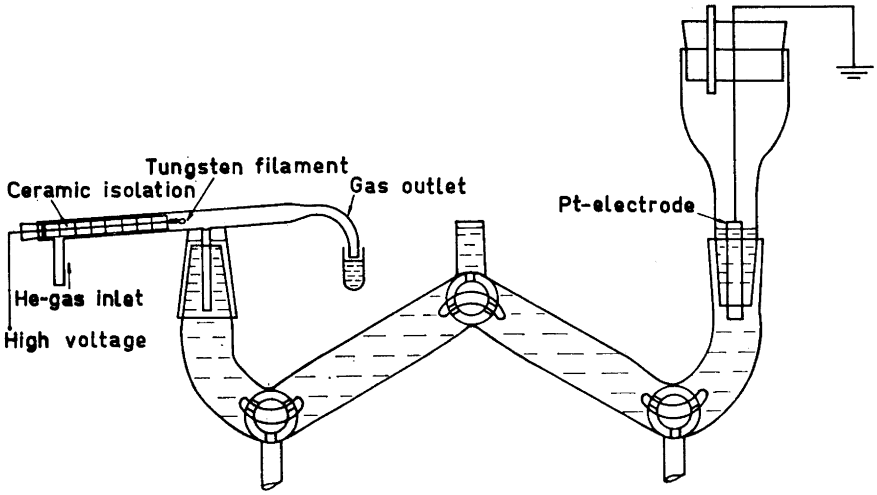

Fig. 1. Glass apparatus for positive gas ion production and performance of radiation-like polymerisation reactions. A series resistor of 100 Mohm is placed between H.T. generator (0—10 keV) and anode filament. The platinum cathode is connected to a current recording device. The left side of the apparatus is denoted cell 1, the next part cell 2 etc. The part on the right containing the platinum electrode is denoted cell 4.

gradual decrease in ion current due to the decrease in level. The molecular weight of the product is not known but, if it is assumed to be 100 000, we arrive at an M/N value (M total number of molecules produced, N total number of ions) of ~ 0.02.

It is hoped that further experiments with the methods described will contribute to an understanding of the initiation process involved in polymerisations of this type. Tye presence of OH groups in the polymers will be investigated using the method of Dainton [5] in order to prove or disprove the formation of OH-radicals by the positive ions.

Preparation of Carbon Isotopically Labelled Thiophenes

BØRGE BAK, JØRN CHRISTIANSEN, and JØRGEN TORMOD NIELSEN

Chemical Laboratory of the University of Copenhagen, Copenhagen, Denmark

As a pre-requisite for a complete determination of the structure of thiophene by microwave technique, enriched samples of 2-^{13}C- and 3-^{13}C-thiophene have been prepared. The methods given below were adopted after repeated experiments with non-labelled compounds. The purity of the resulting isotopically labelled samples was satisfactorily checked by controlling the vapor-pressure and by recording the infra-red absorption curves. Microwave lines from the ^{13}C-labelled species appeared with expected intensity. No lines from impurities were observed in the microwave region, but the infra-red spectra showed the presence of about 5 % CS_2.

Experimental. Preparation of 2-^{13}C-thiophene. Ethylene bromide (3.99 g, 0.0212 mole) and 2.90 g (0.0446 mole) of potassium cyanide, 22 % enriched in ^{13}C, were placed in a 50 ml glass ampulla with 5.2 ml of water and 10.5 ml ethanol. The ampulla was sealed-off under a high vacuum and heated for 3 h on a steam bath under occasional shaking, after which the contents were transferred to a small distilling flask. 10 ml of water and 20 ml of conc. hydrochloric acid was added. Water, ethanol and surplus halogen acids were removed by a slow distillation (1—2 h) at atmospheric pressure, the final temperature of the oilbath applied being 180°C. During this distillation the hydrolysis of the dicyanide is completed. The remainder was quantitatively transferred to a 1 l beaker by means of 200 ml water. 24 g crystalline $BaCl_2$ was added and dissolved. Also, 400 ml of ethanol were added. At this stage, minor quantities of solid impurities were filtered off. 6 ml conc. NH_4OH was added to the filtrate, hereby causing barium succinate (I) to precipitate. The yield was 4.46 g (0.0175 mole). Its purity was checked by comparing its infra-red spectrum (1 mg sample to 300 mg KBr, disk technique) with the spectrum of an authentic sample.

4.46 g (I) was transformed to sodium succinate (II) by adding 50 ml of water and 5.58 g of Na_2SO_4,10 H_2O (0.0174 mole). This mixture was shaken vigorously for 18 h, followed by removal of the $BaSO_4$-precipitate by filtering, whereafter the filtrate was evaporated to dryness. 2.84 g of (II) was obtained, its purity being checked as above. A completely dry sample is essential for the final transformation into thiophene.

2.84 g of (II) was thoroughly mixed with 13 g P_4S_6 (from P and S) [1] in a 50 ml reaction flask which could be heated and swept with dry N_2. The flask was immersed in a bath of 110°C and quickly heated to 300°C. At this temperature a gas mixture was evolved, carried off by the stream of N_2, and finally condensed in a liquid-air cooled trap. After 30 min. heating at 300—310°C the trapped, volatile products (*e.g.* H_2S) were removed by distillation *in vacuo*, the liquid-air bath being substituted by a dry-ice bath. The remainder was distilled *in vacuo* at room temperature into a fresh ampulla containing crushed NaOH pellets in order to retain mercaptanes, CS_2, *etc.* After one hour the liquid product was distilled *in vacuo* onto fresh NaOH, this time allowing for a contact period of 24 h. After a new distillation *in vacuo* the final product had the correct vapor-pressure (21.5 ± 0.5 mm at 0°C). The infra-red spectrum indicated about 95 % purity, a 5 % impurity apparently consisting entirely of CS_2. Since microwaves are not absorbed by CS_2 the purity was satisfactory for our purpose. The contents of 2,5-^{13}C-thiophene (4 %) did not interfere with the spectral interpretation. The yield of 2-^{13}C-thiophene (30 % enriched) was 430 mg (0.0051 mole), representing 23 % with respect to applied, enriched potassium cyanide.

As to the reproducibility of the procedure, compare the next section.

Preparation of 3-^{13}C-thiophene. 1.63 g (0.025 mole) K^{13}CN (22 % enriched in ^{13}C) was transformed into 0.93 g enriched $CH_3{}^{13}CH_2OH$ (0.020 mole), following our earlier procedure [2]. This quantity of ethanol was mixed with 25 g P_2O_5 in a 350 ml glas ampulla, evacuated and sealed-off. After 1.5 h heating at 180°—190°C the volatile products were condensed. By distillation *in vacuo* from a dry-ice bath, 0.0175 mole of gaseous ethylene of high purity (~ 98 %) was collected. In a new ampulla, 0.0166 mole of bromine was reacted with all the ethylene at room temperature, admitting small quantities of ethylene at a time. 0.0166 mole of ethylene bromide was formed, the

purity of which was assumed equal to the purity of ethylene bromide, produced in model experiments and checked by its infra-red spectrum. From hereon the procedure given under 2-^{13}C-thiophene was followed. The final yield of 3-^{13}C-thiophene was 0.0061 mole (510 mg), 22 % enriched in ^{13}C and with no carbon isotopic impurities other than thiophene. The over-all yield thus becomes 24 % as compared to 23 % in the previous case.

These syntheses are of value not only to spectroscopists wanting the ^{13}C-species but also to biochemists wanting radioactive labelled ^{14}C-thiophene or one of its derivatives.

ACTA CHEMICA SCANDINAVICA 14 (1960) 1867–1878

The Infrared Absorption Spectra of some Mono-unsaturated and Saturated Fatty Acids and Esters

AAGE JART

Danish Fat Research Institute, Copenhagen, Denmark

Infrared spectra (from 600 to 4 000 cm^{-1}) of 43 different fatty acids and fatty acid esters in carbon disulphide solution have been recorded. Main stress has been laid on the study of the *trans* absorption at 962 cm^{-1}, and extinction coefficients of the pure substances at the *trans* maximum have been calculated. Beer's law has been shown to apply for concentrations upto 200 g substance per liter of solution. Mention is further made of a base line method for the quantitative determination of *trans* monoene fatty acids in mixtures with saturated acids and *cis* forms of unsaturated fatty acids and fatty acid esters. Ten of the recorded infrared spectra are reproduced.

The study of the *cis-trans* isomerism of unsaturated fatty acids is of interest in connection with the industrial production of hydrogenated edible fats as well as the preparation of pure organic compounds in the laboratory. For quantitative determination of a *trans* isomer of the type RCH:CHR [1] occurring together with the corresponding *cis* isomer and the saturated compound the absorption at 960—970 cm^{-1} in the infrared spectrum may be used. The absorption is the result of a deformation vibration of the carbon-hydrogen bond; on account of this origin of the absorption band, the weight of the groups linked to the carbon atoms of the double bond has only a slight influence on the location of the band.

In 1950 the results were published of the first systematic determinations of the extinction coefficients at 965 cm^{-1} of certain fatty acids, fatty acid methyl esters and triglycerides [1,2]. The extinction values determined in these works were mainly those of four systems of "corresponding compounds", *viz.* derived from 9-octadecenoic acid, its methyl ester, the corresponding alcohol and 6-octadecenoic acid (petroselinic acid). For this purpose the term "corresponding compounds" is intended to cover a monounsaturated *cis* compound, the *trans* compound and the corresponding saturated compound; oleic acid, elaidic acid and stearic acid thus form a system of "corresponding acids".

In a work [3] from 1953, which deals exclusively with C_{18}-fatty acids, extinction coefficients are given for the oleic acid system and, in addition, for the

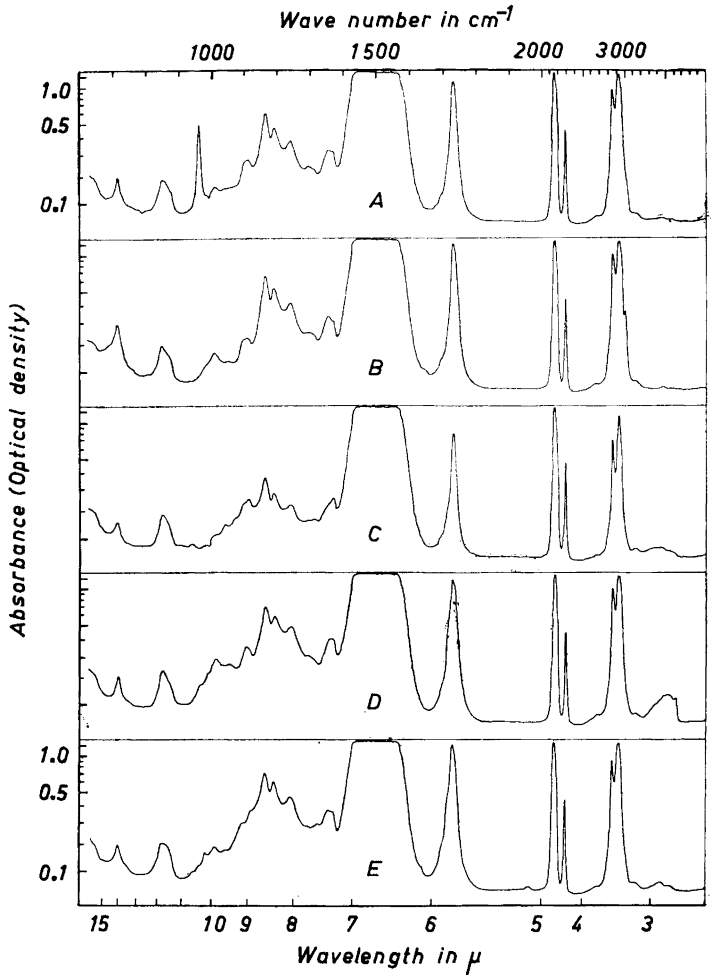

Fig. 1. Infrared spectra. (Carbon disulphide solutions; 0.0110 cm sodium chloride cell). A, Methyl brassidate (98.8 g/l); B, Methyl erucate (108.4 g/l); C, Methyl behenate (57.9 g/l); D, Methyl 12-hydroxy-stearate (102.8 g/l); E, Methyl stearolate (100.6 g/l).

two 12-hydroxy-9-octadecenoic acids (ricinoleic acid and ricinelaidic acid) and for various conjugated and non-conjugated polyene fatty acids.

In a study from 1955 of glycerides [4] mention is made of triolein and trielaidin, various butyro- and aceto-glycerides as well as tributyrin and triacetin.

A work [5] from 1956 gives extinction coefficients of the oleic acid system (in the form of acids, methyl esters and triglycerides) as well as of lauric acid, myristic acid and palmitic acid and the corresponding methyl esters. In another work [6] from 1956 mention is made of the oleic acid system, palmitic acid and linoleic and linolenic acid.

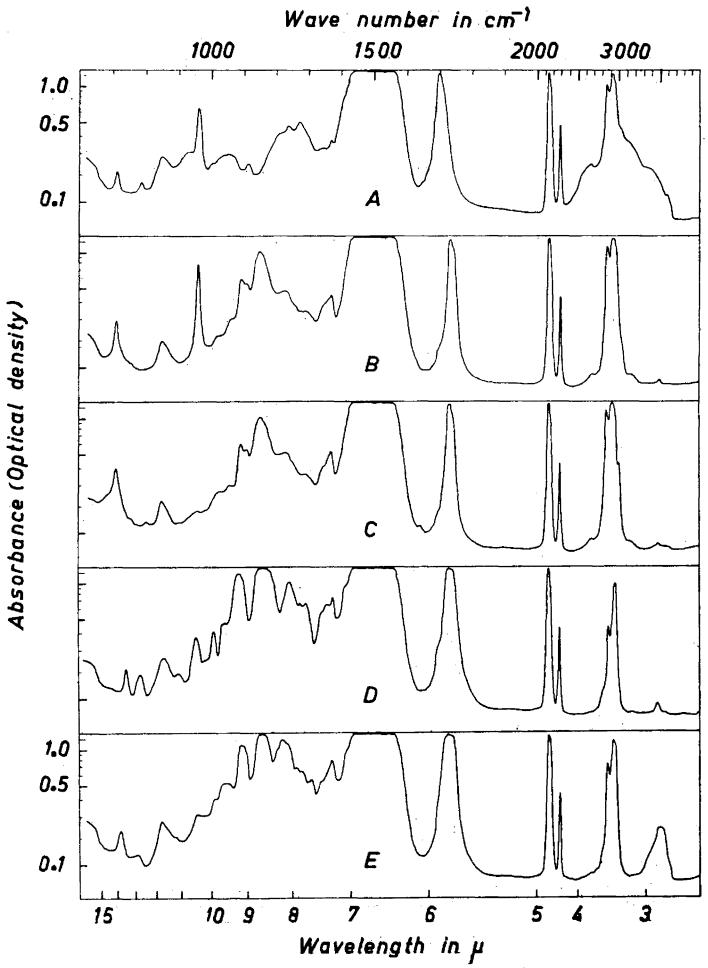

Fig 2 Infrared spectra (Carbon disulphide solutions; 0.0110 cm sodium chloride cell). A, Ricinelaidic acid (99.9 g/l); B, Tribrassidin (152.0 g/l); C, Trierucin (159.7 g/l); D, Tributyrin (116.6 g/l); E, Tricaproin (126.0 g/l).

The determination of ricinelaidic acid and its methyl ester as well as various derivatives of ricinelaidic acid is studied in two works [7,8], published in 1959. Another work [9] dealing with the oleic acid, elaidic acid, erucic acid and brassidic acid, the corresponding methyl esters and barium salts as well as a few glycerides of lower fatty acids appeared also at this time.

The aims of the present work are to perform a systematic determination of extinction coefficients at the *trans* maximum (960—970 cm^{-1}) of a series of monounsaturated and saturated fatty acids and fatty acid esters by means of a widely used spectrophotometer (Perkin-Elmer, Model 21) and to study

conditions in connection with the quantitative determination of *trans* monoene fatty acids with a particular view to the study of the *cis-trans* transformation which may occur during the catalytic hydrogenation of fats.

DETERMINATION OF EXTINCTION COEFFICIENTS AT 962 cm^{-1}

The examination has dealt with eight systems of corresponding compounds (Table 1) based on oleic acid and consisting of acid, methyl ester and triglyceride, on erucic acid in the form of acid, methyl ester and triglyceride, as well as on ricinoleic acid in the form of acid and methyl ester. Furthermore the methyl ester of stearolic acid (which has a triple bond in the 9,10-position) has been investigated; the results are given in connection with the oleic acid methyl ester system.

The twenty-five compounds comprised by this part of the study were examined in carbon disulphide solution. Usually, concentrations of 20, 50, 100, 150, and 200 g of the compound per 1 liter solution were applied. A 0.0110 cm sodium chloride cell was used. As the solubility of the saturated compounds in carbon disulphide is in many cases rather small, a weaker solution in a 0.114 cm sodium chloride cell has been used in these cases.

A comparison of the spectra of the *cis* compounds, *trans* compounds and saturated compounds will disclose the existence of characteristic differences (*cf.* Figs. 1 and 2 *). Unlike the *cis* compounds and the saturated compounds,

* Owing to considerations of space, it will be impossible in this publication to record the spectra of all the compounds examined.

trans compounds display a considerable absorption at 962 cm^{-1} (CH bending about the *trans* C=C group). The *cis* compounds differ from the other two groups in two ways; in the first place the absorption band at 715 cm^{-1} (CH_2 rocking) is wider, and, in the second place, an absorption band may be observed at 3 020 cm^{-1}, forming a shoulder on the broad band (C—H stretching from $CH_3 + CH_2$), which is located between 2 800 and 3 000 cm^{-1}. A further examination of this part of the spectrum should be performed by means of a fluoride prism, and the following will consequently only deal with the absorption at 962 cm^{-1}.

In the absorption spectrum of the free fatty acids there is a very broad and relatively strong band within the range 925—940 cm^{-1}. This band will always be produced by solutions of fatty acids in carbon disulphide, and it is assumed to be due to an OH-deformation vibration in the carboxyl group. As it will appear from the spectra (Fig. 2, A), this band is partially superimposed on the *trans* band at 962 cm^{-1}, and in the case of free *trans* acids the extinction at 962 cm^{-1} consequently receives contributions both from the *trans* extinction and the extinction deriving from the presence of the carboxyl group. In the ricinoleic acid system the extinction is further increased on account of the broad band with maximum at 1 010—1 015 cm^{-1} (C—O stretching).

Fig. 3 shows the optical density in the ricinoleic acid system plotted against the concentration. The relationship is seen to be rectilinear as long as $D < 0.7$. Closely corresponding pictures are obtained in the case of the oleic acid system and the erucic acid system. The corresponding extinction coefficients calculated from

$$a = \frac{\text{optical density at } 962 \text{ cm}^{-1}}{(\text{concentration in g/l}) \times (\text{width of cell in cm})}$$

are given in Table 1.

In the spectra of the methyl esters of the fatty acids (Fig. 1) the band at 925—940 cm^{-1} is seen to have disappeared completely, and in the case of esters of *trans* configuration the extinction at 962 cm^{-1} derives almost exclusively from the *trans* absorption — in the ricinoleic acid system also from the abovementioned band at 1 010—1 015 cm^{-1}. In Fig. 4 the optical density of the methyl esters of the oleic acid system has been plotted against the concentration; the corresponding graphs for the methyl esters of the two other systems have a very much similar appearance. It should again be noted that the relationship is perfectly linear as long as $D < 0.7$. The calculated extinction coefficients appear from the central column of Table 1.

The spectra of the triglycerides (Fig. 2, B and C) resemble those of the methyl esters very much. Also in the case of the *trans* isomers of these esters it applies that the absorption at 962 cm^{-1} derives chiefly from the *trans* band. The dependence of the optical density on the concentration in the case of the triglycerides of the erucic acid system appears from Fig. 5; a corresponding picture is obtained from the triglycerides of the oleic acid system. Conditions are as in the six systems previously mentioned, the relationship being linear for $D < 0.7$. The extinction coefficients are listed in the last column of Table 1;

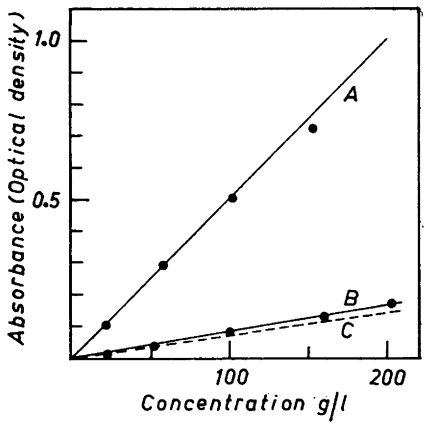

Fig. 5. Relationship between optical density and concentration in the erucic acid triglyceride system (0.0110 cm sodium chloride cell). A, Tribrassidin; B, Trierucin; C, Tribehenin.

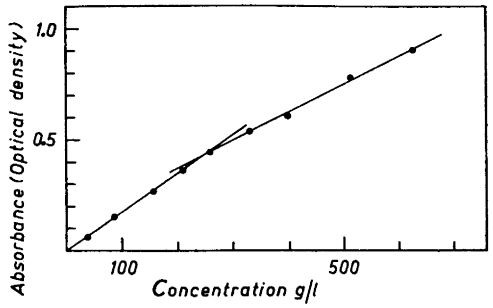

Fig. 6. Relationship between optical density and concentration for methyl elaidate (0.00353 cm potassium bromide cell).

they are somewhat higher than those of the methyl esters, but lower than those of the free fatty acids.

The phenomenon that the optical density is relatively smaller at higher concentrations than at lower concentrations, which is illustrated in Figs. 3—5, may be accounted for in two ways. It may either be the result of a considerable deviation from Beer's law, the extinction coefficient being dependent on the concentration, or the spectrophotometer may exhibit considerable deviation with regard to optical densities higher than 0.7, or both explanations may apply, producing a combined effect. To throw more light on this problem, supplementary investigations were made by means of a thinner cell (0.00353 cm KBr). These experiments showed (Fig. 6) that the relationship is rectilinear up to concentrations of 250 g methyl elaidate per liter solution; the corresponding extinction coefficient was 0.490 — a value which agrees with that found previously. Also in the concentration range 250—650 g per liter solution the relationship seemed to be linear, although the straight line did not coincide with the former, and the dispersion of the points was greater. A corresponding examination was made with respect to trielaidin, and the result corresponds closely to that given for methyl elaidate. Also with respect to ricinelaidic acid it was found that the first part of the curve was a straight line (on account of the lower solubility of this compound in carbon disulphide the shape of the last part of the curve could not be ascertained). For concentrations up to 200—250 g per liter solution no deviations from Beer's law have thus been ascertained.

EXTINCTION COEFFICIENTS OF A NUMBER OF SATURATED FATTY ACID ESTERS

When determining *trans* fatty acids in fatty acid mixtures occurring in practice, it is necessary to make allowance for other saturated acids than those

Table 1. Extinction coefficients at 962 cm^{-1}.

Compound	free acid	methyl ester	glyceride
Oleic acid	0.132	0.041	0.081
Elaidic acid	0.619	0.482	0.538
Stearic acid	0.116	0.028	0.074
Stearolic acid	—	0.066	—
Erucic acid	0.118	0.035	0 077
Brassidic acid	0.537	0.417	0.460
Behenic acid	0.102	0.034	0.067
Ricinoleic acid	0.166	0.094	—
Ricinelaidic acid	0.540	0.460	—
12-Hydroxy-stearic acid	0.242	0.110	—

previously mentioned. Such fatty acids are present in large quantities in a number of natural fats (for instance in coconut oil and consequently in margarine fats) and in certain synthetic triglycerides. A systematic examination of the extinction coefficients at 962 cm^{-1} of the most frequently occurring saturated fatty acid esters was made, and the results are summarized in Table 2. As will be seen from the table, the extinction coefficients of the methyl esters from C_6 decrease with increasing number of carbon atoms in the fatty acid. In the triglyceride series the extinction coefficients decrease steadily with increasing number of carbon atoms, while the molecular extinction coefficient ($= M \times a$, where M is the molecular weight of the triglyceride) is fairly constant (67 ± 9). In the case of triacetin and tributyrin (Fig. 2, D) there are pronounced absorption maxima very near 962 cm^{-1}, *viz.* at 954 cm^{-1} ($a = 0.345$) and at 957 cm^{-1} ($a = 0.260$), while in the case of tricaproin (Fig. 2, E) only an indistinct maximum at 959 cm^{-1} can be observed, and in the case of the higher members of the series the maximum cannot be distinguished from the background.

THE BASE-LINE TECHNIQUE

To be able to determine the content of a *trans* fatty acid in a mixture of fatty acids by means of its extinction coefficient, it is necessary to have a fairly accurate knowledge of the accompanying components of the mixture, which must be determined by gas chromatography or another method. Since the spectra of *cis* fatty acids and of saturated acids resemble each other very much within the range about 962 cm^{-1}, the *trans* absorption may be separated from the "background" absorption by means of a suitable base line. This line may either be drawn in such a way that it approximates the spectrum of the corresponding *cis* isomer, or a straight line may simply be traced as shown in Fig. 7 for a number of *trans* compounds. The distance, D *, from this base line to the peak of the maximum at 962 cm^{-1} corresponds to pure *trans* absorption, and the relationship between this value and the concentration is in principle the same as that found with respect to the total absorption, D, at 962

Table 2. Extinctions at 962 cm^{-1} of methyl esters and triglycerides of saturated acids.

Compound	Methyl ester	triglyceride	
	a	a	ε
Acetic acid	0.036	0.290	63
Butyric acid	0.024	0.246	74
Caproic acid	0.062	0.189	73
Caprylic acid	0.046	0.124	58
Capric acid	0.049	0.116	64
Lauric acid	0.035	0.097	62
Myristic acid	0.037	0.082	59
Palmitic acid	0.031	0.076	61
Stearic acid	0.028	0.074	66
Arachidic acid	0.030	0.078	76
Behenic acid	0.034	0.067	71

cm^{-1}. Fig. 8 shows the curve plotted for tribrassidin; with respect to the remaining seven compounds the curves correspond closely to the *trans* fatty acid curves shown in Figs. 3—5. The curves are straight lines, but also in this case the higher values of the optical density are too small. From the magnitude D^* it is possible to calculate a corresponding *trans* extinction coefficient, a^*, from:

$$a^* = \frac{D^*}{(\text{conc. in g/l}) \times (\text{width of cell in cm})}$$

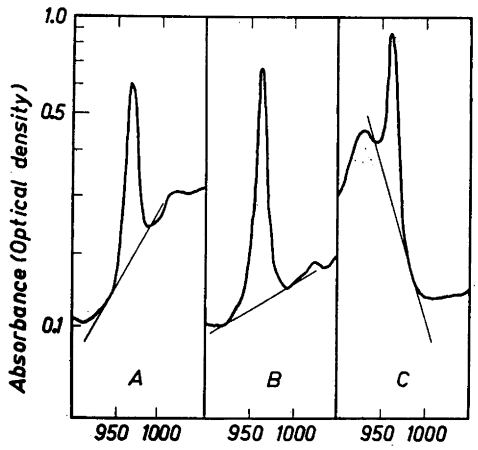

Fig. 7. Tracing of base line for a number of *trans* compounds. A, Methyl ricinoleate (108.6 g/l); B, Trielaidin (105.3 g/l); C, Brassidic acid (147.3 g/l). Abscissas: Wave number in cm^{-1}.

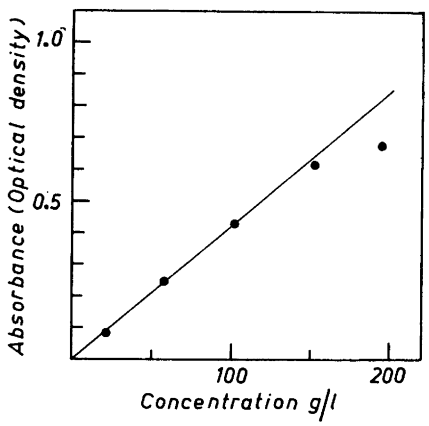

Fig. 8. Relationship between optical density and concentration for brassidic acid triglyceride (base line method, 0.0110 cm sodium chloride cell).

Table 3. Pure *trans* absorptions at 962 cm^{-1}.

Compound	Absorptivity a *	Molar absorptivity ε *
Elaidic acid	0.445	125.9
Brassidic acid	0.376	127.1
Methyl elaidate	0.423	125.4
Methyl brassidate	0.355	125.2
Trielaidin	0.467	413.5 (138)
Tribrassidin	0.387	407.9 (136)
Ricinelaidic acid	0.354	110.6
Methyl ricinelaidate	0.340	101.5

The calculated values are listed in the first column of Table 3. The last column lists the corresponding molecular values, ε *, which are obtained by multiplying values of a * by the corresponding molecular weights. It will be seen that in the case of the simple fatty acids, elaidic acid and brassidic acid and their methyl esters, the molecular value may be taken to be 126. The values for the glycerides are somewhat higher (138 and 136, respectively, calculated per molecule of fatty acid), while those for the hydroxy-substituted compounds are somewhat lower.

In the case that a great precision is not necessary it thus seems favourable to use the base-line technique.

THE PURITY OF THE SUBSTANCES USED

The preparation of the fatty acids and fatty acid esters used in the present investigation is described under the heading Experimental. All *trans* isomers were prepared to such a grade of purity that it was not possible by gas chromatography or other methods to demonstrate the presence of impurities. The purity of the saturated acids is about 99.5 %, which is sufficient for the present purposes as the impurities in this case consist of closely related substances with a corresponding absorption at 962 cm^{-1}. The purity of ricinoleic acid is 99 %, that of oleic acid and erucic acid about 97—98 %, and the same applies to stearolic acid. None of these deviations from 100 % purity should cause any significant alteration of the numerical values of the extinction coefficients. In the case of the triglycerides of some of the lower acids (fats which were originally prepared for feeding experiments) the contents of impurities were determined by gas chromatography, and the extinction coefficients were corrected accordingly. A little content of free hydroxy groups in some of these triglycerides was noticed, but in this connection it does not influence the extinction values.

Direct comparison of extinction values determined by means of different spectrophotometers is not possible, since the individual instruments may differ considerably with regard to scattered radiation, slit width, *etc.* The numerical values found in the present work do, however, agree well with the results of most of the works mentioned in the above. The extinction coefficient values found for the *trans* isomers were, however, about 10 % higher than the results generally given in the literature. The extinction coefficient values given in the following are believed to be in most cases accurate to ± 2 %.

EXPERIMENTAL

Equipment. A Perkin-Elmer spectrophotometer, model 21, with sodium chloride prism was used without any reference cell. The settings used were: speed, 6; automatic suppression, 6; gain, 5.3; intensity, 0.32 A; response, 1; resolution, 927; and slit width at 962 cm^{-1}, 120 μ. Alteration of the speed from 6 to 3 gave no significant alteration of the results.

Cells. The thickness of the 0.0110 cm sodium chloride cell was measured by the interference method. The thickness of the 0.00353 cm potassium bromide cell could not be measured in this way; it was measured by means of pure benzene. The thick cell (0.114 cm, sodium chloride) was measured by means of solutions of fatty acid esters in carbon disulphide.

Determination of extinction coefficients. A sample of the compound under examination was weighed in a calibrated volumetric flask and dissolved in carbon disulphide (Merck, analytical grade). The temperature was 24°C.

I. *Oleic acid.* Olive oil was converted into methyl esters by shaking at 60°C with 1.6 times the theoretical quantity of methanol in which 0.5 % of sodium hydroxide was dissolved; the mixture was set aside for one hour at 60°C and allowed to stand overnight at room temperature. The upper phase was then separated and distilled *in vacuo*. Saturated acids were removed by setting aside the methyl oleate for one week at −40°C in acetone (10 ml per g of methyl ester). Crystallization was effected at −60°C by means of dry ice with gentle stirring; the resulting precipitate was isolated, and oleic acid was recovered by saponifying with 2 N ethanolic potassium hydroxide and acidifying with 50 % sulfuric acid. Linoleic acid was removed from the resulting free acid by recrystallizing three times from acetone at −40°C. The precipitate was evaporated to dryness *in vacuo*. The purity was determined by alkali-isomerization, determination of iodine value and gas chromatography [10].

II. *Elaidic acid.* A commercial product (B.D.H.) was recrystallized three times from three times its volume of 99.9 % ethanol by being allowed to stand at 5°C. Melting point, 43.8−44.0°C.

III *Stearic acid.* A commercial product (B.D.H.), which was found by gas chromatography to contain 96 % stearic acid and 4 % palmitic acid, was fractionated on a 0.6 m packed column (with 1/8 in. Dixon rings). Melting point, 68.6°C.

IV. *Erucic acid.* Rape seed oil was converted into methyl esters as described under I. The esters were carefully fractionated by vacuum distillation, and the C_{22} fraction was allowed to crystallize from acetone at low temperature in a similar manner to that described in the case of methyl oleate under I. The test for purity was performed as in the case of oleic acid.

V. *Brassidic acid.* A commercial product (California Corporation for Biochemical Research) was recrystallized six times from 99.9 % ethanol (at a ratio of 1:1.5) by being allowed to stand at 5°C. Melting point, 59.0−59.2°C.

VI. *Behenic acid.* A technical grade product was converted into methyl esters by means of methanol and sulfuric acid and fractionated on a 0.6 m packed column (Dixon rings). A suitable fraction was recrystallized three times from 96 % ethanol (at a ratio of 1:10) at room temperature. Melting point, 79.8°C.

VII. *Ricinoleic acid.* Castor oil was converted into methyl esters as described under I. The methyl esters were fractionated *in vacuo*, and one fraction which, by gas chromatography, was found to be pure was saponified by means of ethanolic potassium hydroxide

and acidified with 50 % sulfuric acid. Test for purity as described in the case of oleic acid (I).

VIII. *Ricinelaidic acid.* Castor oil was saponified and acidified, and mercury and strong nitric acid were allowed to act on the free fatty acids with stirring. The mixture was washed with water and recrystallized six times from light petroleum at room temperature. Melting point, 50.4°C.

IX. *12-Hydroxy-stearic acid.* Ricinoleic acid methyl ester (*cf.* VII) was hydrogenated with palladium catalyst (10 % Pd on activated carbon) for 8.5 h at 65° in methanol solution; in this way 60 % of the double bonds were hydrogenated. The resulting product was saponified by addition of excess of 2 N aqueous potassium hydroxide and acidified with 50 % sulfuric acid to precipitate the fatty acids. Following two recrystallizations from 96 % ethanol, the melting point of the acids was 76°C. The acids were esterified with methanol and sulfuric acid and fractionated by vacuum distillation. One fraction, with melting point at 49°C, was recrystallized twice from 99.9 % ethanol at 5°C. Melting point, 56.0—56.3°C. The ester was saponified with ethanolic potassium hydroxide and acidified with sulfuric acid. Melting point of the acid, 79.4°C.

X. *Methyl acetate.* A commercial product (B.D.H.) was used.

XI. *Methyl butyrate.* A commercial product was ascertained by gas chromatography to be sufficiently pure.

XII. *Methyl caproate.* Technical grade caproic acid was esterified with methanol and sulfuric acid and fractionated on a 1 m spinning-band column. Tested for purity by gas chromatography.

XIII. *Methyl caprylate.* Prepared in the same way as XII.

XIV. *Methyl caprate.* Prepared in the same way as XII.

XV. *Methyl laurate.* Prepared in the same way as XII.

XVI. *Methyl myristate.* Prepared in the same way as XII.

XVII. *Methyl palmitate.* Prepared in the same way as XII.

XVIII. *Methyl oleate.* Prepared from I by esterification with methanol and sulfuric acid.

XIX. *Methyl elaidate.* A, Prepared from II by esterification with diazomethane [11]. B, Another quantity was prepared by alcoholysis of trielaidin (XXXVIII B) with methanol (according to I) and vacuum distillation of methyl elaidate.

XX. *Methyl stearate.* Prepared from III by esterification with methanol and sulfuric acid.

XXI. *Methyl stearolate.* Prepared according to *Org. Syntheses* [12] by bromination of methyl oleate and treatment of the product obtained with potassium hydroxide and *n*-amyl alcohol. The mixture was acidified with hydrochloric acid to yield the acid which was recrystallized several times from 70 % ethanol, followed by esterification with methanol and sulfuric acid.

XXII. *Methyl arachinate.* Arachidic acid, 95 % pure, war recrystallized three times from 95 % ethanol and esterified with diazomethane [11].

XXIII. *Methyl erucate.* Prepared from IV by esterification with methanol and sulfuric acid.

XXIV. *Methyl brassidate.* Prepared from V by esterification with diazomethane [11].

XXV. *Methyl behenate.* Prepared from VI by esterification with diazomethane [11].

XXVI. *Methyl ricinoleate.* Intermediate from the preparation of VII.

XXVII. *Methyl ricinelaidate.* Prepared from VIII by esterification with diazomethane [11].

XXVIII. *Methyl 12-hydroxy-stearate; cf.* IX. Melting point, 56.0—56.3°C.

XXIX. *Triacetin.* Commercial product (from R de H). Tested for purity by gas chromatography.

XXX. *Tributyrin.* Commercial product (from B.D.H.). Fractionated by vacuum distillation. Tested for purity by gas chromatography.

XXXI. *Tricaproin.* Technical grade caproic acid (R de H) was esterified with methanol and sulfuric acid. After washing with sodium bicarbonate solution and drying with anhydrous sodium sulfate, the methyl ester was fractionated by distillation. Interesterification of methyl caproate and triacetin was effected by heating for 5 h to 80°C with 95 % of the theoretical quantity of neutralized and dried triacetin (R de H) to which had been added 1 % sodium methylate dissolved in methanol; the methyl acetate formed was removed during the process by suction with a water-jet pump. Excess methyl ester

was subsequently removed by passing steam through the triglyceride at 80°C and 20 mm Hg. The resulting triglyceride was treated with 1 % activated carbon and filtered. Composition: 99.5 % C_8; 0.5 % C_8.

XXXII. *Tricaprylin.* Prepared from technical grade caprylic acid (R de H) in the same way as XXXI. Composition: 98.5 % C_8; 1.5 % C_{10}.

XXXIII. *Tricaprin.* Prepared from technical grade capric acid (B D. H) in the same way as XXXI. Composition: 3.1 % C_8; 93.5 % C_{10}; 3.4 % C_{12}.

XXXIV. *Trilaurin.* Prepared from technical grade lauric acid by esterification with 98 % glycerol *in vacuo* at 200°C for 5 h with 0.2 % stannous chloride as catalyst. Washed with aqueous sodium carbonate solution and dried with kieselguhr. Composition: 0.6 % C_8; 10.7 % C_{10}; 86 % C_{12}; 2.7 % C_{14}.

XXXV. *Trimyristin.* Prepared from 98 % myristic acid (B.D.H.) by esterification with 95 % glycerol *in vacuo* at 200°C for 5 h with 1 % stannous chloride as catalyst. Washed with sodium bicarbonate solution and water. Recrystallized three times from benzene. Melting point, 56.8°C.

XXXVI. *Tripalmitin.* Prepared from palmitic acid (B.D.H.) in the same way as XXXV. Recrystallized three times from benzene. Melting point, 65.3°C.

XXXVII. *Triolein.* Prepared from I by esterification with 90—95 % glycerol at 125°C for 8 h, passing nitrogen through the solution and using 1 % *p*-toluene sulfonic acid as catalyst. The mixture was dissolved in two volumes of petroleum ether, washed with two portions of 70 % ethanol, the first containing potassium hydroxide for the purpose of removing free acids, and subsequently with water. Triolein was finally crystallized from acetone (1 g of triglyceride per 10 ml) at −40°C and evaporated to dryness *in vacuo*.

XXXVIII. *Trielaidin.* A, Prepared from II by esterification in the same way as XXXV. Recrystallized several times at 5°C from ethyl ether. Melting point, 42.9—43.2°C. B, Another batch equally pure was prepared from a product obtained from olive oil which was treated with sodium nitrite and nitric acid, the resulting product being washed with water and recrystallized five times at 5°C from ethyl ether.

XXXIX. *Tristearin.* Prepared from III in the same way as XXXV. Melting point, 72.6°C.

XL. *Triarachin.* Prepared from arachidic acid (*cf.* XXII) in the same way as XXXV. Recrystallized three times from benzene. Melting point, 76.9°C.

XLI. *Trierucin.* Prepared from IV by esterification with glycerol as described in the case of XXXVII.

XLII. *Tribrassidin.* Prepared from V by esterification as described in the case of XXXV. Recrystallized five times from ethyl ether at 5°C. Melting point, 58°C.

XLIII. *Tribehenin.* Prepared from VI by esterification as described in the case of XXXV. Recrystallized three times from benzene. Melting point, 81.6°C.

ACTA CHEMICA SCANDINAVICA 14 (1960) 1879–1893

On the Sulfides, Selenides and Tellurides of Platinum

FREDRIK GRØNVOLD, HAAKON HARALDSEN and ARNE KJEKSHUS

Kjemisk Institutt A, Universitetet i Oslo, Blindern, Norway

The phase relationships in the systems platinum sulfur, platinum selenium and platinum tellurium have been studied by means of X-rays. Density determinations and magnetic susceptibility measurements have been carried out. Two new, intermediate phases were identified:

1. $PtSe_{0.80}$, with monoclinic structure, $a = 6.5806$ Å, $b = 4.6248$ Å, $c = 11.145$ Å, $\beta = 78.40°$. The pycnometric density is 12.79 g cm^{-3} at 25°C. The unit cell contains ten formula units and the probable space group is Pc or $P2/c$.

2. PtTe, with orthorhombic structure, $a = 6.6144$ Å, $b = 5.6360$ Å, $c = 11.865$ Å. The observed density is 12.01 g cm^{-3}. The unit cell contains ten formula units.

The earlier known phases PtS, PtS_2, $PtSe_2$ and $PtTe_2$ have been reinvestigated. The lattice constants and the observed densities are:

PtS, $a = 3.4700$ Å, $c = 6.1096$ Å
PtS_2, $a = 3.5432$ Å, $c = 5.0388$ Å, density: 7.83 g cm^{-3}
$PtSe_2$, $a = 3.7278$ Å, $c = 5.0813$ Å, density: 9.53 g cm^{-3}
$PtTe_2$, $a = 4.0259$ Å, $c = 5.2209$ Å, density: 10.16 g cm^{-3}

The correctness of the earlier assumed, tetragonal structure of PtS has been confirmed as result of intensity measurements and calculations.

The value $z = 0.250$ of the parameter in the $Cd(OH)_2$-type structures of PtS_2, $PtSe_2$ and $PtTe_2$ gives the best agreement between observed and calculated X-ray intensities.

The magnetic susceptibilities of the different phases have been measured between −183 and 450°C. The compounds show almost zero magnetic susceptibility.

EARLIER RESULTS

Platinum monosulfide was first prepared by Davey [1] by heating platinum sponge and sulfur in a closed tube. Vauquelin [2] prepared it by heating ammonium hexachloroplatinate(IV) with sulfur and sodium carbonate. According to Schneider [3] such products contain more sulfur than corresponding to the formula PtS, and are better described by the formula $4PtS \cdot PtS_2$, *i.e.* Pt_5S_6. At red heat the reported compound looses one sixth of its sulfur and

PtS is formed. Platinum monosulfide occurs in nature as cooperite and its crystal structure was determined by Bannister and Hey [4].

Platinum disulfide was prepared by Davey [1] by heating ammonium hexachloroplatinate(IV) with sulfur at red heat in the absence of air. Berzelius [5] prepared it by treating a solution of hexachloroplatinum(IV) acid with hydrogen disulfide or alkali metal sulfides. Thomassen [6] tried to make PtS_2 by heating stoichiometric amounts of the elements in an evacuated and sealed quartz tube. He obtained a product with composition $PtS_{1.94}$ and found from X-ray powder photographs that it had a hexagonal structure of the $Cd(OH)_2$-type.

In addition to postulating the existence of Pt_5S_6, Schneider [3] also reported a platinum sulfide with composition Pt_2S_3. Neither of these compounds were found by Wöhler, Ewald and Krall [7], who studied the platinum sulfur system by preparative-analytic methods, or by Biltz and Juza [8], who studied the system by tensimetric analysis. The latter authors found no indications of other compounds than PtS and PtS_2. For further references to earlier studies of the platinum-sulfur system, see Gmelin [9].

The reaction between platinum and selenium was observed by Berzelius [10]. The first analyzed compound in this system was platinum monoselenide, prepared from the elements by Roessler [11]. Its existence has not been confirmed by other investigators.

Platinum diselenide has, however, been described by several investigators. Minozzi [12] synthesized $PtSe_2$ from the elements, while Moser and Atynski [13] prepared the compound by precipitation with hydrogen selenide in aqueous solution. Wöhler *et al.*[7] obtained $PtSe_2$ by heating platinum tetrachloride with a large amount of selenium. Thomassen [6] studied $PtSe_2$ by means of X-rays and found that it had a structure of the $Cd(OH)_2$-type.

Minozzi [12] reports also the existence of $PtSe_3$. This compound was prepared by reacting pctassium hexachloroplatinate(IV) with selenium dioxide in an alkaline formaldehyde solution.

Platinum ditelluride was prepared by Roessler [14] by heating platinum and tellurium. Wöhler *et al.*[7] synthesized $PtTe_2$ from platinum tetrachloride and tellurium. In contrast to Tibbals, Jr.[15], who reported that sodium telluride reduced platinum tetrachloride solutions to elemental platinum, Brukl [16] claimed that $PtTe_2$ could be precipitated from aqueous solutions by means of hydrogen telluride. Thomassen [6] determined the crystal structure of $PtTe_2$ and found that it was of the same type as PtS_2 and $PtSe_2$. The lattice constants of $PtTe_2$ were redetermined by Groeneveld Meijer [17].

Experiments to obtain other platinum tellurides have been less successful. Roessler [14] claims that the compounds PtTe and Pt_2Te are formed by decomposing platinum tellurides richer in tellurium. Attempts by Thomassen [6] to make PtTe resulted in heterogeneous products with $PtTe_2$ as the main constituent.

The existence of a platinum telluride mineral with composition $PtTe_3$ was claimed by Scholtz [18]. The reported X-ray data for the mineral, named niggliite, were interpreted by Groeneveld Meijer [19] as mainly caused by a hexagonal NiAs-like structure. On this basis Groeneveld Meijer assigned the composition PtTe to the mineral.

EXPERIMENTAL

Most of the platinum metal used in this study was kindly placed at our disposal by Falconbridge Nikkelverk A/S, Norway. A spectrographic analysis showed presence of the following impurities: about 0.07 % Au, 0.02 % Ir, 0.01 % Pd, 0.01 % Rh, 0.001 % Cu and less than 0.001 % Ag. Some platinum thermocouple wire was also used. A spectrographic analysis of this platinum showed about 0.05 % Au, 0.05 % Cu, 0.02 % Ir, 0.01 % Pd and 0.01 % Rh.

An X-ray powder photograph of the Falconbridge platinum taken at 19 ± 2°C gave a lattice constant of 3.9232 Å, in close agreement with the value 3.9231 Å by Swanson and Tatge [20].

Sulfur from Schering-Kahlbaum A.G. (Sulfur cryst. puriss.) was purified by double distillation in a silica apparatus. Only the middle fractions were used. The highly purified selenium was a gift from Bolidens Gruvaktiebolag, Sweden. It carried the analysis: 0.0002 % Cu, 0.0007 % Fe, 0.003 % Te, 0.01 % S and 0.003 % non volatile matter. Tellurium from The British Drug Houses Ltd. was purified by vacuum distillation in a silica apparatus. According to the spectrographic analysis the distilled product contained less than 0.01 % Fe and only traces of Al, Mg and Pb.

The alloys were prepared by heating accurately weighed quantities of platinum and sulfur, selenium or tellurium, respectively, in evacuated and sealed silica tubes.

In the platinum-sulfur system alloys with 25.00, 33.33, 40.00, 47.37, 48.72, 50.00, 51.22, 52.38, 54.55, 60.00, 66.10, 66.67 and 75.00 atomic % sulfur were made. All samples except those with 25.00, 40.00 and 54.55 atomic % S were heated at 825°C for 30 days and cooled slowly to room temperature over a period of another 30 days. The samples with 66.67 and 75.00 atomic % S were afterwards annealed for 50 days at a temperature of 650°C. The samples with 25.00, 40.00 and 54.55 atomic % S were quenched in ice water from 1 150, 825 and 650°C, respectively.

In the platinum-selenium system alloys with 25.00, 33.33, 37.11, 38.65, 40.00, 41.18, 42.86, 43.50, 44.44, 45.95, 47.61, 50.00, 60.00, 66.67, 75.00 atomic % selenium were made. All samples except those with 25.00, 40.00 and 50.00 atomic % Se were heated at 825°C for 30 days and cooled slowly to room temperature over a period of another 30 days. The samples with 44.44, 50.00, 66.67 and 75.00 atomic % Se were also heated at 1 000 and 600°C for 20 to 30 days. The alloy with 44.44 atomic % Se was furthermore heated at 400°C for 60 days. The samples with 25.00, 40.00, 44.44 and 50.00 atomic % Se were quenched in ice water from 1 200, 825, 1 155 and 825°C, respectively. For density measurements samples with 41.18, 42.28, 44.44 and 45.95 atomic % Se were heated at 1 150°C for 2 days. The melted alloys were afterwards crushed and annealed at 850°C for 10 days and slowly cooled to room temperature over a period of 14 days.

In the platinum-tellurium system alloys with 33.33, 40.00, 47.37, 50.00, 52.24, 60.00, 66.67, 67.74 and 75.00 atomic % tellurium were synthesized. The alloys were heated for 30 days at 825°C and cooled slowly to room temperature over a period of another 30 days. The samples with 40.00 and 50.00 atomic % Te were afterwards annealed at 750°C for 20 and 30 days, respectively. The alloy with 50.00 atomic % Te was also heated at 400°C for 40 days. The samples with 33.33, 50.00 and 60.00 atomic % Te were quenched in ice water from 750, 925 and 825°C, respectively.

During the heat treatments some of the samples were subject to sintering or melting. The alloys with 33.33 atomic % selenium or tellurium had melted at 825 and 750°C, respectively. In both samples a lump of elemental platinum was present, indicating that during cooling platinum was primarily deposited from the melt. The melting point of the alloys with 44.44 atomic % Se and 50.00 atomic % Te was determined to be 1 055 ± 15 and 925 ± 15°C, respectively. Thus, the composition of the eutectic alloy lies between 33.33 and 44.44 atomic % Se in the platinum-selenium system and between 33.33 and 50.00 atomic % Te in the platinum-tellurium system. The alloys were black or grey in colour. When heated to 825°C and above the platinum tellurium alloys showed metallic lustre.

All samples were crushed and X-ray photographs taken in cameras with 114.6 mm effective diameter and asymmetric film mounting. X-Ray photographs were also taken in a Weissenberg camera with 57.3 mm diameter. X-Ray powder data on PtTe were obtained with a Guinier focusing camera of 80 mm diameter and strictly monochroma-

tized Cu$K\alpha_1$ radiation. Guinier photographs of the $PtSe_{0.80}$-phase were taken in a Nonius camera of 114.6 mm diameter. Spectrometer diagrams were taken in a Philips Geiger spectrometer. For the calculation of lattice constants by the Guinier method, potassium chloride (Analar, The British Drug Houses Ltd. $a = 6.2919$ Å[21]) was added to the specimen as an internal standard. The lattice constant of the different samples of platinum was found by extrapolation according to the method of Nelson and Riley [22].

Lattice constants are expressed in Ångström units on the basis of $\lambda_{CuK\alpha_1} = 1.54050$ Å. Results from earlier investigations expressed in kX-units have been transformed to Å by multiplication by the factor 1.00202.

The density of the phases was determined by the pycnometric method at 25°C with kerosene as displacement liquid. To remove gases adsorbed by the sample, the pycnometer was filled under vacuum with kerosene. Each sample weighed from 2 to 3 g. The magnetic susceptibilities of the phases were measured by the Gouy method at three different maximum field strengths at −183, −78, 20, 150, 300 and 450°C. The samples were filled in thin-walled silica tubes of about 2 mm internal diameter and to a height of about 85 mm.

X-RAY RESULTS

A. Platinum sulfides

In agreement with the results by Biltz and Juza [8] only the PtS-phase and PtS_2-phase were found in the platinum sulfur system. The existence of the compounds Pt_2S_3 and Pt_5S_6, claimed by Schneider [3], was thus not confirmed.

The lattice constant of platinum was found to be 3.9234 Å in an alloy with 33.33 atomic % S, containing Pt and PtS in equilibrium. Within the limits of experimental error this value is equal to that of pure platinum, and indicates that sulfur is practically insoluble in solid platinum.

The PtS-phase. Powder photographs of the PtS-phase were indexed on the basis of a tetragonal unit cell, *cf.* Table 1. The lattice constants of the sample with composition $PtS_{1.00}$ are found in Table 2 together with the lattice constants of the PtS-phase in the samples $PtS_{0.90}$ and $PtS_{1.10}$, in which PtS is in equilibrium with Pt and PtS_2, respectively. As the lattice constants do not vary with composition, the homogeneity range of the PtS-phase is not noticeable. The only previous determinations, due to Bannister and Hey [4], are also given in Table 2. The accordance is very satisfactory.

The systematic missing reflections were of the type *(hkl)* absent when $l = 2n + 1$. The highest symmetric space group is thus $P4_2/mmc$ (D^9_{4h}).

Bannister and Hey [4] described the structure of PtS by means of a *C*-centered unit cell to bring out the relationships with the face-centered unit cell of platinum. In Table 1 the *C*-centered indices *(HKL)* are also listed. The corresponding extinctions are of the type *(HKL)* absent when $H + K = 2n + 1$ and $(H0L)$ absent when $H = 2n + 1$ and $L = 2n + 1$. The corresponding space group orientation is $C4/mcm$. By the transformation to the *C*-centered unit cell only the *a*-axis is changed, and

$$A = a\sqrt{2} \quad , \quad C = c$$

with numerical values

$$A = 4.9073 \text{ Å} \quad , \quad C = 6.1096 \text{ Å}$$

for $PtS_{1.00}$.

Bannister and Hey based their structure determination on the intensities of a few reflections only. For this reason a new comparison of observed and calculated intensities of the reflections was carried out. In terms of the space group $P4_2/mmc$ (D_{4h}^9) the atomic arrangement in PtS is as follows:

2 Pt in (c) $0,\frac{1}{2},0$; $\frac{1}{2},0,\frac{1}{2}$, and 2 S in ($e$) $0,0,\frac{1}{4}$; $0,0,\frac{3}{4}$.

The intensities of the reflections were calculated using the formula

$$I_{calc} = 10^{-5} \times |F|^2 \times Lp \times \nu$$

No corrections for absorption and temperature factors were thus applied. The observed intensities were obtained from photometer recordings and referred to a relative, absolute scale by making the sums of I_{obs} and I_{calc} equal. As can be seen from Table 1 the agreement between the two sets of values is very good, and leaves no doubt about the correctness of the proposed structure.

Table 4. Lattice constants of the PtS_2-phase.

Sample	a(Å)	c(Å)	Reference
$PtS_{1.50}$	3.543	5.040	Present
$PtS_{1.94}$	3.5431	5.0389	Present
$PtS_{2.00}$	3.5432	5.0388	Present
$PtS_{3.00}$	3.5428	5.0415	Present
$PtS_{1.94}$	3.544 ± 0.004	5.029 ± 0.005	Thomassen [6]
$PtS_{2.00}$	3.55	5.03	Bannister and Hey [4]

The interatomic distances are only slightly altered by the new data. Four sulfur atoms are arranged around each platinum atom at the corners of a rectangle (3.040×3.470 Å^2). The shortest interatomic distances are: platinum-sulfur 2.312 Å, sulfur-sulfur 3.040 and 3.470 Å, and platinum-platinum 3.470 and 3.907 Å.

The PtS_2-phase. Powder photographs of the PtS_2-phase were indexed as hexagonal, *cf.* Table 3. The lattice constants of $PtS_{2.00}$ are listed in Table 4 together with the lattice constants of the PtS_2-phase for the samples $PtS_{1.50}$ and $PtS_{3.00}$ in which PtS_2 is in equilibrium with PtS and S, respectively. In addition, a sample with 24.2 weight % sulfur, corresponding to the non-stoichiometric composition $PtS_{1.94}$, found for the PtS_2-phase by Thomassen [6] was prepared and examined. The lattice constants of this sample are listed in Table 4 together with previous lattice constant values by Thomassen [6] and Bannister and Hey [4]. The difference between the values for the *c*-axis in the samples $PtS_{2.00}$ and $PtS_{3.00}$ might indicate a narrow range of homogeneity for the PtS_2-phase.

The pycnometric densities of $PtS_{1.94}$ and $PtS_{2.00}$ at 25°C were found to be 7.80 and 7.83 g cm^{-3}, respectively, in close agreement with the density 7.86 g cm^{-3} calculated for $PtS_{2.00}$ from the X-ray data. Earlier values by Biltz and Juza [8] for samples with composition $PtS_{2.00}$ are about 2 % lower.

According to Thomassen the structure of PtS_2 is of the $Cd(OH)_2$-type. The space group is $P\bar{3}m1$ (D_{3d}^3) with

1 Pt in *(a)* 0,0,0 and 2 S in *(d)* $2/3,1/3,z;1/3,2/3,\bar{z}$.

Thomassen obtained good agreement between I_{obs} and I_{calc} using the parameter value $z = 1/4$. In order to check the parameter value intensities were calculated for $z = 0.240$, 0.245, 0.250, 0.255 and 0.260. The value $z = 0.250$ gives indeed the best agreement between I_{obs} and I_{calc}. The corresponding calculated intensities are listed in Table 3 together with the observed ones.

The interatomic distances are only slightly altered by the new lattice constant values. Each platinum atom is surrounded octahedrally by six sulfur atoms at the distance 2.402 Å. The twelve shortest sulfur-sulfur distances are 3.245 Å and the six shortest platinum-platinum distances are 3.543 Å.

B. Platinum selenides

In the platinum-selenium system two intermediate phases, the $PtSe_{0.80}$-phase and the $PtSe_2$-phase, were identified. This is in accordance with earlier results if the $PtSe_{0.80}$-phase is identified with the monoselenide described by Roessler [11]. The existence of $PtSe_3$, claimed by Minozzi [12], could not be confirmed.

The lattice constant of platinum was found to be 3.9233 Å in an alloy with 33.33 atomic % Se, in which Pt is in equilibrium with $PtSe_{0.80}$. This indicates that selenium is practically insoluble in solid platinum.

The $PtSe_{0.80}$-phase. Powder photographs of different samples of PtSe and $PtSe_{0.909}$ contain some of the strongest reflections from the $PtSe_2$-phase, while powder photographs of $PtS_{0.50}$, $PtSe_{0.667}$ and $PtSe_{0.70}$ contain reflections

from pure platinum. The additional reflections are very weak on photographs of samples with composition $PtSe_{0.75}$ and $PtSe_{0.85}$ and are absent on photographs of samples with composition $PtSe_{0.80}$. Thus the composition of the phase is provisionally designated $PtSe_{0.80}$. As the specific volume turned out to be an approximately linear function of atomic % Se in the whole concentration range from 0 to 66.67 atomic % Se, density determinations alone could not be used for an accurate determination of the composition of the phase.

Since no unit cell fitting all lines on the complex powder photographs could be found, it was tried to isolate crystallites large enough for single crystal work. After several unsuccessful attempts, a fairly useful fragment of a crystal was obtained. Oscillation photographs contained reflections from several crystals and traces of powder lines. By means of Weissenberg photographs the crystal was found to exhibit monoclinic symmetry and these photographs also gave the approximate cell dimensions. The Guinier photographs could then be indexed as shown in Table 5.

The lattice constants of the $PtSe_{0.80}$-phase in the samples $PtSe_{0.70}$, $PtSe_{0.75}$, $PtSe_{0.80}$ and $PtSe_{0.85}$, annealed at 850°C, are listed in Table 6. The slight

Table 5. Guinier powder photograph data of $PtSe_{0.80}$ taken with Cu$K\alpha$-radiation.

Table 6. Lattice constants of the $PtSe_{0.80}$-phase.

Sample	a(Å)	b(Å)	c(Å)	β (°)
$PtSe_{0.70}$	6.5812	4.6255	11.147	78.39
$PtSe_{0.75}$	6.5812	4.6252	11.148	78.39
$PtSe_{0.80}$	6.5806	4.6248	11.145	78.40
$PtSe_{0.85}$	6.5805	4.6244	11.144	78.41

variations in unit cell dimensions indicate that the homogeneity range of the phase is rather narrow.

The $h0l$ reflections are absent when $l = 2n + 1$. The probable space group is thus Pc (C_s^2) or $P2/c$ (C_{2h}^4).

The density of $PtSe_{0.80}$ was determined to be 12.79 g cm^{-3}. This corresponds to 9.91 Pt and 7.93 Se atoms in the unit cell. If the composition of the phase was assumed to be $PtSe_{0.75}$, the observed density 12.92 g cm^{-3} would give a cell content of 10.18 Pt and 7.64 Se atoms, and for $PtSe_{0.85}$ with observed density of 12.41 g cm^{-3}, 9.47 Pt and 8.05 Se atoms. As the probable space groups Pc and $P2/c$ only have four-fold and two-fold point symmetry, a composition $Pt_{10}Se_8$ seems most reasonable. The calculated density for $Pt_{10}Se_8$ from the X-ray measurements is 12.90 g cm^{-3}.

Samples with composition $PtSe_{0.80}$, heated at 400°C for two months, gave diffuse X-ray photographs indicating some sort of disorder in the structure. The annealing time was probably not sufficiently long to establish equilibrium at that temperature.

Heat treatment at 1 050 and 1 150°C of the samples $PtSe_{0.667}$, $PtSe_{0.70}$, $PtSe_{0.75}$, $PtSe_{0.80}$, $PtSe_{0.85}$ and $PtSe_{0.909}$ indicates that the $PtSe_{0.80}$-phase is formed peritectically, as the X-ray photographs show presence of considerable amounts of Pt and $PtSe_2$.

The $PtSe_2$-phase. Powder photographs of $PtSe_2$ were indexed as hexagonal, *cf.* Table 7. The lattice constants of $PtSe_{2.00}$ are listed in Table 8 together with the lattice constants of $PtSe_{1.50}$ and $PtSe_{3.00}$. From these values the homogeneity range of the $PtSe_2$-phase is not noticeable. In the quenched $PtSe_{1.00}$-sample, however, the c-axis of the $PtSe_2$-phase has a smaller value, indicating a slight change in composition of the $PtSe_2$-phase with temperature. The only previous lattice constant determination of $PtSe_2$, due to Thomassen [6] is also listed in Table 8. The values agree best with those for the quenched sample.

The pycnometric density of $PtSe_2$, 9.53 g cm^{-3}, is in close agreement with the density 9.59 g cm^{-3} calculated on the basis of the X-ray data.

Thomassen found that $PtSe_2$ was isostructural with PtS_2. In order to verify the parameter value, intensities were calculated in the same way as for PtS_2. Also here the parameter value $z = 0.250$ gives the best agreement, I_{obs} and I_{calc}, *cf.* Table 7.

The corresponding interatomic distances are: platinum-selenium 2.499 Å, selenium-selenium 3.330 Å and platinum-platinum 3.728 Å.

C. Platinum tellurides

In the system platinum-tellurium the existence of two of the earlier reported intermediate phases, *i.e.*, the PtTe-phase and the $PtTe_2$-phase, was confirmed. A phase with composition Pt_2Te, described by Roessler [14], was not found.

The lattice constant of platinum was found to be 3.9234 Å in an alloy with 33.33 atomic% Te, in which Pt exists in equilibrium with PtTe. Evidently, platinum does not dissolve any appreciable amounts of tellurium.

The PtTe-phase. Samples with the composition PtTe, heated at 825°C for 30 days, give powder photographs containing very few lines. In order

to grow single crystals, the samples were heated to a temperature just below the melting point, 925 ± 15°C. After many trials some crystals with platy, hexagonal habit were obtained. When slowly cooled to room temperature these crystals disintegrated to a powder after some time. In quenched samples the crystals retained their habit at room temperature. Oscillation photographs of the crystals gave only powder lines, some times with preferred orientation. A possible explanation of these phenomena might be sought in a phase transition.

In order to determine the unit cell dimensions of the unknown structure powder photographs were taken in a Guinier focusing camera of high resolution. Using the Lipson [23] method the unit cell of PtTe could be indexed as orthorhombic, *cf.* Table 9. The lattice constants of PtTe and of the PtTe-phase in the samples $PtTe_{0.90}$ and $PtTe_{1.10}$, in which it exists in equilibrium with Pt or $PtTe_2$, respectively, are listed in Table 10. The slight variations in unit cell dimensions between the three samples indicate that the homogeneity range of the PtTe-phase is rather narrow. The reflections observed in the powder photographs show that the unit cell is primitive.

Table 10. Lattice constants of the PtTe-phase.

Sample	*a*(Å)	*b*(Å)	*c*(Å)
$PtTe_{0.90}$	6.6132	5.6351	11.858
$PtTe_{1.00}$	6.6144	5.6360	11.865
$PtTe_{1.10}$	6.6157	5.6369	11.869

On the basis of the observed density, 12.01 g cm^{-3}, the unit cell contains ten platinum and ten tellurium atoms. The calculated density for $Pt_{10}Te_{10}$ from the X-ray measurements is 12.11 g cm^{-3}.

The pronounced orientation effects observed for the PtTe-phase in form of variable intensities for some of the reflections indicate that it must have a typical layer structure. Thus, the same powder sample as was used for the Guinier photographs gave pronounced enforcements of the (h00) reflections (h = 1, 2, 4 and 5) when using a Geiger spectrometer. In contrast to this, a sample of PtTe that had been melted, formed mica-like flakes, which mounted on a glass plate gave a Geiger-spectrogram with (00l) reflections only (l = 1, 2, 3, 4, 6, 7, and 9). The direction of cleavage therefore seems to change as result of melting.

These preliminary results about the structure of PtTe are not consistent with earlier statements. Both Hume-Rothery [24] and Zhdanov and Gladoleva [25], list PtTe among substances having NiAs-type structure. Apparently, no structure determination of PtTe has been made before 1955 when Groeneveld Meijer [19] interpreted the X-ray photograph of niggliite as due to a phase with NiAs-like structure and composition PtTe. It should, however be remarked, that neither Thomassen [6] nor Groeneveld Meijer [17,19] succeeded in

synthesizing any other platinum telluride phases than the ditelluride, and that the monotelluride reported here gives a completely different X-ray picture from that of niggliite. Nevertheless, a PtTe-phase with NiAs-like structure might possibly exist at higher temperatures, and thus explain the observed hexagonal habit of the crystals.

The $PtTe_2$-phase. The lattice constants of the hexagonal $PtTe_2$-phase were redetermined. The results of the X-ray measurements are given in Table 11 and the lattice constant values are listed in Table 12 for samples of various compositions. The homogeneity range of the phase is apparently narrow, and slightly on the tellurium-rich side of the composition $PtTe_2$. The previous determinations by Thomassen [6] and Groeneveld Meijer [17], also given in Table 12, differ to some extent from the values found here for the $PtTe_2$-phase.

The observed density, 10.16 g cm^{-3}, is in close agreement with the density 10.20 g cm^{-3} calculated assuming one platinum and two tellurium atoms in the unit cell.

According to Thomassen, $PtTe_2$ is isostructural with PtS_2 and $PtSe_2$. In order to verify the parameter value, intensities were calculated in the same way as for PtS_2 and $PtSe_2$. Here too, the parameter value $z = 0.250$ gives the best agreement betveen I_{obs} and I_{calc}, *cf.* Table 11.

The shortest interatomic distances are: platinum-tellurium 2.666 Å, tellurium-tellurium 3.495 Å and platinum-platinum 4.026 Å.

Table 14. The field strength dependent susceptibilities of PtS, $PtSe_{0.80}$ and PtTe, $\chi_g \times 10^6$, at liquid air temperature.

H_{max} (Ø)	PtS	$PtSe_{0.80}$	PtTe
4 015	0.20	0.10	0.02
4 700	0.16	0.08	0.01
5 110	0.14	0.06	0.01

MAGNETIC PROPERTIES OF THE PLATINUM CHALCOGENIDES

The magnetic susceptibilities of PtS, PtS_2, $PtSe_{0.80}$, PtTe and $PtTe_2$ were measured at six different temperatures between — 183 and 450°C. The results are listed in Table 13. With three exceptions they are mean values of the susceptibilities at three different field strengths (H_{max} = 4 015, 4 700 and 5 110 Ø, respectively).

The measured susceptibilities are all exceedingly low and almost balanced by the diamagnetism induced in the compounds. The diamagnetic corrections are -27.3×10^{-6} per mole Pt° according to Hoare and Matthews [26], -32.6×10^{-6} per mole S^{2-}, -47.6×10^{-6} per mole Se^{2-} and -70.6×10^{-6} per mole Te^{2-} according to Angus [27]. The corrections are listed for one gram of the compounds in the far right column of Table 13. By subtracting these values from the measured susceptibilities, the susceptibilities of the paramagnetic ions are obtained. These corrected susceptibilities increase from sulfide *via* selenide to telluride both for the di- and »mono»-compounds in accordance with the more metallic behavior of the tellurides.

The effective magnetic moments, ranging from 0.11 to 0.91 Bohr magnetons, show that the compounds are of an essentially metallic or covalent type. In case the bonds had been of ionic type, the »spin only» theory demands a magnetic moment of 2.83 μB for compounds containing the Pt^{2+}-ion and 4.90 μB for compounds containing the Pt^{4+}-ion.

The only irregularities observed are that the susceptibilities of all three »mono»-compounds are slightly field strength dependent at liquid air temperature, *cf.* Table 14. Similar effects, but of a much larger magnitude, have earlier been observed for the palladium chalcogenides Pd_4S, Pd_4Se and Pd_4Te[28].

Acknowledgements. The authors wish to thank Falconbridge Nikkelverk A/S for placing platinum metal at their disposal and to thank Bolidens Gruvaktiebolag for the selenium. They also wish to express their thanks to Dr. Arne Magnéli, Stockholms Høgskola, Sweden, for taking Guinier photographs of PtTe, to Siv.ing. Sigurd Rutlin, Sentralinstitutt for Industriell Forskning, for carrying out the spectrographic analysis and to Mr. Håkon Mohn for carrying out some of the magnetic measurements.

ACTA CHEMICA SCANDINAVICA 14 (1960) 1894–1898

An Apparatus for Following Reactions Evolving Gas

E. A. BIRKHIMER, BØRGE NORUP and THOR A. BAK

Institute for Physical Chemistry, University of Copenhagen, Denmark

An apparatus for investigating the kinetics of reactions which evolve a gas is described. Manometer readings are recorded automatically, and the solution in which the reactions occur is stirred magnetically. The apparatus is used to investigate the decomposition of *o*-nitrophenylazide in dibutylphthalate solution. An *ortho*quinoid structure is proposed for the transition state in this reaction.

In 1925 Brønsted and Duus [1] developed a simple apparatus for studying the kinetics of reactions which evolve gas. Its main feature is that the reaction vessel can be shaken continuously. This prevents the reaction solution from becoming supersaturated with the gas formed by the reaction. The reaction vessel is connected to a mercury manometer by means of a glass capillary which allows motion of the reaction vessel relative to the manometer.

Equipment of this general type has been used several times since then for various investigations [2]. Under some types of use certain weaknesses have appeared.

1. The apparatus is fairly fragile because of the glass capillary.

2. Since the manometer is not immersed in the thermostat, variations in room temperature influence its readings by changing the volume of the gas. This is particulary bad for slow reactions where the room temperature may change considerably during a run. Additional complications in this respect arise at higher temperatures.

3. The apparatus requires an observer for reading the manometer. This is especially inconvenient for measuring slow reactions.

Andersen [2] avoided the first two of these difficulties, but since we were primarily interested in studying fairly slow reactions we decided on a different design of the apparatus. First the shaking of the reaction vessel was abandoned in favor of a vigorous magnetic stirring. This eliminates the capillary and made the apparatus both stronger and more compact. Secondly, the manometer was changed so that it can be read electrically. As a result of this the apparatus can be immersed completely in the thermostat. Complete immersion is especially important for reactions occurring at elevated temperatures. Finally, the manometer was connected to a recording potentiometer which allows us to follow the reaction continuously for long periods.

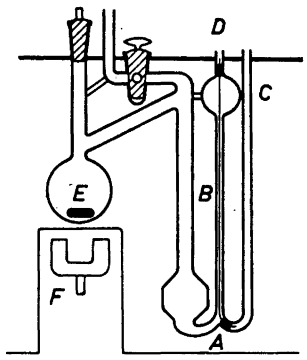

Fig. 1. B is the manometer. A and D are the two points between which the platinum resistance wire is stretched. E is the glasscovered magnet, which is moved by the motor driven magnet F.

2. Fig. 1 shows the construction of the apparatus. A platinum resistance wire is stretched from A to D through the mercury column in the manometer B. The platinum wire is straightened after it has been inserted in the glass [3]. At points A and D the platinum wire passes through the glass and is connected to external leads through pools of mercury. The glass bulb C is inserted to eliminate the effects of traces of air trapped in the manometer when it is filled initially. The reaction solution is stirred by the glass-covered magnet E. The magnet is moved by a motordriven magnet F which is installed under the thermostat as shown in Fig. 1. The entire apparatus is immersed in a suitable thermostat depending on the temperature required.

In order to read the closed manometer B the current from a storage battery is sent through a large constant resistance (about 300 Ω) in series with the platinum wire. The potential across the platinum wire is then a linear function of the height of the mercury in the manometer provided the diameter of the capillary is uniform, and the resistance of the wire is uniform and is much smaller than the constant resistance.

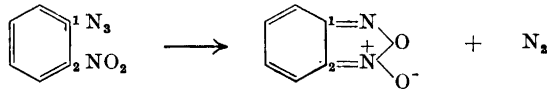
The potential across AD is recorded on a Philips recording potentiometer type PR 3210. In order to check for linearity the reading of the potentiometer was plotted against the height of the mercury read with a kathetometer for various heights of mercury. In the three pieces of apparatus of the above type we have used, the maximum deviation from linearity in the voltage across AD was found to be a few thousandths of the total change in voltage which could be observed as the height of the mercury was increased. As we have constructed it, the apparatus is capable of measuring gas over a 0—100 mm Hg range.

Since we have been interested in investigating first order reactions, we have had no reason to use this linear relationship to obtain the pressure. Instead, we have calculated the rate constant for the reaction from the recorder's curve of voltage *versus* time.

For many of the reactions we have investigated, the change in voltage with time was followed over a period of several days at thermostat temperatures close to 100°C. For such experiments the bath temperature and the voltage across the storage battery were measured continuously by the recording poten-

tiometer. This made it possible to explain most of the irregularities which were occasionally observed in the voltage-time curves and either to apply suitable corrections or reject the data.

3. In order to test the apparatus we have followed the kinetics of the reaction



o-nitrophenylazide benzfurazan oxide

which is known to be a first order reaction for which the reverse reaction can be neglected [4]. Dibutylphthalate was used as a solvent since it is stable and has negligible vapor pressure at the moderately high temperatures that were used. Preliminary experiments showed the first order rate constant to be independent of the concentration of *o*-nitrophenylazide. The following technique was employed. 10 ml of the solvent is put into the reaction vessel and stirred for an hour to reach the thermostat temperature. A small platinum bucket containing about 1 mmole of *o*-nitrophenylazide is dropped into the reaction vessel. The reaction is allowed to proceed for 10 min while the system is being evacuated with an oil pump and the reaction solution regains thermostat temperature. Under these circumstances the nitrogen dissolved in the solution may be expected to be in equilibrium with the free nitrogen when the recording of the pressure begins. If stirring is stopped during these 10 min, a supersaturated solution of nitrogen in the diphenylphthalate is generally formed. This completely distorts the voltage-time curve when stirring is resumed. If stirring is not used during a run, the pressure-time curve is more irregular than usual, and the apparent rate constant is about 10 or 15 % too low.

As is well known, it is usally not advisable to use the infinity value method when calculating first order rate constants. This seems to be true for this apparatus to an even higher degree than usual. By using the trick of estimating the asymptotic value of the voltage by the smallest value obtained during the run, the results are improved somewhat. However, repeated runs under indentical conditions still tend to give rather scattered values for the rate constant, since small variations in the infinity value have a relatively large effect on the rate constant.

The rate constants obtained by the method of Guggenheim [5], or even better by an interative least squares method [6,7], are far more consistent. We have generally used the latter method in spite of the additional work it requires. Although to our knowledge there is as yet no sound theoretical basis for using a least squares method for non-linear curve fitting, the method produces remarkably consistent sets of rate constants from repeated measurements. Table 1 shows the results obtained for the first order rate constant for the decomposition of *o*-nitrophenylazide at various temperatures. The temperatures were read with a 1/10°C thermometer, calibrated by comparing it with a 1/10°C thermometer which had been calibrated at the Physikalisch-Technische Reichsanstalt, Charlottenburg, in 1909 and recalibrated at the Fysisk Laboratorium, Danmarks Tekniske Højskole, in 1957. The temperatures given in

Table 1.

Temp., °C	$k \times 10^4$, sec^{-1}
76.22	0.867
76.23	0.893
76.24	0.873
76.27	0.903
81.14	1.492
81.20	1.488
81.22	1.537
81.28	1.488
90.54	3.759
90.54	3.855
90.54	3.717
90.57	3.770
90.57	3.732
90.58	3.843
90.63	3.997
90.85	3.874

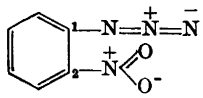
Table 1 have been corrected for exposed stem and are believed to be correct to 0.05°C. Internal consistency is somewhat better and should not be in error more than 0.02°C. It was not possible to detect variations in the temperature of the thermostat during a single run. Therefore, it is to be expected that the variations were not more than 0.02°C.

From the data given in Table 1 the activation energy of the reaction is calculated to be 25.7 cal/mole. The entropy of activation, which is derived from the equation [8]

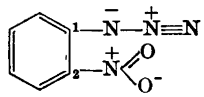
$$k = e \frac{kT}{h} e^{-E/RT} e^{\Delta S^{\neq}/R}$$

is —5.9 cal/mole deg. These values are in reasonable agreement with the results obtained by Fagley *et al.*[4]

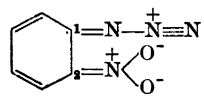
5. The structure of *o*-nitrophenylazide is undoubtedly a resonance hybrid of classical structures I, II, and III. Wheland [9] gives evidence for believing that the azide group ordinarily includes contribution from structures such as I and II. It is also reasonable to expect the azide and nitro groups to interact to form a structure such as III because of the favorable charge distribution which it represents. Scale models show that this structure, which is completely planar, is not sterically hindered. We propose that the reaction proceeds through a transition state with the quinoid structure IV. Such a transition state would be expected to have a small negative entropy of activation which is in agreement with the observed one. The alternative cage-type transition state, V, on the other hand would be expected to have a fairly large negative entropy of activation. In addition, while the quinoid transition state is readily formed from the contribution of structure III to the structure of *o*-nitrophenylazide, both charge distribution and the molecule's tendency toward planarity make the formation of the cage transition state difficult.



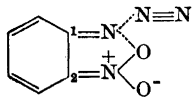
I



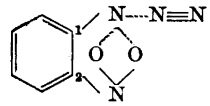
II



III

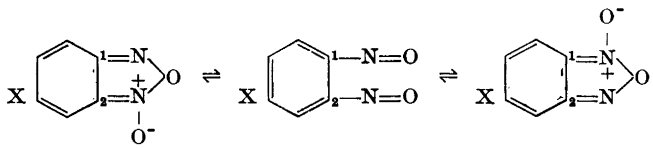


IV



V

However, without the cage model the experimental fact that 4- and 5-substituted *o*-nitrophenylazides give identical products is not easily explained. For an explanation we must assume that the following equilibrium exists:



The fact that benzfurazane oxide solutions become colored on heating and lose the color again when cooled tends to support the existence of such an equilibrium. This problem is discussed in more detail by Hammick *et al.*[10]

An Extension of Hammett's $\sigma - \varrho$ Relation

ELLEN ANDERSEN, E. A. BIRKHIMER and THOR A. BAK

Institute for Physical Chemistry, University of Copenhagen, Denmark

It is proposed that the Hammett $\sigma-\varrho$ relation can be extended to account for the influence of substituents on the rate of reactions in which two groups substituted in a benzene ring react with each other. It is shown experimentally for the reaction of substituted *ortho*nitrophenylazides, in which the azide group reacts with the nitro group, that the more general relation has the form

$$\log_{10}k/k_0 = \sigma_1\varrho_1 + \sigma_2\varrho_2$$

Here σ_1 and σ_2 are the normal substituent coefficients and ϱ_1 and ϱ_2 are partial reaction coefficients. It is argued that they give an indication of the charge distribution in the transition state. The mechanism of the decomposition of *ortho*nitrophenylazide is discussed in terms of the values obtained for ϱ_1 and ϱ_2.

The effect of substituents on the rate of a side chain reaction of benzene derivatives can be described semiquantitatively by means of the Hammett equation [1a]

$$\log_{10}k/k_0 = \sigma\varrho$$

in which k_0 is the rate constant for the reaction of the unsubstituted compound and k is the rate constant for the reaction of a compound which has a substituent *meta* or *para* relative to the reacting group. ϱ is a quantity which depends only on the type of reaction. σ depends only on the substituent one considers and whether it is *meta* or *para* relative to the reacting group.

Since an equilibrium is a balance between two chemical reactions, it is immediately clear that a similar equation will also hold for equilibrium constants of side chain reactions of benzene derivatives.

Clearly the value of a σ-coefficient is only determined relative to some standard reaction for which ϱ is set equal to one. Rather than using a chemical reaction for this, Hammett chose to use the dissociation of benzoic acid. That is, for the equilibrium

$$\varphi^*\mathrm{COOH} \rightleftharpoons \varphi^*\mathrm{COO}^- + \mathrm{H}^+$$

where the star indicates that there is a substituent in the benzene nucleus, one sets arbitrarily

$$\log_{10}K/K_o = \sigma$$

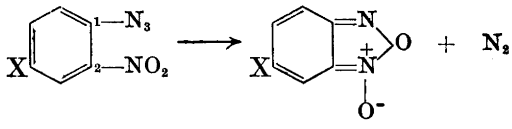
where K and K_o are now equilibrium constants for the dissociation of the substituted and the unsubstituted acid, respectively.

When the σ-values are determined in this way, the ϱ-value for a reaction or an equilibrium is determined by plotting the logarithm of the rate constants of several differently substituted derivatives *versus* the σ-values. Extensive tables of σ- and ϱ-values have been published [2].

Ever since Hammett discovered that the effect of structure on reactivity could be accounted for by this simple relation, attempts have been made to give it some theoretical justification. $\text{Log}_{10}k/k_o$ is proportional to the difference in standard free energy between the reaction of the substituted molecule and the unsubstituted molecule when an equilibrium is considered. For rate constants it is proportional to a similar difference in standard free energies of activation when the transition state theory is assumed. Therefore, the Hammett equation is often called a "linear free energy relationship". Since for many processes of this kind it has been observed that, within the experimental error, the entropy term is independent of the substituent or a linear function of the activation energy it can, however, be restated as a "linear bonding energy relationship". It is therefore reasonable to assume that the σ-values should be correlated with the change caused by the substituents in electron densities at the reaction site.

Corio and Dailey [3] have shown experimentally that there is such a correlation between σ-values and electron densities determined by nuclear magnetic resonance technique. Van Beek [4] has shown that a relation similar to the Hammett equation also holds for dipole moments. This indicates clearly that the σ-values depend on the change of electron density in the benzene ring, produced by the substituent. Jaffe [5] has succeeded in making this statement at least semiquantitative by correlating the σ-values with electron densities obtained from molecular orbital calculations. In spite of all this one must say, however, that the σ-ϱ relationship itself, as well as the ϱ-values, still must be viewed mainly as an empirical result.

This of course limits the use of the σ-ϱ relationship somewhat, but since one can interpret the σ-and the ϱ-values in terms of electron density, albeit somewhat vaguely, the rule can at least be applied to confirm or reject certain reaction mechanisms which involve a specific charge distribution in the transition state. In order to do this is necessary in some cases, to know whether one can extend the Hammett rule to be valid for reactions in which, for instance, two neighbouring groups in a benzene molecule react with each other. To give a specific example in a reaction such as



which we have studied previously, one would like to know the validity of the relation

$$\log_{10}k/k_o = \sigma_A\varrho_A + \sigma_N\varrho_N$$

where σ_A and σ_N are the *meta*- and *para*-substituent coefficients for the substituent X, and ϱ_A and ϱ_N are constants. If this relationship is valid, ϱ_A and ϱ_N would naturally be taken as the reaction coefficient for the reaction "at the azide group" and "at the nitro group". Since ϱ is usually negative when a high electron density is favourable for the reaction, this in turn would indicate the charge distribution in the transition state.

To our knowledge a relationship of this kind has never been checked experimentally, although it is a quite obvious extension of Hammett's idea. The purpose of this paper is therefore primarily to verify the extended rule for the reaction mentioned above, and secondly to discuss the values obtained in this case for ϱ_A and ϱ_N in terms of the mechanism which we have previously suggested.

2. The derivatives of *ortho*nitrophenylazide shown in Table 1 were used in this investigation.

In all cases the compounds were prepared from the corresponding derivatives of *ortho*nitroaniline by diazotization and coupling with azide ions. The *ortho*nitroaniline derivatives used were either the purest grade obtainable from Eastman Kodak Organic Chemicals, or compounds prepared at the Laboratories for Organic Chemistry at the University of Copenhagen and at the Technical University of Denmark *. In all cases the melting points of the *ortho*nitroanilines checked with those reported in the literature.

After preparation, the *ortho*nitrophenylazides were stored at 0°C and in most cases the experiments using any compound were completed within two weeks. Under these circumstances only a negligible amount of the azide had reacted in the solid state, except for the case of 2,4-dinitrophenylazide which reacts very fast. In this case, therefore, several preparations were made.

The measurements of the first order rate constant for the decomposition of the azides were measured in an apparatus described previously [6], following the same method. The results obtained are given in Table 1. It is seen that the reproducibility of an experiment is in general better than 2 %. Barring systematic errors, the average of 3—4 experiments may be assumed to be correct to within 1 %. This is probably the best one may hope to obtain by a method of this kind.

Table 2 gives the average values of the rate constants referred to a common temperature. From this table the values of ϱ_A and ϱ_N in the expression

$$\log_{10} k/k_o = \sigma_A \varrho_A + \sigma_N \varrho_N$$

have been calculated by the method of least squares, using values of σ_A and σ_N taken from the literature. σ_A is the substituent coefficient for the influence of the substituent on the azide group, and σ_N the coefficient for its influence on the nitro group. One obtains

$$\varrho_A = 1.353 \quad \varrho_N = -0.676$$

and Table 2 shows the agreement between measured values of k and the values calculated using the above values of ϱ_A and ϱ_N (and the tabulated values of σ_A and σ_N).

* We are indebted to Mrs. Else Plejl and Mr. Børge Nygaard for letting us have these chemicals.

The σ-values used are those of Hammett [1,7] except for the phenyl group where later work is more accurate. For *m*-phenyl a value of 0.06 was used [8]. For the nitro and phenyl groups *para* to the azide group, the corresponding σ-values for reactions of aniline were used [7,9]. Because of the rather large uncertainty and confusion which still exists in regard to σ-values for the phenyl

Table 2. k_{exp} are the experimental values of the rate constant referred to a common temperature 81.20°C and k_{calc} are the rate constants as calculated from the extended Hammett relation. E are the experimental activation energies and $\Delta S^{\ddagger}$ are the activation entropies.

group, these data were not used in calculating the ϱ-values. However the rate constant has been calculated and correlates moderately well with the experimental one.

From this we may of course only conclude that this extension of the σ-ϱ rule applies to the reaction in question, but it seems most likely that it should be true in general for substituents which are *meta* or *para* to both the reacting groups.

3. It is of some interest to consider the activation energies and activation entropies of the reactions investigated. Table 2 gives the values of the energies and entropies of activation one obtains.

The plot of $\Delta S^{\ddagger}$ *versus* the experimental activation energy in Fig. 1 shows that the activation entropy increases systematically with the activation energy. When the errors in the determination of E and $\Delta S^{\ddagger}$ are taken into account one may almost take this to be a linear relationship. Such a relationship has been observed previously for other reactions and as mentioned above it is the reason that the Hammett equation may hold even when the activation entropy is not independent of the substituents.

It has been stated for instance by Hammett [1b] that there is no reason to expect a correlation between activation entropy and activation energy. Indeed his whole argument for the existence of the σ-ϱ relation was based on the assumption that $\Delta S^{\ddagger}$ is independent of substituents. Contrary to this point

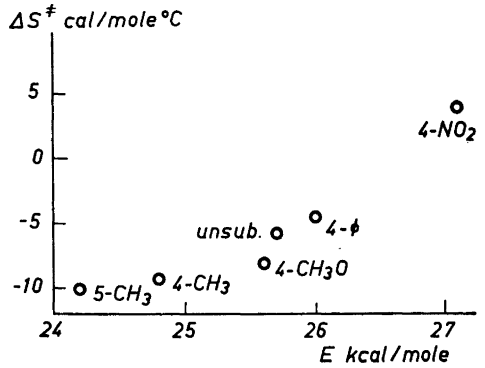

Fig. 1. A plot of $\Delta S^{\ddagger}$ *versus* the experimental activation energy. It shows that the activation entropy increases systematically with the activation energy.

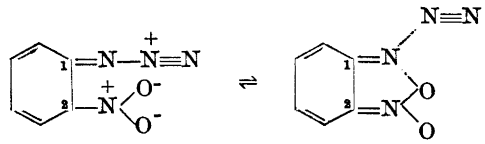
of view, we think that the relation between $\Delta S^{\ddagger}$ and E is perfectly reasonable, at least for unimolecular reactions, and of more general validity than Hammett's assumption. It is clear that if one strengthens the bond which must break by "adding electrons", the molecule must vibrate violently in order to break the bond. This means that the amplitudes of the normal modes in a molecule which is able to break a certain bond when the normal modes get into phase will in general increase as the activation energy increases. This again means that a molecule which can react (*i.e.*, is in the transition state) must have a larger entropy as the activation energy increases. Even though the relationship may not be linear, it will appear almost to be so when used only over a small range of activation energies.

4. We have previously suggested that the reaction of *o*-nitrophenylazides proceeds through the following transition state



in which there is a low electron density around carbon atom No. 1 and a high electron density around carbon atom No. 2. If this mechanism is correct therefore, ϱ_A should be positive and ϱ_N should be negative, since the favourable effect of high electron density implies a negative value of ϱ. The values found experimentally for the two reaction coefficients therefore support the suggested mechanism.

It is seen from this, however, how careful one should be when correlating negative entropies of activation with cyclic transition states and *vice versa* as is often done. In the reaction we have considered here the activation entropy is generally negative and we believe the transition state to be cyclic. For the 2,4-dinitro compound which reacts very fast and has a high activation energy, $\Delta S^{\ddagger}$ is, however, positive and presumably this does not mean that the mechanism of the reaction has changed.

A Colloidal Water-soluble Double Sulphide Containing Mercury(II) and Tin(IV)

C. E. FOVERSKOV and NIELS HOFMAN-BANG

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

If tin(IV), mercury(II) and sodium sulphide are present within certain concentration limits, addition of ammonium chloride yields a red precipitate, which upon washing with water dissolves to a deep red solution. Addition of ethanol to this solution again gives a red precipitate. After the precipitate is completely dried, it becomes almost black, and the compound is no longer water-soluble.

A quantitative analysis of the compound showed a somewhat varying composition, which approximated the formula Hg_2SnS_4 within 10 %.

The red aqueous solution has been the object of different investigations, which all show that a colloidal solution with negatively charged particles is involved. Sedimentation in an ultracentrifuge shows that the particle size varies. The mass of the particles lies in the range 1 300 to 40 000 atomic mass units.

X-Ray investigation of the completely dry double sulphide by the powder method does not show crystallinity.

In inorganic qualitative analysis mercury is often separated from tin, antimony, arsenic and molybdenum by precipitation of mercuric sulphide by the addition of ammonium chloride to a solution containing these metals as thio-ions. When teaching qualitative analysis one of the authors (H-B) has noticed that addition of ammonium chloride to a solution containing thiomercurate, thiostannate and sulphide ions sometimes yields a red precipitate instead of black mercuric sulphide. The red precipitate dissolves readily in water forming a deep red solution.

It is well known that separation of mercury and tin as mentioned above is incomplete. Storch [1] has remarked that mercuric sulphide is soluble to some extent in ammonium thiostannate solution, whereas it is insoluble in ammonium sulphide. He stated that a more detailed investigation would be undertaken, but it evidently has never been published. Wilm [2] has mentioned that mercuric sulphide can be only partly precipitated by ammonium sulphide when tetravalent tin is present. Feigl [3] has observed that mercuric sulphide which is precipitated by the addition of ammonium chloride to a solution of thiomercurate and thiostannate is greatly contaminated with stannic sulphide.

QUALITATIVE EXPERIMENTS

A series of test tube experiments were carried out in order to get an impression of the colour and the amount of impure mercuric sulphide precipitated by the addition of ammonium chloride to a solution containing Sn(IV), Hg(II) and sodium sulphide. The mole ratio of tin to mercury (f), the total molar concentration of tin + mercury (c) and the added amount of ammonium chloride in g/10 ml (m) were varied. The experiments were carried out as follows:

Stock solutions of thiomercurate and thiostannate were made by dissolving mercuric chloride and potassium hexachlorostannate, respectively, in the amount of 2 M sodium sulphide just sufficient to dissolve the primarily formed sulphides, and then diluting with water to the desired concentrations of the metals. In a test tube thiostannate and thiomercurate solutions were carefully mixed so that the total volume was 10 ml; m g ammonium chloride was then added and dissolved by shaking. The progress of the precipitation was observed during the first hour, and after 24 h the colour and amount of the final precipitate and the colour of the clear supernatant solution were judged. Thirty five such experiments were carried out; the values of c were 0.1, 0.2 and 0.5, f varied from 0.4 to 5.7 and m from 0.15 to 2.00.

The results may be summarized as follows:

1. *The progress of the precipitation.* At $f \leq 1.5$ the precipitation takes place immediately upon the addition of ammonium chloride, while at $2.3 \leq f \leq 4.0$ from 2 to 50 min elapse before the precipitation starts. During this period of time the colour of the solution changes from pale yellow to orange. At $f \leq 1$ the precipitate is very dark. At $1.5 \leq f \leq 4.0$ the colour of the precipitate is first yellowish but, as the precipitation is progressing, it gradually changes to orange or orange red. At $m > 1.7$ the precipitate, however, stays yellow.

2. *The amount of the precipitate.* The amounts were only judged visually by comparing the heights of the precipitates in the test tubes after 24 h. The amount of precipitate is not much different at $c = 0.2$ and $c = 0.5$, while it is about half as much at $c = 0.1$. The amount of precipitate rapidly decreases with increasing f; at $f = 4.5$ the amount is negligible, and at $f = 5.7$ no precipitation at all takes place even after 5 days. At $0.5 \leq m \leq 1.5$ the amount of precipitate is fairly constant, but at $m > 1.5$ it increases somewhat and at $m < 0.5$ it decreases; *e.g.* at $m = 0.15$ the amount of precipitate is only 1/5 of the amount at $m = 1$.

3. *The colour of the precipitate.* The colour of the precipitate does not depend upon c, and is fairly independent of f at $1.5 \leq f \leq 4.5$. At $f \leq 1.5$ the precipitate gradually becomes darker with decreasing f, *e.g.* red brown at $f = 1.0$ and very dark brown at $f = 0.4$. However, the colour is strongly dependent upon m; at $0.15 \leq m \leq 0.3$ it is dark red, at $m = 0.5$ bright red, at $m = 1.2$ orange, and at $m > 1.5$ yellow.

4. *The colour of the filtrate.* The colour of the clear supernatant solution is nearly independent of c and f and mostly depends upon m. At $0.15 \leq m \leq 0.3$ the filtrate is red, at $m = 0.7$ orange, and at $m > 1.2$ yellowish. The change of colour is accompanied by decreasing intensity of colour.

PREPARATION OF THE RED DOUBLE SULPHIDES

For the sake of analysis and other investigations several preparations were carried out. After some preliminary investigations the following method was found suitable.

Weighed amounts of potassium hexachlorostannate and mercuric chloride are each dissolved in a slight excess of 2 M sodium sulphide. The two solutions are filtered through a hardened filter paper and the flasks and the filter washed with distilled water. Then the solutions are mixed and diluted with water to 250 ml. Finally the ammonium chloride is added while stirring.

After about 20 h the precipitate formed, 0.6—8 g, is filtered off on a medium filter paper. After as much as possible of the filtrate has run off the filter, the precipitate is transferred to an Erlenmeyer flask containing 50 ml of water at 25—30°C. After complete dissolving (a few of the preparations required somewhat more than 50 ml water) 50 ml ethanol are added. This addition causes reprecipitation of the red double sulphide. After 2 h filtration is carried out and the precipitate is washed first with two 30 ml portions of 50 % ethanol in order to remove ionic impurities, then with three 30 ml portions of ethanol and lastly with three 30 ml portions of dry ether. When especially large precipitates are involved, larger volumes of washing liquid are used.

The precipitate is allowed to dry overnight and is then cautiously pulverized and put into a vacuum desiccator over potassium hydroxide pellets. Drying to constant weight requires nearly a month.

Twelve preparations of the type just described were carried out, *cf.* Table 1. Two of them, Nos. 5 and 8, failed, No. 5 because the yield was negligible, and No. 8 because the precipitate could not be quite redissolved in water for the sake of purification.

ANALYSIS OF THE PREPARED DOUBLE SULPHIDES

The percentages of mercury, tin and sulphur in the completely dried double sulphides were determined by slightly modified standard methods.

Table 1. Preparations of water-soluble double sulphides of tin(IV) and mercury(II). The total volume of sodium thiomercurate and thiostannate solution was 250 ml before addition of ammonium chloride. c is the total molar concentration of tin + mercury, f is the mole ratio tin to mercury, and m is the added amount of ammonium chloride in g/10 ml. The yield is given in g of the totally dried product.

No.	c	f	m	yield
1	0.2	1.0	0.5	5.69
2	0.2	1.5	0.5	3.60
3	0.2	2.2	0.5	1.70
4	0.2	3.0	0.5	0.61
5	0.2	4.0	0.5	nil
6	0.2	2.2	0.25	1.43
7	0.2	2.2	1.0	1.82
8	0.2	2.2	2.0	—
9	0.2	1.8	0.5	2.33
10	0.2	1.8	0.5	1.79
11	0.2	1.8	1.0	1.69
12	0.2	0.5	0.5	7.71

Determination of mercury. The double sulphide is dissolved in 2 M sodium sulphide, after which mercury and tin are separated according to the method of Hiltner and Gittel [4]. Hydrogen peroxide is added dropwise to the sulphide solution with the result that the free sulphide ions and the sulphide in the thiostannate ions are oxidized to sulphate, and mercuric sulphide separates quantitatively. Tartrate ions are present in order to keep the tin in solution. According to our experience no greater excess of 30 % hydrogen peroxide than 0.5 ml should be added. The precipitated mercuric sulphide is filtered off on filter paper, washed and dissolved (both filter and sulphide) in conc. sulphuric acid plus nitric acid. After complete oxidation of the filter the sulphuric acid is diluted with water to twice its volume and boiled again in order to hydrolyze the nitrosyl sulphuric acid formed. After the solution is diluted with water and cooled down to below 15°C the mercury is titrated with standard thiocyanate solution. The thiocyanate solution is standardized against mercuric oxide (Merck, rubrum, p.a.). Experiments show that titration of mercury in sulphuric acid solution yields practically the same results as the usual titration in nitric acid solution. The method has been tested on known mixtures of mercury and tin with good results.

Determination of tin. The determination of tin is simply carried out by roasting the double sulphide, whereby the sulphur is oxidized to sulphur dioxide and the mercury evaporates while the tin is transformed to stannic oxide, which can be weighed. In order to determine the amount of impurities in the stannic oxide, the last compound is volatilized by heating with ammonium iodide according to Caley and Burford [5]. The method has been tested with good results on sulphide precipitates containing known amounts of mercury and tin.

Determination of sulphur. The determination of sulphur is carried out by oxidation of the sulphide to sulphate by means of bromine, the same method as often used for sulphur determination in pyrite [6]. The sulphate formed is precipitated with barium chloride according to Hintz and Weber [7]. The method yields excellent results when no tin is present, but too high results with tin present (coprecipitation of tin). This difficulty can be overcome by allowing the boiling with hydrochloric acid to proceed only to near dryness so that no stannic acid is formed, and further by precipitating the barium sulphate in 0.4 M hydrochloric acid, which at the same time is 0.2 M with respect to sodium chloride.

The results of the analyses carried out are given in Tables 2a and 2b. The estimations of mercury and sulphur were carried out without complications and the results are assumed to be rather accurate. The tin estimations, however, were rather tedious and inaccurate. It appeared that complete volatilization of stannic oxide with ammonium iodide required several heatings with ammonium iodide because of the impurities in the stannic oxide. These impurities turned out to be mainly silica. This silica must come from the

action of sodium sulphide solution upon the glass containers, and then be coprecipitated when precipitating the double sulphides. We assume the tin determinations to be correct within 2 % and we assume them generally to be too low. The general features shown by Tables 2a and 2b are:

a. The sum of the three principal components is somewhat less than 100 %. The sulphur percentages, which correspond to the amounts found for mercury and tin, are somewhat smaller than the experimentally found percentages. The reason for this is partly that the tin determinations are a little too low and partly a considerable impurity of ammonium sulphide. In four of the preparations ammonia was determined. The content calculated as ammonium hydrogen sulphide was between 0.8 and 1.2 %. As will be evident from investigations later mentioned, the red double sulphides are colloidal and the particles negatively charged. The negative charge is presumably caused by adsorbed sulphide ions, which in the solid double sulphide must be accompanied by positive ions, *viz.* ammonium ions. All the solid double sulphides showed a considerable content of ammonia, while no chloride and no sodium could be detected.

b. The atomic ratios show that the composition of the double sulphides is not far from SnS_2,2HgS. However, the deviations from this formula are so considerable that they can hardly be due to analytical errors, and besides the composition is not constant. The atomic ratios Sn/Hg and S/Hg seem to increase with increasing f (the ratio between tin and mercury concentrations in the solution used for preparation). The atomic ratios Sn/Hg and S/Hg increase with increasing m (quantity of ammonium chloride added when precipitating the double sulphides).

c. The yields of both tin and mercury in the precipitates rapidly decrease with increasing f. In all the preparations the yield of mercury is greater than the yield of tin.

PROPERTIES OF THE DRIED DOUBLE SULPHIDES

After complete drying the double sulphides are black powders, some of them with a red tinge. They are nearly insoluble in water. In order to see

whether the substances are crystalline or not, X-ray powder photographs were taken of two of the preparations. The result was entirely negative, there being no indication at all of lines on the film.

PROPERTIES OF THE RED SOLUTION

Right after precipitation the double sulphides are, as mentioned above, readily soluble in water, and even after reprecipitation with ethanol and washing they are still water-soluble. The solution is deep red and of colloidal character.

A double sulphide was prepared as before (Table 1, expt. No. 2). After the ether used for the final washing had been allowed to evaporate, the double sulphide was dissolved in 100 ml water. This solution had a content of dry double sulphide of 3.6 g (solution A).

1. *Ultracentifuge investigation* *. The measurements were carried out in a Svedberg-type oil-turbine ultracentifuge at a speed of 1 000 r.p.s. at 27°C. A mixture of 1 volume "solution A" and 1 volume 0.2 M sodium chloride was used. The sedimentation was followed by the Schlieren-method. The colloidal particles had sedimentation constants between 2×10^{-13} and 20×10^{-13} c.g.s. units. Assuming that the particles are spherical and introducing Stokes's law, and assuming the density of the particles in water to be the same as that measured pycnometrically on the completely dried solid, namely 4, it is found that the mass of the particles lies in the range 1 300 to 40 000 atomic mass units, and their diameter in the range 10 to 30 Å.

2. *Conductance measurements.* The conductance was measured by a commercial instrument with dipping electrodes. The specific conductance of solution A was found to be 2.20 mohms^{-1} cm^{-1}. After 10 times dilution with water the specific conductance decreased to 295 μohms^{-1} cm^{-1} and after 100 times dilution to 47 μohms^{-1} cm^{-1}. The corresponding conductance per gram-atom mercury per cm^3 is calculated to 21, 29 and 45 ohms^{-1} cm^2, respectively. These values are rather high for a colloidal solution. However, the conductance is not only due to the charged colloidal particles and their "gegenions", but at least two thirds of the measured conductance is due to ionic impurities. Solution A diluted 10 times with water was dialysed 5 days; hereby the conductance decreased from 295 to 70 μohms^{-1} cm^{-1}.

3. *Dialysis.* The red constituent of the solution turned out not to be able to penetrate an ordinary dialysis membrane, (Visking cellulose casing), which fact showed that a colloidal solution was involved.

4. *Coagulation by the addition of electrolytes.* In the recorded experiments solution A was used 10 times diluted with water. To 4 ml of this solution was added 1 ml of a solution of an electrolyte. In Table 3 are recorded the electrolyte concentrations which cause half of the red double sulphide to coagulate. It is seen that the ratio of the concentrations of tri-, bi-, and uni-valent cations is 1:3:600. Magnesium does not seem, for some obscure reason, to fit into the scheme. The coagulating effect of electrolytes shows that the red double

* The authors are much indebted to the Research Laboratory of the Carlsberg Breweries, Copenhagen, for running the sedimentation measurements.

Table 3. Coagulation of the red water-soluble double sulphide by addition of different electrolytes. The given concentrations are the concentrations of electrolyte which are able to coagulate half of the red double sulphide.

Electrolyte	Molar conc.
NaCl	0.6
KCl	0.8
$NaNO_3$	0.8
$MgCl_2$	0.03
$ZnCl_2$	0.004
$BaCl_2$	0.003
$MgSO_4$	0.5
$ZnSO_4$	0.003
$AlCl_3$	0.0009
$CeCl_3$	0.0015

sulphide is a negatively charged colloid. The negative charge of the colloid was confirmed by paper electrophoresis.

5. *The action of acids and bases.* Diluted acid coagulated the colloidal particles. Diluted sodium carbonate solution had no influence on the colloidal solution. On the other hand a black precipitate of mercuric sulphide was formed and the supernatant liquid became colourless when the colloidal solution was made 0.1 M with respect to sodium hydroxide.

6. *Absorption spectrum in visible and ultraviolet light.* The absorption spectrum of solution A was measured by means of a recording spectrophotometer (Cary Model 11). In the range 800—700 mμ the absorption coefficient was very small (order of magnitude 0.1) but with decreasing wavelength it increased continuously in the range down to 200 mμ, *e.g.*, it is 3 at 650 mμ and 530 at 400 mμ. The laws of Lambert and Beer were found to be valid. The absorption spectrum is consistent with assuming the solution to be colloidal.

DISCUSSION

The investigated phenomena are consistent with many complications met when precipitating sulphides.

Some of the properties of the colloidal double sulphide can be explained by assuming a mixture of mercuric and stannic sulphide, *e.g.* the behaviour upon dry heating and the action of strong base, whereas other properties indicate a chemical compound, *e.g.* the colour of the substance and the pronounced tendency to form colloidal solutions.

The X-ray powder photographs of the dried double sulphide show that it is either built up of small colloidal crystallites or has a random or almost random structure.

The precipitation of the colloidal double sulphide proceeds rather slowly, and only part of the mercury is precipitated. The solution changes colour before the precipitation has become visible; this indicates that the first stage involves the mercury becoming bound in some way to the tin, possibly by formation of polynuclear sulphide complexes containing sulphide ions in excess to give a negative charge. These polynuclear complexes grow until they reach colloidal dimensions, and may then be precipitated by electrolytes.

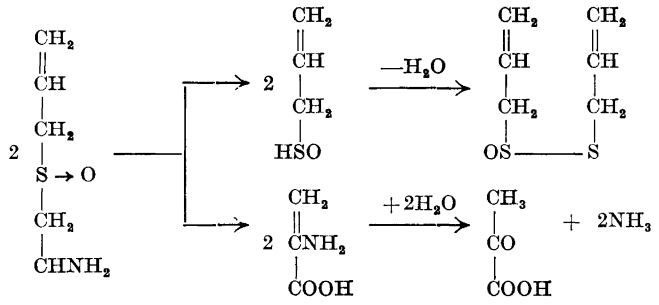
Cleavage of Alkyl Cysteine Sulphoxides by an Enzyme in Onion (*Allium cepa*)

FLOYD P. KUPIECKI* and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

An enzyme which is specific for alkyl cysteine sulphoxides has been partially purified from onion. The enzyme appears to require pyridoxal phosphate as a cofactor, but shows no stimulation in activity by various metals. It shows a very low order of inhibition by various sulphydryl group reagents. Electrophoresis shows a single protein peak at two pH levels.

The first report of the enzymatic degradation of an alkyl cysteine sulphoxide was made by Stoll and Seebeck [1]. They have shown that an enzyme in garlic (*Allium sativum*) catalyzed the splitting of alliin (allyl cysteine sulphoxide) to pyruvic acid, ammonia, and allicin according to the following equation:



These authors postulated that the enzyme, alliinase, brought about the initial cleavage and that the primary products were split spontaneously to allicin, pyruvic acid, and ammonia.

Of the alkyl cysteine sulphoxides occurring naturally, methyl cysteine sulphoxide appears to have the widest distribution [2]. It occurs in several members of the *Liliaceae* and *Cruciferae* families as well as sporadically in the families *Compositae* (in *Lactuca sativa* L.), *Umbelliferae* (in *Cryptotaenia japonica* Hasskare) and *Leguminosae* (*Phaseolus vulgaris* L.) [3]. Propyl- and allyl

* Fulbright Research Fellow, 1959—1960. Present address: Departement of Biological Chemistry, University of Michigan, Ann Arbor, U.S.A.

cysteine sulphoxides have been reported only in *Liliaceae*, where they are less widely distributed than is the methyl homologue. Ethyl cysteine sulphoxide has thus far been reported only in *Ipheon uniformum*, a member of *Liliaceae*. The reported occurrence of specific alkyl cysteine sulphoxide splitting enzymes is restricted to the *Liliaceae* family.

The known occurrence in appreciable quantities of methyl- and propyl cysteine sulphoxides in onion [4], and the release of pyruvic acid in fresh onion extracts [5,6] has led us to choose this plant for studying the cleavage of alkyl cysteine sulphoxides. The following is a report on the partial purification of the enzyme and some of its properties.

EXPERIMENTAL

Preparation of enzyme. All steps were carried out at 0° unless otherwise indicated. 800 g of mature onions freed of skins, tops, and roots were homogenized in a "Waring type" blendor with 400 ml of 0.10 M potassium phosphate, pH 7.4, for 3 min in four equal portions. The thick suspension was stirred for 30 min and filtered through cheese cloth. The filtrate was centrifuged at 12 000 × *g* for 15 min. 40 mg per ml of charcoal was added to the bright yellow solution. After stirring for 15 min the charcoal was removed by centrifugation. This step removes a large amount of the coloured non-protein material as well as about one-half of the proteins. The resulting supernatant solution is almost colourless.

Calcium phosphate gel [7] (1 mg for each 3 ml of solution) was added and after stirring 15 min the suspension was centrifuged. There is only a small increase in specific activity following this step, but more of the non-protein material is removed and the solution becomes colourless.

The enzyme solution was brought to 0.8 saturation by the addition of solid ammonium sulphate during a 20 min period. After stirring 45 min Hyflo Super Cel (1 g per each 200 g of onion) was added and stirring was continued 15 min longer. The precipitate was removed by centrifugation and the Hyflo was washed twice with 0.05 M potassium phosphate pH 7.4 to give a final protein concentration of 30—35 mg per ml. The enzyme solution was brought to 0.40 saturation with ammonium sulphate, stirred 30 min and centrifuged. The precipitate was dissolved in the same phosphate buffer as above to give a solution containing 40—45 mg protein per ml. This was again treated with ammonium sulphate. The fraction obtained at 0.25 saturation was discarded, the solution was brought to 0.60 saturation and the precipitate was dissolved in 0.05 M potassium phosphate, pH 7.4. The resulting enzyme solution was clear and bright yellow. The enzyme is stable at all stages of purification to storage at −20° for several weeks. All fractions, except the extract, retain almost full activity when stored at 0° for 1 to 2 weeks. Protein concentration of the enzyme solutions was determined spectrophotometrically by light absorption at 280 and 260 mμ [8].

Enzyme assay: The enzyme was assayed by measuring the amount of pyruvic acid liberated according to the method of Friedemann and Haugen [9]. The standard assay system contained 125 μmoles of potassium phosphate buffer, pH 7.4, 2.5 μmoles $MgCl_2$, 25 μg of pyridoxal phosphate, 13 μmoles alliin (or other alkyl cysteine sulphoxide), and enzyme in a final volume of 1.0 ml. All components except the substrate were preincubated 10 min at 20°. Addition of substrate was followed by incubation at 20° for 20 min. A control tube without substrate was included for each sample of enzyme. No pyruvate was generated from the substrate in the absence of enzyme. 0.25 ml of 40 % TCA was added after incubation and 0.40 ml aliquots were used in the determination of pyruvic acid. A unit of enzyme is defined as that amount which yields 1 μmole of pyruvic acid under the assay conditions. The specific activity of the enzyme is expressed as the number of units per mg of protein.

RESULTS

Electrophoresis. The enzyme solution was subjected to electrophoresis at two stages of preparation and at pH 6.8 and 7.8. The apparatus was the Perkin-

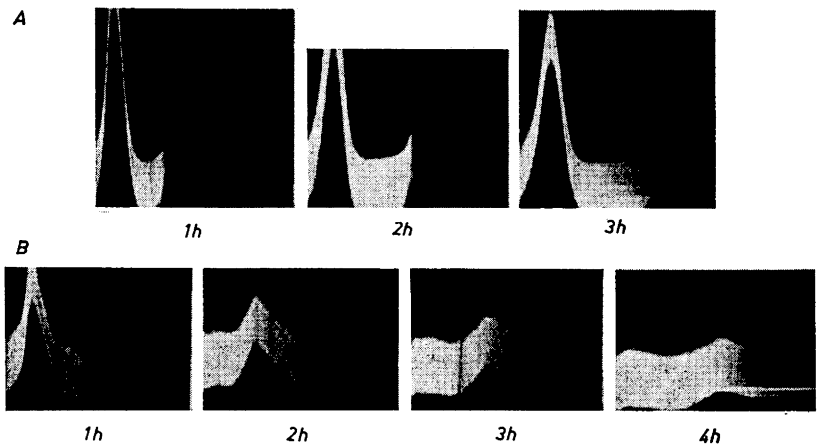


Fig. 1. Electrophoresis patterns. A shows the pattern obtained after calcium phosphate gel treatment (see text), B after 0.25—0.60 ammonium sulphate precipitation.

Elmer Model 38. Fig. 1A shows the pattern given after calcium phosphate gel treatment. To concentrate the protein by a factor of 10 the enzyme was subjected to lyophilization, dialyzed against distilled water and lyophilized again before dialysis against the buffer used for electrophoresis. The fraction obtained at 0.25—0.60 saturation with ammonium sulphate was also subjected to electrophoresis. Both preparations showed similar results at both pH's. The calcium phosphate gel supernate, however, contained a second peak which did not move at either pH. Fig. 1B shows that this peak was removed by precipitation with ammonium sulphate.

Enzyme activity as a function of pH. Fig. 2 shows that the enzyme is active over the range of pH 5.6 to 9.0, with maximal activity at pH 7.4.

Substrate specificity. Table 1 shows the various substrates that have been tested with the enzyme. As can be seen in the table only sulphoxides that are derived from cysteine are cleaved by the enzyme.

Inhibition by carbonyl group reagents. Table 2 gives the results obtained when the enzyme was tested with the three carbonyl group reagents: hydroxyl-

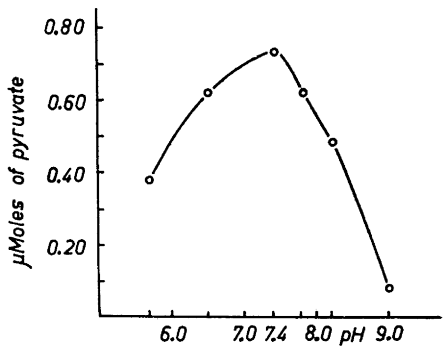

Fig. 2. Enzyme activity as a function of pH. The assay described in the text (with 250 µmoles of buffer) was used with 20 µg of the enzyme after treatment with charcoal. The substrate was synthetic methyl cysteine sulphoxide. Potassium phosphate buffers were used at pH 5.7, 6.5, 7.4, and 7.8. Tris buffer was used at pH 7.4, 8.2, and 9.0.

Table 1. Effect of carbonyl group reagents on enzymatic activity. The standard assay described in the text was used with some modifications. In experiments numbered 1 pyridoxal phosphate was omitted and the appropriate inhibitor was preincubated with all components except alliin for 20 min at 20°. In experiments numbered 2 the inhibitor was preincubated 10 min with the other components, the pyridoxal phosphate was added and preincubation was continued for 10 min. The order of preincubation of pyridoxal phosphate and inhibitor was reversed in experiments numbered 3. Pyridoxal phosphate concentration was 4×10^{-3} M.

No.	Substance added	Molarity of inhibitor	% inhib.	Molar conc. of inhibitor	% inhib.	Molar conc. of inhibitor	% inhib.
1	Hydroxylamine	10^{-6}	38	10^{-5}	75	10^{-4}	93
2	Hydroxylamine + pyridoxal—PO_4	10^{-6}	13	10^{-5}	58	10^{-4}	90
3	Pyridoxal—PO_4 hydroxylamine	10^{-6}	5	10^{-5}	38	10^{-4}	74
1	Hydrazine	10^{-6}	12	10^{-5}	25	10^{-4}	66
2	Hydrazine + pyridoxal—PO_4	10^{-6}	0	10^{-5}	17	10^{-4}	59
3	Hydrazine + pyridoxal—PO_4	10^{-6}	0	10^{-5}	2	10^{-4}	37
1	*Iso*nicotinic hydrazide	10^{-6}	0	10^{-5}	0	10^{-4}	0
2	*Iso*nicotinic hydrazide + pyr.—PO_4	10^{-6}	0	10^{-5}	0	10^{-4}	0
3	*Iso*nicotinic hydrazide + pyr.—PO_4	10^{-6}	0	10^{-5}	0	10^{-4}	0

amine, hydrazine, and *iso*nicotinic acid hydrazide, at three concentrations. At the concentrations used hydroxylamine was the most effective inhibitor. Hydrazine was somewhat less effective, while *iso*nicotinic acid hydrazide failed to show any inhibition at these concentrations.

Stimulation by pyridoxal phosphate. The stimulation due to pyridoxal phosphate is shown in Table 3. As can be seen in the table, very little increase in pyruvate generation is found when pyridoxal phosphate is added to the crude extract. The stimulation shown in other fractions is about 40 %. Dialysis reduces enzymatic activity to less than one-half (Expts. 4 and 5). The stimulation due to pyridoxal phosphate is, however, the same in each case.

The effect of sulphydryl group inhibitors on enzyme activity. The following inhibitors were tested at each of the molar concentrations, 10^{-6}, 10^{-5}, and 10^{-4}: *p*-chloromercuribenzoate, N-ethylmaleimide, iodosobenzoate; none inhibited at these concentrations. The latter two were also tested at a concentration of 10^{-2} M and were found to inhibit 30 % and 25 %, respectively. Iodoacetate and iodoacetamide failed to inhibit at 10^{-2} M but showed an inhibition of 25—30 % at 5×10^{-2} M. When corrected for an observed reaction with pyruvic acid, cyanide showed no inhibition even at 10^{-2} M while sulphide inhibited 30 % at this concentration.

Table 2. Specificity of enzyme. The standard assay described in the text was used except with benzyl cysteine sulphoxide. Because of the low solubility the substrate concentration was only half of the concentration used in the standard assay.

DISCUSSION

The experimental data presented here show the results of our attempts to purify the S-alkyl cysteine sulphoxide splitting enzyme. Renis [10] states that all attempts to purify the enzyme from onion were unsuccessful, although active crude extracts could be obtained in his laboratory. We have tried many of the usual procedures for enzyme purification, *e.g.* precipitation with ammonium sulphate, alcohol, or acetone. These procedures, in various combinations, together with gel absorption steps have given about 4—5 fold purification, but with serious losses in enzyme units. Dialysis was tried at various points in the purification and always resulted in a large loss of activity, only a part of

Table 3. The influence of pyridoxal phosphate on enzymatic activity. The standard assay was used except that pyridoxal phosphate was omitted from the experimental tube as well as the control tube (without substrate) where indicated.

Expt. No.	Enzyme fraction	μmoles pyruvate released		% Stimulation

which could be restored with pyridoxal phosphate. Pretreatment of the extract with the relatively large amount of charcoal, as described, removes most of the interfering materials and makes some further purification possible. The series of steps described here results in preparations which have a specific activity about six times as great as the original extracts. However, the electrophoretic pattern of the most purified fraction and failure to increase the specific activity beyond 6 suggest that the purity of the enzyme may already be fairly high.

In all experiments reported here the Mg^{++} ion was used routinely, although no stimulation by this ion or Al^{+++}, Cu^{++}, Co^{++}, and Mn^{++} could be shown. Furthermore, a several fold excess of Versene failed to inhibit the reaction. The loss in units upon dialysis could be only partly regained by addition of pyridoxal phosphate. Addition of concentrated dialysate, boiled enzyme, or preparations from which protein was removed by alcohol did not further increase the activity.

The sharp pH optimum shown at pH 7.4 is in marked contrast to that reported by Stoll and Seebeck [1] for the alliin cleaving enzyme from garlic. Their enzyme was active between pH 4 and 9, but showed a broad optimum range from pH 5 to 8. Unlike the garlic enzyme, which could be precipitated at pH 4, the onion enzyme lost all its activity after this precipitation.

As shown in Table 2, the enzyme cleaves all the alkyl cysteine sulphoxides that were tested and alliin is the best substrate. This fact is somewhat surprising since alliin appears to be absent from onion. An alkyl cysteine sulphoxide splitting enzyme has recently been purified 200 fold from *Albizzia lophanta* by Schwimmer and Kjaer [11] but it splits the S-alkyl cysteines as well as the sulphoxides.

At the present time it is not possible to state conclusively whether one or more enzymes are involved in cleaving the sulphoxides to pyruvic acid, ammonia, and alkyl thiosulphinates. We have tried recombination of various fractions a number of times and have never found any indications that more than a single enzyme could be involved.

Compounds Formed by Air-dried Insulin Crystals on Uptake of Metal Salts from Ethanolic Solutions

E. JENSEN, A. TOVBORG JENSEN and K. MARCKER*

Den Kgl. Veterinær- og Landbohøjskoles Kemiske Laboratorium, København, Denmark

X-Ray powder diffractometer data from air-dried insulin yield good lattice constants and a surmise of degree of crystallinity. Although the uptake by air-dried insulin of zinc ion and zinc chloride from an ethanolic solution seems to follow an adsorption isotherm, chemical compounds are formed, since lattice constants and reflection intensities in the products vary systematically with increasing zinc content. From X-ray data the uptake is seen to fall in three distinct stages: I, until 2 zinc atoms per Sanger unit are taken up; II, till 4 zinc atoms are taken up; III, when more zinc is taken up. As shown earlier step I is an exchange of zinc ions for hydrogen ions. In steps II and III zinc chloride is taken up. Lattice constants for a few compounds with other metal salts are given.

The shrinking of insulin crystals on drying is not reversed by uptake of water vapour. Air-dried insulin took up 18 % of water, but the lattice constants remained unchanged.

Marcker [1] recently described some new compounds of insulin with metals (metal ions) and metal salts, formed by treating air-dried insulin crystals with ethanolic solutions of metal salts. An X-ray crystallographic study of the compounds was begun at an early stage of this work. It has given a more detailed picture of the compounds than unaided chemical methods. A few experiments of the influence of air-drying and subsequent moistening of insulin crystals on their lattice constants will also be described.

X-RAY TECHNIQUE

Insulin crystals under mother liquor are well ordered, and give X-ray reflections up to glancing angles corresponding to interplanar spacings to about 1 Å. Air-dried insulin crystals, on the other hand, have lost the finer details of their internal order. X-Ray reflections corresponding to interplanar spacings shorter than 5—7 Å have vanished on drying. Since Marckers com-

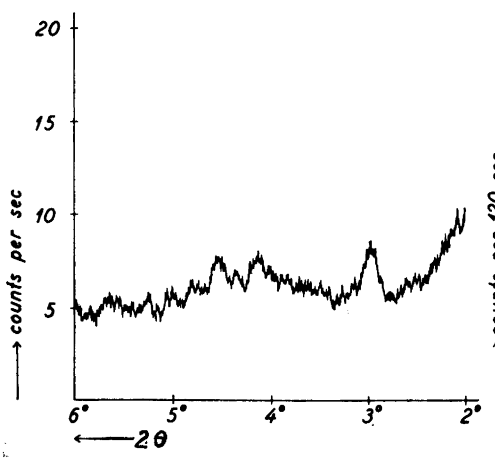

Fig. 1. Powder diagram of air dried insulin crystals. Specimen 1. 6.8 atoms of zinc per Sanger unit. Cu*Kα* radiation, automatic recording. 2Θ from 2 to 6°.

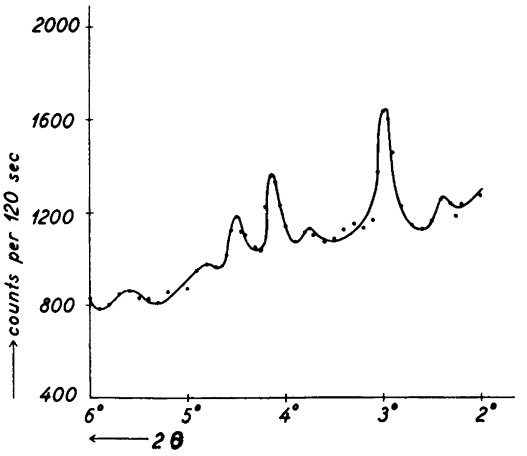

Fig. 2. Powder diagram of air dried insulin crystals. 2Θ from 2° to 6°. Specimen as in Fig. 1. Cu*Kα* radiation. Stationary 120 secs. counting at intervals of 0.05° to 0.10° in 2Θ.

pounds were prepared from air-dried insulin, and because the crystals were small, no attempt was made to apply single crystals methods to them.

The powder method, unpromising at first, was found quite useful. In the early days of protein crystallography, powder methods were used a good deal. However poor the diagrams, they contained lines and gave evidence of internal order, and of the very long interplanar spacings present. But the lines of early powder diagrams of protein crystals were in general »clashings» between several reflections. Only two cases are known to us where the indexing of four or five lines from a protein crystal powder diagram has been claimed: ferritin and apoferritin (Fankuchen [2]).

Fig. 1 shows an automatic recording of the powder diagram of crystalline air-dried insulin from $2\Theta = 2°$ to $2\Theta = 6°$. The diagram was taken with a General Electric X-Ray Diffractometer (XRD-3) fitted with a special linear amplifier, radiation filtered Cu*Kα*. The slit system was very narrow as seen from the low intensity. The diagram shows 3 dubious lines. Fig. 2 shows the improvement obtained when the same diagram is constructed from 120 sec. stationary countings at points 0.05° to 0.10° apart. Seven lines are seen now. The same technique was adopted in all further work, and similar diagrams obtained, except of course for samples whose structure had deteriorated as a result of chemical treatment of the sample. The lines could always be indexed by an adaption of Crowfoots lattice constants for air-dried insulin. An example is given in Table 1, where the results from the diagram, Fig. 2, are given. All lattice constants have been referred to the hexagonal cell whose volume is three times that of the true rhombohedral cell, and contains 18 Sanger units of molecular weight 5 800 plus water *etc.* Since the innermost part of the powder diagram is so easily indexed it is tempting to proceed further out, *inter alia* in

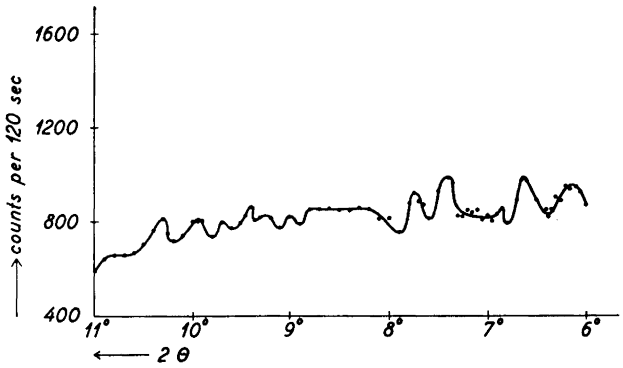

Fig. 3. Powder diagram of air dried insulin crystals. 2Θ from 6° to 11°. Same technique as in Fig. 2.

order to obtain more accurate lattice constants. A glance at Fig. 3 which gives the diagram from $2\,\Theta = 6°$ to $2\,\Theta = 11°$ will show why such attempts at indexing failed. A considerably refined technique or independent knowledge of relative intensities would be necessary, since calculation shows that there are some 30 possible reflections in this part of the diagram.

INSULIN-ZINC AND INSULIN-ZINC-$ZnCl_2$ COMPOUNDS

The following work was done using twice recrystallized pig-insulin *. Table 2 gives lattice constants for 4 chemically untreated samples of insulin crystals, all data obtained as described. The classical data by Crowfoot-Hodgkin [3] and Crowfoot and Riley [4] for dry and wet insulin are also tabulated. In column 4 of Table 2 are given the lattice constants for a specimen of insulin under its mother liquor **. In column 5 is given the lattice constants for the same speci-

men after air drying. The figures in columns 4 and 5 are not as accurate as the other figures in Table 2, but they prove beyond doubt that our wet specimen has been in a higher state of hydration than that of Crowfoot and Riley (column 6). In order to see whether the lattice constants of dry and shrunk insulin crystals varied when the crystals took up humidity from the air — in which case we would have had to work in a controlled atmosphere — we left a specimen overnight in an atmosphere of 95 % relative humidity at room temperature. The weight of the sample increased by 18 %. We registered its powder diagram in the humid state, dried it again and registered the powder diagram a third time. The same glancing angles and reflection intensities were found in the three experiments within experimental error. So the shrinking was not reversed by the uptake of humidity from the air, and controlled atmospheric humidity is unnecessary when working with air-dried crystals. Whether the molecules of the 18 % of water taken up were placed in holes in the insulin crystals proper, or in an amorphous fraction undoubtedly present, is not clear to us.

In Figs. 4 and 5 the lattice constants of one untreated specimen of air-dried insulin crystals and of 7 specimens treated with ethanolic solutions of zinc chloride are plotted against the zinc content of the specimens. For details

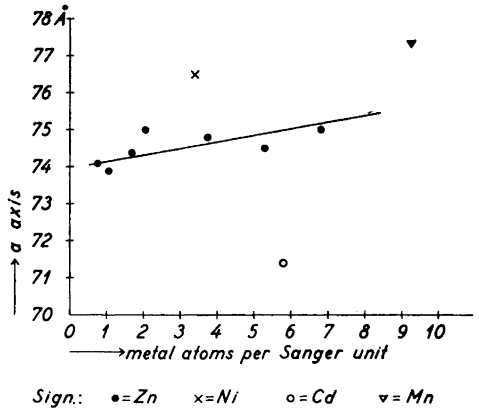

Fig. 4. Variation in *a*-axis length of dry insulin with increasing zinc content.

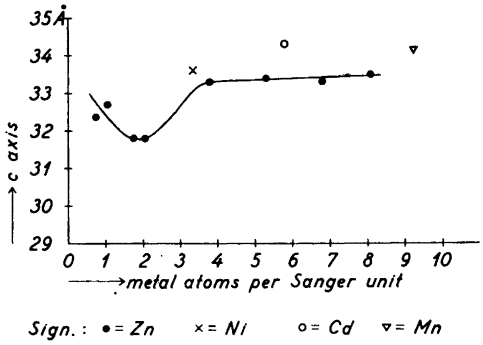

Fig. 5. Variation in *c*-axis length of dry insulin with increasing zinc content.

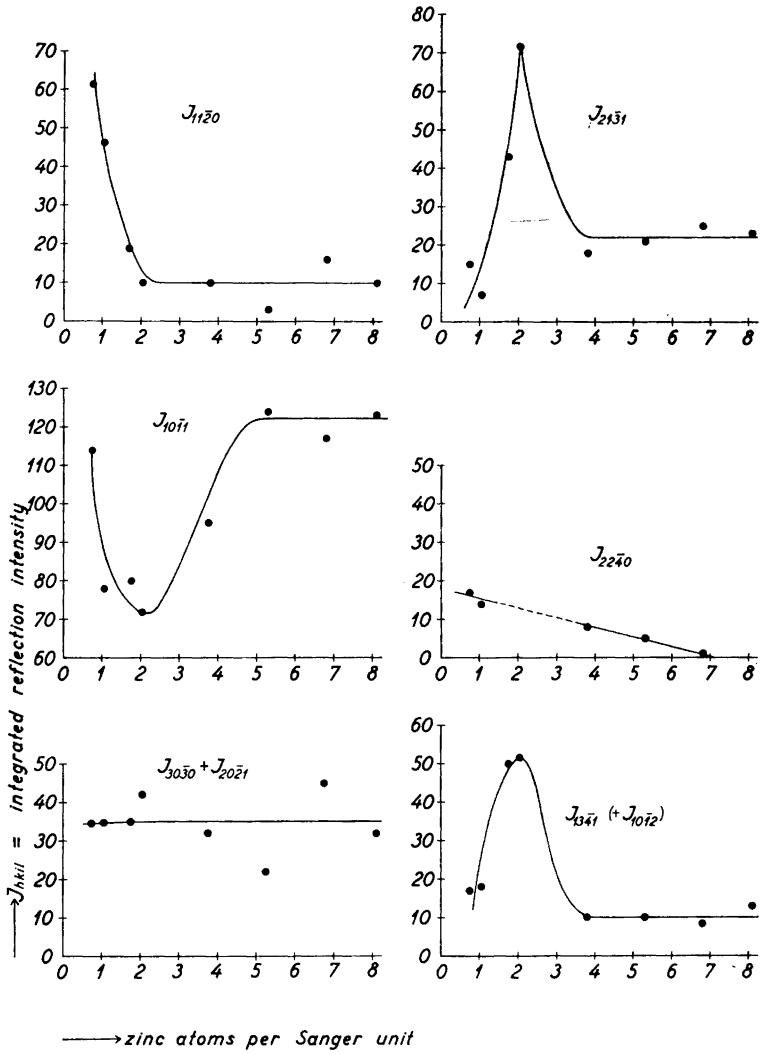

Fig. 6. Variation in integrated reflection intensity with increasing zinc content for the innermost lines in the powder diagram of dry insulin.

of preparation see Ref.[1] When the accuracy of the a-axis values ($\pm$ 0.4 Å) is borne in mind it is difficult to conclude anything from Fig. 4, except that the uptake of zinc brings about a gradual increase in a. On the other hand, it seems legitimate to conclude from Fig. 5 that the c-axis (accuracy $\pm$ 0.2 Å) shrinks when the zinc content increases to 2 atoms per Sanger unit, and expands again as two more atoms are taken up. If the zinc content increases from 4 to the maximal 8 atoms per unit the c-axis remains constant. This indicates

that the reaction is a 3-stage process. Fig. 4 from which nothing definite could be concluded is perhaps not incompatible with a 3-stage process.

Considerably more evidence for a 3-stage process is provided by the variation in reflection intensity with zinc content for 6 lines, as seen from Fig. 6. The intensities are given as integrated intensities measured as peak area over a smoothed background. Four of the curves indicate a break at about 2 zinc atoms per Sanger unit, three curves another break at about 4 atoms of zinc per unit. No significant variation occurs at higher values. The diagram for reflection $30\bar{3}0$ plus $20\bar{2}1$ presents a confused picture. The shape of the combined peaks made a graphical separation impossible. In addition the combined peak area contained in 2 out of 3 diagrams a third peak of an unknown impurity. This peak was the only one found in any diagram which could not be accounted for by the "quadratic form" for insulin. Its area could not be measured and subtracted, and since it varied between zero and a finite value its presence adds to the confusion in reflection intensity.

The break at 2 atoms of zinc was explained later when it was found by chemical analysis that at this point the reaction between insulin crystals and an ethanolic zinc chloride solution changes from an exchange of hydrogen ions in the crystal for zinc ions from the solution to an uptake of zinc and chloride ions [1]. The break at 4 zinc per Sanger unit is so far unexplained chemically. From chemical evidence, especially the remarkable work by Schlichtkrull [5], it seems beyond doubt that the zinc atom per 3 Sanger units which is necessary to obtain insulin in the crystalline state, is placed in a fixed position in the crystal. From our work we think it may be safely concluded that the zinc ions subsequently taken up by ion exchange until two atoms are present, *and* the first two moles of zinc chloride taken up when the ion-exchange capacity is exhausted, are likewise placed in fixed positions. Were they placed at random it would be difficult to understand the gradual but drastic changes in reflection intensity caused by their gradual introduction. So we must conclude that these products are chemical compounds. On the other hand, there seems to be no evidence for a fixed position of the last four molecules of zinc chloride, since they cause no systematic change in reflection intensities.

It is somewhat unexpected that the reaction between insulin crystals and an ethanolic solution of zinc chloride is a three-stage process where first and second stage lead to chemical compounds, since the entire reaction seems to follow an adsorption isotherm; see Fig. 1 in Ref.[1] But there is in fact nothing contradictory in the findings. Stage 3 *is* most probably an adsorption process, stage 2 is the formation of a kind of interstitial compound, and stage 1 an ion exchange process, all of which follow a function similar to an adsorption isotherm. The experiments, the results of which are given in Fig. 1 in Ref. [1] could hardly be expected to distinguish between one adsorption isotherm and three adsorption isotherms pieced together: one from ordinates 0 to 2, another between ordinates 2 and 4 and a third at ordinate values higher than 4.

COMPOUNDS OF ZINC-INSULIN WITH OTHER METAL CHLORIDES

The reaction between dry insulin crystals and ethanolic solutions of $NiCl_2$, $CdCl_2$, $CaCl_2$, $MgCl_2$, $MnCl_2$ and $CoCl_2$, briefly mentioned in Ref.[1] was

Table 3. Chemical composition and X-ray characterisation of compounds formed when crystalline zinc-insulin was suspended in an ethanolic solution of another heavy metal chloride.

Metal chloride	Me atoms/unit	Zn atoms/unit	*a*, Å	*c*, Å	powder diagram
$NiCl_2$	2.8	0.5	76.5	33.6	good
$MnCl_2$	8.8	0.4	77.3	34.1	good
$CdCl_2$	5.4	0.3	71	34	bad
$CoCl_2$	7.8	<0.1			no diagram
[untreated	0	0.7	74.1	32.4	good]

not followed up by a systematic X-ray study as in the case of the reaction with a $ZnCl_2$ solution. Lattice constants and compositions for three compounds of insulin and manganese, nickel and cadmium chlorides are given in Table 3. The compounds are also entered in Figs. 4 and 5. The lattice constants are seen to differ widely from those of compounds in the $ZnCl_2$ series. The partial replacement of zinc ions with other heavy metal ions, and the uptake of additional metal ion and metal chloride apparently cause more drastic changes than the reaction with zinc chloride.

This phenomenon deserves a closer study. Chemical composition of the products and the character of their powder diagrams are also given in Table 3. It is seen that as long as 0.4 atoms of zinc per Sanger unit are left in the crystals their X-ray diagram is good. When only 0.3 atoms are left their structure has deteriorated, and when less than 0.1 atom is left the structure is so deranged that no powder diagram lines are visible, although the appearance of the crystals under the microscope is unchanged. The deterioration sets in between the limits of 0.4 and 0.3 atoms of zinc per Sanger unit. It will be remembered that one metal atom per 3 Sanger units is the minimum number of metal atoms that can produce crystalline insulin. It is tempting to identify the minimum number of zinc atoms (roughly 0.35) that must be left in air-dried insulin if the ordered internal structure shall not break down, with the number of atoms (*i.e.* 0.33) that must be built in, if insulin shall crystallize from an aqueous solution. It is true — as known from Schlichtkrulls tracer experiments [6] with ^{65}Zn — that any zinc atom in wet insulin crystals can be replaced rapidly by any other zinc atom without deterioration of structure. But it is not improbable that the replacement of a zinc atom with another zinc atom be a milder process than the replacement of a zinc atom with a cobalt atom. The cobalt atom might cause a change of coordination, or it might occupy another site than the zinc atom and hereby cause a breakdown of the order still left in insulin crystals after drying.

CONCLUSION

The study of powder diagrams — or as here diffractograms — is not a general method for the investigation of crystalline proteins. Insulin with its small and highly symmetric unit cell is uniquely favourable. There is hardly any other proteins with which experiments similar to those described above could be made. But the method might be of interest in other studies of

that particularly important protein. It is a routine method, it is "non-destructive", and it yields well defined physical constants, *viz.* degree of crystallinity, lattice constants and reflection intensities from known sets of lattice planes, properties whose variations under different circumstances are of some interest.

ADDENDUM

The number (N) of metal atoms per Sanger unit has been calculated from

$$N = \frac{\%\ \text{Me}}{\text{atomic weight of Me}} \Big/ \frac{100 - \%\ \text{Me} - \%\ \text{Cl}}{6\,000} \qquad \text{(A)}$$

In this equation the weight of a Sanger unit of air-dry pig-insulin including 6 % of water has been set equal to 6 000, and it has been assumed that no water is expelled when metal and salt are taken up. In a previous paper [1] the metal contents of the same specimens were calculated from

$$N = \frac{\%\ \text{Me}}{\text{atomic weight of Me}} \Big/ \frac{100}{6\,000} \qquad \text{(B)}$$

which gives the number of metal atoms per Sanger unit, provided the amount of water expelled equals that of the metal plus metal salt taken up. We think (A) is less arbitrary than (B). However, only complete analysis of a specimen can decide which assumption be the better. For specimens containing less than four metal atoms per Sanger unit there will be no significant differences. For the specimens with higher metal contents discussed in Ref.[1] we think the following stoichiometric formulae calculated from (A) are more probable than those given by Marcker (shown in brackets)

Insulin, 2 Zn, 6 $ZnCl_2$	(Insulin, 2 Zn, 5 $ZnCl_2$)
Insulin, $\frac{1}{3}$ Zn, $1\frac{2}{3}$Mn, 7 $MnCl_2$	(Insulin, $\frac{1}{3}$ Zn, $1\frac{2}{3}$ Mn, 6 $MnCl_2$)
Insulin, $\frac{1}{3}$ Zn, $1\frac{2}{3}$ Cd, 4$CdCl_2$	(Insulin, $\frac{2}{3}$Zn, $1\frac{2}{3}$ Cd, 3 $CdCl_2$)
Insulin, 2 Co, 6 $CoCl_2$	(Insulin, 2 Co, 5 $CoCl_2$)

IX *. Polarography and Reduction of Substituted Aryl Alkyl Ketones

HENNING LUND

Leo Pharmaceutical Products, Ballerup, Denmark **

Ketones with the general formula Ar—CO—CRR'X, where R and R' are hydrogen, alkyl or aryl and X is —Cl, —OH, —OCH_3, —OC_6H_5, —OOCR, —SC_6H_5, —SCN, —CN, or —ONO_2, have been investigated polarographically and by means of controlled potential reductions at a macro mercury cathode. In most cases the reduction of the C—X bond occurs at less negative potentials than that of the carbonyl group.

Some types of 2-substituted acetophenones have previously been investigated polarographically. Thus Pasternak and Halban [1] studied 2-bromoacetophenone, Adkins and Cox[2] 2-bromo*iso*butyrophenone, Elving and Leone [3] 2-fluoroacetophenone, and Zuman and Horak [4] investigated a series of N-substituted 2-aminoacetophenones. Methylbenzoylcarbinol has been studied by Fedoronko [5] and benzoin by Pasternak [6] and Santavy [7].

Elving and Leone [3] studied the electrode reaction by means of controlled potential reductions at a macro mercury electrode and Zuman and Horak [4] identified the reduction products from a prolonged electrolysis at the dropping mercury electrode by means of paper chromatography. In both cases the electrode reaction corresponding to the first wave was a reduction to acetophenone.

Benzoin has been investigated by means of controlled potential reductions by Pasternak [6], and it was found that the reduction product at pH 8 was hydrobenzoin, whereas the isolated product from a reduction at pH 1.3 was the higher melting form of deoxybenzoin pinacol, 1,2-diphenyl-1,2-dibenzylethylene glycol.

In the present investigation compounds with the general formula Ar—CO—CRR'—X, where R and R' are hydrogen, alkyl or aryl, X is —OH, —OCH_3, —OC_6H_5, —OOCR, —SC_6H_5, —SCN, —ONO_2, or —CN, have been

* Part VIII: *Collection Czechoslov. Chem. Communs. In press.*

** Present address: Chemical Department, University of Aarhus, Denmark

investigated polarographically and the electrode reactions have been studied by means of controlled potential reductions at a macro mercury electrode. The results obtained at the micro and the macro electrodes are compared and discussed.

RESULTS

In Table 1 are given polarographic data for 2-hydroxyacetophenone (I), 2-acetoxyacetophenone (II), 2-benzoxyacetophenone (III), 2-phenoxyacetophenone (IV), phenacyl phenyl sulfide (V), 2-thiocyanatoacetophenone (VI), and phenacyl nitrate (VII).

2-Hydroxyacetophenone shows in mineral acid solution two waves. The height of the first wave corresponds to a two-electron reduction, whereas the second one is somewhat smaller than corresponding to a one-electron reduction. The half-wave potential of the second wave coincides with that of acetophenone in the same solution. This suggests that the electrode reaction corresponding to the first wave is a reduction of the primary alcohol to a methyl group and the second wave is due to the reduction of the acetophenone thus formed, and this has been confirmed by a controlled potential reduction. The electrode reaction is analogous to that of certain 16-hydroxy-17-ketosteroids [8], in which the hydroxyl group is reduced at less negative potentials than the carbonyl group; the half-wave potentials of the steroids are, however, considerably more negative.

At higher pH-values the waves of 2-hydroxyacetophenone merge; the reduction path is not clear and the low stability of the compound at high pH-

Table 1. Limiting currents in μA and half-wave potentials *vs* S.C.E. of 2-hydroxyacetophenone (I), 2-acetoxyacetophenone (II), 2-benzoxyacetophenone (III), 2-phenoxyacetophenone (IV), phenyl phenacyl sulfide (V), 2-thiocyanatoacetophenone (VI), and phenacyl nitrate (VII). Concentration 10^{-3} M. 0.008 % gelatin added as maximum suppressor.

a. The compound is hydrolyzed; b. Minimum between the two waves;
c. Poorly defined wave.

values makes the results from the preparative reductions dubious. The results seem to indicate that more than two electrons are involved in the reaction and from a partially reduced reaction mixture a minor amount (10 %) of acetophenone was isolated as the 2,4-dinitrophenylhydrazone.

As in the reduction of tropyl alcohol [9] the first wave in acid solution of 2-hydroxyacetophenone corresponds to the reduction of the protonated compound, but whether the reaction is a direct reduction of the carbon-oxygen bond or the reduction is preceded by formation of a "phenacylium ion" by loss of water from the protonated compound is not known.

The acetylated compound, 2-acetoxyacetophenone, shows both in acid and alkaline solution two polarographic waves and the more negative wave occurs at the same potential as that of acetophenone in the same solution. The polarographic data thus suggest that the electrode reaction corresponding to the first wave is a reduction of the acetoxyacetophenone to acetophenone according to

$$C_6H_5COCH_2OCOCH_3 + 2\ e^- + 2\ H^+ \rightarrow C_6H_5COCH_3 + CH_3COOH$$

and this was confirmed by a controlled potential reduction in acid solution from which acetophenone was isolated in good yield as its 2,4-dinitrophenylhydrazone.

In alkaline solution both waves correspond to two-electron reductions, but no preparative reduction has been made due to the hydrolysis of the compound at high pH-values. The polarographic data, however, strongly suggest a reduction to acetophenone in this case too. The reduction of 2-acetoxyacetophenone thus resembles that of the acetyl derivatives of the above mentioned steroids [8].

The polarographic reduction of phenacyl phenyl ether and phenacyl phenyl sulfide gives at most pH-values rise to two well defined waves. As is found in the polarographic reduction of most of the 2-substituted acetophenones the height of the second wave is from pH about 1 to pH about 6 smaller than the height of the polarographic wave of an equimolar solution of acetophenone. This is believed to be connected with the rate of a reaction between protons and the primarily formed product.

The polarographic data suggest an electrode reaction corresponding to the first wave in which the carbon-oxygen or carbon-sulfur bond is cleaved thus yielding acetophenone and phenol or thiophenol. By controlled potential reduction of phenacyl phenyl ether it was found that acetophenone was formed in good yield both in mineral acid solution and at pH 13.

The polarographic reduction of an aryl alkyl ether is not a frequent polarographic electrode reaction, but has previously been found in the reduction of phenoxyacetamidines [10]. The protection of a phenolic group by transforming it to a benzyl ether followed by a cleavage of the ether bond by hydrogenation is well known; it was attempted to reduce phenyl benzyl ether in buffered media, but no reduction wave was found between 0 and 2.0 V *vs* S.C.E. A protection of a phenolic group by a phenacyl group followed by an electrolytic cleavage of the ether bond might be possible, but whether it would present any advantage in comparison with the known method will be investigated.

The half-wave potential of the first wave of 2-thiocyanatoacetophenone is independent of pH at pH-values higher than about 3, whereas the half-wave potential of the second wave is similar to that of acetophenone in the media employed. The polarographic data thus suggest that acetophenone is formed in the electrode reaction corresponding to the first wave and this was also found by a controlled potential reduction of 2-thiocyanatoacetophenone in an acetate buffer pH 5. The electrode reaction can be formulated as

$$C_6H_5COCH_2SCN + 2\ e^- \rightleftharpoons C_6H_5COCH_2^- + SCN^-$$
$$+ H^+ \rightarrow C_6H_5COCH_3$$

The electrode reaction is thus different from those of aromatic thiocyanates [11,12], which are reduced to the mercapto derivative and cyanide ion.

The half-wave potential of the first wave of phenacyl nitrate is independent of pH. The following waves are consistent with the assumption that 2-hydroxyacetophenone and nitrous acid are formed in the electrode reaction which thus would be similar to that of other organic nitrates [13].

In Table 2 are found polarographic data for 2-acetoxy-4′-chlorobutyrophenone (VIII), 2-thiocyanato-4′-chloro-butyrophenone (IX), and 4′-chlorobutyrophenone (X).

a. The compound is hydrolyzed.

The polarographic reduction of the 4′-chlorobutyrophenones resembles that of the corresponding acetophenones. The height of the second wave is, however, in acid solution much smaller than that of an equimolar solution of the parent ketone and from pH about 3 the wave is hardly visible. The region in alkaline solution where the second wave is found begins at a higher pH value than for the corresponding acetophenone derivative. The electrode reactions are similar to those of the corresponding acetophenone derivatives.

In Table 3 are given polarographic data for 2-hydroxy*iso*butyrophenone (XI), 2-acetoxy*iso*butyrophenone (XII), and 2-thiocyanato*iso*butyrophenone (XIII).

a. Poorly defined wave.
b. The compound is hydrolyzed.

In the polarographic reduction of derivatives of *iso*butyrophenone a reduction wave of the *iso*butyrophenone formed in the first electrode reaction is hardly visible in acid solution and in alkaline solution the wave can only be seen at high pH-values (pH > 10.5). The compounds here investigated are, however, hydrolyzed at high pH-values which makes measurements difficult.

Controlled potential reductions in mineral acid solution at a cathode potential corresponding to the half-wave potential of the compound in the medium employed showed that the electrode reaction of 2-hydroxy*iso*butyrophenone and 2-thiocyanato*iso*butyrophenone was a two-electron reduction to *iso*butyrophenone. Although it thus is demonstrated that *iso*butyrophenone is formed in the reduction of 2-thiocyanato*iso*butyrophenone no polarographic wave of *iso*butyrophenone is found on the polarographic curve obtained in a solution of 2-thiocyanato*iso*butyrophenone in the medium and concentration here employed.

In the preparative reduction of 2-hydroxy*iso*butyrophenone it is not possible to use a cathode potential corresponding to a potential where the polar-

c. 40 % dioxane.

ographic limiting current is reached as the half-wave potential of the *iso*-butyrophenone formed in the reduction is only 0.2 V more negative than that of 2-hydroxy*iso*butyrophenone. This can not be predicted from the polarographic curve of 2-hydroxy*iso*butyrophenone and the polarographic data are thus in such a case not a reliable guide for the reduction.

The polarographic data of the following derivatives of deoxybenzoin are found in Table 4: benzoin (XIV), acetylbenzoin (XV), 2-thiocyanatodeoxybenzoin (XVI), 2-chlorodeoxybenzoin (XVII), and deoxybenzoin (XVIII).

The polarographic behaviour of derivatives of deoxybenzoin resembles that of the above mentioned compounds. Whereas 2-thiocyanatodeoxybenzoin only yields a single wave acetylbenzoin shows a small second wave in strongly acid solution and a second wave with a height corresponding to a two-electron reduction in alkaline solution. The second wave appears in both cases at the potential at which deoxybenzoin is reduced in the same solution. The assumption that the reduction corresponding to the first wave of acetylbenzoin yielded deoxybenzoin was confirmed by a controlled potential reduction of acetylbenzoin from which deoxybenzoin could be isolated in good yield.

Benzoin yields in alkaline solution quantitatively hydrobenzoin [6] but from a reduction in mineral acid solution Pasternak [6] isolated the highest melting form (α-form) of deoxybenzoinpinacol (1,2-diphenyl-1,2-dibenzyl-ethylene glycol). Wawzonek [14] has interpreted the occurrence of this reduction product as being due to a reduction of the benzoin to hydrobenzoin followed by an acid catalyzed dehydration to deoxybenzoin which on reduction produced among other compounds the isolated pinacol.

A solution of hydrobenzoin in N hydrochloric acid solution containing 40 % alcohol was, however, not dehydrated to deoxybenzoin on standing at room temperature for 18 h as no polarographic wave of deoxybenzoin appeared, and in view of the results from the reduction of acetylbenzoin in mineral acid solution it seems just as plausible that the secondary alcohol group of benzoin is reduced directly to a methylene group and the deoxybenzoin thus formed is reduced further. A polarographic reduction of a secondary alcohol to a methylene group has also been assumed by Wawzonek and Fredrickson [15] in the reduction of α-hydroxy-*p*-methoxy-phenylacetonitrile, and it was shown that α-benzoxy-*p*-methoxy-phenylacetonitrile in good yield formed *p*-methoxyphenylacetonitrile on electrolytic reduction at a mercury cathode.

The reduction of deoxybenzoin is of some interest. It has long been known that two pinacols of deoxybenzoin exist, "α", m.p. 212°, and "β", m.p. 173°; the existence of these two forms is due to two asymmetric carbon atoms in the pinacols. From a controlled potential reduction of deoxybenzoin in mineral acid solution the pinacol with m.p. 212° ("α") precipitated; this is in agreement with Pasternak's results from the reduction of benzoin under similar conditions. Other compounds, probably formed by dehydration and rearrangement of the pinacol, were also formed. In strongly alkaline solution in 60 % dioxane some secondary alcohol was formed but the main product was a mixture of pinacols which consisted mainly of the lower melting isomer; an infrared analysis of the mixture suggested about 80 % "β-pinacol" and 20 % "α-pinacol". In acid solution thus mainly the highest melting and in alkaline solution mainly the lowest melting pinacol is formed. A similar observation

has been made by Allen [16] in the reduction of *p*-dimethylaminoacetophenone which in acid solution was reduced to the higher melting pinacol and in alkaline solution to a lower melting pinacol. The reduction of certain α,β-unsaturated 3-ketosteroids [17] also produced a different mixture of pinacols in acid and alkaline solution, and in this connection it is also of interest that the polarographic reduction of α-methyldeoxybenzoin in weakly alkaline solution primarily yielded the *erythro*-alcohol [18].

In Table 5 are found polarographic data for phenylbenzoin (XIX), 2-acetoxy-2,2-diphenylacetophenone (XX), 2-methoxy-2,2-diphenylacetophenone (XXI), and 2,2-diphenylacetophenone (XXII).

The polarographic behaviour of derivatives of diphenylacetophenone resembles that of the derivatives of deoxybenzoin; the second wave of, *e.g.*, 2-acetoxy-2,2-diphenylacetophenone which is due to the reduction of the diphenylacetophenone formed in the first electrode reaction is, however, only visible at pH-values higher than 11, whereas the second wave of acetylbenzoin can be seen from about 7.5.

The reduction of 2-methoxy-2,2-diphenylacetophenone is interesting as only few examples of a polarographic reduction of an alkyl arylalkyl ether bond have been reported. A similar reaction has, however, been found in the reduction of *o*-benzoylbenzoic acid *pseudo*ethylester [19].

Diphenylacetophenone was once believed to exist mainly as triphenylvinyl alcohol; one of the arguments in favour of this formulation was the easy formation of the O-benzoylated derivative, triphenylvinyl benzoate. The polarographic data are consistent with the formulation of 2,2-diphenylacetophenone as a carbonyl compound as the half-wave potentials are close to those of deoxybenzoin, and as it was found that triphenylvinyl benzoate did not yield a polarographic wave in the pH-region in which it is sufficiently stable for a polarographic investigation.

The polarographic behaviour of 2-cyanoacetophenone is quite different from the above mentioned compounds. In acid solution is found one wave with a wave height corresponding to a two-electron reduction, but about

pH 7 the height of the wave diminishes and the wave disappears about pH 11 (Table 6).

The reason for this disappearence of the polarographic wave is that the ketone exists in equilibrium with its enol form, and that this enol form in the pH-interval pH 7 to 11 increasingly is found as the enolate-ion according to

$$C_6H_5COCH_2CN \rightleftharpoons C_6H_5C(OH)=CHCN \rightleftharpoons C_6H_5C(O^-)=CHCN + H^+$$

The enolate-ion is not reducible in the potential interval 0—2.0 V *vs* S.C.E.

This explanation was corroborated by a potentiometric titration of 2-cyanoacetophenone in 40 % alcohol which yielded a normal titration curve, the midpoint being at pH 7.8. When the height of the polarographic wave is plotted against pH the pH-value at which the height of the wave has diminished to half of the value in acid solution is 8.2. The curve obtained is not symmetrical as the wave height diminishes too slowly in alkaline solution compared with the decrease about pH 7 to yield a symmetrical curve. This is probably due to a recombination at the electrode surface of the non-reducible enolate anion with a proton to yield the reducible keto form, as the height of the polarographic wave of 2-cyanoacetophenone at pH 10 was not dependent on the height of the mercury reservoir.

The reduction of 2-bromoacetophenone has been investigated previously [1]; the reduction of the carbon-bromine bond occurs at a very positive potential. When the compound is transformed into its ethylene ketal, 2-(bromomethyl)-2-phenyl-1,3-dioxolane, the reduction of the carbon-bromine bond occurs at a much more negative potential. The half-wave potential in a 40 % alcoholic solution containing 4 % tetramethylammonium hydroxide was found to be —1.78 V *vs* S.C.E. This is consistent with the very much lower reactivity of the ketal compared with that of the phenacyl bromide.

DISCUSSION

When the results from the polarographic investigation and from the controlled potential reductions are compared it is seen that the data obtained at the dropping mercury electrode are not always a reliable guide for the preparative reductions. The observed effects are caused by differences in the duration of the experiments and in the concentrations employed at the dropping mercury electrode and at the macro-scale reductions.

A species formed as an intermediate in the electrode reaction will at the dropping mercury electrode behave as the final reduction product if it is stable for more than a few seconds; in that case it is able to diffuse from the electrode to the bulk of the solution before it is transformed to the stable reduction product. The concentration of the stable reduction product will remain low and although the compound might be reducible at the electrode its concentration will be too low to influence the recorded polarographic curve.

Differences between the results obtained at the dropping mercury electrode and at the macro electrode are found, *e.g.*, when the relatively stable intermediate is non-reducible and the stable reduction product can be reduced further.

At the macro-electrode the intermediate also is transformed to the stable reduction product in the bulk of the solution but in the course of the reduction a high concentration of this product is built up; if the cathode potential is sufficiently negative the reduction product is reduced further. According to the polarographic data any potential where the diffusion plateau is reached would be equally satisfactory for a preparative reduction but this does not hold true in the case under discussion. The cathode potential must under such circumstances be held more positive than the foot of the polarographic wave of the partially reduced compound and that means that in some cases it is not advisable to employ a cathode potential more negative than the half-wave potential of the compound reduced, if a selective reduction is to succeed.

In this connection it can be recalled that the half-wave potentials of many irreversibly reduced compounds are dependent on the concentration and that the waves at high concentrations often "cover" a greater potential interval than under normal polarographic conditions. The separation of waves obtained in solutions of high concentrations is often less satisfactory than at low concentrations and this makes it advisable always to employ as positive a cathode potential as possible in preparative reductions.

In the present investigation it is found for most of the compounds that in a certain pH-interval either only one wave is detectable, although the product from the first reduction is reducible, or the second wave is smaller than the wave of an equimolar solution of the partially reduced compound. A typical example is 2-thiocyanato*iso*butyrophenone which shows only one wave in the pH-interval in which this compound can be investigated; the preparative reduction at controlled cathode potential shows that the product from the electrode reaction corresponding to the observed wave is the reducible *iso*-butyrophenone.

A comparatively stable, non-reducible intermediate is thus likely to be formed during the electrode reaction. The half-wave potential of the wave of 2-thiocyanato*iso*butyrophenone is independent of pH and the reaction can thus be formulated

$$C_6H_5COC(CH_3)_2SCN + 2\ e^- \rightarrow C_6H_5COC(CH_3)_2^- + SCN^-$$

$$+ H^+ \rightarrow C_6H_5COCH(CH_3)_2$$

where the species $C_6H_5COC(CH_3)_2^-$ is the non-reducible, relatively stable intermediate. A similar species must be assumed to be formed in the corresponding

electrode reactions of the compounds investigated, and it is probably stabilized in some way at the electrode.

There seems to be a connection between the strength of the acid from which the substituent is derived and the pH-dependence of the first wave. When the substituent is derived from a strong acid as HCl, HBr, HSCN, or HNO_3 the half-wave potential of the first wave is independent of pH above pH 2-3; when the substituent, however, is derived from a weak acid as HF[3], CH_3COOH, C_6H_5OH, C_6H_5SH, or CH_3OH the half-wave potential is in acid solution dependent on pH. Considerations as those used by Elving and Leone to explain the pH-dependence of the reduction of 2-fluoroacetophenone may be applied in those cases.

It is of interest to compare for the same derivative of different ketones the pH-intervals in which only one wave is observed. It is found that the interval grows in the order $C_6H_5COCH_2X < ClC_6H_4COCH(C_2H_5)X < C_6H_5COCH(C_6H_5)X < C_6H_5COC(CH_3)_2X \leqq C_6H_5CO(C_6H_5)_2X$. This sequence is understandable in view of the reduction route indicated above. The postulated primarily formed carbanion is stabilized by substitution by alkyl or aryl at the carbon atom at which the reduction occurs, and the carbanion thus reacts more slowly with protons to form the reduction product, the ketone. Besides stabilizing the carbanion the substituents may produce a shielding effect which lowers the rate of the reaction with protons.

In the acid region the second wave is greater at the lowest pH-values which is understandable if the rate of a reaction between a carbanion and a proton determines the height of the wave. In the alkaline region the formation of the reducible ketone is most rapid at high pH-values, as if the hydroxyl ions catalyzed the reaction between the carbanion and a water molecule to form the ketone and a hydroxyl ion. This is also found in the reduction of benzil which in most buffers yields only a single wave, although a preparative reduction at controlled potential has shown [6] that the reducible benzoin is formed. In 0.1 N sodium hydroxide, however, a wave due to the reduction of the benzoin formed in the first electrode reaction is visible which indicates that the non-reducible intermediate is transformed to benzoin most rapidly in strongly alkaline solution.

EXPERIMENTAL

The polarograph was a recording polarograph Radiometer Type PO 3 a. The capillary delivered 2.27 mg of mercury at a corrected mercury column height of 48.5 cm. The drop time 3.90 sec. (H_2O, open circuit). The capillary constant, $m^{2/3}t^{1/6} = 2.13$ $mg^{2/3}sec^{-\frac{1}{2}}$.

The apparatus used for the controlled potential reductions was an electromechanical potentiostat of the Lingane-Jones type. The buffer solutions employed were from pH 2.5 to 8 a sodium phosphate-citric acid buffer and from pH 8 to 11 a sodium borate buffer. The medium generally used was 40 % aqueous alcohol containing 1 M potassium chloride and 0.008 % gelatin. In a few cases the alcohol was replaced by peroxide-free dioxane.

The following compounds were prepared according to *Organic Syntheses:* 2-Bromoacetophenone, desylchloride, deoxybenzoin, benzoin, and acetylbenzoin. By reaction between a bromoketone and an alkali metal salt in alcohol or acetonitrile were prepared: 2-Acetoxyacetophenone, m.p. 48.5°—49.5°, 2-acetoxy-4′-chlorobutyrophenone, m.p. 73.5°—74°, 2-acetoxy*iso*butyrophenone, m.p. 61°—61.5°, 2-thiocyanatoacetophenone, m.p. 72.5°—73.5°, 2-thiocyanato-4′-chloro-butyrophenone, m.p. 67°—67.5°. (Found: C 55.05; H 4.36; N 6.01; S 13.60. Calc. for $C_{11}H_{10}ClNOS$: C 55.10; H 4.20; N 5.85; S 13.37). 2-Thiocyanato*iso*butyrophenone, m.p. 20°—22°. (Found: C 64.31; H 5.31; N 6.60; S 15.56.

Calc. for $C_{11}H_{11}NOS$: C 64.36; H 5.40; N 6.83; S 15.63). 2-Thiocyanatodeoxybenzoin, m.p. 112.5°—113°. (Found: C 71.06; H 4.14; N 5.46; S 12.71. Calc. for $C_{15}H_{11}NOS$: C 71.12; H 4.38; N 5.53; S 12.66). Phenacyl phenyl ether, m.p. 73°—73.5°, phenacyl phenyl sulfide, m.p. 53°—53.5°, 2-cyanoacetophenone, m.p. 80.5°—81°, phenacyl nitrate, m.p. 53.5°—54° (4°—5° [20]). (Found: C 53.06; H 3.98; N 5.6—7.3. Calc. for $C_8H_7NO_4$: C 53.04; H 3.89; N 7.72). Although the nitrogen determinations were low and variable the compound isolated from the reaction between phenacyl bromide and silver nitrate in acetonitrile is believed to be phenacyl nitrate. The infrared spectrum of the compound contains strong bands at 1 640 cm^{-1} and 1 283 cm^{-1}; covalent nitrates generally absorb in the region 1 650—1 600 cm^{-1} and 1 300—1 250 cm^{-1}.

2-Bromo-2,2-diphenylacetophenone, 2-methoxy-2,2-diphenylacetophenone, and 2-hydroxy-2,2-diphenylacetophenone were made according to Stevens and DeYoung [21], and 2-(bromomethyl)-2-phenyl-1,3-dioxolane according to Kuhn [22].

Reduction of 2-acetoxyacetophenone: 1.00 g of 2-acetoxyacetophenone was reduced in 55 % alcoholic 0.1 N hydrochloric acid at a cathode potential of −0.9 V *vs* S.C.E. The reduction consumed 2.1 electrons per molecule. The odour of the reduction mixture suggested the presence of acetophenone, which was confirmed by polarographic analysis. To the solution were added 2.5 g of 2,4-dinitrophenylhydrazine; the precipitate was filtered off and recrystallized from amyl acetate, 1.05 g, m.p. 246°—248°. It was identified as the 2,4-dinitrophenylhydrazone of acetophenone.

2-Hydroxyacetophenone was reduced in 50 % alcoholic N hydrochloric acid as described above, $n = 2.0$. The product was isolated as described above; 1.55 g of acetophenone 2,4-dinitrophenylhydrazone.

In a similar manner *2-phenoxyacetophenone* was reduced at −0.85 V *vs* S.C.E.; $n = 2.0$. Isolated were 1.1 g of 2,4-dinitrophenylhydrazone of acetophenone.

2-Phenoxyacetophenone was also reduced in 50 % alcoholic 0.1 N sodium hydroxide at −1.5 V *vs* S.C.E., and in this case, too, the only isolated compound was the 2,4-dinitrophenylhydrazone of acetophenone (0.65 g).

2-Thiocyanatoacetophenone (1.00 g) was reduced in an acetate buffer, pH 5, containing 50 % alcohol at −0.85 V *vs* S.C.E., $n = 2.0$. From the reduction were isolated acetophenone as its 2,4-dinitrophenylhydrazone (1.5 g).

Reduction of 2-hydroxyisobutyrophenone: 1.00 g of 2-hydroxy*iso*butyrophenone was reduced in 50 % alcoholic N hydrochloric acid at −0.85 V *vs* S.C.E., $n = 2$. On the polarograms from the reaction medium a high wave followed by a very small one were visible at the beginning of the reduction; the first wave disappeared gradually whereas the second wave grew. After completion of the reduction 2,4-dinitrophenylhydrazine was added and the precipitate recrystallized from *n*-butanol, 1.65 g, m.p. 161°—162.5°. It was identified as the 2,4-dinitrophenylhydrazone of *iso*butyrophenone by the mixed m.p. 160°—162° with an authentic sample of *iso*butyrophenone 2,4-dinitrophenylhydrazone.

In a similar manner *2-thiocyanato*iso*butyrophenone* was reduced at −0.65 V *vs* S.C.E. in 50 % alcoholic N hydrochloric acid; $n = 2.0$. From the reduction mixture *iso*butyrophenone was isolated as its 2,4-dinitrophenylhydrazone (1.50 g) as described above.

Acetylbenzoin was reduced (1.00 g) in N hydrochloric acid containing 50 % dioxane; $n = 2$. The reduction mixture was diluted with water and extracted with ether which was dried and evaporated. The residue, 0.83 g, m.p. 45°—50°, was recrystallized from 4 ml methanol. Isolated were 285 mg deoxybenzoin, m.p. 60°, and from the mother liquor 430 mg of deoxybenzoin 2,4-dinitrophenylhydrazone, m.p. 201°—203°.

Cyclizations of Thiocarbohydrazide and its Mono-hydrazones Part II *. Reactions with Dialkyl Trithiocarbonates

JAN SANDSTRÖM

Department of Organic Chemistry, University of Lund, Lund, Sweden

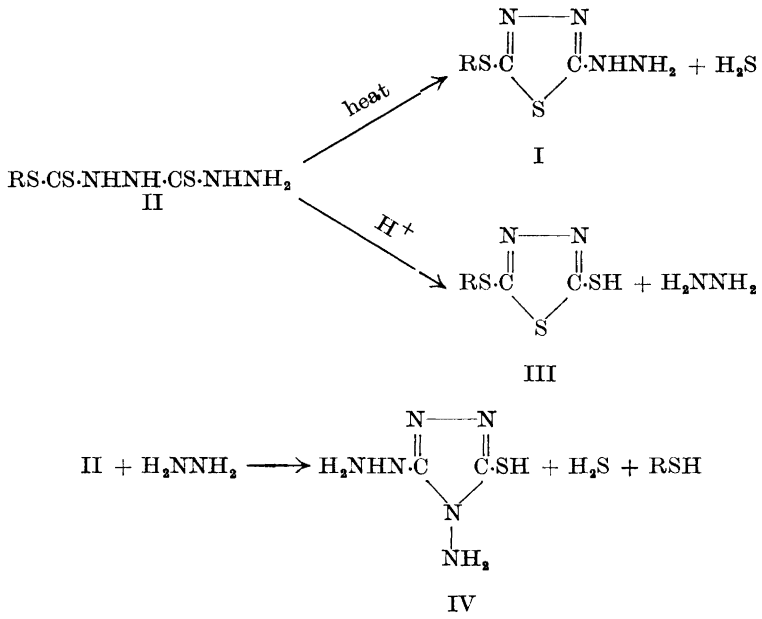
Thiocarbohydrazide and mono-thiocarbohydrazones react with trithiocarbonates in strongly alkaline solution to form dithiocarbalkoxy-thiocarbohydrazides and their hydrazones, respectively. When heated in the solid state, these compounds are cyclized, with elimination of hydrogen sulphide, to alkylthio-thiadiazolhydrazines and hydrazones, respectively. In acid medium, the products of decomposition are mercapto-alkylthio-thiadiazoles.

The present investigation was undertaken to test the possibilities of preparing 5-alkylthio-1,3,4-thiadiazol-2-yl-hydrazines (I) by reactions of thiocarbohydrazide or derivatives thereof with dialkyl trithiocarbonates. Thiocarbohydrazide was found to react with dimethyl trithiocarbonate only in strongly alkaline solution, with liberation of methanethiol and formation of 1-dithiocarbomethoxy-thiocarbohydrazide (II, R = CH_3) as alkali salt. The dithiocarbomethoxy-thiocarbohydrazide (II, R = CH_3) could be cyclized by two different methods. When heated above its melting point it eliminated hydrogen sulphide, methanethiol, and hydrazine, and from the reaction mixture could be isolated 5-methylthio-1,3,4-thiadiazol-2-yl-hydrazine (I, R = CH_3, isolated in 55 % yield as acetone hydrazone), 2-mercapto-5-methylthio-1,3,4-thiadiazole [1] (III, R = CH_3, 23 % yield), and 3-mercapto-4-amino-5-hydrazino-4,1,2-triazole [2] (IV, 10 % yield). The triazole (IV) may be formed in a side reaction between dithiocarbomethoxy-thiocarbohydrazide (II) and hydrazine.

The cyclization of (II) in acid medium followed a different course, with exclusive formation of 2-mercapto-5-methylthio-1,3,4-thiadiazole (III, R=CH_3) and hydrazine.

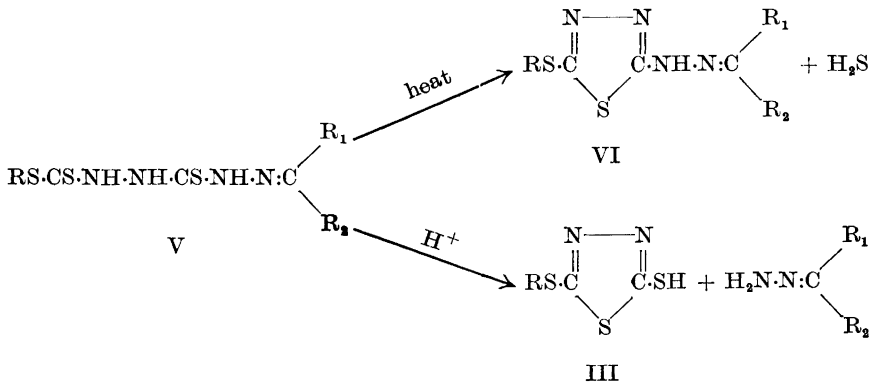
Mono-thiocarbohydrazones were found to react with dialkyl trithiocarbonates under the same conditions as thiocarbohydrazide, and the products were 5-dithiocarbalkoxy-thiocarbohydrazones (V). When heated above their melting points they eliminated hydrogen sulphide and gave alkylthio-thiadiazolylhydrazones (VI). The acetone 5-dithiocarbalkoxy-thiocarbohydrazones

* Part I. *Acta Chem. Scand.* **14** (1960) 1037.



I III IV

(V, $R_1 = R_2 = CH_3$) gave some acetone 5-mercapto-1,3,4-thiadiazol-2-yl-hydrazone (VI, R = H, $R_1 = R_2 = CH_3$) as by-product. The structure of the benzaldehyde 5-methylthio-1,3,4-thiadiazol-2-yl-hydrazone was demonstrated by its formation from benzaldehyde 5-mercapto-1,3,4-thiadiazol-2-yl-hydrazone (prepared according to Stollé and Fehrenbach [3]) and methyl iodide in alkaline solution.



V VI III

When the dithiocarbalkoxy-thiocarbohydrazones (V) were heated in hydrochloric acid solution, mercapto-alkylthio-thiadiazoles (III) were formed with elimination of the corresponding hydrazone, which could then be disproportionated to azine and hydrazine.

Like the analogues described in part I, the alkylthio-thiadiazolylhydrazones (VI) are weak acids. The alkylthio-thiadiazolylhydrazines (I) are quite stable in acid solution, and are conveniently prepared by acid hydrolysis of the corresponding acetone hydrazones.

EXPERIMENTAL

Preparation and decomposition of 1-dithiocarbomethoxy-thiocarbohydrazide (II, R = CH_3)

Thiocarbohydrazide (10.6 g, 0.1 mole) was dissolved in 2 N KOH in 75 % aqueous ethanol (50 ml), and dimethyl trithiocarbonate (7.0 g, 0.05 mole) in ethanol (50 ml) was added. After a few hours, the excess thiocarbohydrazide began to separate, and on the following day the filtrate was acidified with acetic acid, and the ethanol was taken off *in vacuo* at 20°. Then, colourless plates had separated (9.2 g, 93 % yield), m.p. 134—135° (decomp.) after recrystallization from 50 % aqueous ethanol. (Found: C 18.6; H 4.07; N 28.6; S 48.5. $C_3H_8N_4S_3$ (196.30) requires C 18.4; H 4.11; N 28.5; S 49.0).

Thermal decomposition.

Dithiocarbomethoxy-thiocarbohydrazide (II, R = CH_3, 98 g) was heated at 160° until the evolution of gas had ceased. After cooling, the residue was extracted at 50° with N HCl (600 ml). The mixture was cooled to 0°, and the undissolved material was separated (18.5 g). It crystallized from toluene as colourless rods, m.p. 136—137°, consisting of 2-mercapto-5-methylthio-1,3,4-thiadiazole (III, R = CH_3). (Found: C 22.0; H 2.60; N 16.8; S 58.5. $C_3H_4N_2S_3$ (164.25) requires C 21.9; H 2.45; N 17.1; S 58.6).

The acid filtrate was evaporated *in vacuo* to about one fourth of the original volume. A further quantity (0.8 g) of less pure mercapto-methylthio-thiadiazole was separated, and then a solution of crystalline sodium acetate (140 g) in water (100 ml) was added. A pale brown crystalline deposit (68.5 g) was obtained, which was extracted with three portions of boiling ethanol (together 400 ml). The undissolved material was a white, microcrystalline powder (7.2 g), m.p. 226—227° (decomp.), consisting according to analysis of 3-mercapto-4-amino-5-hydrazino-4,1,2-triazole (IV). For this compound Hoggarth [2] reports m.p. 232°. (Found: C 16.5; H 4.23; N 57.9; S 22.3. $C_2H_6N_6S$ (146.18) requires C 16.4; H 4.14; N 57.5; S 21.9).

A dibenzylidene derivative was prepared according to Hoggarth as pale yellow plates, m.p. 242—244° (245—246° according to Ref.[2]) (Found: C 60.2; H 4.62. $C_{16}H_{14}N_6S$ (322.38) requires C 59.6; H 4.38).

To the ethanolic filtrate from the triazole (IV) was added acetone (40 ml) in water (400 ml). Pale yellow rods separated (56.0 g), which crystallized from ethanol as colourless rods, m.p. 162—163°, consisting of acetone 5-methylthio-1,3,4-thiadiazol-2-yl-hydrazone (VI, R = R_1 = R_2 = CH_3). (Found: C 35.4; H 4.92. $C_6H_{10}N_4S_2$ (202.29) requires C 35.6; H 4.98). λ_{max}: 2 980 Å with ε : 14 900. From the filtrate of the acetone thiadiazolylhydrazone no further definable products could be isolated.

Decomposition in acid solution.

Dithiocarbomethoxythiocarbohydrazide (II, 2.0 g) was refluxed for 10 min. in ethanol (10 ml) and 5 N HCl (5 ml). The ethanol was removed *in vacuo*, and the solution was cooled. Colourless rods separated (1.5 g, 90 % yield), m.p. 136—137° after recrystallization from toluene, consisting of 2-mercapto-5-methylthio-1,3,4-thiadiazole (III). (Found: N 16.9; S 58.4. $C_3H_4N_2S_3$ (164.25) requires N 17.1; S 58.6). For this compound Busch [1] reports m.p. 136°.

Benzaldehyde (2.2 g) in ethanol (10 ml) was added to the acid filtrate, and benzalazine (1.9 g, 90 % yield) crystallized at once, m.p. and mixed m.p. 92—93°.

5-Dithiocarbalkoxy-thiocarbohydrazones (V)

The general procedure for the preparation of these compounds was to dissolve the appropriate mono-thiocarbohydrazone (Part I) in 2 equivalents of N sodium ethoxide in absolute ethanol, add the calculated quantity of the dialkyl trithiocarbonate, and leave the solution at room temperature for 24 h. Addition of the calculated volume of N acetic acid was generally sufficient to precipitate most of the product, but often a further quantity could be obtained by evaporating the mother liquor. On recrystallization, prolonged heating must be avoided. As the compounds melt with decomposition, the melting points are not sharp and are of little use for characterization.

Acetone dithiocarbomethoxy-thiocarbohydrazone (V, R = R_1 = R_2 = CH_3) was obtained in 65 % yield and crystallized from ethanol as colourless rods, m.p. 134–139° (decomp.). (Found: C 30.1; H 5.13; N 23.4; S 41.0. $C_6H_{12}N_4S_3$ (236.37) requires C 30.5; H 5.12; N 23.7; S 40.7). λ_{max}: 3 200 Å with ε: 13 300, λ_{max}: 2 690 Å with ε: 22 800.

Acetone dithiocarbobenzoxy-thiocarbohydrazone (V, R = $PhCH_2$, R_1 = R_2 = CH_3) was obtained from acetone mono-thiocarbohydrazone and dibenzyl trithiocarbonate in 55 % yield, and crystallized from absolute ethanol as colourless rods, m.p. 132–138° (decomp.). (Found: C 46.3; H 5.28; N 17.9; S 31.0. $C_{12}H_{16}N_4S_3$ (312.46) requires C 46.1; H 5.16; N 17.9; S 30.8).

Benzaldehyde dithiocarbomethoxy-thiocarbohydrazone (V, R = CH_3, R_1 = H, R_2 = Ph) was obtained in quantitative yield, and crystallized from a mixture of absolute ethanol and toluene as colourless hairs, m.p. 185–195°. (Found: C 42.2; H 4.23; N 19.9; S 33.6. $C_{10}H_{12}N_4S_3$ (284.41) requires C 42.2; H 4.25; N 19.7; S 33.8).

Acetophenone dithiocarbethoxy-thiocarbohydrazone (V, R = C_2H_5, R_1 = CH_3, R_2 = Ph) was obtained in 85 % yield when monoacetophenone thiocarbohydrazone reacted with diethyl trithiocarbonate under the conditions described above. It crystallized from ethanol as colourless plates, m.p. 178–179° after considerable sintering between 130 and 140°. (Found: C 46.4; H 5.16; N 18.0; S 30.8. $C_{12}H_{16}N_4S_3$ (312.46) requires C 46.1; H 5.16; N 17.9; S 30.8).

Monobenzophenone thiocarbohydrazone has not been described before. It was prepared like the mono-thiocarbohydrazones described in Part I, in 45 % yield, and it crystallized from glacial acetic acid as long, pale yellow plates, m.p. 213–214° (decomp.) (Found: C 62.5; H 5.20; N 20.5; S 11.7. $C_{14}H_{14}N_4S$ (270.34) requires C 62.2; H 5.22; N 20.7; S 11.9).

Benzophenone dithiocarbomethoxy-thiocarbohydrazone (V, R = CH_3, R_1 = R_2 = Ph) was obtained in quantitative yield and crystallized from a mixture of absolute ethanol and toluene as colourless rods, m.p. 155–158°. (Found: C 53.7; H 4.60; N 15.6; S 26.8. $C_{16}H_{16}N_4S_3$ (360.50) requires C 53.3; H 4.47; N 15.6; S 26.7).

Alkylthio-thiadiazolylhydrazones (VI)

These were prepared by heating the dithiocarbalkoxy-thiocarbohydrazones above their melting points until the evolution of gas had ceased. The molten residues crystallized on cooling and could in most cases be recrystallized directly, if the comparatively small amounts of by-products did not interfere.

Acetone 5-methylthio- and 5-mercapto-1,3,4-thiadiazol-2-yl-hydrazone (VI, R = R_1 = R_2 = CH_3, and VI, R = H, R_1 = R_2 = CH_3). The residue after melting acetone dithiocarbomethoxythiocarbohydrazone consisted of a mixture of acetone methylthiothiadiazolylhydrazone and its 5-mercapto analogue. Boiling toluene extracted the former, and when the toluene was taken off *in vacuo* the product was obtained in 80 % yield. It crystallized from ethanol as colourless rods, m.p. 162–163°, not depressed on admixture with the hydrazone described on p. 000. (Found: C 35.2; H 4.95; N 27.4; S 32.0. $C_6H_{10}N_4S_2$ (202.29) requires C 35.6; H 4.98; N 27.7; S 31.7). The toluene-insoluble material (VI, R = H, R_1 = R_2 = CH_3, 15 % yield) crystallized from ethanol as colourless rods, m.p. 216–217° (decomp.). (Found: C 31.9; H 4.14; N 29.8; S 34.2; equiv.wt.: 189.6. $C_5H_8N_4S_2$ (188.26) requires C 31.9; H 4.28; N 29.8; S 34.1). λ_{max}: 3 270 Å with ε: 17 500. When this compound was methylated with methyl iodide in alkaline solution, the methylthio derivative described above was formed.

Acetone benzylthio-thiadiazolylhydrazone (VI, R = $PhCH_2$, R_1 = R_2 = CH_3) was obtained in 70 % yield after separation from 15 % of the thiol (VI, R = H, R_1 = R_2 = CH_3).

It crystallized from absolute ethanol as colourless rods, m.p. 139—140°. (Found: C 51.5; H 5.07; N 20.3; S 23.3. $C_{12}H_{14}N_4S_2$ (278.38) requires C 51.8; H 5.07; N 20.1; S 23.0).

Benzaldehyde methylthio-thiadiazolylhydrazone (VI, R = CH_3, R_1 = H, R_2 = Ph) was obtained in 70 % yield after recrystallization from *n*-butanol, colourless rods, m.p. 208—209°. (Found: C 48.3; H 4.08; N 22.4; S 25.6. $C_{10}H_{10}N_4S_2$ (250.33) requires C 48.0; H 4.03; N 22.4; S 25.6). λ_{max}: 3 350 Å with ε: 25 000; λ_{max}: 2 540 Å with ε: 8 300; λ_{max}: 2 260 Å with ε: 13 700.

Benzaldehyde 5-mercapto-1,3,4-thiadiazol-2-yl-hydrazone (V, R = R_1 = H, R_2 = Ph, 0.20 g), prepared according to Stollé and Fehrenbach [3], was dispersed in ethanol (3 ml). Methyl iodide (0.2 g) and N NaOH (1 ml) were added, and the hydrazone rapidly dissolved. Within a few minutes a pale yellow precipitate began to form (0.22 g), which crystallized from *n*-butanol as colourless rods, m.p. and mixed m.p. 208—209°. The UV spectrum of this specimen was found to be identical with that of the benzaldehyde methylthio-thiadiazolylhydrazone described above.

Acetophenone ethylthio-thiadiazolylhydrazone (VI, R = C_2H_5, R_1 = CH_3, R_2 = Ph) was obtained in 80 % yield after recrystallization from ethanol. Colourless rods, m.p. 182—183°. (Found: C 51.9; H 5.04; N 20.2; S 22.9. $C_{12}H_{14}N_4S_2$ (278.38) requires C 51.8; H 5.04; N 20.1; S 23.0). λ_{max}: 3 250 Å with ε: 20 500; λ_{max}: 2 260 Å with ε: 11 700.

Benzophenone methylthio-thiadiazolylhydrazone (VI, R = CH_3, R_1 = R_2 = Ph) was obtained in 87 % yield. It crystallized from toluene as pale yellow, irregular prisms, m.p. 170—171°. (Found: C 58.9; H 4.41; N 17.2; S 19.6. $C_{16}H_{14}N_4S_2$ (326.42) requires C 58.9; H 4.32; N 17.2; S 19.6).

Decomposition of dithiocarbalkoxy-thiocarbohydrazones in acid solution

Acetone dithiocarbomethoxy-thiocarbohydrazone was decomposed exactly as dithiocarbomethoxy-thiocarbohydrazide (II, p. 1941). The same products were obtained in much the same yields.

Benzaldehyde dithiocarbomethoxy-thiocarbohydrazone (2.8 g) was refluxed in ethanol (50 ml) and concentrated hydrochloric acid (1 ml) for 5 min. The mixture was evaporated to dryness on a boiling water bath, and the residue was extracted with water (10 ml), and the extract added to benzaldehyde (1.2 g) in ethanol (10 ml). Benzalazine (0.95 g, 90 % yield) separated, m.p. and mixed m.p. 92—93°. The water-insoluble residue was ground with N NaOH (20 ml), and benzalazine (1.0 g, 96 % yield) remained undissolved. The alkaline solution was acidified with N HCl, and colourless rods were deposited (1.4 g, 87 % yield), m.p. 135—136°, not depressed by addition of mercapto-methylthio-thiadiazole (III, R = CH_3). Obviously the initially formed benzaldehyde hydrazone had disproportionated to benzalazine and hydrazine.

Alkylthio-thiadiazolylhydrazines (I)

Methylthio-thiadiazolylhydrazine (I, R = CH_3). Acetone methylthio-thiadiazolylhydrazone (20.3 g) was refluxed for one hour with ethanol (100 ml) and 5 N HCl (100 ml). The solvents were removed by distillation under reduced pressure, and the flask was immersed in a boiling water bath to prevent the separation of unchanged starting material. The dry residue was dissolved in ethanol (200 ml) and ether (800 ml) was added. A hydrochloride of not very well defined composition separated as colourless prisms (18.3 g). It was dissolved in water (200 ml), and the free thiadiazolylhydrazine was precipitated by the addition of crystalline sodium acetate (30 g). Colourless rods separated at once (13.5 g, 83 % yield), m.p. 117—118° after recrystallization from toluene. (Found: C 22.4; H 3.69; N 34.6; S 39.4. $C_3H_6N_4S_2$ (162.23) requires C 22.2; H 3.73; N 34.5; S 39.5). λ_{max}: 2 820 Å with ε: 8 200.

Benzylthio-thiadiazolylhydrazine (I, R = $PhCH_2$). Acetone benzylthio-thiadiazolylhydrazone was hydrolyzed as above, but the isolation of a crystalline hydrochloride was not attempted. Instead, the residue after evaporation was directly dissolved in water, and the hydrazine was precipitated by the addition of crystalline sodium acetate. The

yield was 76 %, colourless rods with m.p. 111—112° after recrystallization from absolute ethanol. (Found: C 45.4; H 4.30; N 23.5; S 26.7. $C_9H_{10}N_4S_2$ (238.32) requires C 45.4; H 4.32; N 23.5; S 26.9).

The UV-spectra were recorded with a Beckman DU spectrophotometer in absolute ethanol solution.

The technical assistance of Miss Monica Linders is acknowledged. The investigation has been supported by grants from the *Swedish Natural Science Research Council*, from *Stiftelsen Lars Hiertas Minne*, and from *Hierta-Retzius Stipendiefond*.

The Extraction of Uranium(VI) with DBP in the Presence of TBP. The "Synergic" Effect: Substitution or Addition?

DAVID DYRSSEN and LIBOR KUČA*

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The nature of the mixed complexes, $UO_2A_2(HA)_xB_y$, of the uranyl ion with di-*n*-butyl phosphate (DBP = HA) and tri-*n*-butyl phosphate (TBP = B) in carbon tetrachloride has been investigated at at 25°C by measuring the distribution ratio q of ^{233}U between carbon tetrachloride and 0.1 M sulfuric acid. At concentrations of DBP between 0.0003 and 0.06 M, and of TBP between 0 and 0.1 M, two complexes are formed, namely $UO_2A_2(HA)_2$ at low $[B]_{org}[HA]_{org}^{-1}$, and $UO_2A_2(HA)B$ at high $[B]_{org}[HA]_{org}^{-1}$. The value obtained for the equilibrium constant of the following reaction in carbon tetrachloride

$$UO_2A_2(HA)_2 + B \rightleftharpoons UO_2A_2(HA)B + HA$$

is $\log K_{20}^{-1}K_{11} = -3.0 \pm 0.2$. The concentrations of free HA and B were calculated from data of Dyrssen and Liem [9].

It may thus be stated that in the present case the »synergic» effect is due to substitution rather than addition.

Dialkyl phosphates have proved to be efficient extraction agents for lanthanide and actinide ions. At present, extraction with dialkyl phosphates has been developed by Brown and his co-workers at Oak Ridge to an industrial process for extraction of uranium from acid solutions [1]. In the course of systematic studies of various classes of organic phosphorus compounds as extracting agents for uranium, it was noticed that the addition of non-ionic phosphorylated reagent, X_3PO (X = alkyl group R or alkoxy group RO), to the dialkyl phosphate, $(RO)_2POOH$, increased the distribution ratio considerably. This enhancement of U(VI) extraction has been called a »synergic» (synergistic, synergetic) effect.

Let us denote the dialkyl phosphate, which is an acid, by HA, and the non-ionic phosphorylated compound, *i.e.* TBP, by B. It should be noted that HA, dissolved in an inert organic solvent like CCl_4 or hexane, exists predo-

* Present address: Institute of Nuclear Research, Prague, Czechoslovakia.

minantly in the form of a dimer, H_2A_2. The extraction of uranyl, in the absence of B, may be expressed by the equation [2-4]:

$$UO_2^{2+}(aq) + 2H_2A_2(org) \rightleftharpoons UO_2A_2(HA)_2(org) + 2H^+(aq)$$

Two explanations of the »synergic» effect have been proposed, but neither has had up to now, adequate experimental support.

According to one hypothesis, which has been proposed by Brown *et al.*[1] the non-ionic molecule B is *added* to the previous complex through a hydrogen bond:

$$UO_2A_2(HA) + B \rightleftharpoons UO_2A_2(HA)_2B$$

There is said to be some experimental evidence for this hypothesis [5].

On the other hand, Kennedy [6] suggests that two molecules of B substitute for two molecules of HA:

$$UO_2A_2(HA)_2 + 2B \rightleftharpoons UO_2A_2B_2 + (HA)_2$$

Some indirect evidence [7] for this hypothesis is given by Kennedy's observation that a non-ionic phosphorylated resin absorbs uranium as UO_2A_2 from a solution of uranium di-*n*-butyl phosphate in benzene, and liberates HA.

In two preceding papers from this laboratory [8,9], the reactions of di-*n*-butyl phosphate (DBP = HA) with various solvents — among these tri-*n*-butyl phosphate (TBP = B) — was studied. The data make it possible to calculate the concentrations of individual species in the system DBP-TBP-CCl_4-H_2O, namely, HA and A^- in the aqueous phase, and HA, H_2A_2, B, and HAB in the organic phase.

The present work has aimed at studying the distribution of uranium (VI) between CCl_4 and 0.1 M H_2SO_4. The experiments were so planned that either the concentration of free HA in the organic phase, $[HA]_{org}$ was kept constant, and $[B]_{org}$ was varied, or $[B]_{org}$ was kept constant, and $[HA]_{org}$ was varied.

Our results elucidate the mechanism of the so-called synergic effect for the DBP-TBP-CCl_4 system, and it seems possible in this case to decide between the two mechanisms proposed: addition or substitution.

EXPERIMENTAL

The di-*n*-butyl phosphate (DBP = HA) was supplied by Albright and Wilson Ltd, London. It was purified in the way previously described [9]. Tri-*n*-butyl phosphate (TBP = B), Kebo, Stockholm, was purified as follows: first it was stirred for several hours with the same volume of 4 % NaOH. After that, 4 % $KMnO_4$ was added dropwise to the NaOH, still with vigorous stirring. At first, the solution was decolorized, but after the addition of a certain amount of $KMnO_4$, the color remained constant. The TBP was then washed with 0.1 M HNO_3 and water, and finally dried at 130°C in a slow current of dry N_2 gas at reduced pressure. Carbon tetrachloride (Merck) was of analytical grade and was not further purified.

A solution of $^{233}U(VI)$ in 0.1 M H_2SO_4 was made from sulfuric acid, *pro analysi* (Merck). The α-emitter ^{233}U was purchased in the form of $UO_3(H_2O)_2$ from AERE, Harwell, England. In most experiments, the initial concentration of U(VI) in the aqueous phase was 6.9×10^{-6} M, which is negligible in comparison with the total concentration of HA(B).

In experiments with log $[HA]_{org} = -5.50$, the concentration of uranium(VI) was 3.7×10^{-5} M. Also in this case, the concentration of U in the organic phase was negligible in comparison with the concentration of HA (see below).

All experiments were carried out at 25°C in thermostated rooms. The practical details of the distribution experiments have been described in a previous paper [4]. The α-activity was measured in a Tracerlab SC-16 windowless proportional counter. The distribution ratio q of ^{233}U was calculated as before [4].

In the measurements, the aqueous phase contained 0.1 M H_2SO_4; thus we may calculate $[H^+] = 0.133$ M, using the data of Bray and Liebhafsky [10].

We decided to work with sulfate medium in order to bring the distribution ratio into a suitable range for measurement ($3 > \log q > -3$). A 1 M $HClO_4$ medium might have been used, but extraction of some $HClO_4$ with TBP [11], and of some uranium as $UO_2(ClO_4)_2(TBP)_2$, might occur. Nitrate medium would not be suited for these studies, since uranium would be extracted — in the form of $UO_2(NO_3)_2(TBP)_2$ or $UO_2(NO_3)_2(DBP)_2$ — to an even greater extent than from perchlorate medium [12-15].

CALCULATION OF $[HA]_{org}$ AND $[B]_{org}$

The symbols are in general the same as in our earlier work on similar systems [9]. Let us denote the concentrations of free HA and B in the organic phase as:

$$[HA]_{org} = a;\ [B]_{org} = b$$

Let K_d be the distribution constant for monomer HA between organic and aqueous phase, K_a the acidity constant of HA in the aqueous phase, K_2 the equilibrium constant for dimerization of HA in the organic phase and K the association constant of HA and B. Then we have ([HA] and $[A^-]$ refer to the aqueous phase):

$$[HA] = aK_d^{-1};\ [A^-] = aK_d^{-1}K_a h^{-1};\ [H_2A_2]_{org} = K_2a^2\ ;\ [HAB]_{org} = Kab$$

Since the volumes of the organic and aqueous phases are equal, we may simply add the concentrations in two phases; the »total concentrations» of HA and B are then:

$$A = a(1 + K_d^{-1} + K_d^{-1}K_a h^{-1}) + 2K_2a^2 + Kab$$

$$B = b(1 + Ka)$$

Since K and K_2 refer to reactions in the organic phase only, it seems reasonable that they would be almost the same as in previous studies [9] on the distribution between CCl_4 and 0.1 M HNO_3, namely:

$$\log K_2 = 6.49\ ;\ \log K = 2.84$$

In the first calculation, a value of K_d (determined for the 0.1 M HNO_3 medium), was used: $\log K_d = -1.44$. Due to the difference in ionic strength between 0.1 M $HClO_4$ and 0.1 M H_2SO_4, $\log K_a$ was chosen as -0.98 instead of -1.00 (Ref.[8]). These values were used initially, since no radioactive DBP was available at the time, to measure the distribution of HA between CCl_4 and 0.1 M H_2SO_4 directly. However, as we shall see later, the measurements on uranium distribution will suggest that the constants for the sulfuric acid system are somewhat different from those determined for 0.1 M HNO_3. We

may note that Hardy and Scargill [16] give values of K_2 and K_d with 1 M HNO_3 that differ somewhat from our values [9] with 0.1 M HNO_3.

As already mentioned, the concentration of uranium is always so low in the organic phase that it can be neglected in comparison with A and B.

THE DATA

The Tables 1 and 2 gives the primary experimental data which consist of the total concentrations A and B, the distribution ratio q and the calculated values for $[HA]_{org} = a$ and $[B]_{org} = b$. The values of A and B have been chosen to give the values for a and b, using the known equilibrium constants.

Table 1. Data for the distribution of ^{233}U between equal volumes of CCl_4 and 0.1 H_2SO_4 at different total molar concentrations of DBP (= A) and TBP (= B). These concentrations have been calculated (see text) in such a manner that the concn. of free DBP was kept constant in the organic layer while the concn. of free TBP was varied stepwise. In Fig. 1 the distribution of U(VI) is plotted as log q $[A^-]^2$ against log $[HA]_{org}$ (= log a) for different values of log $[B]_{org}$ (= log b).

	−2.30	+0.81	−3.30	−1.71

In Fig. 1, the data are plotted in the form log $q[A^-]^{-2}$ *versus* log $[HA]_{org}$. Points with the same symbol have the same calculated value for b. (The values of a and b were calculated with the set of constants for 0.1 M HNO_3 and may thus have to be slightly corrected later on). The numbers in Fig. 1 denote the slope of the linear parts of the curves.

At the lowest value for b, up to log $b \sim -3$, the experimental points approached the curve obtained for $b = 0$. As shown in earlier papers [2-4] this curve is determined in an inert solvent by the reaction

$$UO_2^{2+}(aq) + 2(HA)_2(org) \rightleftharpoons UO_2A_2(HA)_2(org) + 2H^+(aq)$$

The slope of the limiting curve in Fig. 1 is not exactly 2.0 as one might have expected, but about 2.3. This discrepancy can probably be ascribed to small errors in the equilibrium constants used for the calculation of a and b.

At the highest values for a, the curves bend in the other direction, with a slope of −1.7 instead of +2; moreover, the addition of B now has no influence at all. This effect has not been studied more closely. It may be that UO_2SO_4 is extracted to some extent and, UO_2^{2+} and A^- possibly form complexes in the aqueous phase. It should be noted also that in this region, HA is further polymerized in the organic phase according to physico-chemical experiments made at our institute. Furthermore, there may be minor impurities [12,23] in the sample of ^{233}U, which could influence the measurements at $100 > q < 0.01$.

The fact that the curves spread out as log b increases above −2.5, proves that B in some way enters into complexes with the uranium. (It should be noted that the complex between HA and B has been allowed for and the concentrations used in Fig. 1 are the calculated concentrations of free HA and B).

As may been seen in Fig. 1 the slope of the curves decreases with increasing b. This indicates that some of the complexes, which may in general be written as $UO_2A_2(HA)_xB_y$, contain less than 2 HA. Thus the effect cannot be explained by addition compounds only.

At low $[HA]_{org}$ the same upward bend in the curves is observed as previously [4] with the DBP-hexone system. In this case it was concluded, that in addition to $UO_2A_2(HA)_2$ a complex $UO_2A_2(hexone)_x$ was extracted at low [HA].

Let us start with the simplest assumption that might be consistent with these data, namely that, besides $UO_2A_2(HA)_2$, only the first substitution complex, $UO_2A_2(HA)B$, appears in the organic phase.

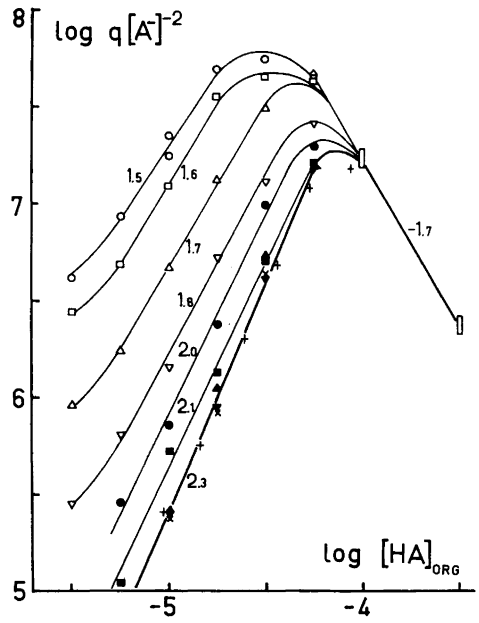

Fig. 1. The distribution of U(VI) between solutions of DBP (= HA) and TBP (= B) in CCl_4 and 0.1 M H_2SO_4. Each curve represents a constant value of the pre-calculated molar concn. of free TBP, $[B]_{org}$. The limiting curve for $[B]_{org} \leq 10^{-3}$ is shown as a thick line. The slopes of linear parts of the curves ars noted in the figure. Symbols (log $[B_{org}]$: ○ (0), □ (−0.5), △ (−1), ▽ (−1.5), ● (−2), ■ (−2.5), ▲ (−3), ▼ (−4), × (−5), and + (−∞, no TBP). The distribution of ^{233}U is independent of $[B]_{org}$ at log $[HA]_{org} = -4$ and −3.5.

For this case, let us define the equilibrium constants

$K_{20} = [UO_2A_2(HA)_2]_{org}\ [UO_2^{2+}]^{-1}[A^-]^{-2}[HA]_{org}^{-2}$

$K_{11} = [UO_2A_2HAB]_{org}\ [UO_2^{2+}]_{org}^{-1}[A^-]^{-2}[HA]_{org}^{-1}[B]_{org}^{-1}$

Moreover we use the conventional notation that $[UO_2^{2+}]$ stands for the sum of all complexes of UO_2^{2+} including those with SO_4^{2-} with the aqueous medium *. Assuming that $UO_2A_2(HA)_2$ and UO_2A_2HAB are the only species formed in the organic layer, the net distribution ratio is then:

$$q = ([UO_2A_2(HA)_2]_{org} + [UO_2A_2HAB]_{org})[UO_2^{2+}]^{-1} = [A^-]^2(K_{20}a^2 + K_{11}ab)$$

and

$$q[A^-]^{-2}a^{-2}K_{20}^{-1} = 1 + K_{11}K_{20}^{-1}ba^{-1}$$

* The amount of UO_2^{2+} bound to SO_4^{2-} can be estimated from separate experiments with 0.133 M $HClO_4$ (*cf.* Fig. 3). These data indicate that $[UO_2^{2+}]_{H_2SO_4}\ [UO_2^{2+}]^{-1}_{HClO_4} = 1 + \beta_1[SO_4^{2-}] + \beta_2[SO_4^{2-}]^2 \sim 10$, which agrees fairly well with the value that can be estimated from values of Davies and Monk [17] for β_1 and β_2.

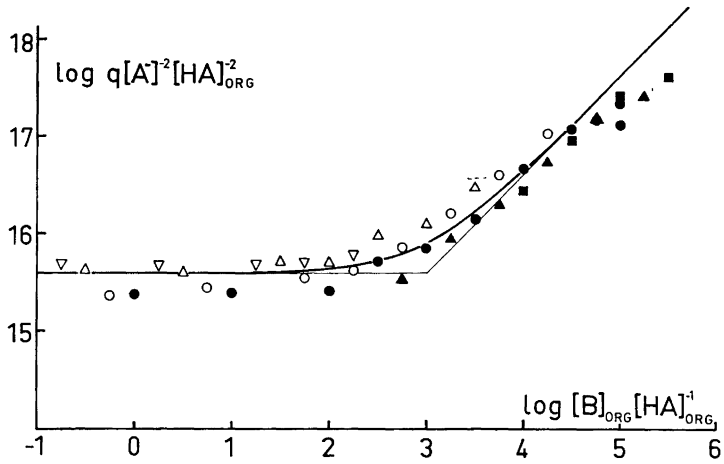

Fig. 2. Plot based on the assumption of the formation of a substitution complex in the CCl_4 phase, $UO_2A_2(HA)B$. The normalized curve log Y = log (1 + X) is fitted to the data. K_{20} and $K_{20}K_{11}^{-1}$ (see text) are obtained from the position of the asymptotes (thin lines) to the curve. Symbols denote different constant values of log [HA]org: ▽(−4.25), △(−4.50), ○ −4.75), ● (−5.00), ▲ (−5.25), and ■ (−5.50). The variables are calculated from data in Table 1.

In Fig. 2, the quantity log $q[A^-]^{-2}a^{-2}$ is plotted as a function of log ba^{-1}. Values on the descending parts of the curves in Fig. 1 are not included in Fig. 2. It can be seen from the figure that the experimental points fall reasonably well on the normalized curve log Y = log (1 + X). From the position of the asymtotes of the normalized curve one may calculate the values log K_{20} = 15.6 ± 0.2 and log K_{20} — log K_{11} = 3.0 ± 0.2. Hence log K_{11} = 12.6 ± 0.2

It thus seems that the data may be rather well explained by assuming that one HA in the original complex is substituted with B. From the present data there is no strong evidence for the second complex, $UO_2A_2B_2$, which, in the diagram, Fig. 2, would have caused a steeper slope of the curve at high ba^{-1}. However, it is quite possible that the second type of substitution complex, which has been proposed by Kennedy [6], may well exist with other more basic substituting substances B, for instance with phosphine oxides, R_3PO.

CONCLUSION

It does not seem possible to explain the data on the increased (synergic) extraction of uranyl by DBP in the presence of TBP by assuming the formation of addition compounds only, since with this assumption, one would have had a constant slope of 2 to the right in Fig. 1. In fact the slope really decreases with increasing b.

On the other hand, the substitution hypotesis seems to explain the data well; the diagram in Fig. 2 gives a good fit of the theoretical curve assuming

only one substitution. Thus, in addition to $UO_2A_2(HA)_2$ we would have $UO_2A_2(HA)B$ in the following concentration ranges: 0.0003 — 0.06 M DBP (= HA) and 0 — 1 M TBP (= B).

ADJUSTMENT OF $K_aK_d^2$

It remains however, to explain why in Fig. 1 the limiting slope for $b \to 0$ is +2.3 rather than +2.0 because the difference is, we feel, outside of the experimental error. There seems to be no reason to doubt the formula $UO_2A_2(HA)_2$ for the predominant complex in the organic phase [2-4] since it has been proved in many other systems. Small amounts [12,23] of the decay products of ^{232}U present in the sample of ^{233}U would rather have decreased the slope, and it is therefore reasonable to suppose that the difference is due to small errors in the values assumed for the equilibrium constants that determine a and b. Let us consider the case of a solution with no B added. The total concentration of A is then

$$A = [HA]_{org} + [HA] + [A^-] + 2[H_2A_2]_{org} = a(1 + K_d^{-1}(1 + K_a h^{-1})) + 2a^2K_2$$

With the previous definition of K_{20} we have

$$[UO_2A_2(HA)_2]_{org} = K_{20}[UO_2^{2+}][A^-]^2a^2 = [UO_2^{2+}]K_{20}a^4h^{-2}K_d^{-2}K_a^2 = q[UO_2^{2+}]$$

In these experiments, the hydrogen ion concentration h is a constant, and we may simplify these equations. Normalizing, we find

$A = \alpha + L_2\alpha^2$ and $q = L_1\alpha^4$, where

$$\alpha = a(1 + K_d^{-1}(1 + K_a h^{-1})) \simeq aK_d^{-1}(1 + K_a h^{-1})$$

$$L_1 = K_{20}h^{-2}K_a^2(1 + K_d^{-1}(1 + K_a h^{-1}))^{-4} \simeq K_{20}h^{-2}K_d^2K_a^2(1 + K_a h^{-1})^4$$

$$L_2 = 2K_2(1 + K_d^{-1}(1 + K_a h^{-1}))^{-2} \simeq 2K_2K_d^2(1 + K_a h^{-1})^{-2}$$

L_2 and L_1 may be obtained by plotting on one axis (Fig. 3)

$$\log A - \tfrac{1}{4}\log q = \log(1 + L_2\alpha) - \tfrac{1}{4}\log L_1$$

and, on the other axis,

$$\tfrac{1}{4}\log q = \log \alpha + \tfrac{1}{4}\log L_1$$

Comparing this plot with the normalized curve, $Y = \log(1 + X)$ we find, from the positions of the coordinates,

$$\tfrac{1}{4}\log L_1 - \log L_2 = 0.35 \text{ and } \tfrac{1}{4}\log L_1 = 2.74$$

Using $K_a h^{-1} = 0.8$ we obtain

$$\log K_2 + 2\log K_d = 3.3_0$$

whereas the value for this sum was 3.61 for nitrate medium. Fig. 3 also gives the corresponding data for 0.133 M $HClO_4$, which can be fitted, within the experimental error, with $\log K_2K_d^2 = 3.61$, the same value as in 0.1 M HNO_3.

For 0.1 M H_2SO_4 we may accept $\log K_2K_d^2 = 3.3_1$ assuming $\log K_2 = 6.49$ as with 0.1 M HNO_3 and thus giving $\log K_d = -1.59$. Using these constants

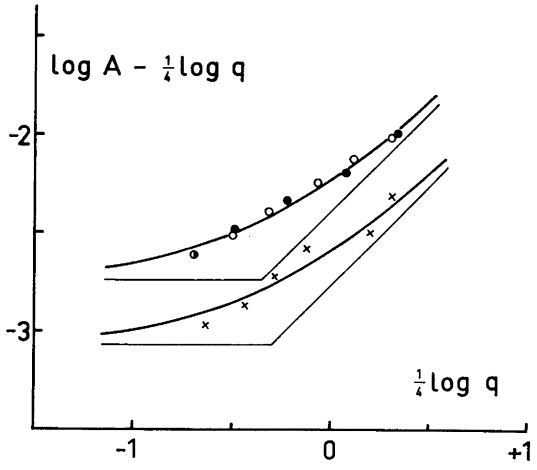

Fig. 3. Determination of $K_2K_d^3$ for the 0.1 M H_2SO_4 medium. The normalized curve log Y = log (1 + X) is fitted to the data: O experiments with no TBP, ● experiments with $[TBP]_{org} \leq 10^{-3}$M, × aq. phase 0.133 M $HClO_4$, no TBP. The point of intersection of the asymptotes to the curves gives the values of ¼ log L_1 − log L_2 and ¼ log L_1 (se text).

the data in Table 1 were recalculated. They are plotted in Fig. 4, and it is seen that the spread is less than in Fig. 2. This gives additional support to the interpretation of the nature of the complexes $UO_2A_2(HA)_xB_y$. The deviation from the theoretical curve at high ba^{-1} is probably due to a decrease in

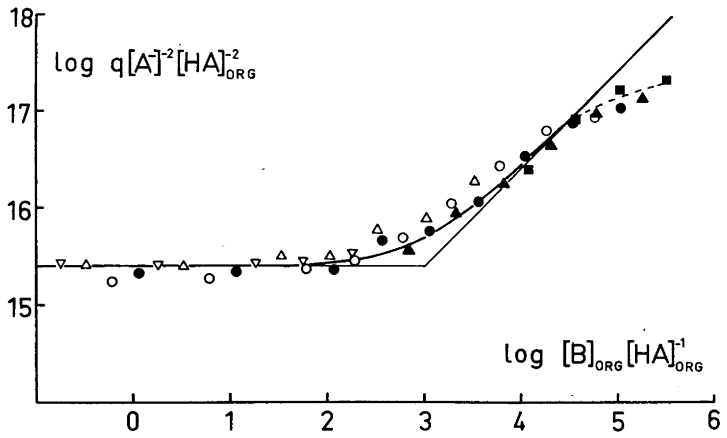

Fig. 4. Plot based on recalculated values of $[HA]_{org}$ (= a) and $[B]_{org}$ (= b) using log K_d = − 1.59 instead of −1.44 (*cf.* Fig. 2). The symbols refer to the same concentrations of DBP as in Fig. 2. The curve log Y = log(1 + X) is fitted to the data; deviation from this curve occurs with b = 0. 0.316 and 1 M. The position of the asymptotes (thin lines) gives log K_{20} = 15.4 ± 0.2 and log $K_{20}K_{11}^{-1}$ = 3.0 ± 0.2.

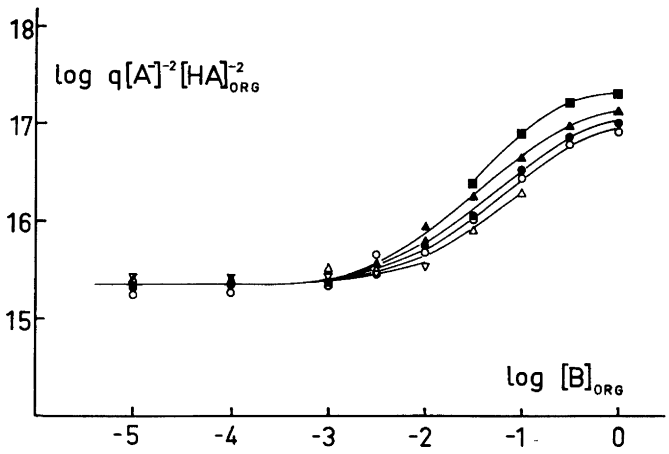

Fig. 5. Attempt to explain the synergic effect with the formation of $UO_2A_2(HA)_2B$. The choice of the variables is explained in the text. The symbols are defined in Fig. 2.

the activity coefficient of TBP in CCl_4 at $b = 0.317$ and 1 M (undiluted TBP is 3.66 M). From Fig. 4 one may calculate $\log K_{20} = 15.4 \pm 0.2$ and $\log K_{11} = 12.4 \pm 0.2$.

It may be worthwile to see whether the data can be explained by a simple addition mechanism, as proposed by Brown *et al.*[1], even if the curves in Fig. 1 are not favorable for such a hypothesis. If this were so, we would, instead of K_{11}, have to consider the equilibrium constant:

$$K_{21} = [UO_2A_2(HA)_2B]_{org}[UO_2^{2+}]^{-1}[A^-]^{-2}[HA]_{org}^{2}[B]_{org}^{-1}$$

As before, we would have obtained the expression

$$q[A^-]^{-2}a^{-2}K_{20}^{-1} = 1 + K_{20}^{-1}K_{21}b$$

Thus, if the experimental data had been plotted as $\log q[A^-]^{-2}a^{-2}$ *versus* $\log b$, a single curve should have resulted, which would have been fitted with a normalized curve $\log Y = \log (1 + X)$. As seen in Fig. 5, the spread is considerable at high b where the complex $UO_2A_2(HA)_2B$ would be formed. As in Fig. 4 the curves fall off at $b = 0.317$ and 1 M.

The calculations we have made in this part support the conclusion that was drawn from the uncorrected data in Figs. 1 and 2.

DISCUSSION

In calculating the economy of using the synergic effect with dialkyl phosphates, one must consider not only the formation of substitution complexes like $UO_2A_2(HA)B$ but also the dimerization of HA and the complex formation between HA and B in the organic phase.

If the cost of organic phosphorus per mole of uranium to be extracted is important, then the economy of a process should gain if the more expensive

dialkyl phosphates (HA) can in part be replaced by the less expensive trialkyl phosphates (B). However, if the constants K_{20} and K_{11} are compared, it may be seen that the replacement of HA with B requires a large value for $[B]_{org}[HA]_{org}^{-1}$ (*cf.* Figs. 2 and 4). The reason may be that the extra HA in $UO_2A_2(HA)_2$ are not only bound with the phosphoryl oxygens to U (which probably has the coordination number of 8 as in $UO_2(CH_3COO)_3^-$, Ref.[18]), but also with strong hydrogen bonds to the oxygen atoms in UO_2^{2+}; the basicity of the PO groups in DBP and TBP should be about the same.

The difference between DBP (= HA) and TBP (= B) as solvate molecules may be further stressed if we compare the two reactions

$UO_2^{2+}(aq) + 2\ NO_3^-(aq) + 2HA\ (toluene) \rightleftharpoons UO_2(NO_3)_2(HA)_2\ (toluene)$

and

$UO_2^{2+}(aq) + 2NO_3^-(aq) + 2B\ (benzene) \rightleftharpoons UO_2(NO_3)_2B_2\ (benzene)$

From data as Hardy [12] and of Healy and Kennedy [19] we may calculate the equilibrium constants of these reactions as log K = 6.76 and 1.44. With the more basic compound tributyl phosphine oxide, Bu_3PO, the value of log K is 4.62 for benzene.

It may be noted that Brown *et al.*[1] have shown that q increases more (using dioctyl phosphate as HA), if the more basic tributyl phosphine oxide (TBPO) is added than if TBP is added. It is possible that B = TBPO can replace two HA = DBP (*cf.* Kennedy [7]) at a value of $[B]_{org}[HA]_{org}^{-1}$ where TBP only replaces one DBP. In the case of hexone [4], which is 8 M, evidence was found of UO_2A_2 at low [HA].

The complex formation between HA and B will diminish the loss of HA to the aqueous phase, but at the same time, this reaction will decrease the amount of free HA and B that can react with UO_2^{2+}. If the total load of organic phosphate per unit volume of the organic diluent, *e.g.* kerosene, needs to be kept low, then it might be more favorable to increase the concn. of HA than to add B. The situation should be different with a chelating agent like TTA, where the acid hydrogen is engaged in an intramolecular hydrogen bond and the tendency for the formation of H_2A_2 and HAB is thereby weak (*cf.* Edgington and Irving [20]).

As the extraction of tri- and tetravalent ions seems to decrease on the addition of neutral esters of phosphoric acid (*cf.* Refs.[21,22]), it may be possible in many cases to increase the separation of di- and tri- or tetravalent ions by adding neutral ligands to the organic layer.

Acknowledgements. The present investigation has been supported by the *Swedish Council of Atomic Research*, and by a grant from the *Institute of Nuclear Research*, Prague. The data have been treated in collaboration with the head of the department, Professor Lars Gunnar Sillén. The English text has been revised by Dr. Valentine Tyrrell. We wish to thank Mr. H.A.C. McKay for valuable comments on the manurcript and for support io obtaining the uranium-233.

Quantitative Determination of Pentetrazol

EVA ANDERSSON, MILES FORS and JAN-ERIK LINDGREN

Laboratory of the Swedish Pharmacopoeia Commission, Stockholm, Sweden

A method for quantitative determination of pentetrazol has been worked out based on the precipitation of the cadmium chloride complex and subsequent complexometric titration of the cadmium content in the precipitate.

Pentetrazol [Cardiazol ®, Leptazol (Belg. 30, Suppl. 51, B.P. 58), Pentylenetetrazol (U.S.P. 55)] has usually been determined with the help of its more or less insoluble complexes with different inorganic salts [1–8]. Several authors [1,4,5,7] have found the complex with cuprous chloride to be the most convenient for this purpose. Ph. Helv. 33, Add. 55 has admitted the cuprous chloride method of Dister [4], and the British Pharmacopoeia of 1958 a modification of it, worked out by Sharp [5]. We have examined both methods and found none of them to be accurate enough despite rigorous precautions. Since the accuracy of other methods, cited in literature, was judged not to be greater, we have on the suggestion of Dr. T. Canbäck * investigated the possibilities of using the complex proposed by Warren [2] for identification purposes, *i.e.* with cadmium chloride even for quantitative determination. The solubility of the cadmium chloride complex of pentetrazol in water is reported by several authors to be too great for quantitative precipitation. Warren [2] found it to be about 1:95 and Paulsen [7] reports the solubility in 0.1 M cadmium chloride to be 0.25 %. Paulsen [7] moreover reports that there are two different complexes with cadmium chloride, one with a composition of $CdCl_2 \cdot 2C_6H_{10}N_4$, obtained by mixing about equimolecular quantities of pentetrazol and cadmium chloride, and the other with a composition of $CdCl_2 \cdot C_6H_{10}N_4$, obtained by adding cadmium chloride in excess to a solution of pentetrazol, both compositions being determined after drying at 150°C.

As a result of this we have tried to find a suitable medium, where the solubility of the cadmium chloride complex, obtained by excess of the reagent, is small enough for quantitative precipitation. We have found that a mixture of *iso*propanol and water complies with this requirement and have worked out a method for quantitative determination of pentetrazol based on the precipi-

* Chairman of the Swedish Subcommittee on Chemistry.

tation of the cadmium chloride complex and subsequent complexometric titration of the cadmium content in the precipitate.

EXPERIMENTAL

The cadmium chloride complex, $C_6H_{10}N_4 \cdot CdCl_2 \cdot 3H_2O$ was precipitated with an excess of the reagent and isolated. The solubility of the complex was determined in different solutions of alkaline salts, hydrochloric acid and in some organic solvents. The complex was found to be more or less soluble in the solutions of alkaline salts and hydrochloric acid but almost insoluble in *iso*propanol. Cadmium chloride was found to have a solubility of about 1:1 000 in *iso*propanol and by using a mixture of *iso*propanol and water, it is possible to get a relatively strong reagent solution, without any risk of precipitation of the reagent. After some preliminary work we have found the following method suitable.

Mix 0.1500 g, dissolved in 2 ml of a mixture of 3 volume parts of *iso*propanol and 2 volume parts of water, with 10 ml of cadmium chloride-*iso*propanol-R. Filtrate the mixture after 10 min, during which time the bottle from time to time is swirled, through a glass crucible (3 G 4). Transfer the precipitate completely with the aid of the filtrate. Wash the filter twice with 5 ml of a mixture of 9 volume parts of *iso*propanol and 1 volume part of water, and finally 3 times with *iso*propanol, each time with 10 ml. Transfer the filter to another suction flask and dissolve the precipitate in 100 ml of water, heated to boiling-point. Cool the solution, add 10 ml of ammonium chloride-ammonia-R and 5 drops of eriochrome black-I and titrate immediately with 0.1 N tetracemindisodium to a blue colour. Each ml of 0.1 N tetracemindisodium is equivalent to 0.006909 g of $C_6H_{10}N_4$.

Reagents

Iso*propanol*, purum min. 99 %. B.p. 81–83°C.

Cadmium chloride-iso*propanol-R.* Dissolve 15.0 g of cadmium chloride ($CdCl_2 \cdot 2\frac{1}{2} H_2O$) in 40 ml of water by warming. Filter the solution and dilute with *iso*propanol to 100 ml after cooling. The solution must be freshly prepared.

Ammonium chloride-ammonia-R *. Dissolve 6.75 g of ammonium chloride (NH_4Cl) in 57 ml of strong ammonia solution and dilute with water to 100 ml.

Eriochrome black-I *. Dissolve 0.50 g of eriochrome black T and 4.5 g of hydroxylamine hydrochloride in 100 ml of methanol.

*0.1 N Tetracemindisodium 0.05 M**. Tetracemindisodium (EDTA, Komplexon, Titriplex) dissolved in water to contain in 1 000 ml 18.61 g of $C_{10}H_{14}O_8N_2Na_2 \cdot 2H_2O$.

DISCUSSION

The content of cadmium in the precipitate was determined after repeated washings and drying in the air and found to be 34.96 % (calculated for

$C_6H_{10}N_4 \cdot CdCl_2$: 34.96 %). By heating at 105°C and 150°C for about 20 h it did not lose appreciably in weight. According to Zwikker [1] and Paulsen [7] the complex hydrate $C_6H_{10}N_4 \cdot CdCl_2 \cdot 3H_2O$ (= 29.93 % Cd) loses its water by drying at 150°C and becomes anhydrous. The precipitate obtained in the mixture of *iso*propanol and water is therefore obviously anhydrous and has a composition of $C_6H_{10}N_4 \cdot CdCl_2$.

The solubility of the complex is 0.61 g/100 g (Table 1) in a mixture of 3 parts of *iso*propanol and 2 parts of water but in the presence of cadmium chloride, the solubility decreases so that a quantitative precipitation is possible. The solubility in the wash liquid, 9 parts of *iso*propanol and 1 part of water is 0.10 g/100 ml but the loss in the washing is unnoticeable, owing to the excess of cadmium chloride in the precipitate, which is only gradually washed out, and to the short time of the washing. For that reason correction for solubility is not necessary.

To obtain quantitative precipitation a certain excess of the precipitant is necessary. We have found that under the present conditions a quantity of cadmium chloride is required which is about 4 times that calculated (Fig. 1). We have chosen a somewhat greater excess, about 6 times the quantity calculated.

The precipitate does not appear until about half a minute after the addition of the reagent and it takes some minutes until the precipitation is complete. If the precipitate stands in contact with the mother liquid for a longer time than about 2.5 h, the precipitate is changed and passes easily through the filter, perhaps owing to hydrolysis to basic complexes (Fig. 2).

1 × 2 ml	2 × 2 ml	3 × 2 ml	1 × 5 ml	2 × 5 ml	3 × 5 ml	4 × 5 ml
36.47 %	35.60 %	34.82 %	35.25 %	34.96 %	34.98 %	34.98 %

Table 4. Results obtained with commercial samples: I, In original state; II, After one recrystallization from water.

	Sample A	Sample B	Sample C
I.	99.1—99.2—99.3— —99.1—99.2 %	100.2—100.2—100.0— —100.0—100.2—99.9— —100.2—100.0— —100.0—100.1 %	99.9—100.2—99.9— —100.1—99.9—99.8— —99.8—99.9—99.9— —99.8—99.6 %
II.	99.5—99.6 %	— — — — —	100.0—99.8 %

During the precipitation the bottle must be swirled from time to time, as otherwise low results are obtained (Table 2) and the precipitate sometimes becomes fine-grained and passes easily through the filter.

To wash out the great excess of cadmium chloride it is necessary to use a mixture of *iso*propanol and water. The water content of the wash liquid can however be decreased considerably compared with the mixture that is used in the reagent solution, since the precipitation of cadmium chloride of the reagent solution on the addition of more *iso*propanol is markedly delayed. When washed with 2×5 ml of a mixture of 9 volume parts of *iso*propanol and 1 volume part of water, the excess of cadmium chloride is removed from the precipitate (Table 3).

The results obtained with commercial samples are tabulated in Table 4.

The method can also be used for the determination of pentetrazol in plain aqueous solutions by adding *iso*propanol to the solution in the amount required to get the same proportion of *iso*propanol and water as is used for the substance.

The Structures of Co_2P, Ru_2P and Related Phases

STIG RUNDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structures of Co_2P and Ru_2P have been refined using single-crystal methods. Both phosphides crystallize in the *C* 23 structure type. A structural comparison with related phosphides and silicides is given.

Co_2P has an extended homogeneity range at higher temperatures, the phosphorus-rich limit at 1 000°C corresponds to the formula $Co_{1.94}P$. There are evidences that the widening of the homogeneity range is connected with random vacancies on metal atom sites.

The structure of Co_2P was originally determined by Nowotny [1]. According to him, the Co_2P structure belongs to the *C* 23 (anti-$PbCl_2$) type. The structure of Co_2Si was first investigated by Borén [2]. Borén *et al.*[3] also made a structure proposal based on X-ray powder data. This structure was later shown to be incorrect by Geller [4], who determined the Co_2Si structure by X-ray single-crystal methods. It was then recognized by Laves [5] that Co_2P and Co_2Si are isotypic, which was the first known case of isomorphism between a silicide and a phosphide of the same metal. Recently, a second case has been found for Ru_2P[6] and Ru_2Si[7], which are isostructural with Co_2P and Co_2Si.

From the crystal-chemical point of view it seems valuable to possess detailed structural information on the four above-mentioned phases. This paper gives an account of single-crystal structure determinations of Co_2P and Ru_2P. Some phase-analytical data for the binary Co_2P and Ru_2P, and the ternary $Co_2(P, Si)$ phases are also reported and discussed.

EXPERIMENTAL

Preparation. The starting materials for the preparation of the phosphides were cobalt rods (Johnson, Matthey & Co., Ltd., London, spectrographically standardized), ruthenium sponge (Heraeus, Hanau, Germany claimed purity 99.8 %) and red phosphorus (purity higher than 99 %). Master alloys of Co_2P were prepared according to a method, described in principle by Haughton [8] and Hägg [9]. Pellets of red phosphorus were dropped into molten cobalt. The melting was done by induction heating in a closed chamber in a purified argon atmosphere under reduced pressure. Cobalt phosphides of varying compositions were prepared by mixing appropriate quantities of the crushed master

alloys and heating the mixtures in evacuated and sealed silica tubes. Ruthenium phosphides were prepared directly by heating ruthenium sponge and red phosphorus in evacuated silica tubes. The alloys of both cobalt and ruthenium were protected from contacting the silica tube walls by placing them in small crucibles of recrystallized alumina (Degussit Al 23 from Degussa, Frankfurt).

Chemical analyses. Chemical analyses were made at the Department of Analytical Chemistry of this Institute under the direction of the head of the department, Dr. F. Nydahl.

The cobalt phosphides were dissolved in *aqua regia*, and the hydrochloric acid removed by evaporation with nitric acid. The residue was dissolved in dilute nitric acid and made up to volume. Aliquots were analysed for phosphorus and cobalt. Phosphate was precipitated as ammonium molybdophosphate and weighed as $P_2O_5 \cdot 24\ MoO_3$ according to Nydahl [10]. Cobalt was determined by titration with EDTA, standardized against pure cobalt (cobalt rods, Johnson, Matthey & Co., Ltd.). Murexid was used as indicator and the pH adjusted with sodium carbonate in stead of ammonia to avoid formation of ammines [11].

The compositions of the ruthenium phosphides were checked by analyses for phosphorus only. The alloys were dissolved in hydrochloric acid — chlorine by heating in sealed glass tubes at 300°C for 24—48 h [12-15] (*cf.* [16]). Perchloric acid was used as oxidant for the evolution of chlorine. 1—2 g of sodium chloride was added to the solution, which was then evaporated to dryness to remove traces of silicic acid. The residue was taken up in hydrochloric acid and filtered. Ruthenium was removed by precipitation as the sulphide and phosphorus determined in the filtrate according to the method described above.

X-Ray methods. X-Ray powder photographs were taken using Guinier-type focussing cameras and Cr-$K\alpha_1$ and Cu-$K\alpha$ radiation ($\lambda_{Cr\text{-}K\alpha_1} = 2.2896$ Å; $\lambda_{Cu\text{-}K\alpha} = 1.5418$ Å). Calcium fluoride ($a = 5.4630$ Å) or silicon ($a = 5.4306$ Å) was used as the internal calibration standard on each powder film. Differences larger than 0.02 % for lattice parameters of the same phase, measured in different alloys, were estimated to be significant, whereas the absolute accuracy of a single lattice parameter measurement is not claimed to be greater than 0.04 %.

For the structure determinations, single-crystal fragments were picked from crushed alloys. Weissenberg photographs were taken with niobium-filtered Mo-K radiation. The multiple-film technique was used, and thin iron foil was placed between successive films. The intensities were estimated by visual comparison with a standard intensity scale. Since it was only possible to obtain single-crystals of rather irregular shape, absorption corrections could not be readily applied. However, care was taken to use small crystals (maximum thickness not exceeding 0.04 mm) with a fairly uniform cross-section, thus minimizing the influence of absorption as well as secondary extinction.

The refinement of the structures was made with the aid of the electronic digital computer BESK. The programs for Fourier summations and structure factor calculations are designed by Edstrand, Westman *et al.*[17] and Åsbrink *et al.*[18] For the atomic scattering factors f_i, analytical expressions of the type $f_i = A_i \exp\left(-\frac{a_i}{\lambda^2}\sin^2\Theta\right) + B_i \exp\left(-\frac{b_i}{\lambda^2}\sin^2\Theta\right) + C_i \exp\left(-\frac{c_i}{\lambda}\sin^2\Theta\right) + D_i$ were used. The constants A_i, B_i, C_i and a_i b_i, c_i, have been determined by Appel [19] on the basis of atomic scattering factor tables given by Thomas and Umeda [20] for Co and Ru, and by Tomiie and Stam [21] for P. The following constants were used:

	A_i	B_i	C_i	a_i	b_i	c_i
Co	9.319	10.181	7.273	0.328	3.556	25.673
Ru	15.176	16.599	11.760	0.240	2.637	20.292
P	1.447	7.971	5.588	0.001	1.528	37.194

In the case of Ru, a correction for dispersion was made by introducing the real part of the dispersion correction as the constant D_i in the above-mentioned expression for the scattering factors. This was taken as the value calculated by Dauben and Templeton [22].

PHASE-ANALYTICAL INVESTIGATIONS

In the binary system Co—P, three intermediate phases have been reported, *viz.* Co_2P, CoP and CoP_3, [23-25,1,26], and in the binary system Ru—P three phases Ru_2P, RuP and RuP_2 are known [27,6].

Nowotny [1] found that the unit cell dimensions of Co_2P are variable, indicating an extended homogeneity range. The present investigation shows that the unit cell of Co_2P decreases with decreasing cobalt content, which has also been verified by Nowotny [28]. The phase-analytical data are collected in Tables 1 and 2. On account of the difficulties of detecting small amounts of cobalt with the X-ray method, the cobalt-rich limit of the homogeneity range could not be accurately located. Judging from the lattice parameter measurements in Table 2, this limit is probably not far from the ideal composition Co_2P. The X-ray method is more sensitive for the detection of small amounts of CoP. The data in Tables 1 and 2 show that the phosphorus-rich limit at 1 000°C is very close to the composition $Co_{1.94}P$, and furthermore that the homogeneity range of Co_2P becomes larger when the temperature is increased from 900°C to 1 100°C.

No lattice parameter variations were found for Ru_2P in alloys with different compositions quenched from temperatures up to 1 100°C. The composi-

	b	3.513	3.507	3.505
	c	6.608	6.603	6.601

tion of Ru_2P at 1 100°C was "bracketed" with two annealed and quenched alloys; one containing (besides Ru_2P) traces of ruthenium, and the other containing (besides Ru_2P) traces of RuP. Chemical analysis of the first alloy gave a phosphorus content of 13.20 wt % and the other 13.34 wt %. The phosphorus content calculated for the ideal composition Ru_2P is 13.29 wt %. Thus, at 1 100°C, the composition of Ru_2P is close to the ideal formula. (There is no reason to believe that the alloys take up any appreciable amount of impurities during the preparations.) The melting point of Ru_2P is much higher than that of Co_2P, and a widening of the homogeneity range of Ru_2P at temperatures above 1 100°C cannot be excluded. In fact, the structure determination made on a single-crystal picked from an arc-melted alloy, indicates such a possibility (*vide infra*).

THE REFINEMENT OF THE Co_2P STRUCTURE

In view of the phase-analytical results it was thought worthwhile to collect intensity data for two Co_2P single-crystals with different compositions. One crystal was selected from a cobalt-rich alloy sintered at 1 100°C. Since it proved very difficult to obtain phosphorus-rich single-crystals from alloys sintered in silica tubes, a very small single-crystal was finally taken from an alloy, melted in an argon-filled arc furnace and rapidly cooled. The composition of the alloy before melting was $Co_{1.89}P$, but some phosphorus was lost during the melting. The powder photograph of the arc-melted alloy gave the following lattice parameter values: $a = 5.638$ Å; $b = 3.507$ Å; $c = 6.603$ Å, corresponding to a composition around $Co_{1.94}P$. Since the diffraction lines were not as sharp as those of carefully annealed alloys, the arc-melted alloy may have been slightly inhomogeneous.

In the following text, the sintered crystal is denoted as Co_2P and the arc-melted crystal $Co_{1.94}P$. Weissenberg diagrams of both crystals were taken about the b axis.

According to Nowotny [1], the structure of Co_2P is based on space-group $Pnma$ — (D_{2h}^{16}), with eight cobalt atoms in two 4(c) positions and four phosphorus atoms in one 4(c) position *. If the space-group is $Pnma$, the reflexions (h00) with $h = 2n + 1$ are extinct. However, a weak (300) reflexion was observed for both crystals (although relatively weaker for the $Co_{1.94}P$ crystal than for the Co_2P crystal), and these spots on the photographic films were not significantly different in shape from the spots of other reflexions. It was nevertheless suspected that (300) might arise from double-reflexion. Calculations showed that the geometrical conditions for double-reflexion from ($\bar{2}1\bar{1}$) and (511) were closely fulfilled. Furthermore, (211) and (511) were observed to be among the very strongest reflexions. It has been pointed out by Jellinek [29] that the effect of double-reflexion can be recognized in single-crystal photographs taken with unfiltered radiation. If the geometrical conditions for

* The C 23 structure has been described with different settings of the unit cell. Nowotny [1] (and *Strukturbericht*) used the space-group $P\,b\,n\,m$, and Geller [4] $P\,n\,a\,m$. In the present paper, the C 23 structure is always described on space-group $P\,n\,m\,a$, following the standard setting (No. 62) in the 1952 edition of *International Tables for X-ray Crystallography*.

double-reflexion are fulfilled for the $K\alpha$ radiation this will not hold for the $K\beta$ radiation. A special exposure with unfiltered MoK radiation was therefore made. β-reflexions corresponding to α-reflexions of equal or even lower intensity than (300), *e.g.* (400), were clearly seen but no β-reflexion corresponding to (300) was discernible. This was taken as definite evidence that (300) arises from double-reflexion.

All the remaining reflexions were consistent with space-group $Pnma$ or $Pn2_1a$. Since the intensity sequences for the ($h0l$) and the ($h2l$) reflexions were equal, and the same was true for the ($h1l$) and ($h3l$) reflexions, it was not considered necessary to take the lower space-group $Pn\ 2_1a$ into account, and it was assumed that Nowotny's structure proposal was essentially correct. The signs of the $F(h0l)$-values were obtained from the atomic parameters given by Nowotny, and the electron density projections $\varrho(xz)$ were computed. All atoms are well resolved in this projection, and maxima appeared at the expected positions. The structures were refined with successive difference syntheses.

In the difference synthesis of the $Co_{1.94}P$ crystal, a distinct negative region of "electron density" was observed at the Co_{II} position, whereas the electron density was not very different from zero in other parts of the difference map, including the regions around the Co_I and P positions. No such phenomenon was observed in the difference maps for the Co_2P crystal. The minimum may originate from various sources. A closer analysis of the electron density maxima in the ϱ_{obs} and ϱ_{calc} projections showed that the effect must be ascribed to an incorrect scale factor for the Co_{II} atoms rather than an incorrect temperature factor. There were no definite indications that the temperature factors for Co_I, Co_{II} and P were very different or anisotropic. It was found that the minimum at the Co_{II} position was removed from the difference map, when an atomic scattering factor $f_{CoII} = 0.96 \cdot f_{CoI}$ was inserted in the structure factor calculations. The introduction of the lower scattering parameter for Co_{II} resulted in a decrease of the R-value for the 87 observed F-values from 0.060 to 0.053. An overall temperature factor with B = 0.40 Å^2 was applied.

$Co_{1.94}P$ presents a favourable case for scattering parameter comparison of the metal atoms from relative intensities only. Since the same kind of "heavy" atoms is compared in the same type of crystallographic position, the choice of scale factor between absolute and observed structure factors is not critical. However, the influence of absorption and extinction may not be negligible, and the question still remains whether the observed difference between the scattering parameters of Co_I and Co_{II} is significant or not. An attempt to study this problem was made in the following way.

A difference synthesis map for $Co_{1.94}P$, based on F_c-values computed with the atomic scattering factors $f_{CoII} = 0.96 \cdot f_{CoI}$, was prepared by calculating $\Delta\varrho$-values for every sixtieth x and z. The standard deviation $\sigma(\Delta\varrho) = \{\overline{(\Delta\varrho)^2}\}^{\frac{1}{2}}$ was calculated for the 900 independent $\Delta\varrho$-values. In the $\varrho_{obs}(xz)$ projection, the area around each cobalt position, in which the electron density values rose appreciably over the background, extended over some 30—40/3 600 of the projection. 35 $\Delta\varrho$-values for adjoining points in the difference map were summed over areas in various positions of the unit cell. The standard deviation of this sum is $\sqrt{35} \cdot \sigma(\Delta\varrho) = \sigma(N)$. The value of the sum in the area around an atomic position, gives a measure of the difference between the observed and calculated scattering parameter of the actual atom, and the sum is not very sensitive to errors in the assigned temperature factors. It was found that the numerical value of the sum never exceeded $4 \cdot \sigma(N)$ wherever the closed area was placed in the difference map.

Another difference map was calculated on the basis of equal scattering parameters for Co_I and Co_{II}. As mentioned before, this map contained a large minimum at the Co_{II} position; this minimum was not removed by omitting $F_o - F_c$ values for the strong reflexions, which shows that it cannot be ascribed to secondary extinction. When the sum over 35 $\Delta\varrho$-values was evaluated in the area around the Co_{II} position the numerical value of the sum was found to be 14 times larger than $\sigma(N)$, whereas the sum did not exceed $4 \cdot \sigma(N)$ in other areas of the difference map. This indicates that the difference between the scattering parameters of Co_I and Co_{II} is a significant effect. It is felt, however, that only a limited confidence can be attached to the actual numerical value of 1.1 electrons.

The interpretation of the difference is not obvious, and several explanations are possible. It will be shown later, however, that the assumption of random vacancies on the Co_{II} position leads to a satisfactory agreement with phase-analytical data and crystal chemical considerations. The final structural data obtained for the two crystals are the following:

Space-group $Pnma - (D_{2h}^{16})$, (No. 62)
All atoms in 4(c) positions.

The Co_2P crystal

$a = 5.646$ Å; $b = 3.513$ Å; $c = 6.608$ Å; $U = 131.1$ Å^3

	Atomic parameters and standard deviations				*Scattering parameters* (electrons)
	x	$\sigma(x)$	z	$\sigma(z)$	
Co_I	0.8560	0.0003_8	0.0647	0.0003_3	27.0
Co_{II}	0.9685	0.0003_8	0.6657	0.0003_3	27.0
P	0.2461	0.0007_8	0.1249	0.0006_7	15.0

The $Co_{1.94}P$ crystal

$a = 5.638$ Å; $b = 3.507$ Å; $c = 6.603$ Å; $U = 130.6$ Å^3

	Atomic parameters and standard deviations				*Scattering parameters* (electrons)
	x	$\sigma(x)$	z	$\sigma(z)$	
Co_I	0.8562	0.0003_3	0.0631	0.0002_8	27.0
Co_{II}	0.9684	0.0003_3	0.6664	0.0002_8	25.9
P	0.2437	0.0006_5	0.1232	0.0005_5	15.0

The standard deviations of the atomic parameters were estimated by Cruickshank's [30] formula. Observed and calculated structure factors for both crystals are collected in Table 3. For the Co_2P crystal (which was larger than the $Co_{1.94}P$ crystal) the R-value for the 104 observed reflexions is 0.088. An overall temperature factor with $B = 0.42$ Å^2 was applied.

Interatomic distances are listed in Table 4a and b. The standard deviations of the Co—Co distances are smaller than 0.004 Å; those of the Co—P distances smaller than 0.005 Å. (Errors in the unit cell dimensions have not been taken into account.) A comparison of corresponding interatomic distances in Co_2P and $Co_{1.94}P$ shows that the differences are very small.

Table 3. Calculated and observed F(*h*0*l*)-values for Co_2P, $Co_{1.94}P$ and Ru_2P.

THE REFINEMENT OF THE Ru_2P STRUCTURE

Since it was virtually impossible to obtain single-crystals of Ru_2P in alloys sintered in silica tubes, single-crystal fragments were picked from an arc-melted alloy. Within experimental error the lattice parameters of Ru_2P in this alloy were equal to those measured in carefully annealed alloys. How-

Table 4a. Interatomic distances in Co_2P (Å). (Distances shorter than 3.3 Å listed).

	Co_I	Co_{II}	P
Co_I	$2.54_2(2)$	$2.62_4(2)$, 2.66_5 $2.69_1(2)$, 2.71_2	2.14, 2.23(2) 2.24
Co_{II}	$2.62_4(2)$, 2.66_5 $2.69_1(2)$, 2.71_2	$2.83_0(2)$ $3.03_5(2)$	2.29, 2.40(2) 2.54(2)
P	2.14, 2.23(2) 2.24	2.29, 2.40(2) 2.54(2)	3.27(2)

Table 4b. Interatomic distances in $Co_{1.94}P$ (Å). (Distances shorter than 3.3 Å listed).

	Co_I	Co_{II}	P
Co_I	$2.53_0(2)$	$2.62_5(2)$, 2.66_0 $2.69_1(2)$, 2.69_5	2.17, 2.21(2) 2.22
Co_{II}	$2.62_5(2)$, 2.66_0 $2.69_1(2)$, 2.69_5	$2.83_4(2)$ $3.02_7(2)$	2.29, 2.41(2) 2.54(2)
P	2.17, 2.21(2) 2.22	2.29, 2.41(2) 2.54(2)	3.28(2)

ever, the powder diffraction lines of the arc-melted alloy were not very sharp and the experimental error was therefore rather large (about 0.1 %). A widening of the homogeneity range of Ru_2P at higher temperatures (in analogy to Co_2P) cannot be excluded.

The Weissenberg photographs showed that Ru_2P is isostructural with Co_2P. The $\varrho(xz)$ projection was refined in a similar way to that described for Co_2P. It was observed in the difference syntheses of Ru_2P that there was a strong minimum of electron density at the Ru_{II} position as for $Co_{1.94}P$. Furthermore, an anisotropic temperature factor for Ru_{II} was indicated. The axes of the projected vibration ellipsoid for Ru_{II} happened to coincide rather closely to the directions of the crystallographic axes, and therefore, an anisotropic temperature factor of the simple form $\exp -(ah^2 + \gamma l^2)$ was applied.

The absorption was stronger in the Ru_2P crystal than in the Co_2P crystals, but it seems improbable that absorption errors would accumulate in such a way that a strong minimum of electron density is created at the Ru_{II} position, leaving the remaining part of the difference map, especially the vicinity of the Ru_I position, almost unaffected. After lowering the scattering parameter of Ru_{II} by 5.9 %, the resulting difference synthesis was free from large maxima and minima. A significance test, made in the way described earlier, yielded a similar result to that obtained for $Co_{1.94}P$.

The final structural data of the Ru_2P crystal are as follows:

Space-group *Pnma* – (D_{2h}^{16}) No. 62.
All atoms in 4(*c*) positions.

	Atomic parameters and standard deviations				*Scattering parameters* (electrons)
	x	$\sigma(x)$	z	$\sigma(z)$	
Ru_I	0.8585	0.0003_0	0.0736	0.0002_6	44.0
Ru_{II}	0.9780	0.0003_3	0.6586	0.0002_9	41.4
P	0.2455	0.0009_5	0.1135	0.0008_1	15.0

The standard deviations were estimated by Cruickshank's [30] formula. Observed and calculated structure factors are given in Table 3. For Ru_I and P, isotropic temperature factors with $B_{Ru_I} = 0.30$ Å^2 and $B_P = 0.40$ Å^2 were applied, whereas for Ru_{II} the anisotropic temperature factor, exp—(0.00265 h^2 + 0.00120 l^2), was applied. The R-value for the 124 observed reflexions is 0.073.

Table 5. Interatomic distances in Ru_2P (Å). (Distances shorter than 3.5 Å listed).

	Ru_I	Ru_{II}	P
Ru_I	$2.74_6(2)$	2.75_8, $2.83_0(2)$ $2.84_0(2)$, 2.94_7	2.26, 2.30 2.40(2)
Ru_{II}	2.75_8, $2.83_0(2)$ $2.84_0(2)$, 2.94_7	$2.92_8(2)$ $3.20_9(2)$	2.32, 2.55(2) 2.82(2)
P	2.26, 2.30 2.40(2)	2.32, 2.55(2) 2.82(2)	

Interatomic distances calculated on the basis of the unit cell dimensions $a = 5.902$ Å; $b = 3.859$ Å; $c = 6.896$ Å; (obtained from powder photographs of carefully annealed alloys) are given in Table 5. The standard deviations for the Ru—Ru distances are smaller than 0.004 Å; those for the Ru—P distances smaller than 0.006 Å.

DESCRIPTIONS OF THE Co_2P AND Ru_2P STRUCTURES COMPARISONS WITH RELATED STRUCTURES

A projection of the Co_2P structure on the *ac* plane is shown in Fig. 1. The phosphorus atoms are situated in triangular prismatic "holes" in the metal atom lattice, with six metal atoms in the corners of the prism, and three metal atoms outside each rectangular side of the prism forming a triangle around the phosphorus atoms. The environment of the phosphorus atoms is shown for Co_2P in Fig. 2, and for Ru_2P in Fig. 3. These phosphides have their type of non-metal atom coordination in common with many other transition metal phosphides as well as with several transition metal borides, silicides and carbides. A study of the coordination of the phosphorus atoms around the metal

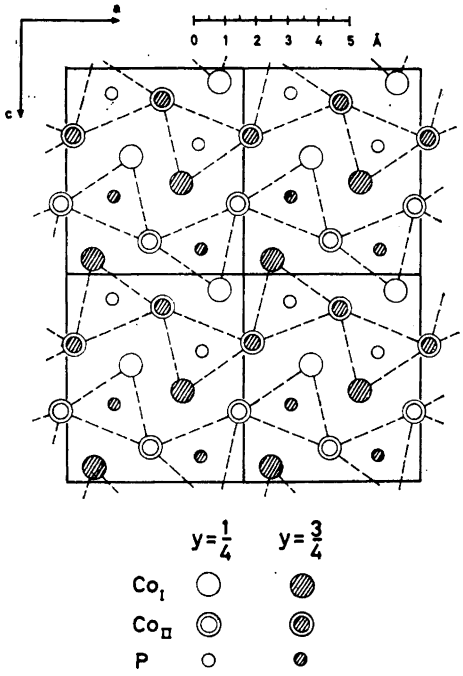

Fig. 1. The structure of Co_2P projected on (010).

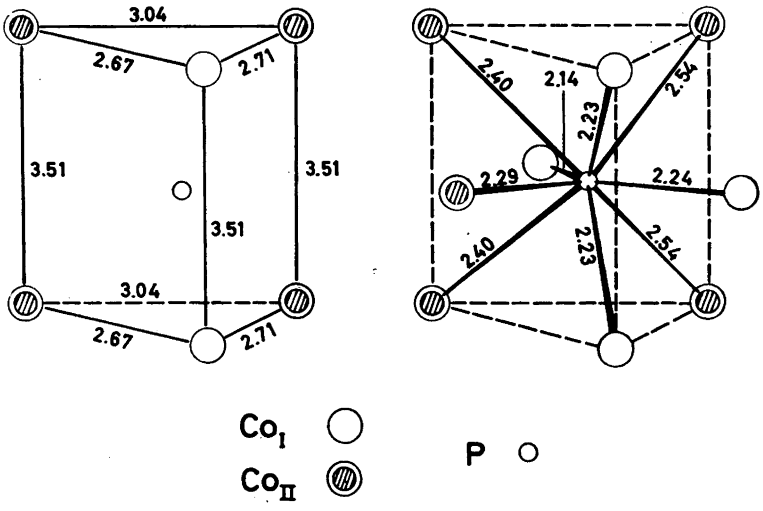

Fig. 2. The environment of the phosphorus atoms in Co_2P.

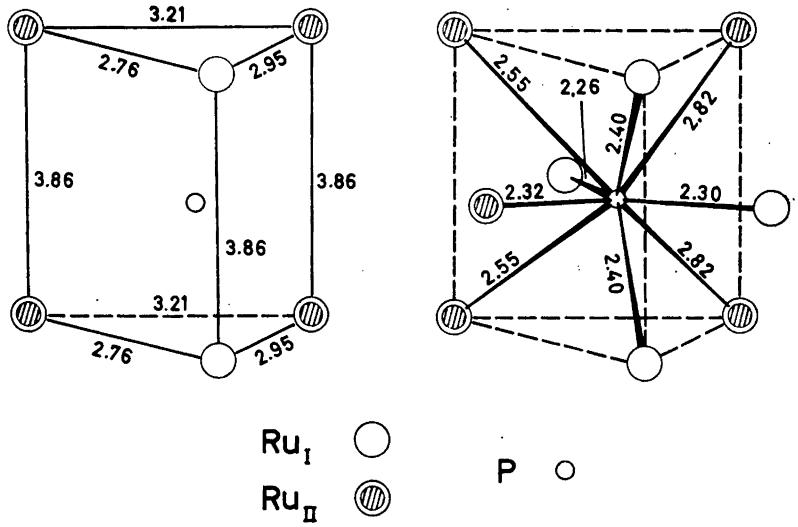

Fig. 3. The environment of the phosphorus atoms in Ru_2P.

atoms shows that Co_I and Ru_I have four phosphorus neighbours arranged in a slightly deformed tetrahedral configuration. The mean value of the Co_I—P distances is 2.21 Å and the mean of the Ru_I—P distances is 2.34 Å. These values are considerably smaller than the average Co_{II}—P and Ru_{II}—P distances. Co_{II} and Ru_{II} have five phosphorus neighbours with a mean Co_{II}—P distance of 2.44 Å and a mean Ru_{II}—P distance of 2.61 Å.

Besides Co_2P and Ru_2P, the structures of the following Me_2P phosphides (Me = transition metal) have been reported; *viz.* Mn_2P, Fe_2P and Ni_2P, which belong to the (revised) *C* 22 structure type [28], and Rh_2P and Ir_2P, which crystallize in the *C* 1 (anti-fluorite) structure [31,6].

The Co_2P and Ru_2P structures bear many resemblances to the *C* 22 type. A projection of the hexagonal Fe_2P structure on the basal plane is shown in Fig. 4. The coordination around the phosphorus atoms in Fe_2P is closely similar to the coordination of the phosphorus atoms in Co_2P. The Fe_I atoms have four phosphorus neighbours in a slightly distorted tetrahedral arrangement (average Fe_I—P distance 2.26 Å) and the Fe_{II} atoms have five phosphorus neighbours (average Fe_{II}—P distance 2.46 Å).

In Rh_2P and Ir_2P, all metal atoms have tetrahedral phosphorus coordination with the Rh—P distance 2.381 Å and the Ir—P distance 2.400 Å.

It was mentioned earlier in this paper that the structures of Co_2P and Co_2Si as well as those of Ru_2P and Ru_2Si are isotypic. A detailed comparison of Co_2P and Co_2Si, however, reveals distinct differences. The situation is quite analogous for Ru_2P and Ru_2Si.

A projection of the Co_2Si structure on the *ac*-plane (according to Geller [4]) is shown in Fig. 5. The near environment of the silicon atoms consists of ten cobalt atoms at distances between 2.32 and 2.57 Å. (An eleventh cobalt atom is

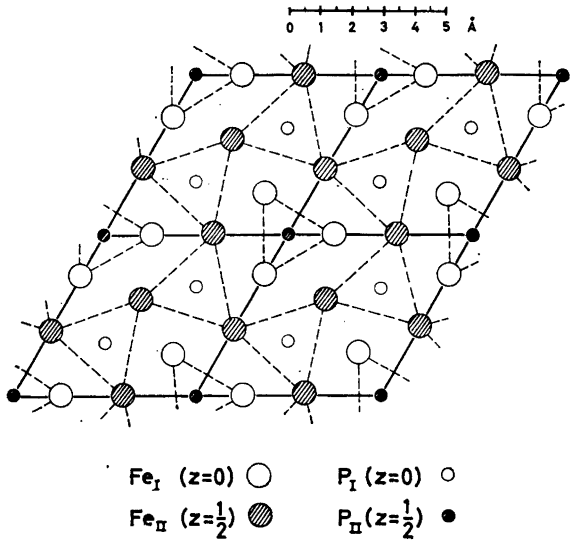

Fig. 4. The structure of Fe_2P projected on (001).

situated at a distance of 3.25 Å and four silicon atoms at a distance of 3.15 Å). In Co_2P, the phosphorus atoms have only nine close cobalt contacts with P—Co distances between 2.14 and 2.55 Å. (Two additional cobalt atoms are situated at distances of 3.42 Å and 3.47 Å, and two phosphorus atoms at a distance of 3.27 Å.) As pointed out before, the coordination of the Co_I atoms in Co_2P is markedly different from that of the Co_{II} atoms. The situation is not analogous in Co_2Si, where the two sets of cobalt atoms each have eight cobalt neighbours and five silicon neighbours:

Co_I —8Co, average distance 2.63 Å; Co_I —5Si, average distance 2.39 Å
Co_{II}—8Co, average distance 2.59 Å; Co_{II}—5Si, average distance 2.46 Å

The unit cell volume of Co_2P is 131.1 Å^3 and the volume of Co_2Si is 130.7 Å^3. The two unit cells are, however, rather different in shape. The *b* and *c* axes in Co_2Si are larger than the corresponding axes in Co_2P, but the reverse is true for the *a* axis. There exists a limited mutual solid solubility between Co_2P and Co_2Si. The changes of the unit cell dimensions of Co_2P and Co_2Si, when these phases dissolve silicon and phosphorus respectively, are seen in Table 6, where lattice parameter measurements have been collected from two-phase Co_2P + Co_2Si alloys, quenched from various temperatures. As seen in Table 6, the mutual solid solubility increases with increasing temperature. Data obtained with the "disappearing phase" method indicated that neither the solid solubility of Co_2P in Co_2Si, nor the solid solubility of Co_2Si in Co_2P exceeds 15 % in the investigated temperature range. In view of the differences between the structures of Co_2P and Co_2Si, it is not surprising that the mutual solid solubility is restricted, although the size-factor is favourable.

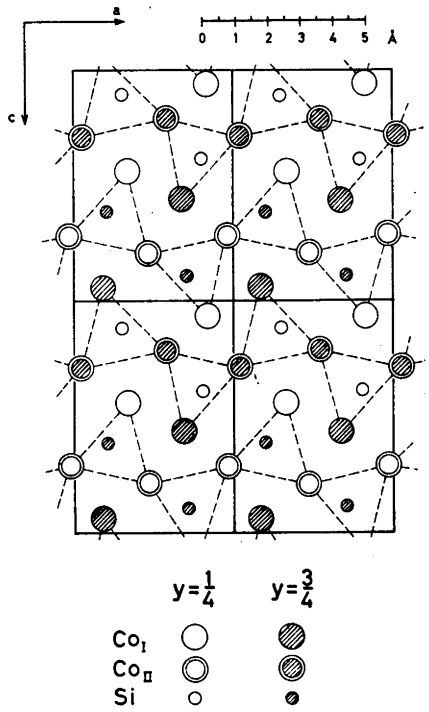

Fig. 5. The structure of Co_2Si projected on (010).

THE HOMOGENEITY RANGE OF Co_2P

The *C* 23 type of structure is rather close-packed, and the "holes" in the structure are not large enough for accomodation of additional atoms without profound distortion of the structure. The extended homogeneity range of Co_2P, (and probably of Ru_2P too), must therefore arise either from metal/phosphorus substitution or from vacant metal atoms sites (or possibly a combination of substitution and vacancies). This is also evident from the decrease of the Co_2P unit cell with increasing P/Co ratio.

The structure determinations on Co_2P and Ru_2P show that there are conspicuous differences between the Co_I and Ru_I atoms on one hand, and the Co_{II} and Ru_{II} atoms on the other. The coordination around the Co_I and Ru_I atoms is different from that of the Co_{II} and Ru_{II} atoms, and furthermore the electron counts indicate a lower scattering parameter for Co_{II} than for Co_I in the $Co_{1.94}P$ crystal (and analogously in the Ru_2P crystal).

The scattering parameter fo Co_{II} in the $Co_{1.94}P$ crystal was observed to be 1.1 electrons less than that of Co_I. If the scattering parameter difference is entirely ascribed to Co_{II}/P substitution, the calculated composition of the crystal is $Co_{1.75}P$, which is not compatible with the phase-analytical results. If the possibility of simultaneous vacancies on the P position is taken into account, the calculated composition of the crystal may be brought to a more

Table 6. Lattice parameters of Co_2P—Co_2Si mixed crystals. (Measurements made on a two-phase alloy with the composition $Co_2P_{0.5}Si_{0.5}$, quenched from various temperatures).

Quenching temp. °C	Phase	Lattice parameters (Å)		
		a	*b*	*c*
—	Co_2P	5.646	3.513	6.608
—	Co_2Si	4.918	3.737	7.109
1 000	$Co_2P(Si)$	5.607	3.537	6.644
	$Co_2Si(P)$	4.954	3.719	7.065
1 075	$Co_2P(Si)$	5.600	3.540	6.650
	$Co_2Si(P)$	4.965	3.715	7.048
1 150	$Co_2P(Si)$	5.595	3.543	6.654
	$Co_2Si(P)$	4.982	3.709	7.039

reasonable value, but this idea seems far-fetched and it is not supported by the data of the structure determination. On the other hand, if the lowering of the Co_{II} scattering parameter is ascribed only to random vacancies among the Co_{II} atoms, the composition of the crystal should be $Co_{1.96}P$, which is in fairly good agreement with the phase-analytical data. This supports the hypothesis of metal atom vacancies. It must be remembered, however, that it is possible to interpret the observed difference between the scattering parameters of Co_I and Co_{II} in other ways than those mentioned here.

Although the existence of metal/phosphorus substitution has been recognized in transition metals, *e.g.* in α-iron [32], the conditions for metal/phosphorus substitution in Co_2P and Ru_2P are probably less favourable. In the structures of transition metal phosphides with phosphorus contents of 50 atom per cent or less, P—P distances shorter than 3.0 Å have not been observed [33,34,26,28,35] Considering that metal/phosphorus substitution in Co_2P or Ru_2P would imply P—P distances shorter than 2.4 Å, the hypothesis of metal/phosphorus substitution in these phases appears less attractive. However, vacancies on transition metal sites has been found in phases similar to Ru_2P and Co_2P, *e.g.* in many phases belonging to the NiAs structure family.

Since strong arguments in favour of the hypothesis of metal/phosphorus substitution are lacking, it seems most reasonable to assume that the extended homogeneity range of Co_2P is connected with vacancies on cobalt atom sites.

One might ask if an analogous phenomenon exists in phosphides of the Fe_2P type. As mentioned earlier, the Fe_2P structure closely resembles the Co_2P structure. Unfortunately, accurate phase-analytical data are not available for any of the Fe_2P type phosphides, but a qualitative observation by Haughton [8] indicates an extended homogeneity range of Fe_2P. In his metallographic investigation of iron phosphides, Haughton found signs of secondary precipitation of FeP in the Fe_2P phase. His equilibrium diagram of the Fe—P system therefore contains a (dotted) line, which extends the Fe_2P single-phase field at higher temperatures towards the phosphorus-rich side of the diagram.

ACTA CHEMICA SCANDINAVICA 14 (1960) 1980–1984

Cysteamine S-Phosphoric Acid

STIG ÅKERFELDT

Biochemistry Section, Eastern Pennsylvania Psychiatric Institute, Philadelphia 29, Pennsylvania, U.S.A.

Free cysteamine S-phosphoric acid has been prepared. The effect of pH on the hydrolysis of the synthesized compound has been studied and a mechanism for its reaction with iodine is suggested. Some solvent systems and spray reagents useful in paper chromatography of cysteamine S-phosphate are described.

A convenient, high yield method for the synthesis of trisodium phosphorothioate, used in the preparation of the title compound, has been worked out.

In two earlier papers [1,2] a method employing trisodium phosphorothioate for the preparation of some S-substituted phosphorothioic acids was reported. Among the compounds thus prepared was the sodiumhydrogen salt of cysteamine S-phosphoric acid (S-(2-aminoethyl) phosphorothioic acid). This compound was later found to be enzymically hydrolyzed to *ortho*-phosphate and cysteamine by human erythrocytes [3].

In the present paper the preparation of free cysteamine S-phosphoric acid is reported and some of its properties are described.

Cysteamine S-phosphoric acid has been prepared by dissolving the sodiumhydrogen salt in glacial acetic acid. Upon standing the free acid crystallizes out, whereas the simultaneously formed sodium acetate remains in solution.

The S-P bond in cysteamine S-phosphoric acid is extremely acid labile. Thus a 2.5 mM solution of the compound in 1 M HCl is completely hydrolyzed in less than one minute at 100°, giving a quantitative yield of cysteamine and *ortho*-phosphate. In neutral or slightly alkaline solutions the compound is relatively stable at room temperature.

The rate of hydrolysis of cysteamine S-phosphate as a function of pH at 37° is described in Fig. 1. The reaction was followed by the appearance of thiol groups [4] and (ethylenedinitrilo) tetraacetic acid was added to prevent heavy metal catalyzed oxidation of the cysteamine formed. Standardization of the colorimetric method was carried out as described previously [3]. A maximum rate of hydrolysis takes place around pH 3, where the compound is primarily in the form of $NH_3^+CH_2CH_2SPO_3H^-$ as concluded from acid-base titrations.

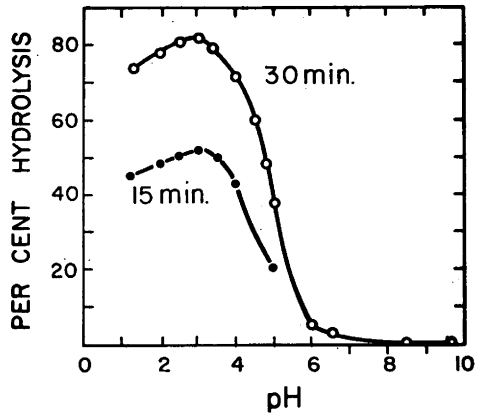

Fig. 1. Effect of pH on the hydrolysis of cysteamine S-phosphate (5 mM) at 37° in the presence of (ethylenedinitrilo)tetraacetic acid (13 mM). Ionic strength close to 0.15.

Such titrations were performed on both the free cysteamine S-phosphoric acid as well as on the sodiumhydrogen salt (10 mM solutions, 25°). Since the formation of some *ortho*-phosphate during the course of the titrations is inevitable in the acid region, other pK_a measurements were performed by adding just enough HCl to solutions of sodiumhydrogen cysteamine S-phosphate to reach the half titration points. The pH was then determined instantly. The apparent pK_a values obtained in this way agreed within ± 0.05 pK_a units with those obtained from rapidly performed acid-base titrations.

The results are reported in Table 1, from which it is evident that the second and third apparent pK_a values of cysteamine S-phosphate are relatively similar to those reported for 2-aminoethanol O-phosphate. The largest deviation in the results is to be found in the first pK_a, which for cysteamine S-phosphate is close to the lowest pK_a of *ortho*-phosphate ($pK_a = 2.1$), whereas the value for 2-aminoethanol O-phosphate is considerably lower.

In comparison with 2-aminoethanol O-phosphate cysteamine S-phosphate melts appreciably lower and is hydrolyzed by 1 M HCl at 100° some 1 000 times faster than the former (Table 1).

The observed rate of hydrolysis of cysteamine S-phosphate as a function of pH is qualitatively similar to that found for S-(*n*-butyl) phosphorothioate

Table 1. Comparison between some properties of cysteamine S-phosphoric acid and 2-aminoethanol O-phosphoric acid.

Property	$NH_2CH_2CH_2SPO_3H_2$	$NH_2CH_2CH_2OPO_3H_2$
Melting point	156°	244° [10]
Half life in 1 M HCl at 100°	<1 min	≈ 17 h [11]
pK_a	2.2; 5.0; 10.3	<1; 5.57; 10.10 [12]
		<1; 5.84; 10.89 [13]

by Herr and Koshland [5]. These authors proposed a mechanism for the observed hydrolysis. Several monoesters of *ortho*-phosphoric acid also give hydrolysis curves similar to those obtained for the S-substituted phosphorothioic acids mentioned here (see, *e.g.*, Ref.[6]).

Above pH≈2 cysteamine S-phosphate reacts momentarily with iodine, one atom of iodine being consumed per molecule of S-phosphate. During this process *ortho*-phosphate is formed together with a ninhydrin and cyanide-nitroprussiate positive substance with the same R_F-value in ethanol : pyridine : water, 2 : 1 : 1, and in *n*-butanol : acetic acid : water, 4 : 1 : 1, as cystamine (2,2′-dithiobisethylamine).

At pH≤1 the reaction between cysteamine S-phosphate and iodine is very slow *. At this pH at least part of the observed decolorization of iodine could be attributed to release of thiol groups by hydrolysis of the S-P bond.

The reaction between cysteamine S-phosphate and iodine in slightly acid and neutral solutions is similar to that described by Wieland and Lambert [7], who found that iodine is momentarily decolorized by a solution of S-(*n*-butyl) phosphorothioate around pH 7. These authors proposed a mechanism for the interaction between iodine and the S-substituted phosphorothioate used. However, this mechanism does not explain the failure of iodine to react rapidly with cysteamine S-phosphate at pH≤1.

A mechanism that explains the experimental results is given in Fig. 2. This is essentially a combination of the Herr and Koshland [5] mechanism with that of Wieland and Lambert [7].

In their suggested mechanism for acid hydrolysis of *S*-(*n*-butyl) phosphorothioate, Herr and Koshland [5] propose that one (and only one) of the OH-groups attached to the phosphate residue should be dissociated for maximum rate of hydrolysis. The dissociated OH-group should serve to activate a hydro-

* For instance, 3 mmole of cysteamine S-phosphate in 50 ml of 2 M HCl required more than 12 h to decolorize an equivalent amount of iodine.

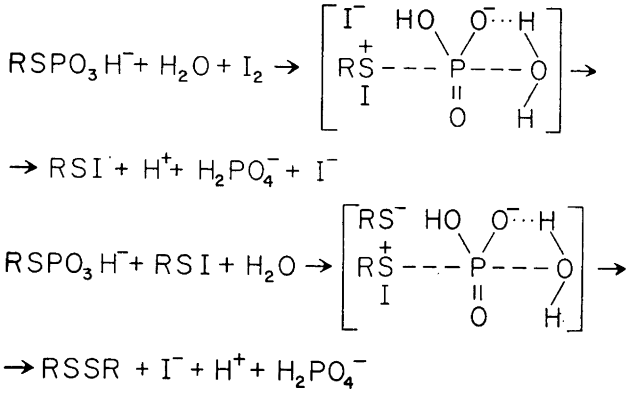

Fig. 2. Suggested mechanism for the reaction between iodine and cysteamine S-phosphate (R = $NH_3^+CH_2CH_2^-$).

gen bonded water molecule attached to the phosphate residue. The second (undissociated) OH-group on the phosphate residue should serve as a proton donor to the sulfur atom. When this OH-group is also dissociated, the molecule is thus stable.

In the scheme in Fig. 2 the dissociated OH-group serves the same purpose as in the Herr and Koshland mechanism as explained above. The presence of an undissociated OH-group, however, is not needed, since the intermediary step, like in the Wieland and Lambert scheme, is suggested to be RSI. This explains the fact that the cysteamine S-phosphate — iodine reaction (in contrast to the hydrolysis) proceeds rapidly also at pH 7.

Cysteamine S-phosphate can be separated from *ortho*-phosphate and from phosphorothioate by paper chromatography. Some solvent systems for this purpose are listed in Table 2. In addition to the commonly used phosphate sprays, the following spray reagents were useful in the identification of the above mentioned substances on the chromatograms:

1. 0.2 % ninhydrin in ethanol : pyridine, 8 : 2. Cysteamine S-phosphate gives a violet spot after heating for 5 min at 100°. (Ninhydrin in ethanol without added pyridine gives only weakly colored spots).
2. 0.1 % iodine in 5 % KI gives decolorized zones for cysteamine S-phosphate and phosphorothioate.
3. 1 % copper(II)chloride in 50 % ethanol containing 5 % NH_3 gives yellow brown spots with trisodium phosphorothioate and black spots with cysteamine S-phosphate.

Trisodium phosphorothioate, which was utilized for the synthesis of cysteamine S-phosphate [1], was previously prepared in about 40 % yield according to Yasuda and Lambert [8]. In this method $PSCl_3$ and a solution of sodium hydroxide in water are refluxed together. However, during this operation much phosphorothioate is hydrolyzed and large amounts of *ortho*-phosphate are formed. Improved experimental conditions for this reaction were therefore worked out. Lowering the reaction temperature to 75—85° gave 85—90 % final yield of anhydrous trisodium phosphorothioate of high purity. The decrease in reaction temperature did not unduly decrease the reaction rate *.

Table 2. Approximate R_F-values in three solvent systems. Solvents: 1, Ethanol:pyridine: water, 10:5:8. 2, 2-Methoxyethanol:NH_3(29 %):water, 3:2:2. 3, Ethanol:NH_3 (29 %): water, 6:1:3. The substances were chromatographed (ascending solvents) on Whatman No. 4 papers.

Substance	Solvent No. 1	2	3
$NH_2CH_2CH_2SPO_3HNa$	0.39	0.71	0.54
K_2HPO_4	0.18	0.54	0.29
Na_3SPO_3	0.30	0.62	0.31

* Yasuda and Lambert have later published a slightly modified procedure, which gives a yield of *ca.* 57 % Na_3SPO_3[14].

Binkley [9] performed the same reaction at 0°. In the present author's experience, however, the reaction rate at this temperature is inconveniently slow.

EXPERIMENTAL

Cysteamine S-phosphoric acid. 5.0 g of freshly prepared sodiumhydrogen cysteamine S-phosphate [1] were stirred at 25° in 100 ml of glacial acetic acid under exclusion of moisture for 30 min. During the process the S-phosphate dissolved completely and after a few minutes of stirring the crude free acid started to separate. The crystalline precipitate was filtered off and washed thoroughly with glacial acetic acid and with dry petroleum ether (b.p. 30–60°). The product was further purified by dissolving it in 50 ml of 10 % acetic acid and reprecipitating with 150 ml of ethanol. This purification process was repeated twice. 2.9 g (66 %) of crystalline substance were thus obtained (average of three prepns.) melting at 156° (corr.). Further reprecipitations did not increase the melting point. (Found: C 15.3; H 5.2; P 19.8. Calc. for $NH_2CH_2CH_2SPO_3H_2$ (157.14): C 15.3; H 5.1; P 19.7.)

Trisodium phosphorothioate. 80 g (2.0 mole) of sodium hydroxide were dissolved in 500 ml of water and 35 ml (0.34 mole) of $PSCl_3$ were added. The reaction flask was equipped with a reflux condenser and the synthesis was carried out on a combined magnetic stirrer-hot plate. After initial heating to about 80°, the reaction was allowed to proceed at 75–85° under constant stirring until all $PSCl_3$ had reacted (about 2 h). The slightly yellow solution was kept in the refrigerator (4°) over night. The precipitated white crystals were filtered off and washed with ethanol (100 ml). They were dissolved in 250 ml of distilled water at 45° and reprecipitated by the slow addition of 200 ml of ethanol under constant, rapid stirring. The solution was cooled under tap water, filtered and the crystals washed with ethanol (100 ml). The substance was dehydrated by stirring in 600 ml of dry methanol for 1.5 h, filtered and finally dried at 105° for 1 h. 52–55 g (85–90 %) of anhydrous trisodium phosphorothioate were thus obtained.

Phosphate determinations [9] and iodine titrations [8] showed the substance to be 99–100 % pure.

The author is indebted to Miss S. Perry and to Mrs. M. Gale for skillful assistance.

The Chemistry of the Natural Order Cupressales

XXIX *. Heartwood Constituents of *Juniperus thurifera* L.

JARL RUNEBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The heartwood of *Juniperus thurifera* contains α-cedrene, thujopsene, two apparently new $C_{15}H_{24}$ hydrocarbons, cuparene, cedrol, a compound $C_{20}H_{16}O_6$, a diol $C_{30}H_{54}O_2$, carvacrol, nootkatin, β-thujaplicin, hinokiic acid and "Widdringtonia acid II". Two further sesquiterpene hydrocarbons were present, which contained vinylidene groups; one of these probably has a curcumene skeleton.

In continuation of the studies at present being carried out in this laboratory on the heartwood constituents of the genus *Juniperus* [1-3], an investigation was made of a sample of *Juniperus thurifera* obtained from Spain.

The wood was extracted with acetone and the light petroleum-soluble part of the acetone extract was separated into neutral and acid fractions. Crystallisation of the acidic material gave two sesquiterpene acids, hinokiic acid [4], which has also been found in *J. chinensis* [1] and in *J. utahensis* [2], and the "acid II" previously isolated from *Widdringtonia* [5], from *J. chinensis* [1] and from several other species of the *Cupressaceae*.

The acidic material was treated with copper acetate to precipitate any tropolones present. The product obtained on decomposition of the precipitate with hydrochloric acid gave nootkatin; according to paper chromatography it also contained β-thujaplicin. Paper chromatography showed the presence of carvacrol in the remaining acidic material.

The neutral oil was distilled. The lowest boiling part of the main sesquiterpene fraction was chromatographed on polyvinyl chloride powder impregnated with light petroleum, using a solution of silver fluoborate in aqueous methanol as eluant. This gave five main fractions x, y, z, u and v. Compounds containing vinylidene groups would be expected to form relatively strong silver complexes and therefore to be eluted first. In accordance with this the infrared spectrum of the first fraction x showed strong absorption at 1 635, 1 645 and 883 cm^{-1} indicating the presence of vinylidene groups.

* Part XXVIII. *Acta Chem. Scand.* 14 (1960) 1288.

Gas chromatographic analysis showed that fraction x contained two components (X_1 and X_2) in about equal amounts. The retention time (R_t) of X_1 was close to that of α-cedrene and that of X_2 was close to that of thujopsene. It was thus impossible to detect the compounds X_1 and X_2 by gas chromatography with the system used when α-cedrene and thujopsene were present.

On dehydrogenation with selenium, X_2 gave dihydro-*ar*-curcumene, previously obtained in the same way from "Substance Y" of a crude sesquiterpene hydrocarbon fraction isolated from *Juniperus virginiana* [3]. Gas chromatography showed that X_1 remained almost unchanged after similar treatment with selenium.

Fraction y was pure thujopsene and on ozonolysis gave the corresponding keto-carboxylic acid [4].

Fractions z and u gave two sesquiterpene hydrocarbons Z and U which, apparently, have not been isolated previously. According to elemental analysis and infrared spectra both compounds may be tricyclic with one double bond. On gas chromatography both had almost the same R_t-value but were easily separated from α-cedrene and thujopsene. The R_t-values of Z and U agree well with the R_t-value of peak x_3 on a gas chromatogram of a crude sesquiterpene hydrocarbon fraction from *Juniperus virginiana* [3]. A sample of U was dehydrogenated with selenium and the product was chromatographed but no crystalline picrate could be obtained.

Fraction v was α-cedrene and gave on oxidation α-cedrenic acid [6].

The sesquiterpene hydrocarbon fraction, b.p. 121—123°/10 mm, showed aromatic absorption in the ultraviolet. It was redistilled and ozonised at low temperature. The material unaffected by ozone was identified as cuparene [7].

Chromatography of the sesquiterpene alcohol fraction gave cedrol but no widdrol [5] was detected. This fraction, however, also gave a mixture of carbonyl compounds.

The highest boiling neutral oil afforded a small amount of crystalline material. On chromatography this was separated into three compounds:

The waxy compound I, m.p. 67.5—68.5° was not further investigated.

Compound II, m.p. 156.0—157.5° analysed for $C_{20}H_{16}O_6$ and contained no methoxyl group, its ultraviolet spectrum showed a shoulder at 220 mμ (ε 19 200) and maxima at 237 mμ (ε 19 030), 293 mμ (ε 16 600) and 333 mμ (ε 22 300). The infrared spectrum showed aromatic absorption (1 495, 1 507, 1 606 and 1 625 cm^{-1}) and appeared to indicate the presence of a lactone ring (1 745 cm^{-1}). In addition there was a medium strength absorption peak at 1 644 cm^{-1}. A small amount of a substance now shown to be identical with "compound II" has previously been isolated from *J. communis* [8]. This compound is presently under investigation.

Compound III, m.p. 243.5—244.0° analysed for $C_{30}H_{54}O_2$. It appeared to contain two hydroxyl groups; an acetate was prepared but it gave a poor analysis.

The compounds isolated are listed below with very approximate estimates of the amounts present (as percentages of the air-dried wood). Total acetone extract 9.9, ether-soluble acetone extract 7.3, light petroleum-soluble acetone extract 5.7, sodium bicarbonate-soluble 0.03, potassium hydroxide-soluble 1.0, neutral 4.6, nootkatin 0.01, β-thujaplicin 0.001, carvacrol 0.1, hinokiic acid

0.2, "Widdringtonia acid II" 0.07, sesquiterpene hydrocarbons $X_1 + X_2$ 0.3, sesquiterpene hydrocarbon Z 0.01, sesquiterpene hydrocarbon U 0.05, α-cedrene 0.6, thujopsene 0.4, cuparene 0.1, cedrol 0.7, "compound II" 0.005, "compound III" 0.003, high-boiling carbonyl compounds 0.03.

EXPERIMENTAL

Rotations were measured in chloroform unless otherwise specified; melting points were taken on a hot stage and are corrected; boiling points are uncorrected. Light petroleum refers to the fraction b.p. 40—60°.

Isolation of the oils. Ground, air-dried heartwood (15.2 kg) of *J. thurifera* was extracted with acetone for 24 h. The acetone was evaporated and the oil obtained was poured with stirring into ten volumes of ether. The ether solution was filtered (precipitate A, 388 g), evaporated and the residue was poured into ten volumes of light petroleum. After filtration (precipitate B, 254 g) the solution was evaporated to dryness, diluted with two volumes of light petroleum and extracted successively with sodium bicarbonate (saturated solution) and potassium hydroxide (2 N). Acidification of the alkaline solutions and extraction with ether gave a sodium bicarbonate-soluble fraction C (4.4 g), which was not further investigated, and a potassium hydroxide-soluble fraction D (152 g). The remaining light petroleum solution was washed with water, dried and evaporated giving neutral material E (704 g).

Alkali-soluble fraction. The potassium hydroxide-soluble oil D was diluted with two volumes of ether and extracted with sodium carbonate-solution (2 N). On acidification and extraction with ether an oil F (124 g) was obtained, which partly crystallised on standing. The material insoluble in sodium carbonate was an oil G (24 g).

The crystalline part (41.4 g) of F was filtered off and a sample (3 g) was fractionally recrystallised from ether. The material less soluble in ether (0.9 g) was recrystallised from light petroleum, m.p. 190.0—191.5°, $[\alpha]_D$ —99° (*c*, 1.5), and identified (mixed m.p., IR) as the "acid II", isolated from *Widdringtonia* [5]. The material slightly more soluble in ether, m.p. 166.0—167.5°, was identified as *hinokiic acid* [4].

The oil G (24.0 g) was dissolved in five volumes of ligroin (b.p. 100—125°) and shaken with aqueous copper acetate (saturated solution). The copper salts were filtered off and washed with ligroin and water to give a combined ligroin phase H. The salts were decomposed with hydrochloric acid (2 N) and the resulting product was extracted with ether. The residue obtained on evaporation of the ether solution (2.4 g) was recrystallised from light petroleum and sublimed in a high vacuum, m.p. 93.5—95.0°. It was identified as *nootkatin* (mixed m.p., IR). The presence of *β-thujaplicin* in the mother liquors was demonstrated by paper chromatography [9].

The ligroin phase H was separated, washed with water and evaporated to dryness. The residue was shown by paper chromatography [9] to contain *carvacrol.*

Neutral fraction. The neutral oil E (518 g) was subjected to a quick preliminary distillation up to 150°/2 mm giving a distillate K (476 g) and a high-boiling residue L (43 g). A sample of the neutral oil K was distilled through a one meter, vacuum-jacketed, packed column giving the fractions listed in Table I.

Fraction Ib was redistilled through a 70 cm spinning band column and the first fraction (IIa, 3.0 g), b.p. 136—137°/25 mm, $[\alpha]_D$ —42°, n_D^{25} 1.4975 was chromatographed according to a method developed by B. Wickberg using polyvinylchloride powder impregnated with light petroleum and eluting with a solution of silver fluoborate in aqueous methanol. A detailed account of the separation will be published later in this journal. The main fractions, x, y, z, u and v, were eluted in this order. Fraction x (279 mg) b.p. 121°/10 mm was a mixture of two compounds X_1 and X_2 which both, according to the infrared spectrum, appear to contain vinylidene groups. The ultraviolet spectrum of the fraction (in 95 % ethanolic solution) showed maxima at 205, 206 and 242 mμ.

Thujopsene. Fraction y (314 mg) was redistilled and a sample (200 mg) in ethyl acetate-methanol (4:1, 10 ml) was ozonised at —70° until the blue colour indicating excess ozone appeared. When the reaction mixture had reached room temperature zinc dust (1 g) activated with acetic acid was added. After one hour, ether (50 ml) was added

Table 1. Distillation of neutral fraction K (256 g). Total distillate 212 g or 83 %.

Fraction	Weight (g)	B.p. (°C)	Pressure (mm Hg)	Rotation $[\alpha]_D$	Refractive index (n_D^{25})
Ia	9.5	64—126	14	−39	1.4968

Ig	11.4	160—163	14	+23	—
Ih	12.3	142—145	3	+22	1.5145

followed by aqueous acetic acid (10 %, 50 ml); the reaction mixture was filtered and the organic phase was separated, washed with water, dried and evaporated to dryness. The residue (0.65 g) was recrystallised from ethyl acetate, m.p. 165.0—166.0°, and identified as thujopsene ketocarboxylic acid [4] (mixed m.p., IR).

Fraction z (73 mg, from 6 g of IIa) was redistilled to give *sesquiterpene hydrocarbon Z*, b.p. 122°/10 mm, $[\alpha]_D$ + 75° (*c*, 2.2), n_D^{25} 1.4942. (Found: C 88.2; H 11.8; CH_3-(C) 5.6. $C_{15}H_{24}$ requires C 88.2; H 11.8; CH_3-(C) (one) 7.4.) Infrared spectrum (in carbon tetrachloride solution): 3 010 s, 2 960 vs, 2 870 vs, 2 720 w, 1 640 w, 1 462 vs, 1 450 vs, 1 433 vs, 1 375 vs, 1 364 vs, 1 346 m, 1 327 w, 1 315 m, 1 296 m, 1 279 s, 1 186 s, 1 175 m, 1 154 s, 1 129 s, 1 102 w, 1 062 m, 1 045 w, 1 021 s, 958 w, 945 w, 925 m, 910 cm^{-1} s. The ultraviolet spectrum of this fraction (in 95 % ethanolic solution) showed a maximum at 207 mμ (ε 1 050).

Fraction u (298 mg, from 6 g of IIa) was redistilled to give *sesquiterpene hydrocarbon U*, b.p. 122°/10 mm, $[\alpha]_D$ + 33° (c, 2.2), n_D^{25} 1.4961. (Found: C 88.0; H 11.7; CH_3-(C) 6.5; M 209 (Rast). $C_{15}H_{24}$ requires C 88.2; H 11.8; CH_3-(C) (one) 7.4; M 204.) Infrared spectrum (pure oil): 3 065 s, 2 950 vs, 2 745 w, 1 647 w, 1 485 s, 1 467 vs, 1 448 vs, 1 390 s, 1 378 vs, 1 366 vs, 1 341 m, 1 330 m, 1 320 m, 1 295 w, 1 280 w, 1 223 w, 1 211 w, 1 194 w, 1 175 m, 1 134 w, 1 098 w, 1 083 w, 1 063 w, 1 035 w, 1 023 m, 1 005 m, 983 w, 972 m, 925 s, 909 w, 867 w, 839 m, 794 s, 777 s, 695 cm^{-1} w.

A sample of fraction x (52 mg) was heated with selenium (50 mg) in a carbon dioxide atmosphere for 24 h at 270°. A gas chromatogram showed that the compound X_1 was largely unchanged; no peak corresponding to X_2 could be detected but a new peak was obtained with the same R_f-value as dihydro-*ar*-curcumene [3]. The dehydrogenation product was ozonised as described for cuparene (see below) and the material unattacked by ozone (20 mg), n_D^{25} 1.4865, was identified as dihydro-*ar*-curcumene by comparison of its infrared spectrum with that of a synthetic sample [10,11].

α-Cedrene. Fraction v (1.47 g, from 3 g of IIa) was redistilled, b.p. 113°/11 mm, $[\alpha]_D$-86° (c, 2.8), n_D^{25} 1.4960. A sample (0.78 g) in ethanol (95 %, 15 ml) was refluxed with selenium dioxide (0.47 g) for 3 h. The reaction product was filtered, the alcohol-solution was evaporated to dryness and the residue was distilled under reduced pressure. The distillate (0.54 g) was added to a suspension of silver oxide (sodium hydroxide (0.38 g), silver nitrate (0.79 g)) in water (60 ml) and the mixture was refluxed with vigorous stirring for 9 h. The solution was then filtered, and after extraction with ether to remove neutral material, the alkaline solution was acidified and extracted with ether. This ether extract was evaporated and the product (0.26 g) was sublimed three times in a high vacuum giving a substance, m.p. 123.0—124.5°, which was identified as α-cedrenic acid [6] (mixed m.p., IR).

Cuparene. Fraction Ic was redistilled through a 70 cm spinning band column and the fractions obtained were analysed by gas chromatography (*cf.* below). The material (3.0 g) containing most cuparene was dissolved in methylene chloride (15 ml) and treated at −70° with an excess of ozone. When the reaction mixture had reached room temperature, hydro-

gen peroxide (30 %, 8 ml) in potassium hydroxide (10 %, 3 ml) was added and the organic phase was separated, washed with water and evaporated giving a viscous oil. This was chromatographed on basic alumina (40 g). The first 100 ml of light petroleum eluted a hydrocarbon (0.13 g) which was distilled under reduced pressure, b.p. 117°/7 mm, $[\alpha]_D$ + 63° (*c*, 2.0), n_D^{25} 1.5207, and identified (IR) as cuparene [7].

Gas chromatographic investigation of the sesquiterpene hydrocarbon fractions. Gas chromatograms were run on a Pye Argon Chromatograph using a system described in a previous paper in this series [3]. (Temp. 150°, charge 0.025 µl, argon flow rate 27 ml/min). This gave the following retention times (min): Compound Z 13.2, compound U 13.7, compound X_1 17.3, α-cedrene 17.4, thujopsene 19.1, compound X_2 20.2, dihydro-*ar*-curcumene 21.6 and cuparene 42.8.

Cedrol. The crystalline part (1.36 g) of Ig was separated by filtration (filtrate Ig_2) and a sample (300 mg) was chromatographed on basic alumina (50 g). Ether-benzene (1:5) eluted a substance (210 mg) which was recrystallised from ethanol (95 %), m.p. 88.5—89.5°, $[\alpha]_D$ + 11°, (*c*, 1.9); this was identified as cedrol (mixed m.p., IR). Ether-benzene (1:1) and ether eluted small amounts of an oil with an infrared spectrum different from that of widdrol [5].

High-boiling carbonyl compounds. Fraction Ig_2 (5.5 g) in ethanol (95 %, 20 ml) containing acetic acid (10 %) was refluxed with Girard D reagent (2.0 g) for 30 min and the reaction product was extracted with ether at 0°. The aqueous solution was acidified with an equal volume of hydrochloric acid (4 N) while kept cool and then extracted with ether. The ether solution yielded a liquid mixture of carbonyl compounds (0.88 g); these were not further investigated.

The high-boiling neutral residue L, on standing, deposited a small amount of crystalline material. This was filtered off (1.49 g) and recrystallised from benzene to give compound III (240 mg, see below). The mother liquor was evaporated to dryness and the residue (1.25 g) was chromatographed on silica gel (200 g).

Compound I. Ether-benzene (1:17) eluted a substance (93 mg) which was recrystallised from ethanol (95 %) giving compound I, m.p. 67.5—68.5°, $[\alpha]_D$—2° (*c*, 1.3). (Found: C 78.3; H 12.7.)

Compound II. Ether-benzene (3:7) eluted a yellowish compound, m.p. 141—144°, $[\alpha]_D$—75° (*c*, 1.4). On recrystallisation from benzene and then from ethanol (95 %) followed by sublimation in a high vacuum the compound melted at 146—150°, $[\alpha]_D$ —20° (*c*, 2.9) and two further sublimations gave colourless crystals, m.p. 156.0—157.5°, $[\alpha]_D$ —4° (*c*, 0.7). (Found: C 68.5; H 4.7; CH_3O— 0.0; CH_3—(C) 2.5; M (Rast) 346. $C_{20}H_{16}O_6$ requires C 68.2; H 4.6; CH_3—(C) (one) 4.3; M 352.) Compound II in methanol gave no colour with methanolic ferric chloride. On attempted acetylation with acetic anhydride and pyridine at 100° for 5 h most of the starting material was recovered unchanged. Compound II did not react with 2,4-dinitrophenylhydrazine in dilute hydrochloric acid and was recovered unchanged when treated for 24 h with a mixture of diazomethane in ether and methanol.

Compound III. Ether-benzene (7:3) eluted a compound (143 mg) which was combined with the sample of compound III obtained above. The combined material was recrystallised from benzene and then from ethanol (95 %) and sublimed in a high vacuum, m.p. 243.5—244.0°, $[\alpha]_D$ + 14° (*c*, 2.2). (Found: C 80.3; H 11.9; active H 0.43; CH_3—(C) 9.4. $C_{30}H_{54}O_2$ requires C 80.6; H 12.2; active H (one) 0.22; CH_3—(C) (one) 3.4.) Infrared spectrum (KBr): 3 430 s, 2 935 vs, 2 880 vs, 2 660 w, 1 633 w, 1 465 s, 1 450 s, 1 386 s, 1 370 m, 1 336 m, 1 304 w, 1 285 m, 1 270 m, 1 252 m, 1 235 m, 1 211 w, 1 166 m, 1 140 w, 1 120 w, 1 075 m, 1 050 w, 1 035 m, 1 005 s, 974 s, 963 m, 945 w, 902 w, 880 w, 870 w, 845 w, 826 w, 730 w, 702 cm^{-1}w.

Compound III on acetylation (acetic anhydride/pyridine) afforded an acetate, m.p. 127.0—128.0°. (Found: C 76.1; H 10.8. $C_{34}H_{58}O_4$ requires C 76.9; H 11.0.)

Acknowledgements. My thanks are due to Professor H. Erdtman for his interest in this work, to Ingeniero José Benito Martinez, Instituto Forestal, Madrid, Spain, for his kind assistance in obtaining the wood sample, to Miss G. Hammarberg for infrared and ultraviolet spectra and to the *Swedish Natural Science Research Council* for financial support.

The Chemistry of the Natural Order Cupressales

XXX *. Heartwood Constituents of *Juniperus cedrus* L.

JARL RUNEBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The heartwood of *Juniperus cedrus* contains thymoquinone, thujopsene, cuparene, cedrol, δ-cadinol, widdrol, "Widdringtonia acid II", nootkatin, β-thujaplicin and carvacrol.

The genus *Juniperus*, which comprises about 60 species, is divided into the sections *Oxycedrus* and *Sabina*. Previous papers [1] have dealt with the wood constituents of a number of junipers, all belonging to the section *Sabina*. In order to compare the two sections chemically a sample of *J. cedrus* (*Oxycedrus*) has now been investigated. The wood was obtained from the Canary Islands.

Only a few papers have been published on the wood oils of *Oxycedrus* junipers. From branches of *J. taxifolia* Shinozaki [2] obtained an oil containing 50 % α-pinene, an alcohol $C_{10}H_{18}O$, an unknown sesquiterpene hydrocarbon and a sesquiterpene alcohol. According to Mousseron [3] a wood pyrolysate of *J. oxycedrus* contained a *d*-cadinene and an *l*-cadinol in addition to a sesquiterpene hydrocarbon and a sesquiterpene alcohol which have not been further investigated. From the wood of *J. communis* Bredenberg [4–6] has isolated ferruginol, Δ^9-dehydroferruginol, 9-ketoferruginol and 9,10-diketoferruginol. Cedrene and cedrol have not previously been found in any *Oxycedrus* junipers and Bredenberg [7] has suggested that the presence or absence of cedrene and cedrol can be used to differentiate between the sections *Sabina* and *Oxycedrus*. However, the isolation of cedrol from *J. cedrus* (*Oxycedrus*) described in the present paper makes this suggestion untenable.

In this investigation the wood was extracted with acetone and the acetone extract was evaporated and poured into ten volumes of light petroleum. The light petroleum-soluble oil was separated into neutral and acidic fractions by extraction with alkali. The acidic material afforded the "acid II", m.p. 190.0—191.0°, of *Widdringtonia* [8]. The presence of nootkatin, β-thujaplicin

* Part XXIX. *Acta Chem. Scand.* **14** (1960) 1985.

and carvacrol in the remaining acidic material was indicated by paper chromatography.

The neutral oil was distilled and the fractions analysed by gas chromatography. According to its infrared spectrum the first fraction, which was yellow, appeared to contain thymoquinone. It also contained hydrocarbons and traces of alcohols. A sample was reduced, and from the product hydrothymoquinone was isolated.

The main component of all the hydrocarbon fractions was thujopsene [9] which was oxidised to the corresponding crystalline aldehyde (widdrenal) [8]. The infrared spectra of these fractions indicated the presence of small amounts of two compounds containing a vinylidene group (1 645 cm^{-1}, 883 cm^{-1}). One of these hydrocarbons may be identical with the curcumene isomer which appears to be present in corresponding sesquiterpene hydrocarbon fractions of *J. virginiana* and *J. thurifera* [1]. This has not been separated from thujopsene by the gas chromatographic system used.

The question of the presence or absence of α-cedrene in this wood could not be settled. On gas chromatography several of the hydrocarbon fractions gave a small peak with a retention time very close to that of α-cedrene but the infrared spectra of these fractions did not show any bands typical of α-cedrene; this, however, does not exclude the presence of small amounts.

The highest boiling hydrocarbon fraction was ozonised at low temperature and the material unattacked by ozone was identified as cuparene [10].

Chromatography of the sesquiterpene alcohol fraction gave cedrol, δ-cadinol [11] and widdrol [8]. Carbonyl compounds present in the residue, obtained on distillation of the neutral oil, were isolated using the Girard D reagent and chromatographed on alumina. Several liquid fractions were obtained but these have not been further investigated.

The compounds isolated are listed below with very approximate estimates of the amounts present (as percentages of the air-dried wood). Total acetone extract 6.1, light petroleum-soluble acetone extract 5.4, sodium bicarbonate-soluble 0.02, potassium hydroxide-soluble 0.09, neutral 5.3, nootkatin 0.0003, β-thujaplicin (traces), carvacrol 0.01, thymoquinone 0.04, thujopsene 2.2, cuparene 0.1, cedrol 0.06, δ-cadinol 0.04, widdrol 0.07, high-boiling carbonyl compounds 0.2.

EXPERIMENTAL

Rotations were measured in chloroform unless otherwise specified; melting points, taken on a hot stage, are corrected; boiling points are uncorrected. Light petroleum refers to the fraction b.p. 40 – 60°.

Isolation of the oils. The ground, air-dried, heartwood (3.90 kg) was extracted with acetone for 48 h. The acetone was evaporated and the remaining oil poured with stirring into ten volumes of light petroleum. The solution was filtered (precipitate A, 30.1 g) and evaporated. The remaining oil was diluted with two volumes of light petroleum and extracted successively with solutions of sodium bicarbonate (saturated) and potassium hydroxide (2 N). On acidification and extraction with ether the sodium bicarbonate solution afforded a viscous oil B (0.74 g) which was not further investigated. The potassium hydroxide-soluble material C (3.62 g) was isolated in the same way by acidification and extraction with ether. The remaining light petroleum solution was washed with water, dried and evaporated giving neutral material E (205 g).

Table 1. Distillation of neutral fraction E. Total distillate 149 g or 73 %.

Fraction	Weight (g)	B.p./22 mm Hg (°C)	Rotation ($[\alpha]_D$)	Refractive index (n_D^{25})
Ia	10.0	119–136	−47	1.5018
Ib	19.1	136–137	−78	1.5017
Ic	19.8	137–138	−91	1.5024
Id	16.6	138–139	−87	1.5030
Ie	23.4	139–148	−48	1.5063
If	14.1	148–150	+21	1.5126
Ig	22.5	150–164	+12	1.5131
Ih	14.8	164–166	+ 4	1.5062
Ii	8.7	166–168	+ 5	1.5071
Ik (residue)				

Alkali-soluble fraction. The alkali-soluble oil C was dissolved in ten volumes of ether and extracted with a solution of sodium carbonate (2 N). The ether solution on evaporation afforded an oil F (0.98 g). The sodium carbonate solution was acidified, extracted with ether and the ether solution was evaporated yielding an oil G (2.41 g) which partly crystallised on standing. The crystals (32 mg) were filtered off, recrystallised from light petroleum, m.p. 190.0–191.0°, $[\alpha]_D$ −98° (*c*, 2.1) and identified (mixed m.p., IR) as the *acid II* isolated from *Widdringtonia* [8]. Paper chromatography [12] showed that the non-crystalline part of G contained *nootkatin* and *β-thujaplicin* and the oil F contained *carvacrol.*

Neutral fraction. The neutral oil E was distilled through a one metre, vacuum-jacketed, packed column giving the fractions listed in Table 1.

Gas chromatographic examination of the sesquiterpene hydrocarbon fractions. Gas chromatograms were run on a Pye Argon Chromatograph as described in a previous paper [13] (temperature 150°, charge 0.025 μl).

In Table 2 the approximate areas of individual peaks of different retention times are given as percentages of total peak area.

With an argon flow rate of 25 ml/min the R_t-values (min) of the following known compounds were: α-cedrene (prepared from cedrol) 19.1, thujopsene 21.0 and cuparene 46.0.

Identification of thymoquinone. The yellow fraction Ia (2.0 g) was suspended in water (5 ml), and the mixture was saturated with sulphur dioxide. The reaction flask was stoppered and allowed to stand for three days. The product was then dissolved in ether, extracted with sodium hydroxide (2 N) and the alkaline solution was acidified and extracted with ether. On evaporation the ether solution gave a crystalline product (0.28 g), which was sublimed in a high vacuum, and identified (mixed m.p., IR) as hydrothymoquinone, m.p. 143.5–144.5°.

Table 2. Gas chromatographic analysis of the sesquiterpene hydrocarbon fractions in Table 1. Argon flow rate 25 ml/min.

Fraction	Peak retention time (min)											
	10.1	12.4	14.6	18.9	21.0	22.9	30.4	33.2	34.9	46.0	48.4	49.9
Ia	1	2	6	6	73						12	
Ib		1	3	9	87							
Ic			1	4	95							
Id					100							
Ie					60	9	9	15		5		2
If					1	2	9	42	20	20		6

Identification of thujopsene. Fraction Id (1.0 g) in ethanol (95 %, 20 ml) was refluxed with selenium dioxide (0.6 g) for 4 h and the product was filtered and evaporated to dryness. The residue (0.82 g) was recrystallised from light petroleum, m.p. 73.5—74.5°, and identified as widdrenal [8] (mixed m.p. IR).

Cuparene. Fraction If (3.0 g) in methylene chloride (15 ml) was ozonised at −70° until an excess of ozone was indicated by the appearance of a blue colour. When the reaction mixture had reached room temperature, hydrogen peroxide (30 %, 8 ml) in potassium hydroxide (10 %, 3 ml) was added dropwise and the mixture was heated on a water bath for 5 min. The organic phase was diluted with a large quantity of ether, separated and evaporated to dryness. The remaining viscous oil was chromatographed on basic alumina (40 g). The first fraction of light petroleum (100 ml) eluted a hydrocarbon (460 mg) which was distilled under reduced pressure. The fraction boiling at 118°/8 mm, n_D^{25} 1.5206, $[\alpha]_D$ + 65° (*c*, 2.2) was identified as *cuparene* [10] by comparing its physical constants and infrared spectra with those of an authentic sample.

Sesquiterpene alcohols. Fraction Ii (2.52 g) was chromatographed on basic alumina (100 g). Light petroleum eluted an oil (0.22 g), benzene also eluted oily material (0.39 g) (neither of these have been investigated further). Ether-benzene (1:50) eluted a compound (0.26 g) which was recrystallised from ethanol (95 %), m.p. 88.0—88.5°, and identified as *cedrol.* Ether-benzene (3:7) eluted *δ-cadinol* [11] (0.17 g) which after recrystallisation from acetonitrile had the m.p. 138.0—139.0°. Ether eluted a compound (0.31 g) which was recrystallised from acetonitrile and sublimed in a high vacuum to yield *widdrol* [8], m.p. 95.0—96.0°, $[\alpha]_D$ + 105° (*c*, 2.2). (All identifications were made by mixed m.p. and IR.) Elution of the column with methanol gave a resinous material.

High-boiling carbonyl compounds. A mixture of carbonyl compounds (0.72 g) was separated from a sample of the neutral distillation residue Ik (5.0 g) using Girard D reagent (2.0 g) as described in a previous paper in this series [13].

Acknowledgements. My thanks are due to Professor H. Erdtman for his interest in this work, to Ingeniero José Benito Martinez, Instituto Forestal, Madrid, Spain, for his kind assistance in obtaining the wood sample, to Miss G. Hammarberg for infrared and ultraviolet spectra and to the *Swedish Natural Science Research Council* for financial support.

The Chemistry of the Natural Order Cupressales

XXXI *. Heartwood Constituents of *Juniperus phoenicea* L.

JARL RUNEBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The heartwood of *Juniperus phoenicea* contains thujopsene, cuparene, cedrol, widdrol, "Widdringtonia acid II", hinokiic acid, nootkatin, β-thujaplicin and carvacrol.

The phoenicean juniper is widely distributed throughout the Mediterranean region, growing in dry situations on rocky hills. In Algeria it ascends to an altitude of about 6 000 feet. It also occurs in the Canary Islands where it is reported to attain a great age and enormous size [1].

Little has been published on the wood oil of *J. phoenicea*. Umney and Bennett [2] analysed an oil consisting mainly of α-pinene and also containing cadinene and traces of aldehydes. Rodié [3] made a study of an oil obtained from berryless branches. He identified pinene, camphene, phellandrene and cadinene and observed the presence of alcohols, esters and small amounts of aldehydes.

Commercial savin oil, obtained by steam distillation of branches and leaves of *J. sabina* has been adulterated by similar preparations obtained from *J. phoenicea*. Manceau [4] however noticed that while only about 24 % of the former oil distils below 170—175°, 79 % of the oil of *J. phoenicea* distils below 180°. This observation has been used to detect adulteration of savin oil. The oil described in this paper, obtained exclusively from heartwood, contained only about 4 % of monoterpenes or compounds with similar boiling points.

The previous paper [5] in this series described some constituents of *Juniperus cedrus*. This paper deals with the heartwood constituents of a sample of *J. phoenicea* obtained from the island of Cyprus.

The wood was extracted with acetone and the light petroleum-soluble part of the acetone extract was separated into neutral and acid fraction. Crystallisation of the acidic material gave "Widdringtonia acid II" [6], m.p. 190.0—191.5° and hinokiic acid [7]. The presence of nootkatin, β-thujaplicin and carvacrol in the remaining acidic material was shown by paper chromatography.

* Part XXX. *Acta Chem. Scand.* 14 (1960) 1991.

The neutral oil was distilled. The lowest boiling part of the oil, which apparently contains monoterpenes, has not been investigated. The next higher boiling sesquiterpene fraction had a relatively simple composition with thujopsene [7] as the main constituent.

J. phoenicea appears to be the most convenient source of thujopsene so far encountered. In all thujopsene-producing conifers so far investigated in this laboratory thujopsene occurs mixed with comparatively large amounts of compounds with very similar boiling points such as α-cedrene or certain incompletely characterised dextrorotatory sesquiterpene hydrocarbons. Large amounts of pure thujopsene can, however, be obtained by a simple distillation of the oil described in this paper.

The highest boiling part of the sesquiterpene hydrocarbon fraction was ozonised at low temperature and the material unaffected by ozone was identified as cuparene [8].

One of the sesquiterpene alcohol fractions crystallised on standing. The crystalline part was separated by chromatography into cedrol and widdrol [6].

Carbonyl compounds present in the residue obtained on distillation of the neutral oil were isolated using the Girard D reagent.

The compounds isolated are listed below with very approximate estimates of the amounts present (as percentages of the air-dried wood). Total acetone extract 8.9, ether-soluble acetone extract 7.5, light petroleum-soluble acetone extract 6.0, sodium bicarbonate-soluble 0.03, potassium hydroxide-soluble 0.5, neutral 5.5, carvacrol 0.1, "Widdringtonia acid II" 0.1, hinokiic acid 0.04, thujopsene 2.2, cuparene 0.08, cedrol 0.2, widdrol 0.003, high-boiling carbonyl compounds 0.05.

EXPERIMENTAL

Rotations were measured in chloroform unless otherwise specified; melting points, taken on a hot stage, are corrected; boiling points are uncorrected. Light petroleum refers to the fraction b.p. 40–60°.

The air-dried heartwood of *J. phoenicea* (7.0 kg) was extracted with acetone for 24 h and fractionated as described in a previous paper in this series [11] (precipitate A, 96 g, precipitate B 108 g, sodium bicarbonate-soluble oil C 2.3 g, potassium hydroxide-soluble oil D, 35 g, neutral oil E, 384 g).

Alkali-soluble fraction. The oil D crystallised partly on standing. The crystals (F, 6.0 g) were filtered off and the remaining oil was dissolved in ether and separated into a sodium carbonate-soluble fraction (G, 15.1 g) and a sodium carbonate-insoluble oil (H, 11.5 g). A crude tropolone fraction (I, 1.22 g) was separated from this oil *via* the copper complexes.

A sample of fraction F was fractionated by crystallisation from ether. The material less soluble in ether was sublimed in a high vacuum, m.p. 190.0–192.0°, and identified (mixed m.p., I.R.) as the "acid II", isolated from *Widdringtonia* [6]. The material slightly more soluble in ether, m.p. 165.5–167.0°, was identified as *hinokiic acid* [7]. From fraction G an additional amount (2.1 g) of the above mixture of acids crystallised on standing.

On paper chromatography [9] fractions I and G were shown to contain *nootkatin* and *β-thujaplicin*. Paper chromatography also showed the presence of *carvacrol* in the oil H.

By a fast preliminary distillation the neutral oil E was divided into fraction K, b.p. up to 50°/70 mm (16.0 g), fraction L (264 g), b.p. 50°/70 mm–140°/1 mm, and a residue M (100 g). The oil L was distilled through a 1 m, vacuum-jacketed, packed column giving the fractions listed in Table 1.

Table 1. Distillation of neutral fraction L. Total distillate 220 g or 83 %.

Fraction	Weight (g)	B.p./15 mm Hg (°C)	Rotation $[\alpha]_D$	Refractive index (n^{25}_D)
Ia	13.7	123–127	−94	1.5020
Ib	21.2	127	−101	1.5026
Ic	26.5	127	−106	1.5030

Ie	23.4	127	−115	1.5031
If	34.0	127–128	−106	1.5030
Ig	21.1	128–138	−12	1.5070
Ih	13.9	138–147	+ 52	1.5093
Ii	10.9	147–154	+ 34	1.5071
Ik	18.5	154–156	+ 37	—
Il	14.4	156–159	+ 25	1.5060

Gas chromatographic analysis of sesquiterpene hydrocarbon fractions. Gas chromatograms were run on a Pye Argon Chromatograph as described in a previous paper in this series [10]. (Temperature 150°, charge 0.025 μl.)

In Table 2 the approximate areas of individual peaks of different retention times are given as percentages of total peak area.

Identification of thujopsene. Fraction Ie (2.0 g) in ethanol (95 %, 40 ml) was refluxed with selenium dioxide (1.2 g) for 4 h and the product was filtered and evaporated to dryness. The crystalline residue (1.8 g) was recrystallised from light petroleum and sublimed in a high vacuum, m.p. 73.5–74.5°, and identified as widdrenal [6,7] (mixed m.p., I.R.).

Cuparene. Fraction Ih (3.0 g) was ozonised and treated as described in a previous paper [10]. The material unaffected by ozone (0.43 g), b.p. 121°/10 mm), $[\alpha]_D$ + 65° (*c*, 2.1), n_D^{25} 1.5200, was identified as cuparene [8] by comparing its physical constants and infrared spectrum with those of an authentic sample.

Sesquiterpene alcohols. Fraction Ik crystallised partly on standing. A sample (5.1 g) was mixed with ethanol (95 %, 10 ml), filtered and the crystalline precipitate (1.8 g) was chromatographed on basic alumina (40 g). Ether-benzene (1:99) eluted *cedrol* (1.60 g), recrystallised from ethanol (95 %), m.p. 85.0–86.0°, $[\alpha]_D$ + 11° (*c*, 1.7) and ether-benzene (1:1) eluted *widdrol* [6] (0.09 g), sublimed twice in a high vacuum, m.p. 95.0–96.0°, $[\alpha]_D$ + 103° (*c*, 2.2) (identifications by mixed m.p. and I.R.).

Table 2. Gas chromatographic analysis of the sesquiterpene hydrocarbon fractions in Table 1. Argon flow rate 25 ml/min.

Fraction	Peak retention time (min)				
	15.1	21.0	29.8	33.2	46.0
Ia	1	99			
Ib–If		100			
Ig		58	12	19	11
Ih			10	47	43

With an argon flow rate of 25 ml/min the retention times of the following known compounds were: thujopsene 21.0, and cuparene 46.0.

High-boiling carbonyl compounds. A liquid mixture of carbonyl compounds (N, 0.16 g) was separated from a sample of the neutral distillation residue M (5.0 g) using Girard D reagent (2.0 g) as described in a previous paper in this series [10].

Studies on the Hydrolysis of Metal Ions

31. The Complex Formation between Pb^{2+} and OH^- in Na^+ (OH^-, ClO_4^-) Medium

BIRGITTA CARELL and ÅKE OLIN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The complex formation between Pb^{2+} and OH^- has been studied in alkaline solution at 25°C. From measurements on the cell

Pb (in Hg)/ *B* M $Pb(ClO_4)_2$, *A* M NaOH, (*I*−*A*) M $NaClO_4$/ ref.

it is concluded that the mononuclear species $Pb(OH)_2$ and $Pb(OH)_3^-$ are formed. No evidence of the species $Pb(OH)_4^{2-}$ was found in the $[OH^-]$ range ($[OH^-] < 0.5$ M) studied. The following values of the equilibrium constants were obtained.

		3 M $Na(ClO_4)$	0.3 M $Na(ClO_4)$
$Pb^{2+} + 2OH^- \rightleftharpoons Pb(OH)_2$	$\log \beta_2$	10.90 ± 0.1	10.34 ± 0.1
$Pb^{2+} + 3OH^- \rightleftharpoons Pb(OH)_3^-$	$\log \beta_3$	13.66 ± 0.05	13.29 ± 0.05

The solubility of lead oxide in alkali has been studied by a number of authors [1–6] and found to be proportional to the concentration of free alkali. The results have been interpreted in terms of the formation of $Pb(OH)_3^-$ as the main leadbearing species in alkaline solution. $HPbO_2^-$ or $PbOOH^-$ is equivalent to $Pb(OH)_3^-$ and these species cannot be distinguished by this type of measurement. In the following we shall write $Pb(OH)_3^-$. — The interpretation is not unequivocal since any species $Pb_n(OH)_{2n+1}^-$ would be compatible with the experimental facts (Leden [7]).

Polarographic measurements have been carried out by Heyrovský [8], Lingane [9] and Goward [10] and their results indicated that $Pb(OH)_2$ and $Pb(OH)_3^-$ are formed. Also from polarographic measurements, Akselrud [11] has suggested that Pb(II) is present as a trinuclear anionic complex in alkaline solution.

Johnson and Kraus [12] have concluded from ultracentrifugation studies that the system is monodisperse and mononuclear. They ascribed to the ion present the formula PbO_2^{2-}. According to Johnson [13] $Pb(OH)_3^-$ would also be in agreement with the experimental data.

The reversibility of the lead amalgam electrode in alkaline solution as shown by Lingane [9] and Goward [10] suggested that the complex formation

between Pb^{2+} and OH^- could be studied by the titration technique with a stationary lead amalgam electrode as the indicator electrode. This is the aim of the present work.

SYMBOLS

A	total concentration of OH^-.
a	$[OH^-]$, concentration of free OH^-.
B	total concentration of Pb(II).
b	concentration of Pb^{2+}.
Z	average number of OH^- per Pb(II) in complexes.
η	$\log \frac{B}{b}$
β_n	formation constant of $Pb(OH)_n^{(n-2)-}$ from Pb^{2+} and OH^-.
$*K_n$	acidity constant of $Pb(OH)_{n-1}^{(n-3)-}$

All concentrations in tables and figures are expressed in M (moles/l), and equilibrium constants are given on the M scale. In the text, however, the more convenient unit mM will be used frequently.

METHOD

The concentration of Pb^{2+} (b) has been measured electrometrically, using a lead amalgam electrode, in a large number of equilibrium solutions(S) which had the analytical composition

S = B M $Pb(ClO_4)_2$, A M NaOH, $(I-A)$ M $NaClO_4$

Since the Pb(II) in alkaline solution is present almost exclusively as uncharged and anionic species, the cationic composition of the solutions S is constant and equal to I M Na^+. In the following we shall, therefore, assume that the variations of the activity factors are so small that activities can be replaced by concentrations in the equations expressing the chemical equilibria in our solutions.

The cell used was

$$-\text{Pb(in Hg)} \;/\; \text{S} \;/\; \text{ref.} + \qquad \text{(I)}$$

$$E_{Pb} = E^\circ_{Pb} - 29.58 \log b - 29.58 \log f_{Pb^{2+}} - E_j \qquad (1)$$

the reference half-cell was

$$/I \text{ M } NaClO_4/ \; (I - 0.01) \text{ M } Na^+, \; 0.01 \text{ M } Ag^+, \; I \text{ M } ClO^-/ \; Ag, AgCl \qquad \text{(II)}$$

and the salt bridge was of the "Wilhelm" type [14].

Eqn.(1) is the simplest relation between the measured potential and the concentration of one of the lead species in solution. It also offers a simple means of putting the results of the emf measurements on an absolute scale by determining E°_{Pb} in acid solution.

Attempts were made to measure $\log[OH^-]$ in these solutions, but we were unsuccessful in finding a glass electrode which functioned like a hydrogen electrode when $\log [OH^-] > -3$. This failure is not serious since $[OH^-]$ can readily be calculated from the analytical OH^- concentrations and the amalgam data.

The liquid junction potential (E_j) in cell (I) was determined on the assumption that it has the same value as in the cell

$$-\text{Pt/H}_2, \; A \text{ M NaOH}, \; (I-A) \text{ M } NaClO_4/ \text{ ref} + \qquad \text{(III)}$$

$$E_H = E^\circ_H + 59.15 \log A + 59.15 \log f_{OH^-} - E_j \qquad (2)$$

E_j, or rather ($59.15 \log f_{OH^-} - E_j$) was obtained from the measurements by the method described by Biedermann and Sillén [15]. It was found to be 7.8 [OH^-] mV. This agrees well with the result obtained by Ingri *et al.*[16] who got 8 [OH^-] mV.

The amalgam electrode [17], which consisted of a pool on the bottom of the titration vessel, was quite slow in attaining its equilibrium value. We had to wait 0.5 to 1 h after each addition before a constant reading was obtained.

Chemicals. The chemicals used in this work were prepared and analysed as described previously [17].

PRELIMINARY EXPERIMENTS

Since previous work on the behaviour of Pb(II) in alkaline solution indicated that the main lead-bearing species is mononuclear with a charge of —1, some preliminary measurements were carried out in order to verify these results.

Measurements at constant a and varying B. These measurements were carried out at $a = (A—3B) = 0.25$ M and B was varied between 0.1 and 10 mM. The results were plotted as $\log B(\log b)$. The plot was linear with a slope close to unity, which shows that the complexes are mononuclear.

Measurements at constant B and varying a. These measurements were made with the values of $B = 0.2$ and 0.5 mM and $0.1 < [OH^-] < 0.5$ M. The results were plotted as $\eta(\log(A—2B))$. The actual OH^- concentration is unknown, but it is reasonable to assume at least two OH^- groups attached to a Pb(II). The use of a high ligand concentration and low metal ion concentrations makes $(A—2B)$ a good approximation for a. The experimental data when plotted as described fell on a single straight line of slope $\simeq 3$.

The concentration of Pb^{2+} in these solutions is very small and we therefore have

$$B = \Sigma\beta_n b a^n; \quad \eta = \log \Sigma\beta_n a^n \qquad (3)\ (3a)$$

and from (3a)

$$\frac{d\eta}{d \log a} = \frac{\Sigma n\beta_n a^n}{\Sigma\beta_n a^n} = Z \qquad (4)$$

The invariance of the difference quotient $\Delta\eta/\Delta\log a$ with a suggest the presence of only one complex and with $\bar{Z} = 3$. The preliminary measurements thus show that $Pb(OH)_3^-$ is formed as the main species in strongly alkaline solution.

A numerical calculation on the data, however, showed that they were not entirely satisfactory. $\Delta\eta/\Delta\log a$ was found to reach a maximum value of $\simeq 2.97$ and then it started to decrease and reached the value 2.9 at [OH^-] = 0.5 M. This would contradict the law of mass action and we began to search for the cause of this behavior. The measurements had been carried out in unprotected glass vessels and dissolution of silica was therefore suspected to occur. A titration carried out in a vessel covered with paraffin gave, however, the same results. The constancy of the amalgam potential for long periods of time would also indicate that no dissolution occurs (see also Ref.[18]).

Contamination of the alkali from the polyethylene bottles used to store the alkali was next considered. Titrations with alkali which had been stored in bottles covered with paraffin gave the same results. A very large contamination of the alkali by carbonate could also be responsible for the observed effect, but this is unlikely since tests with Ba^{2+} gave no precipitate of $BaCO_3$. A titration with alkali to which Na_2CO_3 has been added to give a OH^-/CO_3^{2-} ratio = 10 gave the same results as the other titrations. We were thus unable to find a simple explanation in terms of faulty experimental technique, for

this apparent contradiction of the law of mass action as applied by us and we have been led to the conclusion that deviations in the activity factors occur when the ionic medium is changed considerably.

FINAL EXPERIMENTS

The equilibrium solutions were prepared by a titration technique. Usually the experiments were started from an acid solution of the following composition

$$B \text{ M } Pb(ClO_4)_2,\ H \text{ M } HClO_4,\ I \text{ M } NaClO_4$$

To the starting solution, 50 ml by volume, equal volumes of solution from two burets were added. One buret contained an A M NaOH solution and the other contained a solution of composition $2B$ M $Pb(ClO_4)_2$, $(2I—A)$ M $NaClO_4$. Thus the concentrations of Pb(II) = B and of $Na^+ = I$ M were maintained constant during a run.

In order to ensure a broad range in $[OH^-]$ we always attempted to start with an OH^- concentration close to the solubility limit of $Pb(OH)_2$, although no particular care was taken to be very close to it. The solubility data by Garrett, Vellenga and Fontana [6] were used as a guidance. No troubles were experienced on passing from the acid to the alkaline range from the intermediate formation of lead hydroxide. The precipitate dissolved rapidly and completely in the excess alkali.

Titrations were frequently made on alkaline starting solutions prepared a couple of days before an experiment was performed in order to see if there was any difference between fresh and aged alkaline solutions. The results from these titrations did not differ from the other titrations. As a further check on the reversibility of the equilibria, back-titrations were made. The initial solution was made strongly alkaline and acid was added. These titrations gave the same results as the preceding ones. It is therefore likely that true equilibria were measured.

RESULTS WITH 3 M $Na(ClO_4)$ AS MEDIUM

With 3 M $Na(ClO_4)$ as medium the following total Pb(II) concentrations were used; B = 10, 5, 2.5, 1, 0.5 and 0.25 mM. Since log $[OH^-]$ was not measured it had to be calculated. Hedström [19] has given formulas which allow the calculation of the free ligand concentration from a knowledge of the total ligand concentration and the free metal ion concentration only. The preliminary measurements had shown that the complexes formed were mononuclear and moreover the concentration of free ligand is large compared to B. In our case, therefore, the method developed by Leden [20] easily leads to the goal. With our notations we have

$$\frac{\partial \eta}{\partial \log a} = Z \tag{4}$$

$$a = A—BZ \tag{5}$$

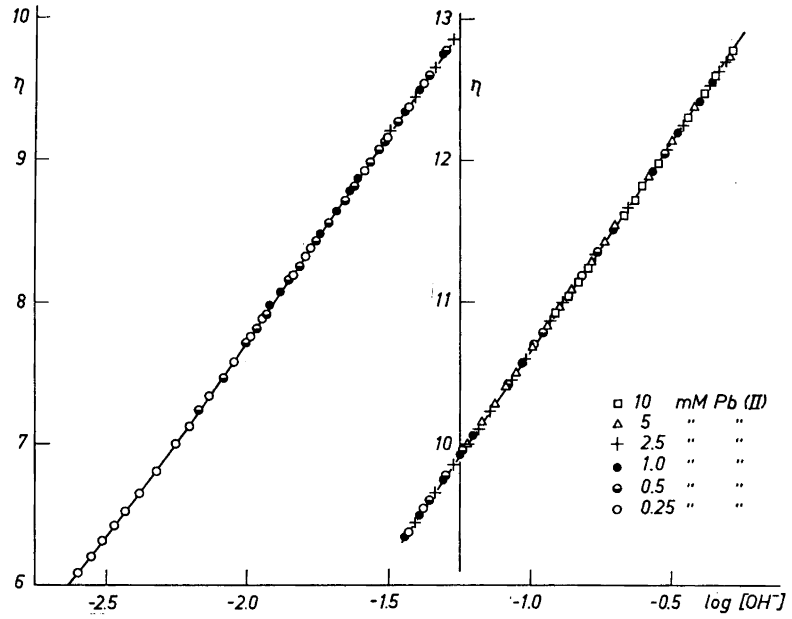

Fig. 1. η = log [Pb(II)]$_{tot}$/[Pb^{2+}] as a function of log[OH$^-$]. The solid line is calculated with log β_2 = 10.9 and log β_3 = 13.66.

Neighbouring points were used to find $\Delta\eta/\Delta\log a$ and as a first estimate of a, $(A—3B)$ was used. The successive approximations were repeated till the third place in log$a$ did not change on a further calculation.

The η values at low B and [OH$^-$] have been corrected for the presence of small amounts of $PbOH^+$ and $Pb_3(OH)_4^{2+}$, which still persist in these solutions [17]. The data plotted as η(log [OH$^-$]) fall on a single curve as can be seen from Fig. 1.

Determination of the equilibrium constants. The mononuclear complexes present are most likely to be only $Pb(OH)_3^-$ and $Pb(OH)_2$, whereas $Pb(OH)_4^{2-}$ and higher complexes cannot be present in larger amounts since Z never exceeds 3. We have

$$B = \beta_2 ba^2 + \beta_3 ba^3 + \beta_4 ba^4 + \text{----------} \quad (6)$$

$$Ba^{-2}b^{-1} = \beta_2 + \beta_3 a + \beta_4 a^2 + \text{----------} \quad (7)$$

By plotting $Ba^{-2}b^{-1}$ as a function of a, β_2 is found from the intercept on the $Ba^{-2}b^{-1}$ axis and β_3 from the slope of the straight line which should be obtained if the hypothesis is valid. The presence of $Pb(OH)_4^{2-}$ *etc.* should make the line bend upwards at high a. The plot is shown in Fig. 2.

It is obvious that the data can not be fitted to a straight line over the whole log[OH$^-$] studied. This leads to a certain ambiguity when fitting the data to

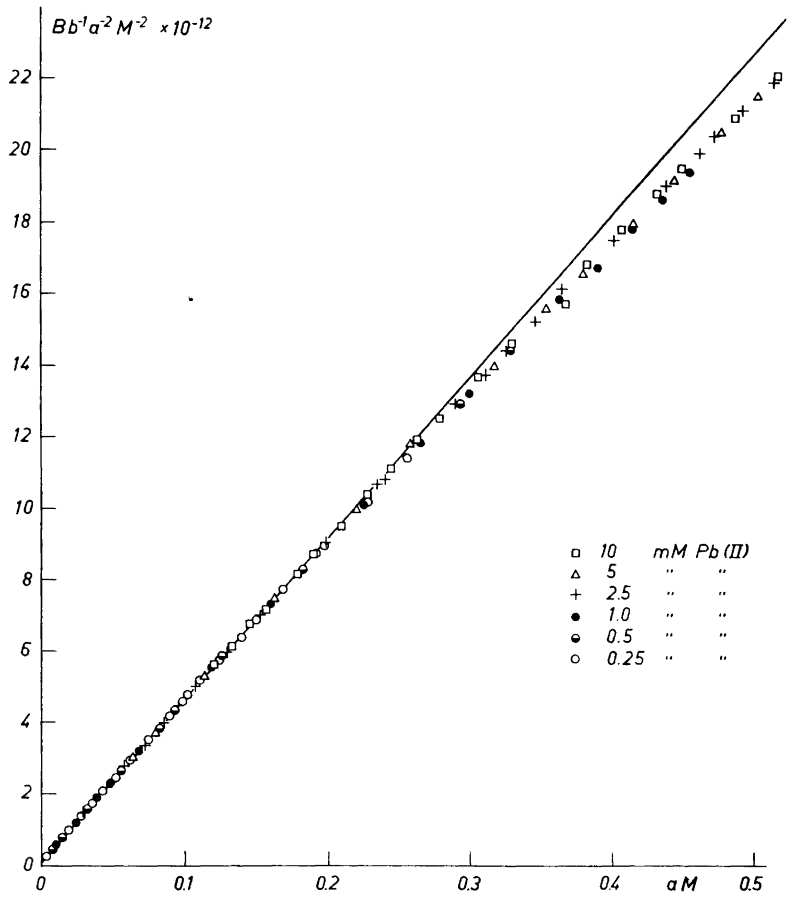

Fig. 2. $[Pb(II)]_{tot}/([Pb^{2+}][OH]^2)$ as a function of $[OH^-]$. The straight line gives $\log \beta_2 = 10.9$ and $\log \beta_3 = 13.65$.

the best straight line. Two such lines have been drawn. The first line was drawn so as to fit all the data for $[OH^-] < 0.2$ M best (Fig. 2). For $[OH^-] > 0.2$ M the deviations from linearity are so large that these data can not be used for the determination of the equilibrium constants. The values of the constants obtained from the line were

$$\log\beta_2 = 10.9 \pm 0.1$$

$$\log\beta_3 = 13.65 \pm 0.05$$

The deviations are in a direction opposite to that expected for the formation of $Pb(OH)_4^{2-}$. A tentative explanation could be variations in the activity factors when the composition of the medium has been changed considerably.

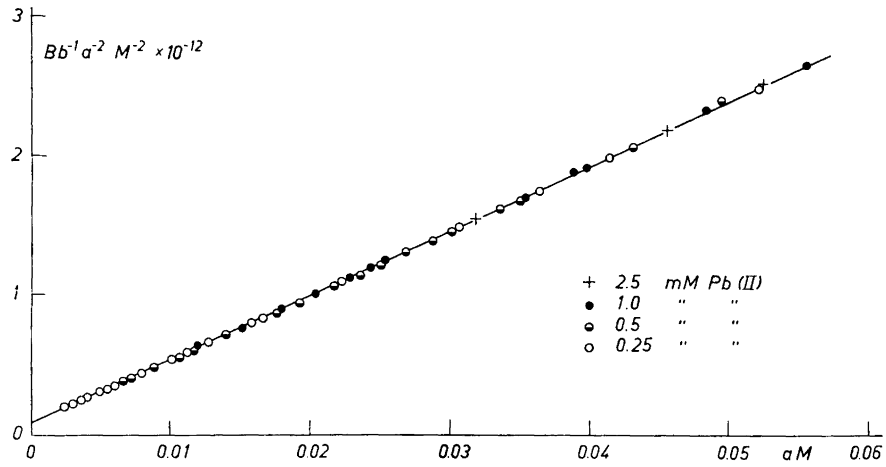

Fig. 3. $[Pb(II)]_{tot}/([Pb^{2+}][OH^-]^2)$ as a function of $[OH^-]$. The straight line gives $\log \beta_2 = 10.9$ and $\log \beta_3 = 13.66$.

This would suggest that the data at low $[OH^-]$ give better values of the equilibrium constants. A straight line drawn through the points for $[OH^-] < 0.05$ M (Fig. 3) gave

$$\log\beta_2 = 10.9 \pm 0.1$$

$$\log\beta_3 = 13.66 \pm 0.05$$

The deviations at large $[OH^-]$ are somewhat surprising in view of the measurements of Garrett, Vellenga and Fontana [6]. They determined the equilibrium constant for the reaction

$$PbO\ (s) + OH^- \rightleftharpoons Pb(OH)_3^-$$

$$K = \frac{[Pb(OH)_3^-]}{[OH^-]} \tag{8}$$

and calculated K by inserting analytical concentrations in (8). For $[OH^-] < 1$ M, K did not vary systematically with $[OH^-]$ and this would indicate that $f_{Pb(OH)_3^-}/f_{OH^-}$ is close to unity. We have calculated the activity factor ratio by combining the measurements from the cells (I) and (III). The variation in the water activity is very small and is neglected.

From eqn. (2) we obtain

$$E_H - E_H^\circ - 59.15 \log a = 59.15 \log f_{OH^-} - E_j = -7.8\,a \tag{2a}$$

and substituting $bf_{Pb^{2+}}$ from

$$\beta_3 = \frac{[Pb(OH)_3^-]}{ba^3} \frac{f_{Pb(OH)_3^-}}{f_{Pb^{2+}} f_{OH^-}^3} \tag{9}$$

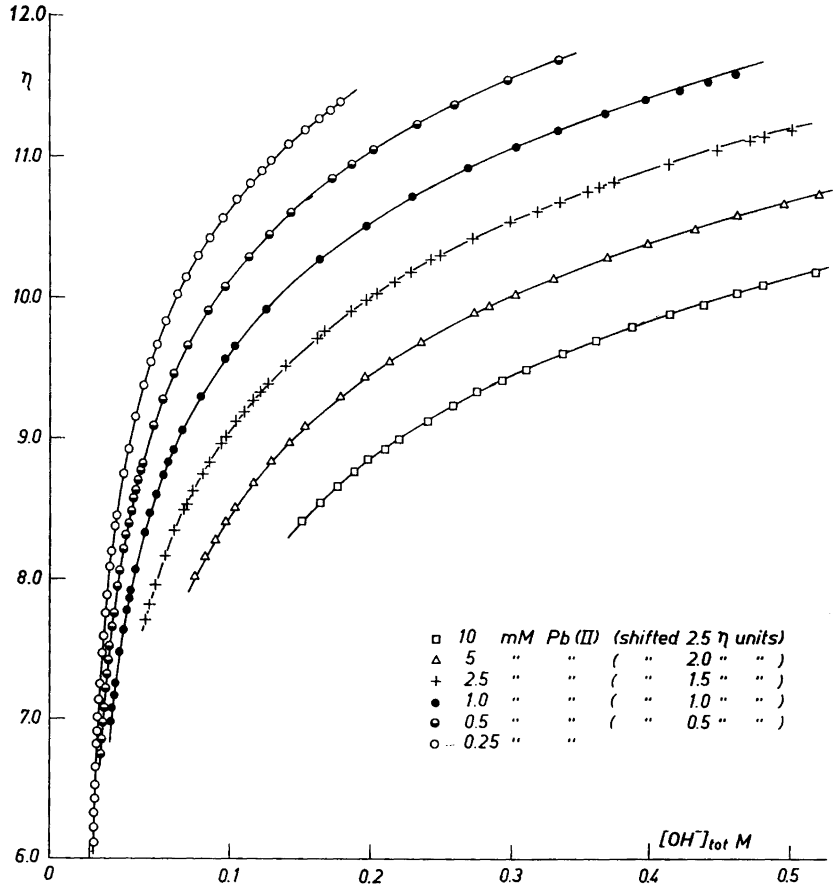

Fig. 4. η as a function of $[OH^-]_{tot}$. The solid lines are calculated using $\log \beta_3 = -10.9$ and $\log \beta_3 = 13.66$.

in eqn. (1) and putting $a = (A—3B)$ and $[Pb(OH)_3^-] = B$ we get

$$\log f_{OH^-}/f_{Pb(OH)_3^-} = (E_{Pb}—E^o_{Pb})/29.58 + \log B—\log\beta_3— \\ — 3 \log (A—3B) + 7.8 (A—3B)/29.58 \quad (10)$$

The expression is valid for $[OH^-] > 0.2$ M where $[Pb(OH)_2]$ can be neglected. $f_{OH^-}/f_{Pb(OH)_3^-}$ was found to decrease from unity to $\simeq 0.93$ at 0.5 M OH^-.

If the assumption of constant activity factors is still upheld the result would have to be explained in terms of incomplete dissociation of NaOH. It would, however, be necessary to assume that "$(OH)_2^{2-}$" complexes are formed. The formation of NaOH although leading to a $f_{OH^-}/f_{Pb(OH)_3^-}$ ratio different from unity, would not give a ratio varying with $[OH^-]$.

The previous measurements [17] on the hydrolysis of Pb(II) in acid and neutral solution had been discontinued at $\log h \simeq —8.5$ when a precipitate of basic

lead perchlorates started to form. Thus there is a gap between the old and the new sets of data of *ca.* 3 log$h$ units. We have tried to fill this gap by measurements with $B = 0.1$, 0.2 and 0.4 mM in 0.3 M Na(ClO_4). We were, however, unsuccessful and could not obtain stable potentials when $\log[OH^-] < -3$. In more alkaline solutions the potentials were stable and yielded the following values of the equilibrium constants.

$$\log\beta_2 = 10.34 \pm 0.1$$
$$\log\beta_3 = 13.29 \pm 0.05$$

In order to show the agreement between the experimental data and the values calculated from the equilibrium constants given, Fig. 4 was constructed. Note that the $\eta(A)_B$ curves have been successively displaced by 0.5 η unit in order to increase the clarity of the figure.

DISCUSSION

With the exception of Akselrud's work, all investigations on the behavior of Pb(II) in alkaline solution point to the formation of $Pb(OH)_2$ and $Pb(OH)_3^-$. The table gives the values of $\log\beta_2$ and $\log\beta_3$ found in the literature.

			$\log\beta_2$	$\log\beta_3$
Heyrovský [8]	var. NaOH		———	12.15
Lingane [9]	var. NaOH	25°C	———	12.9
Goward [10]	1 M KNO_3	25°C	10.77	13.31
This work	3 M $NaClO_4$	25°C	10.90	13.66
This work	0.3 M $NaClO_4$	25°C	10.34	13.29

From solubility measurements we may calculate

$$K_3 = \frac{[Pb(OH)_3^-]}{[Pb(OH)_2]\,[OH^-]} = \frac{\beta_3}{\beta_2} \qquad (11)$$

and find from the data by Garrett, Vellenga and Fontana [6] $\log K_3 = 2.86$ for the yellow oxide and 3.06 for the red oxide. Our value of $\log K_3$ is 2.76 (3 M $NaClO_4$) and 2.95 (0.3 M $NaClO_4$).

Considering that the constants have been obtained under different experimental conditions the agreement between the numerical values may be considered satisfactory.

Published values of the solubility product of lead oxide vary considerably [22]. The highest value of $\log K_{S0}$ is —13.96 and the smallest value is —19.96. From our value of β_2 in 3 M Na(ClO_4) and the solubility of $Pb(OH)_{2(aq)}$ ($1 \cdot 10^{-4}$ M for the yellow oxide and $4 \cdot 10^{-5}$ for the red oxide[6]) we may estimate $\log K_{S0} \simeq$ —14.9 and —15.3. This agrees fairly well with the value of $\log K_{S0} =$ —15.04 and — 15.23 found by Applebey and Reid [3] from measurements of the cell Pb, PbO/1 M NaOH/ HgO, Hg.

From the β values and the ionic product of water ($\lg K_w =$ —14.22 in 3 M $NaClO_4$ (Ingri *et al.*[15]) and $\log K_w =$ —13.76 in 0.3 M $NaClO_4$ (determined by us) we find the following values of the acidity constants of Pb^{2+}.

	3 M $NaClO_4$	0.3 M $NaClO_4$
log $*K_1$	— 7.9	— 7.8
log $*K_2$	— 9.6	— 9.4
log $*K_3$	—11.5	—10.8

The regular sequence of the log$*K_n$ values shows an interesting break after log$*K_3$. The value of log$*K_4$ must be much smaller than expected from the sequence. The ratio between the successive acidity constants of Pb^{2+} ($10^{-1.4}$ to $10^{-1.9}$) is considerably larger than for hydroxide acids (such as H_3PO_4), where the ratio is around 10^{-5}, but smaller than found for other metal ions. For a large number of metal ions log$*K_1$ and log$*K_2$ have about the same value (Sillén [21]).

Acknowledgements. We wish to thank Professor Lars Gunnar Sillén for his continual interest in our work and to Dr. V. Tyrrell for having corrected the English of this paper. Thanks are also due to Mr Frans Ericson for construction of the apparatus. This work has been supported by *Statens Tekniska Forskningsråd* (*Swedish Technical Research Council*).

Radiochemical Determination of Polythionates

NILS-HERMAN SCHÖÖN

Department of Engineering Chemistry, Chalmers Tekniska Högskola, Göteborg, Sweden

Two radiochemical methods have been developed for the determination of polythionates. In the first method, the polythionates are reacted with sulphite and with a mixture of sulphite and sulphide. The thiosulphate formed in these reactions is then determined with ^{110}AgSCN. In the second method, the sulphide contains the radioactive isotope ^{35}S and the amount of radioactive thiosulphate formed is instead determined. A correction must be applied for the amount of radioactive thiosulphate formed by isotopic exchange between the sulphide and thiosulphate.

The common method for determining polythionates in mixtures is based on the fact that these ions, on reaction with sulphite, sulphide, cyanide, and hydroxide, give amongst other compounds thiosulphate [1,2]. The thiosulphate formed can be determined iodometrically in a weakly acid solution after the disturbing influence of sulphite, sulphide and cyanide has been eliminated.

In the present work, two radiochemical methods for the determination of the total amount of polythionate have been developed. Both of the methods are intended for use in the determination of polythionate in spent liquors from the sulphite cellulose process. With the iodometric method, the errors are considerable in this case and with many types of liquors it is impossible to use a method of this sort.

In the first method, the amount of thiosulphate formed in the reaction with sulphite and the amount of thiosulphate formed in the reaction with a mixture of sulphite and sulphide are determined. The thiosulphate determinations are performed by means of the silver thiocyanate method using silver thiocyanate containing the radioactive isotope ^{110}Ag. From these two determinations, it is possible to calculate the amount of polythionate as well as the mean number of sulphur atoms per mole polythionate.

In the second method, the polythionates are first made to react with sulphite and then with sulphide containing the radioactive isotope ^{35}S. After precipitation of sulphide, the amount of radioactive thiosulphate formed is determined. From this determination, it is possible to calculate the original amount of polythionate after correcting for the radioactive thiosulphate which is formed by isotope exchange between thiosulphate and sulphide.

I. THE SILVER(^{110}Ag) THIOCYANATE METHOD

Polythionates with more than three sulphur atoms per molecule react in alkaline solution with sulphite forming thiosulphate and trithionate according to the equation:

$$S_nO_6^{2-} + (n-3)\ SO_3^{2-} \rightarrow S_3O_6^{2-} + (n-3)\ S_2O_3^{2-},\ n > 3 \qquad (1)$$

Even at room temperature, the reaction proceeds very rapidly in the presence of an excess of sulphite. Trithionate does not react with sulphite under the conditions existing in this case. In weakly acid or neutral solutions, the reaction proceeds slowly. Moreover, the reaction does not give a complete yield, a state of equilibrium being instead obtained.

In the reaction between polythionates and a mixture of sulphite and sulphide, it has been found that all of the polythionates give thiosulphate according to the equation:

$$S_nO_6^{2-} + S^{2-} + (n-3)\ SO_3^{2-} \rightarrow (n-1)\ S_2O_3^{2-},\ n \geq 3 \qquad (2)$$

This reaction is carried out at about 100°C since the reaction rate is relatively low at room temperature.

If the amount of thiosulphate formed in these two reactions is determined, it is possible to calculate the total amount of polythionate in the following way:

In a solution containing a_2 mole $S_2O_3^{2-}$, a_3 mole $S_3O_6^{2-}$, a_4 mole $S_4O_6^{2-}$, ... a_n mole $S_nO_6^{2-}$, we obtain after the reaction with sulphite a thiosulphate amount, $A = a_2 + \Sigma(n-3)\ a_n$, and after the reaction with sulphite-sulphide a thiosulphate amount, $B = a_2 + \Sigma(n-1)\ a_n$. From these two quantities, the amount of polythionate is obtained as $\Sigma a_n = \frac{B-A}{2}$ while the average number of sulphur atoms per molecule is

$$\bar{n} = \frac{n\Sigma a_n}{\Sigma a_n} = \frac{B + \frac{B-A}{2} - a_2}{\frac{B-A}{2}}$$

In order to calculate $\bar{n}$, it is evident that the original thiosulphate content of the solution must be determined. As has been previously shown [3], it is also possible to perform this determination with the silver thiocyanate method.

The determination of thiosulphate with the silver thiocyanate method is based on the property of the thiosulphate ion of forming stable silver thiosulphate complexes with silver ions [4]. Thus, if an excess of solid silver thiocyanate is shaken with a thiosulphate solution, the following equilibrium between the solid phase and solution is obtained after only 10 min at 20°C:

$$m\ AgSCN_{(s)} + n\ S_2O_3^{2-} \rightleftharpoons Ag_m(S_2O_3)_n^{(2n-m)-} + m\ SCN^-$$

Since the silver thiocyanate contains the radioactive isotope ^{110}Ag, the total amount of silver in the solution can be determined by measuring the activity of the solution after removal of the solid phase. The thiosulphate content is then calculated by means of a calibration curve between thiosulphate content and silver content.

The determination of the thiosulphate which is formed in the sulphite reaction is complicated by the fact that the sulphite ions like the thiosulphate ions give stable complexes with silver ions. The formation of silver sulphite complexes can, however, be completely avoided if the solution is acidified before the analysis. This is due to the fact that hydrogen sulphite ions in contrast to sulphite ions do not form complexes with silver ions. However, it has been found [3] that hydrogen sulphite has a certain effect on the determination of thiosulphate by the silver thiocyanate method. In the present work, it has therefore been necessary to study how this effect depends on the pH of the solution, in order to determine to what pH the solution should be adjusted after the sulphite reaction.

Before determining the thiosulphate after the sulphite-sulphide reaction, the remaining sulphide is removed by precipitation with zinc carbonate. The solution is thereafter acidified in order to convert the sulphite to hydrogen sulphite. The effect on the thiosulphate determination of any possible remaining traces of sulphide was also studied.

Experimental

Chemicals

Potassium trithionate, $K_2S_3O_6$, has been prepared according to Kurtenacker and Matejka [5] and potassium pentathionate, $K_2S_5O_6 \cdot 1.5\ H_2O$, according to Stamm, Siepold and Goehring [6]. Sodium tetrathionate, $Na_2S_4O_6 \cdot 2\ H_2O$, was prepared by shaking solid sodium thiosulphate with an excess of iodine dissolved in absolute alcohol. The purity of the trithionate and pentathionate was better than 97 % while the impurity content in the tetrathionate was less than 0.5 %. The purity of these substances was determined using the sulphite method and the sulphite-sulphide method as described by Kurtenacker [1] and using the mercury(II) chloride method according to Jay [7].

The sodium sulphide solution was prepared by passing hydrogen sulphide into a sodium hydroxide solution. The surface of the sulphide solution was covered with paraffin oil in order to minimize aerial oxidation. The sulphite solution was freshly prepared for each series of experiments.

The silver isotope, ^{110}Ag, was provided by AB Atomenergi — it had been prepared by neutron irradiation of a piece of silver foil. About 1 g of foil was irradiated to an activity of 1—2 mC. It was then dissolved in 50 ml hot nitric acid (diluted 1:4) and diluted to 500 ml. Of this solution, 100 ml was taken and sufficient inactive silver nitrate added to lower the activity to 800—1 000 c.p.m./10^{-4} M silver (GM-tube for liquids). The solution obtained was diluted and silver thiocyanate was precipitated at about 100°C using an excess of potassium thiocyanate solution. The precipitate was washed with water until the washings no longer produced a colour with iron(III) nitrate. In order to determine the relation between activity and silver content, a weighed amount of silver thiocyanate was dissolved in an excess of 1 M potassium cyanide. After diluting, 10 ml of the solution was taken for activity measurements.

Apparatus

The shaking of the silver thiocyanate suspension was carried out using a "Microid flask shaker" from Griffin and George Ltd. The filtering of the suspension was performed in a Thiessen filtration apparatus provided with a colloid filter (according to Zsigmondy). The pore width of the colloid filter was 200—300 mμ.

The radioactivity was measured with a GM-tube for liquids made by Mullard Ltd. Before each measurement, the GM-tube had to be washed with conc. potassium cyanide solution. The scaler used was a Type 1 000 apparatus from AB Nukleonikinstrument, Göteborg.

Procedure

The sulphite reaction. To 10 ml of the sample, 5 ml 0.4 M sodium sulphite was added after which the solution was allowed to stand for 15 min at room temperature. The solution was acidified with 5 ml 0.5 M formic acid and, to 10 ml of the solution thus obtained, 10 ml silver thiocyanate suspension containing 10—25 mg precipitate was added. The mixture was shaken vigorously for 15 min at 20 ± 1°C after which the solution was filtered. The activity was measured on 10 ml of the filtrate. The activity obtained was corrected for background radiation and radioactive decay.

The sulphite-sulphide reaction. To 25 ml of the sample, 5 ml 0.4 M sodium sulphite and 5 ml 0.25 M sodium sulphide were added and the solution was heated in boiling water for 15 min. Then, 10 ml 0.35 M freshly prepared zinc carbonate suspension was added and the mixture was cooled to room temperature and filtered. After adding 10 ml 1 M formic acid, the filtrate was diluted to 100 ml. A 10 ml sample of this solution was taken and 10 ml silver thiocyanate suspension was added. Shaking and filtration were performed as described above.

Results

Determinations of the thiosulphate formed in the sulphite and sulphite-sulphide reactions are shown in Table 1. In order to be able to compare the

results in the sulphite series with those in the sulphite-sulphide series, the silver concentrations measured are given in the table instead of the thiosulphate concentrations calculated from the calibration curve. All the concentrations in the table refer to the filtrate obtained after shaking with silver thiocyanate.

The concentrations are given in mole/litre.

Under "calc." are reported the silver contents which were obtained in parallel experiments with thiosulphate.

As may be seen from the table, the agreement between the calibration series with thiosulphate and the actual experiments with polythionates is good. The maximum deviation amounts to 3 %. The results of the sulphite series show, in addition, that the trithionate formed by the reaction does not affect the thiosulphate determination. A comparison of the silver concentrations in the sulphite series and sulphite-sulphide series is not possible in the table since the thiosulphate concentrations in the sulphite-sulphide series are, owing to aerial oxidation of the sulphide, somewhat higher than those in the sulphite series. A comparison between the calibrations with thiosulphate for both of the experimental series has instead been made in Fig. 1. As may be seen from the figure, the agreement between the two series is good which shows that the higher silver content which is obtained in the sulphite-sulphide series can be completely attributed to the amount of thiosulphate which is formed by aerial oxidation of the sulphide.

Influence of hydrogen sulphite at various pH values. In all experiments reported in Table 1, the solution has been acidified with formic acid to pH 4.0 before the determination of thiosulphate. Since the formation of the silver thiosulphate complexes is influenced by the presence of hydrogen sulphite, this effect has been studied as a function of the pH of the solution. The pH interval studied was 2.6—4.9 and the sulphite concentrations were 0.01, 0.05, and 0.1 M. Comparative experiments with thiosulphate solutions in the absence of hydrogen sulphite have also been performed. As is obvious from Table 2, a change in the total sulphite content or in the pH has only a very slight effect on the formation of the silver thiosulphate complexes. The variations in the silver content which have been obtained lie, with exception of the smallest

thiosulphate content, within the experimental error for the method. The acidification after the sulphite reaction can therefore be performed to any pH within the interval 2.6—4.9 without the formation of the silver thiosulphate complexes being thereby appreciably affected. From the comparative experiments performed without the addition of hydrogen sulphite, it is evident that a decrease in the formation of the silver thiosulphate complexes occurs only at a relatively low pH. Whether or not this decrease is due to a decomposition of the thiosulphate added has not been investigated.

Influence of sulphide. For a complete precipitation of sulphide ions as zinc sulphide, it is important to use a freshly prepared zinc carbonate suspension and to filtrate the solution after cooling to room temperature. Otherwise the filtrate will contain a small amount of sulphide ions which give a precipitation of silver sulphide on shaking with solid silver thiocyanate according to

$$2\ AgSCN_{(s)} + S^{2-} \rightarrow Ag_2S_{(s)} + 2\ SCN^-$$

The thiocyanate ions formed in this reaction would then displace the equilibrium between the solid silver thiocyanate and the thiosulphate ions in such a way that the total amount of complex-bound silver would decrease. Some experiments carried out at 24 ± 1°C were performed in order to illustrate how the sulphide and thiocyanate ions affect the formation of the silver thiosulphate complexes. A zinc carbonate suspension was not added in these experiments (*cf.* Table 3). It is seen that the influence of thiocyanate ions is considerable. A corresponding decrease in the total silver content has, however, not been obtained in the presence of sulphide ions. The silver content was found instead to have increased. This is due to the fact that part of the precipitated silver sulphide exists in a colloidal state with such a small particle size that it can pass through even a very fine colloid filter (pore diameter 150 mμ). The presence of silver sulphide in the solution is apparent from its weakly yellow colour.

* One μmole KSCN was added per ml solution.

II. THE SULPHIDE(^{35}S) METHOD

In this method, the polythionate solution is first of all allowed to react with an excess of sulphite thus forming thiosulphate as well as one mole of trithionate per mole polythionate (*cf.* eqn. (1) given above). The solution is then made to react at about 100°C with an excess of sulphide containing the radioactive isotope ^{35}S. In this reaction, one mole radioactive thiosulphate is obtained per mole trithionate, *i.e.* one mole radioactive thiosulphate per mole polythionate in the original sample.

The reaction between sulphide and trithionate can be written as follows:

$$S_3O_6^{2-} + {}^*S^{2-} \rightarrow {}^*S_2O_3^{2-} + S_2O_3^{2-}$$

After the remaining sulphide has been precipitated with zinc carbonate, an excess of alkali is added and the thiosulphate and sulphite are oxidized at about 100°C to sulphate by means of hydrogen peroxide. The sulphate is precipitated as barium sulphate and the activity of the precipitate is measured in a proportional counter of the "flow-counter" type. Because the sulphur isotope ^{35}S is a very weak β-emitter ($E_{max} = 0.167$ MeV), the measurements have been performed using the "infinitely thick layer" method. In this method, the thickness of the barium sulphate layer is chosen so that it exceeds the maximum range of the β-radiation. Since the absorption coefficient for β-radiation in barium sulphate is of the order of 0.2 cm^2/mg[8], it can be calculated that the required thickness corresponds to 25 mg $BaSO_4$/cm^2. In this method, the activity measured is proportional to the specific activity of the precipitate. The original amount of polythionate in the sample is, however, proportional to the total activity. A relative measure of the total activity can be obtained by multiplying the measured activity by the total weight of precipitate.

Parallel to the reaction between sulphide and trithionate, radioactive thiosulphate is also formed by isotopic exchange between sulphide and thiosulphate in the following way:

$$*S^{2-} + S{-}SO_3^{2-} \rightarrow *S{-}SO_3^{2-} + S^{2-}$$

This reaction has been studied by Voge [9] who found that the exchange took place very slowly even at 100°C. In the present investigation, it was however found that this exchange is of such a magnitude that it cannot be neglected in the determination of polythionate. Hence, a correction has to be applied if the original sample contains thiosulphate or higher polythionates.

Experimental

Chemicals

Except for the potassium pentathionate, the polythionate preparations have been the same as in the previous section. The pentathionate sample used here contained a relatively large amount of tetrathionate (*cf.* Table 5).

Radioactive sodium sulphide was obtained from the Radiochemical Centre, Amersham, England. The radioactive sulphide solution was prepared by dissolving about 3 mC radioactive sulphide in 1 l 0.25 M inactive sulphide solution containing at most 0.5 mole per cent thiosulphate. In order to determine the relationship between sulphide content and activity, one aliquot of the solution was taken and, after addition of inactive sulphate, oxidized at 90—100°C with hydrogen peroxide. The activity of the precipitated barium sulphate was then measured. Because the sulphide solution contained thiosulphate with a high specific activity, it was necessary to correct the relation between activity and sulphide content for the activity of the thiosulphate. In order to perform this determination, the sulphide was first of all precipitated using zinc carbonate after which the filtrate was treated as above.

Apparatus

In order to obtain reproducible measurements of the activity of the barium sulphate, it is necessary that the precipitate should be spread evenly over a given surface. This has been accomplished by means of a filtration procedure. The suspension of barium sulphate was transferred by means of a slow filtering to a plexiglas crucible provided with a fine filter paper. The inner diameter of the crucible was 3 cm and thus an "infinitely thick layer" could be obtained since the amount of precipitate exceeded 175 mg. When filtering, the plexiglas crucible was mounted between a porcelain muff and a glass sleeve. After filtration and drying, the crucible was placed in a proportional counter in order to measure the activity.

The counter was of the "flow-counter" type. It was equipped with a thin window consisting of a plastic film in order to diminish the comsumption of the gas used for the measurements. This gas was a mixture of 20 % methane and 80 % argon. The counter, amplifier and scaler were manufactured by AB Nukleonikinstrument, Göteborg.

Procedure

To 10—15 ml of the sample, about 5 ml 0.4 M sulphite solution was added after which the liquid was allowed to stand for 15 min at room temperature. Radioactive sulphide solution, 5 ml 0.25 M, was added and the resultant solution was heated in boiling water for 15 min. Then, 10 ml 0.35 M freshly prepared zinc carbonate suspension was added after which the mixture was cooled and filtered. To the filtrate, 5 ml 1 M sodium hydroxide and 10 ml 30 % hydrogen peroxide were added and the solution obtained was heated for 20 min in boiling water. Then, 15 ml 1 M hydrochloric acid was added and, thereafter, an excess of hot 0.2 M barium chloride, dropwise under stirring. After cooling, the solution obtained was filtered in the same way as described above. The precipitate was washed with alcohol and ether and dried at 50°C. The activity and weight of the precipitate were then measured. The activity was corrected for the background radiation. The correction for the radioactive decay was obtained by comparing in each series, the activity

obtained with the activity of a standard sample of radioactive barium sulphate. Since it was found to be difficult to transfer the barium sulphate quantitatively to the filter and, at the same time, to obtain a completely even surface, another procedure has also been tried. In it, the barium sulphate suspension was filtered through a glass filter and the weight of the precipitate was obtained. Thereafter, the precipitate was suspended once again in water and then transferred to the plexiglas crucible in order to measure the activity. Hence, in this case, it was not necessary to transfer the precipitate quantitatively to the plexiglas crucible.

Results

The radioactive sulphide method has been tried, first of all, for the determination of trithionate. The results are shown in Table 4. The table contains three series which have been performed at intervals of about one month. The values given under "Activity × Weight of $BaSO_4$" have been corrected for the value obtained in the blank measurement. It is seen that a large amount of radioactive thiosulphate is obtained in the blank. This amount of thiosulphate was found already in the original sulphide solution and thus the formation of thiosulphate by aerial oxidation during the heating must be negligible. The more laborious filtration procedure described above (*cf.* under Procedure) has only been used in the third series. It is seen that the difference from the calculated value is least in this series, at most 2 %. In the other two series, it is somewhat larger, *viz.* 5 %.

The mean values obtained for the activity in the three series correspond to a 100 % yield of radioactive thiosulphate which means that the isotope exchange between the radioactive sulphide and the inactive thiosulphate formed by the reaction falls within the experimental error for the method. If, on the other hand, the solution contains thiosulphate at the beginning of the sulphide reaction, the formation of radioactive thiosulphate will be greater. As can be seen from Table 5, this formation of radioactive thiosulphate is proportional to the thiosulphate content and amounts to 10 % of this content. From the experiments with polythionates, it is seen in addition that the isotope exchange between thiosulphate and sulphide occurs independently of the presence of trithionate. This means that, with tetrathionate, a 10 % and, with pentathionate, a 20 % larger amount of radioactive thiosulphate is obtained than in the reaction with trithionate. For a correct determination of the total amount of polythionate, it is therefore necessary to determine, in addition, the total thiosulphate content after the sulphite reaction. This determination can, of course, be performed by means of the ^{110}AgSCN-method but an indirect determination should also be possible by means of the ^{35}S-method. If the latter procedure is used, the solution is oxidized with iodine after the sulphite reaction, and sulphite and radioactive sulphide are thereafter added to the solution as above. The amounts of radioactive thiosulphate formed by means of the original procedure ($*a_2^{I}$) and by means of the modified procedure including oxidation with iodine ($*a_2^{II}$) can be written:

$$*a_2^{I} = \Sigma a_n + 0.1\ [a_2 + \Sigma(n-3)\ a_n]$$
$$*a_2^{II} = \Sigma a_n + 0.55\ [a_2 + \Sigma(n-3)\ a_n]$$

where a_2 and a_n are the amounts of thiosulphate and polythionate $S_nO_6^{2-}$ in the original sample. From these two equations, the amount of polythionate can be calculated as:

$$\Sigma a_n = 1.22\ *a_2^{I} - 0.22\ *a_2^{II}$$

DISCUSSION

In the determination of the total amount of polythionate by the ^{110}AgSCN-method, the uncertainty in the measurement is dependent on the amount of thiosulphate in the original sample and also on $\bar{n}$, the average number of

sulphur atoms per mole polythionate. This is due to the fact that the amount of polythionate is calculated as half the difference between the thiosulphate amounts present in the solution after the sulphite-sulphide and the sulphite reactions. If an excess of thiosulphate is present in the original sample or if $\bar{n}$ is large, the total polythionate content is obtained as a relatively small difference between two large quantities. As appears from the results in Table 1, the largest difference in the determination of thiosulphate amounted to 3 %. From this, it follows that, in a solution which contains only trithionate, the maximum error in the determination of polythionate amounts to 3 %. This error rises to 33 % if the solution also contains, besides trithionate, an amount of thiosulphate which is ten times greater than the amount of the trithionate present. If the solution contains, instead, a higher polythionate, *e.g.* pentathionate, then the maximum error amounts to 9 % if the pentathionate is present alone. In the same way, the error rises to 39 % if the thiosulphate to pentathionate ratio is 10:1.

For a maximum error of 3 % in the thiosulphate determination, the maximum error in $\bar{n}$ can be estimated, according to the conventional calculation of error, to be 10—20 % (for $\bar{n}$ = 3—6) in the case where the sample contains only polythionates. If thiosulphate is present in a ten times larger amount, then the error in $\bar{n}$ is larger.

The determination of polythionates by the ^{35}S-method can be performed with a smaller error than that in the $^{110}AgSCN$-method. The amount of polythionate is obtained in this case as the difference in relative total activity (Weight × Activity of $BaSO_4$; Table 5) between the sample and the blank. Even in the less laborious procedure, the maximum error is less than 5 % despite the relatively high activity in the blank. In the presence of thiosulphate or with higher polythionates, the activity must be corrected for the activity arising from the isotopic exchange between the thiosulphate and sulphide. This correction does not have any appreciable influence on the accuracy of the polythionate determination if the thiosulphate content is determined using the $^{110}AgSCN$-method. The maximum error in the correction will in this case amount to 0.3 % of the thiosulphate content. If the amount of thiosulphate is ten times greater than the amount of trithionate, the maximum error in the polythionates will thus increase from 5 % to 8 %. Due to the greater accuracy in the determination of polythionates by this method, it is clear that the error in $\bar{n}$ will also be smaller. The maximum error in $\bar{n}$ has been calculated to be about 10 %. If, on the other hand, the correction for the isotopic exchange is determined by the ^{35}S-method, the maximum error in the polythionate determination will be much greater. This error increases from 5 % to 19 % if the amount of thiosulphate is ten times greater than the amount of trithionate. The maximum error in $\bar{n}$ also increases in this case.

A further comparison between the two methods shows that, in the ^{35}S-method, the activity is proportional to the amount of polythionate. This is not the case with the $^{110}AgSCN$-method due to the fact that a displacement of the equilibrium between the solid silver thiocyanate and the thiosulphate solution occurs when the concentration is increased. As far as the sensitivity of these methods is concerned, it is seen that the $^{110}AgSCN$-method is sensitive

to much lower contents than the ^{35}S-method. This comparison is of course based on the experimental procedures used as well as on the specific activities of the silver and sulphur which have been employed in this work.

Finally, it should be mentioned that the ^{35}S-method can be used for an indirect determination of thiosulphate. The sample is first oxidized with iodine after which the amount of tetrathionate formed is determined. In the presence of polythionates, it is necessary to perform two determinations, one before and one after the oxidation with iodine. This method has been tested for the determination of thiosulphate in spent liquors from the sulphite cellulose process. The results of these determinations will be published later.

Benzaurinstudien

V. Gleichgewichte und Reaktionskinetik des 3,3′-Dimethoxy-benzaurins in wässrigen Lösungen

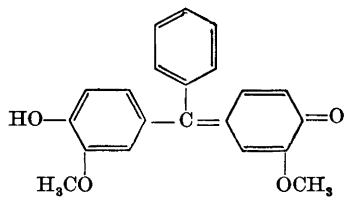
HANS GUSTAF HANSSON

Abteilung für anorganische und physikalische Chemie des Chemischen Instituts der Universität Lund, Schweden

In two previous papers [1,2] the equilibrium and kinetic conditions in aqueous solutions of benzaurin and three substituted benzaurins, 3,3′,5,5′-tetrabromo-benzaurin, 3,3′-dibromo-5,5′-dimethyl-benzaurin and 4″-chloro-benzaurin, were laid down in an equilibrium system that consists of three coloured "anhydrous" forms and three colourless "carbinolic" forms. The equilibrium constants of the protolytic reactions between the "anhydrous" or the "carbinolic" forms, and of the hydration reactions between corresponding "anhydrous" and "carbinolic" forms were determined through calculations on values, belonging together, of the light absorption E and the $[H^+]$. The velocity constants of the hydration reactions, which appear as a gradual fading of the colour of the solutions until equilibrium is reached, were determined by following E as a function of time.

In the present paper the corresponding investigation of the 3,3′-dimethoxy-benzaurin is presented according to the same scheme. The constants determined refer to the ionic strength 0.50 M, the temperature 20°C and a solvent with the composition 98 % water + 2 % acetone.

In zwei früheren Veröffentlichungen [1,2] wurde über Untersuchungen über die Gleichgewichtsverhältnisse in wässriger Lösung bei Benzaurin und drei substituierten Benzaurinen, nämlich 3,3′,5,5′-Tetrabrom-benzaurin, 3,3′-Dibrom-5,5′-dimethyl-benzaurin und 4″-Chlor-benzaurin, berichtet. Die zum Gleichgewichtsschema gehörenden Protolysen-, Hydratations- und Geschwindigkeitskonstanten wurden bestimmt. In der vorliegenden Arbeit werden die Resultate einer entsprechenden Untersuchung über 3,3′-Dimethoxy-benzaurin dargelegt. Wie erwartet können die Verhältnisse bei diesem Farbstoff mit demselben Schema beschrieben werden, das sich für die früher untersuchten Farbstoffe des Benzaurintypus [1,2] als gültig zeigte. Das Schema wird unten wiedergegeben, wobei die Konstanten in derselben Weise wie in den vorhergehenden Arbeiten definiert werden.



3,3′-Dimethoxy-benzaurin.
Anhydrid (G_1).

Die in das Schema * eingehenden Konstanten werden folgendermassen definiert:

Die Protolysenkonstanten:

$$K_1 = \frac{[G_1]}{[H^+] \cdot [R]} ; K_7 = \frac{[H^+] \cdot [G_1]}{[G_2];} ; K_3 = \frac{[H^+] \cdot [F_2]}{[F_1]} ; K_4 = \frac{[H^+] \cdot [F_3]}{[F_2]}$$

Die Hydratationskonstanten bei konstanter Wasseraktivität:

$$K_2 = \frac{[F_1]}{[G_1]} ; K_6 = \frac{[R]}{[F_2]}$$

Aus den Definitionen erigbt sich $K_1 \cdot K_2 \cdot K_3 \cdot K_6 = 1$.
Ferner wird $K_6/K_4 = K_5$ gesetzt.

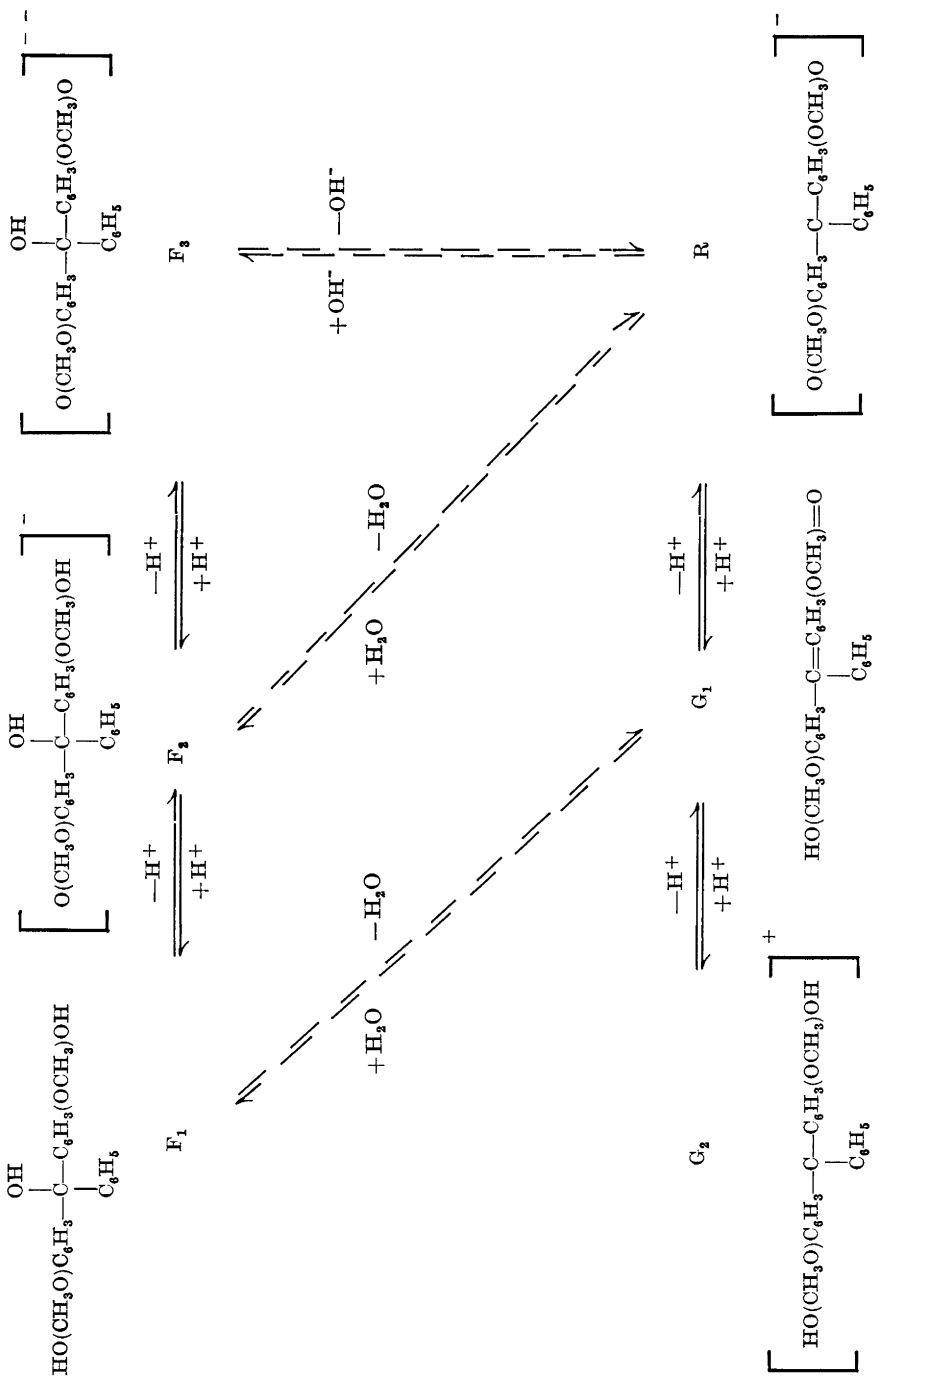
Die Geschwindigkeitskonstanten:

k_1 für die Reaktion $G_1 + H_2O \rightarrow F_1$
k_2 für die Reaktion $F_1 \rightarrow G_1 + H_2O$
k_3 für die Reaktion $R + H_2O \rightarrow F_2$ einschliesslich $R + OH^- \rightarrow F_3$
k_4 für die Reaktion $F_2 \rightarrow R + H_2O$ einschliesslich $F_3 \rightarrow R + OH^-$

k_1 und k_3 enthalten die Aktivität des Wassers. Es gilt, dass $k_2 = k_1/K_2$ und $k_4 = k_3 \cdot K_6$ ist.

Es wird also angenommen, dass der Farbstoff in wässriger Lösung teils eine Reihe von gefärbten Formen (R, G_1 und G_2) bildet, die in momentanem Protonengleichgewicht mit einander stehen, teils eine Reihe von farblosen Formen (F_1, F_2 und F_3) bildet, die gleichfalls in momentanem Protonengleichgewicht mit einander stehen. Eine farblose Form entsteht aus der entsprechenden gefärbten durch Aufnahme von Wasser, ein reversibler Prozess, der meistens eine Zeitreaktion ist. Durch Auflösen des Farbstoffes (G_1) in wasserfreiem Aceton erhält man eine Stammlösung, die keine der F—Formen enthält. Beim Mischen einer solchen Stammlösung mit einem Puffer wird eine Lösung erhalten, deren Farbe wegen der fortlaufenden Hydratation aufhellt. Nachdem Gleichgewicht eingetreten ist, wird im allgemeinen ein konstanter Endwert,

* Ausgezogene Pfeile bezeichnen Momentanreaktionen, gestrichelte Pfeile Zeitreaktionen.



E_∞, der Lichtextinktion der Lösung erhalten. Aus zusammengehörigen Werten von E_∞ und $[H^+]$ können in geeignet gewählten pH-Intervallen die Konstanten K_2, K_3, K_4 und K_6, und in sauren Lösungen, wo sich das Gleichgewicht fast momentan einstellt, K_7 ermittelt werden. Dadurch dass der Verlauf der Aufhellung spektrophotometrisch verfolgt wird, werden die Geschwindigkeitskonstanten und (durch Extrapolation auf die Zeit $t = 0$) die Lichtextinktion, E_0, im Moment des Mischens bestimmt. Aus zusammengehörigen Werten von E_0 und $[H^+]$ wird K_1 bestimmt. Die Formeln für die Berechnung der verschiedenen Konstanten sind in den früheren Aufsätzen [1,2] abgeleitet worden und werden im Folgenden durch die Bezugszahlen in diesen Arbeiten gekennzeichnet. "Formel (10; III.)" bezieht sich folglich auf die Formel mit der Nummer (10) im Aufsatz "Benzaurinstudien III." [2].

Dimethoxy-benzaurin unterscheidet sich von den früher untersuchten Farbstoffen [1,2] vor allem dadurch, dass die Hydratations- (Aufhellungs-) Geschwindigkeit im ganzen in Frage kommenden pH-Gebiet wesentlich geringer ist. Die Wartezeit vor der Messung von E_∞ wird also länger und die störende Einwirkung evtl. irreversibler Verläufe stärker hervortretend. Die Reproduzierbarkeit bei Messung von E_∞ war aus dem Grunde weniger gut als bei den früheren Untersuchungen und die erhaltenen Werte der Konstanten demzufolge mit grösserer Unsicherheit behaftet.

MESSUNGEN UND ERGEBNISSE

Allgemeines. Apparatur und Methoden bei den Messungen waren die gleichen wie bei den früheren Untersuchungen [1,2]. Für die Messungen der Lichtextinktion wurde folglich ein Beckman-Quarz-Spektrophotometer, Modell DU, benutzt. Die Messungen von $[H^+]$ wurden mit Chinhydronelektroden für $pH \leq 8{,}2$ und mit Platin-Wasserstoffgaselektroden für $pH > 8{,}2$ ausgeführt. Als Vergleichs-Lösung wurde eine HCl-NaCl-Lösung mit bekannter $[H^+]$ verwendet.

Bei der Bereitung der Messlösungen wurden zu 49,0 ml Puffer 1,050 ml Stammlösung des Farbstoffes in Aceton mit einer Injektionsspritze hinzugefügt. Die Stammlösungen waren in Bezug auf den Farbstoff $1{,}8 \times 10^{-4}$ M. Um ihre Empfindlichkeit gegen Spuren von Wasser (Hydratation) zu verringern wurden sie mit Triäthylamin [3] zu einer ungefähren Konzentration von 5×10^{-3} M versetzt. Die Ionenstärke der Puffer war so bemessen, dass die Ionenstärke der Endlösungen 0,50 * betrug. Als Zusatzsalz wurde NaCl verwendet.

Die bestimmten Konstanten beziehen sich also auf ein Lösungsmittel von der Zusammensetzung 98 % Wasser + 2 % Aceton; Ionenstärke 0,50 M.

Die Temperatur im Küvetten-Haus des Beckman-Apparates betrug 20°C. Die Puffer und die Endlösungen für die Bestimmung von E_∞ wurden im Thermostaten bei 20°C aufbewahrt. Beim Mischen von 1 ml Aceton mit 49 ml Wasser (Puffer) steigt die Temperatur um etwa 0,5°. Folglich werden die Geschwindigkeitskonstanten zu Mittelwerten im Temperaturintervall 20,0° – 20,5°. Die für die Bestimmung von K_1 berechneten E_0-Werte beziehen sich auf die Temperatur 20,5°. Dasselbe gilt von den früheren Untersuchungen [1,2].

Die Geschwindigkeitskonstanten sind mit Brigg'schen Logarithmen berechnet worden; enthalten daher die Grösse $^{10}\log e$.

---

* Bei der Bestimmung von K_7 musste eine primäre Mess-serie bei der Ionenstärke 1,00 M ausgeführt werden.

Das verwendete Präparat des Farbstoffes war das in einer früheren Arbeit beschriebene Anhydrid [3]. Der Farbstoff wurde in den Gebieten $5{,}5 < \mathrm{pH} < 12{,}0$ und $0 \leq \mathrm{pH} < 1{,}1$ untersucht.

In sämtlichen untenstehenden Messungen war, bis auf einige nicht aufgeführte Kontrollmessungen, die Gesamtkonzentration C des Farbstoffes in der Messlösung $3{,}8 \times 10^{-6}$ M. Die eingeführten Bezeichnungen haben dieselbe Bedeutung wie früher [1,2]. Folglich stellt E_R (E_{G_1}, E_{G_2}) die Extinktion bei der jeweiligen Schichtdicke für eine Lösung dar, in der [R] ([G_1], [G_2]) gleich C ist.

Als *Puffersubstanzen* wurden Dinatriumhydrogenphosphat-Natriumhydroxyd, Borsäure-Natriumhydroxyd und Natriumdihydrogenphosphat-Dinatriumhydrogenphosphat in folgenden ungefähren pH-Intervallen verwendet: 9,8—11,6; 7,8—9,5; 5,5—7,8. Im Gebiet $0 \leq \mathrm{pH} < 1{,}1$ wurde [H^+] durch Zusatz von bestimmten Mengen HCl definiert. Im Gebiet $\mathrm{pH} > 11{,}6$ wurde [OH^-] durch Zusatz von bestimmten Mengen NaOH definiert. $K_w = [H^+] \cdot [OH^-]$ ist früher [1] zu $1{,}22 \times 10^{-14}$ bestimmt worden.

Die Lichtabsorptionskurven für die gefärbten Formen R, G_1 und G_2 finden sich in Fig. 1 wieder, die den molekularen Lichtextinktionskoeffizienten ε als Funktion der Wellenlänge λ in mμ zeigt.

Die Aufnahme der R-Kurve wurde in einer Lösung mit pH = 9,47 vorgenommen. Aus den gemessenen Extinktionen (E) wurde ε_R unter Berücksichtigung der Konzentrationen der übrigen Formen berechnet.

Die G_1-Kurve wurde in Lösungen mit pH = 5,59 aufgenommen. Da die Gleichgewichtsextinktionen (E_∞) klein sind, wurde E_0 durch Extrapolation ermittelt. Aus E_0 wurde auf dieselbe Weise wie früher [1,2] ε_{G_1} berechnet.

Die G_2-Kurve wurde in einer Lösung mit $[H^+] = 1{,}00$ M (Ionenstärke = 1,00 M) aufgenommen. Aus den erhaltenen E-Werten wurde ε_{G_2} in der früher beschriebenen Weise [2] mit $E_{G_2}/E = 4{,}2(1)$ berechnet.

Sämtliche Kurve wurden bei der Schichtdicke $d = 5$ cm aufgenommen.

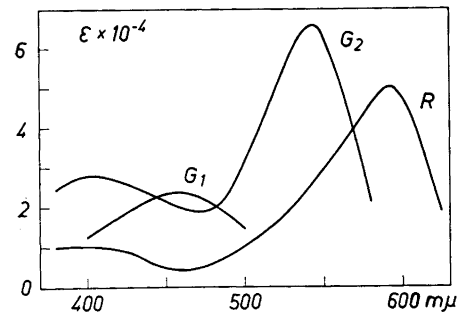


Fig. 1. Lichtabsorptionskurven. R ist das blaue Ion $[(O\ CH_3O\ C_6H_3)_2\ C(C_6H_5)]^+$; G_1 das gelbe Molekül $(HO\ CH_3O\ C_6H_3)C(C_6H_5)(C_6H_3\ CH_3O\ O)$ und G_2 das rote Ion $[(HO\ CH_3O\ C_6H_3)_2\ C(C_6H_5)]^+$.

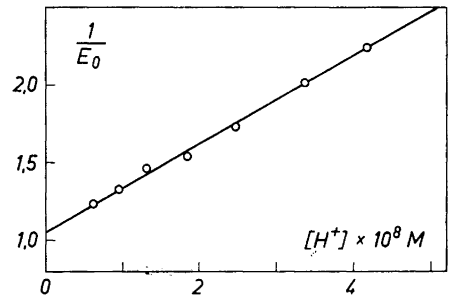

Fig. 2. $1/E_0$ als Funktion von $[H^+]$ für die Bestimmung von K_1 (und E_R). $\lambda = 592$ mμ und $d = 5$ cm.

Die Daten für die Maxima betrugen:

$(\varepsilon_R)_{max} = 5{,}0 \times 10^4$ bei $\lambda \approx 592$ mμ
$(\varepsilon_K)_{max} = 1{,}0 \times 10^4$ bei $\lambda \approx 400$ mμ
$(\varepsilon_{G_1})_{max} = 2{,}4 \times 10^4$ bei $\lambda \approx 458$ mμ
$(\varepsilon_{G_2})_{max} = 6{,}6 \times 10^4$ bei $\lambda \approx 544$ mμ
$(\varepsilon_{G_3})_{max} = 2{,}8 \times 10^4$ bei $\lambda \approx 404$ mμ

Bestimmung von K_1 im Intervall $7{,}3 < \text{pH} < 8{,}3$. Die Aufhellung der Messlösungen wurde extinktiometrisch bei $\lambda = 592$ mμ (Absorptionsmaximum von R) und mit $d = 5$ cm verfolgt. Durch Extrapolation auf die Zeit $t = 0$, wo nur die Formen R und G_1 vorliegen, wurde E_0 erhalten. In Fig. 2 ist $1/E_0$ als Funktion von $[H^+]$ aufgetragen. Man erhält eine Gerade laut Formel:

$$\frac{1}{E_0} = \frac{1}{E_R} + \frac{K_1 \cdot [H^+]}{E_R} \qquad (1;\ \text{II.})^1$$

Graphische Bestimmung ergab als Resultat:
$E_R = 0{,}95(5)$; $K_1 = 2{,}7(1) \times 10^7$; $1/K_1 = 3{,}7 \times 10^{-8}$.

Bestimmung von K_3K_6 *und* K_6 im Intervall $8{,}4 < \text{pH} < 9{,}4$. E_∞ wurde bei $\lambda = 592$ mμ mit $d = 5$ cm gemessen. Entsprechendes E_R wurde durch Extrapolation auf die Zeit $t = 0$ für fünf Lösungen im selben pH-Gebiet bestimmt. Aus den E_0-Werten wurde, nach Korrektion für $[G_1]$, $E_R = 0{,}949 \pm 0{,}004$ erhalten; der Wert stimmt gut überein mit dem oben erhaltenen bei der Bestimmung von K_1. Es gilt die folgende Formel:

$$\frac{1}{E_\infty} = \frac{1 + 1/K_6}{E_R} + \frac{1}{E_R \cdot K_3K_6} \cdot [H^+] \qquad (3;\ \text{II.})^1$$

Die gemessen E_∞-Werte wurden, wie früher beschrieben [1], korrigiert und zwar mit Rücksicht auf die geringen Konzentrationen von G_1 und F_3, die

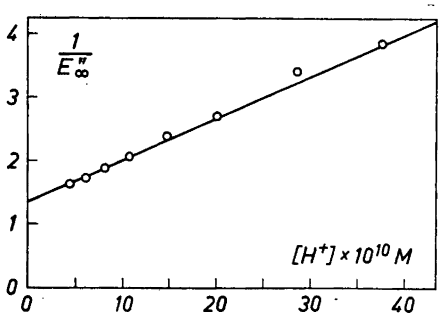

Fig. 3. $1/E''_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_3K_6 und K_6. $\lambda = 592$ mμ und $d = 5$ cm.

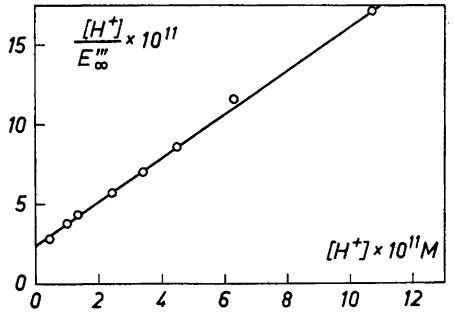

Fig. 4. $[H^+]/E'''_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_5 und K_6. $\lambda = 592$ mμ und $d = 5$ cm.

nicht ganz vernachlässigt werden können *. (Die Formel oben setzt voraus, dass $[G_1]$ und $[F_3]$ Null sind.) Aus den korrigierten Werten, E''_∞, ist in Fig. 3 $1/E''_\infty$ als Funktion von $[H^+]$ aufgetragen. Man erhält, nach Formel (3; II.) oben, eine Gerade. Die graphische Bestimmung ergab das Resultat:

$$K_6 = 3{,}6 \qquad K_3K_6 = 1{,}60 \times 10^{-9}$$

Bestimmung von $K_5 = K_6/K_4$ *und* K_6 im Intervall $9{,}8 < \mathrm{pH} < 11{,}4$. E_∞ wurde bei $\lambda = 592$ mμ mit $d = 5$ cm gemessen. Da die Stammlösung nicht dieselbe wie oben war, wurde die Bestimmung von E_R durch Extrapolation wiederholt. Aus sieben Versuchen im Intervall $9{,}8 < \mathrm{pH} < 10{,}9$ wurde $E_R = 0{,}983 \pm 0{,}003$ erhalten. Es gilt die folgende Formel:

$$\frac{[H^+]}{E_\infty} = \frac{1}{E_R \cdot K_5} + \frac{1 + 1/K_6}{E_R} \cdot [H^+] \qquad (4;\ \mathrm{II.})^1$$

Da die Formel voraussetzt, dass $[F_1]$ (und $[G_1]$) Null sind, wurden die gemessenen E_∞-Werte mit Rücksicht auf die kleine Menge F_1*, die nicht ganz zu vernachlässigen ist, korrigiert [1]. Aus den korrigierten Werten, E'''_∞, ist in Fig. 4 $[H^+]/E'''_\infty$ als Funktion von $[H^+]$ aufgetragen. Man erhält eine Gerade gemäss der Formel (4; II.). Durch graphische Bestimmung wurde das Resultat

$$K_6 = 2{,}9; \qquad K_5 = K_6/K_4 = 4{,}2(4) \times 10^{10}$$

erhalten.

Aus obenstehendem Ergebnis wurde

$$K_6 = 3{,}2(5); \qquad K_3 = 4{,}(93) \times 10^{-10}; \qquad K_4 = 7{,}(7) \times 10^{-11}$$

erhalten.

Bestimmung von $(E_\infty)max$. Im Gebiet $9{,}1 \leq \mathrm{pH} \leq 10{,}2$ kann E_∞ (nach Korrektion für $[G_1]$, falls dieses nicht vernachlässigt werden kann) als Funktion von $[H^+]$ mit der Formel

$$E_\infty = E_R \frac{K_6}{1 + K_6 + [H^+]/K_3 + K_4/[H^+]} \qquad (2;\ \mathrm{II.})^1$$

wiedergegeben werden.

Dann gilt ferner, dass

$$\frac{(E_\infty)_{max}}{E_R} = \frac{K_6}{1 + K_6 + 2 \cdot \sqrt{K_4/K_3}} \qquad (5;\ \mathrm{II.})^1$$

ist.

* Die Korrektionen betragen höchst 3—4 % von E_∞.

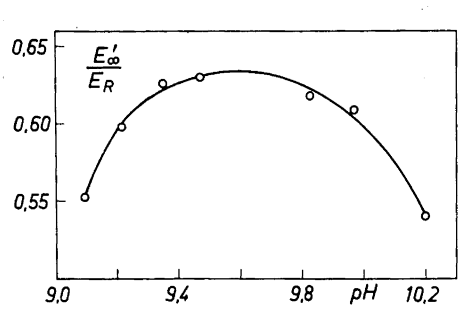

Fig. 5. E'_∞/E_R als Funktion von pH für die graphische Bestimmung von $(E_\infty/E_R)_{max}$. $\lambda = 592$ mμ und $d = 5$ cm. $(E'_\infty/E_R)_{max} = 0{,}63$.

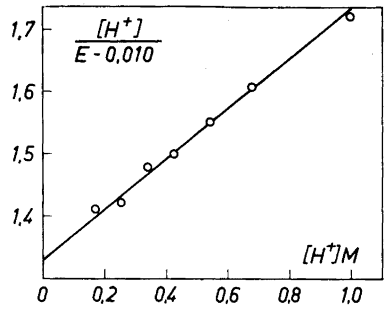

Fig. 6. $[H^+]/\left(E - \frac{E_{G_1}}{1+K_2}\right)$ als Funktion von $[H^+]$ für die Bestimmung von E_{G_1}. $\lambda = 542$ mμ und $d = 10$ cm.

E_∞ wurde wie oben bei $\lambda = 592$ mμ mit $d = 5$ cm gemessen. In Fig. 5 ist E'_∞/E_R* als Funktion von pH aufgetragen worden. Durch graphische Bestimmung wurde $(E'_\infty/E_R)_{max} = 0{,}63$ bei pH = 9,62 erhalten; die Berechnung des zweiten Gliedes in der Formel (5; II.) mit den oben erhaltenen Werten von K_3, K_4 und K_6 eingesetzt, ergab in guter übereinstimmung damit $(E_\infty)_{max}/E_R = 0{,}65$

Bestimmung von K_2 erfolgte im Intervall $7{,}8 < \text{pH} < 8{,}5$. E_∞ wurde bei $\lambda = 592$ mμ mit $d = 5$ cm gemessen. K_2 wurde aus

$$K_2 = \frac{E_R - E_\infty(1 + K_1[H^+] + 1/K_6)}{E_\infty \cdot K_1\,[H^+]} \qquad (6,\ \text{II.})^{1}$$

unter Einsetzen der oben bestimmten Werte von K_1 und K_6 berechnet. E_R war für die verwendete Stammlösung zu 0,949 bestimmt worden (siehe "Bestimmung von K_3K_6 und K_6" oben).

Folgende Resultate wurden erhalten:

$[H^+] \times 10^9$ M	13,1(2)	9,4(9)	6,18	3,77
E_∞	0,102(5)	0,137	0,196	0,253
K_2	21,4	20,9	20,1	23,0

Mittelwert: $K_2 = 21{,}(3)$.

Mit den oben erhaltenen Werten wird das Produkt $K_1 \cdot K_2 \cdot K_3 \cdot K_6 = 0{,}92$.

Bestimmung von K_7 erfolgte gemäss der früher beschriebenen Methodik [2] durch Messungen der Extinktion, E, im Intervall $0 \leq \text{pH} < 1{,}1$ **. E wurde

* E'_∞ = korrigiertes E.

** Das Gleichgewicht stellt sich hier zwischen den Formen F_1, G_1 und G_2 momentan ein.

bei $\lambda = 542$ mμ (Absorptionsmaximum von G_2) mit $d = 10$ cm gemessen. Zur Bestimmung von E_{G_2} wurde zuerst eine Mess-serie bei der Ionenstärke 1,00 M ausgeführt. $[H^+]$ variierte zwischen 0,17 und 1,00 M. Es gilt *, dass

$$\frac{[H^+]}{E - \frac{E_{G_1}}{1+K_2}} = \frac{K_7(1 + K_2)}{E_{G_2} - \frac{E_{G_1}}{1 + K_2}} + \frac{[H^+]}{E_{G_2} - \frac{E_{G_1}}{1 + K_2}} \quad (7;\ \text{III.})^2$$

ist.

In Fig. 6 ist $[H^+]/\left(E - \frac{E_{G_1}}{1 + K_2}\right)$ als Funktion von $[H^+]$ aufgetragen worden. Gemäss Formel (7; III.) erhält man eine Gerade. Durch graphische Bestimmung wurde das Resultat

$$E_{G_2} = 2{,}4(8); \qquad (K_7(1 + K_2) = 3{,}29)$$

erhalten.

Danach wurde eine Mess-serie bei der Ionenstärke 0,50 M (mit selbem λ und d wie oben) ausgeführt. $[H^+]$ variierte zwischen 0,085 und 0,49 M. Es gilt die folgende Formel **

$$\frac{E - \frac{E_{G_1}}{1 + K_2}}{E_{G_2} - E} = \frac{[H^+]}{K_7(1 + K_2)} \quad (8;\ \text{III.})^2$$

In Fig. 7 ist $\left(E - \frac{E_{G_1}}{1 + K_2}\right)/(E_{G_2} - E)$ als Funktion von $[H^+]$ aufgetragen. Man erhält nach Formel (8; III.) eine Gerade. Durch graphische Bestimmung wurde

$$K_7(1 + K_2) = 4{,}4(1) \text{ erhalten.}$$

Das Einsetzen von $K_2 = 21{,}3$ ergibt $K_7 = 0{,}19(8)$

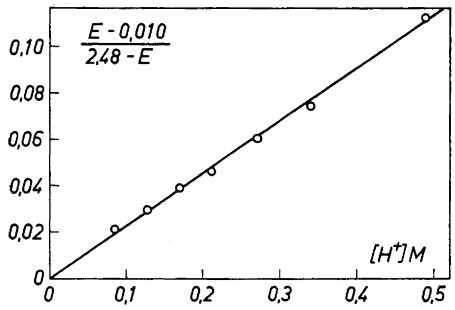

Fig. 7. $\left(E - \frac{E_{G_1}}{1 + K_2}\right)/(E_{G_2} - E)$ als Funktion von $[H^+]$ für die Bestimmung von K_7. $\lambda = 542$ mμ und $d = 10$ cm.

* $\frac{E_{G_1}}{1 + K_2}$ wird durch Messung der Extinktion in einem Puffer mit pH = 3,87 bestimmt.

** Es ist nicht vorteilhaft Formel (7;III.) hier zu verwenden, weil $[H^+]$ im Vergleich zum Produkt $K_7(1 + K_2)$ klein ist. In Formel (8; III.) wird das oben erhaltene E_{G_2} eingestezt.

Messung der Reaktions(Aufhellungs)-Geschwindigkeiten.

Die Geschwindigkeitskonstante k für den Aufhellungsverlauf wird aus den experimentellen Daten mit Hilfe der Formel

$$k = \frac{1}{t} \cdot \ln \frac{E_0 - E_\infty}{E - E_\infty} \qquad (7;\ \text{II.})^1$$

berechnet.
k wird aus den einzelnen Geschwindigkeitskonstanten nach Formel

$$k = \frac{k_2[H^+]^2 + k_4K_3[H^+]}{[H^+]^2 + K_3\,[H^+] + K_3\,K_4} + \frac{k_1K_1[H^+] + k_3}{1 + K_1\,[H^+]} \qquad (8;\ \text{II.})^1$$

zusammengesetzt.

k ist im Intervall $5{,}5 < \text{pH} < 12{,}0$ experimentell bestimmt worden. Die Extinktionsmessungen wurden durchgehend bei 5 cm Schichtdicke ausgeführt; für $7{,}3 < \text{pH} < 12{,}0$ bei $\lambda = 592$ mμ (Absorptionsmaximum für R) und für $5{,}5 < \text{pH} < 6{,}6$ bei $\lambda = 450$ mμ (ungefähres Absorptionsmaximum von G_1). Die Figuren 8 und 9 zeigen die kinetischen Verläufe in den sauren und alkalischen Lösungen, bei denen die Messungen der Berechnung von k_1 und k_2, bzw. k_3 und k_4 zu Grunde liegen. Fig. 10 zeigt k als Funktion vom pH-Wert, (vgl. Formel (8; II.) oben).

Bestimmung von k_1 und k_2. Im Gebiet $5{,}5 < \text{pH} \leq 6{,}5$, in dem die Reaktion $G_1 + H_2O \rightleftharpoons F_1$ dominiert und man die Reaktion $R + H_2O \rightleftharpoons F_2$ nicht zu berücksichtigen braucht, geht Formel (8; II.) in

$$k = k_1 \cdot \frac{K_1\,[H^+]}{1 + K_1\,[H^+]} + k_2 \qquad (9;\ \text{II.})^1$$

über.

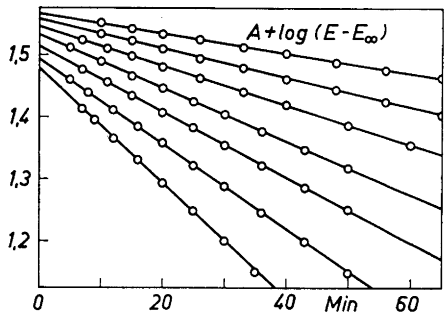

Fig. 8. Reaktionskinetik bei $\lambda = 450$ mμ und $d = 5$ cm. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

A	2,00	1,97	1,95	1,93	1,91	1,89	1,87
pH	6,541	6,292	6,124	5,975	5,854	5,731	5,589

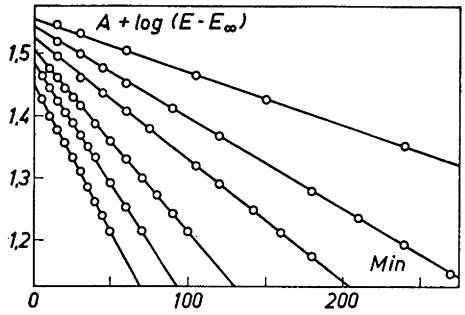

Fig. 9. Reaktionskinetik bei $\lambda = 592$ mμ und $d = 5$ cm. Für die Linien gelten in der Ordnung von oben nach unten die folgenden Daten:

A	1,70	1,63	1,59	1,57	1,54	1,50
pH	11,00(5)	11,33(5)	11,53]	11,69(5)	11,82	11,91(5)

Durch Einsetzen von zusammengehörigen experimentell bestimmten Werten von k und $[H^+]$ und der Beziehung $k_2 = k_1/K_2$ in (9; II.) wurde k_1 bei verschiedenen $[H^+]$-Werten berechnet. Wie bei den früher untersuchten Farbstoffen [1,2] zeigte es sich, dass k_1 eine lineare Funktion von $[H^+]$ ist, gemäss der Formel

$$k_1 = k_1^\circ + k_1' \, [H^+] \qquad (10; \text{ II.})^1$$

in der k_1^0 von Null verschieden ist. In Fig. 11 * ist k_1 als Funktion von $[H^+]$ aufgetragen worden. Durch graphische Bestimmung wurde $k_1^0 = 0{,}8(2) \times 10^{-3}$ und $k_1' = 3{,}1 \times 10^3$ ermittelt. Man erhält also

$$k_1 = 0{,}8(2) \times 10^{-3} + 3{,}1 \times 10^3 \, [H^+];$$
$$k_2 = 0{,}39 \times 10^{-4} + 1{,}4(7) \times 10^2 \, [H^+]; \; (\text{Min}^{-1}); \; [H^+] \text{ in Mol/l.}$$

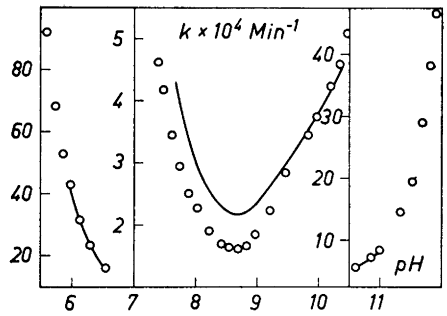

Fig. 10. Die Geschwindigkeitskonstante k als Funktion von pH. Die experimentellen Werte sind mit Kreisen ausgezeichnet. Die ausgezogene Kurve ist aus Formel (8; II.) berechnet.

* Die gestrichelte Abweichung wird später erläutert.

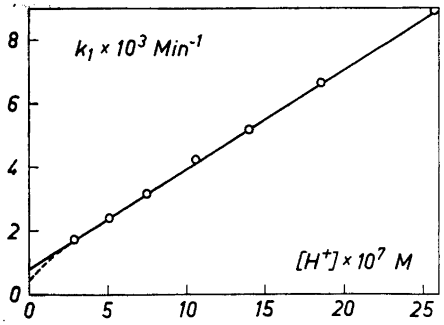

Fig. 11. Die Geschwindigkeitskonstante k_1 als Funktion von [H$^+$]. Zur Erläuterung der gestrichelten Abweichung, siehe den letzten Absatz im Text.

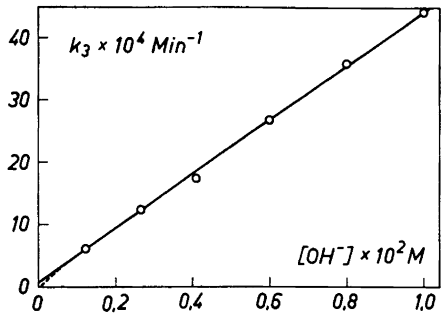

Fig. 12. Die Geschwindigkeitskonstante k_3 als Funktion von [OH$^-$]. Zur Erläuterung der gestrichelten Abweichung, siehe den letzten Absatz im Text.

Bestimmung von k_3 und k_4. Im Gebiet pH $\geq$ 11,0, wo die Reaktion $G_1 + H_2O \rightleftharpoons F_1$ vernachlässigt werden kann, geht Formel (8; II.) in

$$k = k_4 \cdot \frac{[H^+]}{[H^+] + K_4} + k_3 \qquad (12;\ II.)^1$$

über.

Durch Einsetzen von zusammengehörigen experimentellen Werten von k und [H$^+$] und der Beziehung $k_4 = k_3 \cdot K_6$ in (12; II.) wurde k_3 bei verschiedenen [H$^+$]-Werten berechnet. Man fand wie früher [1,2], dass k_3 eine lineare Funktion von [OH$^-$] nach der Formel

$$k_3 = k_3^0 + k_3' \ [OH^-] \qquad (13;\ II.)^1$$

ist, in der k_3^0 von Null verschieden ist. In Fig. 12 * ist k_3 als Funktion von [OH$^-$] aufgetragen worden. Die graphische Bestimmung ergab das Resultat:

$$k_3^0 \approx 0{,}8 \times 10^{-4}; \qquad k_3' = 0{,}43(4)$$

Weil die Linie die Ordinate nahe Origo schneidet, wird die Bestimmung von k_3^0 äusserst unsicher. Aus diesem Grunde wurde eine zusätzliche Bestimmung von k_3^0 bei niedrigerer [OH$^-$] gemacht. Durch Einsetzen von zusammengehörigen Werten von k und [H$^+$] und der Relation $k_4 = k_3 K_6$ in Formel (8; II.) wurde k_3 (mit den oben erhaltenen Werten für die übrigen in die Formel eingehenden Konstanten) für fünf Lösungen berechnet. Aus den erhaltenen k_3-Werten wurde $k_3^0 = k_3 - k_3' \ [OH^-]$ berechnet. Resultat:

[H$^+$] × 10^{10} M	0,449	0,629	1,07(2)	1,48(4)	3,37
$k \times 10^4$ Min^{-1}	4,60	4,24	3,75	3,45	2,84
$k_3^0 \times 10^4$ Min^{-1}	0,94	0,92	0,88	0,84	0,82

* Die gestrichelte Abweichung wird später erläutert.

Tabelle 1. Zusammenfassung der Ergebnisse. $[H^+]$ und $[OH^-]$ in Mol/l.

K_7	$1/K_1$	K_3	K_4	K_2	K_6
0,20	$3,7 \times 10^{-8}$	$4,(9) \times 10^{-10}$	$7,(7) \times 10^{-11}$	21	3,2

k_1 Min^{-1}	k_2 Min^{-1}
$0,8(2) \times 10^{-3} + 3,1 \times 10^{3} [H^+]$	$0,39 \times 10^{-4} + 14(7) [H^+]$

k_3 Min^{-1}	k_4 Min^{-1}
$0,8(8) \times 10^{-4} + 0,43 [OH^-]$	$2,8(7) \times 10^{-4} + 1,4(1) [OH^-]$

Mittelwert: $k_3^0 = 0,88 \times 10^{-4}$.
Man erhält also:
$k_3 = 0,8(8) \times 10^{-4} + 0,43\ [OH^-]$;
$k_4 = 2,8(7) \times 10^{-4} + 1,4(1)\ [OH^-]$; (Min^{-1}); $[OH^-]$ in Mol/l.

Wenn man mit den oben bestimmten Konstanten die Geschwindigkeitskonstante k für die Hydratation bei den verschiedenen $[H^+]$-Werten aus Formel (8; II.) berechnet, erhält man die ausgezogene Kurve in Fig. 10. Die Kurve schliesst sich selbstverständlich gut an die experimentell gefundenen Punkte in den sauren und alkalischen Randgebieten an, in denen k_1 und k_2, bzw. k_3 und k_4 aus den experimentell gefundenen Daten berechnet worden sind. Im Gebiet um das Minimum liegt dagegen eine verhältnissmässig grosse Abweichung (25—30 %) zwischen berechneten und experimentell gefundenen Werten vor. Die Ursache dieser Abweichung kann nicht mit Sicherheit festgestellt werden. Wie schon erwähnt, war die Reproduzierbarkeit bei der Messung von E_∞ weniger gut im vorliegenden Falle als in den früheren Untersuchungen [1,2]; daher wird die Unsicherheit in einigen von den berechneten Gleichgewichtskonstanten grösser als früher. Möglicherweise könnte die Abweichung links des Minimums einem zu grossen K_1-Wert entsprechen und die Abweichung rechts des Minimums einem zu hohen K_6-Wert entsprechen. Eine andere mögliche Erklärung ist auch die, dass k_1 und k_3 nicht, wie angenommen wurde, lineare Funktionen von $[H^+]$ bzw. $[OH^-]$ sind (bei *geringen* Werten derselben), sondern dass sie in der Nähe der Ordinate gemäss den gestrichelten Kurven in den Figuren 11 und 12 * abbiegen. Letzterer Hypothese wird nicht von dem Gang in den oben bestimmten Werten von k_3^0 widersprochen. Die Abbie-

* Die Grösse der Abweichungen ist in den Figuren mit Absicht übertrieben worden.

gung kann durch das Vorhandensein einer Nebenreaktion erklärt werden. Eine ähnliche, geringere Abweichung bei k_3 ist früher bei Untersuchungen von 3,3'-Dibrom-5,5'-dimethyl-benzaurin beobachtet worden [1].

Mein besonderer Dank gilt Herrn Professor Sven Bodforss, Herrn Professor Sture Fronæus und Herrn Dozent Rune Cigén, die mir durch guten Rat und wertvolle Diskussionen bei der Durchführung dieser Arbeit behilflich waren.

Die Untersuchung wurde mit finanzieller Hilfe von *Statens Naturvetenskapliga Forskningsråd* und *Kungliga Fysiografiska Sällskapet i Lund* ausgeführt.

Die Übersetzung ins Deutsche wurde von Fil.mag. Ingrid Wartenberg ausgeführt.

ACTA CHEMICA SCANDINAVICA 14 (1960) 2035–2045

New Methods for the Determination of Free Acid in the Presence of Large Amounts of Uranyl Salt

STEN AHRLAND*

Eurochemic, Mol-Donk, Belgium

Two new methods have been developed for the determination of free acid in solutions containing large amounts of uranyl salt. Both methods are based upon the weakening of the acidic properties of the uranyl ion which is brought about by its bonding to sulphate ions. By utilizing this complex formation it is in fact possible to arrive at a titration curve of two distinct steps. According to the first method, the free acid is determined by potentiometric titration to the well determinable point of inflexion between these steps. For low concentrations of acid, however, when a titration is not practical, the free acid is instead determined by direct measurement of pH, according to the second method described.

For all methods of aqueous reprocessing of irradiated uranium fuel, the concentration of free acid in the uranyl salt solutions to be treated is one of the most important process variables. Frequent and reliable determinations of this quantity are therefore wanted. On account of the acid properties of the uranyl ion, UO_2^{2+}, these cannot, however, be performed as simple alkalimetric titrations. Even if the concentration of uranyl salt, C_U, is fairly low, the hydrolysis of UO_2^{2+} will be appreciable before the free acid has been completely titrated [1]. Further, direct measurement of the pH of the process solutions by, *e.g.*, the glass electrode is not attractive as the reading will depend very much on C_U. In solutions of low acidity UO_2^{2+} will affect the pH both by acting as an acid and by influencing the activity coefficient of the hydrogen ions. The latter effect is present even in strongly acid solutions, where in any case direct pH measurements are not very suitable because of the large and variable liquid junction potentials.

With increasing C_U, the conditions for the determination of free acid grow worse at a rate much faster than would be expected from the simple rise in concentration of the hydrolyzable species UO_2^{2+}, on account of the increase in

* Present address: Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden.

the degree of hydrolysis at a given pH which is a consequence of the formation of polynuclear aggregates in the solution [1].

In this connection it should be emphasized that the concentration of "free" acid to be determined is by definition the acidity of the solution when the uranium(VI) is present solely as the unhydrolysed ion UO_2^{2+} (or, of course, as complexes formed by this ion). If only anions of strong acids are present, (*e.g.* nitrate, chloride or perchlorate ions) this concentration of free acid, C_H, will be $= [H^+]$, the concentration of hydrogen ions. If however anions of weaker acids are also present (*e.g.* sulphate ions), C_H will be equal to the sum of $[H^+]$ and the concentrations of species of undissociated acid (*e.g.* HSO_4^-). In this latter case, the pH will, of course, depend very much upon the concentrations of the proton accepting anions. If these vary, the possibility of an accurate measurement of C_H by the pH is obviously less than in a solution containing only anions of very strong acids.

In practice, nitrate solutions are by far the most important and they will therefore be the main consideration of this work.

METHODS FOR MEASURING THE FREE ACID IN URANYL SALT SOLUTIONS

A number of methods have been used, or could be conceived, to avoid the interference of uranyl ions with the determination of free acid. However, by dividing according to the principle applied, they fall into a few classes only which are specified below, together with a discussion of their relative merits.

Measurements of pH in salt media, acid enough to prevent hydrolysis of UO_2^{2+}. As has already been stated, accurate values of C_H cannot be obtained by direct measurements of the pH of the process solutions. The position can be very much improved, however, by measuring in the presence of a high and approximately constant concentration of a neutral salt (*e.g.* sodium perchlorate or sodium nitrate). In such solutions, the liquid junction potentials are mostly suppressed and the activity conditions stay fairly constant even if C_U and C_H vary considerably, Thus the values of pH found will give true values of $[H^+]$, and this quantity equals C_H, as long as the hydrolysis of UO_2^{2+} is negligible. In order to determine the range of acidity where this condition is actually fulfilled, the measurements can be arranged as follows [2]. To a slightly acidified solution of a certain C_U, containing a high concentration of sodium salt, portions of a strongly acid solution of the same C_U and salt content are added. After each addition, the pH (*i.e.* $[H^+]$) of the resulting mixture is measured. If the uranyl salt preparation contains free acid, this value of $[H^+]$ will be higher than that calculated from the amount of strong acid deliberately added. At the beginning of the titration, however, still another rise in $[H^+]$ is likely to occur due to a partial hydrolysis of the uranyl salt. As the acidity of the mixture increases, the hydrolysis will be more and more suppressed, and finally its influence on $[H^+]$ will practically cease. As C_U is kept constant, and hence also the amount of acid coming from the original uranyl salt, the virtual suppression of the hydrolysis will be indicated by the appearance of a constant difference between the found and calculated values of $[H^+]$. The free acid contamination of the original uranyl preparation is easily calculated from this difference.

Once the acidity ensuring a complete suppression of hydrolysis is known as a function of the uranyl salt concentration, then the measurements can also be arranged in the following way. A solution is prepared which contains, as well as a high concentration of neutral salt, enough acid to prevent hydrolysis of uranyl ions even if added in considerable concentration. To this solution, another solution is added which has the same content of neutral salt and deliberately added acid, but also contains a fairly high concentration of uranyl salt. As long as the uranyl concentration of the mixture stays within a certain known limit, the increase of $[H^+]$ measured is due to the content of free acid of the original uranyl salt preparation. The increase should be proportional to C_U which gives a good check on the reliability of the measurements.

This method of determining C_H by measurement in solutions where it is simultaneously proved that no hydrolysis exists is certainly the least objectionable one from a theoretical point of view. On the other hand, the procedure cannot easily be adapted to very small samples, as several portions of uranyl solution have to be added in order to ensure a good result. The measurements also require a fair amount of care and time, as the value of pH has to be accurately determined for each point in the series of titration.

It is therefore preferable to use this as a reference method by which other methods more suited to routine work can be checked. As such it has been employed in the present investigation.

Precipitation of uranium(VI) with subsequent conventional alkalimetric titration of acid. As precipitating agents cyanoferrate(II)[3], iodate [4] and hydrogen peroxide [3] have been used. After precipitation, the solution is centrifuged and samples taken from the supernatant solution.

All precipitation methods depend on the assumption that the precipitate is strictly an uranyl compound, *i.e.* no hydrolysis of the group UO_2^{2+} must take place. Moreover, no occlusion of acid is supposed to occur within the precipitate. These conditions are, of course, serious weaknesses common to all precipitation methods. As to convenience, the centrifugation introduces an extra handling step.

Removal of uranium(VI) by means of ion exchange with subsequent conventional titration of acid. If the sample is passed through a cation exchange column, saturated with hydrogen ions, the uranyl ions will be exchanged for an equivalent amount of hydrogen ions. The pure acid solution thus obtained can then be titrated without complications, and C_H is found as the difference between the amount of acid thus found and the amount arising from the exchange which equals $2C_U$ (*cf.* Ref.[5]).

The method therefore presupposes that the C_U of each sample is accurately known. If this concentration is high relative to C_H, the latter quantity will however not be determined very precisely.

Suppression of the hydrolysis of the uranyl ion by means of complex formation, with subsequent potentiometric titration of the free acid. The formation of a metal complex in solution implies as a rule that one or more water molecules in the hydration shell of the metal ions are replaced by the complex forming ligand. The acid properties of the metal ion, which are due to the dissociation of hydrogen ions from the hydration shell, are therefore likely to decrease on complex formation, *i.e.* the hydrolysis at a given pH will generally be less

for the complex than for the simple hydrated ion. If the ligand is an anion, the decrease of ionic charge brought about by its association will further decrease the probability of hydrogen ion dissociation from the remaining water of hydration. In such cases the effect of complex formation upon the hydrolysis should thus be especially marked.

In order to be analytically useful for the determination of free acid in solutions of hydrolyzable ions, the effect brought about by the complex formation must be large enough to give a titration curve with two steps which are distinctly separated. In the case of uranyl salt solutions, this means a rather large displacement of the metal ion step. It is therefore necessary to add a ligand which binds practically all uranium(VI) into complexes which are not easily hydrolyzed. Unfortunately, most ligands forming strong complexes with the uranyl ion are also fairly basic and thus convert the strong acid of the solution into weaker acids, thereby displacing the acid steps towards a higher pH region as well. The crucial point is thus to find a ligand combining a strong affinity for UO_2^{2+} with as low a basicity as possible. Once a ligand has been found that really separates the acid step from the uranyl one, then the acid can be determined by a straightforward potentiometric titration. The simple procedure thus arrived at, demanding neither a separation of the uranium nor an exact knowledge of its concentration, makes the complex formation approach the most attractive one for removing the uranium interference. It therefore seems natural to choose this line for further development.

Up till now, oxalate [6-8] and fluoride [9] have been the most widely used complexing agents. The basicity of the oxalate ion is however unsuitably high so that the separation between the acid and uranyl steps is still rather poor. The inflexion point is therefore rather difficult to determine, and if the molar ratio C_U/C_H is high, the value of C_H tends to come out too high. This is especially the case at high uranium concentrations, as has also been shown in the present investigation. Thus if $C_U = 0.84$ M (= 200 g U/l), a significant deviation occurs if the molar ratio exceeds 3 (*cf.* tab. 1). Evidently, oxalate prevents interference from the uranyl hydrolysis only if the conditions are not very severe *. As to fluoride, the attack on glass by acid fluoride solutions will always make it impossible to perform reliable potentiometric titrations involving a glass electrode. One might resort to conductometric titration, though this method seems to work only for rather low concentrations of uranyl salt [9].

Among complexing agents which have so far not been used for the present purpose, the sulphate ion especially seems to be quite promising. Its basicity is fairly low, yet it forms rather strong complexes with the uranyl ion [10], without any tendency to precipitation at high ligand concentrations. In the last respect, the sulphate ion differs favourably from, *e.g.*, oxalate.

In the present investigation, a potentiometric titration method based upon sulphate complex formation has been worked out for the determination of free acid in the presence of even very large amounts of uranyl salt. In order to achieve as good a suppression of the hydrolysis as possible, a saturated ($\approx$ 4

* Oxalate works better at 0°C than at room temperature [8], but the cooling certainly means a complication in routine work.

M) solution of ammonium sulphate has been chosen as ionic medium, this salt being the most soluble of the readily available sulphates. In this medium, the free acid of samples containing as much as 400 g U/l can still be fairly correctly determined even at a molar concentration ratio uranyl/acid of 5 to 6, as will be described below in greater detail. This implies that acidities as low as 0.3 M can be determined in an almost saturated uranyl solution. For acidities below 0.3 M, the determined value is too low in solutions containing C_U = 400 g U/l, but correct at lower C_U. However the quantity of base required for the titration soon becomes inconveniently small for samples of the desired volume.

For samples of low acidity, a new approach, utilizing direct pH measurement in a complex forming medium, is therefore applied.

Measurement of pH in a salt medium where the hydrolysis has been extensively suppressed by means of complex formation. If the salt medium, which is in any case necessary for a successful direct measurement of pH, is chosen so that its anions form strong complexes with the uranyl ion, then it might be expected that the influence of the uranium on pH will be much less than in a non-complexing medium. Therefore, it should be possible to treat a value of pH determined in such a solution as a measure of the free acid content of the sample, even if the uranium/acid ratio is much too high for a successful direct measurement of pH in a medium where no complexes are formed. In the present investigation it has in fact been shown that fairly good values of C_H can be obtained in this way, even for solutions of rather unfavourable composition. As in the titration method just described, the sulphate ion was used as the complex forming ligand, and moreover the same medium, $\approx$ 4 M ammonium sulphate, was chosen. From the measured values of pH correct values of C_H (down to C_H = 25 mM) can be calculated directly if $C_U \lesssim$ 100 g U/l. For more concentrated uranyl solutions the method can still be used if empirical corrections are applied to the measured values of pH. At least up to C_U = 200 g U/l, the corrections are quite modest and presuppose only a very rough knowledge of C_U.

As a measured value of pH corresponds to one single value of C_H once the correction for the influence of uranium (if any) has been introduced, only one measurement is necessary in order to determine the acidity (once the glass electrode has been duly calibrated, as described below). No elaborate titrations with accurate determinations of several pH values are needed, contrary to what is the case if C_H is to be reliably determined by pH measurement in a non-complexing medium, according to the first method mentioned above. As only small samples are wanted ($\lesssim$ 0.2 ml) and a minimum of manipulation, the present method is especially well suited for highly active solutions. On the whole it is the most suitable method for all samples that contain so little acid that the otherwise more precise titration in sulphate medium is not feasible.

In the following, a detailed description will be given of the two new methods which have been developed in the present investigation. Each of them has so far been used successfully for more than 200 routine analyses.

THE TESTING OF REAGENTS FOR ACID IMPURITIES

Ideally, the salts used in the present investigation should have been free from acidic or basic impurities, but as this could not be guaranteed it was necessary to examine them and determine the exact concentration of any such impurities so that a correction could be made.

The *uranyl nitrate* (Hoboken "nucléairment pure") was tested by pH measurements in an approximately constant ionic medium, according to the first method given above. The second variant of the method was applied, *i.e.* the concentration of uranyl salt in the solution was increased at approximately constant concentration of acid. Titrations were performed at four acidities, ranging from 10 mM to 110 mM. The ionic strength of the medium was 2 M, sodium nitrate being used as the supplementary neutral salt. The temperature was kept constant at 25°C. As was also the case for all other measurements reported in this paper, the values of pH were determined by a glass electrode, in connection with the Radiometer pH Meter pHM 4. As reference, a saturated calomel electrode was used.

In fact, no free acid could be found in the uranyl nitrate preparation within the experimental error of the method applied. This means that the acid contamination, if any, is certainly < 2 % of the concentration of the uranyl ions.

Ammonium sulphate. The value of the pH of a saturated ammonium sulphate sclution of the correct stoicheiometric composition was found by potentiometric titration of a slightly acidified solution. Before titration the solution was freed from carbon dioxide by a stream of nitrogen gas.

The inflexion point, corresponding to equivalent amounts of NH_4^+ and SO_4^{2-}, was found at pH $= 5.2 \pm 0.1$. In fact, solutions having $5.0 <$ pH < 5.4 gave the same result when tried in actual titrations. If a preparation has a value of pH outside these limits, it must be adjusted by a small addition of strong base or acid. In order to arrive at a reasonably stoicheimetric composition it was necessary to dissolve the salt without heating the solution. From a solution that had been boiled, so much ammonia had been expelled that the pH afterwards was only 3.20.

No difficulties were met in the measurement of pH in this concentrated salt solution by the glass electrode in the experiments just described, nor in the later ones where uranyl salt was also present.

THE DETERMINATION OF FREE ACID IN AN URANYL SALT SOLUTION BY POTENTIOMETRIC TITRATION IN A SULPHATE MEDIUM

Trying out the most favourable complex forming medium. Preliminary experiments showed that weakly complexing agents, such as nitrate and chloride ions [11], could not create a sufficiently wide interval between the steps of strong acid and uranyl ion in the titration curve, in spite of the fact that such ions do not move the acid step at all toward higher pH. This is evident from Table 1 which gives the results of titrations of 0.2 ml samples of the composition stated, added to 15 ml of the salt media tried. Even in very concentrated salt solutions the found values of C_H are always too low.

As has already been mentioned, decidedly better results were obtained with the more strongly complex forming sulphate ion, in spite of the fact that this agent also moves the acid step towards higher pH. When a 2 M sodium sulphate medium was used, the error was considerably less than for 2 M nitrate, and still better was saturated ammonium sulphate.

Titrations in saturated ($\approx$ 4 M) ammonium sulphate medium. For this medium, an elaborate testing was carried out, using values of $C_U = 400$ and 200 g U/l. In each series, C_H was varied within wide limits. All titrations were performed as before with solutions prepared by adding 0.2 ml of the acid uranyl solution to 15 ml of the neutral salt medium. The concentration of the sodium hydroxide titrant was chosen so that 1 to 3 ml was used.

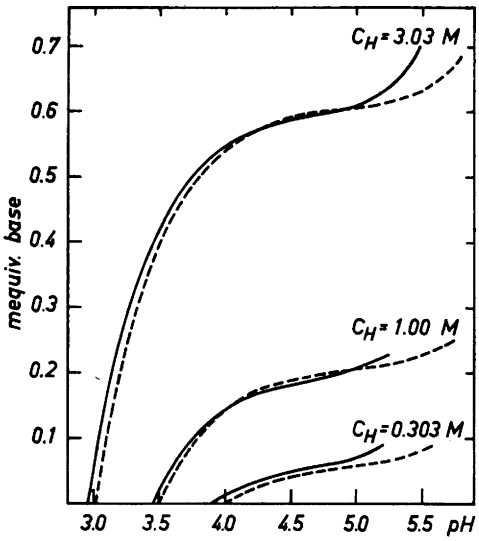

Fig. 1. Titration curves for samples of acid uranyl nitrate solutions in a large excess of saturated ammonium sulphate solution. Samples of 0.2 ml, with the concentrations of nitric acid indicated in the figure, have been added to 15 ml of the ammonium sulphate solution. Fulldrawn and dashed curves refer to samples containing 400 and 200 g U/l, respectively.

In Table 2, the concentrations of acid found, C_{Hd}, are given together with their deviations, δ, from the actual concentrations C_H. The maximum random errors, δ_r, expected to arise under the prevailing experimental conditions are also given. These errors are mainly due to (*i*) the uncertainty in the determination of the inflexion point of the titration curve and (*ii*) the error inherent in measuring the sample aliquot of 0.2 ml. The latter error might be estimated as 1—2 % while the former one varies with C_H and C_U. Its relative amount is roughly inversely proportional to C_H, as the slope of the titration curve is practically independent of C_H, and the absolute error (expressed in equivalents of base) in the determination of the inflexion point is therefore the same for all values of C_H. The error becomes larger with increasing C_U as the uranyl step then comes closer to the strong acid step which results in a steeper slope of the curve between them. In Fig. 1, some titration curves are given in order to illustrate these points.

As is evident from Table 2, the deviations found are of the same magnitude as the estimated values of δ_r down to $C_H = 0.3$ M for the series of $C_U = 400$ g U/l, though the negative deviations seem to preponderate somewhat over the positive ones. For values of $C_H = 0.3$ M, the negative deviations become significant. For such extremes of the ratio C_U/C_H, not even the strong complex formation in a concentrated sulphate solution is sufficient to ensure a good determination of C_H.

For $C_U = 200$ gU/l, the present method works well over the whole range of C_H investigated, down to $C_H = 0.2$ M (Table 2).

For comparison, some of the test solutions were also titrated according to the oxalate method mentioned above, which uses a 0.43 M oxalate solution (80 g $K_2C_2O_4 \cdot H_2O$/l) as complex forming medium. The results (Table 1) show that large positive deviations are found for solutions which are correctly determined by the sulphate method.

THE DETERMINATION OF FREE ACID IN AN URANYL SALT SOLUTION BY pH MEASUREMENTS IN A SULPHATE MEDIUM

A prerequisite for every reasonably accurate determination of C_H from pH measurements is careful calibration of the glass electrode. Preferably, the calibrations should be arranged in such a way that the electrode need not afterwards be transferred to another solution for the main measurement. Such a transfer, with accompanying partial drying *etc.*, is apt to cause small alterations in the asymmetry potential of the electrode, which encroach upon the precision of the measurement. In the present work, the following procedure was therefore adopted. To V ml saturated ammonium sulphate solution, v_1 ml of an a M nitric acid was added and the pH value of the resulting solution measured. As soon as a stable value ($= pH_O$) had been read for this calibration mixture, v_2 ml was added of the acid uranyl solution to be tested and the new value of pH ($= pH_U$) measured. The difference $\Delta pH = pH_O - pH_U$ is a function of the concentration of free acid of the uranyl solution, C_H, and to some degree also of C_U, if the hydrolysis of the uranyl group is not completely suppressed. If it is, the value of pH found should agree with that value which is calculated in the following way.

If $[H^+]_O$ and $[H^+]_U$ are the hydrogen ion concentrations of solutions after the addition of v_1 and v_2 respectively, then

$$\Delta pH = \log[([H^+]_U/[H^+]_O) \qquad (1)$$

The corresponding total concentrations of acid (= $[H^+] + [HSO^-_4]$) are called C_{HO} and C_{HU}. As $V[SO^{2-}_4] \gg v_2\ C_H$, the concentration of sulphate ions is virtually constant during the measurements which implies that $[H^+]_U/[H+]_O = C_{HU}/C_{HO}$. As $C_{HO} = v_1a/(V + v_1)$ and $C_{HU} = (v_1a+v_2C_H)/(V + v_1 + v_2)$, the following expression for pH results:

$$\Delta\,\mathrm{pH} = \log \frac{(v_1a + v_2C_H)\ (V + v_1)}{v_1a\ (V + v_1 + v_2)} \qquad (2)$$

In the present experiments, a value of $V = 15$ ml has been chosen. As to a, v_1 and v_2, two different sets of values have been used, as stated in Table 3. In this table, the results of the tests performed are given in a summarized form. For each solution, only the mean value is stated out of at least two and often up to five measurements actually carried out. The table first contains the values of ΔpH, calculated according to eqn. (2) for each value of C_H used. Then the differences δ between the (mean) values of ΔpH actually measured and those calculated are tabulated for each solution, and finally C_{Hd}, the concentrations of acid found from the *measured* values of ΔpH. Two series have been performed with solutions free from uranium. From the values of δ found in these series, as well as from the reproducibility of pH for the individual solutions, it seems realistic to reckon an error of at least $\pm$ 0.015, or rather $\pm$ 0.020 units in the determination of pH. The error seems to be about the same in the whole range of C_H measured. The corresponding relative error in C_H depends upon the relation between the amounts of acid added for calibration, v_1a, and that added with the sample, v_2C_H. With the volumes and concentrations used here, an error of 5—7 % should be expected at $C_H = 250$ mM, increasing to $\approx$ 20 % for $C_H = 25$ mM.

The values of pH actually found for the series of $C_U = 50$ and 100 g U/l do not deviate more from those calculated than can be explained by the random errors. For unknown samples of $C_U \leqq 100$ g U/l, correct values of C_H can thus be calculated according to eqn. (2), direct from the measured value of pH, as has already been stated above. For $C_U = 200$ g U/l, however, a significant deviation of + 0.03 pH units appears. For $C_U = 400$ g U/l, a rather large deviation is found, evidently decreasing for increasing acidity of the solution, which is also to be expected.

The determination of nitric acid in a solution of uranyl nitrate in tributyl phosphate — kerosene. The direct measurement of the pH can be used also for the determination of acid in the TBP-kerosene solutions of the Purex process. Because of the small volume v_2 of the organic sample added, an almost complete extraction of the acid into the sulphate solution will always take place. Once extracted, the acid can be determined exactly in the same way as described above. The small amount of organic solvent present does not seem to impair the function of the electrodes.

I am indebted to the General Director of Eurochemic, Dr Erich Pohland, and to the Director of Research, Dr Rudolf Rometsch, for permission to publish this investigation. The experimental assistance of Mr Hanns-Peter Wichmann, Chemie-Ingenieur, and Mr Emil Vervecken is gratefully acknowledged. My thanks are also due to Dr George Gamlen, Manchester, for his linguistic revision of my manuscript.

Short Communications

On the Half-Life of ^{33}P

INGRID FOGELSTRÖM-FINEMAN
and TORBJÖRN WESTERMARK

Division of Physical Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

^{33}P was discovered by three teams independently, *viz.* Sheline *et al.*[1], Jensen *et al.*[2] and Westermark [3], but unfortunately there exists a discrepancy in the half-life determinations on this isotope. In his first experiments [3], Westermark found a half-life of 25 ± 2 days by studying the beta activity from a mixed sample of ^{32}P and ^{33}P and correcting for the amount of ^{32}P by using absorbers of aluminium. Later measurements [4], begun with a sample containing about 70 % ^{33}P and 30 % ^{32}P, gave 25.4 ± 0.3 days. Sheline *et al.*[1] give the value 25 ± 2 days, while Jensen and Nichols [2] in their first publication on the subject give 24.8 ± 0.5 days. Further experiments [5], where the amount of ^{33}P was determined from its area in a beta-spectrum from a mixture of ^{32}P and ^{33}P, gave a half-life of 24.4 ± 0.2 days.

Russell [6] found a half-life for ^{33}P of 25 ± 1 days by calculating it from an analysis of the decay curve of a $^{32}P-^{33}P$ mixture taken with a Lauritsen electroscope.

As can be seen there is a discrepancy between the two most accurate figures, namely those given by Westermark [4] and by Nichols and Jensen [5]. As ^{33}P will probably be important in the future [7], especially for biochemists, it is of interest to determine the half-life of ^{33}P with a greater accuracy.

In this laboratory it was found that ^{33}P was formed almost free from ^{32}P upon irradiating sulphur far out at the end of the thermal column in the Norwegian D_2O-reactor [8]. It was also found that large amounts of sulphur (1–10 kg) could be irradiated between the concrete wall and the reflector and that a P activity containing about 25 % ^{33}P was thereby formed.

Preparation of the ^{33}P samples. In order to produce a sample of ^{33}P with a low ^{32}P-content, two batches of sulphur were irradiated. A 200 g sample of sulphur was irradiated in the outmost part of the JENER reactor for one month and then left to age for about two months. Another sample consisting of 1 kg was irradiated between the reflector and the concrete wall for one month and then left to age for about six months.

The radioactive phosphorus was separated from the sulphur by dissolving in CS_2 and filtering through a filter paper. About 50 % of the P activity was then found in the amorphous sulphur lying on the filter paper as shown by earlier experiments in this laboratory [3,9]. The PO_4^{3-} was extracted from the amorphous sulphur by boiling with 5 N HNO_3 and PO_4^{3-} carrier. The phosphate was then precipitated from the filtered solution as a coprecipitate with lanthanum hydroxide formed by adding lanthanum nitrate and then ammonia. The lanthanum hydroxide (after filtering and washing) was dissolved in HCl and the solution purified, after evaporation and dissolution in 0.02 N HCl, by cation exchange and then by several evaporations with H_2O_2 and a final evaporation with H_2SO_4. The residue was then taken up in a small volume of water and transferred to a lucite cup which had been painted with graphite in ethanol (a commercial mixture of "aqua-dag") and evaporated to dryness. The cup was covered with pliofilm (thickness 0.36 mg/cm^2).

Activity measurements. Beta activity measurements were performed over a period of about half a year. During all measurements, which were made with an end window GM-tube (1.4 mg/cm^2), the cup containing the sample was connected electrically to ground. The distance between the cup and the window of the tube was about 3 cm. Measurements with absorbers consisting of 10.1 mg/cm^2 Al and 55.2 mg/cm^2 Al were also made. Each measurement involved more than 15 000 counts

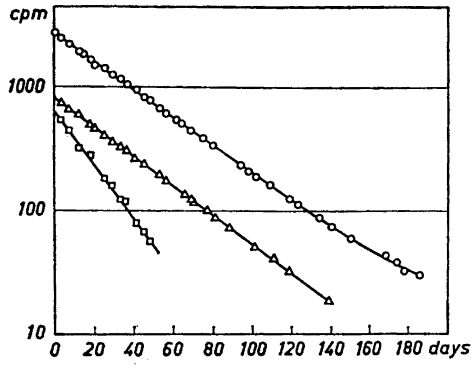

Fig. 1. Activity measurements of ^{33}P sample 2: O No aluminium absorber; △ 10.10 mg/cm² aluminium absorber; □ 55.22 mg/cm² aluminium absorber (scale raised by factor of 10).

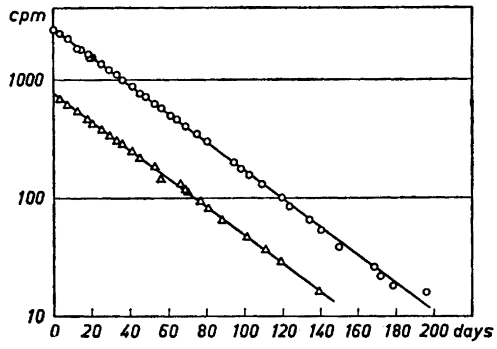

Fig. 2. Decay curves for ^{33}P sample 2: O No aluminium absorber; △ 10.10 mg/cm² aluminium absorber.

and usually more than 40 000. A non-aged ^{32}P source was measured both without any absorber and also with 10.1 mg/cm² Al and 55.2 mg/cm² Al absorbers in the same geometry as that for the ^{33}P-samples. The source was prepared from a carrier-free ^{32}P sample obtained from AERE, Harwell. This sample had been separated from sulphur shortly after the irradiation and probably contained some ^{33}P although not much. As a reference, a standard preparation of ^{60}Co was used.

Results. Fig. 1 shows the results obtained for sample 2 prepared from the 0.2 kg batch. It contained the largest fraction of ^{33}P (the rest being ^{32}P). The figures have been corrected for dead time losses and background. By means of the ^{60}Co standard which has a maximum beta energy (310 keV) not very far from that of ^{33}P (250 keV), corrections for changes in the apparatus, for instance due to changes in the GM-tube or the high voltage, and for changes in temperature and air pressure have been made. The activity measured with the absorber consisting of 55.2 mg/cm² Al should originate from ^{32}P alone since there is very little possibility of activities other than ^{32}P, ^{33}P and ^{35}S being present in the sample and since the ^{33}P and ^{35}S beta radiations have a shorter range than 55.2 mg/cm² apart from a small amount of bremsstrahlung. The measurements on the almost pure ^{32}P-sample (less than 1 % ^{33}P) with different absorbers gave a counting rate ratio $I_0/I_{55.2}$ (index refers to aluminium absorber used, index 0 means no absorber) of 1.218 and $I_{10.1}/I_{55.2}$ of 1.176. From the 55.2 mg/cm² curve for the sample and the above data, the GM response from the ^{32}P activity could be calculated and corrected for.

As can be seen in Fig. 1, the curve with no aluminium absorber for sample 2 bends off towards a longer half-life after about 150 days. It is very probable that this is

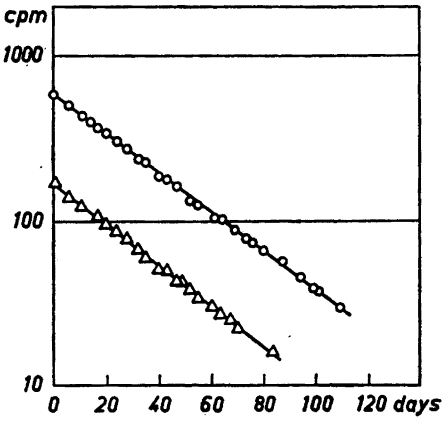

Fig. 3. Decay curves for ^{33}P sample 1: Q No aluminium absorber; △ 10.10 mg/cm² aluminium absorber.

caused by some ^{35}S being present in the sample despite the elaborate chemical procedures. The amount of ^{35}S giving rise to this longer half-life was calculated from the activity figures for the sample under the assumption that the half-life of ^{33}P is 25 days. It should be pointed out that this iterative procedure does not influence the main half-life determination because the correction for ^{35}S is rather small. From absorption curves for pure ^{35}S, corrections for ^{35}S could also be made for the 10.1 mg/cm^2 curve. The composition of the activity from the sample counted by the GM-tube with no aluminium absorber when the measurement started could thus be calculated to be: 95 % ^{33}P, 2.7 % ^{32}P and 2.2 % ^{35}S. The relative contributions of the radiation passing through the 10.1 mg/cm^2 absorber were 90 % ^{33}P, 9 % ^{32}P and 0.8 % ^{35}S.

Fig. 2 shows the ^{33}P decay curves, with no absorber and with 10.1 mg/cm^2 Al, obtained from Fig. 1 when corrections determined by means of the ^{60}Co standard and corrections for ^{32}P and ^{35}S had been made. The 10.1 mg/cm^2 curve gives, when evaluated with the least square method using the figures from 0—119 days, a half-life for ^{33}P of 25.36 $\pm$ 0.27 days with a confidence level of 95 %. The values from the decay curve with no absorber are rather scattered after about 100 days and a small error in the ^{35}S-correction might interfere with these figures. Therefore the half-life of ^{33}P has been calculated using this curve only from 0—98 days, *i.e.* about four half-lives. The value thus found was 25.34$\pm$0.22 days.

Sample 1, prepared from the 1 kg batch, produced a radiation composed of 87 % ^{33}P and 13 % ^{32}P when using no absorber and 69 % ^{33}P and 31 % ^{32}P when using a 10.1 mg/cm^2 absorber. Fig. 3 shows the decay curves obtained after correcting by means of the ^{60}Co standard and after correcting for ^{32}P. No indications of ^{35}S in the sample could be found. The values obtained for the half-life of ^{33}P were with no absorber 25.19 $\pm$ 0.23 days and with the 10.1 mg/cm^2 Al absorber 24.08 $\pm$ 0.46 days.

We feel that the results with sample 2 should be given about three times the weight of sample 2. A weighted mean would thus be 25.2 $\pm$ 0.2 days. This uncertainty includes counting statistics only. The accuracy of this half-life determination is further dependent on the uncertainty of the half-life of ^{35}S and of the ^{33}P content of the "fresh" sample. The final uncertainty is further dependent on the absorber procedure and might therefore be estimated conservatively to be half a day. Our final result is thus 25.2 $\pm$ 0.5 days.

The figure obtained is in accord with Westermark's determination [4] but is not in accord with that of Nichols and Jensen. The uncertainty is however still too high and a new determination would be desirable. Since a ^{35}S enrichment apparatus (based on ion exchange) is in operation here now, we hope to produce millicurie amounts of rather pure ^{33}P and to determine its decay properties, including the half-life, more accurately than has been possible with the rather weak samples studied hitherto.

Acknowledgements. We thank Professor Ole Lamm, Head of this institute, for promoting these studies and providing working facilities.

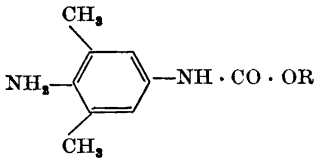
Note on the Preparation of Some 4-Amino-3,5-dimethyl- and 2-Amino-3-methyl-phenylurethanes

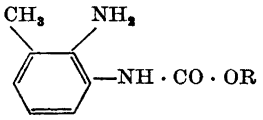
RICHARD DAHLBOM* and ALFONS MISIORNY

Research Laboratories, AB Astra, Södertälje, Sweden

Several amino- and methyl-substituted phenylurethanes (Types I and II) were required as starting material for certain syntheses in the field of local anesthetics.



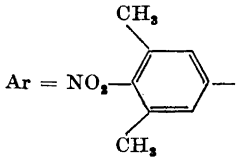
I



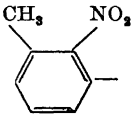
II

R = C_2H_5, *n*-C_3H_7, *n*-C_4H_9 and *n*-C_5H_{11}.

These compounds were obtained by the Curtius degradation of the appropriate nitro-substituted carboxylic acid.



or



Degradation was followed by hydrogenation of the nitro group to the amino compound.

Experimental. *4-Nitro-3,5-dimethylbenzoyl chloride* was obtained from 4-nitro-3,5-dimethylbenzoic acid according to the method of Löfgren *et al.*[1]. B.p. 144–145°/9 mm, yield 86 %.

2-Nitro-3-methylbenzoyl chloride was similarly prepared by refluxing 2-nitro-3-methylbenzoic acid[2] (45 g, 0.25 mole) and thionyl chloride (89 g, 0.75 mole) for 4 h. The thionyl chloride was removed *in vacuo* and the residue (without purification) was used for further syntheses. An attempt to distill this compound *in vacuo* led to *a violent explosion.*

4-Nitro-3,5-dimethylbenzoyl azide. 4-Nitro-3,5-dimethylbenzoyl chloride (42.7 g, 0.2 mole) was dissolved in acetone (80 ml) and cooled to 10°. Sodium azide (14.3 g, 0.22 mole) in water (45 ml) was then added dropwise with stirring over a period of 15 min.; the temperature was maintained at 25° by external cooling. After one hour, water (100 ml) was added, and the reaction product which separated was collected and dried in a vacuum desiccator. Yield 40.8 g (93 %), m.p. 82–83° (decomp.). Without purification the product was used for further syntheses.

2-Nitro-3-methylbenzoyl azide was prepared as above. Yield 98 %, m.p. 86–87° (dec.).

4-Nitro-3,5-dimethyl- and *2-nitro-3-methyl-phenylurethanes.* A solution of the appropriate azide (0.05 mole) in an alcohol (50 ml) containing the desired alkyl group was heated on the water bath until nitrogen evolution had ceased (2 h). Excess of the alcohol was removed *in vacuo*, leaving an oil which in most instances quickly solidified. The resulting product, obtained in yields of 95–100 %, was practically pure. A sample was recrystallised for analysis.

The nitro compounds are listed in Table 1. The oils of the three compounds which did not

Chromatographic Separation of Carotenes and Other Chloroplast Pigments on Aluminium Oxide-Containing Paper

ARNE JENSEN

Norwegian Institute of Seaweed Research, NTH, Trondheim, Norway

Whereas many of the hydroxylated carotenoids are readily separated by adsorption chromatography on kieselguhr-containing filter paper[1], the less polar carotenes showed too high mobilities to permit a good separation within the latter group of compounds. It is to be expected that a paper with a stronger adsorbent embedded in it might allow the desired separation to be carried out. On our request the filter paper manufacturers Carl Schleicher & Schüll, Dassel, West Germany, very promptly prepared a filter paper (No. 667) which contained approximately 20 % aluminium oxide. Circular chromatography on this paper using petroleum ether as solvent and following the technique previously described [1], gave satisfactory separation of a series of carotenes as seen from Table 1. It was observed that the separations of chloroplast pigments were generally better on this paper than on the kieselguhr-containing (SS No. 287) paper, the zones being narrower on the former. In addition several mixtures of carotenoids from *Viola tricolor* and from *Ranunculus acris* that exhibited similar R_F-values on the kieselguhr paper were readily separated on the aluminium oxide paper since their relative mobilities were different on this adsorbent.

As expected, the activity of the aluminium oxide-containing paper was dependent on its moisture content. The papers were generally heated at 150°C for 15 min. and then immediately used for the chromatographic separation. Activated papers which were left in the air for even short periods gradually lost their activity to a certain extent. The activation mentioned above secured reproduceable R_F-values and gave the paper an activity comparable to that of aluminium oxide, activity grade 2 of Brockmann and Schodder [2]. (R_F × 100 of azobenzene = 80 in petroleum ether containing 20 % benzene). It is recommended, however, always to add a reference compound, such as β-carotene or azobenzene, and to give the mobilities of the compounds in question relative to that of the test substance.

Table 1. R_F-values of carotenes on Schleicher & Schüll Paper No. 667. Activated at 150°C for 15 min. Solvent: Petroleum ether, boiling range 60–80°C.

Compound	R_F-value × 100	
	Petroleum ether	20 % Benzene
α-Carotene[a]	43	66
β-Carotene[b]	38	62
γ-Carotene[c]	5	15
Phytofluene[c]	77	88
ζ-Carotene[c,d]	36	60
Neurosporene[c,d]	15	25
Lycopene[b]	2	8

Alkaline Hydrolysis of Glycosidic Linkages

V *. The Action of Alkali on Some Methyl Furanosides

JAN JANSON and BENGT LINDBERG

Institutionen för Träkemi, Kungl. Tekn. Högskolan, Stockholm, Sweden

The aim of our studies on the alkaline hydrolysis of glycosidic linkages has been to illuminate possible reactions of the polysaccharides during the alkaline pulping

* Part IV. *Acta Chem. Scand.* **13** (1959) 138.

Table 1. Alkaline hydrolysis of some methyl glycosides in 10 % sodium hydroxide at 170°.

Sugar	Configuration	Relationship between OCH_3 and $C_{(2)}-OH$	Furanosides $10^3 \times k^a$	Pyranosides $10^3 \times k^a$
D-Glucose	α	*cis*		1.0
»	β	*trans*	>100	2.5
D-Galactose	α	*cis*	7.8	1.0
»	β	*trans*	28	5.7
D-Mannose	α	*trans*	30	2.8
»	β	*cis*		1.1
D-Xylose	α	*cis*	8.1	1.2
»	β	*trans*	>100	5.8
L-Arabinose	α	*trans*	32	10.0
»	β	*cis*		1.0

a) Rate constants are expressed in Brigg's logarithms and hours.

of wood. Previous communications have dealt with the hydrolysis of various types of pyranosidic linkages. The present investigation is concerned with the alkaline hydrolysis of several methyl furanosides which serve as model substances for the furanosidic residues found in wood hemicelluloses. The results are given in Table 1.

The rate constants for the alkaline hydrolysis of the corresponding pyranosides [1,2] are included in the table for comparison.

It can be seen that the furanosides are considerably more labile than the pyranosides. Furthermore, those furanosides containing the *trans*-configuration about C_1 and C_2 are hydrolysed at a much higher rate than the *cis*-isomers. This fact supports the mechanism which involves elimination of the aglycon group with the subsequent formation of a 1,2-anhydride. Somewhat unexpected is the very high reactivity of the β-gluco- and β-xylofuranosides compared to the other 1,2-*trans*-glycofuranosides studied. The corresponding pyranosidic glycosides of these sugars are the most stable of the hexosides and pentosides studied; this is to be expected because of their greater conformational stability compared to the other pyranosides.

In the case of all *trans*-glycofuranosides, small amounts of neutral products (other than the starting material) were detected in the reaction product. Thus, methyl-β-D-xylopyranoside and levoglucosan were isolated from the products obtained by alkaline treatment of methyl-β-D-xylofuranoside and methyl-β-D-glucofuranoside, respectively. They were formed in small quantities (about 2 %) and it is unknown whether they are reaction products or whether their presence is due to impurities in the non-crystalline starting materials. (It may be noted that small amounts of unidentified, neutral products were formed by alkaline treatments of the other *trans*-furanosides which were crystalline and highly purified).

Preliminary experiments on the alkaline hydrolysis of methyl-α- and -β-D-glucopyranosyl uronic acid have also been conducted. These substances, which were non-crystalline and incompletely characterised, are hydrolysed by alkali at even a higher rate than the furanosides.

Hamilton and co-workers [3] have recently studied the alkaline pulping of coniferous wood. These woods contain arabino-glucurono-xylans and they showed that the L-arabinofuranose residues were rather resistant, whereas the 4-*O*-methyl-D-glucopyranosyluronic acid residues were easily cleaved during the pulping operation. It is not known whether the L-arabinofuranosidic linkages in the polysaccharide have the α- or β-configuration. Only an α-arabinofuranoside was studied in the present investigation and it was found to be rather labile; the β-anomer would be expected to be more stable. The 4-*O*-methyl-D-glucopyranosyl uronic acid residue is known to be α-linked, and the corresponding model substance was found to be quite labile.

However, it should be stressed, that the reactivities of the arabinoglucuronoxylan and the model substances are not strictly comparable, for the reactivity of the furanosidic residues is undoubtedly influenced by its position in the polysaccharide molecule.

Experimental. All melting points are corrected. Distillations were carried out under reduced pressure. Paper chromatography was conducted on Whatman No. 1 filter paper using the following solvent systems:

A. Butanol-pyridine-water, 6 : 2 : 3

B. Butanone, saturated with water.

Substances. The D-xylo- and D-galacto-furanosides were prepared according to Augestad and Berner.[4] Methyl-α-D-mannofuranoside was prepared according to Haworth *et al*[6]. Methyl-α-L-arabinofuranoside was prepared as described for the corresponding D-form by Wright and Khorana[5]. It had m.p. 45–48° and $[\alpha]_D^{20}$ — 124°(water) in good agreement with reported values.

Methyl-β-D-glucofuranoside was prepared by a Fisher synthesis, following the technique devised by Augestad and Berner[4]. Glucose (60 g) was dissolved by stirring in 0.55 % methanolic hydrogen chloride; the solution was kept at room temperature overnight. The acid was removed by treatment with lead carbonate and the solution concentrated to a syrup. Paper chromatographic analysis of this syrup in solvent system B revealed the presence of four components: glucose; a mixture of α- and β-pyranosides, migrating as a single component; and the α- and β-furanosides, which were well separated. Part of the syrup (37 g) was added to the top of a cellulose column (6.4 × 130 cm) which was then eluted with solvent system B. Methyl β-D-glucofuranoside, the faster of the two anomers, was eluted between 18 000–30 000 ml. Concentration of this fraction gave methyl β-D-glucofuranoside as a chromatographically-pure syrup showing $[\alpha]_D^{20}$ −54° in water. Comparison with the reported value $[\alpha]_D$ −77°) indicated that the substance was incompletely dried.

Reaction of the glycosides with alkali was carried out as previously described[2]. In the case of the uronides, the following procedure was employed. After alkaline hydrolysis the reaction mixture was neutralised with hydrochloric acid and concentrated to dryness. The residue was dissolved in water and an aliquot concentrated and subjected to methoxyl analysis.

Confirmation of the Structure of Ketomanoyl Oxide

C. ENZELL

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Recent work in this laboratory has shown that hinokiol, hinokione[1] and totarolone[2] all have an oxygen function at C(3) (steroid numbering). The original assignment[3] of the keto group of ketomanoyl oxide to the 2-position has recently been questioned[4]*.

In connection with mass-spectrometric work on related substances[5] the mass-spectra of the tetra-deuterated and non-deuterated dihydroketomanoyl oxide were recorded (Figs. 1 and 2). A comparison of the two spectra shows clearly that 4 hydrogen atoms have been replaced by deuterium, since the peaks at *m/e* 307 (*M* + 1), 291 (*M*-15), and 277 (*M*-29) in the spectrum of dihydroketomanoyl oxide (Fig. 2) are found 4 mass units higher, at *m/e* 311, 295, and 281, in the spectrum of deuterated dihydroketomanoyl oxide (Fig. 1). These peaks are probably due to ions obtained from the molecule after addition of a proton (307 and 311), removal of a methyl group (291 and 295) and an ethyl group (277 and 281), respectively. The result shows that position 2, originally assigned to the oxo

Chromatographic Separation of Carotenes and Other Chloroplast Pigments on Aluminium Oxide-Containing Paper

ARNE JENSEN

Norwegian Institute of Seaweed Research, NTH, Trondheim, Norway

Whereas many of the hydroxylated carotenoids are readily separated by adsorption chromatography on kieselguhr-containing filter paper[1], the less polar carotenes showed too high mobilities to permit a good separation within the latter group of compounds. It is to be expected that a paper with a stronger adsorbent embedded in it might allow the desired separation to be carried out. On our request the filter paper manufacturers Carl Schleicher & Schüll, Dassel, West Germany, very promptly prepared a filter paper (No. 667) which contained approximately 20 % aluminium oxide. Circular chromatography on this paper using petroleum ether as solvent and following the technique previously described [1], gave satisfactory separation of a series of carotenes as seen from Table 1. It was observed that the separations of chloroplast pigments were generally better on this paper than on the kieselguhr-containing (SS No. 287) paper, the zones being narrower on the former. In addition several mixtures of carotenoids from *Viola tricolor* and from *Ranunculus acris* that exhibited similar R_F-values on the kieselguhr paper were readily separated on the aluminium oxide paper since their relative mobilities were different on this adsorbent.

As expected, the activity of the aluminium oxide-containing paper was dependent on its moisture content. The papers were generally heated at 150°C for 15 min. and then immediately used for the chromatographic separation. Activated papers which were left in the air for even short periods gradually lost their activity to a certain extent. The activation mentioned above secured reproduceable R_F-values and gave the paper an activity comparable to that of aluminium oxide, activity grade 2 of Brockmann and Schodder [2]. (R_F × 100 of azobenzene = 80 in petroleum ether containing 20 % benzene). It is recommended, however, always to add a reference compound, such as β-carotene or azobenzene, and to give the mobilities of the compounds in question relative to that of the test substance.

Table 1. R_F-values of carotenes on Schleicher & Schüll Paper No. 667. Activated at 150°C for 15 min. Solvent: Petroleum ether, boiling range 60–80°C.

Compound	R_F-value × 100	
	Petroleum ether	20 % Benzene

Confirmation of the Structure of Ketomanoyl Oxide

C. ENZELL

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Recent work in this laboratory has shown that hinokiol, hinokione[1] and totarolone[2] all have an oxygen function at C(3) (steroid numbering). The original assignment[3] of the keto group of ketomanoyl oxide to the 2-position has recently been questioned[4]*.

In connection with mass-spectrometric work on related substances[5] the mass-spectra of the tetra-deuterated and non-deuterated dihydroketomanoyl oxide were recorded (Figs. 1 and 2). A comparison of the two spectra shows clearly that 4 hydrogen atoms have been replaced by deuterium, since the peaks at *m/e* 307 (*M* + 1), 291 (*M*-15), and 277 (*M*-29) in the spectrum of dihydroketomanoyl oxide (Fig. 2) are found 4 mass units higher, at *m/e* 311, 295, and 281, in the spectrum of deuterated dihydroketomanoyl oxide (Fig. 1). These peaks are probably due to ions obtained from the molecule after addition of a proton (307 and 311), removal of a methyl group (291 and 295) and an ethyl group (277 and 281), respectively. The result shows that position 2, originally assigned to the oxo

* During the preparation of this manuscript a communication has appeared in which the same approach led to similar results. Grant, P.K. and Hodges, R. *Chem. & Ind. London* **1960** 1300.

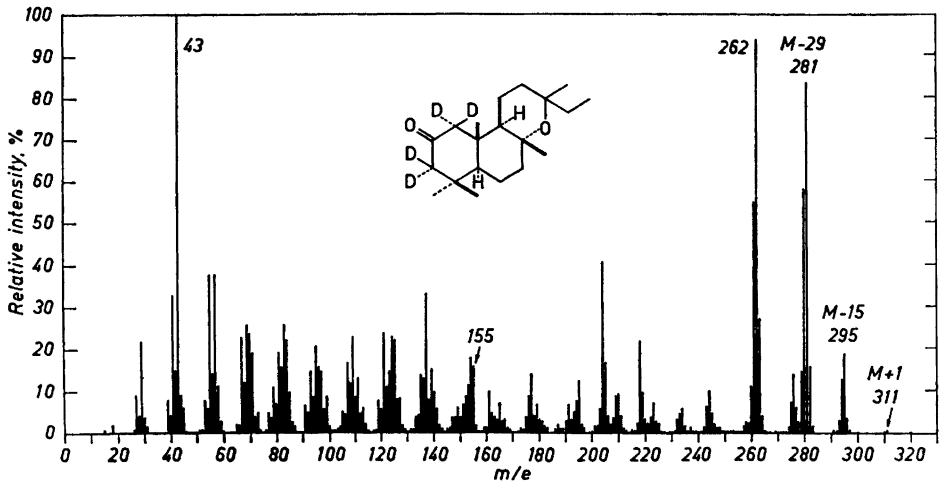

Fig. 1. Mass-spectrum of tetradeuterodihydroketomanoyl oxide.

group, is the only possible position for this group in ketomanoyl oxide.

The peak at *m/e* 151 in the spectrum of dihydroketomanoyl oxide, which occurs at *m/e* 155 in the spectrum of deuterated dihydroketomanoyl oxide, most probably is due to an ion originating from ring *A* by rupture of the C(6)—C(7) and C(9)—C(10) bonds and removal of a proton. Corresponding peaks have been observed in spectra of compounds with the same configuration as in ketomanoyl oxide at C(5), C(9), and C(10), *e.g.* torulosol, dihydrotorulosol, torulosal, manool, dihydromanool, manoyl oxide, agathadienecarbinolcarboxylic acid [5], methyl cryptopimarate and methyl pimarate [6] (dextropimarate) and are more fully discussed elsewhere [5].

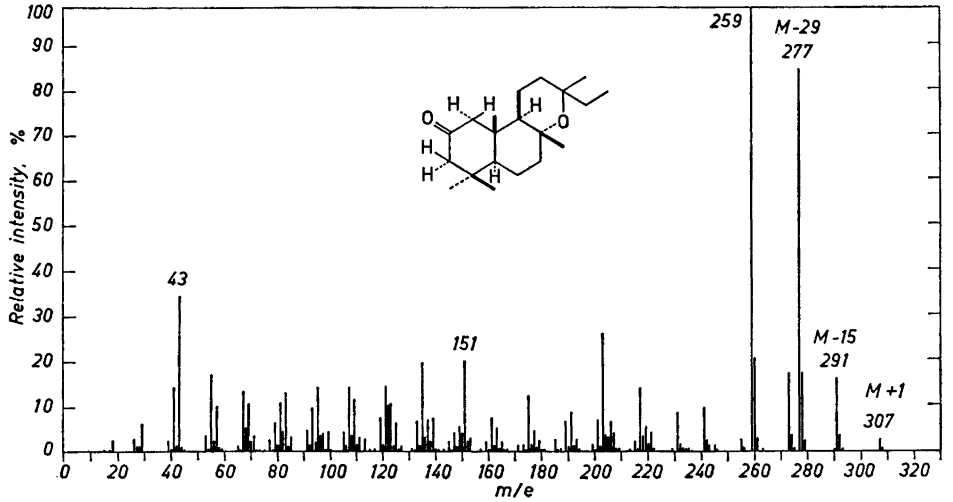

Fig. 2. Mass-spectrum of dihydroketomanoyl oxide.

Examination of the PMR-spectrum of dihydroketomanoyl oxide confirms the mass-spectrometric results. The intensity of the signal at 206 c/s (from internal benzene standard in dilute CCl_4 solution; 40 Mc/s) indicates the presence of four hydrogen atoms on the carbon atoms adjacent to the keto group.

Ketomanoyl oxide, in methanol solution, showed a comparatively [7,8] large positive Cotton effect ($[\alpha]_{600}$ + 400°; $[\alpha]_{313}$ + 3 300°; $[\alpha]_{275}$ −3 700°; $[\alpha]_{273}$ −3 600°), which, as in the case of 3-oxo terpenoid-type compounds, was not lowered on addition of hydrochloric acid [9]. The inability to form a hemiketal is probably caused by 1,3-interaction of the axial methyl substituents.

Deuterium exchange [10] was effected by boiling dihydroketomanoyl oxide [4], m.p. 91−92° (50 mg), with a solution obtained from sodium (7 mg), O-deuteromethanol (1.5 ml) and deuterium oxide (0.5 ml) under oxygen-free nitrogen for 10 min. followed by removal of the solvents. The proceedure was repeated three times with fresh solvents. Addition of deuterium oxide (3 ml) to the residue and extraction with dry ether gave, after drying, removal of the solvent and sublimation of the residue, tetradeuterodihydroketomanoyl oxide, m.p. 89 −92°.

Inductive Effects on the Donor Strengths of Some Oxo Compounds

INGVAR LINDQVIST and BERT FJELLSTRÖM

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

In a recent paper [1] it was reported that esters and ketones have almost equal donor strengths in reactions with $SbCl_5$. Passing from ketones to esters two main effects can be predicted. Thus the inductive effect would lead to a reduction of the donor strength owing to withdrawal of electrons from the carbonyl oxygen atom. This would be opposed, however, by delocalization of one of the lone pair of electrons of the ether oxygen atom. For the carbonyl oxygen atom the two effects seem to be of the same magnitude and on balance no appreciable difference is obtained. This is also reflected in the C=O bond lengths, which are almost equal in ketones and esters. On the other hand, in the presence of halogens, the inductive effect is dominant and the C=O bond lengths are shorter [2]. It has been shown moreover that halogen substitution has the same effect on the donor strengths of compounds containing S=O, Se=O and P=O bonds [1]. In this paper we report the effect of alkoxy substitution on the donor strengths of these compounds in order to determine the balance between the inductive and delocalization effects. The following esters have been studied: $(CH_3O)_2SeO$, $(CH_3O)_2SO$, $(CH_3O)(CH_3)SO_2$ and $(CH_3O)_3PO$.

Experimental. Dimethylselenite, $(CH_3O)_2SeO$, was prepared according to Michaelis and Landmann [3]. B.p. + 62−65°/11 mm.

Dimethyl sulfite, $(CH_3O)_2SO$, was prepared according to Woss [4]. B.p. + 125°.

Examination of the PMR-spectrum of dihydroketomanoyl oxide confirms the mass-spectrometric results. The intensity of the signal at 206 c/s (from internal benzene standard in dilute CCl_4 solution; 40 Mc/s) indicates the presence of four hydrogen atoms on the carbon atoms adjacent to the keto group.

Ketomanoyl oxide, in methanol solution, showed a comparatively [7,8] large positive Cotton effect ($[\alpha]_{600}$ + 400°; $[\alpha]_{313}$ + 3 300°; $[\alpha]_{275}$ −3 700°; $[\alpha]_{273}$ −3 600°), which, as in the case of 3-oxo terpenoid-type compounds, was not lowered on addition of hydrochloric acid [9]. The inability to form a hemiketal is probably caused by 1,3-interaction of the axial methyl substituents.

Deuterium exchange [10] was effected by boiling dihydroketomanoyl oxide [4], m.p. 91−92° (50 mg), with a solution obtained from sodium (7 mg), O-deuteromethanol (1.5 ml) and deuterium oxide (0.5 ml) under oxygen-free nitrogen for 10 min. followed by removal of the solvents. Inductive Effects on the Donor Strengths of Some Oxo Compounds

INGVAR LINDQVIST and BERT FJELLSTRÖM

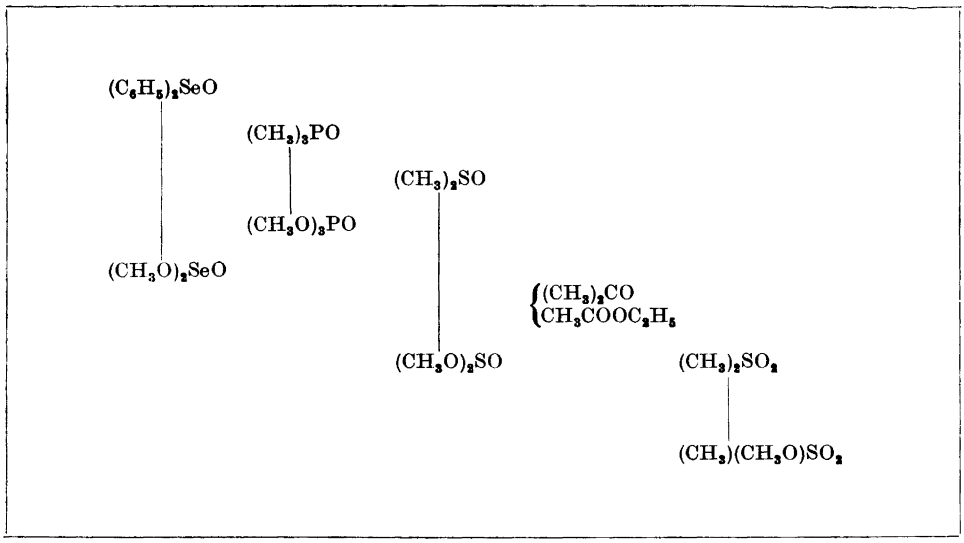
Institute of Chemistry, University of Uppsala, Uppsala, Sweden

In a recent paper [1] it was reported that esters and ketones have almost equal donor strengths in reactions with $SbCl_5$. Passing from ketones to esters two main effects can be predicted. Thus the inductive effect would lead to a reduction of the donor strength owing to withdrawal of electrons from the carbonyl oxygen atom. This would be opposed, however, by delocalization of one of the lone pair of electrons of the ether oxygen atom. For the carbonyl oxygen atom the two effects seem to be of the same magnitude and on balance no appreciable difference is obtained. This is also reflected in the C=O bond lengths, which are almost equal in ketones and esters. On the other hand, in the presence of halogens, the inductive effect is dominant and the C=O bond lengths are shorter [2]. It has been shown moreover that halogen substitution has the same effect on the donor strengths of compounds containing S=O, Se=O and P=O bonds [1]. In this paper we report the effect of alkoxy substitution on the donor strengths of these compounds in order to determine the balance between the inductive and delocalization effects. The following esters have been studied: $(CH_3O)_2SeO$, $(CH_3O)_2SO$, $(CH_3O)(CH_3)SO_2$ and $(CH_3O)_3PO$.

Experimental. Dimethylselenite, $(CH_3O)_2SeO$, was prepared according to Michaelis and Landmann [3]. B.p. + 62−65°/11 mm.

Dimethyl sulfite, $(CH_3O)_2SO$, was prepared according to Woss [4]. B.p. + 125°.

Table 1. Relative donor strengths (decreasing from top to bottom). The magnitudes of the displacements between the molecules do not correspond to quantitative measurements.



Methyl methansulfonate, $(CH_3O)(CH_3)SO_2$, was prepared according to Karbatow [5]. B.p. + 200–202°.

Trimethyl phosphate, $(CH_3O)_3PO$, was prepared according to Drushel [6]. B.p. 85–87°/12 mm.

All experiments were made in ethylene chloride solutions as described in an earlier paper [1].

Results and discussion. The relative donor strengths with $SbCl_5$ as acceptor molecule are given in Table 1. It is immediately clear that in all cases the substitution has produced quite a different result from that obtained for ketones. The inductive effect is obviously dominant. It is too early to conclude from the individual differences anything which would indicate particularly large inductive effects on the Se = O bond. Further structural and thermochemical work is needed.

In this connection, consideration of the consequence of adduct formation on the bonds in the oxo compounds shows that the inductive effect should be most pronounced. The weakening of the carbonyl bond in esters of carboxylic acids and the strengthening of the adjacent C–O bond can also be described primarily, as an inductive effect [7] further favoured by the delocalization effect. Thus by adduct formation the two effects reinforce giving a particularly large net effect in esters of carboxylic acids. However, by substitution (passing from ketone to ester) they are opposed, so that the net effect is almost negligible. In resonance language the effect of delocalization is expressed by the formulae $RO^+=C-O-Sb^-Cb^-Cl_5$ and $RO^+-C=O^-$.

A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged. Finally we wish to thank Mrs. Zackrisson for valuable discussions and Professor Hägg for all facilities put at our disposal.

The Determination of Small Proportions of Linolenic Acid in Vegetable Oils by Alkaline Isomerization

JENS G. NØRBY

Biokemisk Institut, Århus Universitet, Denmark

Brice and Swain [1] have devised a method for the accurate determination of small proportions of polyenoic fatty acids in vegetable oils based on the ultraviolet spectra of the oils before and after alkaline isomerization. The method, which includes corrections for background absorption, may be used on a variety of fatty acid mixtures containing conjugated and unconjugated dienoic and trienoic acids, but requires about 200 mg fatty acids for each analysis. The microisomerization method of Herb and Riemenschneider [2] has made it possible to use as little as 1—10 mg fatty acids. The present paper concerns the determination of small proportions of trienoic acid by the isomerization method of Herb and Riemenschneider [2] and the calculation method of Brice and Swain [1].

Reagents and methods are described by Nørby [3]. *Symbols:* k_{262}, k_{268}, and k_{274} are observed specific extinction coefficients ($E^{1g/l}_{1cm}$) before isomerization, the subscripts denoting the wave lengths. k'_{262}, k'_{268}, and k'_{274} are the same coefficients after isomerization. k_3 is the specific extinction coefficient before isomerization at 268 mμ (maximum for triene conjugation) after correction for bakground absorption according to eqn. II of Brice and Swain [1]. k'_3 is the same coefficient after isomerization.

Calculation of k'_3. Two equations can be used for the calculation of k'_3:

$$k'_3 = k'_{268} - k_{268} \quad \text{(I)}$$

$$k'_3 = 4.1\ [k'_{268} - \tfrac{1}{2}(k'_{274} + k'_{262})] - k_3 \quad \text{(II)}$$

As k'_3 is the specific extinction coefficient of the sample after isomerization due to triene conjugation produced by the isomerization, eqn. I is used when the background absorption is not changed during isomerization. In this case $k'_{268} - k_{268}$ is the increase due to triene conjugation.

If, however, isomerization increases the background absorption, $k'_{268} - k_{268}$ will be higher than k'_3, and eqn. I can not be used. Brice and Swain [1] have shown that if the increased background absorption is linear in the region 262—274 mμ, eqn. II will give the correct value for k'_3 (k_3 is zero if no conjugated material is present before isomerization). The correction factor 4.1 ($= F_3$) was derived from experiments on isomerized pure linolenic acid as:

$$F_3 = 4.1 = \frac{k'_{268}}{k'_{268} - \tfrac{1}{2}(k'_{274} + k'_{262})} \quad \text{(III)}$$

From the paper of Brice and Swain [1] it is seen that F_3 is the total height of the triene peak at 268 mμ divided by the height of the peak taken with a straight line between the minima at 262 and 274 as a base line. For a given sample the denominator will not change if a linear background absorption is added and hence II will give the correct k'_3 in such cases.

When k'_3 is known, % triene is $1.105 \cdot k'_3$ (Herb and Riemenschneider [2]).

Results. Determination of correction factor F_3 *for the method of Herb and Riemenschneider* [2]. Different amounts of two samples of linolenic acid (Hormel Foundation) and soybean oil (containing 51.8 % diene and 7.67 % triene) were isomerized and k'_{262}, k'_{268}, and k'_{274} determined. At the same time k_{262}, k_{268}, and k_{274} were determined on unisomerized samples. As all samples analyzed showed some absorption before isomerization, the following expression, which is a modification of that of Brice and Swain [1] (III), was used for the calculation of F_3:

$$F_3 = \frac{k'_{268} - k_{268}}{k'_{268} - k_{268} - \tfrac{1}{2}[(k'_{274} - k_{274}) + (k'_{262} - k_{262})]} \quad \text{(IV)}$$

In IV $k' - k$ is the increase in specific extinction coefficient due to isomerization of pure linolenic acid.

The value 4.12 found for F_3 (Table 1) agrees well with 4.1 found by Brice and Swain [1] for their method. F_3 did not vary with sample size in the range indicated in Table 1.

Determination of small amounts of triene. In the first experiment (Table 2) the specific extinction coefficients before and after isomerization were determined for five samples of linoleic acid (Hormel Foundation)

Table 1. Determination of correction factor F_3 for the method of Herb and Riemenschneider.

Sample	Sample weight mg	Number of determinations	F_3	SD
Linolenic acid I	2.3 – 3.5	9	4.124	0.012
" " II	0.08–12.2	22	4.112	0.013
Soybean oil	1.8 –40	19	4.123	0.018

Table 2. Determination of small amounts of triene calculated according to equation II and I.

Sample	Sample weight mg	% diene	% triene eqn. II	% triene eqn. I	F_3

acid	5.5	24.5	55.6	54.6	55.6	98.2	100.0	4.19

Table 4. k'_{233} k'_{268} and F_3^{sample} for all experiments mentioned in the present paper.

Sample	k'_{233}	k'_{268}	k'_{233}/k'_{268}	F_3^{sample}
Sunflower seed oil	ca. 54	0.27–0.39	142–199	5.82–13.6
Linoleic acid	ca. 90	1.4 –1.8	50–64	4.7 –11.3
Soybean oil + linoleic acid	72–82	2.8 –4.2	17–29	4.4 – 4.9
Soybean oil	51	7	7.3	4.12
Soybean oil + linolenic acid	49–52	14–63	0.8–3.7	4.18
Linolenic acid	46	92	0.5	4.11

and sunflower seed oil. The content of triene was determined after calculation of k'_3 by eqn. I or eqn. II and F_3^{sample} was calculated by eqn. IV. It is seen that F_3^{sample} is consistently higher than 4.12 indicating that a background absorption has developed during isomerization. In accordance with this, calculation of k'_3 by eqn. I gives higher values than by eqn. II.

In order to determine whether the use of eqn. II, when F_3^{sample} is higher than 4.12, will give the *correct* value for % triene, a number of recovery experiments were carried out. Known mixtures of soybean oil and linoleic or linolenic acid were isomerized and % triene determined after calculation of k'_3 by eqn. I or II. F_3^{sample} was calculated by eqn. IV. The results in Table 3 confirm, that when F_3^{sample} is higher than 4.12, as seen in the isomerized mixtures of soybean oil and linoleic acid, calculation of k'_3 by eqn. II gives the correct value for % triene.

In conclusion it can be said that the value of F_3^{sample} will indicate which of the eqns. I or II will give the correct value for k'_3 and thereby the correct value for the triene content of the sample. If F_3^{sample} is higher than 4.12 eqn. II should be used, in all other cases eqn. I will give the correct k'_3.

In an attempt to standardize the spectrophotometric determination of polyenoic fatty acids and to simplify the calculations involved, Brice *et al.*[4] have recommended the use of eqn. II only when k'_{268} is lower than 1. In Table 4 the values for k'_{233} k'_{268}, k'_{233}/k'_{268} and F_3^{sample} found in the experiments described in this paper are collected. It is clearly seen that in several experiments, in which k'_{268} is greater than 1, eqn. II must be used since F_3^{sample} is higher than 4.12. From Table 4 it furthermore appears that if the ratio k'_{233}/k'_{268} is higher than 7, F_3^{sample} is higher than 4.12. Inspection of spectral curves for isomerized samples of this type clearly shows that the diene peak, with maximum at 233 mμ, contributes significantly to the absorption in the region 262—274 mμ. As this "tail absorption" is approximately linear, eqn. II will give the true k'_3 for these samples.

Studies on Rennin

IV. Chromatographic Fractionation of Rennin

BENT FOLTMANN

Carlsberg Laboratory, Copenhagen, Denmark

In previous papers of this series rennin was considered a rather homogeneous protein. Only one peak was observed on moving boundary electrophoresis at pH 5.8, and in a solubility test the enzyme behaved nearly as a single-component system (Foltmann [1,2]).

On the other hand, Ernstrom [3] reported that although rennin only showed one peak on electrophoresis in buffers of ionic strength 0.1—0.2, it would split up in 3—4 peaks on moving boundary electrophoresis in buffers of ionic strength 0.033 and pH 6.8. In a personal communication to the author, Ernstrom added that on zone-electrophoresis in buffers of ionic strength 0.033 he had observed a slight displacement of enzymatic activity as compared with optical density; however, no separation into discrete peaks was achieved by such zone-electrophoresis.

Jirgensons *et al.*[4] have reported chromatography of a commercial crystalline rennin on diethylaminoethylcellulose. They found that the rennin could be fractionated into one inactive and two active fractions. However, these experiments were carried out at pH 6.7, which is somewhat above the stability range of the enzyme (Foltmann [1]).

The present communication deals with fractionation at a more appropriate pH of rennin by chromatography on diethylaminoethylcellulose (DEAE-cellulose) as described by Peterson and Sober [5]. The ion-exchange cellulose used was a commercial

Studies on Rennin

IV. Chromatographic Fractionation of Rennin

BENT FOLTMANN

Carlsberg Laboratory, Copenhagen, Denmark

In previous papers of this series rennin was considered a rather homogeneous protein. Only one peak was observed on moving boundary electrophoresis at pH 5.8, and in a solubility test the enzyme behaved nearly as a single-component system (Foltmann [1,2]).

On the other hand, Ernstrom [3] reported that although rennin only showed one peak on electrophoresis in buffers of ionic strength 0.1—0.2, it would split up in 3—4 peaks on moving boundary electrophoresis in buffers of ionic strength 0.033 and pH 6.8. In a personal communication to the author, Ernstrom added that on zone-electrophoresis in buffers of ionic strength 0.033 he had observed a slight displacement of enzymatic activity as compared with optical density; however, no separation into discrete peaks was achieved by such zone-electrophoresis.

Jirgensons *et al.*[4] have reported chromatography of a commercial crystalline rennin on diethylaminoethylcellulose. They found that the rennin could be fractionated into one inactive and two active fractions. However, these experiments were carried out at pH 6.7, which is somewhat above the stability range of the enzyme (Foltmann [1]).

The present communication deals with fractionation at a more appropriate pH of rennin by chromatography on diethylaminoethylcellulose (DEAE-cellulose) as described by Peterson and Sober [5]. The ion-exchange cellulose used was a commercial

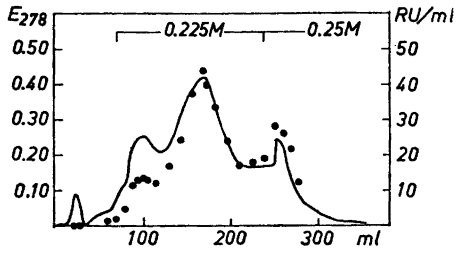

Fig. 1. Chromatography of dissolved rennin crystals on DEAE-cellulose, using stepwise elution with phosphate buffers pH 5.7; 0.20 M, 0.225 M and 0.25 M. Load 40 mg. Column 0.9 × 17 cm. Flow rate 13.5 ml/h, collected in fractions of 4.5 ml. ● milk-clotting activity (RU/ml). Experimental points have been omitted from the extinction curve (E_{278})for the sake of clarity.

product (Eastman-Kodak, lot no. 7392). The rennin was prepared and recrystallized as earlier described [1]. After the crystals had been dissolved by dialysis of the suspending medium (4 M NaCl), the sample was applied to a column of DEAE-cellulose previously equilibrated with 0.20 M phosphate buffer of pH 5.7. The elution was carried out by stepwise increase of the phosphate concentration to 0.225 M and 0.25 M. Fig. 1 illustrates one of the experiments. In the figures the concentration of protein is expressed by the optical density at 278 mμ. The enzymatic activity is expressed in rennin units (RU) according to Berridge [6].

The chromatogram shows a slight front peak of inactive material. After change of the buffer concentration to 0.225 and further to 0.25 M phosphate, a complex system of three peaks develops. Each of the three peaks contains milk-clotting activity, but the specific activity, *i.e.* the ratio RU/E_{278} is different for the three peaks. The component which is eluted last has the highest specific activity; RU/E_{278} equals about 125. This fraction is called the A-rennin. The main component which is called B-rennin has a specific activity of about 100, while the first eluted component, the C-rennin, has a specific activity of 55—60. The recovery of milk-clotting activity was 98 % and on an optical density basis the recovery was 102 %. Calculated from optical densities the first peak of inactive material represents *ca.* 3 % of the total, while the

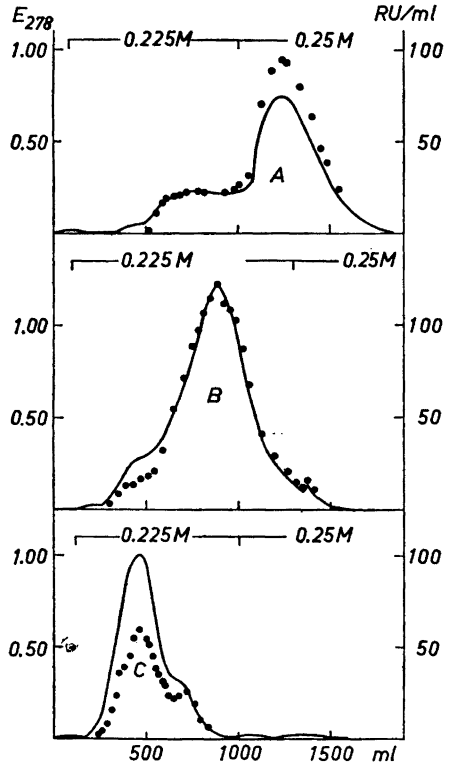

Fig. 2. Rechromatography of pooled fractions containing A, B, and C rennins, respectively. Columns of DEAE-cellulose 2 × 23 cm. Stepwise elution with phosphate buffers pH 5.7; 0.20 M, 0.225 M and 0.25 M. Load 160 to 300 mg per run. Flow rate 25—57 ml/h, three fractions collected per hour. ● milk-clotting activity (RU/ml). Solid line, optical density at 278 mμ.

A, B, and C peaks represent 22, 55, and 20 %, respectively.

For each of the three components, the corresponding fractions from several runs were pooled, and after concentration each component was further analysed and purified by rechromatography. Fig. 2 illustrates three such experiments involving rechromatography of pooled fractions. In these chromatograms the main peaks appear at three different positions corresponding to the A-, B-, and C-rennins, thus indicating that peak formation in the first

run with the crystalline material is not due to artefacts arising during chromatography. Furthermore the specific activities of the purified components also agree with those found in the peaks obtained in the first run of rennin crystals. In each of the A- and B-peaks, the specific activity is constant (within experimental error) across the peak, but over the C-peak there is a slight increase in specific activity. Whether this is due to overlapping contamination with B-rennin, or whether the C-rennin is a mixture itself is not yet clear.

The experiments indicate that the crystalline rennin investigated contains only small amounts of inactive material, and further that the crystals contain at least three components with different enzymatic activity.

Examination of the results of Jirgensons *et al.*[4] shows that the main component in their chromatogram has increasing specific activity over the peak, suggesting that this peak in fact represents a mixture of A- and B-rennins. This assumption is supported by the failure of attempts to separate A- and B-rennins by chromatography at pH 6.2 in this laboratory.

Full details of these experiments and further studies on the rennin fractions will appear in the *Comp. rend. trav. lab. Carlsberg.*

Enzymatic Hydrolysis of Bifunctional S-Substituted L-Cysteine Derivatives

SIGMUND SCHWIMMER* and SVEND E. HANSEN

*The Western Regional Research Laboratory **, Albany, California and Organic Chemical Laboratory of the Royal Veterinary and Agricultural College, Copenhagen, Denmark*

Previous publications [1,2] have reported that the C—S-lyase of the endosperm of the seeds of *Albizzia lophanta* can act on a variety of S-substituted cysteine and cysteine sulfoxide derivatives. Whereas a typical monofunctional derivative such as S-ethyl-L-cysteine can undergo complete hydrolysis to pyruvic acid [3], results presented in this communication show that the two bifunctional cysteine derivatives investigated, djenkolic acid and L-lanthionine sulfoxide, are not fully hydrolyzed. The extent of hydrolysis of djenkolic acid, as measured by formation of pyruvic acid, amounted to 66.0, 67.2, and 65 % at substrate concentrations of 1, 2, and 2.5 mM, respectively (Fig. 1). Thus the actual maximum amount of pyruvate formed was pro-

Previous publications [1,2] have reported that the C—S-lyase of the endosperm of the seeds of *Albizzia lophanta* can act on a variety of S-substituted cysteine and cysteine sulfoxide derivatives. Whereas a typical monofunctional derivative such as S-ethyl-L-cysteine can undergo complete hydrolysis to pyruvic acid [3], results presented in this communication show that the two bifunctional cysteine derivatives investigated, djenkolic acid and L-lanthionine sulfoxide, are not fully hydrolyzed. The extent of hydrolysis of djenkolic acid, as measured by formation of pyruvic acid, amounted to 66.0, 67.2, and 65 % at substrate concentrations of 1, 2, and 2.5 mM, respectively (Fig. 1). Thus the actual maximum amount of pyruvate formed was pro-

* Senior Postdoctoral Fellow, National Science Foundation, 1958—1959.

** A laboratory of the Western Utilization Research and Development Division, Agricultural Research Service, U. S. Department of Agriculture.

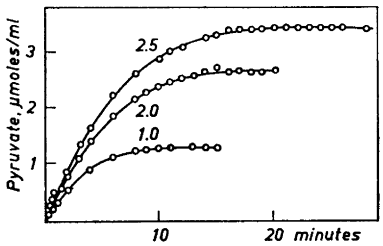

Fig. 1. Course of hydrolysis of djenkolic acid by *Albizzia* C—S-lyase. One ml of reaction mixture at 37° contained 35 μg of enzyme (specific acitivity = 200)[4], 40 μmoles of borate buffer, pH 8.0 and 0.02 μmole of pyridoxal phosphate. Micromoles per ml of djenkolic acid are indicated for each curve.

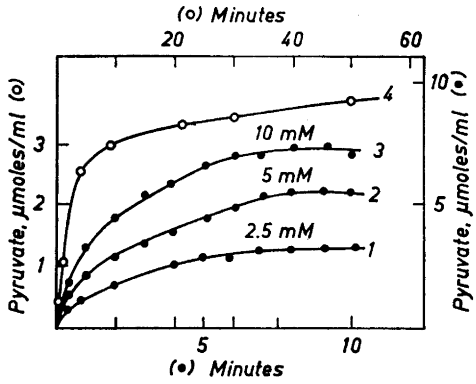

Fig. 2. Curves 1, 2, and 3-course of hydrolysis of L-lanthionine sulfoxide by *Albizzia* C—S-lyases at indicated substrate concentration under the same conditions as in Fig. 1. Curve 4,hydrolysis of mixture of 3,3-bis-(2-aminoethylthio)-*iso*butyric acid and 3-(2-carboxy-2-ethylaminothio)-3-hydroxybutyric acid by 172 μg/ml of enzyme. Concentration of substrate = 3.05 mg/ml, equivalent to 10 μmoles/ml of bisubstituted derivative.

portional to the substrate concentration, or the percentage hydrolysis was independent of the substrate concentration. On the other hand percent maximum hydrolysis of L-lanthionine sulfoxide was found to be dependent on the substrate concentration (Fig. 2). The three values found, 26 %, 22 %, and 14 % for substrate concentration 2.5, 5.0, and 10.0 mM fell on a straight line (in a substrate *vs* hydrolysis plot) which extrapolated to 30 % hydrolysis at zero substrate concentration.

It is suggested that the cessation of enzyme action prior to complete hydrolysis arises as a result of the inactivation of the enzyme by the highly reactive expected end products:

1. $R-S-CH_2-S-R + 2\ H_2O \longrightarrow S-CH_2-S + 2NH_3 + 2CH_3COCOOH$
2. $R-SO-R + 2\ H_2O \longrightarrow HSOH + 2NH_3 + 2CH_3COCOOH$

where $R = CH_2-CHNH_2-COOH$.
Thus djenkolic acid yields methylene dithiol and L-lanthionine sulfoxide yields the hypothetical sulfenic acid. Both of these sulfur-containing products could presumably react with the enzyme and inactivate it.

In addition to the above-mentioned difference between these two substrates, their course-of-hydrolysis curves appear to be quite distinct. Thus the course of hydrolysis of djenkolic acid is characterized by a linearity of rate for the first 20 to 30 % hydrolysis, followed by a progressive decrease in rate until the maximum is reached. The hydrolysis of L-lanthionine sulfoxide does not exhibit a distinct linear rate at the initial stages of the reaction. A linearity in rate at the later stage of hydrolysis prior to achievement of maximum hydrolysis was observed. In this respect, the course of hydrolysis resembles more closely that of a monosubstituted cysteine derivative (S-ethyl-L-cysteine [3]) and suggests that considerable product inhibition of the enzyme occurs during the reaction. The superimposition of product inhibition on product inactivation would then explain why the percent hydrolysis decreases with increasing substrate concentration.

Fig. 2 includes the course of hydrolysis of a preparation consisting mainly of 3,3'-bis-(2-carboxy-2-aminoethylthio)-*iso*butyric acid, which may be considered as an analogue of djenkolic acid [2]. The distinctly biphasic mode of the course of liberation of pyruvic acid probably arises from the presence of the impurity 3-(2-carboxy-2-aminoethylthio)-3-hydroxy*iso*butyric acid.

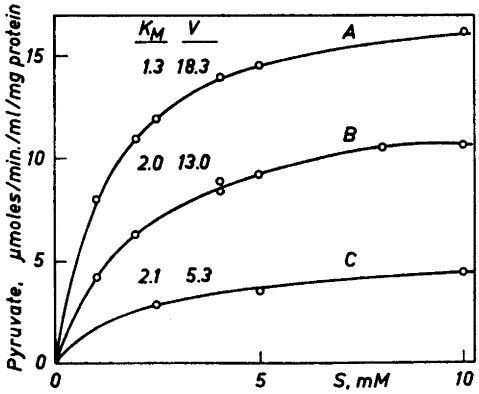

Fig. 3. Effect of substrate concentration on the initial rate of hydrolysis of djenkolic acid (A), S-ethyl-cysteine (B), and L-lanthionine sulfoxide (C) under the conditions of Fig. 1. The smooth curves were calculated from the classical Michaelis equation using values for the constants K_M and V shown in this figure. The points are the experimental values.

The ratio of the initial fast rate to the slow rate at the later stage of hydrolysis is equal to roughly about ten times the estimated ratio of the intensity of the ninhydrin spots on paper chromatograms of this preparation. This suggests that the mono-substituted cysteine derivative is much less susceptible to hydrolysis by the C—S-lyase than is the disubstituted derivative.

Fig. 3 shows the influence of substrate concentration on the rate of hydrolysis of djenkolic acid (A), S-ethyl-L-cysteine (B), and L-lanthionine sulfoxide (C). It will be noted that the Michaelis constants K_M vary considerably less than the values for V, the maximum rate when the enzyme is saturated with substrate. Let us assume as a first approximation, that K_M is a measure of the traditional steady-state constant $(k_{-1} + k_2)/k_1$ according to the usual formation $E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E +$ product, and that V is a measure of the magnitude of k_2. If K_M remains constant while k_2 increases, then k_1 (the velocity constant for combination of enzyme with substrate) must also increase. This analysis corroborates the previous conclusion that the susceptibility to hydrolysis as function of the S-substituent depends upon the absence of structures in this substituent which would tend to interfere with hydrogen bond formation between the pyridoxal phosphate moiety of the enzyme and the substrate [2]. Such interference would tend to decrease the rate of formation of enzyme-substrate complex (k_1) and also decrease the rate of decomposition of the complex (k_2). This would tend to maintain K_M at a constant value, as was found experimentally.

Preparation and Properties of Human Thyroglobulin

CLAES WEIBULL and LARS LINDER

Central Bacteriological Laboratory of Stockholm City, Stockholm, Sweden

The preparation and properties of thyroglobulin of animal origin has been described by several investigators [1-5]. Some chemical and physico-chemical studies on human thyroglobulin will be described briefly in the following.

The thyroid glands were frozen, sliced and extracted with 0.15 M NaCl for about 20 h at 5°C. The mixture was then centrifuged and the sediment discarded. Neutralized, saturated ammonium sulphate was added to the supernatant at a final saturation of 33 %. The sediment was removed by centrifugation and additional ammonium sulphate was added to the supernatant at a final saturation of 50 %. The sediment was collected by centrifugation and dissolved in distilled water. The solution was dialyzed against distilled water, and the dialysate was treated with ammonium sulphate as described above. The protein fraction precipitated between 33 and 50 % salt saturation was collected and investigated chemically and physico-chemically.

The iodine content of the material isolated from the thyroid glands was determined according to Kendall [6]. Nitrogen was determined by the Kjeldahl method. Ultracentrifugal studies were performed using the Spinco analytical ultracentrifuge working at 59 780 rpm. The protein concentration in the samples used for the ultracentrifugal analyses was 1 % and the total salt concentration in these samples was 0.17 M (0.15 M NaCl and 0.02 M phosphate, pH 7.0).

The main part of the iodine of the thyroid extracts was recovered in the protein fraction precipitated between 33 and 50 % saturation of ammonium sulphate. Table 1 gives the results of the chemical analyses carried out on the proteinaceous material thus obtained. The values for iodine and nitrogen content agree with those reported previously for animal thyroglobulin [2,3].

Table 2 shows the results of the ultracentrifugal analyses. It can be seen that the main high molecular weight component of the analyzed solutions has a sedimentation constant ($S_{20,\,aq}$) of about 17 *S*. Similar

The ratio of the initial fast rate to the slow rate at the later stage of hydrolysis is equal to roughly about ten times the estimated ratio of the intensity of the ninhydrin spots on paper chromatograms of this preparation. This suggests that the mono-substituted cysteine derivative is much less susceptible to hydrolysis by the C—S-lyase than is the disubstituted derivative.

Fig. 3 shows the influence of substrate concentration on the rate of hydrolysis of djenkolic acid (A), S-ethyl-L-cysteine (B), and L-lanthionine sulfoxide (C). It will be noted that the Michaelis constants K_M vary considerably less than the values for V, the maximum rate when the enzyme is saturated with substrate. Let us assume as a first approximation, that K_M is a measure of the traditional steady-state constant $(k_{-1} + k_2)/k_1$ according to the usual formation $E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E +$ product, and that V is a measure of the magnitude of k_2. If K_M remains constant while k_2 increases, then k_1 (the velocity constant for combination of enzyme with substrate) must also increase. This analysis corroborates the previous conclusion that the susceptibility to hydrolysis as function of the S-substituent depends upon the absence of structures in this substituent which would tend to interfere with hydrogen bond formation between the pyridoxal phosphate moiety of the enzyme and the substrate [2]. Such interference would tend to decrease the rate of formation of enzyme-substrate complex (k_1) and also decrease the rate of decomposition of the complex (k_2). This would tend to maintain K_M at a constant value, as was found experimentally.

Preparation and Properties of Human Thyroglobulin

CLAES WEIBULL and LARS LINDER

Central Bacteriological Laboratory of Stockholm City, Stockholm, Sweden

The preparation and properties of thyroglobulin of animal origin has been described by several investigators [1-5]. Some chemical and physico-chemical studies on human thyroglobulin will be described briefly in the following.

The thyroid glands were frozen, sliced and extracted with 0.15 M NaCl for about 20 h at 5°C. The mixture was then centrifuged and the sediment discarded. Neutralized, saturated ammonium sulphate was added to the supernatant at a final saturation of 33 %. The sediment was removed by centrifugation and additional ammonium sulphate was added to the supernatant at a final saturation of 50 %. The sediment was collected by centrifugation and dissolved in distilled water. The solution was dialyzed against distilled water, and the dialysate was treated with ammonium sulphate as described above. The protein fraction precipitated between 33 and 50 % salt saturation was collected and investigated chemically and physico-chemically.

The iodine content of the material isolated from the thyroid glands was determined according to Kendall [6]. Nitrogen was determined by the Kjeldahl method. Ultracentrifugal studies were performed using the Spinco analytical ultracentrifuge working at 59 780 rpm. The protein concentration in the samples used for the ultracentrifugal analyses was 1 % and the total salt concentration in these samples was 0.17 M (0.15 M NaCl and 0.02 M phosphate, pH 7.0).

The main part of the iodine of the thyroid extracts was recovered in the protein fraction precipitated between 33 and 50 % saturation of ammonium sulphate. Table 1 gives the results of the chemical analyses carried out on the proteinaceous material thus obtained. The values for iodine and nitrogen content agree with those reported previously for animal thyroglobulin [2,3].

Table 2 shows the results of the ultracentrifugal analyses. It can be seen that the main high molecular weight component of the analyzed solutions has a sedimentation constant ($S_{20,\,aq}$) of about 17 *S*. Similar

values have been reported for thyroglobulin isolated from hog [4,7] and calf [5].

It therefore seems very probable that the main, high molecular weight component in the extracts studied by us represents human thyroglobulin.

The data given above suggest that the chemical and physico-chemical properties of human thyroglobulin are similar to those of thyroglobulin of animal origin.

We wish to thank Dr. A. Ehrenberg for carrying out the ultracentrifugal analyses.

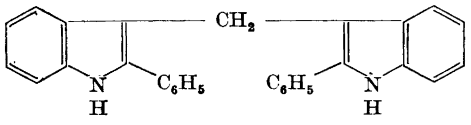
2,2′-Diphenyl-3,3′-diindolylmethane

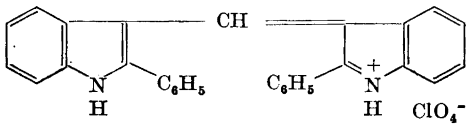
EDWARD LEETE

School of Chemistry, University of Minnesota, Minneapolis 14, Minnesota, USA

In a recent paper [1] on the chemistry of 3-hydroxymethylindoles we reported on their self-condensation to 3,3′-diindolylmethanes on boiling with water or aqueous sodium hydroxide. An exception was 3-hydroxymethyl-2-phenylindole which yielded 2-phenylindole on refluxing with 10 % sodium hydroxide. The expected product, 2,2′-diphenyl-3,3′-diindolylmethane (I), was described by Dahlbom and Misiorny [2] who claimed to have obtained this compound from 2-phenylindole and formaldehyde. However, the melting point which



I



II

they reported (184—185°) for this substance seemed to be unusually low, since all the other known 3,3′-diindolylmethanes melt considerably above the corresponding indoles, as indicated in Table 1.

This led us to suggest that the compound, m.p. 184—185°, was not authentic 2,2′-

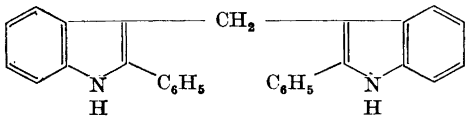
2,2′-Diphenyl-3,3′-diindolylmethane

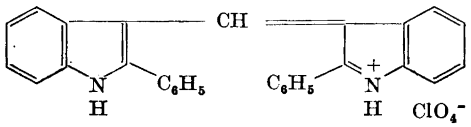
EDWARD LEETE

School of Chemistry, University of Minnesota, Minneapolis 14, Minnesota, USA

In a recent paper [1] on the chemistry of 3-hydroxymethylindoles we reported on their self-condensation to 3,3′-diindolylmethanes on boiling with water or aqueous sodium hydroxide. An exception was 3-hydroxymethyl-2-phenylindole which yielded 2-phenylindole on refluxing with 10 % sodium hydroxide. The expected product, 2,2′-diphenyl-3,3′-diindolylmethane (I), was described by Dahlbom and Misiorny [2] who claimed to have obtained this compound from 2-phenylindole and formaldehyde. However, the melting point which



I



II

they reported (184—185°) for this substance seemed to be unusually low, since all the other known 3,3′-diindolylmethanes melt considerably above the corresponding indoles, as indicated in Table 1.

This led us to suggest that the compound, m.p. 184—185°, was not authentic 2,2′-

Table 1. Melting points of substituted indoles and 3,3′-diindolylmethanes. °C.

Substituent	Indole	3,3′-Diindolylmethane
None	52—53	167—168
1-Methyl	below 0	112.5—113
2-Methyl	62	237—238
1,2-Dimethyl	56	161.5—162.5
1-Methyl-2-phenyl	100—101	185—186
2-Phenyl	187—188	184—185

diphenyl-3,3′-diindolylmethane. Dahlbom and Misiorny were quick to reply [3] to our unworthy suggestion, and in the light of further work to be described here, we offer our sincere apologies to these authors for suggesting that they had failed to perform a mixed melting point between 2-phenylindole and the product, m.p. 184—185°.

In the present work 2-phenylindole was refluxed in ethanol, containing a trace of hydrochloric acid, with ethyl orthoformate for 24 h. The product was 2,2′-diphenyl-3,3′-diindolylmethene which was isolated as its perchlorate (II) according to the procedure of Harley-Mason and Bu'Lock [4]. Crystallization from acetic acid afforded orange-red prisms, m.p. 289—290° (decomp.) (Found: C 69.83; H 4.34; N 5.58. Calc. for $C_{29}H_{21}O_4N_2Cl$: C 70.09; H 4.26; N 5.64.) This methene salt was hydrogenated in ethanol in the presence of platinum oxide. Evaporation of the filtered solution yielded I which was obtained as colorless needles from ethanol, m.p. 188—189° (Found: C 87.50; H 5.77; N 6.78. Calc. for $C_{29}H_{22}N_2$: C 87.40; H 5.57; N 7.03). The di-1,3,5-trinitrobenzene complex of 2,2′-diphenyl-3,3′-diindolylmethane was obtained as reddish brown needles from methanol, m.p. 161—162°(Found: C 59.86; H 3.62; N 13.82. Calc. for $C_{29}H_{22}N_2 \cdot 2C_6H_3O_6N_3$: C 59.71; H 3.42; N 13.59). In order to confirm that we had obtained authentic I, the compound m.p. 188—189° was N-methylated according to the procedure of Potts and Saxton [5] to yield 1,1′-dimethyl-2,2′-diphenyl-3,3′-diindolylmethane, m.p. 185—186°, identical (mixed m.p., I.R. spectrum) with material previously obtained [1] by the self-condensation of 3-hydroxymethyl-1-methyl-2-phenylindole.

It is thus evident that Dahlbom and Misiorny obtained authentic I (the slight difference in our observed melting points for this compound is probably not significant) and it is remarkable that 2-phenylindole, 2,2′diphenyl-3,3′-diindolylmethane and its 1,1′-dimethyl derivative should melt so close together. We have also reinvestigated the self-condensation of 3-hydroxymethyl-2-phenylindole. In agreement with our previous results we obtained 2-phenylindole when this compound was refluxed with 10 % sodium hydroxide. However, when exactly neutral or slightly acidic conditions were used the product was in fact the diindolylmethane I. We suspect that traces of alkali caused the formation of 2-phenylindole when 3-hydroxymethyl-2-phenylindole was refluxed with water in our previous experiments.

This investigation was supported by a research grant CY-5336 from the *National Institutes of Health*, Public Health Service, U.S.A. The analyses were performed by Mrs. Olga Hamerston of the University of Minnesota.

Acid Soluble Nucleotide Linked Peptides in Extracts of Ascites Tumor Cells

GUNNAR ÅGREN

From the Department of Medical Chemistry, University of Uppsala, Sweden

In a recent paper [1] it was reported that trichloroacetic acid (TCA) extracts of rabbit livers contained at least four ultra violet (UV) absorbing peaks with bound ninhydrin positive material. These four fractions were eluted immediately after adenosine diphosphate (ADP) and guanosine diphosphate (GDP) with a formic acid-ammonium formate system [2] from a Dowex 1 column. The positions on the elution curve of the UV-linked ninhydrin positive material were in the same region where we previously had found the uridine nucleotide bound peptides in *L. casei* [3]. Using a modification of the method of Strominger and Threnn [4] it was possible to isolate from the four fractions ten UV-absorbing spots. Seven of these contained from three up to seven amino acids, some of them at least bound to uridylic acid [5].

Since these data seemed to prove that animal tissues also contained acid soluble nucleotide bound peptides of a type previously only observed in extracts of different

diphenyl-3,3′-diindolylmethane. Dahlbom and Misiorny were quick to reply [3] to our unworthy suggestion, and in the light of further work to be described here, we offer our sincere apologies to these authors for suggesting that they had failed to perform a mixed melting point between 2-phenylindole and the product, m.p. 184—185°.

In the present work 2-phenylindole was refluxed in ethanol, containing a trace of hydrochloric acid, with ethyl orthoformate for 24 h. The product was 2,2′-diphenyl-3,3′-diindolylmethene which was isolated as its perchlorate (II) according to the procedure of Harley-Mason and Bu'Lock [4]. Crystallization from acetic acid afforded orange-red prisms, m.p. 289—290° (decomp.) (Found: C 69.83; H 4.34; N 5.58. Calc. for $C_{29}H_{21}O_4N_2Cl$: C 70.09; H 4.26; N 5.64.) This methene salt was hydrogenated in ethanol in the presence of platinum oxide. Evaporation of the filtered solution yielded I which was obtained as colorless needles from ethanol, m.p. 188—189° (Found: C 87.50; H 5.77; N 6.78. Calc. for $C_{29}H_{22}N_2$: C 87.40; H 5.57; N 7.03). The di-1,3,5-trinitrobenzene complex of 2,2′-diphenyl-3,3′-diindolylmethane was obtained as reddish brown needles from methanol, m.p. 161—162°(Found: C 59.86; H 3.62; N 13.82. Calc. for $C_{29}H_{22}N_2 \cdot 2C_6H_3O_6N_3$: C 59.71; H 3.42; N 13.59). In order to confirm that we had obtained authentic I, the compound m.p. 188—189° was N-methylated according to the procedure of Potts and Saxton [5] to yield 1,1′-dimethyl-2,2′-diphenyl-3,3′-diindolylmethane, m.p. 185—186°, identical (mixed m.p., I.R. spectrum) with material previously obtained [1] by the self-condensation of 3-hydroxymethyl-1-methyl-2-phenylindole.

It is thus evident that Dahlbom and Misiorny obtained authentic I (the slight difference in our observed melting points for this compound is probably not significant) and it is remarkable that 2-phenylindole, 2,2′diphenyl-3,3′-diindolylmethane and its 1,1′-dimethyl derivative should melt so close together. In a recent paper [1] it was reported that trichloroacetic acid (TCA) extracts of rabbit livers contained at least four ultra violet (UV) absorbing peaks with bound ninhydrin positive material. These four fractions were eluted immediately after adenosine diphosphate (ADP) and guanosine diphosphate (GDP) with a formic acid-ammonium formate system [2] from a Dowex 1 column. The positions on the elution curve of the UV-linked ninhydrin positive material were in the same region where we previously had found the uridine nucleotide bound peptides in *L. casei* [3]. Using a modification of the method of Strominger and Threnn [4] it was possible to isolate from the four fractions ten UV-absorbing spots. Seven of these contained from three up to seven amino acids, some of them at least bound to uridylic acid [5].

Since these data seemed to prove that animal tissues also contained acid soluble nucleotide bound peptides of a type previously only observed in extracts of different

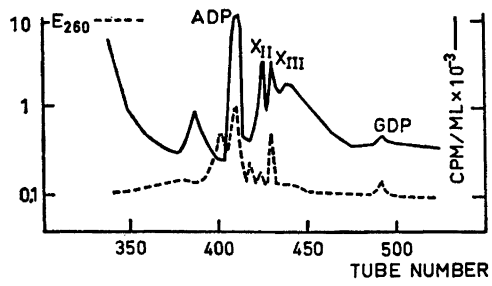

Fig. 1. Acid soluble nucleotides from 3.8 × 10^9 tetraploid tumor ascites cells. The nucleotides were separated on a 3 × 50 cm Dowex 1 formate column by gradient elution with reservoir content changed at the tubes numbered as follows: *72*, 1 N formic acid; *164*, 4 N formic acid; *390*, 0.2 M ammonium formate + 4 N formic acid; *510*, 0.4 M ammonium formate + 4 N formic acid. The continuous line represents radioactivity and the broken line represents optical density values at 260 mμ ($\bar{E}_{260}$).

microorganisms it was of interest to look for them in other animal cells. In connection with other experiments the TCA-extracts of ascites tumor cells were chromatographed in the usual way [3]. In Fig. 1 a section of an elution diagram is presented consisting of the peaks immediately before and after ADP. The tumor cells had been separated by counter-streaming centrifugation [6] (by prof. Lindahl) into mainly tetraploid (3.8 × 10^9) and octaploid cells (10.9 × 10^9) and incubated for 30 min. with ^{32}P in relation to cell numbers. The TCA extract in Fig. 1 was from the tetraploid cells. The TCA extract from the octaploid cells qualitatively gave a similar elution diagram. In view of the low UV-absorbtion values the X_{II} and X_{III} peaks from the tetraploid cells were taken together with the corresponding peaks from the octaploid cells. After charcoal-absorbtion and elution less than 0.5 mg material was obtained from each of the combined X_{II} and X_{III} peaks. No attempt was therefore made to separate the material on an electrophero-chromatogram. After acid hydrolysis all material was put on each of two papers for two dimensional paper chromatography. Both papers showed stronger spots in positions corresponding to glycine, serine, glutamic acid and aspartic acid. Weaker spots were obtained in the positions of leucine or *iso*leucine, lysine, arginine and threonine. At least four more unidentified spots were also observed on both papers.

Preliminary estimations of the specific activity calculated as counts per minute per μmole of nucleotide compound gave the following values:

	X_{II}	X_{III}
Tetraploid	40 × 10^5	8.9 × 10^5
Octaploid	11 × 10^5	3.0 × 10^5

The figures are of interest since the tetraploid cells are the more rapidly dividing of the two cell types [7] and nucleotide linked peptides in microorganisms have been claimed as precursors in the formation of cell wall proteins [8].

The investigation was supported by grants from the *Swedish Cancer Society*.

The Phase Diagram of the System $SrCl_2$—$BaCl_2$

A. SCHEI and H. FLOOD

Royal Norwegian Council for Scientific and Industrial Research, Institute of Silicate Science, Technical University of Norway, Trondheim, Norway

The liquidus curve of the system $SrCl_2$ – $BaCl_2$ was determined by thermal analysis and by high-temperature filtration, the solidus by a tracer technique previously described.[3] The system shows complete miscibility in both liquid and solid phases, with a freezing point minimum of 852.0°C at about 68 mole percent $SrCl_2$.

Assuming ideal behaviour of the liquid mixtures, and positive deviations with symmetrical activity coefficients of the type $RT \ln \gamma_A = b N_B^2$ for the solid mixtures, it is shown that with a value of $b \simeq 1$ kcal, a phase diagram can be calculated which gives fairly good agreement with the experimental values.

The binary system $SrCl_2$—$BaCl_2$ was investigated about 45 years ago by Vortisch[1], who also quotes the results of previous workers. More recently, Bergman and Bukhalova[2] checked the earlier results by means of a thermal visual method. According to Vortisch, the system shows complete miscibility in both liquid and solid phases. Our own investigation was aimed particularly at a more precise determination of the solidus curve.

RESULTS AND DISCUSSION

The results are given in Table 1 and in Fig. 1. A comparison between the present and earlier results is given in Table 2. The diagram (Fig. 1) is quite similar to that of Vortisch [1], although in his work, the solidus was largely estimated.

At the strontium chloride side of the diagram, the difference between the solidus and liquidus curves proved to be very small, so small in fact, that the separation of the two curves could not be effected by the present method.

The shape of the phase diagram indicates that the tendency towards forming a solution is weaker in the solid than in the liquid state. Hence the solid solutions will show more positive (or less negative) deviations from ideality than the liquid solutions. The scanty information available regarding the mixing behaviour of molten salt mixtures of the type AX_2 — BX_2 indicates that the deviations from ideality are generally smaller here than in the corre-

sponding mixtures of the type A'X — B'X. From the phase diagram $CaCl_2$ — $FeCl_2$ it can be concluded that the liquid mixtures in this system show very nearly ideal behaviour.[5] It seems reasonable as a first approximation to assume ideal behaviour for the liquid $BaCl_2$ — $SrCl_2$ mixtures, and interpret the minimum of the liquidus curve as due to positive deviations from ideality in the solid solutions. It is then of interest to see whether the phase diagram can be interpreted by applying simple symmetrical expressions for the activity coefficients of the solid solutions.

A frequently applied set of expressions for the activity coefficients is

$$\begin{aligned} RT \ln \gamma_A &= b\ N_B^2 \\ RT \ln \gamma_B &= b\ N_A^2 \end{aligned} \qquad (1)$$

where γ is the activity coefficient, N the mole fraction and b is a constant. If the entropy of mixing is ideal (*i. e.*, the Sr^{++} and Ba^{++} ions are distributed at random over the cation positions, and the change in vibrational entropy

upon mixing is zero), then b is equal to the partial molar heat of solution of one component in the pure second component.

The equilibrium between solid and liquid phases may be expressed by the well-known equation (valid for both components)

$$\ln a_l - \ln a_s = \frac{\Delta H_m}{R}\left(\frac{1}{T_m} - \frac{1}{T}\right) \quad (2)$$

where the a's are the activities, ΔH_m is the heat of melting, assumed to be independent of temperature (Δc_p for the melting process is neglected) and T_m is the melting point of the pure component. Assuming ideal behaviour of the liquid, eqns. (1) and (2) are combined to give

$$RT \ln N_l/N_s = \Delta H_m\left(\frac{T}{T_m} - 1\right) + b\,(1 - N_s)^2 \quad (3)$$

which is also valid for both components. The heats of melting for $SrCl_2$ and $BaCl_2$ are taken as 4.1 and 5.4 kcal/mole, respectively, as estimated by Kelley[6] from phase diagrams.

The experimental data do not fit this equation too well, since the best-fit value of b differs for the two sides of the diagram; a value of about 1.2 kcal is found for the $SrCl_2$ side, 0.6 kcal for the $BaCl_2$. The uncertainty in these b-values is rather large, however, and application of the symmetrical equation (3) with a value of $b = 1.0$ kcal may be equally reasonable. Fig. 2 shows that this gives a phase diagram quite similar to the experimental (minimum at 847°C and 71 mole percent $SrCl_2$). The differences between calculated and

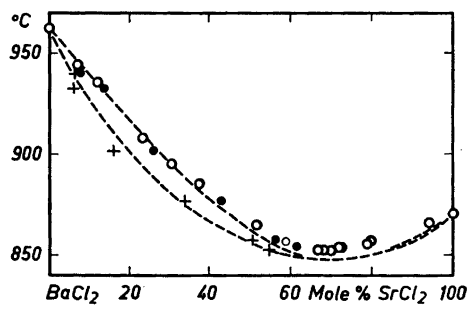

Fig. 2. The system $SrCl_2$ — $BaCl_2$. Dashed lines calculated (see text). Experimental points, same as in Fig. 1, shown for comparison.

experimental values seems not to be outside the possible errors caused by the approximations involved in eqn. (2) and by the probably inaccurate values for the heats of fusion.

EXPERIMENTAL

The liquidus of the system was determined by ordinary thermal analysis. A Pt/90 Pt 10 Rh thermocouple, with the bare leads dipping into the molten salt, was used for temperature measurement. The thermocouple was checked against the melting point of pure NaCl (800.4°C).

The solidus was determined by a method developed by Seltveit and Flood[3]. The principle is as follows: To a mixture of known composition within the system is added a small amount (*e.g.*, 0.05 %) of a radioactive third component which is soluble in the liquid, but insoluble in the solid phase of the system. The mixture is heated to complete fusion and the specific activity of this liquid is determined. Next, the mixture is cooled to a temperature where liquid and solid phases are coexistent, and kept at this temperature until equilibrium is established (usually overnight). A small sample of the liquid is then filtered off and its composition determined by chemical analysis. This analytical composition serves as a check on the liquidus obtained from thermal analysis. On another sample of the liquid, the specific activity is determined. From the increase in tracer content per gram of liquid (as compared to the content when the whole system was fused) the weight-ratio of liquid to solid can be determined, and thus the solidus.

The chemicals used were $BaCl_2$ *p.a.* and $SrCl_2$ *puriss. cryst.* (both from Merck A.G.) dried at 150°C. As tracer component was used $CsCl_2$ with a content of ^{134}Cs (half life 2.3 years) obtained from JENER, Lilleström, Norway. The assumption that the Cs^+ ion cannot enter the solid solutions of $SrCl_2$ — $BaCl_2$ was not proved by experiment. But it is known from previous work[3] that NaCl does not enter into solid solution in the $CaCl_2$ lattice, and the radius ratio r_{Cs+}/r_{Ba++} is more unfavourable than the ratio r_{Na+}/r_{Ca++} with respect to solid solution formation.

The salt mixtures were analyzed by conventional methods[4]. Barium was precipitated by an excess of potassium dichromate, and after filtration the excess of chromate was titrated with sodium thiosulphate. Strontium was taken as difference. As an extra check, the chloride content was determined by titration with silver nitrate, using chromate as indicator (after removal of barium by sulphate addition). The tracer activity was determined by an EKCO Scintillation Counter N 550.

The Binding of the "Structural" Zinc Ions in Crystalline Insulin

K. MARCKER

Universitetets Fysisk-kemiske Institut, Copenhagen, Denmark

The site of binding of zinc in crystalline insulin has been investigated by determinations of the molecular weight of insulin which has been substituted on the N-terminal amino groups by phenyl-*iso*cyanate and of insulin in which all carboxyl groups have been methylated. It is shown that the N-terminal amino groups are essential for the zinc-binding capacity of insulin whereas the carboxyl groups are without importance as regards the binding of zinc to insulin. In conclusion it is made probable that the zinc is attached to the N-terminal amino group of phenylalanine.

It has long been known that insulin can only be crystallized in combination with a trace of zinc ions. The minimum amount of zinc ions sufficient for crystallization, *i.e.* the amount of zinc ions which belong to the crystal structure as an integral part was originally believed to be three atoms of zinc per unit cell. By repeated crystallization Schlichtkrull [2], however, demonstrated that the minimum amount of zinc sufficient for crystallization was only two atoms per unit cell. This result is in accordance with the work of Cunningham *et al.*[3] who studied the zinc-insulin system by the equilibrium dialysis technique at pH 7.3—7.6 in barbiturate-acetate buffer. These investigations demonstrated that 0.6—0.8 gram atom zinc per 12 000 g of insulin were bound so tightly to insulin that they could not be dialyzed away. This amount of zinc corresponds very closely to the two atoms of zinc per unit cell which were found by Schlichtkrull to have a structural significance in the crystal structure of insulin. The site of binding of these two zinc ions has been investigated by Tanford and Epstein [4], who obtained the hydrogen ion titration curves of zinc-free insulin and crystalline zinc-insulin. The crystalline insulin used was claimed to contain three atoms of zinc per unit cell. By comparison of the two titration curves obtained and by calculations in which the three zinc atoms were treated alike as being identically bound to insulin the authors concluded that each zinc atom is bound to two imidazole groups. To the author this conclusion seems not the only possible one. The titration data of Tanford and Epstein does not exclude the possibility of the participation of α-amino groups in the binding of zinc to insulin as also pointed out by Gurd and Wilcox [5]. As mentioned Tanford and Epstein in their calculations treated the zinc atoms as

being bound to identical sites. In view of the findings of Schlichtkrull and Cunningham *et al.* it remains questionable if this assumption is correct. It would seem that one of the three atoms of zinc is bound by a weaker force than the other two.

In a previous publication [6] a difference in the behaviour of zinc-free insulin from that of crystalline zinc-insulin was demonstrated. It was shown that in the entire pH range investigated, pH 2.10—9.10, zinc-free insulin is inhomogeneous with respect to molecular weight, which depended upon pH and insulin concentration of the solution. This is in contrast to crystalline zinc-insulin which at neutral and basic pH is monodisperse in solution having a molecular weight of 36 000. It is therefore possible to obtain information about the site of binding of zinc to insulin by using zinc-free substituted insulin and measure the molecular weights by means of osmometry with and without the addition of the calculated amount of zinc sufficient for crystallization (2 atoms per unit cell).

The determinations of the molecular weights were performed as described in a previous publication [6]. In this investigation two substituted insulins * were used: One being substituted by phenyl*iso*cyanate, and one in which the carboxyl groups have been esterified by methanol. The insulin substituted by phenyl*iso*cyanate (*Iso*insulin) was prepared according to Hallas-Møller [7]. In this procedure two groups are substituted. By chromatography according to the method of Andersen [8] it was shown that the groups substituted were the N-terminal amino groups of phenylalanine and glycine. Phenylhydantoins of glycine and phenylalanine which were prepared by the method of Mouneyrat [9], were used as standards.

The methylinsulin was prepared by the method of Mommaerts and Neurath [10]. The methylinsulin was shown to be biologically inactive. Its methoxyl content was determined at 3.27 % (theoretical 3.05 %). It can therefore be concluded that all six available carboxyl groups have been esterified. Both the *iso*insulin and the methylinsulin were prepared free of zinc.

The determinations of the molecular weights of the substituted insulins with and without zinc were first performed at neutral pH. On account of the solubility properties of *iso*insulin, methylinsulin, and crystalline zinc-insulin it is unfortunately impossible to measure all three insulins at the same pH. Therefore the methylinsulin was measured at pH 6.7 and *iso*insulin and crystalline zinc-insulin at pH 7.4. The buffer used was barbiturate-acetate adjusted to an ionic strength of 0.06. The results of these measurements are recorded in Fig. 1. The curves I and II represent the results obtained with zinc-free *iso*insulin and methylinsulin. It is seen that the shape of these curves in identical with that obtained for zinc-free insulin which was recorded in a previous publication [6]. By addition of the calculated amount of zinc (the zinc was added as the chloride) however, the curve representing the results obtained for zinc-free methylinsulin is transformed into curve III, which represents a monodisperse compound having a molecular weight of 36×10^3. By addition of the calculated amount of zinc to *iso*insulin it is seen that no effect could be demonstrated thus indicating that *iso*insulin is unable to bind zinc whereas the opposite is true of methylinsulin. Crystalline zinc-insulin containing two zinc atoms per unit cell is used as reference. The results obtained with this sample

* The substituted insulin was kindly prepared by "Novo Terapeutisk Laboratorium".

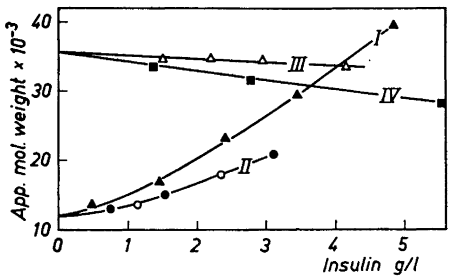

Fig. 1. Molecular weight determinations on *iso*insulin, methylinsulin and crystalline zinc-insulin. Ordinate: Apparent molecular weight; Abscissa: Concentration in g/l. All measurements performed in barbiturate-acetate buffer. I = 0.06 and temperature 20°C.

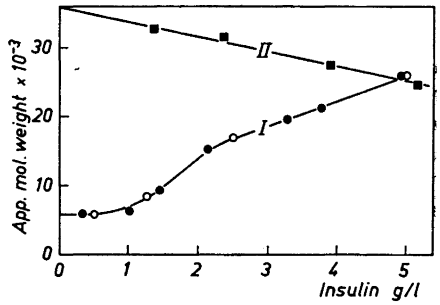

Fig. 2. Molecular weight determinations on *iso*insulin and crystalline zinc-insulin. I: *Iso*insulin, ● without Zn^{++}, ○ with Zn^{++}; II: Crystalline zinc-insulin. All measurements performed in barbiturate buffer. pH = 8.6, I = 0.2 and temperature 20°C.

are represented by curve IV, which indicates a monodisperse compound with a molecular weight of 36 × 10^3. The difference in the slopes of curve III and IV may be due to the difference in charges on methylinsulin and crystalline zinc-insulin.

In order to examine the behaviour of *iso*insulin more closely measurements were performed at pH = 8.6 in barbiturate buffer adjusted to the ionic strength 0.2 by addition of KCl. Crystalline zinc-insulin containing two zinc atoms per unit cell was again used as reference. The results are recorded in Fig. 2. It is clearly demonstrated that addition of the calculated amount of zinc has no effect on the behaviour of *iso*insulin.

From the experiments reported here one can safely conclude that the N-terminal amino groups of insulin are essential for the zinc-binding capacity of insulin, whereas the carboxyl groups seem to be without importance with respect to the binding of zinc to insulin. In insulin, however, there are two N-terminal amino groups, one from glycine and one from phenylalanine and the question still to be solved is the problem whether the zinc is bound to both amino groups or only to one of them. Support for the latter view comes from the experiments performed by Christensen [11] and especially from the work of Andersen [8]. Using the Edman procedure Christensen demonstrated that the N-terminal amino group of phenylalanine in crystalline zinc-insulin reacted to a much lesser extent than did the N-terminal amino group of glycine. By substitution of crystalline zinc-insulin with phenyl*iso*cyanate Andersen demonstrated that the first group to be substituted by this reagent was the N-terminal amino group of glycine. The N-terminal amino group of phenylalanine reacted more sluggishly with a considerably lower reaction rate. By column chromatography Andersen was able to separate two reaction products;

a mono-derivative which was substituted at the N-terminal amino group of glycine and a di-derivative which was substituted at both the available N-terminal amino groups. By sedimentation experiments performed with crystalline zinc-insulin and the mono- and di-derivatives of the substituted insulin Andersen [12] showed that crystalline zinc-insulin and the mono-derivative behaved identically in the ultracentrifuge as monodisperse compounds having a molecular weight of 36×10^3. The behaviour of the di-derivative in the ultracentrifuge was quite different from the behaviour of crystalline zinc-insulin and the mono-derivative. The di-derivative showed an inhomogeneous pattern and, under the experimental circumstances chosen, had a higher molecular weight than the crystalline zinc-insulin. This result is in complete agreement with the osmotic pressure data recorded here. Andersen interpreted his results in terms of interaction of non-polar groups, but in view of the findings herein presented a much more plausible explanation is possible. The explanation simply implies that the "structural" zinc is attached to the N-terminal amino group of phenylalanine. By assuming this it is readily understandable that the N-terminal amino group of glycine is the first to be substituted. Furthermore it is to be expected that substitution of this amino group will have no influence on the structure of the zinc-insulin complex, *i.e.* the substituted insulin should be monodisperse having a molecular weight of 36×10^3 in complete agreement with the findings of Andersen. By substitution also on the N-terminal amino group of phenylalanine, however, the structure of the insulin would be expected to deteriorate, since zinc is essential for the structure of the hexamer unit (mol.wt. 36×10^3). The behaviour of the di-substituted insulin should therefore be identical with the behaviour of zinc-free insulin in being polydisperse and having a molecular weight depending upon the insulin concentration and pH of the solution. This prediction is in complete accordance with the results obtained in this investigation and with the results obtained by Andersen. The above mentioned experiments therefore strongly support the view that in crystalline zinc-insulin the "structural" zinc is attached to the N-terminal amino group of phenylalanine.

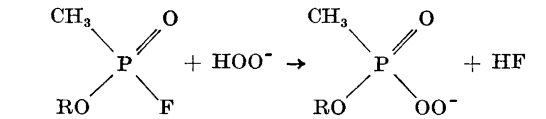
The Reaction between *Iso*propoxy-methyl-phosphoryl Fluoride and Hydrogen Peroxide

GUNNAR AKSNES*

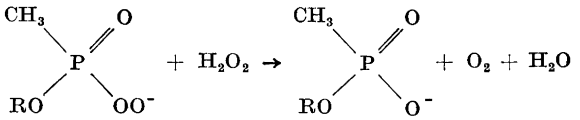
Norwegian Defence Research Establishment, Toxicological Group, Kjeller pr Lillestrøm, Norway

The reaction between *iso*propoxy-methyl-phosphoryl fluoride and hydrogen peroxide has been studied by measuring the amount of oxygen evolved during the reaction.
The mechanism of the decomposition reaction is discussed.

The bimolecular reaction between *iso*propoxy-methyl-phosphoryl fluoride and hydrogen peroxide has been studied by Larsson [1] by means of an automatic titration method. He concludes that the rate of the bimolecular reaction is proportional to the concentration of the anion of hydrogen peroxide. Gehauf *et al.*[2], Epstein *et al.*[3] and Larsson [1] suggest that the decomposition of the intermediately formed peroxyphosphorus acid is due to a bimolecular reaction of this acid with hydrogen peroxide. This last step is believed to be rate determining:



(1)



(2)

The kinetic of the second step of the above reactions has been the main interest of the present work. For this reason a volumetric method of measuring the oxygen evolution during the reaction has been developed.

* Present address: Chemical Institute, University of Bergen, Bergen, Norway.

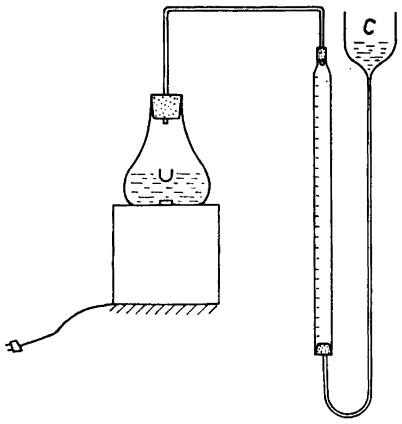


Fig. 1. Apparatus used for determination of the rate of oxygen evolution.

EXPERIMENTAL

*Materials. Iso*propoxy-methyl-phosphoryl fluoride was synthesized in this institute. Hydrogen peroxide was an E. Merck anal. reagent. The concentration of the hydrogen peroxide solutions was determined by titration with 0.1 N solution of potassium permanganate.

Kinetic measurements. The apparatus used for the study of the oxygen evolution is shown in Fig. 1. The oxygen is collected in a burette of 50 ml capacity connected by a glass tube to the reaction vessel. The reaction vessel consisted of a 100 ml Erlenmeyer flask. Fifty ml of hydrogen peroxide solution containing 0.2 M buffer was placed in the reaction vessel. The weighed sample of the fluorophosphorus compound was placed in a small conical glass vessel. The vessel was brought into the Erlenmeyer flask and placed on the surface of the hydrogen peroxide solution in floating position. The reaction is started by tipping the content of the conical flask into the solution. This is simply obtained by starting the magnetic stirrer whereupon the reaction vessel was placed. The amount of oxygen evolved is found by lowering of the level of the water in the container

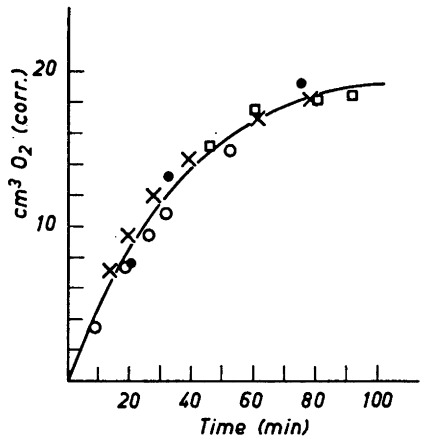

Fig. 2. The evolution of oxygen at different hydrogen peroxide concentration. Buffer 0.2 M citrate-phosphate, pH = 7.00. Temp. 18°C. Concentration of *iso*propoxy-methyl-phosphoryl fluoride: 0.0016 M. Hydrogen peroxide concentration: ×, 1.93 %; O, 2.98 %; ●, 3.94 %; □, 4.78 %.

C until the same level as the water in the burette. The water in the burette and the container is saturated with oxygen at room temperature. Correction was always made for the amount of oxygen evolved at the different pH studied due to the self-decomposition of the hydrogen peroxide solution. The self-decomposition was found to rise rapidly with increasing pH.

RESULTS

In Table 1 are recorded the experimental values of the oxygen evolution of two different concentrations of the fluorophosphorus compound when the hydrogen peroxide concentration is maintained constant. We find that the amount of oxygen evolved is proportional to the concentration of the fluorophosphorus compound.

In Fig. 2 are recorded the rates of oxygen evolution at four different concentrations of hydrogen peroxide. The concentration of the *iso*propoxy-methyl-

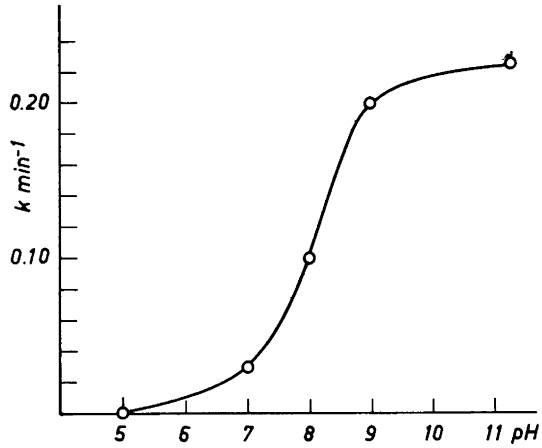

Fig. 3. The relation between the rate of oxygen evolution and pH of the solution. Buffers: 0.2 M citrate-phosphate (pH = 5, 7 and 8). 0.2 M boric acid-sodium hydroxide pH = 9. 0.2 M potassium dihydrogenphosphate-potassium hydroxide (pH = 11.3). Hydrogen peroxide concentration = 4 %.

phosphoryl fluoride is maintained constant. The full-drawn curve in Fig. 2 shows a first order reaction with a rate constant of 0.03 min^{-1}. The experimental points of the oxygen evolution at the four different hydrogen peroxide concentrations in Fig. 2 show average deviation of about 5 % from the first order reaction curve. This is within the limits of the experimental errors of the applied technique.

In Fig. 3 is plotted the rate constants of the oxygen evolution at five different pH (5, 7, 8, 9 and 11.3) as function of pH.

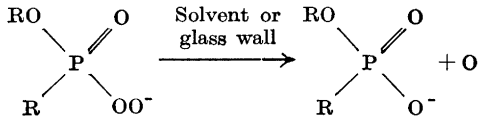
Some experiments were performed in order to determine the amount of hydrogen peroxide consumed when the decomposition reaction approached completion. When the initial concentration of hydrogen peroxide in the reaction solution varied between 0.010 M and 0.1 M the ratio between the hydrogen peroxide decomposed and the total concentration of fluorophosphorus compound varied between 1.5 and 1.9.

DISCUSSION

The first order rate of oxygen evolution which is observed under the conditions of the present experiments shows that the formation of the peroxyphosphorus acid according to eqn. (1) must be much more rapid than its decomposition, *i.e.* the decomposition of the peroxyphosphorus acid is the rate determining step. This observation is in agreement with the findings of Larsson [1]. From his calculated pseudo first order rate constant of the reaction between *iso*propoxy-methyl-phosphoryl fluoride and hydrogen peroxide at 25°C we may estimate that the pseudo first order reaction of the same step under the present conditions will be so rapid that the deviation of the second step from the first order reaction rate will not be observable.

The present results do not confirm the assumption of Gehauf *et al.*[2] and Epstein *et al.*[3] that the decomposition of the peroxyphosphorus acid is a true bimolecular reaction with hydrogen peroxide. If that had been so the ratio between the amount of hydrogen peroxide decomposed and the total concentration of fluorophosphorus compound should approach 2 at all concentrations of hydrogen peroxide. The present results and the observation of Larsson [1] are not in accordance with this reaction scheme. Another argument against this view is found in the results quoted in Fig. 2. The hydrogen peroxide in the four separate experiments is in sufficiently great excess as compared with the fluorophosphorus compound to give the postulated second order reaction between the peroxyphosphorus acid and hydrogen peroxide a pseudo first order character. The rate of oxygen evalution should therefore be expected to be proportional to the hydrogen peroxide concentration. On the contrary the results show nearly the same rate of oxygen evolution at the four different concentrations of hydrogen peroxide. It seems therefore reasonable to conclude that the hydrogen peroxide does not participate in the rate determining decomposition of the peroxyphosphorus acid. Larsson [1] has postulated a competing reaction between peroxyphosphorus acid and unreacted fluorophosphorus compound to explain the deviation of the second order kinetics of the decomposition of the peroxyphosphorus acid at low concentration of hydrogen peroxide. But it is difficult to explain the results quoted in Fig. 2

according to such a hypothesis. A more reasonable explanation seems therefore to be that the decomposition of the peroxyphosphorus acid is a rate-determining unimolecular reaction (perhaps influenced by the solvent or the glass wall) and that the oxidation of the hydrogen peroxide is a rapid process between "active oxygen" and hydrogen peroxide. The decreasing consumption of hydrogen peroxide with decreasing hydrogen peroxide concentration can then be explained to be due to a competing pairing formation of "active oxygen" to molecular oxygen:



(1)

$$O + H_2O_2 \rightarrow O_2 + H_2O \text{ and } O + O \rightarrow O_2 \quad (2)$$

A support for this view may be found from different sources concerning the decomposition of peroxide compounds [6].

The S-shaped relation between the decomposition of the peroxyphosphorus acid and the pH of the solution suggest that the decomposition proceeds *via* the anion of the peroxy acid and that the pK of this acid may have a value of approximately 8. Everett *et al.*[4] have found that the pK values of peroxy fatty acids lie in the range of pK 7.1—8.3. By analogy to the difference between the pK values of fatty acids and substitued phosphorus acids (the last-mentioned are 2—3 pH-units lower) Larsson [1] assumes that the difference between the pK of the corresponding peroxyacids is of the same order of magnitude. This need not necessary be so because the stabilization effect due to the perfect resonance of the anions of the oxyacids do not exist in the peroxyacids. It seems therefore doubtful that the inductive mechanism which must be assumed to be the chief electronic effect operating in the peroxyacids is able to maintain the same difference between pK-values of different peroxyacids as between corresponding oxyacids This argument is strengthened by the observation of Everett *et al.*[4] that the differences in the inductive effects between H, CH_3, C_2H_5, *iso*-C_3H_7 which are clearly reflected in the differences between the pK-values of water and alcohols are almost absent in the same serie of hydroperoxides. It is also some reason to question the accuracy of the titrimetric method used by Everett *et al.*[4] for determination of the pK-values of peroxyacids. This method may be encumbered with error due to the instability of the peroxyacids. This decomposition which produces the corresponding oxyacids increases rapidly with the rise of pH and will give as result that the observed pK-value of the peroxyacid will lie below the actual one. The error will increase with increasing rate of decomposition and increasing length of time used to obtain the titration curve. In Holleman-Richters' textbook of organic chemistry [5] the dissociation constant of peroxyacetic acid is quoted as 4×10^{-10} (pK = 9.4). Unfortunately the authors give no reference to the original work from which this value is taken. It seems also worth while to mention that the pK of the bisulphate ion and its corresponding peroxyacid are 1.7 and 9.4, respectively [7].

Oxidation of 3-Hydroxy-Anthranilic Acid by Human Serum

GÖSTA EHRENSVÄRD*, JAN LILJEKVIST**, and ROBERT G. HEATH***

Institute of Biochemistry, University of Lund, Lund, Sweden, and Department of Psychiatry and Neurology, Tulane University School of Medicine, New Orleans, Louisiana, U.S.A.

The oxidation of 3-hydroxy-anthranilic acid by human serum has been investigated by fluorimetric techniques. The influence of some activators and inhibitors has been studied. By examination of approximately one hundred samples of sera from various origins, it has been found that the partial inhibition by cyanide is subject to a considerable variation. In sera from schizophrenic subjects the cyanide inhibition in per cent of total oxidation ranges from 0 to 6 %; in some cases there is a slight activation. In normal controls the corresponding range is from 6 to 20 %. The overlapping between the groups is about 15 %.

In the plethora of reactions involved in tryptophan metabolism 3-hydroxy-anthranilic acid (HOA) keeps a position as an intermediary metabolite. Its formation through enzymatic cleavage of 3-hydroxy-kynurenine has been demonstrated in a variety of organisms [1–4]. In man the main route for disposal of 3-hydroxykynurenine seems to involve its transformation *via* oxidative desamination and ringclosure to xanthurenic acid and derivatives of this compound [5]. Since, however, a minor fraction of tryptophan metabolized in man is providing part of his nicotinic acid supply [6,7], and this reaction in mammals has been demonstrated to involve an oxidative splitting and rearrangement of HOA [3–10] the existence of the latter compound in human organism is indirectly indicated. The demonstration by Wiss [3] of the presence of kynureninase in pig liver, catalyzing the conversion of 3-hydroxy-kynurenine to HOA, gives additional, although indirect, support to the assumption of HOA partaking in human metabolism as an intermediate. Another indication is the recent finding of conjugated derivatives of HOA in human urine [11,12].

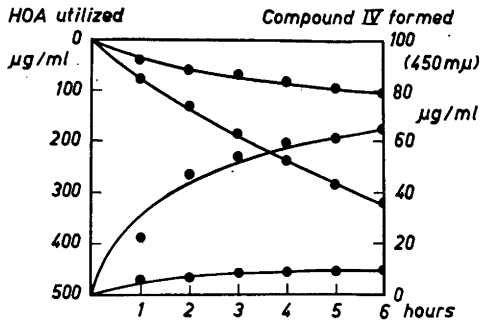

Fig. 1. Diagram of HOA-oxidation by human serum and the corresponding formation of compounds absorbing at 450 mµ. Figures in µg per ml of reaction mixture.

In view of the marked tendency of HOA to form a variety of oxidation products under various conditions, as shown by Butenandt *et al.*[13], it should be expected that a small fraction of HOA in circulation should give rise to similar products, related to phenyl-quinoneimides and phenoxazines. An indication of this is a finding that rat liver homogenate forms from HOA a red pigment, possibly related to the phenoxazines of Butenandt [14]. The present work is an investigation of the oxidation of HOA by human serum under different conditions.

As a preliminary experiment 2 ml of serum were incubated at 30°C with 2 ml of a 0.1 % solution of HOA in 0.02 M tris-buffer. At intervals 25 µl samples were taken and analyzed for HOA and compounds absorbing at 450 mµ; see Fig. 1. The result showed a rapid disappearance of HOA and a steady, but not stoichiometric rise of compounds absorbing at 450 mµ. The similar situation, but at a slower rate appears in a parallel run without serum; *i.e.* the result of pure autoxidation. Examination by paper chromatography of the formed reaction products showed the same distribution of spots, coloured and fluorescent in UV, for both runs, the solvent being butanol-propanol-water (1:2:1). The R_F-values and the colours of some of the spots indicate identity with Butenandt's "compounds III and IV" [14].

In order to elucidate some aspects of the serum factors involved in HOA-oxidation, a series of experiments with various inhibitors were performed. The results indicate that only a part of the total oxidation was sensitive to inhibitors, and thus could represent an enzymatic mechanism. In view of the fact that metal ions in combination with serum proteins could bring about a nonspecific oxidation of a variety of substances (for a general review of this subject see Ref.[15]) the influence of some metal ions upon the HOA-oxidation was studied with and without the presence of human serum. As a further development a comparative study of the HOA-oxidation in human serum from various sources was performed, with special reference to subjects with clinical symptoms of schizophrenia, and with normal healthy subjects as controls.

EXPERIMENTAL

For the determination of the rate of HOA-oxidation under various conditions the following procedure was used: To a series of 10 ml Erlenmeyer flasks 2 ml of serum, or 2 ml of a 0.9 % NaCl-solution, was added, followed by additional solutions of various activators and/or inhibitors in 100 μl quantities. (Corrections for these minor additions were made when necessary in order to keep the volumes constant.) When cyanide was used as inhibitor, the solution (0.4 M) was neutralized with HCl against phenol red. Thereafter 2 ml of a 0.1 % HOA-solution in 0.02 M tris-buffer, pH 7.5, were added and the flasks incubated at 30°C under gentle shaking. (Dubnoff Metabolic Shaking Incubator). At intervals, 25 μl samples were withdrawn and diluted with 2 ml of a 0.9 % NaCl-solution. These diluted samples were analyzed in an Aminco-Bowman Spectrophotofluorimeter, for their HOA-content; activation maximum 330 mμ fluorescence wave-length 415 mμ. The instrument was calibrated within the range used by a series of HOA-solutions of known concentrations with the same amount of serum added from a mixture of 2 ml of HOA-solution and 2 ml of serum, 25 μl were taken and diluted as above with 2 ml of saline solution.

The human sera were usually prepared from bloodsamples drawn in the early morning, before eating. They were immediately stored at + 2°C, and, as a rule, analyzed the same day. The schizophrenic patients providing the serum for this study were hospitalized on a special Tulane University research unit at the East Louisiana State Hospital at Jackson. These patients were under intensive observation on the unit for a minimum period of 3 years. Agreement on the diagnosis of schizophrenia had been reached by a minimum of 4 psychiatrists and 2 clinical psychologists. The various clinical subcategories of schizophrenia were represented almost equally, *i.e.*, catatonia, paranoia, hebephrenia, and chronic undifferentiated schizophrenia. All patients selected for these special wards were required to meet exacting clinical and laboratory criteria. They had been hospitalized for a minimum of 3 years without clinical remission. They were under 45 years of age

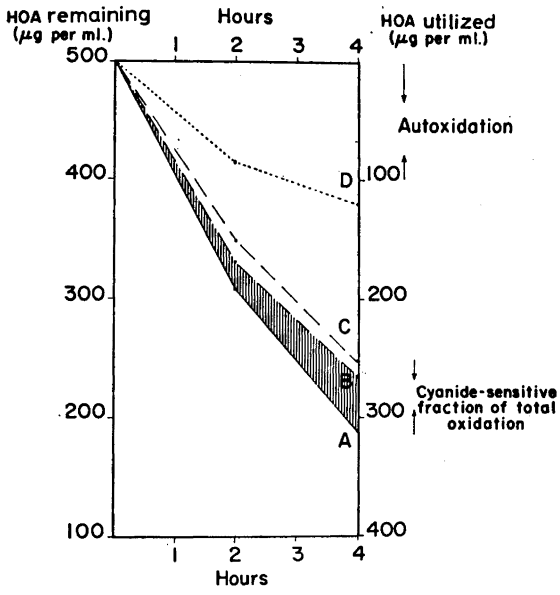

Fig. 2. Diagram of HOA-oxidation by human serum during 4-hour period, curve A. The curves B and C represent the rate of oxidation in the presence of 0.01 M NaCN, and 0.001 M NaN_3. The shaded region between curves A and B represents the cyanide-sensitive fraction of total oxidation. Curve D shows the oxidation rate without serum.

Table 1. Influence of Cu^{2+} and Mn^{2+} in a concentration of 0.0001 M upon the oxidation of HOA in the presence of human serum and without, 4 hours incubation at 30°C. Figures denote μg HOA consumed per ml of incubation mixture. Starting concentration 500 μg per ml.

	Without serum			With serum		
	0	Cu^{2+}	Mn^{2+}	0	Cu^{2+}	Mn^{2+}
+ 0.01 M NaCN	50	145	405	280	310	437
0	30	195	170	315	328	472
Difference:	+ 20	−50	+ 235	−35	−18	−35

completely negative on physical and neurological examinations and on a large number of routine laboratory tests, including a battery of liver tests. The minimal educational level for the group was 9th grade. A special diet was provided for the patients on these wards which included extra rations of meat and daily vitamin supplements.

The normal control group was composed of staff and faculty of the Tulane Department of Psychiatry and Neurology and carefully selected medical students. Each student was screened by a minimum of 2 members of the team of research psychiatrists after having been observed for a minimum of 3 weeks while on the psychiatric teaching block of the curriculum. All normal controls were required to have a negative family history for nervous and mental disease.

RESULTS

A comparison between the rate of HOA-oxidation by human serum and plain autoxidation gives an approximate ratio of 2:1 for a 2-hour period, and 2.5:1 for a 4-hour period; see Fig. 2. The influence of inhibitors is shown in curve B and C, depicting the oxidation rate in the presence of 0.01 M NaCN and 0.001 M NaN_3. As seen the inhibition is not very great, 15 % at the most for a 4-hour run. However, this percentage represents most likely the part of the total oxidation, which is connected with an enzymatic mechanism; the rest being a non-specific oxidation brought about by metal-protein complexes. For simplicity in the following, we will use the category type I- and type II-oxidations, of which type II represents the cyanide-azide-sensitive fraction.

In order to evaluate the influence of metal ions upon HOA-oxidation of type I and type II, experiments were carried out under the same standard conditions, with and without the presence of various metal ions at a total concentration of 0.0001 M. The result is shown in Table 1.

This experiment demonstrates the relative activating influence of copper and manganese ions upon the HOA-oxidation, whereby manganese exerts a stronger influence than copper. The activating effect of the manganese is especially marked in the presence of cyanide, without serum. In the presence of serum, the activating effect of manganese is not further enhanced by cyanide. Probably the effect of Mn^{2+} in the concentration used, both upon cyanide, 0.01 M, and serum, has a common denominator, namely a tendency to formation of a complex which would function as a HOA-"pseudo"-oxidase.

Table 2. Influence of Cu^{2+} and Mn^{2+} in a concentration of 0.0001 M upon the oxidation of HOA in the presence of coeruloplasmin, 300 μg per ml, 3 hours incubation at 30°C. Figures denote μg HOA consumed per ml of incubation mixture. Starting value 500 μg per ml.

	Without Coeruloplasmin		With Coeruloplasmin		
	Cu^{2+}	Mn^{2+}	0	Cu^{2+}	Mn^{2+}
+ 0.01 M NaCN	75	340	66	120	315
0	130	90	45	330	210
Difference:	−55	+ 250	+ 21	−210	+105

As both Cu^{2+} and Mn^{2+} are normal serum constituents, the former to some extent or possibly totally, protein bond as coeruloplasmin [16], it was appropriate to investigate the oxidation of HOA by this metal-protein alone, and in the presence of cyanide, with and without the addition of free Cu^{2+} and Mn^{2+} ions. For comparison, a similar set of experiments was carried out with the copper-containing enzyme ascorbic acid oxidase (AAO), isolated by Dawson [17]. The results of these two experiments are shown in Tables 2 and 3.*

As seen, the pattern of activation and inhibition of coeruloplasmin compared to AAO differs so far as AAO is a quite effective oxidase for HOA, whereas coeruloplasmin (CP) is a very sluggish enzyme against this substrate. With regard to inhibition AAO is almost completely inhibited by cyanide, in contrast to CP. The two Cu^{2+} enzymes differ also with regard to the activation. CP is strongly activated by Cu^{2+}, and to a less extent by Mn^{2+}, whereas the activity of AAO on the whole is not enhanced by Cu^{2+}, but is activated to some extent by Mn^{2+}. The intricate interplay between inhibition and activation is illustrated for instance in the case of AAO, where cyanide apparently does not

Table 3. Influence of Cu^{2+} and Mn^{2+} in a concentration of 0.0001 M upon the oxidation of HOA in the presence of ascorbic acid oxidase (AAO), 5 units per ml, 3 hours incubation at 30°C. Figures denote μg HOA consumed per ml of incubation mixture. Starting value 500 μg per ml.

inhibit the Mn^{2+}-activated enzyme. Yet the explanation could be that the cyanide inhibition of AAO (difference −225) is in this case counteracted by a pure cyanide-activation of Mn^{2+} as such (difference + 272). With regard to CP, it is evident that Cu^{2+} and, to a less extent Mn^{2+}, evoke a HOA-oxidase activity in this copper-protein complex, which may have a bearing to the HOA-oxidase activity in serum, of the cyanide sensitive type II.

DISCUSSION

As a tentative hypothesis we suggest that in human serum the cyanide sensitive part of HOA-oxidation — type II — is brought about by some combination of metal ions and some special proteins. Cu^{2+} and Mn^{2+} have been shown to exert an activating influence upon coeruloplasmin, in itself a copper-protein complex, still it is possible that another complex of similar kind, not implicating coeruloplasmin, could be involved in the HOA-oxidation, type II.

With regard to the absolute rate of HOA-oxidation in sera from various human subjects, it has been found that this rate varies from case to case. Examining the material from approximately one hundred HOA-oxidation tests, we found that on the whole the rate of oxidation is lower for sera from subjects with chronic schizophrenia as compared to sera from the groups of normal, healthy subjects. As seen from Table 4, the differences in oxidation rate between schizophrenics and normals is partly eliminated when cyanide or azide is added to the reaction.

Expressing the cyanide effect, Δ %, as $\frac{a-b}{a} \times 100$, where a is the total HOA consumed during a 4-hour period, and b is the corresponding amount of HOA consumed in the presence of cyanide, we find that the value for schizophrenics is encountered in the lower range −2→6, and the normal controls in the higher range 6→20; see Fig. 3.

These findings indicate that in serum from schizophrenics, the type II-oxidation of HOA constitutes a smaller fraction of the total HOA-oxidation, as compared with serum from the control group. In about 20 % of the schizophrenics type II-oxidation is virtually absent.

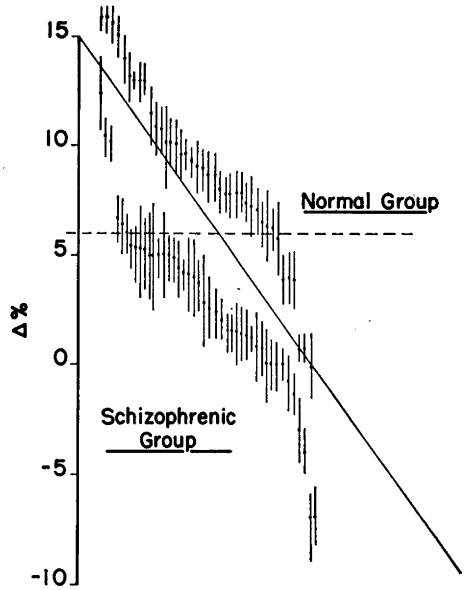

Fig. 3. Diagrammatic representation of Δ %-values for the cyanide effect on HOA-oxidation by serum from schizophrenic subjects as compared with the corresponding values for normal controls. Standard variations of individual test-runs are shown as verticals lines. Overlapping of the two groups less than 15 %. The division line at value 6 is arbitrarily taken as a boundary between the two groups.

Being aware of the fact that the rate of oxidation of various substrates by human serum could be influenced by various external factors, as well as internal, we have, whenever possible, tried to sample the sera examined from subjects on the same diet. With regard to different levels of ascorbic acid in sera, which previously has been shown to influence the rate of other oxidation reactions [18], we find that addition of 50 μg per ml serum before running a HOA test did not influence either the reaction rate or the cyanide effect. With regard to the general concept of diurnal variations under fasting and non-fasting conditions the results of a test series from two schizophrenics show slight variations in the Δ % values, the range being for one subject 1.4→1.6, for the other —4.8 → 2.3 (samples taken at 07.30 and 19.30). As comparison, two normal controls were tested in the same way, one showing the range 7.9→4.9, the other 15.0→3.8, thus considerable variation during the day. It should, however, be emphasized that the delta values recorded in Fig. 3 are all derived from morning samples of sera in order to eliminate diurnal variations. These data demonstrate a convincing difference between the two groups, the overlapping being less than 15 %. The question of the diurnal variations in normals, as well as the general problems of the relationship of the HOA oxidation to the clinical syndrome of schizophrenia, will be subject of continuing investigation.

Dehydrogenation of Phenols

II. Dehydrogenation Polymers from Guaiacol

BENGT O. LINDGREN

Wood Chemistry Department, Swedish Forest Products Research Laboratory, Stockholm Ö, Sweden

The dehydrogenation polymers which are obtained from guaiacol by treatment with silver oxide, potassium ferricyanide, sodium persulphate and an oxygen-laccase system have been examined. The first two reagents gave polymers in which the phenol units were linked together with ether bonds (Formula II) while the other two reagents produced polymers with carbon-carbon bonds (Formulae III and IV).

It was shown in an earlier paper [1] that 2,6-dimethylphenol on dehydrogenation with silver oxide is transformed mainly into a polymer * with ether linked phenol units (I). In connection with studies on lignin, which is probably formed by dehydrogenation of coniferyl alcohol by an oxygen-laccase system [2], it seemed to be of interest to examine the dehydrogenation of guaiacol also. Silver oxide, potassium ferricyanide, persulphate catalysed with ferro-ions, and oxygen-laccase were used as oxidation systems.

Silver oxide dehydrogenation

The dominant product obtained on treating a benzene solution of guaiacol with silver oxide was a polymeric material. 3,3′-Dimethoxy-4,4′-dihydroxydiphenyl was also isolated but the yield was low. This compound has previously been obtained in low yield from guaiacol by electrolytic oxidation [3].

The polymeric material was an amorphous, light-coloured powder with the formula $[C_6H_3O(OCH_3)]_n$, where n is higher than 6. Its structure was determined mainly by using spectrophotometric methods.

The NMR spectrum of the polymer showed no peak for aliphatic or olefinic hydrogen except that for the hydrogen in methoxyl groups. The aromatic structure of at least the greater part of the guaiacol nuclei had therefore not been destroyed during the oxidation. The UV spectra in neutral (Fig. 1) and alkaline solutions differed only slightly showing that the proportion of phenolic groups present was low [4].

* See addendum p. 2096.

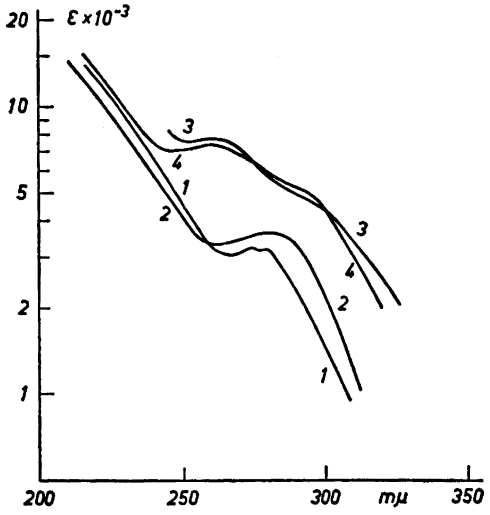

Fig. 1. UV spectra of guaiacol polymers. Oxidation reagents: 1) silver oxide, 2) potassium ferricyanide, 3) laccase plus oxygen, and 4) sodium persulphate plus ferro-ions. Solvent: ethanol. The ε values are calculated for one C_6-unit.

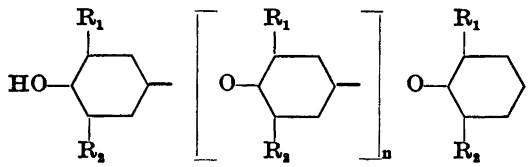
The IR spectrum of the polymer (Fig. 2) has no or, in some preparations, only weak carbonyl bands. Its hydroxyl content, determined by acetylation, was low. The two samples examined contained one hydroxyl group to 14 and to 5 C_6-units, respectively. The polymer contained no peroxide groups.

Most of its oxygen atoms must for these reasons be present in ether groups, and the polymer is therefore built up in the same way as the polymer from 2,6-dimethylphenol *i.e.* phenol units linked by ether bonds. Its formula is then (II).



I. $R_1 = R_2 = CH_3$
II. $R_1 = OCH_3$, $R_2 = H$

It has been assumed that the ether bond links the carbon atom of guaiacol which in almost all reactions has the greatest reactivity, *i.e.* that in the *para* position to the phenolic group. Even if an *ortho* carbon linkage seems less likely it cannot however at present be excluded.

The dimeric compound (II, n = 0) could not be isolated from the oxidation mixture even though a considerable amount of guaiacol was recovered. This may be explained as in the dimethylphenol oxidation [1] by a faster rate of oxidation for the dimer than for guaiacol.

When the silver oxide dehydrogenation was done in a mixture of dimethylformamide and methyl iodide, veratrol and the polymer (II) were obtained, indicating that the methylation competed better with the oxidation of guaiacol than with the oxidation of the dimer. This is a further proof of the easier oxidation of the dimer than of the guaiacol.

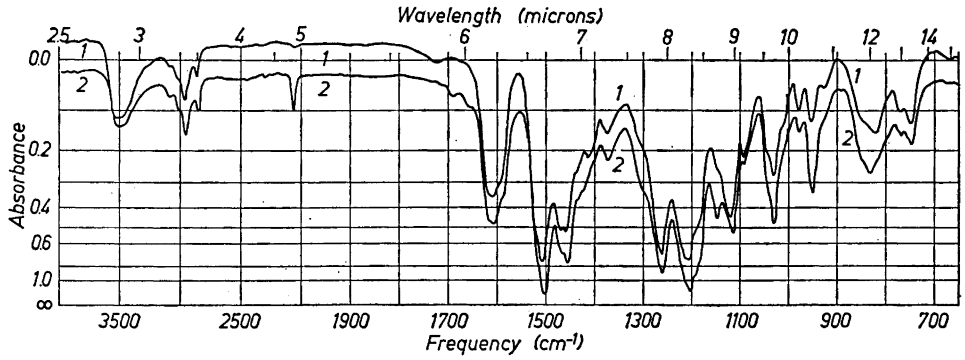


Fig. 2. IR spectra of guaiacol polymers. Oxidation reagents: 1) silver oxide, and 2) potassium ferricyanide. Potassium bromide disc.

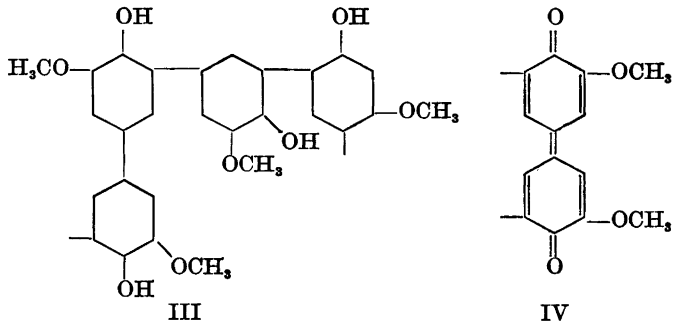
Potassium ferricyanide dehydrogenation

Potassium ferricyanide in alkaline solution transformed guaiacol into a grey amorphous product, the UV and IR spectra of which (Figs. 1 and 2) agreed so closely with those of the silver oxide polymer that they must be structurally similar.

Laccase-oxygen dehydrogenation

Treatment of guaiacol with oxygen in the presence of laccase or peroxidase gives a bright red dehydrogenation polymer, which has been called "tetraguaiacoquinone" by Bertrand [5]. Booth and Saunders [6] in addition to "tetraguaiacoquinone" also obtained a very small amount of 2,2′-dihydroxy-3,3′-dimethoxy-diphenyl. Reductive acetylation of the polymer gave, also in a very low yield, the diacetate of 3,3′-dimethoxy-4,4′-dihydroxy-diphenyl. From this they concluded that "tetraguaiacoquinone" is a polymer of guaiacol units linked together with carbon-carbon bonds (III) and that the red colour is due to the oxidation of some units to diphenoquinone (IV) residues.

As the support for their assumption is rather indirect, a further examination was made of "tetraguaiacoquinone".



III IV

Analyses of the polymer gave the formula

$$C_6H_{2.4}O_{0.32}^{carbonyl}\ (OH)_{0.7}\ (OCH_3)_{1.0}$$

which is consistent with the assumption that (III) should be the predominant structural element. After reduction with sodium borohydride, which removed the red colour, the polymer did not react with dibromoquinone-monochloroimide. Evidently the *para* positions in the polymer were substituted. On the other hand, *p*-diazobenzenesulphonic acid gave a red colour with the reduced polymer and thus at least a part of the *ortho* positions (possibly those belonging to the end groups) are free.

Further support for the structure (III) was given by UV spectra, as shown below. The bonds from a benzene nucleus in the polymer to the two proximal nuclei are in *meta* position to each other. The largest mesomeric system in the polymer consists therefore of only two nuclei and the UV maximum should therefore be at the same wavelength as that of the corresponding diphenyl (*cf.* Ref[7].). Two guaiacyl nuclei can be linked in either *o,o'*-, *p,p'*- or *o,p'*-positions to the phenol groups. The *ortho*-substituents decreased the extinction value of the diphenyl maximum as is evident from the fact that the diphenyl maximum has a higher extinction value for 3,3'-dimethoxy-4,4'-dihydroxy-diphenyl than for 3,3'-dimethoxy-2,2'-dihydroxy-diphenyl (Table 1) (*cf.* Ref.[8]). A polymer (III) would therefore be expected to have a UV maximum reminiscent of that of 3,3'-dimethoxy-4,4'-dihydroxy-diphenyl. In reality it was found that even if there are some differences between the spectrum of "tetraquinone" and that of the diphenyl they are certainly of the same type (Table 1).

The presence of the diphenoquinone structure (IV) was supported by the IR spectrum of the polymer. The carbonyl band was at 1 625 cm^{-1}, close to the aromatic 1 600 cm^{-1} band (Fig. 3). This frequency, which is unusually low for a carbonyl band, agrees with that of diphenoquinones (diphenoquinone [9] at 1 626 cm^{-1}, its 3,3', 5,5'-tetramethyl derivative at 1 633 cm^{-1}, and the 3,3',5,5'-tetramethoxy derivative at 1 628 cm^{-1}). The carbonyl peaks of benzoquinones are in the vicinity of 1 650^{-1} cm (benzoquinone [10] at 1 667 cm^{-1}). In the visible part of the polymer spectrum there is a maximum at 475 mμ which was evidently due to the diphenoquinone groups since they absorb in this region.

Persulphate oxidation

Erdtman [11] has pointed out that a polymer similar to "tetraguaiacoquinone" is formed when guaiacol is treated with sodium persulphate in acidic aqueous solution containing a small amount of ferrosulphate. The results of analyses on material prepared here indicated a formula

$$C_6H_{2.3}O_{0.40}^{carbonyl}\ (OH)_{1.0}(OCH_3)_{0.75}$$

(This formula agrees reasonably well with data by Erdtman and Johanson [12]).

The persulphate polymer differed in several respects from "tetraguaiacoquinone". The lower methoxyl value showed that some methoxyl had been eliminated during the persulphate oxidation and that a part of the aromatic

Table 1. UV data for "tetraguaiacoquinone", the persulphate polymer, and two related diphenyl derivatives.

Substance	Neutral solution [1] Diphenyl maximum mμ	ε	Benzene maximum mμ	ε	Alkaline solution [2] mμ	ε
"Tetraguaiacoquinone"	257	7 520	300*	3 600	298	5 250
Reduced ditto	261	7 750	300*	4 300		
Persulphate polymer	258	6 900	295*	4 300	298	8 350
Reduced ditto	261	7 350	295*	5 000		
3,3′-Dimethoxy-4,4′-dihydroxy-diphenyl	268	7 800	291	6 600	308	11 200
3,3′-Dimethoxy-2,2′-dihydroxy-diphenyl [3]	247	4 100	283	2 500	304	3 650

Extinction values (ε) calculated per C_6-unit for both polymers and diphenyls. The maxima marked with * were noticeable only as inflections in the absorption curves

[1] Solvent: ethanol.

[2] Solvent: 0.1 N ethanolic potassium hydroxide solution.

[3] Synthesised according to Ref.[6]

nuclei might have been destroyed. Even though the IR spectra of the two polymers were of the same aromatic type (Fig. 3) they show distinct dissimilarities. For instance the spectrum of the persulphate polymer showed no diphenoquinone band in the vicinity of 1 625 cm^{-1} but, on the other hand, it had an absorption peak at 1 645 $cm,^{-1}$ which might be due to benzoquinone groups. The visible light spectrum also indicated differences between the carbonyl groups of the two polymers, the persulphate polymer having a maximum at

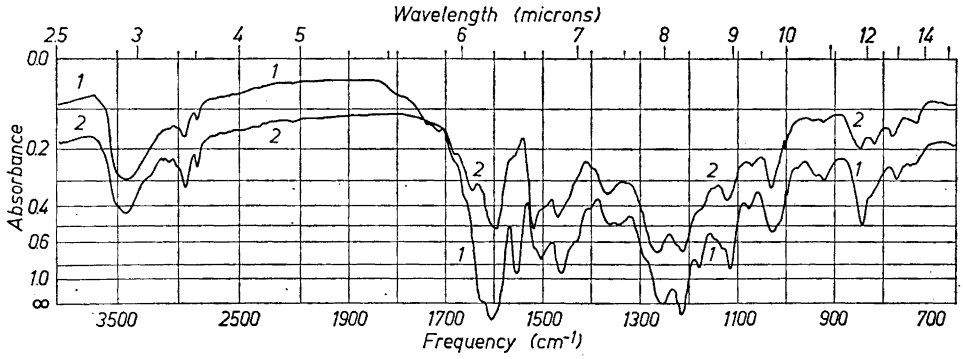


Fig. 3. IR spectra of guaiacol polymers. Oxidation reagents: 1) laccase plus oxygen, and 2) persulphate plus ferro-ions. Potassium bromide disc.

438 mμ, significantly different from the wavelength of that of "tetraguaiacoquinone" (475 mμ). It therefore seems probable that the greater part of the carbonyl groups in the persulphate polymer are benzoquinone groups formed by an Elbs persulphate reaction [13].

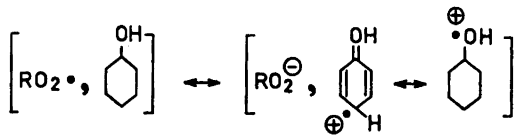
The UV spectra of the polymer (Table 1 and Fig. 1) closely resembled that of the "tetraquaiacoquinone". Furthermore the reduced persulphate polymer did not react with dibromo-quinone-monochloroimide and gave only a weak colour reaction with diazobenzene-sulphonic acid. Together with the general conformity of the IR spectra, these results indicated that the persulphate polymer contained a large proportion of the predominant structural elements in "tetraguaiacoquinone", *i.e.* (III).

DISCUSSION

It is apparent from these experiments that different types of dehydrogenation polymers are obtained from guaiacol depending on the type of oxidation reagent used. Polymers with ether-linked units are obtained when silver oxide and potassium ferricyanide are used while persulphate and the oxygen-laccase system link the units by carbon-carbon bonds.

The formation of both types of polymers can be explained according to the well known scheme for dehydrogenation of phenols (reviewed in Refs. [14,15]) in which the primary reaction products are considered to be phenoxyl radicals. These radicals may combine with each other or with phenol molecules. The formation of both oxygen bonds and carbon-carbon bonds can be accounted for by this process.

However, that the oxidation reagent should affect the manner of linking is not indicated in this simplified scheme; it might be explained in several ways. One alternative is that the radicals are never really free but form π-complexes with the oxidation reagents such as those assumed by Hammond and co-workers [16] to be the primary products obtained by reaction of peroxy radicals with phenols or amines (V).



V

EXPERIMENTAL

Oxidation of guaiacol with silver oxide in benzene solution. Isolation of the polymer. Guaiacol (15 g) dissolved in benzene (140 ml) was shaken with silver oxide (16 g) for 48 h. Undissolved material (15 g) was removed and the filtrate was shaken with 2 N sodium hydroxide solution, which dissolved a part of the product. The benzene solution was dried and evaporated. The residue was dissolved in chloroform, and light petroleum was added to the solution. The white precipitate obtained was collected (1.4 g, Preparation A).

The alkaline solution was acidified and the solution decanted from the sticky precipitate, which was washed with water and dissolved in dioxane. The dioxane solution was

dried and evaporated. The residue (5.2 g) was precipitated from chloroform solution by addition of light petroleum, and the white precipitate obtained was collected (3.3 g, Preparation B).

The acidified aqueous solution was extracted with ether and the ether solution was combined with the chloroform-light petroleum filtrate. The combined solution was evaporated. The residue (10 g) yielded guaiacol (5 g) on distillation.

Examination of the polymeric preparations A and B. Analyses: Preparation A, found C 68.8; H 5.0; O 26.7; OCH_3 26.6; OH 1.1. Preparation B, found C 67.3, H 5.3, O 27.2, OCH_3 24.4, OH 2.7 peroxide [17] 0.0, molecular weight at least 750.

The hydroxyl content was determined by heating the preparations with acetic anhydride and pyridine for 3 h, precipitating the acetylated material by addition of water and determining the acetyl content of this material.

UV and IR spectra of the two preparations were the same. They are shown in Figs. 1 and 2, respectively.

NMR spectrum of preparation B in a benzene solution showed a peak at a shift of 3.7 p.p.m. relative to the benzene peak. The peak due to the hydrogen of the methoxyl group in guaiacol has a shift of 3.8 p.p.m.

Isolation of 3,3'-dimethoxy-4,4'-dihydroxy-diphenyl. Guaiacol (20 g) was treated with silver oxide (21 g) as described. The alkaline solution was acidified and extracted with benzene, which was then dried and evaporated. Distillation of the residue gave guaiacol (8.5 g) and a fraction, distilling at 0.3 mm Hg/160—180° (bath temperature). The latter partly crystallised and on recrystallisation from methanol gave a product (0.15 g), m.p. 153°, raised to 166—167° by further recrystallisation from methanol. (Found C 68.3; H 5.9. Calc. for $C_{14}H_{14}O_4$ (246): C 68.3; H 5.7.) UV data are given in Table 1. Its structure was determined by methylation to 3,3'4,4'-tetra-methoxy-diphenyl.

Methylation of 3,3'-dimethoxy-4,4'-dihydroxy-diphenyl. Dimethyl sulphate (1 ml) was added with vigorous agitation to a solution of the dimethoxy-dihydroxy-diphenyl (3.4 mg) in 3 N potassium hydroxide (1 ml). When the solution turned acidic 3 N potassium hydroxide (1 ml) was added. The treatment with dimethyl sulphate (1 ml) and 3 N potassium hydroxide (1 ml) was repeated once and then dimethyl sulphate (1 ml) and solid potassium hydroxide were added. The temperature was kept at about 80° during the whole methylation procedure. When all the dimethyl sulphate had reacted the crystals were removed from the solution and washed with water, m.p. 129—130°, undepressed by addition of 3,3'4,4'-tetramethoxy-diphenyl prepared by Ullman coupling of 3,4-dimethoxyphenyl iodide [18]. The IR spectrum of the methylation product was identical with that of the tetramethyl-diphenyl.

Oxidation of guaiacol with silver oxide in dimethylformamide-methyl iodide solution. Silver oxide (25 g) was added in portions during 1 h to a solution of guaiacol (10 g) in dimethylformamide (50 ml) and methyl iodide (30 ml). The mixture was then shaken for 17 h, undissolved material was removed and benzene was added to the filtrate. The precipitate obtained was removed and the benzene solution was extracted with 5 % sodium thiosulphate solution, then water, and dried. Light petroleum was added to the benzene solution. The white amorphous precipitate obtained was collected (3.2 g). (Found: C 68.9; H 5.0; O 25.6; OCH_3 27.1; OH 0.0.) IR and UV spectra were identical with those of the polymer preparations obtained by oxidations in benzene solution.

The light petroleum-benzene solution from the polymer precipitation was evaporated. The residue (2.2 g) distilled at 130° (bath temperature); the m.p. of the distillate, 22°, was undepressed by addition of veratrol. Its IR spectrum was identical with that of veratrol.

Oxidation of guaiacol with potassium ferricyanide. An aqueous solution of potassium ferricyanide (30 g in 100 ml) was added during 1 h to a solution of guaiacol (5 g) in $\frac{1}{4}$N sodium hydroxide solution (150 ml) which was strongly agitated (room temperature). The reaction mixture was agitated for a further 5 h and then extracted with chloroform. The chloroform solution was dried and evaporated. The residue (0.5 g) was reprecipitated from a chloroform solution by addition of light petroleum. Weight 0.3 g. (Found: C 66.2; H 5.3; O 25.1; OCH_3 22.8.)

The chloroform-extracted alkaline solution was acidified and extracted again with chloroform. The extract was dried and added to light petroleum. The precipitate obtained was collected (1.5 g). (Found: C 64.6; H 4.9; O 27.0.) UV and IR spectra are shown in Figs. 1 and 2, respectively.

Oxidation of guaiacol with sodium persulphate. The polymer was prepared as described by Erdtman [11]. (Found: C 65.4; H 4.4; O 28.4; OCH_3 18.2.)

The carbonyl group content was determined by sodium borohydride reduction according to Lindberg and Paju [19]. The reduction time was about half an hour. Found: 0.20 moles of hydrogen consumed per equivalent weight of 122. The UV and IR results are shown in Figs. 1 and 3 and in Table 1.

Reductive acetylation: A mixture of zinc powder (5 g), the polymer (2 g) and acetic anhydride-pyridine (10 ml, v/v) was heated on a boiling water bath for 1 h. Undissolved material was removed and water was added to the filtrate. The light brown precipitate obtained was collected and washed with water. Weight: 2.7 g. (Found: OCH_3 12.1, CH_3CO 26.3.) The formula given in the discussion was calculated on the assumption that the carbonyl groups are reduced to hydroxyl groups and then acetylated in this procedure.

"*Tetraguaiacoquinone*". A dialysed solution from a culture of *Polyporus versicolor* (3 ml) was added to guaiacol (1 g) dissolved in a 0.01 M acetic acid-sodium acetate buffer of pH 4.8 (80 ml). The solution was shaken for 24 h. The precipitate obtained was collected and washed with water. (This experiment was kindly performed by Dr. Gösta Fåhraeus and Mr. Hans Ljunggren). Weight 770 mg. (Found: C 67.8; H 4.9; O 25.8; OCH_3 25.4.) Carbonyl was determined as in the case of the persulphate polymer. Found: 0.16 moles of hydrogen consumed per equivalent weight of 122. Reductive acetylation was also carried out as with the persulphate polymer. (Found: OCH_3 18.7; CH_3CO 22.0.) UV and IR data are collected in Figs. 1 and 3 and in Table 1.

Acknowledgement. I wish to thank Miss Marit Goliath and Mr. Sigurd Söderberg for valuable experimental assistance. The IR spectra were recorded at the Department of Organic Chemistry, Royal Institute of Technology, by Miss Gurli Hammarberg, and the NMR spectrum were determined in the Department of Physical Chemistry at the same institute by Mr. Jan-Christer Eriksson to both of whom I am greatly indebted. I also wish to thank Dr. Gösta Fåhraeus and Mr. Hans Ljunggren, Royal Agricultural College of Sweden Ultuna, for their preparation of "tetraguaiacoquinone".

Added in proof. This polymer recently been synthesised by two other methods (Hay, A. S. *et al. J. Am. Chem. Soc.* **81** (1959) 6335, and Staffin, G. D. and Price, Ch. C. *ibid.* **82** (1960) 3632).

N-Substituted Alkyltriaminosilanes

IV. On Intermolecular Condensation

LEWI TANSJÖ

Department of Organic Chemistry, University of Lund, Lund, Sweden

Ammonolysis of methyl-, ethyl-, and *n*-propyltrichlorosilane gave no distillable products. Alkyltriaminosilanes were presumably first formed but condensed intermolecularly with evolution of ammonia to give polymers. The corresponding N-substituted alkyltriaminosilanes, however, were obtained in good yields. In the presence of a small amount of a proton donor also these compounds condensed intermolecularly, the reactivity being greatly depending upon the nature of the groups attached to the silicon and nitrogen atoms.

This paper describes the intermolecular condensation of some alkyltriaminosilanes and their N-substituted derivatives, which proceeds with evolution of ammonia or amine and the first stage of which would be according to the general equation

$$2RSi(NHR')_3 \longrightarrow \begin{matrix} & NHR' & & NHR' & \\ & | & & | & \\ RSi & -NR'- & Si & R & \end{matrix} + R'NH_2$$
$$\qquad\qquad\quad NHR' \qquad\quad NHR'$$

This reaction has been performed for R = H, CH_3, C_2H_5 and n-C_3H_7 and R′ = H, CH_3 and C_2H_5.

When methyl-, ethyl-, or *n*-propyltrichlorosilane reacted with ammonia, the monomeric alkyltriaminosilanes, $RSi(NH_2)_3$, were not obtained even if the reactions were performed in liquid ammonia. Presumably these compounds were first formed according to the equation

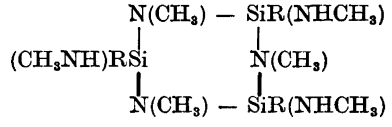
$$RSiCl_3 + 6H_3N \longrightarrow RSi(NH_2)_3 + 3H_4NCl$$

but they very easily condensed intermolecularly, as mentioned above, with the formation of ether-soluble polymeric silazanes with Si—NH—Si linkages, which, after evaporation of the solvent gave viscous oils. Upon heating of these, more ammonia was split out and high polymers with a three dimensional

network resulted. This is analogous to the ammonolysis of trichlorosilane [1] which gave a polymer, $HSi(NH)_{1.5}$, with a cross-linked structure and a very high degree of polymerization. Nor did Larsson [2] observe any low-molecular products from the ammonolysis of *n*-butoxitrichlorosilane. Chugunov [3], however, obtained a compound which appeared to be α-$C_{10}H_7Si(NH_2)_3$, by bubbling dry gaseous ammonia into an ether solution of α-naphthyltrifluorosilane, but no analyses or further studies of the compound were given to authorize the formula. It was mentioned only that the compound rapidly hydrolyzed in contact with moist air with evolution of ammonia. The bulky α-naphthyl-group can certainly be expected to exert a greater retarding influence on the intermolecular condensation than the R-groups investigated in this paper, but it seems not unlikely that what was interpreted as a hydrolysis may have been the first stages of a condensation of the type mentioned above.

It was reported in a previous paper [4] that *n*-propyltri-(methylamino)-silane and *n*-propyltri-(ethylamino)-silane are stable at their normal boiling points and it was now found that the corresponding methyl- and ethyl-compounds could be isolated without difficulty. This shows that organic groups on the nitrogen atoms effectively impede the tendency toward intermolecular condensation of the compounds compared with that of the unsubstituted alkyltriaminosilanes. Tri-(ethylamino)-silane, with the silicon bearing only a hydrogen atom beside the ethylamino groups, could also be isolated, but no uncondensed products were obtained from the reaction mixture of trichlorosilane and methylamine.

The accelerating effect of hydrogen ion on the reaction of N-substituted *n*-propyltriaminosilanes with primary and secondary amines was demonstrated in part II of this work [5]. As can be expected the intermolecular condensation, which is apparently of the same nature as the exchange reactions studied in the previous paper, is also catalyzed by the hydrogen ion. Thus, methyl-, ethyl- and *n*-propyltri-(methylamino)-silane all gave a vigorous evolution of methylamine far beneath their ordinary reflux temperatures when heated with a small amount of ammonium sulfate. The reaction mixtures, which were soluble in organic solvents, crystallized on cooling and gave good yields of compounds the analyses of which corresponded to the cyclic structure I.



I

The building up of high-molecular-weight cross-linked structures from these by further condensation seems to be effectively sterically hindered for they could all be heated with ammonium sulfate present to 200°C for several hours without any noteworthy liberation of methylamine. However, when the mixture of low-molecular condensation products which was obtained from the reaction of trichlorosilane and methylamine was heated with a small amount of ammonium sulfate to the same temperature, a considerable evolution of methylamine occurred, and after a few hours there remained an insoluble hard and glassy mass, typical of cross-linked structures.

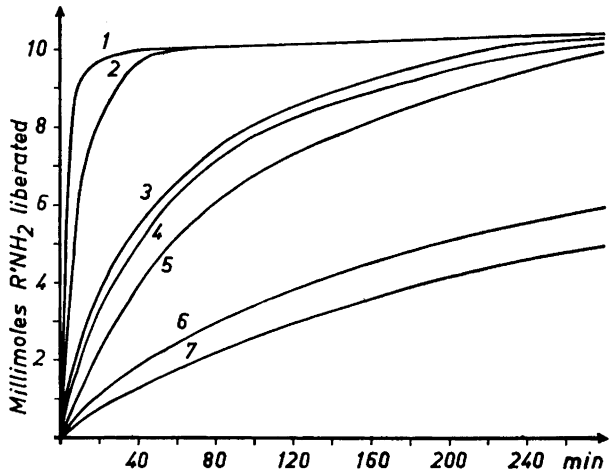


Fig. 1. Intermolecular condensation of $RSi(NHR')_3$. 1. $HSi(NHC_2H_5)_3$; 2. $CH_3Si(NHCH_3)_3$; 3. $C_2H_5Si(NHCH_3)_3$; 4. n-$C_3H_7Si(NHCH_3)_3$; 5. $CH_3SiNHC_2H_5)_3$; 6. $C_2H_5Si(NHC_2H_5)_3$; 7. n-$C_3H_7Si(NHC_2H_5)_3$.

In Fig. 1 are given the results of a series of experiments in which 0.01 mole of some substituted triaminosilanes, $RSi(NHR')_3$, were heated in the presence of a small amount of ammonium sulfate at 120°C and the liberated amine, $R'NH_2$, was titrated with standard acid. It appears that the rate of evolution of amine depends on the nature of R and R', being increased in the order R = n—C_3H_7, C_2H_5, CH_3, H and R' = C_2H_5, CH_3.
The physical constants and analyses of the following compounds are given in Table 1: I, $CH_3Si(NHCH_3)_3$; II, $CH_3Si(NHC_2H_5)_3$; III, $C_2H_5Si(NHCH_3)_3$; IV, $C_2H_5Si(NHC_2H_5)_3$.

EXPERIMENTAL

The method of the determination of the physical constants of the compounds and the analyses have been previously described [4]. The experiments, the results of which are given in Fig. 1, were performed in the following way. The triaminosilanes (0.01 mole) and 6 mg (5×10^{-5} mole) of ammonium sulfate were introduced into a 10 ml flask which was heated to 120 ± 0.5°C in a thermostat. The liberated amine was withdrawn by a weak, uniform stream of nitrogen, which had been carefully dried with conc. sulphuric acid and phos-

phorus pentoxide, and had to pass a reflux condensor cooled with water before it was absorbed in a known volume of standard hydrochloric acid. The acid was added in small portions into the absorption vessel and the times of neutralization (methyl red as the indicator) were noted. All the investigated N-substituted alkyltriaminosilanes gave only a very slow evolution when heated without ammonium sulfate but tri-(ethylamino)-silane condensed rapidly even in the absence of the catalyst.

Ammonolysis of ethyltrichlorosilane. In a 500 ml three-necked flask immersed in a Dry Ice and acetone-bath were placed about 100 ml of liquid ammonia. From a dropping funnel, 16.4 g (0.1 mole) of ethyltrichlorosilane in 250 ml of ether was added dropwise during 2 h to the stirred ammonia. The temperature was slowly raised by the removal of the bath. After 2 h at room temperature most of the excess of ammonia had evaporated. Ether was distilled from the mixture until the distillation temperature reached 35°C and about 50 ml were removed at this temperature to take away most of the residual ammonia. Filtration left 16.0 g (calc. for the total exchange of chlorine 16.0 g) of ammonium chloride on the filter. No silicon was found in the precipitate so the reaction product was still quite ether soluble. The filtrate gave after the filtration only a weak odour of ammonia, but after standing for a few hours in a sealed bottle, an additional pressure, owing to free ammonia, had been formed. During the course of the distillation of ether ammonia continuously escaped, and after the last traces of ether had been removed at reduced pressure, there remained a viscous, colourless oil which could again be dissolved in ether and neutralized some acid when agitated with 0.1 N hydrochloric acid. Attempts to distil the oil at reduced pressure only caused more ammonia to evolve giving a residue of an amorphous plastic solid which on heating to about 200°C lost a little more ammonia and changed to a brittle, colourless resin. When treated with strong warm alcoholic potassium hydroxide, ammonia was set free in an amount corresponding to a nitrogen content of 26.0 %; calc. for $C_2H_5Si(NH)_{1.5}$ N 26.4. The silicon content was 34.2 against 35.3 for the formula above. The low silicon content points to incomplete condensation. Wagner *et al.*[6] found that brittle polymers obtained by hydrolysis of vinyltrichlorosilane contained as much as 9.5 % silanol hydroxyl so it is apparent that complete condensation is not necessary to give silicon polymers with a high degree of polymerization. That there was not found a corresponding increase of the nitrogen content of the product is probably due to partial hydrolysis.

The ammonolysis of *methyltrichlorosilane* and *n-propyltrichlorosilane* was performed in the same way and proceeded analogously to give insoluble, high-molecular-weight products as above.

Tri-(methylamino)-silane. 27.1 g (0.2 mole) of trichlorosilane in 100 ml of ether were added dropwise to an ice-cooled, stirred solution of 50 g (1.6 mole) of methylamine in 300 ml of ether. The temperature was then slowly raised by the removal of the ice-bath. Filtration of the reaction mixture left 40.3 g (calc. 40.5 g) of methylamine hydrochloride on the filter. On distillation of the filtrate, no distillate was obtained beneath 100°C (9 mm Hg) where tri-(methylamino)-silane can be supposed to distil. Between 125—175°C/9 mm, however, 8.0 g of an ether soluble product were obtained (Found: Equiv. wt. 43.8; Si 30.6. Calc. for $[HSi(NHCH_3)(NCH_3)]_n$: Equiv. wt. 44.1; Si 31.8.) On further heating of the distillation flask a vigorous evolution of methylamine took place and 5.5 g of an insoluble, hard and glassy residue were obtained.

When the distillate was heated to 200°C with a small amount of ammonium sulfate, methylamine was set free and after 3 h a high-molecular-weight product had been formed as above.

Tri-(ethylamino)-silane. 27.1 g (0.2 mole) of trichlorosilane in 100 ml of ether were added to 75 g (1.7 mole) of ethylamine in 400 ml of ether, cooled to 0°C. On filtration, 48.7 g (calc. 48.9 g) of ethylamine hydrochloride were left on the filter. On distillation of the filtrate, 8.0 g (25 %) of tri-(ethylamino)-silane were obtained, b.p. 62—63°/10 mm, (Found: Equiv. wt. 54.0; Si 17.5. Calc. for $HSi(NHC_2H_5)_3$: Equiv. wt. 53.8; Si 17.4.) On further heating a considerable amount of ethylamine escaped from the distillation flask. After the content had been heated for two hours at about 150°C the distillation was continued giving:

125—45°/0.5 mm: 2.0 g; equiv. wt. 57.5; Si 22.7;
145—60°/0.5 mm: 7.2 g; equiv. wt. 57.5; Si 22.9;
160—80°/0.5 mm: 4.2 g; equiv. wt. 58.1; Si 23.6.

Methyltri-(methylamino)-silane. To an ice-cooled, stirred solution of 30 g (1.0 mole) of methylamine in 300 ml of ether, a solution of 15.0 g (0.1 mole) of methyltrichlorosilane was added dropwise. The stirred mixture was heated to reflux temperature for 1 h and was then filtered giving 20.2 g (calc. 20.3 g) of methylamine hydrochloride on the filter. Distillation of the filtrate gave 9.5 g (71 %) of methyltri-(methylamino)-silane with the data given in Table 1.

5.8 g of the compound was heated for 5 h at 150°C with 10 mg of ammonium sulfate and gave a product which crystallized on cooling (m.p. 133—36°). Recrystallization from pentane at —20° gave 2.0 g, m.p. 136—38° (Found: Equiv. wt. 52.0, Si 27.9, *M* (in benzene) 320. Calc. for $[CH_3Si(NHCH_3)(NCH_3)]_3$ (I): Equiv. wt. 51.1, Si 27.5, M 307.)

Methyltri-(ethylamino)-silane. 11.1 g (0.074 mole) of methyltrichlorosilane in 50 ml of ether were added to 45 g (1.0 mole) of ethylamine in 300 ml of ether. The stirred mixture was refluxed for 1 h. Filtration left 18.0 g (calc. 18.1 g) of ethylamine hydrochloride on the filter. On distillation of the filtrate 10.1 g (78 %) of methyltri-(ethylamino)-silane were obtained.

Ethyltri-(methylamino)-silane (22.3 g; 76 %) was obtained in the same way as described for methyltri-(methylamino)-silane from 32.7 g (0.2 mole) of ethyltrichlorosilane and excess of methylamine. 6.0 g of it were heated for 5 h at 150°C with 10 mg of ammonium sulfate. The reaction mixture, which crystallized on cooling, was recrystallized from pentane at —20° and gave 2.2 g, m.p. 189—92° (Found: Equiv. wt. 59.0, Si 24.2, *M* 355. Calc. for $[C_2H_5Si(NHCH_3)(NCH_3)]_3$: Equiv. wt. 58.1, Si 24.2, *M* 349.)

Ethyltri-(ethylamino)-silane (33.5 g; 88 %) was obtained in the same way as was described for methyltri-(methylamino)-silane, from 32.7 g (0.2 mole) of ethyltrichlorosilane and excess of ethylamine.

The synthesis of *n-propyltri-(methylamino)-silane* and *n-propyltri-(ethylamino)-silane* was described in a previous paper[4].

16.1 g of *n*-propyltri-(methylamino)-silane were heated for 5 h at 180°C in the presence of 20 mg of ammonium sulfate. On distillation of the reaction mixture, no *n*-propyltri-(methylamino)-silane was removed. Between 167—75°/1 mm 11.1 g of a product were obtained which crystallized on cooling (m.p. 67—70°). Recrystallization from pentane at —20° gave 7.5 g, m.p. 69—70° (Found: Equiv. wt. 65.9, Si 21.6, *M* 404. Calc. for $[n\text{-}C_3H_7Si(NHCH_3)(NCH_3)]_3$: Equiv. wt. 65.1, Si 21.6, M 391.)

The author wishes to thank Professor E. Larsson for his kind interest in this work.

Betaine-Homocysteine-Methyl-Transferases

I. Distribution in Nature

L.-E. ERICSON

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Various types of living material have been homogenized and incubated with betaine and homocysteine in order to test their ability to form methionine by means of methyl group transfer. Enzymes that catalyze this reaction are called betaine-homocysteine-methyl-transferases and were found in the livers of all the vertebrates investigated, ranging from *Homo sapiens* to *Petromyzon fluviatilis*. These enzymes were not found in appreciable amounts in any other vertebrate organ except in the kidney of the guinea pig. The only non-vertebrate in which a betaine-homocysteine-methyl-transferase has been detected so far is the pond mussel *Anodonta cygnea* [4]. Methyl transferases were not found in plants and microorganisms.

The transferases were partially purified from some materials. Dimethyl-β-propiothetin but not choline could replace betaine as methyl group donor in all cases tested. Dimethylglycine but not choline markedly inhibited the transfer reaction. The methyl-transferase of human liver was much more stable to heat than that of pike liver. The apparent pH-optima of the transferases studied varied from about 7.0 for pike to about 8.5 for pond mussel. Only L-homocysteine seemed to be methylated.

In the present paper some observations are reported on the distribution in Nature of enzymes that catalyze the transfer of a methyl group form betaine (carboxymethyl-trimethyl-ammonium chloride) to homocysteine. These enzymes will be called betaine-homocysteine-methyl-transferases. A comparison of some of the properties of transferases of different origin will also be made. Methionine and dimethylglycine are produced in the enzymic reaction [1,2] and enzyme activity has been measured as the amount of methionine formed per hour.

Some of the results of this investigation have already been briefly mentioned elsewhere.[2–4] The existence of a betaine-homocysteine-methyl-transferase in *Anodonta cygnea*, for instance, has recently been reported from this laboratory [4] and will therefore not be dealt with in detail here.

EXPERIMENTAL

The material to be tested for betaine-homocysteine-methyl-transferase activity was homogenized in a Potter-Elvehjem-homogenizer (or crushed in a mortar and homogenized) in ice-cold 0.05 M phosphate buffer having a pH-value of 7.8. In some cases other pH-values were tried (see Table 1). Betaine hydrochloride (California Corporation for Biochemical Research, Cal., USA, or L. Light & Co., Ltd., England) and DL-homocysteine (Nutritional Biochemicals Corporation, Ohio, USA) were added to the homogenate and the mixture was incubated aerobically for 2—4 h at 37°C. Another mixture consisting of homogenate, DL-homocysteine and buffer was incubated under the same conditions and served as the blank.

Methionine was determined chemically by the method suggested by McCarthy and Sullivan [5] and modified by Borsook and Dubnoff [6] and others [7]. The red colour obtained upon addition of the hydrochloric-phosphoric acid mixture was developed overnight at 4°C [7]. The solution was then filtered and the light absorption at 5 100 Å was measured in a Beckman Model DU spectrophotometer. Also a microbiological method using *Leuconostoc mesenteroides* P-60 according to the procedure given by Steele *et al.*[8] was used for the estimation of methionine. Standard methionine solutions were prepared from L-methionine (Nutritional Biochemicals Corporation, Ohio, USA).

RESULTS

Distribution studies. Table 1 summarizes the results of the attempts to find betaine-homocysteine-methyl-transferase activity in various types of living material. Only when significant amounts of methionine could be detected by both the chemical and the microbiological methods of analysis was the presence in the incubation mixture of a methionine producing system considered as certain. A pig liver homogenate was always run at the same time as the unknown sample to ensure that the test system functioned. The data presented here de not permit a direct comparison of the concentrations of the transferases in the various materials, as the specific activity of the different transferases are not known. It is also probable [3] that the homogenates used contained inhibitors or activators. A very great variation in activity was furthermore encountered between different samples of the same test material, *e.g.* between different human livers.

With some organs the test was repeated many times. For instance, about forty human livers from patients suffering from various diseases were studied *. The data presented in Table 1 are the highest and the lowest values observed and give an indication of the variation in transferase activity that was encountered in these patients. In none of the cases could transferase activity be detected in the blood.

It can be seen in Table 1 that betaine-homocysteine-methyl-transferases were found in the livers of all vertebrate animals investigated ranging from *Homo sapiens* to *Petromyzon fluviatilis*. These enzymes could not be detected in any other organ of these animals except in the kidney of the guinea pig. Using dimethyl-β-propiothetin as the methyl donor, methyl group transfer was found to take place also in rat kidney homogenates. The pancreas, spleen, small intestine, lung, heart, striated muscle, testicles, cerebellum and cerebrum seemed to lack betaine-homocysteine-methyl-transferase activity.

* These samples were kindly supplied by Dr. W. Graf, St. Erik's Hospital, Stockholm.

[h] Immediately after harvesting the leaves were put into ice-cold buffer to which betaine and homocysteine had been added.

[i] The cells were crushed in a mortar with sand and buffer at + 2°C.

With the method used betaine-homocysteine-methyl-transferase activity could not be detected in any non-vertebrate except in *Anodonta cygnea* [4]. Nor was it found in the plants or the microorganisms tested.

The chemical method of methionine determination gave in most cases slightly lower values than the microbiological method. The data indicate that only L-metionine was formed in the enzymic reaction and consequently that only L-homocysteine was methylated.

Some properties of the methyl-transferases from various sources. It has been shown by Sloane *et al.*[9] and from this laboratory [2-4,10] that dimethylglycine is a potent inhibitor of betaine-homocysteine-methyl-transferase. It is also well established that choline can not function as a donor of methyl groups with enzyme preparations lacking choline oxidase activity,[1,3,6,10-12] nor does choline interfere with the utilization of betaine.[2-4,10] It was considered of interest to determine whether the methyl-transferases of some of the organs investigated here fulfilled these criteria. Partially purified enzyme preparations were therefore made from human, monkey, chicken and pike livers and incubated with combinations of betaine, choline, dimethylglycine and homocysteine. The results, which are summarized in Table 2, indicate that dimethylglycine caused an almost complete inhibition of the methyl transfer when present in the incubation mixture at the same molar concentration as betaine. Choline had in no case an inhibitory effect nor did it act as a methyl donor. In other experiments, dimethyl-β-propiothetin was found to be an excellent methyl donor with these purified enzyme systems and with some liver homogenates from other animals.

Table 2. The influence of choline and dimethylglycine on the amount of methionine formed by betaine-homocysteine-methyl-transferases of different origin.

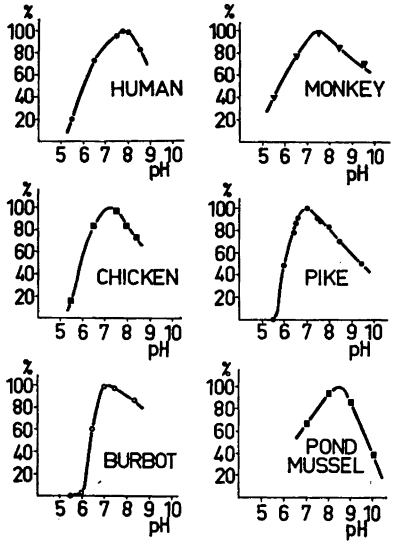

Fig. 1. Apparent activity-pH curves for betaine-homocysteine-methyl-transferases of different origin.

The apparent pH-optima of the transferases of human, monkey, chicken, pike and burbot livers were also determined. Fig. 1 shows the activity-pH curves for these enzymes and also, for the sake of comparison, the corresponding curve for the transferase of *Anodonta*-liver. The lowest apparent pH-optimum that was observed occurred at about 7 (pike) and the highest at 8.5 (pond mussel).

In connection with the purification of some of the transferases mentioned above it was noticed that the transferases of fish livers were much more *heat labile* than those of human, pig and rat livers. Crude and purified betaine-homocysteine-methyl-transferase of pig liver, for instance, could be kept at 80°C for several minutes without appreciable loss of activity (*cf.* Ref.[10]), whereas pike liver transferase suffered complete loss of activity from such treatment. This difference in heat stability is exemplified in Fig. 2. The curves shown in this figure were obtained with solutions of transferases purified from human liver and from pike liver containing approximately 0.5 % of protein and having a pH of 7.5. The solutions were heated at 60°C and the enzyme activity of samples taken at different time intervals was determined. The results show that the pike liver enzyme is much more sensitive to heat than the enzyme from human liver.

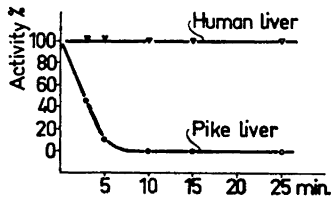

Fig. 2. A comparison of the temperature stability of betaine-homocysteine-methyl-transferase purified from human and from pike liver. The enzyme preparations were adjusted to pH 7.5 and kept at 60°C for various periods of time.

It might also be mentioned that the betaine-homocysteine-methyl-transferases of different origin behaved quite differently during the purification procedure. The transferase from human liver could be purified according to the first three steps used in the fractionation of the pig liver enzyme [10]. This was not possible with the transferase of pike liver. It was, as just mentioned, destroyed on heating at 80°C (step 2 in the fractionation of pig liver transferase [10]) and was not adsorbed on calcium phosphate gel under conditions which would retain the pig liver enzyme. The pike liver transferase was therefore purified by means of pH-adjustment and precipitation with ethanol.

DISCUSSION

The results of this investigation make it probable that betaine-homocysteine-methyl-transferases occur in the livers of all vertebrates. In other organs (*e.g.* kidneys) of vertebrates these transferases are encountered only occasionally.

A betaine-homocysteine-methyl-transferase has been found also in a member of the *Mollusca* [4]. This shows that formation of methionine by means of methyl group transfer does take place also in lower animals.

That betaine-homocysteine-methyl-transferases could not be observed in plants or in microorganisms must not be taken as conclusive evidence that they do not exist in such materials. It may only show that the method used was unsuitable for their detection. However, to the author's knowledge, no evidence for the transfer in plants or microorganism of an intact methyl group from betaine or from a thetin to homocysteine has yet been provided by any other research group. Dubnoff [13,14] found that in the presence of homocysteine, dimethyl-β-propiothetin but not betaine could replace the vitamin B_{12}-requirement of a mutant of *E. coli* but states [14] that "this reaction is not the simple methyl transfer demonstrated in animal tissues". Schlenk and De Palma [15] could not demonstrate any methyl group transfer from betaine, choline, dimethyl-acetothetin or dimethyl-β-propiothetin to homocysteine in *Torulopsis utilis*. Dimethyl-acetothetin and dimethyl-β-propiothetin are inactive as methyl donors also in *Aerobacter aerogenes*, *Saccharomyces cerevisiae* and some strains of *E. coli* [16]. Other examples of the inability of choline, betaine and the thetins to serve as donors of methyl groups in microorganisms have been cited.[17] — Challenger and his collaborators have isolated dimethyl-β-propiothetin from red [18] and green [19] algae but no evidence is as yet available indicating that this compound can donate its methyl groups to homocysteine in these or other plants. Dimethyl-acetothetin, although a potent methyl group donor in animal systems, has not been found to occur naturally.

On the other hand, methyl group transfers *from* methionine derivatives * to various acceptors take place in both microorganisms and plants as well as in animals. This has been amply demonstrated for microorganisms by Schlenk and De Palma [20], Shapiro [16,21,22], Alexander and Schwenk [23], Parks [24], Melville *et al.*[25], Birch *et al.*[26] and Remy [27], and for plants by Byerrum *et al.*[28–30],

* Dimethyl-β-propiothetin is here not considered as a derivative of methionine although it could be looked upon as a breakdown product of this amino acid.

Kirkwood *et al.*[31,32] and Mudd [33,34]. It is of interest to recall that in some of these reactions methionine is produced by methyl group transfer to homocysteine. Examples of such reactions are

S-methylmethionine + homocysteine → 2 methionine

and

S-adenosylmethionine + homocysteine → S-adenosyl homocysteine + + methionine

which have been studied in particular by Shapiro [16,21,22] and by Schlenk and De Palma [20]. S-Methylmethionine stimulated methionine formation also with the horse liver "thetin-homocysteine methylpherase" of Durell *et al.*[12], with the "thetin-homocysteine transmethylase" purified from rat liver by Maw [35] and with our betaine-homocysteine-methyl-transferase from pig liver [10]. For the moment it therefore seems that S-methylmethionine and betaine are interchangeable as methyl donors to homocystein in animal but not in microbial transferase reactions.

After this investigation had been completed and the results prepared for publication, a paper by Maw appeared [36] which dealt with the distribution of thetin-homocysteine transmethylase. The data presented here are in general agreement with the conclusions presented by Maw.

The author would like to express his thanks to Miss I. Frölich for technical assistance and to Dr. P. Lundberg for the biological classification of the material tested. The financial support of the *Medical Research Council* and the *Knut and Alice Wallenberg Foundation* is also acknowledged.

Betaine-Homocysteine-Methyl-Transferases

II. Isolation and Properties of the Transferase of Pig Liver

L.-E. ERICSON

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Procedures for the purification of the betaine-homocysteine-methyl-transferase of pig liver are described and discussed. Using these procedures, an enzyme preparation was obtained which was essentially homogeneous, as judged by sedimentation, chromatography and electrophoresis experiments. The molecular weight of the transferase monomer was found to be about 270 000. The transferase did not appear to be a metalloenzyme and no bound co-factors related to vitamin B_{12}, vitamin B_6, folic or folinic acid could be detected in the purified enzyme. The transferase showed a single light absorption maximum near 276 mμ. The apparent pH-optimum of the reaction catalyzed by the enzyme was approximately 7.5. In this reaction one molecule of betaine and homocysteine gave one molecule of dimethylglycine and methionine. Reversibility could not be demonstrated.

Enzymes that catalyze the transfer of an intact methyl group from betaine or some thetins to homocysteine thereby making methionine seem to occur in the livers of most vertebrates.[1] Enzymes with this property have been purified from rat liver by Ericson *et al.*[2], Maw [3], and Fromm and Nordlie [4], and from horse liver by Durell *et al.*[5]

In this laboratory we have for some years been engaged in a study of procedures for the purification of betaine-homocysteine-methyl-transferases from a variety of sources. Most work has been devoted to the methyl-transferase of pig liver and we have in a previous publication reported a method for the purification of this enzyme [6]. Since then some modifications have been made in the fractionation procedure and it is the purpose of this paper to describe in detail the method now in use in our laboratory, as well as some of the properties of the purified enzyme.

EXPERIMENTAL

The pig livers were purchased from a slaughter-house. They were removed and packed in ice immediately after the animals had been killed and bled. In the laboratory the livers were kept frozen before use. No decrease in the betaine-homocysteine-methyl-transferase activity of frozen livers could be detected over a period of several months. The methyl-transferase activity of different fresh livers varied considerably, in extreme cases by a factor of four or five. A similar variation in activity has been observed for instance with human livers [1] as well as with the livers of rats given various diets [7-9].

The activity of the enzyme solutions obtained during the fractionation was estimated by determining the amount of methionine formed aerobically per hour at 37°C during the initial phase of the reaction. The volumes of the different enzyme solutions used in the tests were chosen so that approximatively the same amount of methionine (and of dimethylglycine) was formed per hour from each enzyme fraction. All incubation mixtures contained 0.11 M betaine hydrochloride (California Corporation for Biochemical Research, Cal., USA, or L. Light & Co., Ltd., England) and 0.025 M DL-homocysteine (Nutritional Biochemicals Corporation, Ohio, USA). Methionine was determined chemically [2,10] or microbiologically [11]. The protein content of the different enzyme preparations was estimated by the biuret reaction [12] or by the optical method suggested by Kalckar [13]. In some cases the results were checked with the Kjeldahl procedure of Perrin [14].

The fractionation procedure for the preparation of purified betaine-homocysteine-methyl-transferase comprised the following steps:

Step 1

Alternative 1. 200 g of pig liver were cut into pieces and homogenized in 600 ml ice-cold water in a Waring blender. The pH of the homogenate was 6.4—6.8. The homogenate was centrifuged in a Spinco Model L ultracentrifuge at 44 000 × *g* for 25 min. and the supernatant fluid was adjusted to approximatively pH 7.7. The precipitate was washed with 250 ml ice-cold water and again spun down at 44 000 × *g* for 25 min. The supernatant fluid was combined with the fluid obtained after the first centrifuging. The total volume of the enzyme solution was approximately 810 ml.

Alternative 2. 200 g of frozen pig liver were cut into pieces and homogenized in 600 ml ice-cold water in a Waring blender. The homogenate was kept at 0°C while the pH was adjusted to approximately 5.1 with 1 N H_2SO_4. The slurry obtained was centrifuged in a Spinco ultracentrifuge at 44 000 × *g* for 15 min. The pH of the supernatant fluid was immediately adjusted to 7.5—8.0 with 1 N NaOH. The precipitate was suspended in 250 ml of ice-cold water and homogenized in a Waring blender. The suspension was centrifuged at 44 000 × *g* for 15 min. and the supernatant fluid was added to the fluid obtained after centrifuging the homogenate. The total volume was generally of the order of 890 ml. As the enzyme is very labile at pH 5.1 it is essential to keep the temperature near 0°C and to work quickly.

Foaming can be controlled with a few drops of *iso*octyl alcohol.

Step 2

The material from step 1 was adjusted to pH 7.75 and poured into test tubes with a diameter of 17 mm. The tubes were put in a water bath having a temperature of 80°C and stirred for 80—90 sec. The manual stirring of all tubes simultanously was accomplished by means of a rake-like contrivance having two rows of prongs fitting into the two rows of test tubes. After the heating, the tubes were immediately transferred to an ice-bath where the stirring was continued for 2—3 min. The fluid was thereafter centrifuged at 44 000 × *g* for 15 min. The supernatant fluid contained the enzyme. The precipitate was washed with 100 ml of water in a Waring blender and again centrifuged at 44 000 × *g* for 15 min. The combined supernatant fluids had a volume of approximately 800 ml when alternative 1, step 1, was used, and over 870 ml when alternative 2, step 1, was employed.

At this stage of the purification the enzyme can be stored for many months in the frozen state without loss of activity.

Step 3

In this step the enzyme was first adsorbed on and then eluted from calcium phosphate gel.

The calcium phosphate gel was prepared according to Keilin and Hartree [15] and was stored at room temperature. The day before the gel was to be used it was washed three times with 0.01 M phosphate buffer pH 8.0 and finally centrifuged at 4 500 × *g* in an MSE "Major Refrigerator" centrifuge. The dry weight of the washed gel was determined after it had been heated at 105°C for 2 h.

Alternative 1. If in step 1 the enzyme had been purified according to alternative 1, the amount of gel added to the solution obtained in step 2 corresponded to 10 mg dry gel per ml. With the facilities at hand it was found convenient to treat only 200 ml enzyme solution at a time. The gel was suspended in the solution by means of an electric stirrer for 30 min at 0°C and was thereafter recovered by centrifuging at 4 500 × *g* for 2 min. (Table 1). The supernatant fluid which contained only a few per cent of the activity but more than 50 % of the protein of the step 2 material was discarded. The gel was washed three times at 0°C with a total of 100 ml 0.05 M sodium phosphate buffer pH 8.0. Between each washing, the suspension was centrifuged at 4 000—4 500 × *g* for a few minutes (Table 1). The supernatant fluids from the washings were also discarded. They generally contained 5—10 % of the activity and about 25 % of the protein.

The elution of the enzyme from the gel was accomplished by means of five successive washings at 0°C, the first two with 0.15 M sodium phosphate buffer pH 8.5, the following three with a solution containing 0.15 M sodium phosphate and 0.1 M sodium citrate at pH 8.5 (Table 1). Vigorous stirring was used in order to get an even suspension of the gel in the eluting agent. The first two elutions lasted 40 min, the third and the fourth 30 min and the last 10 min. The volumes of the buffer solutions used were 25, 25, 20, 20, and 20 ml, respectively. After each of the first two elutions the suspensions were centrifuged at 4 500 × *g*, after the third and the fourth at 26 000 × *g* and after the fifth at 105 000 × *g*. The volume of the eluate was 110—115 ml.

Alternative 2. When the alternative 2 of step 1 was used, the amount of gel added to the enzyme solution from step 2 corresponded to only 6.5 mg dry gel per ml. All other operations followed the procedure outlined in alternative 1 of step 3.

The conditions used for the adsorption and desorption of the transferase from the calcium-phosphate gel are summarized in Table 1. If necessary a few drops of *iso*octyl alcohol were added to control the foaming.

Table 1. The conditions used for the purification of the transferase by treatment with calciumphosphate gel. All procedures were carried out at 0°C.

Process	No.	Washing or eluting agents	Volume ml	pH	Time min	Gel recovered by centrifuging at

	3rd	0.15 M phosphate + 0.10 M citrate	20	8.5	30	26 000 × *g* 10 min
	4th	—»—	20	8.5	30	26 000 × *g* 10 min
	5th	—»—	20	8.5	10	105 000 × *g* 10 min

Step 4

Alternative 1. The pH of the step 3 eluate was adjusted to 7.80 and the material poured into a row of test tubes. These tubes were submerged into a water bath having a temperature of 80°C. Stirring was performed as in step 2. After 80 sec. the tubes were put in ice-water and the stirring was continued for 2—3 min. The precipitate was removed by centrifuging at 44 000 × *g*. It was washed with 10 ml of water and again spun down at 44 000 × *g*.

This fractionation step was used only with enzyme preparations purified according to the alternative 1 of the first and the third steps. No purification was obtained when it was applied to enzyme solutions made according to alternative 2.

The preparation was dialyzed over night at 2°C against 2 l of distilled water.

Alternative 2. The pH of the eluate from step 3, alternative 2, was adjusted to 7.2 and ice-cold acetone to a final concentration of 55 % was slowly added to the enzyme solution. The mixture was kept at 0°C for 1 h and then centrifuged at 4 500 × *g* for 15 min. The precipitate that contained the enzyme was transferred to a dialysis bag by washing with approximately 5 ml of water. The dialysis was carried out over night at 2°C against 2 l of a 0.0025 M sodium phosphate buffer having a pH of 8.2.

Step 5

Alternative 1. Any precipitate formed during the dialysis was removed by centrifuging at 20 000 × *g* for a few minutes. The pH of the supernatant was then adjusted to 7.2 and ice-cold acetone was added to a final concentration of 60 %. The mixture was kept at 0°C for 2—3 h and then centrifuged at 22 000 × *g* for 25 min. The precipitate was dissolved in 10—15 ml of 0.010 M sodium phosphate buffer at pH 8.0.

Alternative 2. The precipitate formed during the dialysis was removed by centrifuging at 20 000 × *g* for 10 min. The supernatant was adjusted to pH 8.0 before step 6 was carried out.

Step 6

In this step the enzyme was poured through a column of triethylaminoethyl cellulose (TEAE-cellulose) [16] under conditions which retained on the column the remaining impurities in the step 5 preparation but let most of the enzyme pass through. The cellulose ion exchanger was purchased from the Serva Laboratories, Heidelberg, Germany. It was suspended in 0.010 M sodium phosphate at pH 8.0 and after about 45 min. the smallest particles were removed by decanting. Approximately 1 g of TEAE-cellulose was used per 70 mg of protein. The suspension was deaerated before being used for making the column, which had an inner diameter of 17 mm. The material was poured into the column as a slurry and was allowed to settle on the glass filter disc at the bottom. When most of the material had come to rest, a flow of buffer was passed through the column until the pH of the effluent was 8.0. A filter paper disc was then put on the top of the column.

The enzyme solution from step 5 was let through the column at a rate of approximately 0.5 ml per min and at a temperature of about 2°C. The effluent, which was virtually colourless, was collected in fractions of 2 or 5 ml. Fractions containing a substantial amount of activity were freeze-dried. It was possible to store the enzyme in this state for many months at temperatures below 0°C without loss of activity. However, the enzyme was not stable at room temperature.

Tables 2 and 3 summarize the steps used and the yield and purification obtained in the fractionation of betaine-homocysteine-methyl-transferase from pig liver according to alternative 1 and 2 respectively.

Other fractionation experiments

It may be of interest to mention briefly some of the other fractionation methods that have been tried, although they have given less satisfactory results. Precipitation with ammonium sulfate or ammonium phosphate [17] has in our hands consistently given low yields. Fromm and Nordlie [4] had the same experience in attempts to purify thetin-homocysteine transmethylase from rat liver with ammonium sulfate. Durell *et al.*[5], on the

other hand, used ammonium sulfate fractionation successfully for the purification of the thetin homocysteine methylpherase from horse liver.

Organic solvents, *e.g.* methanol, ethanol, *n*-propanol, *iso*propanol, acetone, methylethylketone and dioxane were also tried for the precipitation of the methyl-transferase at different stages of the purification procedure. Although good results were occasionally obtained, particularly with methanol, ethanol and acetone, we had difficulties in obtaining reproduceable results. Only when an excess of the precipitating agent was used (which led to little or no increase in specific activity) as in step 5, alternative 1, could a good yield consistantly be obtained.

Chromatography on the cation exchange resin Amberlite XE-64, treated as recommended by Hirs [18], was also unsuccessful as the degree of separation was poor. Chromatography on a column of the calcium phosphate (hydroxylapatite) prepared by the method of Tiselius, Hjertén and Levin [19] failed, due to irreversible adsorption of the transferase. Also attempts to use this particular calcium phosphate preparation for batch-wise adsorption and desorption (as in step 3) were unsuccessful, as it was very difficult to elute the enzyme from the "gel". To improve the yield when eluting the transferase from this "gel" or the gel prepared according to Keilin and Hartree, we added betaine, homocysteine, sodium chloride or sodium pyrophosphate to the eluting agent without success. Increasing the temperature during the elution step lowered the yield.

Zone electrophoresis on starch [20] or on specially treated cellulose [21] was tried, but low yields were obtained in both cases, probably due to irreversible adsorption of the transferase to the column material. Paper electrophoresis was also unsuccessful for the same reason. Electrophoresis in a density gradient according to Svenson *et al.*[22] was possible and separated the partially purified (step 5) transferase from coloured impurities [6]. However, we consider this method more elaborate and much more time consuming than the TEAE-cellulose treatment of step 6. The latter procedure can moreover be adapted to larger quantities and it does not require that a person works in a cold-room for long periods of time.

It should be pointed out that our failure to use the above mentioned methods for the purification of betaine-homocysteine-methyl-transferase does not mean that they cannot be successfully applied for this purpose under different conditions.

RESULTS AND DISCUSSION

Comments on the fractionation procedure. It can be seen from Table 3 that the purification of the betaine-homocysteine-methyl-transferase of pig liver according to alternative 2 gave satisfactory results in a comparatively large number of cases. The experiments on which the data are based were carried out during 1956, 1957 and the first part of 1958. When the investigations on the transferase were resumed in the summer of 1959, we were surprised to find, on the one hand that the transferase activity of the pig livers then obtained was on the average about three times higher than previously, on the other hand that the purification method that we had successfully applied in earlier experiments failed. This was particularly so in step 1 but also steps 2 and 3 gave unsatisfactory results. As it was impossible to account for all the activity in the different fractions from these steps, it appeared that the methyl-transferase of the high-activity livers was more labile than that of the livers with low transferase activity. Thetin homocysteine methylpherase has been shown by Durell *et al.*[5,23] to consist of a mixture of polymers and this seems to be the case also with the enzyme described here. It is conceivable that in a liver with a high concentration of the betaine-homocysteine-methyl-transferase less depolymerization of the enzyme to the monomer form takes place. The more polymerized form may be more labile than the monomer. This speculation finds some support from the observation that oxidizing agents (iodine and air) were found to make the

[1] Only 200 ml of the material from step 2 was treated at a time.

enzyme more heat labile than reducing agents (cysteine and homocysteine). This observation can, however, not be considered to prove the hypothesis as it is open to several objections, and the explanation for the above-mentioned phenomenon will have to await further and more eleborate experiments in which polymer and monomer forms are quantitatively prepared. It should also be mentioned that we have not yet been able to trace the cause of the increase in transmethylase activity of the pig livers between 1958 and 1959. It is possible that dietary factors play a part.*

The purification of betaine-homocysteine-methyl-transferase from pig liver according to alternative 1 (Table 2) has not been repeated as many times as alternative 2 (Table 3). However, when the procedure had been developed, a skilled technician was able to carry out the fractionation with satisfactory results (Table 2) in five consecutive experiments. The purification took four days. By using a fractionation procedure that is different from alternative 1 or 2, we have occassionally obtained reasonably pure transferase preparations in one day, but it has so far not been possible to get reproduceable results with this procedure.

Purity. The purity of transferase preparations obtained as described under Experimental (alternative 1) have been studied using sedimentation, chromatography and electrophoresis. Fig. 1 shows two photographs from a

* We have since learned from Dr. H. Fredholm of the Swedish Federation of Butchers, Stockholm, that the pigs slaughtered in 1959 and 1960 were on the average younger than in previous years.

Table 3. Data compiled from a number of attempts to purify betaine-homocysteine-methyl-transferase according to alternative 2.

Step	Total protein (approx)	Total volume (approx)	Step to step recovery Average ±standard error	Highest and lowest value	Over all recovery (approx)	Over all purification (approx)

[6] Only four runs performed.

sedimentation experiment in a Spinco Model A ultracentrifuge, taken after 32 and 64 min at 59 780 r.p.m. The enzyme was dissolved in a 0.01 M phosphate buffer having a pH of 8.0. The sedimentation constant s_{20} was approximatively 8.5 Svedberg units. Only if DL-homocysteine was added to the transferase solution was a sedimentation pattern with one peak obtained. In the absence of reducing agents, three peaks could be observed. This indicates that betaine-homocysteine-methyl-transferase can exist in monomer and polymer forms and that the ratio of monomer to polymer is influenced by reducing agents, *e.g.* SH-groups. This situation is analogues to the one discovered for thetin homocysteine methylpherase by Durell *et al.*[5,23], and suggests a close similarity between the two enzymes.

Fig. 2 shows the result of a *chromatography* experiment on a preparation of betaine-homocysteine-methyl-transferase using a TEAE column. In this experiment the enzyme was eluted with increasing concentrations of phosphate buffer at pH 8 and a careful analysis was made of the distribution of protein and enzyme in the effluent. It can be seen that the curves for protein content and enzyme activity are symetrical about the same fraction number. The enzyme activity was determined using either betaine or dimethyl-β-pro-

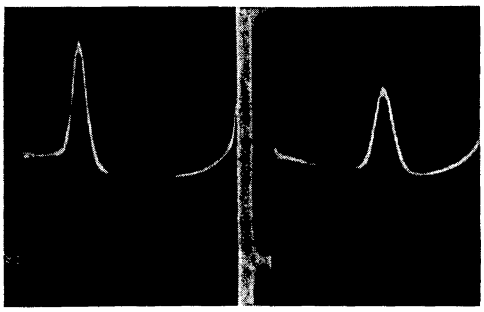

Fig. 1. Sedimentation pattern of purified betaine-homocysteine-methyl-transferase. The pictures were taken after 32 and 64 min at 59 780 r.p.m. in a Spinco Analytical Ultracentrifuge Model E.

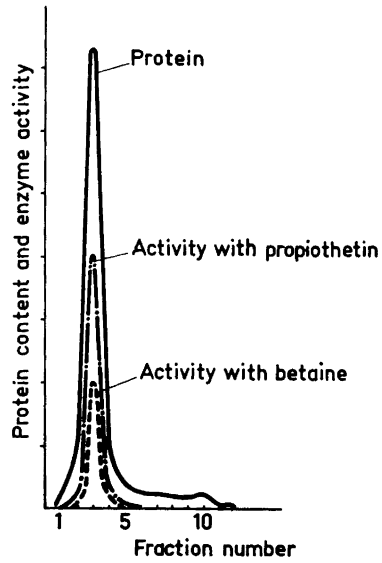

Fig. 2. Chromatography of purified betaine-homocysteine-methyl-transferase on a column of TEAE-cellulose. The units of protein concentration and of enzyme activity (measured either with betaine or dimethyl-β-propiothetin as methyl donor) are arbitrarily chosen to keep the three curves separate from each other.

piothetin as the methyl donor and it is noteworthy that there is no separation of the two activity curves.

In Fig. 3 the *electrophoretic* behaviour of the purified betaine-homocysteine-methyl-transferase is shown. The electrophoresis was carried out in the microcells of a Spinco Model H apparatus. A sodium borate buffer (pH = 9.36, $\mu = 0.1$) containing 1 mg DL-homocysteine per ml was used. Prior to the electrophoresis, the enzyme solution was dialysed against the same buffer, again in the presence of homocysteine.

Figs. 1—3 demonstrate, that although ultracentrifuging, chromatography and electrophoresis revealed minor impurities in the betaine-homocysteine-methyl-transferase purified from pig liver, the transferase protein seemed to dominate according to these criteria of purity.

Molecular weight. An attempt was made to estimate the molecular weight of the transferase monomer using the principle of centrifuging towards sedimentation equilibrium [24]. Calculations at the meniscus and at the cell bottom from a series of concentration gradient patterns, obtained in a run performed in 0.01 M sodium phosphate and at 8 000 r.p.m. in a Spinco Model A ultracentrifuge, gave a mean value of approximatively 270 000.

Absorption spectrum. The light absorption spectrum of a solution of purified betaine-homocysteine-methyl-transferase in a phosphate buffer pH 7.8

Fig. 3. Electrophoresis of purified betaine--homocysteine-methyl-transferase in a sodium borate buffer at pH 9.36, $\mu = 0.1$. The picture was taken after 261 min.

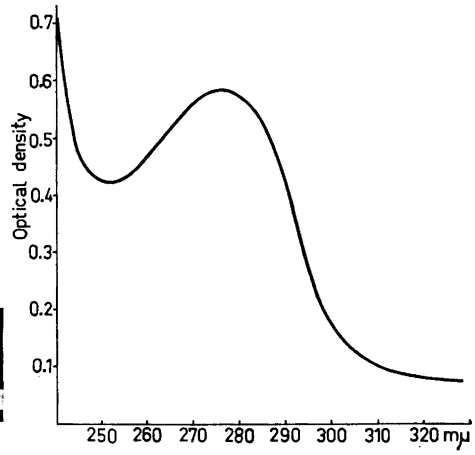

Fig. 4. Light absorption spectrum between 240 and 330 mμ of purified betaine-homocysteine-methyl-transferase.

was determined in a Beckmann Model DU spectrophotometer. The curve shown in Fig. 4 was obtained. This curve, that shows a single absorption peak at 276 mμ, does not suggest the presence of any bound co-factors of, for instance, a vitamin nature. In some preparations a small peak was noticed at 415 mμ. However, we believe that this was caused by an impurity as we have not been able to correlate it with the enzyme activity.

Content of vitamin B_{12}, folic- and folinic acid, and vitamin B_6. Several investigators have noticed that the betaine-homocysteine-methyl-transferase ("betaine-homocysteine-transmethylase") activity is lower in the livers from rats given a diet deficient in vitamin B_{12} than in the livers from normal rats. However, no determination of the vitamin B_{12} content of a purified methyl-transferase has ever been made. A solution of the betaine-homocysteine-methyl-transferase isolated from pig liver was therefore boiled for 10 min. at pH 6.0 in the presence of potassium cyanide in order to release bound vitamin B_{12} from the enzyme. The vitamin B_{12} content of the solution was thereafter determined using the mutant 113—3 of *E. coli* [25] in the medium suggested by Diding [26]. The result of this determination is given in Table 4. It should be mentioned that not only vitamin B_{12} (cyanocobalamin) itself but a large number of vitamin B_{12}-like compounds can support the growth of *E. coli* 113—3. The theoretical content of vitamin B_{12} (and of the other vitamins and growth factors studied, see Table 4) was calculated on the assumption of a one to one relationship between the "co-factor" and the monomer form of the protein moiety and on the basis of a molecular weight of 270 000 for this form of the transferase. It appears unlikely in view of the result of the microbiological assay (Table 4) that vitamin B_{12} or a vitamin B_{12} derivative is present in the betaine-homocysteine-methyl-transferase described here. The fact

Table 4. Calculated and experimentally determined concentrations of microbial growth factors related to vitamin B_{12}, folic- and folinic acid, and vitamin B_6 in solutions of purified betaine-homocysteine-methyl-transferase.

Vitamin or growth factor	Calculated concentration	Experimentally determined concentration

Vitamin B_6	30	< 1.0

* Direct determination.
** Determination after incubation with chicken pancreas conjugase.

that the enzyme is virtually colourless and that its absorption spectrum shows no maximum near 360 mμ also supports this conclusion. The effect of vitamin B_{12} deficiency on the transferase activity must consequently be indirect and is possibly mediated by certain metabolites, which have been shown to affect the enzyme activity *in vitro* [6].

Numerous studies indicate that an intimate relationship exists between the biological function of vitamin B_{12} and of "folic- and folinic acid". An example of this relationship is the series of reactions leading to the *synthesis* of methyl groups, in which both vitamin B_{12} and pteridine co-factors play a rôle. The function of various pteridine derivatives in the transfer of 1-C fragments at the oxidation level of formate or formaldehyde is well established. It was consequently considered of interest to assay the purified betaine-homocysteine-methyl-transferase for microbial growth factors related to folic- and folinic acid, especially in view of the recent findings by Sauberlich, which show a decrease in mouse liver transmethylase activity due to folic acid deficiency[27]. In order to release folic- and folinic acid factors from the enzyme and to obtain microbially active conjugates of these compounds, aliquots of the enzyme solutions were incubated for 20 h at pH 6.8 and 37°C with a chicken pancreas preparation prior to assay. *Streptococcus faecalis* ATCC 8043 and *Pediococcus cereviseae* (*Leuconostoc citrovorum*) ATCC 8081 were used as test organisms in the turbidimetric tube assay media described by Dr. A. Bolinder of this laboratory [28]. Pteroylglutamic acid and N^5-formyl-tetrahydro-pteroylglutamic acid (Leucovorin, Lederle Laboratories Division, Pearl River, N.J., USA) were used as reference substances. As can be seen from Table 4, the transferase could not replace these two substances as a growth factor for *S. faecalis* or *P. cereviseae* either before or after treatment with chicken pancreas. No evidence was thus obtained for the existence of a pteridine-like co-factor in the betaine-homocysteine-methyl-transferase of pig liver.

Fromm and Nordlie have suggested that pyridoxine is a tightly bound co-factor in the thetin homocysteine transmethylase of rat liver [4]. The sugges-

tion was based on the fact that their transmethylase preparations showed flourescence and absorption at 415 mμ. An attempt was therefore made to determine the vitamin B_6 content of the betaine-homocysteine-methyl-transferase of pig liver. A tube assay with *E. coli* 154—59L [29] was used[30]. This organism responds well to pyridoxine, pyridoxal and to a lesser degree also to pyridoxamine. The vitamin B_6 was released from the enzyme by boiling a solution of the transferase at pH 1.0 for 30 min or by autoclaving at pH 1.7 for 60 min. It was not possible to detect any compound in the enzyme solutions treated in this way that could support the growth of *E. coli* 154—59L (Table 4). In a separate experiment it was also shown that the acid treated transferase failed to stimulate the growth of the B_6-requiring *Saccharomyces carlsbergensis* [31]. As we have only occassionally been able to find an absorption maximum at 415 mμ in our transferase preparations (see above) our data do not provide any evidence for the participation of vitamin B_6 in this type of methyl group transfer. Ericson and Harper have previously shown that a vitamin B_6 deficiency does not decrease the transferase activity of rat liver[8].

Dependance on metals. Two solutions of purified betaine-homocysteine-methyl-transferase were dialysed at 2°C for 50 h, one solution against 0.025 M phosphate buffer pH 8.0, the other against 0.025 M phosphate buffer pH 8.0 containing 2×10^{-3} M EDTA (ethylenediamine tetraacetic acid). There was only a slight decrease but no difference in the transferase activity of these two enzyme solutions after the dialysis, which indicates that the activity is not dependent on bound metals. In other experiments it was found that the addition of potassium cyanide, sodium citrate, sodium pyrophosphate or 8-hydroxyquinoline to the incubation mixtures had no effect on the transferase activity. This is in accordance with the results from similar studies with the methyl transferases purified from rat [2,32] and horse liver [5]. Microbial transferases, on the other hand, appear to be metalloenzymes [33].

Activators and inhibitors. Although no evidence was found for the presence of bound co-factors in the betaine-homocysteine-methyl-transferase described in this communication, it can be shown that the activity of the enzyme is greatly influenced by a number compounds, *e.g.* organic acids, amino acids and peptides [6]. This phenomenon will not be further elaborated upon here, but the author hopes to return to the problem of activation and inhibition in connection with a study of some kinetic properties of the enzyme.

Apparent pH-optimum. Incubation mixtures containing betaine-homocysteine-methyl-transferase, betaine and DL-homocysteine in phosphate buffer were adjusted at 0°C to pH-values ranging from approximatively 5.5 to 9.5. They were thereafter kept at 37°C for 3 h whereupon their methionine content was determined. When the activity of the enzyme was plotted against the pH a curve of the type shown in Fig. 5 was obtained. This indicates that the apparent pH-optimum of the pig liver transferase is near 7.5. It should be mentioned that the apparent pH-optimum — as would be expected — is influenced by a number of factors, *e.g.* the type of buffer, the concentration of the components of the incubation mixture, *etc.*

Stoichiometry of the reaction. To study the stoichiometry of the reaction, betaine containing ^{14}C in one of the N-methyl groups was used. This compound was synthesized from dimethylglycine and ^{14}C-methyl iodide (Radio-

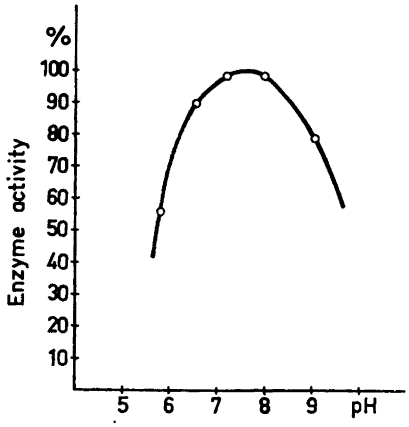

Fig. 5. The apparent pH-optimum of purified betaine-homocysteine-methyl-transferase.

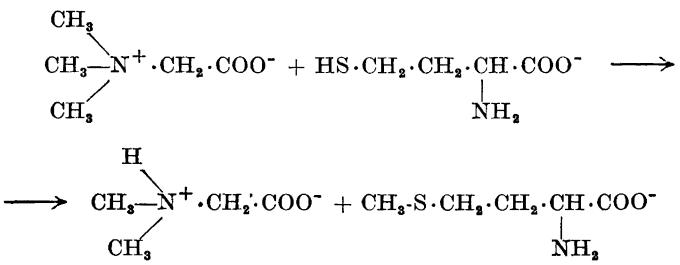
chemical Center, Amersham, England). Carrier betaine was added to make possible crystallization of the product.

The ^{14}C-methyl betaine was incubated overnight together with the enzyme and an excess of DL-homocysteine at 37°C and pH 7.8. The reaction was terminated by boiling and the mixture clarified by centrifuging. The supernatant fluid was chromatographed in a solvent system containing methyl ethyl ketone: acetone: NH_3 (ca. 35 %) at a ratio of 60:27:13 for 30 h at 22°C. After drying, the radioactivity along the chromatogram was measured using a Tracerlab TGC2 Geiger-Müller tube and a LKB Scaler Type Nr 117. At the areas where betaine, dimethylglycine and methionine were located on the chromatogram the following net counts per minute were found in two separate experiments:

	betaine	dimethylglycine	methionine
Expt. 1	204	90	44
Expt. 2	360	180	89

These results show that the radioactivity in counts per min. was twice as high for dimethylglycine (that contains two methyl groups) as for methionine (that contains one methyl group). This suggests that for each molecule of dimethylglycine, one molecule of methionine is formed and that the reaction takes place according to the over all scheme:



At the apparent pH-optimum of the reaction, dimethylglycine exists mainly in the "zwitterion" form shown above, as indicated by the pK_a and pK_b values determined by Bjerrum [34]. Only insignificant amounts of H_3O^+-ions therefore result from this reaction in contrast to the reaction in which a thetin serves as the donor of the methyl group [3,5].

An attempt was also made to determine whether the transferase reaction is reversible or not. L-Methionine containing ^{14}C in the methyl group (Radiochemical Center, Amersham, England), dimethylglycine and the transferase were incubated for several hours at 37°C and the reaction mixture was thereafter boiled, centrifuged and chromatographed. It was not possible to detect any radioactivity at the site of betaine on the chromatogram.

The skilled technical assistance of Miss I. Frölich is gratefully acknowledged. The author would also like to thank Drs. A. Hedbom and S. Åkesson most sincerely for their help with the ultracentrifugal and electrophoretic experiments. Financial support was provided by the *Medical Research Council* and the *Knut och Alice Wallenberg Foundation*.

Betaine-Homocysteine-Methyl-Transferases

III. The Methyl Donor Specificity of the Transferase Isolated from Pig Liver

L.-E. ERICSON

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Studies have been made on the specificity of the methyl donor requirement of a betaine-homocysteine-methyl-transferase purified from pig liver. It was found that a number of betaine derivatives and sulfonium compounds could replace betaine as methyl donor. No evidence was obtained for ethyl group transfer.

Many of the ammonium compounds tested as methyl donors interfered with the utilization of betaine, and betaine itself decreased the rate of methyl transfer from certain sulfonium compounds.

The data presented are tentatively interpreted and discussed.

In a previous communication [1] methods were reported for the preparation of a purified betaine-homocysteine-methyl-transferase from pig liver. It is the purpose of this article to describe some studies on the specificity of the methyl donor requirement of this enzyme preparation. The problem has already been discussed briefly in two earlier papers from this laboratory [2,3], and has been investigated also by other research groups [4,5].

The ability of the substances tested as methyl donors to compete with betaine (carboxymethyl-trimethyl-ammonium chloride) for the active donor site on the transferase was also studied in the investigation reported here.

EXPERIMENTAL

The enzyme preparation used in the experiments described below, was obtained from pig liver by the method given in Ref.[1] (alternative 1). As judged from electrophoretic and ultracentrifuge studies the transferase contributed approximatively 90 % of the total protein of the preparation. The protein content of the incubation mixtures was determined using the method suggested by Kalckar [6]. Enzyme activity was measured as the amount of methionine formed per hour during the initial phase of the reaction when the amount of dimethylglycine was small. The incubations were carried out aerobically at 37°C.

Methionine was determined microbiologically according to Steele *et al.*[7] The nitroprusside method [8] was found unsuitable for this purpose as many of the compounds tested

interfered with the colour formation. Ethionine, however, was measured chemically by determining the optical density at 520 mμ of the nitroprusside reaction product.

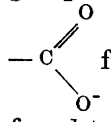
Of the compounds tested as methyl donors betaine, choline, dimethylglycine, acetyl choline, dimethyl-β-propiothetin, trimethylamine hydrochloride, methyl methionine sulfonium chloride, ergothioneine · HCl, and S-adenosyl methionine iodide were commercial products purchased from California Corporation for Biochemical Research, Cal., USA; L. Light & Co., England; Fluka AG, Switzerland, and Nutritionals Biochemicals Corporation, Ohio, USA. Betaine aldehyde; DL-carnitine, O-acetyl-DL-carnitine; muscarine iodide; N-trimethyl taurine; dimethyl acetothetin and trimethylsulfonium chloride were kindly supplied by Drs. D. R. Strength, S:t Louis University School of Medicine, USA; G. S. Fraenkel, University of Illinois, USA; F. Hoffman-La Roche & Co, Switzerland; D. Ackermann, University of Würzburg, Germany; F. Challenger, University of Leeds, England and G. A. Maw, A. Guinness, Son & Co, Ltd., Dublin, Eire.

The methyl and ethyl esters of betaine were synthesized from the methyl and ethyl esters of bromoacetic acid and trimethylamine [9]. The betaine amide was prepared from chloroacetamide and trimethylamine [9]. The nitrile corresponding to betaine was obtained by reacting dimethyl-amino-acetonitrile prepared according to von Braun [10] with methyl iodide. The betaine-like compounds that are formed when one, two or all three of the N-methyl groups are replaced by ethyl groups were prepared *via* dimethyl- or diethyl-amino-acetonitrile [10] and ethyl bromide or methyl iodide [11]. The nitriles were converted to the corresponding betaines according to Klages and Margolinsky [12]. The α-methyl betaine was synthesized by N-methylation of α-alanine with methyl iodide [11]. Propiobetaine was obtained from trimethylamine and propionic acid lactone [13] and butyrobetaine from α-amino buturic acid and methyl iodide [14]. All the compounds synthesized in the laboratory were recrystallized to constant melting points.

RESULTS AND DISCUSSION

It is obvious from the results presented in Tables 1 and 2 that the betaine-homocysteine-methyl-transferase of pig liver can use a variety of compounds as methyl group donors. However, neither choline nor betaine aldehyde can replace betaine in this function (Table 1). The methyl and ethyl esters of betaine, on the other hand, are excellent donors of methyl groups, being equally potent in this respect as betaine itself. This was found to be the case over a wide range of concentrations. It is of interest to notice in this connection the complete lack of donor activity of the betaine amide.

The "betaine nitrile" seems to possess some ability to donate methyl groups with the enzyme preparation used. This would suggest that the



function, present in all the other compounds in Table 1 that were found to act as methyl donors, is not essential for donor activity.

If one of the three N-methyl groups of betaine is replaced by an ethyl groups, a compound is formed that has a methyl donor activity that is only 30 % of that of betaine. Replacement of two of the N-methyl groups by ethyl group lowers the donor activity to 6 %. Ethyl groups cannot apparently be handled by the enzyme, since no ethionine could be detected in incubation mixtures containing betaine derivatives in which one, two or all three of the N-methyl groups had been replaced by ethyl groups. Attempts to detect ethionine were made either by the nitroprusside method or by paper chromatography. It is of course possible that the amount of ethionine formed was too small to be detected by these methods.

Table 1. The ability of some nitrogenous compounds that are structurally related to betaine to serve as donors of methyl groups using a preparation of betaine-homocysteine-methyl-transferase. The enzyme activity is also given for incubation mixtures containing both the compound and betaine at the concentration ratio of 2:1. All incubation mixtures contained 0.025 M DL-homocysteine and approximatively 0.2 mg protein per ml. Anions are omitted in the formulae.

* When tested at a concentration of 0.01 M together with 0.05 M betaine the relative activity was 77 %.

In connection with a discussion on N-substituted betaines it is relevant to draw attention to the fact that dimethylglycine, which at the pH tested can be considered as a betaine molecule in which one of the N-methyl groups has been replaced by a hydrogen atom [15], cannot act as a donor of methyl groups although its affinity to the active center on the enzyme appears to be considerable.

With the purified betaine-homocysteine-methyl-transferase used in the present study, α-methyl betaine showed 13 % donor activity. The decrease in activity caused by the introduction of the α-methyl group in betaine is probably to a large extent due to steric hindrance. With a crude methyl-transferase from *Anodonta cygnea* the α-methyl betaine was found to have 45 % of the donor activity of betaine [3]. The reason for this discrepancy between the two enzyme preparations is not known. It is possible that the betaine-homocysteine-methyl-transferase of *Anodonta cygnea* has a different steric configuration around its active donor site than the betaine-homocysteine-methyl-transferase of pig liver. It is also conceivable that *Anodonta* liver contains more than one transferase. The difference between the results with the two enzyme preparations may of course be caused by the different degree of saturation at which the substrates were tested with the two transferases.

The latter explanation seems less plausible, however, as it has not been possible to increase appreciably the relative activity of α-methyl betaine for the transferase of pig liver by increasing its concentration in the incubation mixture several times above that used in Table 1.

Ergothioneine which has a larger substituent than the methyl radical in the α-position, can apparently not donate its methyl groups under the conditions of the test. It is of interest to notice, however, that ergothioneine is a very potent methyl-transferase inhibitor.

The length of the carbon chain of the ammonium compounds tested is obviously of vital importance for determining the ability to serve as a donor of methyl groups. Propiobetaine, butyrobetaine, carnitine and O-acetylcarnitine were all found to be completely inactive (Table 1). This is in contrast to the results obtained with the sulfonium compounds (Table 2). Not only dimethyl-acetothetin but also dimethyl-β-propiothetin and methyl methionine sulfonium chloride are excellent methyl group donors. Also the difference in behaviour of trimethyl ammonium chloride and trimethyl sulfonium chloride should be noted; the latter but not the former is able to act as methyl group donor.

Only a qualitative comparison can be made between the results reported here and those of other investigators. There is as far as this comparison is

Table 2. The ability of some sulfonium compounds to serve as donors of methyl groups using a preparation of betaine-homocysteine-methyl-transferase. The enzyme activity is also given for incubation mixtures containing both the test compound and betaine at the concentration ratios shown in the table. * Tested at a concentration of 0.005 M.

possible, a general agreement between the methyl donor specificity of the horse liver thetin homocysteine methylpherase of Durell *et al.*[4], the rat liver thetin homocysteine transmethylase of Maw [5], the betaine-homocysteine-methyl-transferase from *Anodonta cygnea* [3] and the methyl transferase purified from pig liver. However, S-adenosyl-methionine was reported to be unable to donate its methyl group using the enzyme isolated from horse liver by Durell *et al.*[4] whereas this compound was found to possess donor activity with our pig liver transferase. Sufficient material has not been available to investigate further the reason for this difference in results. It should be mentioned that the S-adenosyl-methionine used by Durell *et al.*[4] was prepared by them, whereas the compound used in our studies was of commercial origin (California Corporation for Biochemical Research, Cal., USA). Shapiro [16,17] found that S-adenosyl-methionine prepared from yeast cells could donate its methyl group to homocysteine in cell free extracts from both rat liver and from some microorganisms.

Many betaine-like compounds that are not themselves methyl donors have the ability to inhibit the transfer of a methyl group from betaine to homocysteine (Table 1). This is for instance the case with dimethylglycine, betaine aldehyde, betaine amide, "triethyl betaine", propiobetaine, DL-carnitine, O-acetyl-DL-carnitine, ergothioneine, and muscarine [18]. The inhibition is most likely caused by competition between the inactive ammonium compounds and betaine for the active donor site on the transferase. Such a competition is probably also the reason for the decrease in transmethylase activity caused by some of the less potent methyl donors listed in Table 1, *e.g.* betaine nitrile, "mono- and diethylbetaine" and α-methyl betaine. The phenomenon is apparent also from the data in Table 2, where it is shown that betaine, which is less potent as a methyl donor than dimethyl-acetothetin, dimethyl-β-propiothetin, methyl methionine sulfonium chloride or trimethyl sulfonium chloride can markedly interfere with the methyl transfer from the latter compounds. In a previous communication from this laboratory [2] it was reported that all attempts have failed to separate the transferase that uses betaine as the methyl donor from a transferase that uses thetins. It was also observed at that time, that the conditions that altered the rate of transmethylation from betaine to homocysteine also altered in a similar manner the transfer of methyl groups from dimethyl-β-propiothetin to homocysteine [2]. All data accumulated so far therefore indicate that betaine and the thetins are bound to the same active center on the enzyme. However, further studies are necessary to prove conclusively that this is the case.

It appears likely from the observations presented in Table 1 that methyl donors of the ammonium type have to be bound at two (or more) points to the enzyme surface before they can perform their function.

It should be emphasized that the investigation described in this paper must be considered as being of an exploratory nature only. For a correct interpretation of the observations, the studies should be extended over a greater number of compounds. It is also necessary that the tests be performed under a variety of conditions to make possible kinetic evaluation of the data.

The author is indebted to Mr. Nils Walde and Miss I. Frölich for assistance and to Drs. D. Ackermann, F. Challenger, G. S. Fraenkel, G. A. Maw and D. R. Strength as well as F. Hoffman-La Roche & Co. for gifts of some of the compounds tested. He would also like to thank the *Medical Research Council* and the *Knut and Alice Wallenberg Foundation* for financial support.

Investigations on the Molecular Weight of Aqueous Solutions of Potato Amylose by Osmotic Pressure

B. B. JØRGENSEN and O. B. JØRGENSEN

*Department of Technical Biochemistry, Royal Technical University, Copenhagen *, and the University Institute of Physical Chemistry, Copenhagen, Denmark*

The colloid osmotic pressure of aqueous amylose solutions is measured. In concentrations of 0.2–0.6 % amylose the reduced osmotic pressure, p/c, is constant within the experimental error. The influence of heating in alkaline solution on the osmotic pressure and viscosity of amylose solutions is examined. The osmotic pressure of the potato amylose examined corresponds to a molecular weight $\sim 2.02-2.10 \times 10^5$ and to a D.P. $\sim 1\,250-1\,300$.

On account of the difficulties in making stable aqueous solutions of amylose most of the physical determinations of molecular weight of amylose are performed on amylose derivatives in a suitable solvent. Reviews on this subject are given by Greenwood [1] and Whelan [2].

By means of the inverted microosmometer described by Christiansen and Jensen [3] it is possible to measure small osmotic pressures in rather short times. The purpose of this investigation is to examine the possibility of measuring the osmotic pressure of aqueous solutions of amylose by means of the inverted microosmometer before retrogradation of amylose takes place. As the amylose was brought in solution in alkali it was necessary to examine how alkali treatment influenced the osmotic pressure of the amylose solution.

EXPERIMENTAL

Amylose. The amylose examined was prepared from potato starch by precipitation with thymol after the precipitation of the amylopectin as described by Hobson *et al.*[4] The amylose showed a "blue value" = 1.38.

Amylose solution. The amylose solutions were prepared by dissolving a suitable amount of amylose in 0.4 N KOH by shaking for 1 ½ h and filtering through a G4 sintered-glass filter. The solutions were then heated the time wanted (0–16 min) in a boiling water bath. During the shaking and heating the amylose solutions were protected against oxygen by an atmosphere of nitrogen. After the heating the solutions were cooled in running tap water. Immediately before the osmotic measurements a suitable volume of the solutions was neutralized with 0.4 N HCl and eventually diluted with 0.2 M KCl.

* Address: Odensegade 14, Copenhagen Ø.

The exact concentrations of amylose in the solutions were determined by acid hydrolysis according to Pirt and Whelan [5] followed by determination of glucose by the method of Somogyi [6] and Nelson [7].

Osmotic pressure measurements. The colloid osmotic pressures were measured by means of the inverted microosmometer described by Christiansen and Jensen [3]. The semipermeable membranes were prepared as described by Jensen and Marcker [8]. On account of the instability of neutral amylose solutions the measurements were started immediately after the equilibrium was established. The measurements were performed at 21°C. The outer liquid in the osmometer was 0.2 M KCl.

Viscosity measurements. The specific viscosities of the amylose solutions were measured at 25°C in an Ostwald viscosimeter. The measurements of the viscosity were made on the same alkaline solutions as were used for the osmotic measurements (heated different times) after dilution 1:10 with water.

RESULTS

Molecular weight calculations from osmotic pressures were made by means of the equation: $M = k\frac{c}{p}$, where c = concentration of amylose in g/ml and p = osmotic pressure in cm water column. At 21°C the value of k is 247.6×10^5 (Christiansen and Jensen [3]). D.P. = $M/162$.

It was examined how increasing heating times of the alkaline amylose solution influenced the osmotic pressure and the specific viscosity of the amylose solution, see Fig. 1.

Fig. 1 shows that the apparent D.P. obtains a rather constant value after heating of the amylose solution for about 5 min and only decreases slightly for longer heating times.

It is further seen from Fig. 1 that the specific viscosity of the solution, which was used for osmotic measurements but not neutralized after dilution

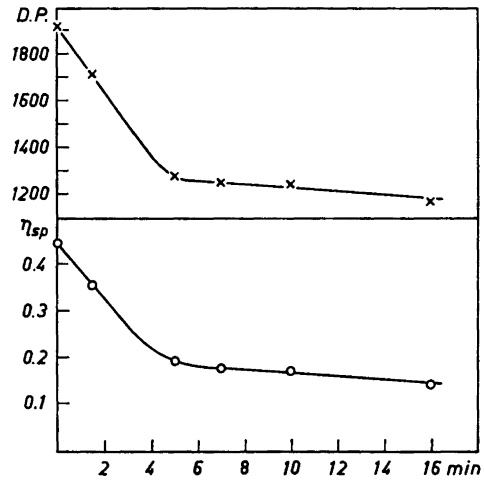

Fig. 1. The graph shows the relation between apparent D.P. and time of heating, t, of amylose in 0.4 N KOH, $c = 4.28 \times 10^{-3}$ g/ml after neutralisation, × — × — ×, and the relation between specific viscosity, η_{sp}, and time of heating of amylose in 0.4 N KOH, $c = 0.43 \times 10^{-3}$ g/ml 0.04 N KOH, ⊙—⊙—⊙.

Table 1. Experiments I—IV show the osmotic pressure of different dilutions of an amylose solution. Experiment V shows the osmotic pressure of the same amylose preparation but in another solution and with another membrane. Experiments VI and VII show the osmotic pressure of another preparation with a known D.P.
c is concentration of amylose in the neutral solution, p is osmotic pressure in cm water column, M is molecular weight and D.P. is degree of polymerisation.

Exp.	$c \times 10^3$ g/ml	p cm	p/c	$M \times 10^{-5}$	D.P.
I	2.15	0.30	140	1.77	1 090
II	2.86	0.41	143	1.73	1 070
III	4.29	0.60	140	1.77	1 090
IV	5.73	0.80	140	1.77	1 090
V	5.02	0.69	137	1.81	1 120
VI	5.14	0.62	121	2.05	1 270
VII	4.96	0.60	121	2.05	1 270

1:10 with water, shows a quite analogous variation. It was further found that η_{sp}/c was independent of c ($c \leq 0.43 \times 10^{-3}$ g/ml), the amylose concentration, by further dilution both in heated and in unheated solutions.

These results seem to show that it is necessary to heat the alkaline amylose solutions at least for 5 min before the osmotic pressure and the viscosity of the solutions are well defined.

It was examined if the proportion p/c, the so-called reduced osmotic pressure, was dependent on the concentration.

In Table 1 are shown the results of these measurements. The alkaline amylose solution was heated for 5 min (these experiments were performed without protection by N_2), and the concentration was varied from 0.215 % to 0.573 % by dilution (Expts. I—IV). It is seen from the table that p/c does not change with concentration in the range of concentration examined; accordingly the molecular weight can be calculated directly from p/c without extrapolating to $c = 0$. This means that the second virial coefficient is negligible at 21 °C in agreement with the light scattering measurements by Everett and Foster [11].

Experiment V, Table 1, shows an experiment, where the osmotic pressure of another solution of the same preparation is measured with another membrane than in experiments I—IV. It is seen that the measurements are reproducible.

The osmotic pressure was then determined of an amylose preparation, that kindly was placed at our disposal by dr. W. J. Whelan, and the D.P. of which was determined by dr. Whelan by periodate oxidation to 1 250. Our results of two independent measurements of the osmotic pressure (without use of N_2) are given as experiments VI and VII in Table 1.

DISCUSSION

It is seen from the reproducibility of the measurements that it is possible, with the technique used, to measure the osmotic pressure of neutral amylose solutions, before the amylose retrogrades.

Fig. 1 shows that the apparent D.P. falls very fast with the time of heating in alkali for the first short heating period, while further fall in apparent D.P.

for heating times longer than 5 min is very slight. As the amylose solutions were protected against oxygen by an atmosphere of nitrogen this effect is hardly due to oxidation. The slow fall for heating times longer than 5 min is possibly due to an alkaline degradation of amylose. The fast fall for shorter heating times may be due to another effect. Either the amylose contains a few very alkali-labile bonds — having eventually been introduced into the amylose during the preparation (Baum and Gilbert [9]) — or the heating in alkali causes a disaggregation of the associated amylose molecules, the amylose only being of molecular form after a heating time of about 5 min. Paschall and Foster [10] have shown that amylose disaggregates by standing in 1 N KOH at room temperature, but this effect is not pronounced for potato amylose. As the potato amylose in our examinations has been heated in alkali it is possible that the phenomenon may be explained as a disaggregation of the amylose.

The most well-defined molecular weight of amylose is found after a heating time of about 5—10 min in 0.4 N KOH under N_2. It is seen from Fig. 1 that D.P. of the amylose preparation examined under these conditions is about 1 250. Extrapolating to a heating time of 0 min a D.P. of about 1 300 is found.

Acknowledgements. We are gratefully indebted to Professor Holger Jørgensen for his interest of this work and to Professor J. A. Christiansen and the late Dr. C. E. Jensen, the University Institute of Physical Chemistry, Copenhagen, for their help in the performance of the osmotic measurements. Financial support from *Det teknisk-videnskabelige Forskningsråd* is gratefully acknowledged.

The Conformational Analysis of *cis*-1,4-Chlorobromo*cyclo*hexane

V. A. ATKINSON and K. LUNDE

Universitetets Kjemiske Institutt, Blindern — Oslo, Norway

Cis-1,4-chlorobromo*cyclo*hexane has been studied in the gaseous state by electron diffraction, and in the liquid and solid states by infra-red spectroscopy. The results show that the compound is all, or nearly all, in the *e*-chloro *a*-bromo conformation.

Some years ago it was found that when crystals of 1*e*,2*e*-dichloro-4*e*,5*e*-dibromo*cyclo*hexane were heated to the melting point they isomerized, and that when the melt cooled it consisted mainly of the 1*e*,2*e*-dichloro-4*a*,5*a*-dibromo isomer [1]. More surprising was the fact that neither infra-red [2] nor electron diffraction [3] investigations were able to establish the expected conformational equilibrium (*ee*Cl_2-*aa*Br_2 ⇌ *aa*Cl_2-*ee*Br_2) between the free molecules of this isomer. The only conformation detectable by both methods was that established by X-ray investigations [4] to exist in the crystal, *viz.* the conformation where the two bromine atoms occupy equatorial positions. These findings were hard to explain by simple steric considerations.

It is true that Kozima and Sakashita [5] did claim to have detected evidence of an equilibrium between the two possible conformations of this compound. However, their infra-red investigation used the KBr-disc method, with high temperatures. These are conditions which are more likely to facilitate an S_N2 reaction (such as the reversal of the isomerization [1]: *ee*Cl_2—*ee*Br_2 ⇌ *aa*Cl_2—*ee*Br_2) than the claimed shift in the conformational equilibrium.

In the circumstances, it seemed worthwhile to investigate another compound which might be expected to have a similar conformational oddity. We chose *cis*-1,4-chlorobromo*cyclo*hexane, which might exist as either of the two conformations shown in Fig. 1, or as a conformational equilibrium between them. To the best of our knowledge this compound has not been described before.

PREPARATION

During the preparation of the *trans*-1,4-chlorobromo*cyclo*-hexane from 4-chloro*cyclo*-hexanol and phosphorus tribromide, an oily fraction boiling between 62°C and 64°C (0.5 mm) was collected [6]. This fraction contains both isomers of 1,4-chlorobromo*cyclo*-hexane. Most of the *trans* isomer was precipitated upon cooling to 5°C. The cooling and

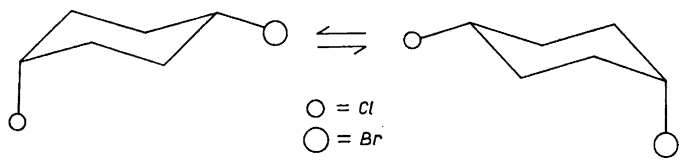

Fig. 1. The possible conformational equilibrium.

filtration was continued until no further crystals formed. Then the filtrate was distilled *in vacuo* in a spinning band column equivalent to 25 theoretical plates. After an appreciable forerun (presumably the remains of the *trans* compound, boiling at about 90°C, 11 mm), a fraction boiling constantly at 97°C (11 mm) was collected. The 97°C fraction solidified on being kept in a refrigerator for some time, and melted again at 21° to 21.5°C. Re-distillation yielded pure *cis*-1,4-chlorobromo*cyclo*hexane with a melting point of 22.0°C.

ELECTRON DIFFRACTION

The electron-diffraction measurements were carried out in the gas phase using the new Oslo apparatus [7] with distances of 19 and 48 cm between the nozzle and the photographic plates. The experimental intensity data, extending from $s = 1.5$ to $s = 45.0$, were treated in the manner described in a series of papers from this institute published after 1955. After appropriate corrections and the inclusion of a damping factor of 0.0024, the experimental intensity curve shown in Fig. 2 was obtained. This was subjected to a Fourier transform to give an initial $\sigma(r)/r$ radial ditribution curve which had substantially the same form as that shown in Fig. 3a.

Theoretical $\sigma(r)/r$ curves (Fig. 3b) were built up from Gauss curves for each of the two possible conformations. The internuclear distances in the two conformations were calculated from models in which the bond distances were: C—H = 1.074, C—C = 1.529, C—Cl = 1.824 and C—Br = 1.981 Å (obtained from the initial radial distribution curve), and the bond angles were C—C—C = 111.5°, C—C—X = 110.0° and X—C—X = 108.7° (obtained from the latest figures for *cyclo*hexane [8]). The models also included a slight distortion of the axial carbon-halogen bonds, suggested by previous work on related compounds [9]. The carbon-chlorine bond was bent outwards 6.3° from the axial position in the *a*-chloro *e*-bromo model, and the carbon-bromine bond was bent outwards 7.7° from the axial position in the *e*-chloro *a*-bromo model.

The two theoretical radial distribution curves were then Fourier transformed back to give two theoretical intensity curves directly comparable with the experimental intensity curve of Fig. 2. It can be seen at once that the theoretical intensity curve for the *e*-chloro *a*-bromo conformation gives the better agreement with the experimental curve. However, this does not eliminate the possibility that both conformations are present together, so a number of composite theoretical intensity curves were also calculated. The values of the dispersion of the standard error between these curves and the experimental intensity curve are given in Table 1. The steady decrease in the standard error as we proceed from 100 % *a*-chloro *e*-bromo to 100 % *e*-

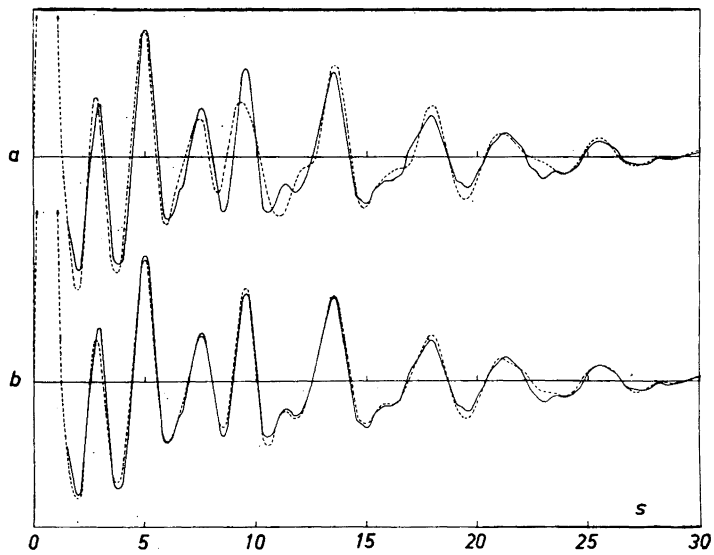

Fig. 2. The experimental intensity curve (full line) compared with the theoretical intensity curves (broken lines) for (a) 1*a*-chloro-4*e*-bromo*cyclo*hexane and (b) 1*e*-chloro-4*a*-bromo*cyclo*hexane. The heavily damped data for $s > 30$ has been omitted so that the figure should still be reasonably distinct after reduction.

chloro *a*-bromo shows that the compound must be all, or nearly all, in the latter conformation.

A final "experimental" radial distribution curve (Fig. 3a) was prepared using the experimental intensity data from $s = 1.5$ to $s = 45.0$, and theoretical intensity data from the *e*-chloro *a*-bromo curve for the experimentally unobtainable inner part from $s = 0$ to $s = 1.5$. It can be seen at once that this final $\sigma(r)/r$ curve agrees well with the theoretical curve for the *e*-chloro *a*-bromo conformation. The dispersion of the standard deviation in that part of the radial distribution curve of relevance for structural assessments ($r > 0.8$ Å) was found to be $\pm$ 8 %.

It is not easy to assess the accuracy of this conformational analysis. While electron diffraction is nowadays very useful in cases where two conformations are present in quantity, it is not very well adapted to the detection of a con-

formation present as a trace. A small quantity of the undetected conformation might easily be masked by the major component. However, we feel safe to conclude from this part of the work, that *at least* 90 % of the substance is in the *e*-chloro *a*-bromo form in the gaseous state. This means that the energy difference between the two conformations must exceed 1.2 kcal/mole.

INFRA-RED SPECTRA

The spectra were recorded on a Perkin-Elmer model 21 spectrometer using a sodium chloride cell which permitted work at high and low temperatures. The vapour pressure of *cis*-1,4-chlorobromo*cyclo*hexane is not high enough to give a satisfactory recording of the spectrum of the gas in a 1 m cell, so only the liquid and solid states could be investigated. No solvents were used. The liquid was pure, and crystallisation of the solid was always confirmed by inspection in polarised light.

Typical spectra of the liquid and solid states are reproduced in Fig. 4. It can be seen that the spectra are practically identical, and contain only such minor variations as might be expected as the effect on the vibrations of the changes of state and temperature. Other spectra, taken of samples with

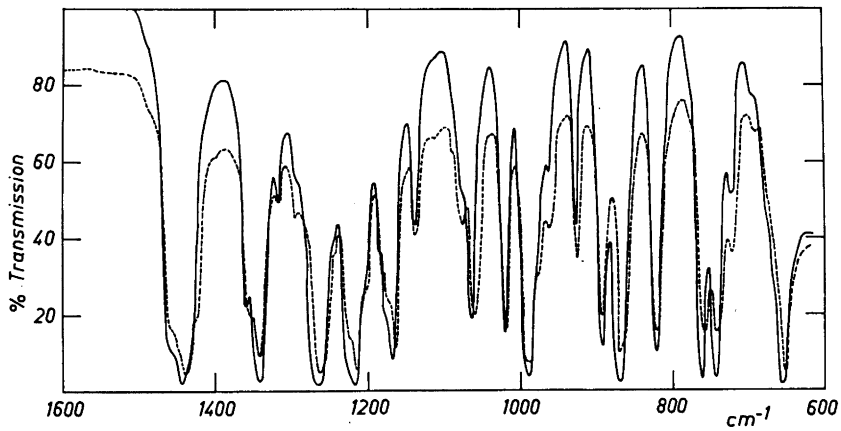

Fig. 4. Infrared spectra of *cis*-1,4-chlorobromo*cyclo*hexane: ———— liquid, at about 30°C; — — — — solid, at about 0°C.

different solidification times and recorded at temperatures down to —170°C, also show little or no variation in the relative intensities and positions of the spectral bands.

The probability of a simultaneous crystallisation of the two conformations, or an unchanging ratio between these conformations under various conditions of temperature and state, must be very low, for this would require not only similar melting points for the two conformations, but also identical lattice packing forces and even identical energy contents for the free molecules.

We therefore conclude that there is only one detectable conformation present in *cis*-1,4-chlorobromo*cyclo*hexane in both the liquid and solid states. This view is supported by our spectral assignments in the carbon-halogen stretching region.

In this region there are strong bands at 743 and 654 cm^{-1}, a weak band at 722 cm^{-1} and an inflection at about 690 cm^{-1}.

Previous work with monohalogeno-*cyclo*hexanes [10], *trans*-1,2-dihalogeno-*cyclo*hexanes [11], *cis*-1,4-dihalogeno-*cyclo*hexanes and the mono-conformational [12] crystals of *trans*-1,4-dihalogeno*cyclo*hexanes, has shown that the different carbon-halogen stretching vibrations are represented by bands which are always found within a few cm^{-1} of the following average frequencies:

C—Cl_e	740 cm^{-1}
C—Cl_a	685 cm^{-1}
C—Br_e	685 cm^{-1}
C—Br_a	655 cm^{-1}

The main bands of the *cis*-1,4-chlorobromo*cyclo*hexane in this region must therefor be assigned to the C—Cl_e and C—Br_a stretching vibrations, and it must be concluded that the compound exists mainly in the *e*-chloro *a*-bromo conformation in the solid and liquid states.

The inflection at 690 cm^{-1} could be assigned to the C—Cl_a and/or C—Br_e vibrations. However, it persists unchanged under all recording conditions,

and must therefore be regarded as doubtful evidence of a possible conformational equilibrium. Even if this inflection is taken as evidence of the existence of an *a*-chloro *e*-bromo form, it could hardly represent more than about 2 % of an equilibrium mixture. This would put the energy difference between the two forms up to at least 2.3 kcal/mole.

DISCUSSION

Only the *e*-chloro *a*-bromo conformation of *cis*-1,4-chlorobromo-*cyclo*hexane has been detected in the gas, liquid and solid states. The infra-red part of this investigation, which is better suited to the detection of traces of the other possible conformation, shows that if this form is present it must be less than 2 % of the whole.

The conclusion must therefore be either (a) there is a conformational equilibrium, but the *e*-chloro *a*-bromo form predominates overwhelmingly and the energy difference between the two forms exceeds 2.3 kcal/mole, or (b) there is no conformational equilibrium, no ring inversion, and the only form produced by our preparative route is the *e*-chloro *a*-bromo conformation. If the latter case is true, it may be that of the disubstituted *cyclo*hexanes only the *ee* forms can invert their rings. In this connection it is interesting to note that a systematic difference has recently been discovered between the proton magnetic resonance spectra of *ee* and *ea* disubstituted *cyclo*hexanes [13].

The preference for the *e*-chloro *a*-bromo conformation, rather than the other possibility, can not be explained on steric grounds. If steric forces were the only ones concerned, we would expect the bulkier bromine atom to prefer the more open equatorial position, as it seems to do in 1,2-dichloro-4,5 dibromo-*cyclo*hexane [2-4]. However, *cis*-1,4-bromomethyl*cyclo*hexane [14] provides another case where bromine is reported to be mainly in the sterically less-favoured axial position.

The authors are grateful to A. Almenningen who kindly made the electron diffraction plates, and to *Norges Teknisk-Naturvitenskapelige Forskningsråd* for a post-doctorate fellowship (to V.A.A.).

The Crystal Structure of the 1:1 Addition Compound Formed by Benzyl Sulphide and Iodine

CHR. RØMMING

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The crystal structure of a compound containing 1 molecule of benzyl sulphide and 1 molecule of iodine has been determined. The space group is *Pnma* with four molecules of $(C_6H_5CH_2)_2S \cdot I_2$ in the unit cell, the dimensions of which are: a = 9.86 Å; b = 16.86 Å; c = 9.36 Å. The investigation reveals a linear sulphur-iodine-iodine arrangement with the observed bond distances 2.78 Å for S-I and 2.82 Å for I-I.

In the course of an investigation of charge transfer complexes in the crystalline state, mainly between halogen molecules and organic electron donor molecules as ethers and amines carried out by Hassel and coworkers, it was found to be of interest to determine whether thioethers form similar compounds with halogen. The 1 : 1 compound benzyl sulphide-iodine was chosen as an object for this investigation. This compound was first prepared by Fromm[1], by whom it was regarded as a compound of quadrivalent sulphur with each of the halogen atoms linked to the sulphur atom. Feigl and Bondi[2], however, investigated further the chemical behaviour of the compound and concluded that it is to be regarded as a polyiodide.

Preliminary results of the present investigation have been reported in a survey article by Hassel[3].

EXPERIMENTAL

The crystals were prepared according to Feigl and Bondi [2] by mixing hot solutions of benzyl sulphide and iodine in glacial acetic acid and heating the mixture for a quarter of an hour at 120°C. By cooling, small dark red crystals of the addition compound (m.p. 63°C) separated. The crystals were approximately octahedral with the orthorhombic axes along the space diagonals. The dimensions were about 0.15 mm along the axes; the crystals were used without further preparations in the X-ray work.

Integrated Weissenberg photographs were taken with rotation about the three orthorhombic axes. The more intense reflections were measured photometrically; the others were estimated visually by comparison with a standard scale. Cu$K\alpha$-radiation was employed, and of the 114 $h0l$, 91 $0kl$ and 104 $hk0$ reflections attainable, 82, 78, and 51 were actually observed, respectively. The intensities were corrected for Lorentz- and polarisation effects, but no corrections for absorption were applied.

The atomic scattering factor used in the last stages of the calculations are given by the analytical approximation $f = A\exp(-ax^2) + B\exp(-bx^2) + C$ with the constants given by Forsyth and Wells[4].

CRYSTAL DATA

The crystals were found to be orthorhombic with the unit cell dimensions: $a = 9.86$ Å ; $b = 16.86$ Å ; $c = 9.36$ Å
The figures given are believed to be accurate to within 0.5 %. By flotation the density was found to be 1.95 g/cm^3, while the calculated value with four molecules per unit cell is 2.00 g/cm^3.

According to the systematically absent reflections the space group might be either *Pnma* or $Pn2_1a$. The former was assumed to be the correct one, and the structure analysis subsequently confirmed this. Since the number of equivalent positions is eight in the space group *Pnma*, the molecules must posess a center of symmetry or a mirror plane. Only the latter is possible in the present compound.

STRUCTURE DETERMINATION

The structure analysis was started with projection along the *b*-axis. This is the longest of the axes, but since the mirror planes of the space group are perpendicular to this axis a well resolved Fourier projection could be expected with ideal overlapping of some of the atoms. A Patterson synthesis showed clearly that the iodine atoms lie in a mirror plane. It indicated also strongly that the sulphur atom is lying in the mirror plane with one benzyl group on each side. The parameters of the iodine atoms were determined from the Patterson synthesis and a set of structure factors was calculated. On the basis of signs from these calculations and the observed data a Fourier synthesis (plane group *pgg*) was computed. The Fourier map not only showed the iodine atoms but also indicated the position of the benzyl sulphide molecule. It became quite clear that the S-I-I arrangement is nearly linear, and tentative parameters for the atoms in the benzyl sulphide group could be found. These were now included in the calculations, and a series of Fourier refinements were carried out. At the stage where no more signs shifted the reliability factor *R* had decreased to 20 %. It became obvious from the corresponding Fourier map, however, that the thermal vibrations of the »outer» iodine atom is anisotropic, the peak being elongated in a direction about normal to the I-I bond.

Now a least squares refinement was carried out, using a Ferranti Mercury computer[5]. Two cycles were computed with variation of the parameters with isotropic temperature functions, then a few cycles with an anisotropic temperature function for the »outer» iodine atom. During the first step the reliability factor decreased from 20 % to 15 %, after the anisotropic temperature function was introduced it dropped to 10.5 %. The positional parameters changed very little during the last cycles, however. The direction of the maximum vibration amplitude of the iodine atom in question as calculated from the constants in the expression for the temperature factor $\exp(-uh^2-vhk-wk^2)$ was found to be within 2° perpendicular to the direction of the I—I bond.

Table 1. Observed and calculated structure factors.

A Fourier map of the projection along the *b*-axis based on the signs arrived at with the final set of parameters is reproduced in Fig. 1. Observed and calculated structure factors are listed in Table 1.

From a model of the benzyl sulphide molecule the *y*-coordinates could be estimated, the sulphur and iodine atoms lying in mirror planes.

A set of structure factors was then calculated for the 0*kl*-zone and the corresponding Fourier synthesis was worked out. The plane group of this projection is *cmm*, the origin being in (1/4, 1/4) relative to the origin of the original unit cell. The iodine peaks were found at the expected positions in the mirror plane at $y = 0$, and the benzyl sulphide molecule showed up clearly in the map. Some atoms from different molecules overlapped, however. After a few Fourier refinements the parameters of this projection were subjected to at least squares refinement. The »outer» iodine atom was not corrected for anisotropic thermal vibrations in this projection, this not being possible for an atom in a mirror plane with the present computer program. The discrepancies of the common parameters of the heavy atoms found in the (010)- and (100)-projections were 0.0005 for I_1, 0.0019 for I_2, and 0.004 for S. The final *R*-factor for the (100)-projection was 13.8 %; the corresponding Fourier map is shown in Fig. 2 and the observed and calculated structure factors (origin in (1/4, 1/4) of the cell given in *International Tables*) are listed in Table 1.

In the *hk*0-zone very few reflections other than the ones with $h = 4n$ were observed. The reason for this is of course the rather special positions of the iodine atoms in this projection, the projection having a pseudo translation 1/4 along the *a*-axis. One iodine atom overlaps with the sulphur atom in this projection, consequently rather few informations is to be had from these

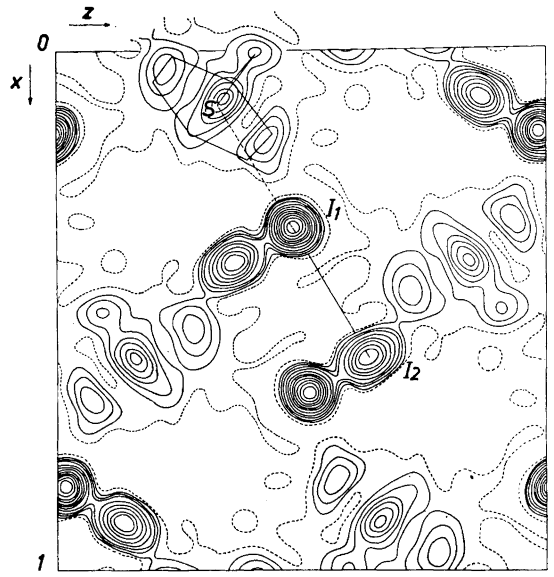

Fig. 1. Electron density projection along the *b*-axis. Contour intervals of 5 e.Å^{-2} up to 20 e.Å^{-2} and of 10 e.Å^{-2} from 30 to 100 e.Å^{-2}.

data. Only the *x*-parameter of the iodine atom nearest the sulphur atom was determined from this projection and it showed good agreement with the one found in the projection along *b*. The final *R*-factor for the *hk*0-zone was 10.4 %. The observed and the corresponding calculated structure factors are listed in Table 1.

DISCUSSION OF THE STRUCTURE

Benzyl sulphide-iodine crystallizes with a nearly linear S-I-I arrangement with a mirror plane through the sulphur and iodine atoms and between the benzyl groups. Figs. 1 and 2 show the electron density projections along the *b* and *a* axes, respectively. For the final parameters listed in Table 2, values from the projections along *b* were used for the sulphur and iodine atoms, whereas a mean value from all projections were used for the lighter atoms.

The distance between the iodine atoms in the iodine molecule is found to be 2.819 Å and between the sulphur atom and the nearest iodine atom 2.78 Å. The standard deviations[6] for these distances are 0.009 Å and 0.02 Å, respectively. The sulphur and iodine atoms are within the accuracy of the investigation lying on a straight line, the S-I-I angle being found equal to 179°.

The sulphur-methylene carbon distance was found to be 1.82 Å, in good agreement with the normal single bond value[7]. The distances between carbon atoms in the benzene ring are of course not well determined in a structure with heavy atoms like the present one, the mean value was found to be 1.38 Å for the nearest C-C distance with deviations of up to 0.1 Å. There is an angle

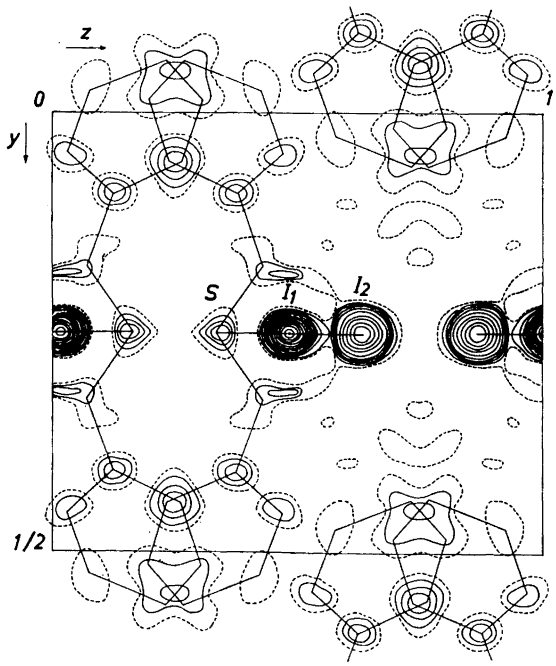

Fig. 2. Electron density projection along the *a*-axis. Contour intervals as in Fig. 1.

of 93° between the two sulphur-methylene carbon directions; the angle between the sulphur-iodine and the sulphur-methylene carbon directions is found to be 100°.

The nearest iodine-iodine approach between the molecules was 4.33 Å, corresponding closely to the van der Waals' distance given by Pauling [7]. The fact that the direction of maximum vibration of the »outer» iodine atom as observed in the projection along the *b*-axis is normal not only to the intramolecular I-I bond but also to the loose intermolecular I-I interaction in the mirror plane suggests that the anisotropy has some structural significance.

Table 2. Atomic coordinates as fractions of the cell edges.

Atom	*x*	*y*	*z*

C_4	0.164	0.554	0.270
C_5	0.223	0.526	0.409
C_6	0.151	0.458	0.454

The investigation shows that organic sulphur compounds may act as electron donors to form molecular addition compounds in the same way as amines. The lengthening of the I-I bond (0.17 Å relative to the sum of the normal covalent radii [7]) is the same as found where an amine act as the electron donor [8]. It agrees also fairly well with the value given by McCullough *et al.* in the compound dithiane · $2I_2$. The lengthening of the S-I bond relative to the covalent bond distance is consistent with the corresponding values in compounds between amines and halogen, it is in very good agreement with the value given by McCullough.

This investigation has been sponsored by the *United States Air Force Development Command* under contract AF 61 (052)—71.

Studies on the Chemistry of Lichens

III *. Long-Chain Tetrahydroxy Fatty Acids from Some Norwegian Lichens

YNGVE JOHANNES SOLBERG

Research Chemical Laboratory, Agricultural College of Norway, Vollebekk, Norway

Norwegian lichen species have been studied with regard to content of higher tetrahydroxy fatty acids. The lichens are found on the bark of trees, on rocks, and on the ground. The hydroxy acids isolated are of the same type as those previously recorded in *Haematomma ventosum*. Infra-red spectra of the acids in solid state have been obtained in the region from 4 000 to 700 cm^{-1} and confirm the similarity.

Semi-solid and solid fatty acids were obtained by reduction with hydrogen iodide and zinc. Paper chromatographic analysis of the products obtained by periodic acid oxidation of ventosic acid from *Haematomma ventosum* showed the presence of tetrahydroxy *heneicosanoic* acid ($C_{21}H_{42}O_6$) and tetrahydroxy *docosanoic* acid ($C_{22}H_{44}O_6$) in the lichen.

Work on *Parmelia centrifuga*, has pointed out the possibility of the presence of tetrahydroxy *tricosanoic* acid ($C_{23}H_{46}O_6$) in the lichen.

Systematic investigations of Norwegian lichen species were made during the period 1955 to 1959. The presence of higher tetrahydroxy fatty acids in some lichens was of special interest. In 1957 ventosic acid was obtained from *Haematomma ventosum* and reported [1] as a tetrahydroxy *docosanoic* acid with the composition $C_{22}H_{44}O_6$. Later uniform substances have been isolated from the lichen species *Parmelia centrifuga, Parmelia encausta, Parmelia furfuraceae, Parmelia physodes, Cetraria nivalis, Cetraria delisei, Cladonia alpestris, Alectoria ochroleuca*, and *Siphula ceratites*.

The plant material was collected in different parts of the country and before the extraction, the material was dried and ground into coarse powder. The extraction process was carried out first with ether for about 24 h, and subsequently with acetone for 48 h in a Soxhlet extractor designed to take 400—500 g of the material. As a rule the main portion of the acids were separated already

* Part II: *Acta Chem. Scand.* **11** (1957) 1477.

under the acetone extraction and could therefore easily be isolated in a pure condition.

After the solvents had been removed from these extracts, the highly coloured solids were examined separately in the usual manner [2,3]. Analytical data will be given only for those compounds for which values have not been reported in the literature. From *Parmelia centrifuga* a relatively larger portion of sugar alcohol and from *Siphula ceratites* a new lichen substance with the probable formula $C_{19}H_{21}O_6$ have been isolated. The investigations are being continued and complete data will be given in a forthcoming paper.

The hydroxy fatty acids which have been isolated so far, at once distinguished themselves by an especially low solubility in the common organic solvents. The acids are less soluble in alcohols, more soluble in warm dioxane, pyridine and glacial acetic acid. Glacial acetic acid has in all cases proved to be the most suitable recrystallization solvent, from which an easily filterable product has been obtained.

The hydroxy fatty acids are colourless, amorphous substances with melting points in the region 180—193° (*cf.* Table 1). Occasionally two different melting points for the same hydroxy acid have been observed. This is probably due to the presence of *cistrans* isomerism, and is otherwise known from tetrahydroxy stearic acid.

The lichen species *Haematomma ventosum* and *Parmelia centrifuga* are distinguished by a particularly high amount of these acids, a fact which gave rise to a further investigation. In both cases the hydroxy acids were reduced to the corresponding fatty acids. However, these seemed not to be identical, but differed with regard to solubility, melting points and by paper chromatographic analysis (Tables 2 and 3).

In *Parmelia physodes* hydroxy fatty acids have been established by means of solubility, X-ray, and infra-red spectra. However, the sample was contaminated with a tenacious impurity which rendered purification extremely difficult and wasteful. The yield of the crude product was too low and further analysis was not possible.

RESULTS AND DISCUSSION

In Table 1 a series of experimental results of the isolated hydroxy fatty acids, or acid-mixtures, from nine different lichen species are listed. The average composition is: C 66.33 %; H 11.05 %.

It is interesting to compare these results with those reported by Zellner [4,5], who isolated the lichen substances *Hypogymnole* I and II from *Parmelia physodes*.

Compound	M.p.	Found by Zellner	
Hypogymnole I	190°	C 64.39 %	H 11.12 %
Hypogymnole II	218°	C 63.64 %	H 11.16 %

Table 1. Analysis of the isolated tetrahydroxy fatty acids.

Lichen species	Yield of purified hydroxy acid, %	Melting point	Analysis, values obtained % C	% H	Characteristic strong peaks in the X-Ray diffraction pattern (Å)			
Haematomma ventosum	0.5	184°	65.29	10.88	32.5	—	4.55	4.05
Parmelia centrifuga	0.5	191°	64.77–64.37	10.84–10.68	31.6	20.5	4.54	4.04

Alectoria ochroleuca	0.05	179°	67.06	11.21	33.2	23.2	4.54	4.04

In the present work the attempts made to resolve the acid-mixture from *Parmelia physodes* failed. Zellner indicated that these two compounds might be *higher aliphatic alcohols*. Today it is fairly obvious that Zellner's *Hypogymnoles* are identical with the isolated hydroxy fatty acids.

The X-ray diffraction patterns show two characteristic peaks at 4.54 and 4.05 Å. With the normal fatty acids the two corresponding peaks are found at 4.1 and 3.7 Å. The technique for the X-ray analysis has already been described in Part II of this series, and two diffraction patterns have been recorded in the same paper.

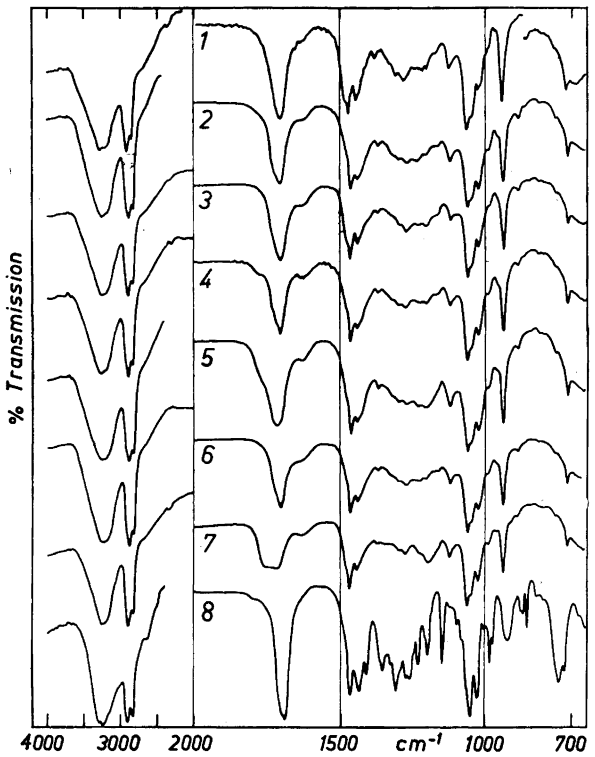
The infra-red absorption spectra of the hydroxy acids in Fig. 1 show a surprisingly close similarity. Bayzer [6] reported broad absorption bands at 3 200—3 300 cm^{-1} for C_{18}-hydroxy acids due to the valence bands of the OH-groups. The hydroxy acids in Fig. 1 show a broad unresolved OH-band around 3 270 cm^{-1}. Further, it is worth noting that this band shows a constant intensity, compared with the well known asymmetric carbon-hydrogen stretching band around 2 900 cm^{-1}. According to Bayzer, all isolated hydroxy acids should contain four OH-groups in the molecule. In all of the IR analyses carried out, the ratio of hydroxy acid to KBr has been nearly constant, 1.5 mg/200 mg. *Previously ventosic acid from Haematomma ventosum has been shown to contain four OH-groups.*

Susi [7] pointed out that the constant position of the 3 270 cm^{-1} band would be expected to depend on a similar position of the hydroxyl groups in the molecule. The associated carboxyl group exhibits a weak band at 2 700 cm^{-1}. The carboxyl band appears to be constant at 1 700 cm^{-1}.

The infra-red spectra are nearly identical above 1 500 cm^{-1}. Curiously enough only a few, effaced bands are found in the region 1 180—1 350 cm^{-1} compared with the spectra of sativic acid (No. 8, Fig. 1).

The bands at 1 465 cm^{-1} and at 715 cm^{-1} in the spectra are attributed to bending and rocking methylene vibrations [8,9].

Spectra of mono-, di-, tetra- and hexahydroxy stearic acid are reported by Bayzer. These spectra show a close similarity to those obtained in the present paper.



Figs. 1—8. Infrared spectra of tetrahydroxy acids from *Haematomma ventosum*(1), *Alectoria ochroleuca*(2), *Parmelia centrifuga*(3), *Cladonia alpestris*(4), *Cetraria nivalis*(5) *Cetraria delisei*(6), *Parmelia furfuraceae*(7) and *Sativic* acid(8). All substances are pressed in KBr-disks.

Several paper-chromatographic analyses of the hydroxy fatty acids have been tried without success.

Reduction to fatty acids. Upon treatment of ventosic acid from *Haematomma ventosum* and the hydroxy acid component from *Parmelia centrifuga* with hydrogen iodide and zinc, as described in the earlier publication, the com-

Table 3. Ascending paper chromatography of the fatty acids obtained by the reduction of hydroxy fatty acids from *Haematomma ventosum* (H.v.) and *Parmelia centrifuga* (P.c.). 50 μg of the fatty acid was chromatographed. The paper was impregnated with A) *n*-undecan (0.23), B) liquid paraffin (0.18), and C) liquid paraffin (0.16). Paper S & S 2043 b. Temperature 47°, 4 h.

Fatty acids	A	B	C
Autentic n-*docosanoic* acid	—	0.35	—
Docosanoic acid (H.v.)	0.18	0.35	0.45
Tricosanoic acid (P.c.)	0.13	0.27	0.35

pounds are converted into *n*-fatty acids. The fatty acids were white, crystalline substances and the elementary results are given in Table 2.

Paper chromatography of the fatty acids. During the period 1954 to 1958, Kaufman and Wagner [10–12] described some paper chromatographic methods for higher *n*-fatty acids. These methods have been useful in the present chromatographic investigations. The results, which are given in Table 3, confirm the fact that *n*-docosanoic acid (C_{22}) is the main component of the reduction products from ventosic acid. The reduction product from *Parmelia centrifuga* is the higher homologous tricosanoic acid (C_{23}). These observations are in agreement with the elementary analysis (Table 2).

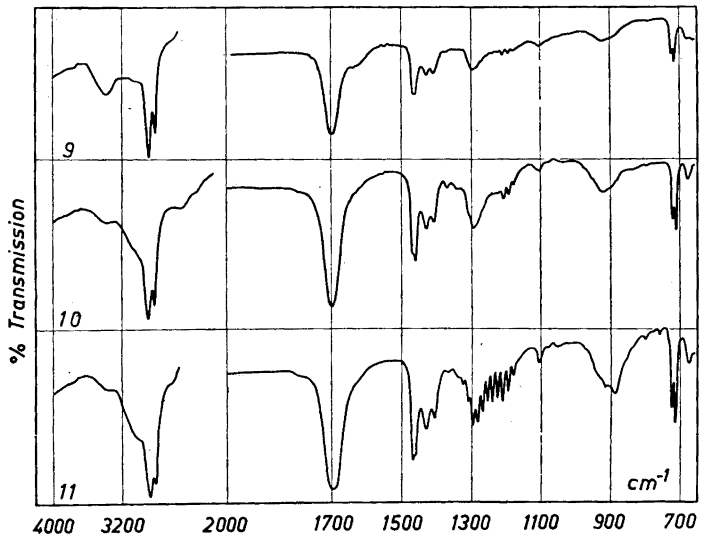
Infra-red analysis of the fatty acids. The infra-red absorption spectra of the fatty acids are shown in Fig. 2. Examination of the spectra of the free acids by the potassium bromide disk technique has definite advantages, and the spectra recorded in this paper show distinctly that by the classical reduction of the hydroxy fatty acids with hydrogen iodide and zinc, long-chain normal fatty acids have been obtained.

The IR-spectra of long chain fatty acids as a class have certain characteristic features which have been discussed by other authors [9,13–16].

The carbonyl stretching band of the carboxyl acid group appeared at very nearly the same wave number, 1 700 cm^{-1}. The two strong bands at 2 900 and 2 830 cm^{-1} are attributable to the asymmetrical and symmetrical methylene stretching and vibrations, respectively.

Strong complex absorption occurs between 880 and 930 cm^{-1}. The bands at 1 460—1 470 cm^{-1} and at 720 cm^{-1} in the spectra of the fatty acids are attributed to bending and rocking methylene vibrations, respectively. The splitting of the 720 cm^{-1} rocking band into two components, in the solid phase spectra, is in accordance with the observations of Stein and Sutherland [17] for *n*-paraffins below the transition point. Some or all of the absorption bands occurring between 1 460 and 1 400 cm^{-1} can probably be attributed also to methylene bending vibrations.

Of particular interest for the study of the spectra is the absence of progression of bands between 1 180—1 350 cm^{-1} spaced at approximately equal intervals of 15—20 cm^{-1}, (compare with spectra of pure *n*-docosanoic acid in the same figure). The progression bands are almost certainly associated with



Figs. 9—11. Infrared spectra of *docosanoic* acid and reduced hydroxy acids from *Haematomma ventosum* and *Parmelia centrifuga*. All substances are pressed in KBr-disks.

methylene wagging and/or twisting vibrations. The introduction of substituents along the molecule-chain alters the appearance of these bands. If the degree of substitution is excessive, the characteristic appearance of the progression is lost. In this work, branched acids have not been established. Infrared spectra of monocarboxylic acids are fairly insensitive in relation to homologous. Therefore, the lack of bands in the region 1 180—1 350 cm^{-1} can scarcely be due to the presence of fatty acid mixtures.

Oxidation of ventosic acid from Haematomma ventosum. A sufficient amount of ventosic acid was available from *Haematomma ventosum* and enabling an

Table 4. R_x values of the 2,4-dinitrophenylhydrazones obtained with the aldehydes from the oxidation of the hydroxy compounds with HIO_4. Paper: S & S 2043b, impregnated with 2-phenoxyethanol. Solvent *n*-heptan and water.

2,4-Dinitrophenylhydrazone of	R_x		
Autentic *n*-decanal			1.00
n-Nonal from 9,10-dihydroxystearic acid		0.89	
n-Hexanal from 9,10,12,13-tetrahydroxy stearic acid	0.58		
Azelaic half-aldehyde ($OHC \cdot (CH_2)_7 \cdot COOH$) from 9,10-dihydroxy stearic acid	0.18		
Azelaic half-aldehyde from 9,10,12,13-tetrahydroxy stearic acid	0.19		
Oxidation products from ventosic acid (*Haematomma ventosum*)	0.17	0.86	1.02

examination of the products obtained by oxidation with HIO_4. In this way the position of the four OH-groups in the molecule were determined.

A sulphuric acid solution of KIO_4 was added to a suspension of ventosic acid in 96 % ethanol. Within a short time and by continuous shaking an almost clear solution with a characteristic smell of higher aldehydes was obtained. After concentration, the aqueous solution was steam distilled and the volatile aldehyde compounds converted into 2,4-dinitrophenylhydrazones. The main amount of the distillate proved to be *n*-decanal. However, small amounts of hydrazones were obtained by careful examination of the filtrate. By chromatographic analysis of the last fraction mentioned, the presence of *n*-nonal and azelaic-half-aldehyde was demonstrated.

For comparison by the chromatographic analysis, di- and tetrahydroxy stearic acid also were oxidized in the same manner, and the following substances were obtained:

Compound	Oxidation products
9,10-dihydroxy stearic acid	*n*-nonal azelaic half-aldehyde
9,10,12,13-tetrahydroxy-stearic acid	*n*-hexanal azelaic half-aldehyde

Chiefly the method of King [18] was used in the oxidation with HIO_4. The hydrazones were separated on paper S & S 2043b, impregnated with 2-phenoxyethanol, (Lynn [19]). The results are summarized in Table 4.

Polymerization products constituted the main part of the non-volatile matter produced under the steam distillation. They were not further examined.

All things considered the facts given in Tables 3 and 4 lend support to the conclusion that a mixture of 9,10,12,13-tetrahydroxy docosanoic acid ($C_{22}H_{44}O_6$) and 9,10,12,13-tetrahydroxy heneicosanoic acid ($C_{21}H_{42}O_6$) must be present in the lichen. By the reduction of the mixture of the two tetrahydroxy acids, and the repeated recrystallization of the reduction products, the heneicosanoic acid was lost. As already mentioned, only docosanoic acid has been recognized on the paper chromatogram. It is, therefore, likely that only a small amount of tetrahydroxy heneicosanoic acid is present in the lichen.

It is known that mixtures of the normal fatty acids C_{21} and C_{22} give melting points in the region 74.9—75.2° [20]. This is in agreement with the melting point found in the present work.

Nor has the reduction product of the tetrahydroxy acid from *Parmelia centrifuga* any distinct melting point. There are some indications that a mixture of two acids is present, with tricosanoic acid (C_{23}) as the main component.

Reduction of tetrahydroxy acids from the lichen species *Parmelia encausta*, *Parmelia furfuraceae*, *Cetraria nivalis* and *Cladonia alpestris* have also been made. Solubilities, melting points and paper chromatographic analysis undoubtedly indicated the presence of mixtures. Work is in progress with a view to establishing the different tetrahydroxy acids in these lichens.

At times it has been supposed that these tetrahydroxy fatty acids might be compounds caused by the extraction of the lichens. However, an intense research in this field, has yielded no facts supporting this hypothesis. It is therefore reasonable to assume that the acids may be a result of biochemical oxidations in the lichens. In 1932 oleic- and linoleic acid were isolated from *Alectoria ochroleuca* by Klima [21].

EXPERIMENTAL

Extraction and isolation of the lichen substances from the different lichen species were carried out according to the procedure described in Part II. The analytical results are summarized in Table 1.

In the same paper reduction with HI and Zn, and methylation of the fatty acids obtained are also described in detail. The analytical results of the fatty acids are given in Table 2.

Oxidation of ventosic acid. The double amount of KIO_4 in N H_2SO_4 (40°) was added to a suspension of ventosic acid in 96 % ethanol (20°), and the mixture shaken for 30 min. The reaction mixture was then filtered, diluted with the same volume of water, and extracted with ether. The ether extract was filtered, concentrated, and distilled with steam. Only polymerisation products could be detected in the distillation remainder.

The aldehydes in the distillate were converted into 2,4-dinitrophenylhydrazones. The crude adduct obtained was filtered off and recrystallized several times from hot 96 % ethanol. The pure hydrazone crystallized as yellow prisms; m.p. 104—105° undepressed when mixed with the authentic hydrazone of *n*-decanal. (Found: C, 7.01; H 7.31; N 16.70. Calc. for $C_{16}H_{24}O_4N_4$: C 57.13; H 57.19; N 16.66.)

The crude hydrazone product obtained by concentration of the filtrate above was crystallized, and melted in the 76—93° range. This mixture of hydrazones was subjected to chromatographic investigations. The results are summarized in Table 4.

The oxidation of di- and tetrahydroxy stearic acids was carried out according to the method described by King [18]. The oxidation products were converted into 2,4-dinitrophenylhydrazones, purified by extraction with petroleum ether (60—70°) and recrystallized from ethanol.

In the X-ray diffraction analysis, a Philips X-ray Geiger Counter Spectrometer with $CuK\alpha_1$ radiation was used.

The elementary analyses have been carried out by *Mikroanalyslaboratoriet, Medicinsk-Kemiska Institutionen, Uppsala Universitet,* and the IR spectra by *Sentralinstitutt for industriell forskning,* Oslo.

I have received a grant from *Nansenfondet,* Oslo, which is gratefully acknowledged.

The author also wishes to thank Dr. Eilif Dahl for his interest and assistance in collecting material.

Die Chemie der Natürlichen Ordnung Cupressales

XXXII *. Über die Inhaltsstoffe des Kernholzes von *Athrotaxis selaginoides* Don, *Athrotaxis cupressoides* Don und *Chamaecyparis pisifera* Sieb. et Zucc.

HOLGER ERDTMAN und HELMUT VORBRÜGGEN

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Schweden

Die Kernholzbestandteile von *Athrotaxis selaginoides* und *Athrotaxis cupressoides* sowie ein Neutralöl aus dem Kernholz von *Chamaecyparis pisifera* wurden untersucht. Aus dem wasserlöslichen Teil von *A. selaginoides* wurde L-Arabinose sowie eine neue phenolische Substanz $C_{17}H_{18}O_7$ isoliert. Die saure Fraktion enthielt kristalline höhere Fettsäuren. Die neutrale Hauptfraktion lieferte eine Cadinen- und eine Cadinolfraktion. Das ölige Cadinolgemisch konnte chromatographisch in kristallines α-, δ- und »x-Cadinol» aufgetrennt werden. Der Destillationsrückstand ergab Hinokiol und β-Sitosterol.

Aus *A. cupressoides* wurde analog L-Arabinose, höhere kristalline Fettsäuren, Cedren, Cadinen, die drei genannten kristallinen Cadinole und Hinokiol isoliert.

Das Neutralöl von *Ch. pisifera* enthielt Cadinene und die drei kristallinen Cadinole.

Zur sehr heterogenen Familie *Taxodiaceae*, die viele kleine Gattungen umfasst und bisher noch wenig untersucht worden ist, gehören drei *Athrotaxis* Arten, zwei Bäume und ein Strauch (*A. laxifolia* Hook.), die alle in Tasmanien heimisch sind. Botanisch nahestehend scheint besonders *Taiwania*, eine monotypische Gattung aus Yunnan und Formosa, zu sein.

In der vorliegenden Arbeit wurden die Kernhölzer zweier *Athrotaxis* Arten, *A. selaginoides* und *A. cupressoides*, genauer untersucht. Im Verlaufe dieser Arbeit konnte neben anderen Substanzen ein öliges Gemisch von Cadinolen isoliert werden, das sich leicht chromatographisch in drei kristallisierte reine Cadinole zerlegen liess. Diese chromatographische Methode wurde anschliessend auf ein Cadinolgemisch aus *Chamaecyparis pisifera* angewandt, um ihre allgemeine Anwendbarkeit zu zeigen.

* Teil XXXI, *Acta Chem. Scand.* 14 (1960) 1995.

Der Acetonextrakt des Kernholzes von *Athrotaxis selaginoides* wurde zuerst mit Äther und dann das ätherlösliche mit Leichtpetroleum gefällt. Aus dem wasserlöslichen Teil der Ätherfällung kristallisierte neben L-Arabinose eine phenolische Substanz, $C_{17}H_{18}O_7$, aus. Schmp. 285° u. Zers. (aus Äthanol) und Schmp. 185° (aus Wasser), $[\alpha]_D$ + 274°. Beide Kristallformen haben ein fast identisches IR-Spektrum (starke breite Bande bei 3 300 cm^{-1} sowie starke Bande bei 1 658 cm^{-1} und 1 610 cm^{-1}). Diese Substanz ist Gegenstand weiterer Untersuchungen.

Der in Leichtpetroleum lösliche Anteil wurde wie üblich in eine bikarbonatlösliche, eine alkalilösliche und eine neutrale Fraktion zerlegt.

Aus beiden sauren Fraktionen kristallisierten beim Stehen geringe Mengen höherer Fettsäuren vom Schmp. 80° bzw. 70—75°. Die charakteristische Serie von Banden zwischen 1 350 und 1 180 cm^{-1} weist auf Säuren im Bereich von C_{20}—C_{24} hin[1].

Der in Petroläther lösliche neutrale Anteil ergab bei der fraktionierten Destillation Kohlenwasserstoff- und Alkoholfraktionen. Die ersteren bildeten mit Chlorwasserstoff (—)-Cadinen-dihydrochlorid und enthalten deshalb Cadinene. Starke Banden im IR-Spektrum bei 890 cm^{-1} zeigten die Anwesenheit von Methylengruppen an.

Die viskosen, höher siedenden Sesquiterpenalkoholfraktionen lieferten ebenfalls mit Chlorwasserstoff (—)-Cadinen-dihydrochlorid und enthalten somit Cadinole. Da diese Öle auch bei längerem Aufbewahren nicht kristallisierten, wurden sie an Aluminiumoxyd chromatographiert. Die kristallinen Fraktionen lieferten bei wiederholter Sublimation und Umkristallisation drei reine kristallisierte Cadinole.

Die zuerst eluierte Substanz schmolz nach wiederholter Sublimation bei 78°, $[\alpha]_D$ — 86,2°, *p*-Nitrobenzoat, Schmp. 104°, und erwies sich als identisch mit dem von Šorm und Mitarbeitern[2] aus dem Beerenöl des Wacholders (*Juniperus communis*) isolierten Cadinol vom Schmp. 78,5—79°, $[\alpha]_D$ —89° (nach Reinigung über das *p*-Nitrobenzoat Schmp. 104°). Dieses Cadinol von unbekannter Struktur wird in dieser Arbeit als »x-Cadinol» bezeichnet.

Die zweite eluierte Substanz wurde nur in geringer Menge erhalten und erwies sich nach der Reinigung als δ-Cadinol (Pilgerol), Schmp. 139°, $[\alpha]_D$ —106°. Diese Substanz wurde kürzlich von Erdtman, Pelchowicz und Topliss[3] aus dem Kernholz von *Pilgerodendron uviferum* und ebenfalls von Šorm und Mitarbeitern[2] aus dem Öl von Wacholder-Beeren isoliert. Ein Vergleich mit einer Probe von Albicaulol[4], (Schmp. und Misch-Schmp. 139°, opt. Drehung und IR-Spektrum) aus *Pinus albicaulis* und *Pinus armandi* zeigte, dass auch diese Substanz mit δ-Cadinol identisch ist.

Die dritte eluierte Substanz schmolz bei 73—74° $[\alpha]_D$ —48,6°, *p*-Nitrobenzoat Schmp. 138° und wurde als α-Cadinol identifiziert.

Reines α-Cadinol, Schmp. 72—74°, $[\alpha]_D$ —39°, wurde zuerst aus Java citronellöl[5] und kürzlich aus *Chamaecyparis lawsoniana*[6] und *Juniperus communis*[2] über das *p*-Nitrobenzoat isoliert. Die Struktur von α-Cadinol sowie seine absolute Konfiguration klärten Šorm und Mitarbeiter[2] sowie Soffer und Mitarbeiter[7] auf.

Aus dem hoch siedenden neutralen Destillationsrückstand wurde eine geringe Menge eines viskosen Öls erhalten, das in seinen Eigenschaften mit dem später beschriebenen Öl aus *Athrotaxis cupressoides* identisch war und worüber weiter unter berichtet wird.

Verseifung des nicht-flüchtigen neutralen Destillationsrückstandes ergab eine Neutralfraktion, aus der beim Stehen mit Leichtpetroleum eine geringe Menge einer kristallinen Substanz ausfiel, Schmp. 195—215°, die nach Sublimation bei 238° schmolz, $[\alpha]_D$ +74,3°, und durch Mischschmp. und IR-Spektrum als Hinokiol[8] identifiziert wurde. Aus der Mutterlauge kristallisierte eine Substanz aus, die nach zwei Umkristallisationen bei 138° schmolz, $[\alpha]_D$ —31,5° und positive Digitoninreaktion zeigte. Die Substanz ist dem IR-Spektrum und den physikalischen Konstanten nach relativ reines β-Sitosterin.

Der Acetonextrakt von *Athrotaxis cupressoides* wurde direkt mit Leichtpetroleum gefällt. Aus dem wasserlöslichen Teil der Fällung kristallisierte L-Arabinose aus.

Beim Einengen der Leichtpetroleum-Lösung fielen schöne Kristalle aus, die durch Schmp., Mischschmp. optische Drehung und IR-Spektrum als Hinokiol identifiziert wurden.

Der in Leichtpetroleum lösliche Anteil wurde in bikarbonatlösliche, alkalilösliche und neutrale Fraktion zerlegt.

Aus der alkalilöslichen Fraktion fiel beim Stehen mit Methanol ein wenig Hinokiol aus. Der neutrale Hauptteil wurde nach einer Vordestillation sorgfältig im Vakuum fraktioniert. Die ersten Kohlenwasserstoff-Fraktionen enthielten nach physikalischen Konstanten und IR-Spektrum α-Cedren. Ozonisierung und Hypobromit-Oxydation lieferte reine Cedren-dicarbonsäure, Schmp. 183—184°, $[\alpha]_D$ —36,5°. Die höher siedenden Kohlenwasserstoff-Fraktionen bildeten mit Chlorwasserstoff (—)-Cadinen-dihydrochlorid und enthielten also Gemische von Cadinenen. Die IR-Spektren dieser Cadinen-Fraktionen stimmten mit den IR-Spektren der Cadinen-Fraktionen aus *Athrotaxis selaginoides* überein. Die Sesquiterpenalkohol-Fraktionen ergaben mit Chlorwasserstoff ebenfalls (—)-Cadinen-dihydrochlorid und wurden durch Chromatographie an Aluminiumoxyd in die drei bereits beschriebenen kristallinen Cadinole aufgetrennt. Cedrol, dessen Anwesenheit wegen des Vorkommens von Cedren erwartet wurde, konnte bisher nicht isoliert werden.

Aus den hochsiedenden, viskos-öligen Alkoholen, die auch aus *Athrotaxis selaginoides* isoliert worden waren und die im IR-Spektrum Hydroxyl-, Methyl-, Isopropylbanden sowie schwache Banden bei 1 675 cm^{-1} und 1 710 cm^{-1} zeigten, konnte bisher weder durch Chromatographie noch durch Acylierung und anschliessende Chromatographie irgendeine kristalline Substanz isoliert werden. Aus dem neutralem Destillationsrückstand wurde noch weiteres Hinokiol gewonnen.

Die oben beschriebene einfache Auftrennung der nicht kristallisierenden öligen Cadinolgemische legte die Annahme nahe, dass viele in der Literatur[9] beschriebene ölige sogenannte L-Cadinole mit einer optischen Drehung zwischen —30 und —80° Gemische von α, δ, und »x-Cadinol» darstellen, die sich leicht chromatographisch trennen lassen sollten. Um dies nachzuprüfen, wurde ein Neutralöl aus *Chamaecyparis pisifera*, in dem Nakatsuka und Hirose[10] Cadinene und (—)-Cadinol nachgewiesen hatten, sorgfältig fraktioniert und wie

beschrieben Cadinene und (—)-Cadinol erhalten. Chromatographie des (—)-Cadinols ergab die obigen drei kristallinen Cadinole in ähnlichen Mengenverhältnissen.

Interessanterweise enthält das Kernholz der mit *Athrotaxis* verwandten *Taiwania cryptomerioides* ebenfalls Cadinole »Taiwanol». Tropolone wurden in der Familie *Taxodiaceae* noch nicht aufgefunden[11].

EXPERIMENTELLER TEIL

Alle Schmelzpunkte wurden mit dem Heizmikroskop nach Kofler bestimmt und sind korrigiert. Die IR-Spektren wurden mit dem Perkin-Elmer Modell 21 aufgenommen (Für kristalline Substanzen Kaliumbromid-Scheiben; Flüssigkeiten als reine Öle in einer 0,025 mm Natriumchlorid Zelle oder in CCl_4 gelöst). Optische Drehungen wurden in Chloroform-Lösung gemessen.

Athrotaxis selaginoides

Extraktion. 16 kg trockenes gemahlenes Kernholz extrahierte man 36 Stunden im Heissextraktor mit Aceton und erhielt 1,955 kg rohen braunen Extrakt I. Der Extrakt wurde mit 300 ml Aceton verdünnt, auf 40° erwärmt und unter heftigem Rühren zu 20 l Äther getropft. Das dabei ausgefallene dunkelbraune, Äther-unlösliche Öl, II (700 g), löste sich grösstenteils in Aceton und ergab beim Filtrieren eine weisse Substanz. Diese wurde in heissem Wasser gelöst, Tierkohle zugesetzt, filtriert und das Filtrat im Vakuum eingedampft. Der Rückstand kristallisierte aus Alkohol und ergab 19 g reine L-Arabinose, Schmpt. 158—160°.

200 g der *Äther-unlöslichen Fraktion II* wurden in 250 ml heissem Aceton gelöst, langsam unter Rühren zu 2 l kochendem Wasser gegeben, vom braun-schwarzen Rückstand dekantiert und filtriert. Das Filtrat behandelte man heiss mit Tierkohle, filtrierte und engte im Vakuum stark ein. Vom ausgefallenen braunen Öl, IIA, wurde dekantiert und schliesslich der Rest des Wassers im Vakuum bei 50° entfernt, wobei ein brauner Syrup anfiel, IIB.

IIA zeigte eine stark positive Reaktion mit Eisen(III)-Chlorid in Äthanol, mit Mg und HCl in Methanol war die Reaktion negativ. Da die Substanz auch bei längerem Stehen im Eisschrank mit Methanol nicht kristallisierte, wurde sie nicht weiter untersucht.

Aus dem braunen Syrup IIB kristallisierte beim Stehen mit Methanol im Eisschrank eine schöne farblose Substanz aus. Schmp. 270—274° unter Zers. nach Absaugen, Waschen mit Methanol und Trocknen. Auf dem Papierchromatogramm (Äthylacetat: Essigsäure:Wasser, 3 : 1 : 1) war noch L-Arabinose nachzuweisen. Eine Umkristallisation aus Äthanol lieferte papierchromatographisch reine Substanz, Schmp. 285° unter Zers. $[\alpha]_D$ —274° (*c* 0,55, Dimethylformamid-Wasser, 1 : 1).

Aus Äthanol-Wasser kristallisiert die Substanz in schönen Nadeln, die bei 185° schmelzen, bei höherer Temperatur wieder teilweise kristallisieren, um dann vollständig bei ca. 280° zu schmelzen. (Getrocknet im Vakuum Gef. C 61,2 : H 5,6. Ber. für $C_{17}H_{18}O_7$: C 61,1; H 5,4). Beim Aufarbeiten des restlichen ätherunlöslichen Teils II wurde weitere Substanz erhalten. Totalausbeute 4,5 g. Beim Trocknen bei 120° wurde die Substanz purpurrot. Kochen mit Salzsäure ergab eine rotviolette Lösung.

Die ätherlösliche Fraktion III wurde konzentriert und unter lebhaftem Rühren in 12 l Leichtpetroleum eingetropft, wobei 400 g gelbliches, in Leichtpetroleum unlösliches Pulver IV ausfiel. Die lösliche Fraktion V wurde in einen bikarbonatlöslichen Teil VI, einen alkalilöslichen Teil VII einen und Neutralteil VIII aufgetrennt.

Die saure Fraktion VI (8,5 g) kristallisierte teilweise beim Stehen mit Methanol im Eisschrank. Filtration und Waschen der Kristalle mit eiskaltem Methanol ergab 0,7 g kristallisierte Fettsäuren, Schmp. 80°.

Die alkalilösliche Fraktion VII (61 g) lieferte wie Fraktion VI ca. 4 g eines Gemisches kristallisierter Fettsäuren, Schmp. 70—75°. Chromatographie des nicht kristallinen Teils an Eisen-freiem Silicagel und Elution mit Benzol, Benzol-Aceton und Benzol-Methanol-Gemischen ergab nur Spuren kristallisierter Fettsäuren.

Die neutrale Fraktion VIII wurde bei 0.2 — 0.3 mm Druck fraktioniert. 400 g Substanz ergaben folgende Fraktionen:

1. Sdp. 99—100°: 170 g, $[\alpha]_D$ −3,8°
2. Sdp. 100—110°: 69 g, $[\alpha]_D$ −26,3°
3. Sdp. 110—113°: 90 g, $[\alpha]_D$ −34,3°
4. Rückstand XI: 25 g

Fraktion 1 wurde in einer Füllkörper-Kolonne mit Vakuummantel (LKB) bei hohem Rückflussverhältnis destilliert. Folgende Fraktionen wurden erhalten:

Fraktion	Sdp./10 mm	Gewicht	n_D	$[\alpha]_D$
1 a	120—130°	8,44 g	1,5018	0°
1 b	130—133°	9,56 g	1,5064	0°
1 c	133—135°	66,16 g	1,5091	+50,9°
1 d	135—138°	8,06 g	1,5124	+58,1°
1 e	138—151,5°	7,47 g	1,5095	−9,95°
1 f	151.5—154°	6,90 g	1,5067	−52,6°
1 g	154—156°	24,29 g	1,5071	−51,1°
1 h	140—150°	13,43 g	1,5070	−50,0°

Bei Fraktion 1 h wurde der Druck auf 3—5 mm gesenkt.

Cadinene (IX). Einen kleinen Teil von Fraktion 1 c löste man in absolutem Äther und sättigte die Lösung mit trockenem Chlorwasserstoff. Verdampfen des Äthers im Vakuum, Umkristallisation des kristallinen Rückstandes aus Leicht-Petroleum und Sublimation bei 0.1 mm Druck ergab lange schöne Nadeln, Schmp. 117—118°, $[\alpha]_D$ −37,9° (*c* 2,8). Der Mischschmelzpunkt mit (−)-Cadinen-dihydrochlorid zeigte keine Erniedrigung.

Cadinole (X). 3,1 g von Fraktion 1 g wurden an Aluminiumoxyd (Brockmann, Aktivität II, 300 g) chromatographiert. Benzol (1 Liter) eluierte 135 mg Öl, weitere 1,5 Liter Benzol lieferten 1,6 g »x-Cadinol», das durch mehrfache Sublimation über einen Temperaturgradienten bei 0,1 mm Druck gereinigt wurde. Schmp. 78°, $[\alpha]_D$ −86,2° (*c* 1,5). Elution mit 3 Litern Benzol + 1 % Äther ergab zuerst 100 mg δ-Cadinol, das nach zweifacher Sublimation rein war. Schmp. 139°, $[\alpha]_D$ −106° (*c* 3,0). Darauf wurden 700 mg eines Gemisches von δ- und α-Cadinol eluiert, gefolgt von 400 mg reinem α-Cadinol. α-Cadinol zeigte nach zweifacher Destillation bei 0,1 mm einen Schmp. von 73—74°. $[\alpha]_D$ −48,6° *c*) 5,7). Die Identität aller drei Cadinole wurde durch Mischschmelzpunkt mit authentischen Substanzen bestätigt.

Aus dem Gemisch von δ- und α-Cadinol konnten durch Kristallisation aus Leichtpetroleum weitere Mengen δ-Cadinol gewonnen werden. Fraktion 1 g enthält ca 50 % »x-Cadinol», ca 10 % δ-Cadinol und ca. 30 % α-Cadinol. Animpfen des restlichen Teils von Fraktion 1 g mit δ-Cadinol und Aufbewahren im Eisschrank ergab weitere Mengen δ-Cadinol. Auch beim Animpfen mit »x-Cadinol» kristallisierte Fraktion 1 g, aber die Kristalle konnten nur sehr schwer vom anhaftenden Öl befreit werden, da »x-Cadinol» wie α-Cadinol mit Leichtpetroleum oder Methanol sofort ein Öl bildet.

Analoge Chromatographie der Destillat-Fraktionen 1h und 2 und 3 ergaben ca 60—70 % α-Cadinol und ca. 30—40 % »x-Cadinol», aber kein δ-Cadinol. δ-Cadinol wird also in den ersten Destillatfraktionen angereichert, was die Gewinnung grösserer Mengen reinen α-Cadinols aus den höher siedenden Destillat-Fraktionen sehr erleichtert.

Bereitung der p-Nitrobenzoate. 0,786 g rohes »x-Cadinol» wurde in 8 ml absolutem Pyridin gelöst und unter Kühlen mit 1,1 g reinem *p*-Nitro-benzoylchlorid versetzt. Nach 50 min. Erhitzen auf dem Dampfbad wurde mit Äther verdünnt, dreimal mit 1 N Salzsäure und dreimal mit 2 N Natriumcarbonatlösung gewaschen. Das nach Trocknen und Abdampfen erhaltene Rohprodukt wurde mit Äther extrahiert und die Lösung über eine kleine Säule von neutralem Aluminiumoxyd (0,7 × 8 cm, Merck) filtriert. Die erste schwach gelbe Zone lieferte nach Umkristallisation aus Leicht-Petroleum und Äthanol 200 mg reines *p*-Nitrobenzoat des »x-Cadinols», Schmp. und Misch-Schmp. 104—105°. Die Mutterlaugen ergaben weitere 250 mg vom Schmp. 102—104°.

Das *p*-Nitro-benzoat des α-Cadinols, Schmpt. 138°, wurde in analoger Weise erhalten.

Hochsiedendes neutrales Öl XI. Redestillation der Fraktionen VIII, 2, 3 und 4 (Seite 2165) bei 0,2—0,3 mm Druck über eine 30 cm lange Vigreux-Kolonne lieferte neben der Hauptmenge an Cadinolen ca. 8—9 g viskoses leicht gelbliches Öl vom Sdp. 132—154°, dessen optische Drehung und IR-Spektrum in CCl_4 praktisch identisch war mit dem hochsiedenden Öl aus *Athrotaxis cupressoides* (Seite 2167).

Neutraler Destillationsrückstand XII. 5,1 g des dunkelbraunen Destillationsrückstandes wurden 1,5 Std mit 5 g Natriumhydroxyd in 50 ml Äthanol auf dem Dampfbad verseift, darauf 50 ml Wasser zugesetzt und der Alkohol unter vermindertem Druck abgedampft. Die alkalische Lösung extrahierte man mit Äther, trocknete den Ätherextrakt mit Natriumsulfat und trieb das Lösungsmittel ab. Aus der Lösung der Substanz in Leichtpetroleum fielen beim Stehen im Eisschrank ca. 105 mg einer kristallinen Substanz aus, Schmp. 195—215°, die nach Sublimation bei 0.01 mm scharf bei 238° schmolz, $[\alpha]_D$ +74,3° (*c* 1,1), und durch Mischschmelzpunkt und IR-Spektrum als Hinokiol identifiziert wurde. Das Filtrat löste man nach Abdampfen des Leichtpetroleums in Methanol und bewahrte es im Kühlschrank auf, wobei 1,3 g einer kristallinen Substanz, Schmp. 122—132° ausfiel. Die Substanz schmolz nach zwei Umkristallisationen aus Äthanol scharf bei 138°, $[\alpha]_D$ −31,5° (*c* 1,9), zeigte eine positive Digitonin-Reaktion und stellt nach IR-Spektrum, Schmelzpunkt und optischer Drehung ziemlich reines β-Sitosterol dar.

Athrotaxis cupressoides

Extraktion. 4,45 kg trockenes, gemahlenes Kernholz extrahierte man 36 Stunden im Heissextraktor mit Aceton und erhielt nach Abdampfen des Lösungsmittels 262 g braunen Roh-Extrakt. Nach Lösen in ca. 200 ml Aceton wurde die Substanz unter lebhaftem Mischen mit einem Vibrator in ca. 5 l Leichtpetroleum eingetropft und noch ca. 2 Stunden vibriert (Fällung = I; Lösung = II.)

Leichtpetroleum-unlöslicher Anteil (I). Den ausgefallenen Niederschlag (I) filtrierte man ab, wusch mit Leichtpetroleum und löste die Substanz (136 g) in wenig Aceton. Nach Eintropfen der Acetonlösung in 2 l siedendes Wasser, Dekantieren und Filtration nach Kohlezusatz wurde die Lösung im Vakuum stark eingeengt, vom ausgefallenen Öl dekantiert und schliesslich der Rest des Lösungsmittels im Vakuum entfernt. Aus dem sirupösen Rückstand kristallisierten nach Zusatz von Methanol und Impfen 8 g reine L-Arabinose aus, Schmp. 158—160°. Animpfen mit der phenolischen Substanz aus *Athrotaxis selaginoides* lieferte keine Kristalle, auch nicht bei wochenlangem Aufbewahren der Substanz im Kühlschrank.

Leichtpetroleum-löslicher Anteil (II). Beim Einengen der Leichtpetroleumlösung II auf ca. 200 ml kristallisierten beim Stehen 2 g einer Substanz aus, (III) Schmp. 231—235°, die nach Sublimation bei 0,01 mm bei 238° schmolz, $[\alpha]_D$ +75,1°, und durch Mischschmelzpunkt und IR-Spektrum als Hinokiol erkannt wurde. Das Filtrat vom Hinokiol trennte man in üblicher Weise in eine bikarbonatlösliche Fraktion IV, eine alkalilösliche Fraktion V und einen Neutralteil VI auf.

Die bikarbonatlösliche, saure Fraktion IV (2.32 g) lieferte geringe Mengen höherer Fettsäuren, *die alkalilösliche Fraktion V* (9.0 g) etwa 100 mg Hinokiol.

Den Neutralteil VI (ca. 90 g) destillierte man bei 0,3 mm Druck und 150° Ölbadtemperatur, wobei 66,5 g flüchtige Substanz VII übergingen und 12,5 g im Rückstand verblieben VIII.

Den flüchtigen Neutralteil VII destillierte man bei hohem Rücklaufverhältnis in einer Füllkörperkolonne mit Vakuummantel (LKB).

Fraktion	Sdp./10 mm	Gewicht	n_D	*D*
VII : 1	90—122°	2,698 g	1,4800	−42,4°
VII : 2	122—126°	4,493 g	1,4978	−50,8°
VII : 3	126—130°	5,763 g	1,5013	−28,4°
VII : 4	130—134°	6,712 g	1,5053	+1,64°
VII : 5	134—138°	6,212 g	1,5078	+17,4°
VII : 6	138—148°	2,254 g	1,5074	+5,13°
VII : 7	148—152°	17,494 g	1,5078	−37,7°
VII : 8 Rückstand		22,0 g		

Cedren. Die physikalischen Daten von Fraktion VII : 1 — VII : 3 sowie ihre IR-Spektren stimmten gut mit α-Cedren überein.

Ozonisierung. Durch eine Lösung von 0,710 g von Fraktion VII : 2 in 10 ml Methylenchlorid leitete man 4 Std. bei −70° einen ca. 3—5 %-igen Ozon-Strom bis Blaufärbung eintrat. Darauf fügte man in der Kälte 5 ml 30 %-iges Wasserstoffperoxyd und 5 ml gesättigte Soda-Lösung hinzu und schüttelte über Nacht. Nach Extraktion mit 50 ml Äther wurde die wässrige Phase abgetrennt, 10 Min. gekocht, mit Eis gekühlt und vorsichtig mit einer Lösung von Natriumhypobromit aus 2 g Natriumhydroxyd und 1 ml Brom versetzt. Nach 3 Std. leitete man Schwefeldioxyd ein bis die Lösung farblos wurde und schüttelte die alkalische Lösung zweimal mit 50 ml Äther aus. Ansäuern der wässrigen Phase mit verd. Schwefelsäure fällte eine weisse Substanz aus, die nochmals in Äther aufgenommen und mit Bikarbonat extrahiert wurde. Nach Ansäuern der Bikarbonatlösung wurden 170 mg weisse Kristalle erhalten, Schmp. 173°. Nach Umkristallisation aus Äthanol-Wasser unter Zusatz von Tierkohle schmolz die Substanz bei 175—184°. Sublimation bei 140—150°/0,01 mm lieferte reine Cedrendicarbonsäure Schmp. 183—184°, $[\alpha]_D$ −35,5°. (*c* 1,9).

Cadinene. Aus Fraktion VII : 4 und in besserer Ausbeute aus Fraktion VII : 5 wurde mit Chlorwasserstoff reines (−) -Cadinen-dihydrochlorid erhalten. Schmp. 117—118°.

Cadinole. 6,2 g von Fraktion VII : 7 wurde wie auf Seite 000 beschrieben an 455 g Aluminiumoxyd chromatographiert und ergab ca. 50 % »x-Cadinol», ca. 15 % δ-Cadinol und ca. 25 % α-Cadinol, die nach Reinigung durch wiederholte Sublimation durch Mischprobe, optische Drehung und IR-Spektrum identifiziert wurden.

Der Rückstand VII : 8 wurde bei 0,3 mm Druck und 110—200° Ölbadtemperatur destilliert.

Fraktion	Sdp.	Gewicht	opt. Drehung
VII : 8 : 1	112—130°	0,66 g	
VII : 8 : 2	130—152°	19,01 g	−32,1°

Da Fraktion VII : 8 : 1 mit Chlorwasserstoff eine gute Ausbeute an (−)-Cadinen-dihydrochlorid lieferte, besteht diese Fraktion grösstenteils aus Cadinolen und wurde nicht weiter untersucht.

Fraktion VII : 8 : 2 ergab nur sehr wenig Cadinen-dihydrochlorid. Chromatographie von Fraktion VII : 8 : 2 an Aluminiumoxyd und aktiviertem Silicagel lieferte nur ölige Alkohole. Acetylierung mit Pyridin-Acetanhydrid und Chromatographie an neutralem Aluminiumoxyd ergab ebenfalls nur ölige Acetate.

Auch nach Reaktion von Fraktion VII : 8 : 2 mit *p*-Nitro-benzoyl-chlorid und Pyridin und nachfolgender Chromatographie an neutralem Aluminiumoxyd wurden keine kristallinen Derivative erhalten.

Der braune harte Destillationsrückstand kristallisierte mit Methanol und erbrachte weitere Mengen Hinokiol.

Chamaecyparis pisifera

Destillation. 81 g Wasserdampf-destilliertes neutrales Öl aus dem Kernholz von *Chamaecyparis pisifera* wurde bei 10 mm Druck in einer Füllkörperkolonne mit Vakuummantel (LKB) sorgfältig fraktioniert.

Fraktion	Sdp.	Gewicht	n_D	opt. Drehung
1	124—132°	8,62 g	1,5052	+9,24°
2	132—135°	9,34 g	1,5073	+28,9°
3	135—142°	13,135 g	1,5093	+50,2°
4	142—153°	5,13 g	1,5079	−15,8°
5	153—156°	26,42 g	1,5073	−39,3°
Rückstand		17,0 g		

Der dunkelbraune Rückstand wurde nicht weiter untersucht.

Cadinene. Aus Fraktion 2 und 3 wurde mit Chlorwasserstoff (−)-Cadinen-dihydrochlorid erhalten, Schmp. und Mischschmp. 117−118°.

Cadinole. 5,298 g von Fraktion 5 chromatographierte man wie auf Seite 2165 beschrieben an Aluminiumoxyd (420 g) und erhielt ca. 40 % »x-Cadinol», 5−10 % δ-Cadinol und 40 % α-Cadinol, die nach wiederholter Sublimation durch Mischschmp., opt. Drehung und IR-Spektrum identifiziert wurden.

Die Verfasser danken der *U.S. Army and Development Liaison Group* unter der Kontrakt Nr DA-91−508−EUC−288 für die finanzielle Unterstützung, welche einem von uns (*H.V.*) die Teilnahme an dieser Arbeit ermöglichte. Wir danken auch Professor W. Dauben für eine Probe von Albicaulol, sowie Professor F. Šorm für Proben von α- und »x-Cadinol».

The Crystal Structure of $Ru_{11}B_8$

JAN ÅSELIUS

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structure of $Ru_{11}B_8$ has been determined by single crystal methods.

The orthorhombic unit cell has the following dimensions: $a = 11.60_9$ Å, $b = 11.34_2$ Å and $c = 2.83_6$ Å.

There are two formula units in the elementary cell and the space-group is $Pbam-(D_{2h}^9)$ No. 55.

The twentytwo ruthenium atoms are situated in one twofold position and five fourfold positions with two ruthenium atoms in 2(*a*), twelve ruthenium atoms in three fourfold positions 4(*g*): $x_{II} = 0.2844$ $y_{II} = 0.3913$, $x_{III} = 0.0429$ $y_{III} = 0.3952$, $x_{IV} = 0.1686$ $y_{IV} = 0.1740$ and eight ruthenium atoms in two fourfold positions 4(*h*): $x_V = 0.4636$ $y_V = 0.2962$, $x_{VI} = 0.3404$ $y_{VI} = 0.0616$.

The sixteen boron atoms are also situated in fourfold positions with four in 4(*g*): $x_{II} = 0.34_{79}$ $y_{II} = 0.21_{56}$, and twelve in 4(*h*): $x_I = 0.13_{98}$ $y_I = 0.01_{81}$, $x_{III} = 0.15_{23}$ $y_{III} = 0.32_{65}$, $x_{IV} = 0.27_{99}$ $y_{IV} = 0.25_{35}$.

Very little is known about the structures of the borides of the platinum metals.

Buddery and Welch [1] have prepared a number of such borides by direct combination of the elements.

Mooney and Welch [2] determined the crystal structure of Rh_2B from single crystal data. Later Aronsson [3] determined the crystal structures of Ru_7B_3 and Rh_7B_3 and Aronsson and co-workers [4] the crystal structures of RhB, PtB and IrB_{1-2}.

An X-ray investigation of the Ru—B system has been started at this Institute in order to establish the existence and compositions of the intermediate phases and to determine the crystal structures. In arc-melted ruthenium-boron alloys five intermediate phases can be identified, Ru_7B_3, $Ru_{11}B_8$, RuB, $RuB_{\sim 1.5}$, $RuB_{\sim 3}$.

The present paper gives an account of the crystal structure of the phase $Ru_{11}B_8$.

EXPERIMENTAL

Alloys were prepared by high frequency-melting ruthenium (claimed purity *ca.* 99.8 %, obtained from Heraeus, Hanau, Germany) and boron (claimed purity 99.0—99.7 %, kindly donated by Borax Consolidated, London). No chemical analyses were carried out and all compositions reported are nominal.

The reaction products were investigated with X-ray powder methods. Guinier-type cameras with Cu$K\alpha$-radiation were used. The unit cell dimensions were determined with CaF_2 as internal calibration standard, $a = 5.4630$ Å.

For the single-crystal work, a small, roughly spherical crystal fragment was selected from a crushed $Ru_{1.25}B$-alloy. Single crystal photographs were taken around the *c*-axis with an equi-inclination Weissenberg camera with niobium-filtered MoK radiation. The multiple film technique was employed with thin iron foil between successive films. The intensities were visually estimated with the aid of a standard intensity scale. The summation of the Fourier series and the structure factor calculations were made on the electronic digital computer BESK with programs (available at BESK) devised by M. Edstrand and Åsbrink *et al.*[5] In the structure factor calculations the atomic scattering factors were approximated to the following expression:

$$f_i = A_i \exp(-a_i/\lambda^2\sin^2\Theta) + B_i \exp(-b_i/\lambda^2\sin^2\Theta) + C_i \exp(-c_i/\lambda^2\sin^2\Theta) + D_i$$

The constants A_i, B_i, C_i and a_i, b_i, c_i have been calculated by Appel [6] on the basis of atomic scattering factor tables given by Tomas and Umeda [7] for ruthenium and by Ibers [8] for boron.

	A	B	C	a	b	c
Ruthenium	15.176	16.599	11.760	0.240	2.637	20.292
Boron	1.644	0.406	2.878	0.6069	4.5832	33.019

The real part of the dispersion correction for ruthenium (D_i in the expression above) was obtained from the table of Dauben and Templeton [9].

RESULTS

The powder photograph of the alloy from which the actual single-crystal specimen was selected, gave the following dimensions of the orthorhombic unit cell:

$$a = 11.60_9 \text{ Å}, \qquad b = 11.34_2 \text{ Å}, \qquad c = 2.83_6 \text{ Å and } U = 373.4 \text{ Å}^3.$$

Small variations of the lattice parameters (0.2 %) have been observed.

It is evident from powder and single-crystal data that $Ru_{11}B_8$ is orthorhombic. Since 0kl reflexions appear only for $k = 2n$, and $h0l$ reflexions only for $h = 2n$, and no limiting conditions are found for hkl,$hk0$ and $00l$ reflexions, the most probable space-groups are *Pbam* and *Pba*2. The distribution of intensities in the $hk0$ and $hk2$ zones are similar, apart from the normal decline. This distribution of intensities indicates that the ruthenium atoms are situated in planes perpendicular to the *c*-axis with a spacing of $c/2$. For that reason, only the $|F|^2$ values for $hk0$ and $hk1$ reflexions were necessary for evaluating the Patterson sections $P(UV0)$ and $P(UV\ 1/2)$. The analysis of these sections showed that the heights and positions of all large peaks in $P(UV0)$ and $P(UV\ 1/2)$ could be interpreted by assuming the space-group to be *Pbam* with twenty ruthenium atoms in five fourfold positions and two ruthenium atoms in a twofold position. If the twofold position 2(a) is chosen, twelve ruthenium atoms are situated in three fourfold positions 4(g) and eight ruthenium atoms in two

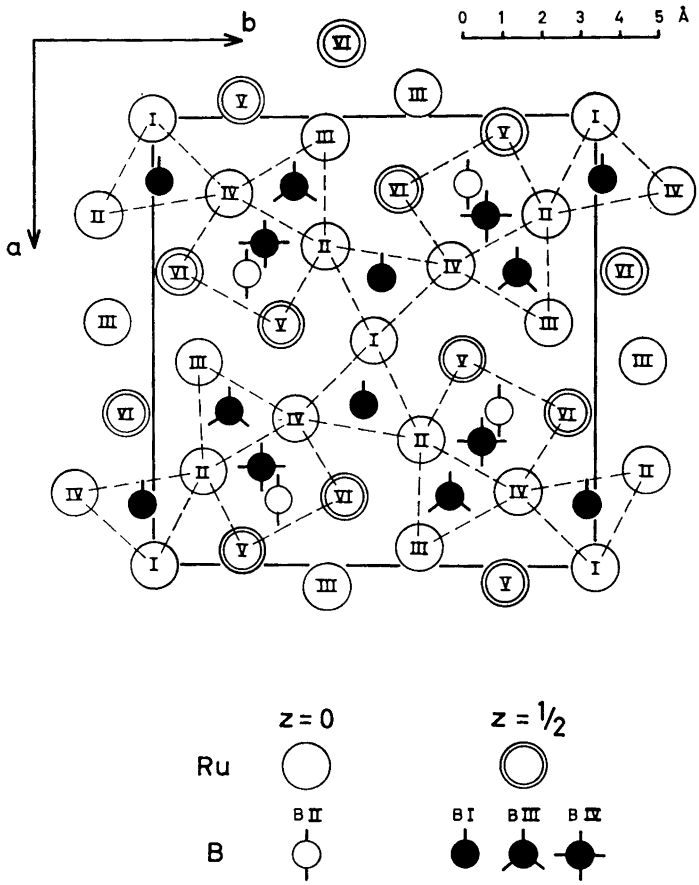

Fig. 1. The structure of $Ru_{11}B_8$ projected on the *ab*-plane.

fourfold positions 4(*h*). During the refinement of the structure nothing was found to contradict the choice of the space-group *Pbam*. (Small deviations from this symmetry for the boron positions cannot be excluded.)

Starting with the rough parameter values obtained from the Patterson maps, signs were calculated for the observed $F(hk0)$ values, and the electron density projection $\varrho\ (xy)$ was computed. The x and y coordinates of the ruthenium atoms were refined from successive difference syntheses. After the final refinement of the ruthenium coordinates, the R value 0.105 was obtained for the observed 310 independent $hk0$ reflexions when an empirical isotropic temperature factor with $B = 0.23_0$ Å^2 was applied. No corrections for absorption and extinction were made.

In the final difference synthesis map, in which all ruthenium atoms were subtracted, four rather well resolved boron maxima were visible. Three of

Table 1. Final atomic parameters of $Ru_{11}B_8$. Space-group *Pbam*. (The standard deviation for all Ru-coordinates is ± 0.0002.)

2 Ru_I	in 2(*a*)		
4 Ru_{II}	in 4(*g*)	$x_{II} = 0.2844$	$y_{II} = 0.3913$
4 Ru_{III}	in 4(*g*)	$x_{III} = 0.0429$	$y_{III} = 0.3952$
4 Ru_{IV}	in 4(*g*)	$x_{IV} = 0.1686$	$y_{IV} = 0.1740$
4 Ru_V	in 4(*h*)	$x_V = 0.4636$	$y_V = 0.2962$
4 Ru_{VI}	in 4(*h*)	$x_{VI} = 0.3404$	$y_{VI} = 0.0616$
4 B_I	in 4(*h*)	$x_I = 0.13_{98}$	$y_I = 0.01_{81}$
4 B_{II}	in 4(*g*)	$x_{II} = 0.34_{79}$	$y_{II} = 0.21_{56}$
4 B_{III}	in 4(*h*)	$x_{III} = 0.15_{23}$	$y_{III} = 0.32_{65}$
4 B_{IV}	in 4(*h*)	$x_{IV} = 0.27_{99}$	$y_{IV} = 0.25_{35}$

these maxima, corresponding to one 4(*g*) position and three 4(*h*) positions had about the same height, but the B_{IV} maxima was considerably lower and not symmetrical in shape. Only one other maximum of the same height as the boron maxima was found, but space considerations showed that this maximum could not be a boron maximum.

With the same temperature factor ($B = 0.23_0$ Å^2) and with all atoms subtracted, a final refinement cycle was made. The reliability index of the observed 310 independant *hk*0 reflexions was found to be 0.097. A list of calculated and observed structure factors can be obtained from this Institute on request.

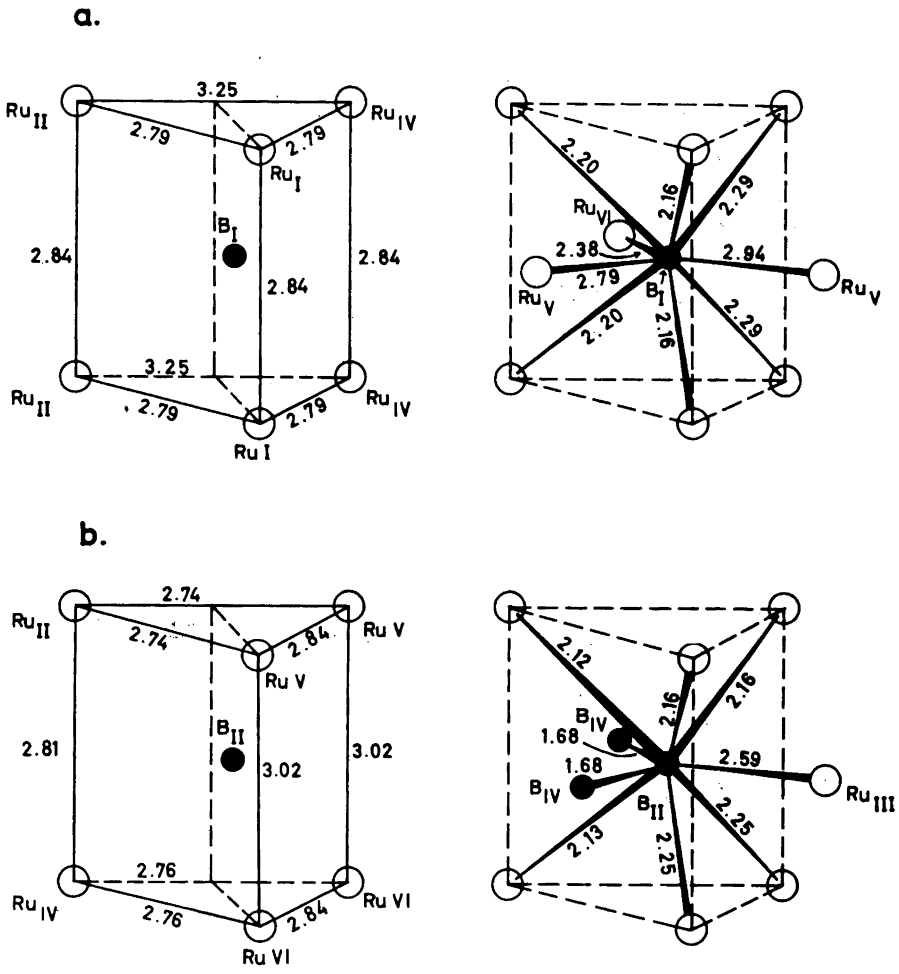

Fig. 3. The environment of the boron atoms in $Ru_{11}B_8$.
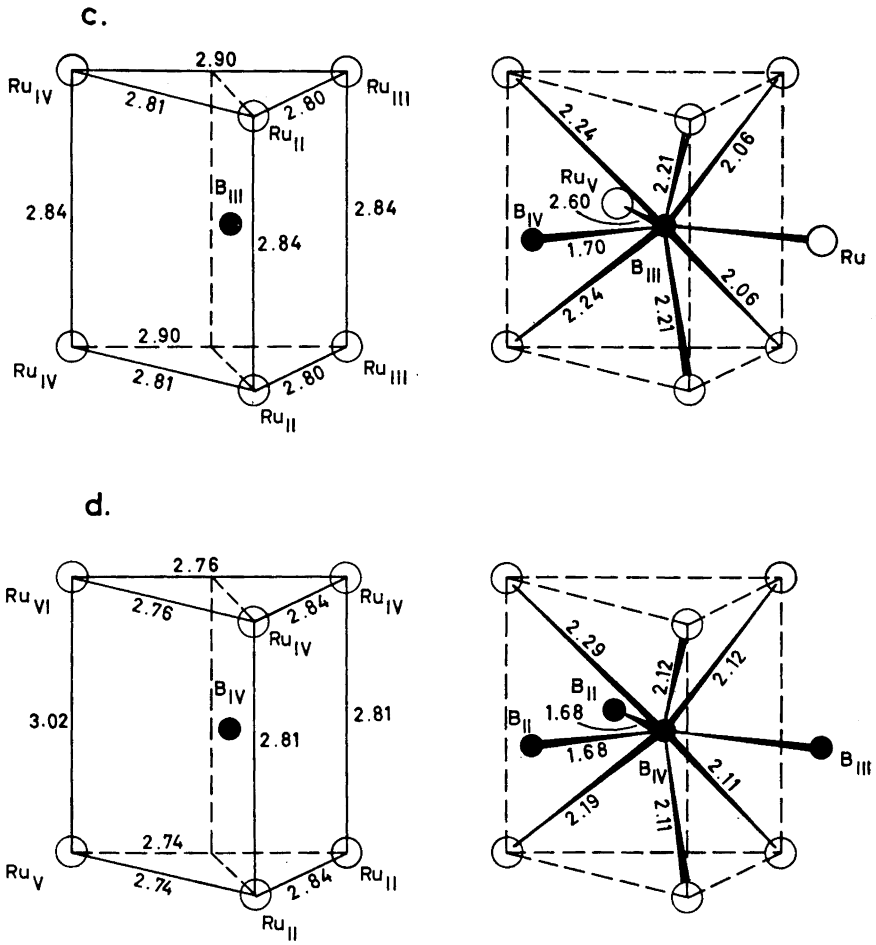
a. the environment of the B_I atoms
b. the environment of the B_{II} atoms

The final atomic parameters with standard deviations and interatomic distances are listed in Tables 1 and 2. (The standard deviations of the atomic parameters of ruthenium were estimated with Cruickshank's [10] formula.)

DESCRIPTION OF THE STRUCTURE

A projection of the structure on the *ab*-plane is shown in Fig. 1.

From the crystal-chemical point of view, the structure of $Ru_{11}B_8$ shows many resemblances to the orthorhombic Ni_4B_3 structure described by Rund-



c. the environment of the B_{III} atoms
d. the environment of the B_{IV} atoms

qvist [11]. Both structures can be described as built-up by interconnected trigonal prisms of metal atoms, with the boron atoms situated in the centers of these prisms. The metal atoms have ten or eleven neighbours of their own kind, and the boron atoms have the usual triangular prismatic environment.

In both the structures the boron atoms are partly isolated without close boron contacts, partly connected to infinite zig-zag chains running throughout the structure in the direction of the shortest axis.

The boron chains in orthorhombic Ni_4B_3 are single zig-zag chains of the same type as the chains in the MeB-borides of the FeB-, MoB- and CrB-types [12]. Every boron atom in the chains is in close contact with two other boron atoms.

In the boron zig-zag chains in $Ru_{11}B_8$ every second boron atom is in close contact with two other boron atoms and every second boron atom is in close contact with three other boron atoms (see Fig. 2 b). In the borides of composition Me_3B_4[12] the boron atoms form double chains.

The boron chain in $Ru_{11}B_8$ can be looked upon as a transition type between a single chain and a double chain.

For comparison a single chain in FeB[13] and a double chain in Mn_3B_4[14] are shown in Figs. 2 a and 2 c.

The four types of trigonal ruthenium atom prisms are shown in Figs. 3 a, b, c and d together with the environments of the B_I, B_{II}, B_{III} and B_{IV} atoms.

The coordination number of the boron atoms is nine, the B_I atoms have nine ruthenium neighbours, the B_{III} atoms have eight ruthenium neighbours and one boron neighbour, the B_{II} atoms have seven ruthenium neighbours and two boron neighbours and the B_{IV} atoms have six ruthenium neighbours and three boron neighbours.

The metal-metal distances are normal with an average distance of 2.79 Å. The average of the twentyfour shortest ruthenium-boron distances is 2.18 Å. This value is in good agreement with the sum, 2.21 Å, of the normal atomic radius of boron, 0.87 Å (Kiessling [12]) and the atomic radius of ruthenium for coordination number 12, 1.34 Å.

Acknowledgements. I wish to thank Professor G. Hägg for his kind interest and for all facilities put at my disposal.

I also want to thank Drs. B. Aronsson, R. Hesse and S. Rundqvist for introducing me into this interesting field of science.

Thanks are also due Mr E. Stenberg for many stimulating discussions.

Studies on the Coagulation of Chicken Blood

I. Factors which Limit Plasma Coagulation Rate during Vitamin K Deficiency and Treatment with Coumarin Drugs

ØYVIND SØRBYE* and INGER KRUSE

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

It is shown that the coagulation time of vitamin K-deficient and dicumarol or coumachlor plasmas is determined by the concentrations of three different types of factors ($\varkappa$-, δ- and φ-factors).

A method for assay of these factors is described. Coagulation tests with thromboplastin, RVV-cephalin or cephalin alone, are all sensitive to $\varkappa$- and δ-factors. The activity measured as φ-factor activity, in the three different coagulation systems, probably includes both system specific entities and entities, common to all three coagulation systems. The relation of these coagulation factors to well-established human coagulation factors is discussed.

In 1948 Dam and Søndergaard [1] observed that mixtures of plasmas from vitamin K-deficient and dicumarol-treated chickens had shorter thromboplastin coagulation times than either plasma alone. The existence of two coagulation factors, different from prothrombin, was assumed to account for the observation: one, which was especially low in vitamin K-deficient plasma, and another, which was especially low in dicumarol plasma. Prothrombin was assumed to be the third rate-limiting factor, lacking in both plasmas.

The factor in dicumarol plasma which accelerated the coagulation of vitamin K-deficient plasma was named δ (delta)-factor, and the factor in vitamin K-deficient plasma which accelerated the coagulation of dicumarol plasma was named $\varkappa$ (kappa)-factor by Sørbye *et al.*[2,3] The factors were concentrated from dicumarol plasma and vitamin K-deficient plasma, respectively.

A full account of the latter findings and recent progress in the study of coagulation factors, responsible for the phenomena described, is presented in this article. Since the first short communications [2,3] were published, our attention has been drawn to the new experimental possibilities offered by use of mixtures of vitamin K-deficient and anticoagulant drug plasmas as test substrates. It seems that this technique will permit more detailed studies of the

* Fellow of the Royal Norwegian Council for Scientific and Industrial Research.

coagulation entities in normal plasma, which are reduced below optimal levels during vitamin K deficiency and anticoagulant drug treatment. Great interest is attached to the possibility of correlating these coagulation entities with coagulation factors, known from studies of human blood. An established correlation between human and chicken coagulation factors will permit problems of human coagulation to be attacked through work on chicken coagulation factors, and *vice versa*.

MATERIALS AND METHODS

"*Normal plasma*". Blood was obtained from the carotid arteries or jugular veins of chickens, reared on a commercial diet [4] or on special diets (Table 1). The chickens were fasted not less than 4—5 h before blood samples were taken, to avoid turbidity in the centrifuged plasma. Nine parts of blood were drawn into one part of 0.15 M potassium oxalate or 0.10 M trisodium citrate and immediately centrifuged at 1 500 *g* for 20 min. After centrifugation the plasma could be poured off after immersion of the centrifuge tubes in ice-water for 5—10 min. It was completely clear and free from blood cells. In cases where the hematocrit value was abnormally low, the concentration of anticoagulant was adjusted to 18—21 mM oxalate or 12—14 mM citrate. Plasma was used fresh or after storage at —20°C.

Vitamin K-deficient plasma. Chickens were reared on a vitamin K-deficient diet [4] until they showed signs of subcutaneous hemorrhage. Blood was obtained as for "normal plasma". Deficiency in δ-factor was pronounced in plasmas with thromboplastin coagulation times more than 7—8 times the normal value.

Dicumarol plasma. Dicumarol was administered orally to chickens on the commercial diet as single dose (0.7—0.9 mg/g) 48—67 h before blood collection, or in two doses (0.7—0.8 and 0.3 mg/g) 50—58 and 24 h before blood collection. The plasmas obtained had thromboplastin coagulation times of 5—12 times the normal plasma value and showed pronounced κ-factor deficiency.

*Coumachlor * plasma.* Coumachlor was administered orally to chickens on the commercial diet in two doses, 44 and 20 h before blood collection. Usually 0.08 and 0.04 mg/g as first and second dose gave plasmas with thromboplastin times of 7—10 times the normal plasma value. Such plasmas had pronounced κ-factor deficiency. Coumachlor gave more uniform responses than dicumarol and was the preferred anticoagulant in the later part of this work. Coumachlor plasma has been shown to behave identically to dicumarol plasma in coagulation tests [5].

Thromboplastin. Chicken brains were carefully freed from blood and vessels and kept frozen in dry ice. For preparation they were dehydrated and ground with acetone and dried to a light powder in air at + 37°C or under vacuum. The powder was stored at —20°C. Of this powder, 0.15 g was triturated with 3 ml of veronal buffer for 30 min at + 37°C and centrifuged for 10 min at 900 *g* and + 2°C. The supernatant normally had optimal coagulation activity, when diluted with 4—5 ml veronal buffer.

Russel's viper venom (RVV). This product was obtained from the Wellcome Research Laboratories, Beckenham, England; it was dissolved in veronal buffer. Dilution 1:12 000 proved optimal in most cases.

Russel's viper venom-Ca (RVV-Ca). This reagent was prepared by dissolving RVV in 30 mM $CaCl_2$-solution (1:12 000).

$CaCl_2$. A stock solution of 100 mM $CaCl_2$ was prepared. This solution was diluted to optimal concentration (25—30 mM) before use.

Brain "cephalin". This phosphatide fraction was prepared from chicken brains, according to Milstone [6]. A 1 % suspension of "cephalin" in buffer was prepared and stored at —20°C. It was thawed and diluted to optimal concentration (0.06—0.09 %) before use.

Blood cell "cephalin". Packed chicken blood cells, separated by centrifugation of blood, were washed with 3 volumes of oxalated saline by suspension and centrifugation,

* 3-(α-*p*-Chlorphenyl-β-acetylethyl)-4-hydroxycoumarin, supplied by J. R. Geigy, Basle.

treated with 2—3 volumes of 96 % ethanol on a steam bath for one hour and filtered. To the filtrate was added 3 volumes of ether and 3 volumes of distilled water. The mixture was shaken and then allowed to stand for separation of the phases. The ether layer was evaporated to dryness with absolute alcohol under reduced pressure. The residue was washed twice with acetone and finally extracted with ether. The clear ether solution was evaporated, and the lipids were suspended in veronal buffer. The suspension was stored deep frozen. It was thawed and diluted to optimal concentration (0.008—0.06 %) before use.

Buffer. 550 ml of 0.1 M sodium barbiturate, 450 ml of 0.1 M HCl, and 5.8 g sodium chloride were mixed with 1 000 ml of 0.9 % sodium chloride. pH was 7.10—7.14. Usually a trace of potassium oxalate (0.009 %) was added.

Oxalated saline. 0.9 g sodium chloride and 0.009 g potassium oxalate in 1 000 ml distilled water.

Citrate-buffer. One part of 0.1 M trisodium citrate was mixed with seven parts of buffer. This solution had the same concentration of anticoagulant as citrate plasma.

Glassware. Thin-walled conical centrifuge glass tubes (15 ml) were used for coagulation time determinations. All glassware were rinsed in chromic-sulfuric acid, washed with tap water at least 10 times and with distilled water 3 times, finally with ethanol and dried at + 80°C.

Coagulation time determination. All reagents, except the trigger solution ($CaCl_2$ or RVV-Ca), were kept in ice-water during the experiment, mixed in desired proportions and placed in a water bath at + 37°C. Coagulation was started by blowing in prewarmed trigger solution with a syringe. Time for formation of a firm clot was noted by means of a stop watch. The glass was tilted slowly until 3—4 sec. before the expected coagulation time when a rapid, but yet cautious tilting began. With some experience and great accuracy it was possible to duplicate the coagulation times within 1/10 of a second for coagulation times up to 40—50 sec. and within half a second for coagulation times up to 2—3 min. A one-stage coagulation test was normally used:

Thromboplastin coagulation time (tpl.-time).

Coagulation system: 0.2 ml plasma or plasma mixture
0.2 ml thromboplastin solution
0—0.2 ml buffer or test solution
0.2 ml $CaCl_2$ (30 mM).

Thromboplastin time is known to depend on the concentration of prothrombin, proconvertin, Stuart factor and proaccelerin, and is said to be insensitive to variations in the levels of intrinsic factors *.

We have also made use of some modifications of this technique:

RVV-cephalin coagulation time (RVV-ceph.-time). Thromboplastin is replaced by cephalin, and $CaCl_2$ is replaced by RVV-Ca. The RVV-ceph.-time depends on the concentration of prothrombin, Stuart factor and proaccelerin, and is not influenced by the concentration of proconvertin or intrinsic factors.

Cephalin coagulation time (ceph.-time). Thromboplastin is replaced by cephalin. Ceph.-time is insensitive to the concentration of proconvertin, but depends on the concentration of intrinsic factors, Stuart factor, prothrombin and proaccelerin. On determination of ceph.-time, tilting of the glass was avoided. The glass was rotated instead. Time for formation of the first visible fibrin threads was noted.

Serum prothrombin activity.

Coagulation system: 0.2 ml serum or plasma
0.2 ml $SrCO_3$-adsorbed oxalated normal plasma
0.2 ml thromboplastin
0.2 ml $CaCl_2$ (50 mM).

A dilution curve was prepared with normal plasma. Dilutions were made with citrate-buffer. The prothrombin activities of serum, read from this curve, were not expected to

* The intrinsic factors include the antihemophilic factor-A, (AHF, factor VIII), antihemophilic factor-B (PTC, Christmas factor, factor IX), antihemophilic factor-C (PTA) and Hagemann factor.

be correct estimates of the prothrombin concentration, as the concentration of accessory factors (proconvertin, Stuart factor, *etc.*) relative to prothrombin generally is higher in serum than in plasma. However, the test is thought to give an idea of the extent of prothrombin consumption during coagulation.

Serum. Blood samples were collected without anticoagulant and allowed to clot at + 37°C. After 2 1/2—3 h the serum was separated and 1/6 volume of 0.1 M trisodium citrate was added. In this work the serum was examined shortly after citrate addition.

Adsorbed plasma. Plasma samples were stirred with the adsorbent for 15 min. at 0°C, centrifuged for 10 min at 1 500 *g* and + 2°C. The supernatant plasma was poured off and stored at 0°C until used.

Elution of adsorbed factors. The sedimented adsorbent, obtained in the procedure above, was first washed twice by stirring for 10 min. with oxalated saline at 0°C. The volume of washing fluid corresponded to the original volume of plasma. After centrifugation the supernatant was discarded. The adsorbed factors were eluted with citrate or phosphate buffers. The pH and molarity of the eluant will be indicated in the text (p. 000). Elution was done by stirring for 15 min. at 0°C, followed by centrifugation. The supernatant was dialyzed against distilled water, when the preparation subsequently was to be freeze-dried. When the preparation could be used immediately after dialysis, oxalated saline was used as dialysis fluid with buffer as the last change of outer phase.

Dialysis. Dialysis was carried out at + 1 — + 2°C for 40—44 h with 5—6 changes of outer phase.

EXPERIMENTS AND RESULTS

Coagulation times for mixtures of different sets of vitamin K-deficient and dicumarol plasmas are seen in Fig. 1 (A, B, C). It is apparent that replacement of small amounts of one plasma by the other causes some acceleration of the coagulation. This indicates the presence of relatively large amounts of a factor in vitamin K-deficient plasma, which is reduced below its optimal level in dicumarol plasma (*x*-factor), and relatively large amounts of a factor

[3] This mixture contained: Thiamine hydrochloride, 6 mg; riboflavin, 8 mg; nicotinic acid, 100 mg; calcium pantothenate, 24 mg; pyridoxine, 7 mg; biotin, 0.2 mg; folic acid, 4 mg; choline chloride, 2 000 mg; inositol, 1 000 mg; *p*-aminobenzoic acid, 300 mg; DL-α-tocopheryl acetate (Ephynal, Roche), 100 mg; bicalcium 2-methyl-1,4-naphthoquinone biphosphate (Synkavit, Roche), 10 mg; mixed with sugar to make 105 g.

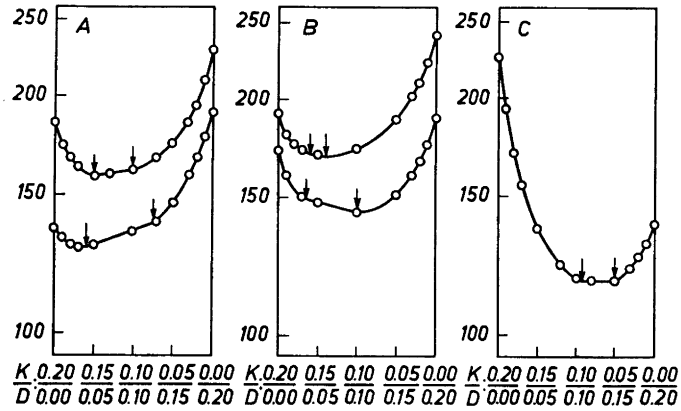

Fig. 1. (*A, B, C*). Coagulation times for plasma mixtures with thromboplastin and 0.2 ml buffer: K, vitamin K-deficient plasma; D, dicumarol plasma; Abscissæ, plasma mixtures in ml; Ordinates, coagulation time in min./100.

in dicumarol plasma, which is below its optimal concentration in vitamin K-deficient plasma (δ-factor). It should be especially noticed, that with increasing concentration of the other plasma in the mixtures a point is reached where the concentration of the factor, supplied by the other plasma, appears to become optimal. These points are indicated by arrows. In the range between the two points the curve appears to be straight-lined when drawn on semi-logarithmic paper.

If the interpretation given above is correct, then plasma mixtures within this range will contain $\varkappa$-factor and δ-factor in optimal amounts. The coagulation time will then depend on the concentration of factors — other than $\varkappa$-factor and δ-factor — which are depressed below optimal levels both in vitamin K-deficient and in dicumarol plasma. In previous reports [1–3] this "common deficiency" has been assumed to be a deficiency in prothrombin. We now prefer to call it a deficiency in φ (phi)-factor(s) until a proper identification with a known coagulation entity becomes possible.

Mixtures of different sets of dicumarol plasmas show no similar depression of the coagulation times (Fig. 2 A), indicating deficiencies in the same rate-limiting factors. The same is true for mixtures of two different vitamin K-deficient plasmas (Fig. 2 B).

These experiments confirm the original observations by Dam and Søndergaard [1].

On treatment of oxalated plasma with $BaCO_3$, all factors, able to shorten the coagulation time of vitamin K-deficient or dicumarol plasma, were removed from normal, vitamin K-deficient and dicumarol plasmas (Fig. 2 C).

It was thus evident that the $\varkappa$, δ- and φ-factors can be adsorbed from oxalated plasma by typical prothrombin adsorbers, such as $BaCO_3$ and $SrCO_3$.

Attempts were made to prepare concentrates of $\varkappa$- and δ-factor from oxalated vitamin K-deficient and dicumarol plasma, respectively, by treatment with

Fig. 2. (*A*, *B*, *C*). 1 % $BaCO_3$, elution twice with 1/3 volume of 0.1 M sodium citrate followed by dialysis and lyophilization. The preparations were redissolved in buffer. Details of the various preparations used in this work are given in Table 2.

The effect of addition of the concentrates of $\varkappa$-factor and δ-factor on the coagulation time of mixtures of vitamin K-deficient and dicumarol plasmas is seen in Figs. 3 and 4.

Figs. 3 A and 4 A show the effect of addition of increasing amounts of δ-concentrates. Coagulation of the plasma mixtures was accelerated only in mixtures with high percentages of vitamin K-deficient plasma. There was no effect on mixtures with high percentages of dicumarol plasma. This proved that the latter mixtures already contained the added factor in optimal concentration. The range for optimal $\varkappa$- and δ-factor concentration (to be referred to

ml of preparation δ-427 (Fig. 4 A). No $\varkappa$- or φ-factor activity could thus be demonstrated in these preparations.

Figs. 3 B and 4 B show the effect of addition of increasing amounts of $\varkappa$-concentrates. Coagulation time of the plasma mixtures was shortened only in mixtures with high percentages of dicumarol plasma. The lack of effect on mixtures with high percentages of vitamin K-deficient plasma proved that these mixtures already contained the added factor in optimal amounts. The optimal range was extended to the right only, proportionally to the amount of $\varkappa$-factor added. Full correction of the $\varkappa$-factor deficiency for all mixtures occurred with 0.1 ml of preparation $\varkappa$-420 (Fig. 3 B) and with 0.1 m l of prparation $\varkappa$-391 (Fig. 4 B). No measurable δ- or φ-factor activity was thus present in these preparations.

In Figs. 3 C and 4 C it is seen that simultaneous addition of sufficient amounts of $\varkappa$- and δ-factors completely wiped out every indication of deficiencies in these factors. The coagulation times were shortened only in mixtures with high percentages of either vitamin K-deficient or dicumarol plasma.

The coagulation times for mixtures within the optimal range were not affected. The curves were completely straightened out to give the expected picture of the coagulation time for mixtures of two plasmas with a slight difference in (Fig. 3 C) or identical amounts (Fig. 4 C) of the same rate-limiting factors.

In the lower curve of Fig. 4 C the $\varkappa$- and δ-factor deficiencies had also been corrected, but the entire curve was shifted to slightly shorter coagulation times, indicating the presence of small amounts of φ-factor in the preparations $\varkappa$-611, or δ-228, or both.

The present experiments very strongly support the original interpretation [1] of the "anomalous" coagulation time observed for mixtures of vitamin K-deficient and dicumarol plasmas. They also justify the more detailed interpretation given here (pp. 2080—2081). Furthermore it is evident that the effect of test solutions on the coagulation time of such mixtures can be used to distinguish sharply between $\varkappa$-, δ- and φ- factor type of activities.

Method for the assay of $\varkappa$-, δ- and φ-factors

The results above suggested the possibility that mixtures of vitamin K-deficient and 'dicumarol (or coumachlor) plasmas might be used as test substrates for individual determinations of $\varkappa$-, δ- and φ-factor levels in plasma. It could be expected that addition of a constant, small amount of plasma to all mixtures would shorten their coagulation times, thereby: 1) extending their optimal range to the left, proportionally to the amount of δ-factor, 2) extending their optimal range to the right, proportionally to the amount of $\varkappa$-factor, and 3) shifting the entire curve to shorter coagulation times, depending on the amount of φ-factor(s), in the plasma added.

These expectations were fully met, as seen in Figs. 5 A and 5 B. Strict proportionality was observed between the amount of added plasma and the extension of the optimal range to either side. Fig. 5 A shows the effect of addition of varying amounts of a plasma (N_1), which appeared to have a relatively high δ- and low $\varkappa$-factor level. The plasma was therefore used to

study the relation between amount of added plasma and extension of the optimal range to the left (δ-effect). The plasma, used in Fig. 5 B (N_2), appeared to have a high $\varkappa$- and a relatively low δ-factor level. It was therefore used to bring out the relation between amount of added plasma and extension of the optimal range to the right ($\varkappa$-effect).

The technique makes it possible to compare the $\varkappa$- and δ-factor levels of different plasmas by comparing the extension of the optimal range to either side, which occurs on addition of a constant, small amount of plasma to mixtures of vitamin K-deficient and anticoagulant drug plasmas.

Comparison of the φ-factor levels of different plasmas is also possible from the results of this type of experiments. Estimation of φ-factor(s) alone is, however, most easily done with a substrate of vitamin K-deficient and anticoagulant drug plasmas in proportion 1:1. Such mixtures normally contain optimal amounts of both $\varkappa$- and δ-factors, and the observed coagulation time depends only on the concentration of φ-factor(s). Fig. 5 C shows the rela-

tion between concentration of added normal plasma (φ-factor(s)) and observed coagulation time with this special mixture of substrate plasmas. The normal plasma and substrate plasmas were the same as those used in Figs. 5 A and 5 B.

Fig. 6 shows the results of an assay of $\varkappa$-, δ- and φ-factor levels in plasmas from 3 different chickens. The chickens were given slightly different diets (Table 1). This experiment may serve as an example of evaluation of the $\varkappa$-, δ- and φ-factor activities of different plasmas. Optimal ranges were read

0.010	plasma F-8	$\frac{0.145}{0.055} - \frac{0.030}{0.170}$	0.045	0.070	4 1/2	7	84

* Read from a φ-factor dilution curve made with F-6 plasma.

from Fig. 6, and φ-factor activities of the other two plasmas were read from a dilution curve (similar to the curves of Fig. 5 C) made with F-6 plasma. The results are given in Table 3.

The variations in the activities of $\varkappa$-, δ- and φ-factors, observed in this experiment, suggest that the concentration of the factors may vary to some extent with the diet. Thus it seems possible that the formation of $\varkappa$-, δ- and φ-factors depends on dietary factors other than vitamin K. This is, however, an entirely new type of problem, which will receive further treatment in later publications.

Substitution of other Procoagulants for Thromboplastin

In all experiments reported so far, coagulation of the plasma mixtures was accelerated by addition of optimal amounts of chicken brain thromboplastin. It was therefore of interest to see if the deficiency symptoms, observed with thromboplastin as procoagulant, also could be observed in other coagulation systems, where thromboplastin was replaced by RVV-cephalin or by cephalin alone.

The results of two different experiments are seen in Figs. 7 (A, B, C). With all procoagulants the same type of curves was obtained. In all coagulation

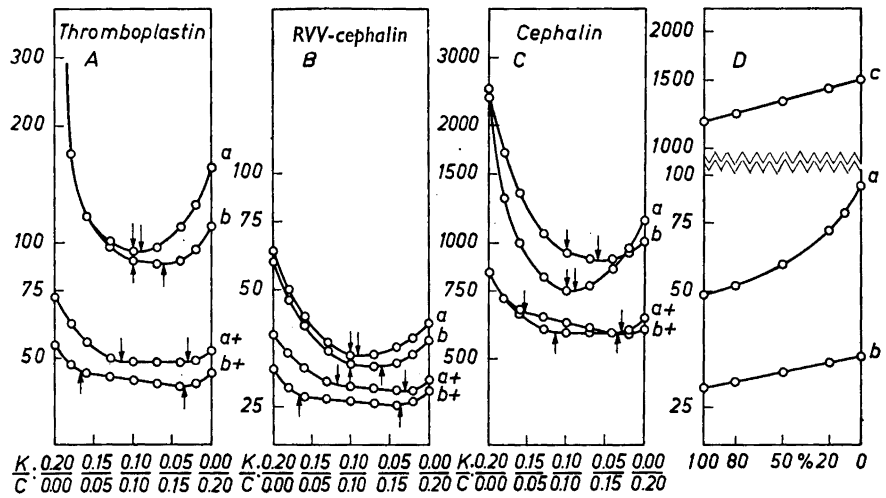

Fig. 7 (A, B, C). Coagulation time for plasma mixtures with thromboplastin (7 A), RVV-cephalin (7 B) and cephalin (7 C). Effect of normal plasma. Fig. 7 D. Dilution curves for φ-factor activity. Diluted normal (N) plasma (0.01 ml) added to a mixture of 0.10 ml vitamin K-deficient (K) and 0.10 ml coumachlor (C) plasma. Curve a, with thromboplastin; Curve b, with RVV-cephalin; Curve c, with cephalin; Abscissa, concentration of normal plasma; Ordinate, coagulation time in min./100.

systems both vitamin K-deficient plasma and coumachlor plasma seemed to contain relatively large amounts of a factor which was reduced below optimal levels in the other plasma. The range, where these factors appeared to be optimal, was, for each set of plasma mixtures, the same in all three coagulation systems (curves a and b). Furthermore, when an assay of the concentration of these factors in normal plasma was performed, according to the method suggested, identical results were obtained with the three different coagulation accelerators (curves a+ and b+).

Thus, it is apparent that $\varkappa$- and δ-factors are important in all three coagulation systems.

It is, however, not immediately clear, whether the activity, measured as φ-factor(s) in the three different coagulation systems, is due to the same factor(s), or if different entities are measured.

The dilution curves for φ-factor(s) appeared to be straight lines with RVV-cephalin and with cephalin, when plotted on semi-logarithmic paper, whereas the curve with thromboplastin was definitely curved (Fig. 7 D).

These findings suggest that the activity, referred to as φ-factor activity, may include one or more factors which are specific for the thromboplastin system. The possibility that the cephalin system may be sensitive to a φ-factor, which is without effect in the two other systems, must also be taken into consideration. The exact number of different entities, measured as φ-factors in the different coagulation systems, is thus still an unsolved problem.

Behavior of $\varkappa$- and δ-factor during coagulation

Comparison of plasma and its corresponding serum, obtained by spontaneous coagulation of blood at + 37°C, showed regularly that δ-factor disappeared during coagulation. The activity of $\varkappa$-factor was, on the contrary, increased. A typical experiment is summarized in Table 4.

The disappearance of δ-factor and activation of $\varkappa$-factor during spontaneous coagulation of blood at + 37°C was measured in all three coagulation systems. Identical results were obtained.

DISCUSSION

The experiments reported demonstrate that the "anomalous" coagulation times, observed for mixtures of vitamin K-deficient and anticoagulant drug plasmas, has been correctly interpreted. Particularly illustrating is the effect

Table 4. Behavior of $\varkappa$- and δ-factors during coagulation.

Activity of	Prothrombin %	δ-factor %	$\varkappa$-factor %
Plasma	100	100	100
Serum	25	0	172

of addition of concentrates, prepared from vitamin K-deficient and anticoagulant drug plasmas, on the coagulation time of such mixtures. The experiments prove that the accelerated coagulation, observed for mixtures of vitamin K-deficient and anticoagulant drug plasmas, is due to great differences in the concentrations of two factors ($\varkappa$- and δ-factors) in these plasmas. However, the prolonged coagulation time of vitamin K-deficient and anticoagulant drug plasmas cannot be completely accounted for by the reduced concentrations of these two factors alone. Three different types of coagulation factors ($\varkappa$-, δ- and φ-factors) are responsible for the prolonged coagulation time of plasma during severe vitamin K-deficiency and after short-time treatment with coumarin drugs.

It is evident that the proposed assay method, based on mixtures of vitamin K-deficient and anticoagulant drug plasmas as substrates, can only be sensitive to the concentration of factors which have been reduced *below optimal levels* in the substrate mixtures. The assay method can therefore not be expected to be sensitive to *all* coagulation factors, affected by vitamin K deficiency and coumarin drug treatment. The reduction of some of the affected factors may not be so extensive that their concentrations drop below optimal levels.

The method should, however, be of value for studies of the factors in normal plasma which are most highly affected by vitamin K deficiency and coumarin drug treatment.

The adsorbability, vitamin K dependence and anticoagulant drug sensitivity of $\varkappa$-, δ- and φ-factors exclude their identity with Hageman factor, PTA, AHF or proaccelerin.

It even seems impossible to identify $\varkappa$- or δ-factor with any of the adsorbable coagulation factors known from studies of human blood. As $\varkappa$-factor and δ-factor are important for the coagulation mechanisms, initiated by addition of thromboplastin, RVV-cephalin and cephalin, neither can be identified with proconvertin or PTC. (RVV-ceph.-time and ceph.-time are not proconvertin sensitive, and tpl.-time and RVV-ceph.-time are insensitive to PTC.) They cannot be identical to prothrombin, as no δ- and increased $\varkappa$-factor activity is found in fresh serum where the prothrombin activity is 25 % of that of plasma.

The possibility discussed by Dam and Søndergaard [7] that differences in ratio of prothrombin to proconvertin might account for the coagulation times of vitamin K-deficient plasma, anticoagulant drug plasma and mixtures of the two, has thus not been supported by the present experiments.

An identification of δ-factor with Stuart factor seems impossible, since this coagulation factor usually is found in serum with unchanged [8] or increased [9] activity. The rate and extent of decrease reported for Stuart factor during anticoagulant drug treatment [9,10], does not conform with the great sensitivity of $\varkappa$-factor to anticoagulant drugs.

Theoretically, it remains a possibility that proconvertin might be registered as a thromboplastin-specific φ-factor, that PTC might behave as a cephalin-specific φ-factor, and that Stuart factor and prothrombin could be measured as φ-factors, common to all three coagulation systems. All these factors are reduced during vitamin K deficiency and coumarin drug treatment, but we do not know if the reduction is so extensive and so rapid that they become

rate-limiting coagulation factors under the conditions described. Further experimentation is necessary to establish the nature and exact number of the different entities in normal plasma, that are measured as φ-factors in the three coagulation systems.

A better knowledge of, and control over, the $\varkappa$-, δ- and φ-factors should be of value for anticoagulant drug therapy, as they seem to control the coagulation rate of plasma during vitamin K deficiency and after treatment with coumarin drugs.

Complex Dibenzofurans

II *. Synthesis of 2,2′,3′,2″-Dioxido-*p*-terphenyl

NILS E. STJERNSTRÖM

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

In a search for a convenient synthetic route to dioxidoterphenyls, Ebel's dibenzofuran synthesis was investigated. 2,2′,3′,2″-Dioxido-*p*-terphenyl (II) was obtained in good yield starting from the sodium salt of 4-hydroxydibenzofuran which reacted with 2-bromo*cyclo*hexanone to give the expected keto-ether. This was cyclised with polyphosphoric acid and the product dehydrogenated with palladium.

The dihydroxy-dioxidoterphenyl obtained by the action of strong sulphuric acid on *p*-benzoquinone has recently been related to similar polymerisation products from monoalkyl-*p*-benzoquinones [1]. These products have for obvious reasons been considered to be derivatives of *o*-terphenyl (Ia) [2] and the structure Ib has consequently been suggested for the phenolic terphenyl derivative from *p*-benzoquinone.

On zinc dust distillation the above *p*-benzoquinone polymerisation product gave a dioxidoterphenyl which accordingly should possess structure Ic. Other structures are of course theoretically possible and an unambigous synthesis of compound Ic is therefore a matter of interest.

Of the five theoretically possible dioxidoterphenyls, only two have been prepared by reliable methods, namely 2,2′, 5′,2″-dioxido-*p*-terphenyl [1,3,4] and 2,6′,4′,2″-dioxido-*m*-terphenyl [5]. During attempts to find convenient methods for the preparation of dioxidoterphenyls 2,2′,3′,2″-dioxido-*p*-terphenyl (II) has now been obtained.

Most of the methods of preparing dibenzofurans appear to be suitable for the synthesis of dioxidoterphenyls. The Pschorr synthesis (for a recent review see Ref.[6]) and the procedure of Ebel [7] seemed to be especially suitable since the starting material would already contain a dibenzofuran nucleus.

The possibility of using the Pschorr synthesis was investigated first. It was found impossible to prepare the intermediate ether from the sodium salt

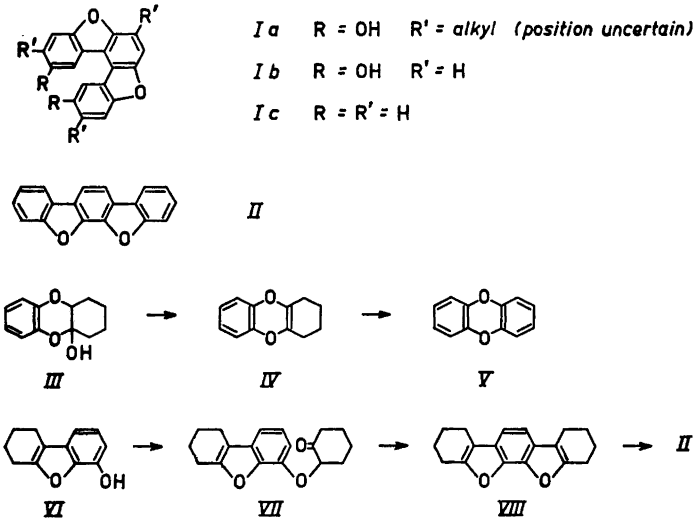
* Part I. *Acta Chem. Scand.* **14** (1960) 1274.

of 4-hydroxydibenzofuran and 2-bromonitrobenzene under sufficiently mild conditions (employing solvents as nitrobenzene, mono- and diglyme), since it was intended later to introduce a blocking bromine group in the dibenzofuran moiety. Blocking groups such as this have been used previously in the synthesis of phenanthrene derivatives in order to affect the direction of ring closure [2].

Ebel's dibenzofuran synthesis has recently been used in this laboratory for the preparation of 2,2′,5′,2″-dioxido-*p*-terphenyl from hydroquinone and 2-bromo*cyclo*hexanone [1].

The disodium salt of catechol reacted with 2-chloro*cyclo*hexanone to give a compound $C_{12}H_{14}O_3$. The infrared spectrum of this substance indicated the presence of a hydroxyl group, a benzene nucleus carrying four adjacent hydrogen atoms and methylene and aryl ether groups. The compound was therefore assumed to be 1,2,3,4-tetrahydro-4a-hydroxydibenzo-*p*-dioxin (III) and this was shown to be correct. Conversion of compound III by treatment with phosphorus oxychloride in pyridine yielded 1,2,3,4-tetrahydrodibenzo-*p*-dioxin (IV) (the position of the double bond in the hydroaromatic ring is slightly uncertain), which was dehydrogenated to dibenzo-*p*-dioxin (V). This was shown to be identical with an authentic specimen [8].

A successful synthesis of compound II was achieved as follows. 4-Hydroxy-6,7,8,9-tetrahydrodibenzofuran (VI) was easily prepared from the known methyl ether [7] by demethylation with hydrobromic acid. Its sodium salt reacted with 2-bromo*cyclo*hexanone to give 4-(2-keto*cyclo*hexyloxy)-6,7,8,9-tetrahydrodibenzofuran (VII). This substance was cyclised with polyphosphoric acid to give what must be 3,4,5,6,3″,4″,5″,6″-octahydro-2,2′,3′,2′-dioxido-*p*-terphenyl (VIII), which was then dehydrogenated to 2,2′,3′,2″-dioxido-*p*-terphenyl (II). This substance was not identical with the dioxidoterphenyl Ic.



A more convenient route to compound II started with the easily available 4-hydroxydibenzofuran [9], the sodium salt of which reacted with 2-bromo*cyclo*hexanone to give 4-(2-keto*cyclo*hexyloxy)-dibenzofuran (VII, left hand ring also aromatic) in a good yield. This keto-ether was cyclised to 3,4,5,6-tetrahydro-2,2',3',2''-dioxido-*p*-terphenyl (VIII, two rings aromatic). The position of the double bond in the hydroaromatic ring of these compounds (VIII, tetrahydro- and octahydro-) is almost certainly that indicated in formula VIII (*cf.* Ebel [7]). The tetrahydro-compound on dehydrogenation with palladium furnished 2,2',3',2''-dioxido-*p*-terphenyl (II).

This method seems to be of general applicability for the synthesis of dioxidoterphenyls and experiments aiming at the synthesis of compound Ic are now in progress.

EXPERIMENTAL

All melting points are uncorrected

1,2,3,4-Tetrahydro-4a-hydroxydibenzo-p-*dioxin (III).* Sodium (2.3 g) was dissolved in absolute ethanol (40 ml) and a solution of cathechol (5.5 g) in absolute ethanol (20 ml) was added with stirring under a stream of dry oxygen-free nitrogen. The alcohol was evaporated under reduced pressure, care being taken to avoid oxidation. The dry catechol sodium salt, 2-chloro*cyclo*hexanone [10] (14.0 g) and dry toluene (100 ml) were stirred and heated under reflux in an atmosphere of nitrogen for 3 h. The reaction mixture was allowed to cool to room temperature and was extracted with sodium hydroxide solution (10 %). The toluene layer was washed with water and saturated sodium chloride solution and then dried over magnesium sulphate. After evaporation of the toluene, the residue, a yellow oil, was thoroughly triturated with boiling light petroleum (400 ml). The petroleum extract was cooled to −40°, precipitating a greasy oil (crop A). The mother liquor was evaporated to a smaller volume (25 ml) and a crystalline material (crop B, 1.1 g) deposited. Crop B was purified by recrystallisation from *n*-pentane and sublimation *in vacuo* (90°, 20 mm), m.p. 104−105°. (Found: C 70.1; H 6.7; mol. wt. (Rast) 192. Calc. for $C_{12}H_{14}O_3$: C 69.9; H 6.8; mol. wt. 206.)

The infrared spectrum of compound III (KBr) was recorded on a Perkin-Elmer No 21 instrument using a sodium chloride prism. Relevant absorption maxima: 3 400 cm^{-1} (s), 3 000 cm^{-1} (w), 2 900 cm^{-1} (m,s), 1 600 cm^{-1} (m), 1 500 cm^{-1} (vs), 1 455 cm^{-1} (m) and 740 cm^{-1} (vs).

Crop A did not crystallise. Chromotography on neutral alumina yielded only a small amount of compound III, eluted with benzene. The desired product 1,2-di-(2-keto*cyclo*hexyloxy)-benzene could not be traced.

1,2,3,4-Tetrahydrodibenzo-p-*dioxin (IV).* 1,2,3,4-Tetrahydro-4a-hydroxydibenzo-*p*-dioxin (300 mg) was dissolved in dry pyridine (4 ml) and freshly distilled phosphorus oxychloride (1 ml) was cautiously added under stirring and cooling under the water tap. The mixture was stirred for three days at room temperature and was then poured into ice-water. The ether extract was washed with dilute hydrochloric acid and water. After drying over magnesium sulphate the solvent was evaporated and the somewhat oily reaction product (225 mg) was collected. The substance was purified by recrystallisation from absolute methanol and sublimation *in vacuo*, m.p. 61−62.5°. (Found: C 76.4; H 6.5. Calc. for $C_{12}H_{12}O_2$: C 76.6; H 6.4.)

Dibenzo-p-*dioxin (V).* Compound IV (40 mg) was thoroughly mixed with a palladium-charcoal catalyst (10 % Pd, 30 mg) and the mixture was heated to 230° for 5 h in an atmosphere of nitrogen. The reaction product was extracted with hot ethanol (15 ml). After evaporation of the alcohol, the residue (28 mg) was purified by sublimation *in vacuo* and recrystallisation from ethanol (0.5 ml). Yield of pure compound 4 mg, m.p. 117−120.5°. A mixed melting point with a sample of dibenzo-*p*-dioxin prepared according to Gilman [8] (m.p. 120.5−121.5°) showed no depression (m.p. 118−121°). The infrared spectra of the two samples were identical.

4-Hydroxy-6,7,8,9-tetrahydrodibenzofuran (VI). The starting material, 4-methoxy-6,7,8,9-tetrahydrodibenzofuran, was prepared according to Ebel [7] by cyclisation of 1-

methoxy-2-(2-keto*cyclo*hexyloxy)-benzene. The use of polyphosphoric acid as condensing agent instead of sulphuric acid as recommended by Ebel, did not increase the yield. The methyl ether (9 g) was stirred and heated under reflux with constant boiling hydrobromic acid (150 ml) for 12 h in an atmosphere of nitrogen. The reaction mixture was diluted with water (300 ml) and the crude product (8.2 g, violet due to superficial oxidation) was collected, thoroughly washed with water and dried. The substance was recrystallised from *cyclo*hexane and sublimed *in vacuo*. Yield 5.8 g, m.p. 117—118°. (Found: C 77.1; H 6.6. Calc. for $C_{18}H_{18}O_2$: C 76.6; H 6.4.)

*4-(2-Keto*cyclo*hexyloxy)-6,7,8,9-tetrahydrodibenzofuran (VII).* Sodium (0.7 g) was dissolved in absolute methanol (20 ml) and compound VI (5.6 g) in absolute methanol (20 ml) was added, care being taken to exclude moisture and air. The methanol was removed under reduced pressure and 2-bromo*cyclo*hexanone [11] (5.3 g) in dry benzene (125 ml) was added with mechanical stirring. The mixture was stirred at room temperature for 0.5 h and at reflux temperature for further 2 h; it was then extracted with dilute sodium hydroxide and water. The benzene solution was dried over magnesium sulphate and the solvent was evaporated under reduced pressure. The remaining brown oil (6.4 g) was chromatographed on neutral alumina. The fractions eluted with benzene-light petroleum mixtures were collected (3.0 g) and made to crystallise by scratching. The substance was purified by recrystallisation from ligroin and distillation *in vacuo*, m.p. 85—87°. (Found: C 75.9; H 7.0. Calc. for $C_{18}H_{20}O_2$: C 76.0; H 7.1.)

*3,4,5,6,3'',4'',5'',6''-Octahydro-2,2',3',2''-dioxido-*p*-terphenyl (VIII).* Compound VII (1.0 g) was stirred with a mixture of phosphorus pentoxide (15 g) and phosphoric acid (*d* 1.7, 30 ml) for 2 h at 100°. The hot reaction mixture was poured into water. The precipitate was collected, washed and dried. The yield almost quantitative. The product was recrystallised from *cyclo*hexane and sublimed *in vacuo*, m.p. 163—164°. (Found: C 81.6; H 6.8. Calc. for $C_{18}H_{18}O_2$: C 81.2; H 6.8.)

*2,2',3',2''-Dioxido-*p*-terphenyl (II) from compound VIII.* Compound VIII (50 mg) was mixed with a palladium-charcoal catalyst (10 % Pd, 50 mg) and the mixture was heated to 230° for 5 h in an atmosphere of nitrogen. The reaction product (30 mg) that sublimed on the cool parts of the reaction vessel was recrystallised from *cyclo*hexane. Two crystalline forms were observed (long needles which gradually changed to leaflets at ~ 179°), m.p. 180—183°. A mixed melting point with a sample of 2,2',3',2''-dioxido-*p*-terphenyl, synthesised as described below, showed no depression (m.p. 179—182°). The infrared spectra of the two samples were identical.

*4-(2-Keto*cyclo*hexyloxy)-dibenzofuran.* The sodium salt of 4-hydroxydibenzofuran [9] (prepared as described above from 1.2 g sodium and 9.2 g phenol), freshly distilled 2-bromo*cyclo*hexanone (9.0 g) and dry benzene (100 ml) were stirred at room temperature for 18 h and heated under reflux for additional 2 h. The reaction mixture was treated with dilute sodium hydroxide and the benzene extract was thoroughly washed with water and saturated sodium chloride solution and then dried over magnesium sulphate. After evaporation of the solvent the reaction product, colourless crystals (11.7 g), was recrystallised from ethanol and sublimed *in vacuo*, m.p. 142—142.5°. (Found: C 77.1; H 5.7. Calc. for $C_{18}H_{16}O_3$: C 77.1; H 5.8.)

*3,4,5,6-Tetrahydro-2,2',3',2''-dioxido-*p*-terphenyl.* The preceding substance (1.0 g) was stirred with a mixture of phosphorus pentoxide (10 g) and phosphoric acid (*d* 1.7, 20 ml) at 100° for 3 h. The reaction mixture was poured into water (250 ml) and the crystalline precipitate was collected, washed with water and dried. The substance (0.8 g) was recrystallised from *n*-butanol and sublimed *in vacuo*, m.p. 149—150°. (Found: C 82.7; H 5.4. Calc. for $C_{18}H_{14}O_2$: C 82.4; H 5.4.)

*2,2',3',2''-Dioxido-*p*-terphenyl (II).* The tetrahydrocompound (300 mg) was thoroughly mixed with a palladium-charcoal catalyst (10 % Pd, 200 mg) and heated to 230° for 5 h in an atmosphere of nitrogen. The reaction mixture was extracted with boiling *cyclo*hexane. The dioxido-*p*-terphenyl (200 mg) crystallised on cooling. Two crystal forms were observed, needles m.p. 178—179° which changed to leaflets m.p. 183—184°. The substance was purified for analysis by sublimation *in vacuo*. (Found: C 84.2; H 3.9. Calc. for $C_{18}H_{10}O_2$: C 83.7; H 3.9.)

The author is thankful to Dr. Brian Thomas for checking the manuscript.

The Crystal Structure of Hg_2O_2NaI Studied by X-Ray and Neutron Diffraction Methods

KARIN AURIVILLIUS

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden; Joint Establishment for Nuclear Energy Research, Kjeller, Norway

The crystal structure of Hg_2O_2NaI has been studied by X-ray (single crystal) and neutron (powder) diffraction methods. The crystals are hexagonal (space group $P6_322$ ($P6_422$)) with the cell edges a = 6.667 Å and c = 10.054 Å. The unit cell contains three formula units. The mercury and oxygen atoms form infinite planar chains, -Hg-O-Hg-O-, lying perpendicularly to the c axis of the unit cell. The Hg-O distance is 2.03 Å and the angles O-Hg-O and Hg-O-Hg are 180° and 110°, respectively.

As earlier reported [1,2], the structures of the orthorhombic and hexagonal modifications of mercury(II)oxide are built up of infinite chains -O-Hg-O- which, in the orthorhombic modification, are of planar zig-zag type and, in the hexagonal modification, of spiral type. Every mercury atom is thus coordinated to two oxygen atoms and every oxygen atom to two mercury atoms. The aim of the present investigation was to find whether such chains -O-Hg-O- are fundamental constituents of other mercury(II)salts containing oxygen and whether this arrangement is independent of the other kinds of atoms occurring in the structure.

PREPARATION AND ANALYSIS

In connection with the preparation of the hexagonal modification of mercury(II)oxide, the complex compound Hg_2O_2NaI, earlier reported by Laruelle [3], was synthesized. The best way for preparing Hg_2O_2NaI is to mix one part of a cold solution of 0.1 M K_2HgI_4 containing an excess of KI with two parts of 10 M NaOH at about 0°C and to keep the solution at this temperature for about 100 h. The temperature was then slowly increased to room temperature and the substance obtained, which consisted of beautiful yellow pencil-shaped crystals, was then filtered off. Another way of preparing this compound is to heat equivalent quantities of mercury(II)oxide and sodium

iodide in a fused glass tube to 130°C for about 100 h. This method, however, did not give a pure sample.

Attempts were made to replace the sodium atoms in the compound with lithium, potassium, rubidium and caesium. However, these efforts have not yet been successful.

The compound Hg_2O_2NaI decomposes into orthorhombic HgO and NaI when heated in open air to higher temperatures. Thus, a powder diagram of the residue, after the substance had been heated to 200°C for 14 days, did not show any lines characteristic for Hg_2O_2NaI.

The compound is not stable if treated with water – it decomposes into other, not yet identified, phases. Upon exposure to light, the yellow crystals of the substance become dark green. To investigate this phenomenon more closely, a sample of Hg_2O_2NaI was exposed to U.V. light for a long time. X-Ray diagrams of the green substance showed only lines characteristic for Hg_2O_2NaI. A microscopic examination revealed, however, the presence of small drops of mercury.

The pure sample was analysed for Hg, Na, K, I and H_2O and was found to contain neither potassium nor water. The mercury analysis was performed using electrolysis [4], the sodium and potassium analyses flame spectrophotometrically using a Beckman D.U. spectrophotometer [5] and the iodine analysis by iodometric titration [6] after the sample had been brought into solution by melting with sodium hydroxide in a gold crucible. The water analysis was performed according to Penfield [7]. The results of the analyses are in fair agreement with the values calculated for Hg_2O_2NaI (Found %: Hg 67.9; Na 3.8; I 20.9. Calc. Hg 68.8; Na 3.9; I 21.8).

CELL DIMENSIONS AND SYMMETRY

The powder photographs were taken in a Guinier focusing camera of 80 mm diameter using Cu$K\alpha_1$ radiation and potassium chloride ($a = 6.2930$ Å[8]) as an internal standard. The powder pattern is given in Table 1. Heavily exposed photographs did not show any lines that were not visible in normally exposed ones. The powder pattern could be interpreted by means of a hexagonal unit cell with the following cell dimensions:

$$a = 6.667 \text{ Å} \qquad c = 10.054 \text{ Å} \qquad V = 387.0 \text{ Å}^3$$

The observed density, 7.0 gcm^{-3}, indicates a cell content of three formula units Hg_2O_2NaI (calculated density 7.5 gcm^{-3}). For the single crystal photographs, CuK and MoK radiations were used. Rotation diagrams were taken around the a and c axes and Weissenberg photographs were used to register the reflexions $h0l$-$h3l$ and $hk0$-$hk5$.

Since $|F(hk0)|^2$ was found throughout to be equal to $|F(hk3)|^2$, $|(F(hk1)|^2$ equal to $|F(hk4)|^2$ and $|F(hk2)|^2$ equal to $|F(hk5)|^2$ within the limits of experimental error, the heavy atoms of the structure must be situated at the planes normal to the c axis of the unit cell at the z values 0 and $\pm\frac{1}{3}$ or $\frac{1}{2}$ and $\pm\frac{1}{6}$. The coefficients

$$\sum_{l=-\infty}^{l=+\infty} |F(hkl)|^2$$

were thus approximated by the expressions

Table 1. Powder diagram (Guinier focusing camera) and powder diffractogram (Geiger Mueller diffractometer) of Hg_2O_2NaI. I_{calc} is normalized so as to give the best agreement with I_{obs}.

$$I^*_{calc} = 10^{-4}p\varphi(\Theta)F^2; \quad \varphi(\Theta) = \frac{1 + \cos 2\alpha\cos^2 2\Theta}{\sin\Theta(1 + \cos 2\alpha)\cos^2(2\Theta - \beta)\sin 2\Theta} \qquad (cf.\ \text{Ref. 9}).$$

$$I^{**}_{calc} = 10^{-4}p\,\frac{1 + \cos^2\Theta}{\sin^2\Theta\cos\Theta}\,F^2$$

$$|F(hk0)|^2 + |F(hk3)|^2 + |F(hk1)|^2 + |F(hk4)|^2 + |F(hk2)|^2 + |F(hk5)|^2.$$

The Laue symmetry found from the Weissenberg photographs was $6/mmm$. In the powder and Weissenberg photographs, the following spectra were systematically missing: $h = 0$, $k = 0$, $l \neq 3n$ and h, k even, $l \neq 3n$ (n is an integer). This is characteristic for the enantiomorphous space groups [10] $P6_222$ (No. 180) and $P6_422$ (No. 181). Possible space groups are: $P6/mmm$ (No. 191), $P\bar{6}2m$ (No. 189), $P\bar{6}m2$ (No. 187), $P6mm$ (No. 183) and $P622$ (No. 177).

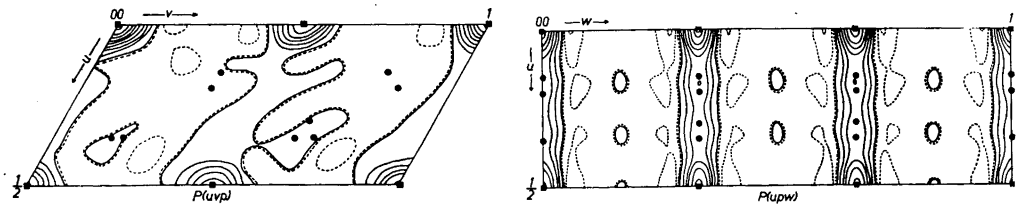

Fig. 1. The Patterson functions $P(uvp)$ and $P(upw)$. The vectors Hg—Hg (□), Hg-I (△) and Hg-O (●) for the final structure are indicated. Dashed lines indicate negative values.

THE POSITIONS OF THE MERCURY ATOMS

To locate the heavy metal atoms in the unit cell, the Patterson projections $P(uvp)$ and $P(upw)$ (Fig. 1) were calculated using F^2 values derived from the visually estimated intensities of the Weissenberg photographs.

Now in space group $P6_622$ (No. 180) and analogously for the enantiomorphous space group $P6_422$ (No. 181), it is possible for the six mercury atoms to occupy one of the sixfold point positions 6(j), 6(i), 6(h), 6(g), 6(f) and 6(e) or a combination of two threefold point positions 3(d), 3(c), 3(b) and 3(a). Since it is not possible to distinguish between the two characteristic space groups, one of them, *viz.* $P6_222$, is chosen arbitrarily.

$P6_222$:

6(j):	$\pm(x, 2x), \frac{1}{2}$;	$\pm(2x, x), \frac{1}{6}$	;	$\pm(x, \bar{x}), \frac{5}{6}$
6(i):	$\pm(x, 2x), 0$;	$\pm(2x, x), \frac{2}{3}$	;	$\pm(x, \bar{x}), \frac{1}{3}$
6(h):	$\pm x, 0, \frac{1}{2}$;	$0, \pm x, \frac{1}{6}$	;	$\pm(x, x), \frac{5}{6}$
6(g):	$\pm x, 0, 0$;	$0, \pm x, \frac{2}{3}$	;	$\pm(x, x), \frac{1}{3}$
6(f):	$\frac{1}{2}, 0, \pm z$;	$0, \frac{1}{2}, \frac{2}{3} \pm z$	;	$\frac{1}{2}, \frac{1}{2}, \frac{1}{3} \pm z$
6(e):	$0, 0, \pm z$;	$0, 0, \frac{1}{3} \pm z$	;	$0, 0, \frac{2}{3} \pm z$
3(d):	$\frac{1}{2}, 0, \frac{1}{2}$;	$0, \frac{1}{2}, \frac{1}{6}$	;	$\frac{1}{2}, \frac{1}{2}, \frac{5}{6}$
3(c):	$\frac{1}{2}, 0, 0$;	$0, \frac{1}{2}, \frac{2}{3}$	;	$\frac{1}{2}, \frac{1}{2}, \frac{1}{3}$
3(b):	$0, 0, \frac{1}{2}$;	$0, 0, \frac{5}{6}$	;	$0, 0, \frac{1}{6}$
3(a):	$0, 0, 0$;	$0, 0, \frac{1}{3}$	;	$0, 0, \frac{2}{3}$

The possible combinations of the threefold point positions are:

3(a) + 3(b); 3(a) + 3(c); 3(a) + 3(d); 3(b) + 3(c); 3(b) + 3(d) and 3(c) + 3(d).

On displacing the origin of the unit cell by $\frac{c}{2}$, however, the point position 6(j) becomes identical to 6(i), 6(h) to 6(g), 3(a) + 3(b) to 3(c) + 3(d), 3(a) + 3(c) to 3(b) + 3(d) and 3(a) + 3(d) to 3(b) + 3(c).

The Hg-Hg vectors u, v, w, required by these possibilities are given in Table 2. This table should be compared with Fig. 1.

The major maxima of the two Patterson projections should be mainly due to mercury-mercury vectors. The point positions 6(e) and 3(a) + 3(d) cannot explain the high maxima at $u = \frac{1}{2}$, $v = 0$; $u = 0$, $v = \frac{1}{2}$ and $u = \frac{1}{2}$, $v = \frac{1}{2}$ in $P(uvp)$ and can thus be excluded. Since there do not exist any heavy maxima at $u = \frac{1}{2}$, $v = \frac{1}{6}$ or $u = 0$, $v = \frac{1}{6}$ in $P(uvp)$, the combination 3(a) + 3(b) can also be ruled out. Nor was it possible to find an x parameter for the vectors u, v, w, of the point positions 6(j) and 6(h) which could satisfy the Patterson projections $P(uvp)$ and $P(upw)$. Thus the remaining possibilities for the positions of the six mercury atoms in $P6_222$ (No. 180) are: 6(f) with $z = 0.333$ or 3(a) + 3(c). By calculating the values of the structure factors $|F_{hkl}| = \sqrt{A^2 + B^2}$ for the two geometrically different arrangements of the six mercury atoms, it was found that they gave the same values. Thus, by evaluating the Patterson projections $P(uvp)$ and $P(upw)$ above, a homometric pair of arrangements for the mercury atoms was found. These two homometric mercury atom positions gave rise to six possible point positions for the three iodine atoms. The Patterson projections $P(uvp)$ and $P(upw)$ were then examined for these different possibilities.

Table 2. Required vectors Hg-Hg in the Patterson functions.

	u	v	w	Relative weight
6(*j*):	$\pm(3x, 3x)$		$\pm\frac{1}{3}$	4
	$\pm(x, \bar{x})$		$\pm\frac{1}{3}$	4
	0	$\pm 3x$	$\pm\frac{1}{3}$	4
	$\pm 3x$	0	$\pm\frac{1}{3}$	4
	$\pm(2x, x)$		$\pm\frac{1}{3}$	4
	$\pm(x, 2x)$		$\pm\frac{1}{3}$	4
	$\pm(4x, 2x)$		0	2
	$\pm(2x, 4x)$		0	2
	$\pm(2x, 2\bar{x})$		0	2
6(*h*):	$\pm(x, \bar{x})$		$\pm\frac{1}{3}$	4
	$\pm(x, x)$		$\pm\frac{1}{3}$	4
	$\pm(x, 2x)$		$\pm\frac{1}{3}$	4
	$\pm(2x, x)$		$\pm\frac{1}{3}$	4

	$\pm x$	0	$\pm\frac{1}{3}$	4
	$\pm 2x$	0	0	2
	0	$\pm 2x$	0	2
	$\pm(2x, 2x)$		0	2
6(*f*):	$\frac{1}{2}$	0	$\pm\frac{1}{3}$	4
	0	$\frac{1}{2}$	$\pm\frac{1}{3}$	4
	$\frac{1}{2}$	$\frac{1}{2}$	$\pm\frac{1}{3}$	4
	0	0	$\pm 2z$	6
	$\frac{1}{2}$	0	$\pm(2z\pm\frac{1}{3})$	4
	0	$\frac{1}{2}$	$\pm(2z\pm\frac{1}{3})$	4
	$\frac{1}{2}$	$\frac{1}{2}$	$\pm 2(z\pm\frac{1}{3})$	4
6(*e*):	0	0	$\pm\frac{1}{3}$	12
	0	0	$\pm 2z$	6
	0	0	$\pm(2z\pm\frac{1}{3})$	8
	0	0	$\pm(2z\pm\frac{2}{3})$	4
3(*a*) + 3(*b*):	$\frac{1}{2}$	0	$\pm\frac{1}{6}$	4
	$\frac{1}{2}$	0	$\pm\frac{1}{3}$	4
	0	$\frac{1}{2}$	$\pm\frac{1}{6}$	4
	0	$\frac{1}{2}$	$\pm\frac{1}{3}$	4
	$\frac{1}{2}$	$\frac{1}{2}$	$\pm\frac{1}{6}$	4
	$\frac{1}{2}$	$\frac{1}{2}$	$\pm\frac{1}{3}$	4
3(*a*) + 3(*c*):	0	0	$\pm\frac{1}{3}$	6
	$\frac{1}{2}$	0	$\pm\frac{1}{3}$	6
	0	$\frac{1}{2}$	$\pm\frac{1}{3}$	6
	$\frac{1}{2}$	$\frac{1}{2}$	$\pm\frac{1}{3}$	6
	$\frac{1}{2}$	0	0	2
	0	$\frac{1}{2}$	0	2
	$\frac{1}{2}$	$\frac{1}{2}$	0	2
3(*a*) + 3(*d*):	0	0	$\pm\frac{1}{6}$	12
	0	0	$\pm\frac{1}{3}$	12
	0	0	$\frac{1}{2}$	6

Thus, if the mercury atoms occupy the combination of threefold point positions 3(*a*) and 3(*c*), the only possible point positions left for the three iodine atoms are 3(*b*) and 3(*d*) since a statistical distribution over a sixfold point

Table 3. Required and observed vectors Hg-Hg and Hg-I in the Patterson projection $P(upw)$. The structure possibility: 6 Hg in 3(*a*) + 3(*c*). The calculated relative weights of the maxima due to the Hg-Hg and Hg-I vectors were calculated using the expression $\nu \sum_{k,l} f_k f_l$ where ν denotes the frequence of the vector and f_k, f_l the scattering factors of the atoms.

position is very improbable. Now, in Table 3, there are listed the required vectors mercury-mercury and mercury-iodine (u, w) for the combinations:

6 Hg in 3(*a*) + 3(*c*), 3 I in 3(*b*) (I)
6 Hg in 3(*a*) + 3(*c*), 3 I in 3(*d*) (II)

From the calculated and observed heights of the maxima in this table, it is clearly seen that the possibilities I and II are inconsistent with the experimental data.

The arrangements I and II seem to be impossible also from space considerations. Case I gives a very short distance Hg-I of only 1.7 Å and case II offers 3 (*b*) as the only possible position for the three sodium atoms which results in the very short distance Hg-Na of 1.7 Å.

However, if the mercury atoms occupy the point position 6(*f*), then a point position for the iodine atoms can be found. This is explained in the following section.

The contribution of the iodine atoms to the X-ray intensities is relatively large and thus the observed Laue symmetry 6/*mmm* must be valid also for the iodine atoms. Attempts have been made to find a mercury arrangement equivalent to 3(*a*) + 3(*c*) in $P6_222$ and to derive possible iodine arrangements, satisfying the observed heights of the maxima of the Patterson projection $P(upw)$, in the possible space groups $P6/mmm$ (No. 191), $P\bar{6}2m$ (No. 189), $P\bar{6}m2$ (No. 187), $P6mm$ (No. 183) and $P622$ (No. 177). The results of these calculations were in no case satisfactory.

Thus, X-ray data were alone sufficient to make a decision between the two homometric mercury atom positions. The only possibility was, namely, the point position 6(*f*) in $P6_222$ (No. 180).

THE POSITIONS OF THE IODINE ATOMS

Since the six mercury atoms occupy the point position 6(*f*) with $z = 0.333$, it is thus possible for the three iodine atoms to occupy one of the threefold point positions 3(*a*), 3(*b*), 3(*c*) or 3(*d*). The required mercury-iodine vectors *u*, *v*, *w* for the four different cases are listed in Table 4. From the Patterson projection $P(upw)$ (Fig. 1), it is seen that it is impossible for the relatively heavy iodine atoms to occupy one of the threefold point positions 3(*b*) or 3(*d*) because the projection does not show any maxima at $u = 0$, $w = \pm\frac{1}{6}$ or $u = 0$, $w = \frac{1}{2}$. On the other hand it is seen that the expected vectors Hg-I for the remaining possibilities for the iodine atoms 3(*a*) and 3(*c*) correspond to the calculated projection. However, the maximum of the projection $P(upw)$ at $u = 0$, $w = \frac{1}{3}$ is about 30 % higher than that at $u = \frac{1}{2}$, $w = \frac{1}{3}$. This can only be explained if the iodine atoms are situated in the point position 3(*c*) (Table 5).

To confirm that 3(*c*) is the actual point position for the iodine atoms, three-dimensional electron density calculations were performed using 860 reflexions (not independent) obtained with Cu*K* radiation. Theoretically, the Fourier projection $\varrho(xyp)$ should differentiate between the possibilities 3(*a*) and

Table 5. Required and observed vectors Hg-Hg and Hg-I in the Patterson projection $P(upw)$. The structure possibility: 6 Hg in 6(*f*). The calculations were performed as in Table 3.

u w	Vectors Hg-Hg 6 Hg in 6(*f*)	Vectors Hg-I 3 I in 3(*a*)	Vectors Hg-I 3 I in 3(*c*)	Rel. weight calc. 3(*a*), 6(*f*)	Rel. weight calc. 3(*c*), 6(*f*).	Rel. weight obs.
0 $\frac{1}{3}$	6	2	4	332	395	400
$\frac{1}{2}$ 0	4	4	4	298	298	310
$\frac{1}{2}$ $\frac{1}{3}$	6	4	2	395	332	310

3(*c*) but, as it is based on only a few reflexions, its exactness is much less than that of the sections of the three-dimensional electron density space. Hence, the electron density sections $\varrho(xyz)$ at $z = 0$, $\frac{1}{6}$, $\frac{1}{3}$, $\frac{1}{2}$ and $\frac{2}{3}$ were computed. The calculations were at first based on F values derived in the usual way from the visually estimated intensities of the reflexions and on the signs and values of the phase angles $\alpha_{hkl} = \text{arctg}\,(\frac{B}{A})_{hkl}$ determined from the mercury contributions for all reflexions except 54 of the weakest.

The sections show high maxima at $0\frac{1}{2}0$, $\frac{1}{2}\frac{1}{2}0$, $\frac{1}{2}0\frac{1}{3}$, $0\frac{1}{2}\frac{1}{3}$, $\frac{1}{2}0\frac{2}{3}$ and $\frac{1}{2}\frac{1}{2}\frac{2}{3}$ which is espected for mercury atoms occupying the point position 6(*f*) that was assumed when calculating the values of the phase angles. Moreover, maxima with a height correct for an iodine atom appear at $\frac{1}{2}00$, $\frac{1}{2}\frac{1}{2}\frac{1}{3}$ and and $0\frac{1}{2}\frac{2}{3}$, indicating that the iodine atoms are situated in the point position 3(*c*). Apart from these maxima, there are only small maxima in the sections $\varrho(xy0)$, $\varrho(xy\frac{1}{3})$ and $\varrho(xy\frac{2}{3})$ and they can be ascribed to diffraction effects from the mercury and iodine atoms and to sodium and oxygen atoms. The sections $\varrho(xy\frac{1}{6})$ and $\varrho(xy\frac{1}{2})$ show small peaks at $x = 0$, $y = 0$ (Fig. 2). Otherwise, these sections do not show any peaks with a height differing from the general background by more than that expected for diffraction effects from the heavy atoms. Using calculated F values (the contributions of the mercury atoms only being taken into account) and the same phase angles as above, the electron density sections $\varrho(xy0)$ and $\varrho(xy\frac{1}{3})$ were also computed. These sections did not show any maxima at $\frac{1}{2}00$ and $\frac{1}{2}\frac{1}{2}\frac{1}{3}$ — only the high maxima at $0\frac{1}{2}0$, $\frac{1}{2}\frac{1}{2}0$, $\frac{1}{2}0\frac{1}{3}$ and $0\frac{1}{2}\frac{1}{3}$. This further confirms that the point position of the iodine atoms is 3(*c*).

The electron density sections $\varrho(xy0)$, $\varrho(xy\frac{1}{3})$ (Fig. 2) and $\varrho(xy\frac{2}{3})$ were then recalculated using the observed F values and the signs and values of the phase angles determined from the contributions of the mercury and iodine atoms for all observed reflexions. There was no difference worth mentioning between these sections and those obtained by the previous calculations. To obtain further proof concerning the positions of the iodine atoms and if possible to get some information on the positions of the sodium and the oxygen atoms, first the mercury atoms and then both the mercury and iodine atoms (Fig. 2) were substracted from $\varrho(xy0)$ and $\varrho(xy\frac{1}{3})$. In this way, most of the diffraction

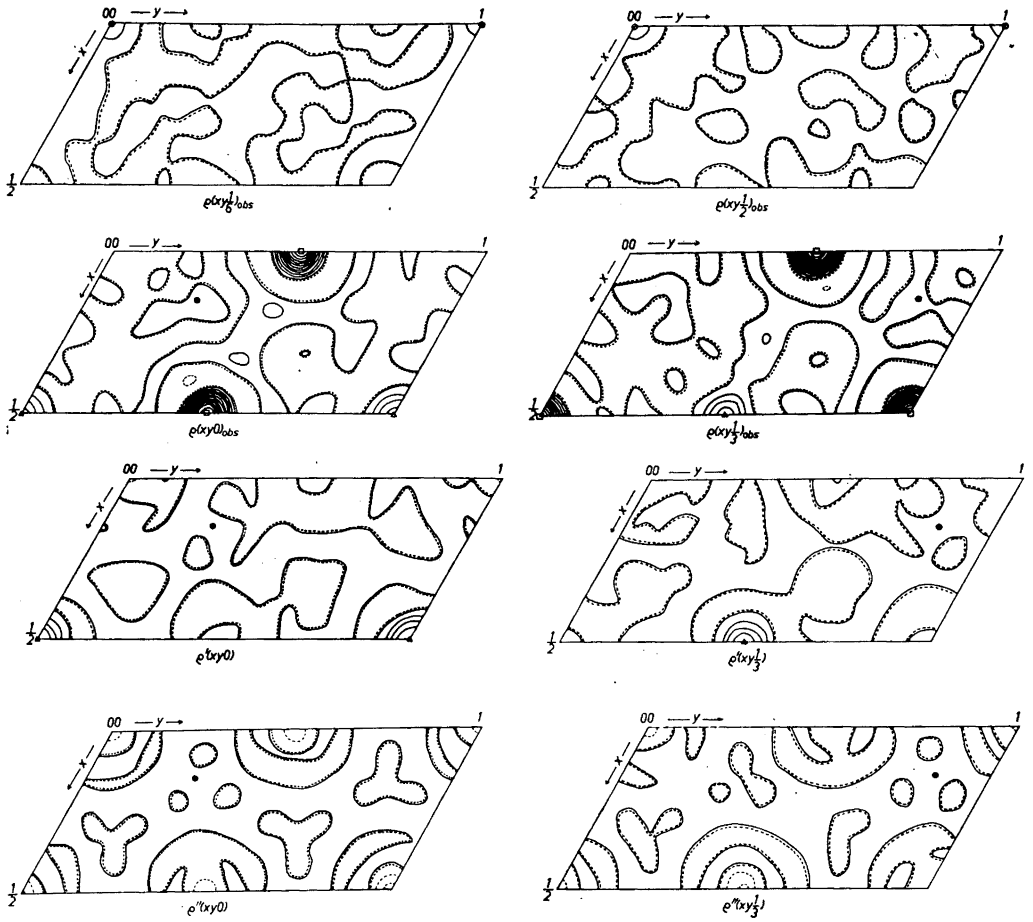

Fig. 2. The observed electron density sections $\varrho(xy\frac{1}{8})$, $\varrho(xy\frac{1}{2})$, $\varrho(xy0)$ and $\varrho(xy\frac{1}{3})$, the electron density sections $\varrho'(xy0)$ and $\varrho'(xy\frac{1}{3})$, where the contributions of the mercury atoms are substracted from $\varrho(xy0)$ and $\varrho(xy\frac{1}{3})$, and the electron density sections $\varrho''(xy0)$ and $\varrho''(xy\frac{1}{3})$, where the contributions of the mercury and of the iodine atoms have been substracted from $\varrho(xy0)$ and $\varrho(xy\frac{1}{3})$. The final mercury (□), iodine (△), oxygen (●) and sodium (○) atom positions are indicated. Dashed lines indicate negative values.

effects from the heavy atoms should disappear and only maxima indicating the iodine atoms and possibly small maxima indicating the sodium and oxygen atoms (Fig. 2) should be obtained. As expected, these calculations show clearly that the point position of the three iodine atoms is 3(*c*).

The temperature factor that should have been introduced in these calculations was found to be negligible when calculated by the ordinary procedure. Probably, it approximately cancels out with the absorption effects.

The positions for the sodium and oxygen atoms which could possibly be obtained from these sections would doubtless be rather uncertain. One reason is that the Fourier series has in fact been broken at $l = 5$, another one is the dominant scattering power for X-rays of the heavy atoms. No attempt was therefore made to utilize the information obtainable from these small maxima for the determination of the positions of the light atoms.

THE POSITIONS OF THE LIGHT ATOMS

The above discussion has shown that the six mercury atoms occupy the point position 6(*f*) and the three iodine atoms the point position 3(*c*) in the space group $P6_222$ (No. 180). Consequently the holes between these atoms must also possess the symmetry $P6_222$. It is therefore probable that the sodium and the oxygen atoms have the same symmetry — it will be seen later on that this is supported by the results of a neutron diffraction investigation. Now, in $P6_222$, the only positions left for the three sodium atoms are 3(*a*), 3(*b*) and 3(*d*) (see p. 2200). The position 3(*d*) would result in a very short distance Hg-Na of only 1.7 Å and can therefore be excluded. The remaining positions 3(*a*) and 3(*b*) are, with regard to the distances Hg-Na and I-Na, equally probable for the sodium atoms. In the unit cell, there are in addition six oxygen atoms. The positions left for them are therefore: 6(*i*), 6(*j*), 6(*h*), 6(*g*), 6(*f*), 6(*e*), the combinations of the threefold point positions 3(*a*) + 3(*d*) and 3(*b*) + 3(*d*) and the less probable arrangement of a statistical distribution over 12(*k*). The possibilities 3(*a*) + 3(*d*), 3(*b*) + 3(*d*), 6(*e*) and 6(*f*) would give a very short distance of 1.7 Å between Hg-O, O-O or I-O and can thus be ruled out. Hence, the possibilities for the oxygen atoms are limited to 6(*j*), 6(*i*), 6(*h*) and 6(*g*). To find the arrangement of the light atoms according to the possible point positions, it is necessary to consider the geometry of the holes in the structure. The following distances from the mercury, sodium and iodine atoms to the oxygen atoms were assumed when drawing *xy*-sections of the unit cell at different *z* values:

$$\text{Hg-O} \geq 2.0 \text{ Å}, \quad \text{Na-O} \geq 2.3 \text{ Å}, \quad \text{I-O} \geq 3.0 \text{ Å}.$$

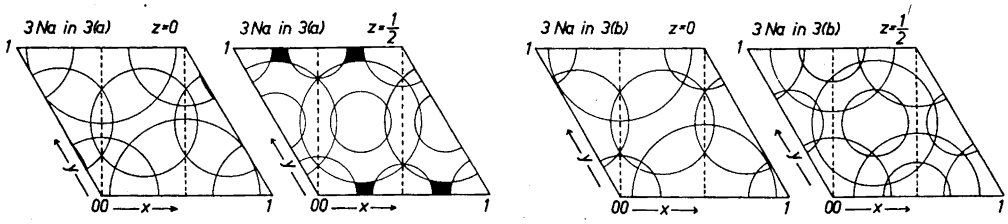

Fig. 3. Survey over the space which is free (black areas) for the oxygen atoms in the planes $z = 0$ and $z = 0.50$. The point position of the sodium atoms is assumed to be 3(*a*) and 3(*b*). The function $y = 2x$ is drawn with dashed lines.

The results are given in Fig. 3. From these figures, it can be concluded that the possible positions for the sodium and oxygen atoms are:

A: 3 Na in 3(*a*), 6 O in 6(*j*) with $x \sim 0.40$.
B: 3 Na in 3(*a*), 6 O in 6(*h*) with $0.30 \geq x \geq 0.20$.
C: 3 Na in 3(*b*), 6 O in 6(*i*) with $x \sim 0.15$.

The combinations A and B give rise to an arrangement for the mercury and the oxygen atoms which seems very unusual. Each mercury atom is coordinated to two oxygen atoms and each oxygen atom to two mercury atoms, giving an arrangement of isolated rhombs of the composition Hg_2O_2. The distances from the mercury and sodium atoms to the oxygen atoms are:

A: $x_0 = 0.40$, Hg-O = 2.6 Å, Na-O = 2.1 Å.
B: $x_0 = 0.25$, Hg-O = 2.4 Å, Na-O = 2.4 Å.

With the combination C, the arrangement of the mercury and oxygen atoms is made up of planar zig-zag chains -Hg-O-Hg- with all distances Hg-O equal to 2.0 Å, the oxygen parameter being 0.15. The structure of orthorhombic mercury(II)oxide described earlier[1] is built up of such chains with the same distance Hg-O and the same values for the angles O-Hg-O and Hg-O-Hg as given here for the possibility C. It seems therefore very probable that the combination C is the most applicable one for this structure problem.

In order to make possible an objective decision between the three geometrically possible structures, the investigation was supplemented by a neutron diffraction study.

NEUTRON DIFFRACTION STUDIES

The coherent scattering amplitudes of mercury, iodine, sodium and oxygen for neutrons and X-rays are given in the following table:

Scattering amplitude (10^{-12} cm), Ref.[11]

	Neutron	X-ray ($\Theta = 0°$)
Hg	1.31	22.5
I	0.52	15.0
Na	0.35	3.09
O	0.58	2.25

The amplitude values for neutrons are independent of the scattering angle while those for X-rays decrease with Θ and relatively more so for sodium and oxygen than for mercury and iodine. Therefore, it seems rather unlikely that one can locate these light atoms from the observed X-ray data but it is evident that neutron diffraction work would provide much better possibilities for the determination of the sites. Since it was impossible to get a crystal large enough for single crystal investigations with the apparatus available, the neutron diffraction work was carried out on a powder sample in a flat aluminium container. Since the cross section for true absorption is very large

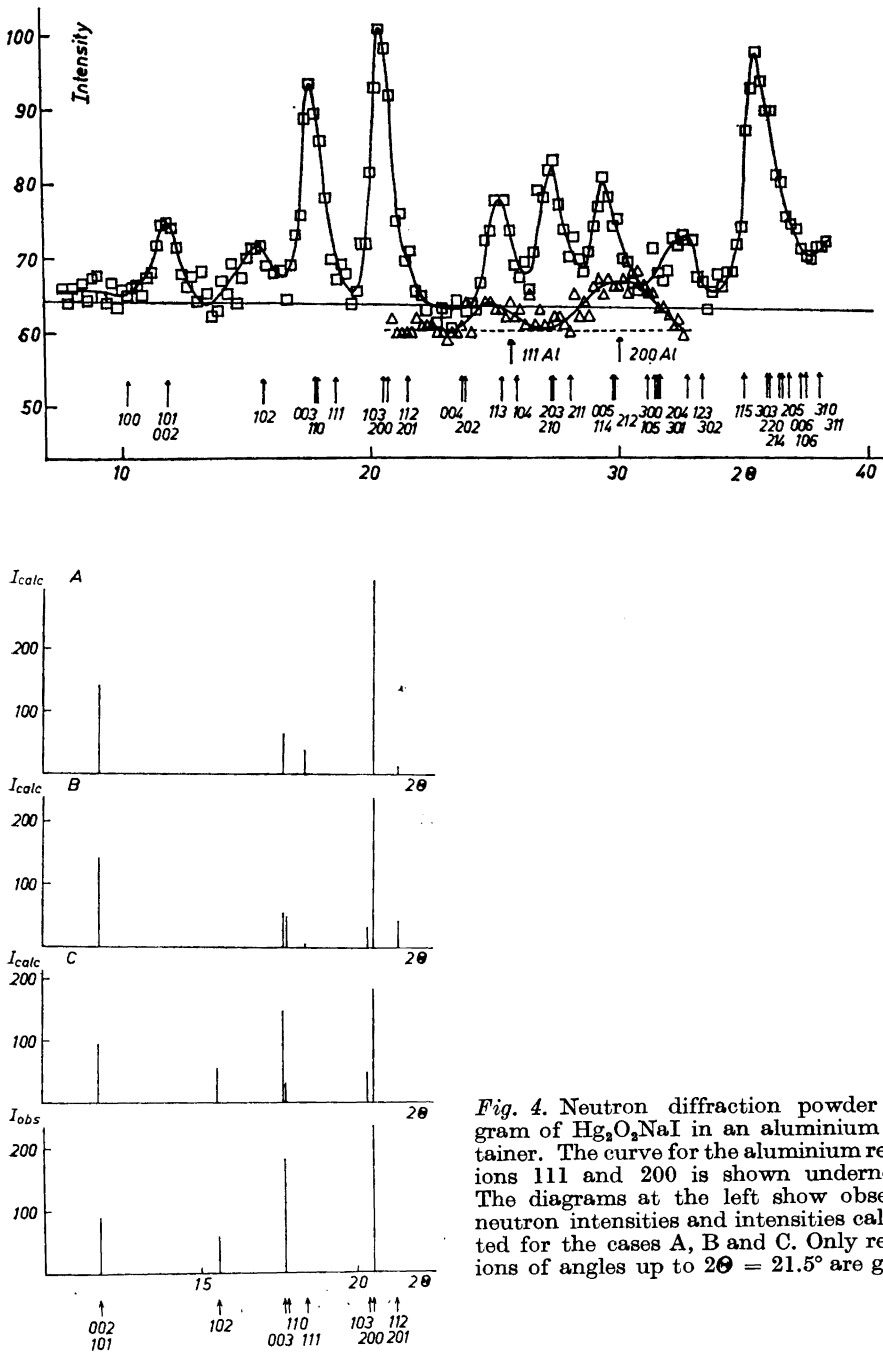

Fig. 4. Neutron diffraction powder diagram of Hg_3O_2NaI in an aluminium container. The curve for the aluminium reflexions 111 and 200 is shown underneath. The diagrams at the left show observed neutron intensities and intensities calculated for the cases A, B and C. Only reflexions of angles up to $2\Theta = 21.5°$ are given.

Table 6. Observed neutron intensities from a powdered sample of Hg_2O_2NaI. The intensities of the coinciding reflexions 113 and 104, from 005 to 212 and from 300 to 302 were corrected for the contributions of the aluminium reflexions 111 and 200. The intensities were calculated for the case C (3(*b*), 6(*i*)): I. neglecting the influence of the oxygen atoms and II. taking the influence of the oxygen atoms into account. $I\text{calc}_I$ and $I\text{calc}_{II}$ are normalized so as to give the best agreement with Iobs.

for mercury, the powder sample had to be thin and the observed neutron intensities were therefore low. The aluminium holder was chosen so that $\mu \cdot t = 0.439$ where μ is the linear absorption coefficient of the compound

Table 7. Observed neutron intensities from a powdered sample of Hg_2O_2NaI and intensities calculated for the structure possibility C. The parameter for the oxygen atom position was varied within the limits $0.10 \leq x_O \leq 0.20$.

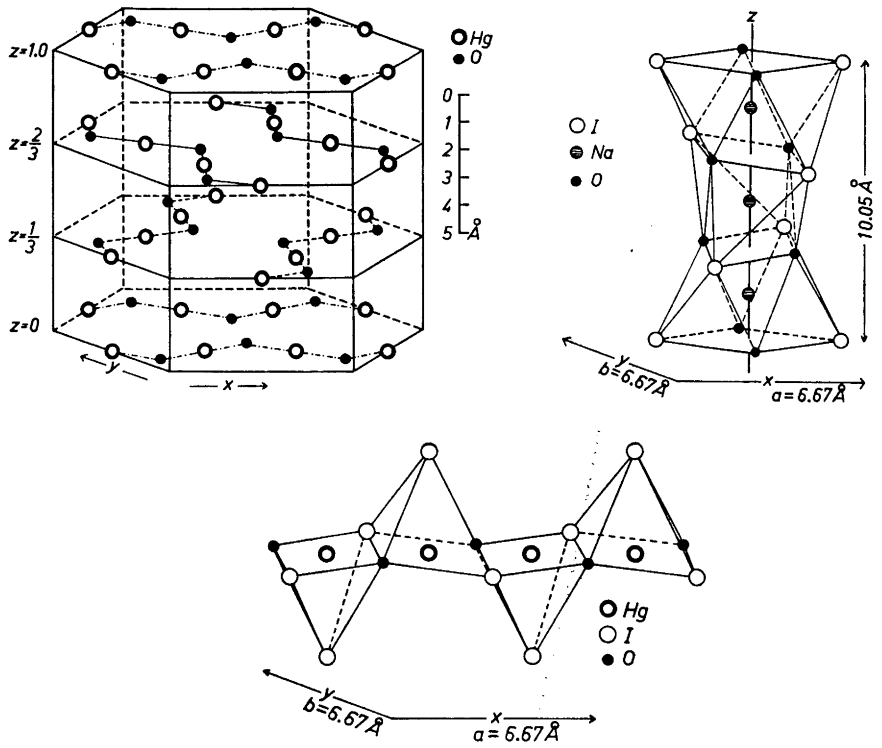

Fig. 5. Schematic drawings showing the infinite planar chains —O—Hg—O—Hg—, lying perpendicularly to the *c* axis at the heights $z = 0$, $\frac{1}{3}$ and $\frac{2}{3}$, showing a chain of deformed Archimedean square antiprisms, running parallel to the *c* axis and showing a chain of pyramids, lying perpendicularly to the *c* axis. Each Archimedean antiprism is made up of four iodine and four oxygen atoms with one sodium atom in its centre. Each pyramid is made up of three iodine and two oxygen atoms with one mercury atom in the centre of its base plane.

and t the length of the sample. The reactor was run at a level of 450 kW. The diffracted intensity was measured at intervals of 0.2° scattering angle, counts being taken during the time necessary for accumulating 500 000 neutron counts in the monitor for the incident neutron beam. The curve that was obtained by plotting the counts against the angles is given in Fig. 4. The observed intensities, obtained by measuring the areas under the peaks with a planimeter and correcting for the contribution of the aluminium reflexions 111 and 200 from the container, are given in Table 6. Due to serious overlapping, only the intensities of the reflexions at low Θ angles could be evaluated with accuracy. The neutron intensities of the observed reflexions were calculated for the structure possibilities A, B and C assuming the parameter values given above and were compared with the observed intensities in a neutron diffraction diagram. The result is given in Fig. 4, from which it is

clearly seen that the possibility C is the only one that is consistent with the experimental data. For the case C, a systematic variation of the parameter for the oxygen atom position gave the best agreement between observed and calculated intensities when $x_o = 0.15$ (Table 7). The neutron intensities of the reflexions were calculated according to Bacon [12], the influence of the temperature factor being, however, neglected.

CORRELATION OF X-RAY AND NEUTRON DIFFRACTION INTENSITIES

The point positions and parameters of the atoms having been determined, the X-ray structure factors of the reflexions *hkl* were then calculated and compared with the observed ones (*cf.* Table 8). The influence of the temperature factor was, however, neglected. The agreement between observed and calculated values was found to be good. To obtain a criterion of the correspondence, the reliability factor $R = \frac{\Sigma \, || F_{obs} | - | F_{calc} ||}{\Sigma \, | F_{obs} |}$ was calculated according to Booth [13] and found to be 13.7 % (absent reflexions included) or 13.0 % (absent reflexions not included), showing that the structure should be essentially correct as regards the heavy atoms.

To reduce the influence of orientation effects observed in the Guinier photogram (*e.g.* the reflexion 303), accurate values for the intensities of the X-ray powder reflexions were measured for a sample mixed with gum arabic (1 : 3) using a Geiger-Mueller diffractometer. The observed intensities obtained by measuring the areas under the peaks are given in Table 1. For overlapping reflexions, the sum of the intensities are given. As seen, the agreement between observed and calculated intensities is good (Table 1).

The calculated and observed neutron intensities for all reflexions that could be evaluated are given in Table 6. The accuracy of the observed reflexions

that had to be corrected for the contributions due to the aluminium reflexions is less than that of those peaks, at low 2 Θ values, which were not affected by these reflexions (Fig. 4). Taking this fact into consideration, it can be concluded that the agreement between calculated and observed intensities is satisfactory, thus showing that the structure should be principally correct also as regards the light atoms.

DESCRIPTION OF THE STRUCTURE

The following structure is therefore proposed for Hg_2O_2NaI:
Cell content: 3 Hg_2O_2NaI

Space croup: $P6_222$ (No. 180)
6 Hg in 6(f): $\frac{1}{2},0,\pm z$; $0,\frac{1}{2},\frac{2}{3}\pm z$; $\frac{1}{2},\frac{1}{2},\frac{1}{3}\pm z$; $z = 0.333$
3 I in 3(c): $\frac{1}{2},0,0$; $0,\frac{1}{2},\frac{2}{3}$; $\frac{1}{2},\frac{1}{2},\frac{1}{3}$
3 Na in 3(b): $0,0,\frac{1}{2}$; $0,0,\frac{5}{6}$; $0,0,\frac{1}{6}$
6 O in 6(i): $\pm(x, 2x), 0$; $\pm(2x, x), \frac{2}{3}$; $\pm(x, \bar{x}), \frac{1}{3}$; $x = 0.15$

A fundamental constituent of the structure is the series of infinite planar zig-zag chains -O-Hg-O-, lying perpendicularly to the c axis at the heights $z = 0,\frac{1}{3}$ and $\frac{2}{3}$ (Fig. 5). The distances Hg-O within the chains are 2.03 Å (Table 9) and the angles O-Hg-O 180° ± 3° and Hg-O-Hg 110° ± 1°. This Hg-O distance and the values of the angles (*cf.* Refs.[14,15]) suggest that the bond between Hg and O within the chains is mainly homopolar. Since the interatomic distances are considerably larger between the chains, the forces between them are far weaker.

Each mercury atom is, in addition to the two oxygen atoms at the close distance of 2.03 Å, also surrounded by three iodine atoms at the distances $\frac{a}{2} = 3.33$ Å and $\frac{c}{3} = 3.35$ Å, the two oxygen and the three iodine atoms thus forming a pyramid with the mercury atom in the centre of its base plane (Fig. 5).

Each iodine atom is octahedrally surrounded by six mercury atoms at the distances 3.33 and 3.35 Å. The calculated sum of the ionic radii is 3.26 Å (Ref.[16]).

Each sodium atom in the structure is surrounded by four oxygen and four iodine atoms, forming a deformed square Archimedean antiprism. These coordination polyhedra share their base planes to form infinite chains running along the c axis of the unit cell (Fig. 5). The interatomic distances in the polyhedra and between the polyhedra and the chains are listed in Table 9 (Fig. 6). The distances Na-I seem to be relatively long but the Na-O distances are close to the sum of the ionic radii (Ref. [16]):

	obs.	calc.		obs.	calc.
Na-I, (Å)	3.73	3.11	Na-O, (Å)	2.41	2.3€

The connection between the chains and the base planes of the Archimedean antiprism is shown clearly in Fig. 7.

The author is greatly indebted to Professor A. Ölander for his kind interest in this work and to Dr. A. Magnéli for many valuable discussions. Thanks are also due to Professor J. A. Goedkoop and Dr. A. F. Andresen for very valuable help in the neutron diffraction work. The author wishes to thank Miss Inga-Britt Carlsson and Miss Birgitta Malmros for valuable help in the chemical work and assistance in the calculations. Thanks are also due to the *Swedish Board for Computing Machinery* for the use of the calculator BESK for a considerable part of the calculating work involved in this investigation. The author is also indebted to G. Blomqvist, S. Westman and S. Åsbrink for access to the programs (*c.f.* Refs.[17,18]) used for calculations with BESK.

These studies form part of a research program on mercury(II)oxide salts, financially supported by the *Swedish Natural Science Research Council.*

On the Stability of Nitrate and Chloride Complexes of Plutonium(IV)

INGMAR GRENTHE and BERTIL NORÉN

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The nitrate and chloride complexes of Pu^{4+} were studied in an acid perchlorate medium of ionic strength $I = 4$ M at a temperature of 20°C, using the cation-exchanger method of Fronæus [1-3]. The calculation method was extended to systems of the type $M^{4+}-A^{-}$, where the central ion, the first, second and third complexes can be sorbed on the ion-exchanger. The complexity constants obtained for the nitrate system were:

$\beta_1 = 5.5 \pm 0.2$ M^{-1}; $\beta_2 = 23.5 \pm 1$ M^{-2}; $\beta_3 = 15 \pm 10$ M^{-3}

and for the chloride system:

$\beta_1 = 1.4 \pm 0.2$ M^{-1}; $\beta_2 = 1.2 \pm 0.2$ M^{-2}; $\beta_3 = 0.1 \pm 0.1$ M^{-3}.

The nitrate and chloride complexes of Pu^{4+} have previously been studied by several authors [4-8] using ion-migration, spectrophotometric, electrometric and solvent extraction methods. Most of the work is of a qualitative nature and all the quantitative measurements are confined to the spectrophotometric and electrometric methods. In the electrometric measurements the variation of the redox potential for the couple Pu(IV)/Pu(III) has been studied. To evaluate the complexity constants for Pu^{4+} it is then necessary to know the corresponding complexity constants for Pu^{3+}. As these are not known with any degree of accuracy the result has a corresponding uncertainty in the magnitude of the Pu^{4+} constants. In addition mixed complexes of Pu^{4+} and Pu^{3+} are neglected.

The ion-exchanger method seems to be a more direct and accurate way of studying these complex systems than theother methods mentioned above.

The hydrolysis [9] and disproportionation [10] reactions of Pu^{4+} must be taken into consideration for work in water solutions. By using a medium with a hydrogen-ion concentration of 4 M, the hydrolysis can be sufficiently suppressed. The disproportionation reaction

$$3\ Pu^{4+} + 2\ H_2O \rightleftharpoons 2\ Pu^{3+} + PuO_2^{2+} + 4\ H^+$$

is also strongly displaced towards left at this high acidity. The disproportionation rate of Pu^{4+} decreases with decreasing plutonium concentration and at the concentrations used here ($< 1.2 \times 10^{-5}$ M) it is entirely negligible. The high acidity and the low plutonium concentration thus removes the complications that would arise because of the presence of hydrolysis-products and oxidation states other than + 4.

THEORETICAL

The calculation of the complexity constants is made according to a method developed by Fronæus [1-3]. In the derivation it is assumed that only mononuclear complexes are formed both in the solution and in the ion-exchanger. This assumption is reasonable because of the low total metal-ion concentration ($< 1.2 \times 10^{-5}$ M) and the high acidity (4 M) of the solution.

The following symbols and equations have been used:

C'_M, C'_A = the total concentrations of metal-ion and ligand in solution before addition of the ion-exchanger.

C_M, C_A = the total concentrations of metal-ion and ligand in the solution in equilibrium with the ion exchanger.

$[M^{4+}]$, $[MA_j^{4-j}]$, $[A^-]$ = equilibrium concentrations of the different species in solution.

$[M^{4+}]_R$, $[MA_j^{4-j}]_R$ = equilibrium concentrations of the different species in the resin phase.

β_j = the complexity constant for the complex MA_j^{4-j} in solution.

v = the volume of the solution before addition of ion-exchanger.

m = the weight in grammes of dried ion-exchanger.

δ = the swelling factor of the ion-exchanger.

$X_n = \sum_{j=n}^{N} \beta_j \cdot [A^-]^{j-n}$; $(\beta_o = 1)$

Using these notations following equations are obtained

$$C_M = [M^{4+}](1 + \sum_{j=1}^{N} \beta_j [A]^j) \tag{1}$$

$$C_{MR} = \sum_{j=0}^{3} [MA_j^{4-j}]_R \tag{2}$$

For each of the ions MA_j^{4-j} $(j \leq 3)$ exchanging for hydrogen-ions in the resin, the following equilibrium can be written

$$MA_j^{4-j} + (4-j)\ H_R^+ \rightleftharpoons MA_{jR}^{4-j} + (4-j)\ H^+$$

Applying the law of mass action gives the expression

$$\frac{[MA_j^{4-j}]_R}{[MA_j^{4-j}]} = k_j \frac{[H^+]_R^{4-j}}{[H^+]^{4-j}} = l_i;\ (j = 0, 1, 2, 3) \tag{3}$$

where the coefficients k_j and l_j are functions of the activity coefficients in resin and solution. In this case the activity coefficients in solution are kept constant by using a medium of constant ionic strength and in the ion-exchanger by having a constant value of C_{MR} and $[H^+]_R$[1,11]. $[H^+]_R$ is constant because the load, C_{MR}, is much smaller (1.2×10^{-7} moles/g) than the total exchange capacity of the resin. The constant C_{MR} is obtained from a determination of the distribution coefficient, φ, at several different C'_M. The original articles should be consulted for further details [1-3].

The distribution of the metal-ion between resin and solution is given by

$$\varphi = \frac{C_{MR}}{C_M} = l_0 \frac{1 + l'_1[A^-] + l'_2[A^-]^2 + l'_3[A^-]^3}{X} \tag{4}$$

where $l'_j = l_j \cdot \beta_j \cdot l_0^{-1}$, $(j = 1, 2, 3)$

and $l_0 = [M^{4+}]_R/[M^{4+}] = \lim_{[A^-] \to 0} \varphi$

Because of the impossibility of an accurate determination of the total metal-ion concentration in the resin phase, φ is obtained from a determination of C'_M and C_M.

Thus $v \cdot C'_M = v \cdot \delta \cdot C_M + m \cdot C_{MR}$

$$\varphi = \frac{C_{MR}}{C_M} = \frac{v}{m}\left(\frac{C'_M}{C_M} - \delta\right)$$

and because $C'_M \ll C'_A$ $\qquad [A^-] \approx C_A = C'_A/\delta$

In order to obtain the complexity constants from corresponding values of φ and $[A^-]$, three new functions φ_1, f and g are introduced.

$$\varphi_1 = \left(\frac{l_0}{\varphi} - 1\right) \cdot \frac{1}{[A^-]} \tag{6}$$

$$f = \left\{\frac{l_0}{\varphi}[(\beta_1 - l'_1)[A^-] - 1] + 1\right\} \cdot \frac{1}{[A^-]^2} \tag{7}$$

$$g = \left\{f - \beta_1 \varphi_1 + \frac{l_0}{\varphi}(\beta_2 - l'_2)\right\} \cdot \frac{1}{[A^-]} \tag{8}$$

By substitution of expression (4) in eqns. (6) and (7) the following limiting values are obtained

$$\lim_{[A^-] \to 0} \varphi_1 = \varphi_1^0 = \beta_1 - l'_1 \tag{9}$$

$$\lim_{[A^-] \to 0} f = f^\circ = \beta_1(\beta_1 - l'_1) - (\beta_2 - l'_2) \tag{10}$$

A combination of eqns. (4), (6) and (7) gives

$$f = \beta_1\varphi_1 - X_2 + (\varphi_1 \cdot [A^-] + 1)(l'_2 + l'_3 \cdot [A^-]) \tag{11}$$

In the same way eqn. (12) is obtained by a combination of eqns. (6), (9), (10) and (11).

$$\frac{\Delta f}{[A^-]} = \beta_1 \cdot \frac{\Delta \varphi_1}{[A^-]} + \varphi_1 (l_2' + l_3' \cdot [A^-]) + l_3' - X_3 \qquad (12)$$

where $\Delta f = f - f^\circ$ and $\Delta \varphi_1 = \varphi_1 - \varphi_1^0$

For small [A] eqn. (12) can be approximated to

$$\frac{\Delta f}{[A^-]} = \beta_1 \frac{\Delta \varphi_1}{[A^-]} + (\beta_1 - l_1') \cdot l_2' + l_3' - \beta_3 \qquad (13)$$

β_1 can thus be obtained by plotting $\Delta f/[A^-]$ against $\Delta \varphi_1/[A^-]$. When β_1 is known $(\beta_2 - l_2')$ can be calculated from eqn. (10). This makes it possible to calculate the function g.

By introducing the functions φ_1, f and g eqn. (4) can be written in the alternate form

$$g = \beta_2 \varphi_1 - X_3 + l_0 l_3' \varphi^{-1} \qquad (14)$$

At small ligand concentrations the last term in eqn. (14) is approximately equal to l_3' and X_3 equal to β_3. Thus g is a linear function of φ_1 with the slope β_2 and the intercept $-(\beta_3 - l_3')$.

It is desirable to know the magnitude of l_2'. This can be obtained from the expression [3]

$$\frac{\beta_1^2}{\beta_2} = \frac{(l_1')^2}{l_2'} \qquad (15)$$

If the term $l_3'[A^-]$ in eqn. (11) can be neglected in comparison with l_2' in a wide range of $[A^-]$ then the constants of higher complexes are obtained from corresponding values of [A] and X_3 using the approximation

$$X_3 = \beta_2 \varphi_1 - g \qquad (16)$$

which also is obtained from eqn. (14) if $l_0 l_3' \varphi^{-1}$ is neglected.

Eqn. (13) cannot always be used for graphical evaluation of β_1 because in some cases $\Delta f/[A^-]$ and $\Delta \varphi_1/[A^-]$ are nearly constant over the entire [A]-range investigated. In this case the quotient $\Delta f/\Delta \varphi_1$, can be used as a first approximation of β_1. Using this value the order of magnitude of β_2 and β_3 can be obtained from eqns. (10), (8) and (14). The approximate value of β_3 is then used for a better estimate of β_1, and so on until the β-values remain constant.

EXPERIMENTAL

A concentrated plutonium solution was prepared as before [12]. From this concentrated plutonium $-HNO_3$ solution, a stock solution of Pu(IV) was prepared by dilution with 4 M $HClO_4$. The final concentration of the stock-solution was $C_H = 4.25$ M, $C_{HNO_3} = 0.25$ M, $C_{Pu} = 0.5 \times 10^{-3}$ M.

More than 99.5 % of the total amount of plutonium was in the oxidation state + 4. Hydrochloric acid, nitric acid and perchloric acid were all of analytical grade. The ion-exchanger Dowex 50, 50—100 mesh, was converted to the hydrogen form by repeated shaking with 6 M HCl. After saturation it was washed with distilled water and finally dried for 15 h at 40°C. The ion-exchanger was then stored in a closed bottle to keep the water content of the resin constant.

The value of v/m was kept constant (4×10^{-2} l/g) in all measurements thus keeping the volume decrease of the solutions, caused by the swelling of the resin, constant. The swelling factor δ was determined by shaking 250 mg ion-exchanger with 10 ml of 4 M $HClO_4$ and 4 M HNO_3. From the change in hydrogen-ion concentration a value of $\delta = 0.99$ was obtained in both cases. The distribution coefficient, φ, was determined by shaking 5 ml of solutions of the following composition to equilibrium at 20° C.

$C_{HClO_4} = 4 - [A]$ M
C_{HNO_3} or $C_{HCl} = [A]$ M
$C_{Pu(IV)} = C'_M$ M
0.125 g Dowex 50

The time necessary for attainment of equilibrium was determined in a separate experiment. The results given in Table 1 show that equilibrium was established after 20 h. A shaking time of 40 h was nevertheless used in most of the experiments.

Table 1. Determination of φ as a function of the shaking time for $[NO_3^-] = 7$, 207 and 707 mM. $C_H = 4$ M, $T = 20$°C, $v/m = 4 \times 10^{-2}$ l/g, $C'_M = 2 \times 10^{-6}$ M

Hours	10	20	60
$[NO_3^-]$ mM	$\varphi \times 10^3$ l/g		
7	559	948	922
207	337	341	333
707	76	72	77

The plutonium concentration of the above solutions was determined by measuring the α-activity of 0.1 ml of the solution before addition of ion-exchanger and after equilibrium was attained. The analytical procedure has been described before [12]. Since the activity of the solution is proportional to the plutonium-concentration, φ can be calculated from the following expression

$$\varphi = 4 \times 10^{-2} \left(\frac{I_0}{I} - \delta \right)$$

where I_0 is the activity in cpm/0.1 ml of the solution before addition of ion-exchanger and I is the activty in the same units after equilibrium.

RESULTS

The plutonium(IV)-nitrate system

The distribution fucntion φ was determined at three different C'_M, Fig. 1. From these values φ, at a constant load, $C_{MR} = 1.2 \times 10^{-7}$ moles/g, was obtained by interpolation. Only a slight variation of φ with C_{MR} was obtained,

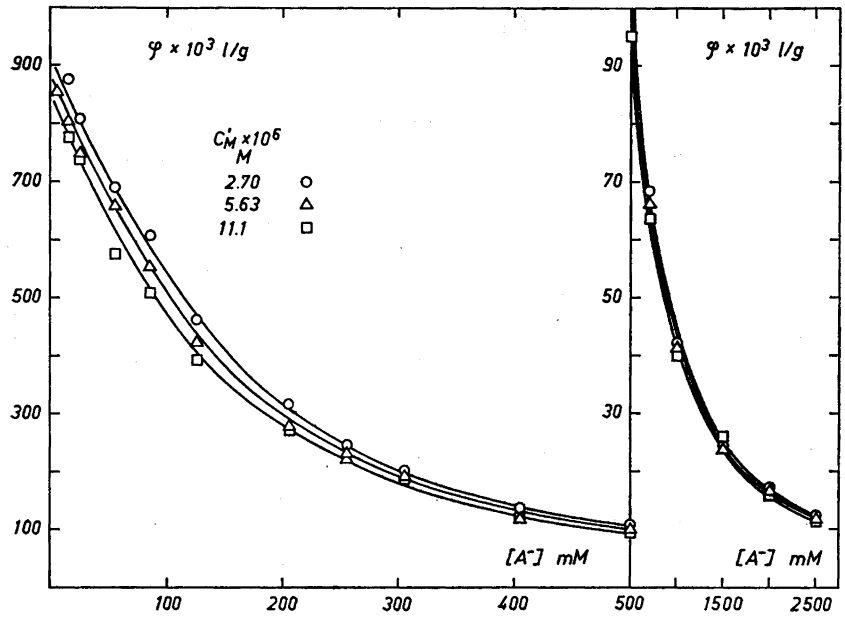

Fig. 1. φ for the nitrate complex system of plutonium(IV). The points refer to determination with different values of C'_M, as indicated by the scheme given in the figure. Note that the ordinate is expanded and the abscissa contracted for $[A^-] \geq 500$ mM. $C_H = 4$ M, $v/m = 4 \times 10^{-2}$ l/g, $T = 20°C$.

Table 2. In Table 3 the values of φ_1, f, g, $\Delta f/[A^-]$ and $\Delta\varphi_1/[A^-]$, valid for $C_{MR} = 1.2 \times 10^{-7}$ moles · g^{-1}, are given. l_0, φ_1^0 and $f°$ are determined with a fairly good accuracy by the graphical extrapolation shown in Figs. 2, 3 and 4. The values obtained are

$$l_0 = 0.92 \pm 0.02 \text{ g/l}$$
$$\varphi_1^0 = 5.3 \pm 0.2 \text{ M}^{-1}$$
$$f° = 6.0 \pm 0.5 \text{ M}^{-2}$$

In Fig. 5, $\Delta f/[A^-]$ has been plotted as a function of $\Delta\varphi_1/[A^-]$. A straight line with the slope $\beta_1 = 5.5 \pm 0.2$ M^{-1} is obtained. With known values of $f°$, β_1 and φ_1^0 a value of $(\beta_2 - l'_2) = 23 \pm 3$ M^{-2} is calculated from eqn. (10). Using this value the function g is determined. The results are given in Table 3. Fig. 6 gives a plot of g against φ_1. From the resulting straight line a value of of $\beta_2 = 23.5 \pm 1$ M^{-2} is obtained. The intercept gives a very uncertain value of $\beta_3 - l'_3 = 15 \pm 10$ M^{-3}, which can be put equal to β_3 since l_0 is much greater than l_3, *i.e.* Pu^{4+} is more strongly sorbed on the ion exchanger than $Pu(NO_3)_3^+$. Another value of β_3 is obtained from eqn. (16), Table 3, which gives $\beta_3 = 11 \pm 7$ M^{-3}.

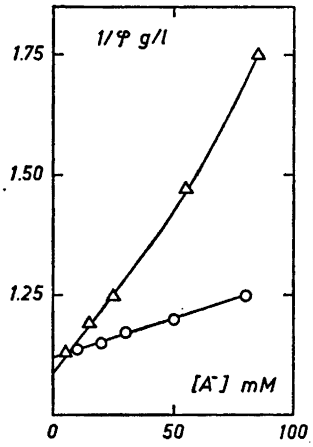

Fig. 2. $1/\varphi$ as a function of [A] for the nitrate △ and chloride ○ systems. C_H = 4 M, T = 20°C.

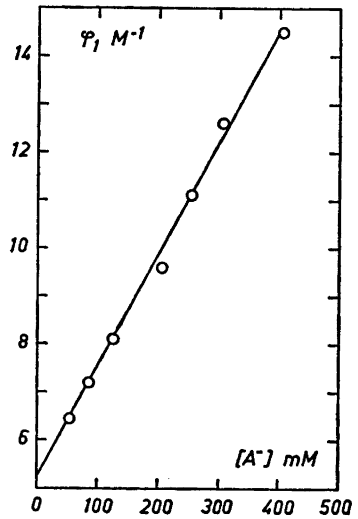

Fig. 3. φ_1 plotted against [A] for the plutonium(IV) nitrate system.

The value of $\beta_1 - l_1' = 5.3 \pm 0.2$ M^{-1} and $\beta_1 = 5.5 \pm 0.2$ M^{-1} gives an upper limit of $l_1' = 0.6$ M^{-1}. Another estimate can be obtained from eqn. (6) which for low values of [A^-] can be written as

$$\varphi_1 \approx (\beta_1 - l_1') + \{\beta_2 - l_2' - l_1' (\beta_1 - l_1')\} [A]$$

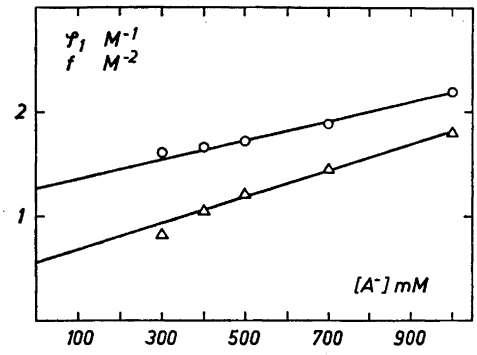

Fig. 8 φ_1 (O) and f (△) as functions of [A] for the plutonium(IV) chloride system.

i.e., φ_1 is a linear function of [A], *cf.* Fig. 3. The slope of the line gives a value of $(\beta_2—l_2')—l_1'$ $(\beta_1—l_1') = 23 \pm 2$ M^{-2} which together with the previously determined values of $\beta_2—l_2' = 23 \pm 3$ M^{-2} and $\beta_1—l_1' = 5.3 \pm 0.2$ M^{-1} gives $l_1' < 1$ M^{-1}. From (15) and the definion of l_i the maximum values of the coefficients l_1 and l_2 can be calculated to be $l_1 < 0.1$ l/g and $l_2 < 0.01$ l/g.

The plutonium(IV)-chloride system

φ was determined at two different C_M' (Fig. 7) and the interpolation to a constant load was made as before. In this case too, the variation of φ with C_{MR} was slight, Table 4. The measured φ-values must be corrected for the complex formation caused by the presence of nitrate ion in the Pu(IV) stock solution. This has been done in the following way: Because of the low nitrate ion concentration (≤ 0.010 M) in the solutions only the prescence of the first nitrate complex has to be considered.

$$\varphi = \frac{l_0\ (1 + l_1'[Cl^-] + l_2' \cdot [Cl^-]^2 + l_3' \cdot [Cl^-]^3 + l_1'^{(NO_3)}[NO_3^-]}{X_{Cl} + \beta_1^{(NO_3)} \cdot [NO_3^-]}$$

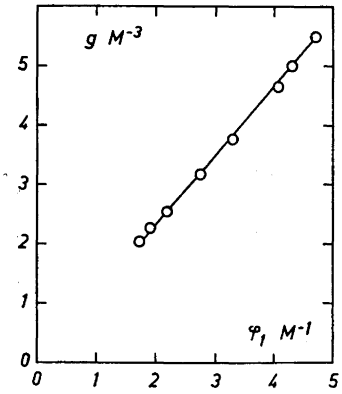

Fig. 9. g as function of φ_1 for the plutonium (IV) chloride system.

Table 6. Formation constants for nitrate and chloride complexes of Pu^{4+}.

	Reference	Medium	β_1 M^{-1}	β_2 M^{-2}	β_3 M^{-3}
NO_3^-	5	$I = 2$ M; 2 M $HClO_4$; $T = 25°C$	2.9		
	6	$I = 1$ M; 1 M $HClO_4$; $T = 25°C$	3.48		
	This work	$I = 4$ M; 4 M $[H^+]$; $T = 20°C$	5.5 ± 0.2	23.5 ± 1	15 ± 10
Cl^-	5	$I = 2$ M; 2 M HNO_3; $T = 25°C$	0.38		
	6	$I = 1$ M; 1 M $HClO_4$; $T = 25°C$	0.58		
	7	$I = 2$ M; 2 M $HClO_4$; $T = 25°C$	0.59		
	7	$I = 1$ M; 1 M $HClO_4$; $T = 25°C$	0.56		
	13	$I = 1$ M; 1 M $HClO_4$; $T = 25°C$	2.10		
	This work	$I = 4$ M; 4 M $[H^+]$ $T = 20°C$	1.4 ± 0.2	1.2 ± 0.2	0.1 ± 0.1

The term $l_1'^{(NO_3)} \cdot [NO_3^-]$ is $< 0.6 \times 0.01$ and is negligible compared with 1. In the denominator the term $\beta_1^{(NO_3)} \cdot [NO_3^-]$ varies from 0.03 to 0.06 and is not negligible for small values of $[Cl^-]$ when $X_{Cl} \approx 1$. Using the above approximation φ can be expressed as

$$\varphi = \frac{l_0 \cdot (1 + l_1'[Cl^-] + l_2' \cdot [Cl^-]^2 + l_3'[Cl]^3)}{X_{Cl}} \left(1 + \frac{5.5 \times [NO_3^-]}{X_{Cl}}\right)^{-1}$$

$$i.e., \varphi_{corr} = \varphi \cdot \left(1 + \frac{5.5[NO_3^-]}{X_{Cl}}\right)$$

where φ_{corr} is the distribution coefficient that would be obtained in abscence of nitrate. φ_{corr} was calculated using approximate values of $\beta_1 = 2$ M^{-1} and $\beta_2 = 10$ M^{-2} for the evaluation of X_{Cl} in the correction term. The φ-values obtained in the following calculation were then used to get a better estimate of φ_{corr} and better values of the complexity constants. The β-values obtained using the second φ_{corr} were the same as the ones obtained in the first approximation. Corresponding values of φ_{corr}, φ_1, f, $\Delta f/\Delta\varphi_1$ and [A] are given in Table 5. The graphical determination of l_0, φ_1^0 and f° are given in Figs. 2 and 8.

$$l_0 = 0.89 \pm 0.02 \text{ g/l} \quad \varphi_1^0 = 1.25 \pm 0.05 \text{ } M^{-1} \quad f^\circ = 0.56 \pm 0.06 \text{ } M^{-2}$$

In this case β_1 can not be determined graphically from the function $\Delta f/[A^-]$ because the values of $\Delta f/[A^-]$ and $\Delta\varphi_1/[A^-]$ are nearly constant over the entire $[A^-]$ range, Table 5. Instead β_1 is calculated from eqn. (9) using the approximate value of l_1 obtained from the nitrate system. In this way a value of $\beta_1 = 1.4 \pm 0.1$ M^{-1} is obtained. Using this value of β_1 the function g is calculated according to eqn. (8). From a plot of g as a function of φ_1, Fig. 9., β_2 is found to be 1.2 ± 0.2 M^{-2}. β_2 can also be determined from eqn. (10) if l_2' is neglected. We obtain in this case $\beta_2 = 1.2 \pm 0.2$ M^{-2}. X_3 calculated from eqn.

Table 7. The nitrate and chloride complexes of Zr^{4+}, Th^{+4} and U^{+4}.

	Metal ion	Ref.	Medium	β_1 M^{-1}	β_2 M^{-2}
NO_3^-	Zr^{4+}	14	2 M $HClO_4$ $T = 25°$	2.0	
		15	4 M $HClO_4$ $T = 20°C$	2.20	1.30
	Th^{4+}	16	2 M $HClO_4$ $T = 20°C$	6.0	13.0
		17, 18	5.97 M $NaClO_4$ $T = 25°C$	2.8	1.4
Cl^-	Zr^{4+}	14	2 M $HClO_4$ $T = 25°C$	2.0	
		15	6.54 M $HClO_4$ $T = 20°C$	8.4	21.0
	Th^{4+}	19	4 M $NaClO_4$ $T = 25°C$	1.7	0.16
		17	4 M $NaClO_4$ $T = 25°C$	1.3	0.11
	U^{4+}	20	1 M $NaClO_4$, $[H^+] = 0.6$ M $T = 20°C$	2.0	
		21	2 M $NaClO_4$ $[H^+] = 1$ M $T = 25°C$	1.8 * 1.2 *	1.15 *

* Alternative interpretation.

(16) gives a very approximative value of $\beta_3 = 0.1 \pm 0.1$ M^{-3}, Table 5. With this value of β_3 eqn. (13) gives, if l_3' is neglected, $\beta_1 = 1.4 \pm 0.2$ M^{-2} in good accordance with the value calculated from eqn. (9).

The distribution coefficients, l_j, show the sorption of the plutonium complexes to be very low compared with the sorption of the uncomplexed Pu^{4+}-ion.

$$l_0 = 0.9 \text{ l/g} \qquad l_1 < 0.1 \text{ l/g} \qquad l_2 < 0.01 \text{ l/g}$$

This means that the absolute decrease of φ will be so small when PuA_2^{2+} is converted into higher complexes that it is impossible to obtain the higher constants with any accuracy.

DISCUSSION

A comparison between the complexity constants obtained in this work and those obtained by other authors is given in Table 6. It is difficult to make any quantitative comparisons because of the differences in experimental conditions. No values of the higher constants have been previously reported in the literature.

It is also of interest to compare the complexity constants of Pu^{4+} with those of other four-valent ions. Values are given in the literature for nitrate and chloride complexes fo Zr^{4+}, Th^{4+} and U^{4+} but they have usually been measured under other conditions than in this work. The results are summarised in Table 7. The corresponding complexity constants of the four-valent actinide elements all have about the same magnitude. As to Zr^{4+} its chloride complexes are decidedly stronger than those of the actinides. This is to be

expected on account of the smaller ionic radius of Zr^{4+} if the complex formation is governed mainly by electrostatic forces which is very likely for complexes of this type. On the other hand, the nitrate complexes of Zr^{4+} seems to be weaker than the corresponding actinide complexes. This is rather unexpected and is possibly an indication of a somewhat different type of bond in these complexes [22].

This investigation has been supported by a grant from *AB Atomenergi*, Stockholm (the *Swedish Atomic Energy Company*).

With Professor Sture Fronæus, Dr Sten Ahrland and Dr Artur Sonesson we have had many fruitful discussions. The have given us views and information, which have strongly promoted our work.

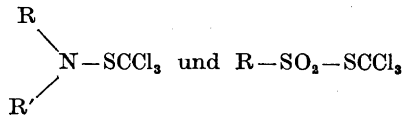
Beiträge zur Chemie α-substituierter Sulfide. II *. Einige potentiell fungizide Verbindungen, die die Trichlormethylmerkaptogruppe enthalten

ALEXANDER SENNING und SVEN-OLOV LAWESSON

Institut für Organische Chemie der Universität Uppsala, Uppsala, Schweden

Um weiteres Material zum Substituenteneinfluss auf die Fungitoxizität der Trichlormethylarylsulfide zu sammeln, wurden die drei Methylmerkaptobenzoesäuren und deren Äthylester chloriert. Die *m*- und *p*-Verbindungen lieferten die erwarteten Trichlormethylmerkaptoderivate, während bei den *o*-Verbindungen Besonderheiten auftraten. Bei der Chlorierung der *o*-Methylmerkaptobenzoesäure führte ein Ringschluss zum 4-Thiaisochromanon-(1)-system. In einem Parallelversuch konnte die Muttersubstanz 4-Thiaisochromanon-(1) durch Kondensation von Thiosalizylsäure mit Formaldehyd dargestellt werden.

Die bekanntesten fungiziden Verbindungen dieses Typus tragen die Trichlormethylmerkaptogruppe an einem Stickstoff- oder Schwefelatom und gehören den beiden Typen



an. Diese Verbindungen werden vom Trichlormethansulfenylchlorid ausgehend dargestellt, dessen Chemie von Sosnovsky [1] in einem Übersichtsartikel eingehend behandelt wurde.

Egen [2] entdeckte, dass Trichlormethylphenylsulfid und kernsubstituierte Trichlormethylarylsulfide fungistatische Eigenschaften besitzen. Solche Verbindungen sind ganz allgemein durch Chlorierung der entsprechenden Methylarylsulfide zugänglich. Trichlormethylarylsulfide wurden zuerst von Zincke [3–5] und in neuerer Zeit von Egen [2] und Böhme [6] dargestellt. Böhme [6] hat auch

* I. Mitteilung: *Acta Chem. Scand.* 14 (1960) 1444.

den Mechanismus der α-Chlorierung der Thioäther aufgeklärt. Die von Sanna [7] beschriebene Darstellung des Trichlormethylphenylsulfids aus Trichlormethansulfenylchlorid und Phenylmagnesiumbromid lässt sich nicht nacharbeiten [8]. Ausserdem besitzen die von diesem Verfasser als Trichlormethylphenylsulfid und Trichlormethylphenylsulfon beschriebenen Verbindungen ganz andere physikalische Eigenschaften als die von Egen und Böhme dargestellten und sind mit diesen offensichtlich nicht identisch.

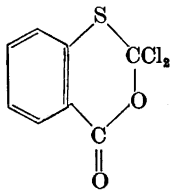
Die von Egen dargestellten und biologisch untersuchten Trichlormethylarylsulfide geben gewisse Hinweise auf den Substituenteneinfluss, jedoch ist das vorliegende Material zu unvollständig, um exakte Schlussfolgerungen zuzulassen. Um weiteres Material zum Substituenteneinfluss zu sammeln, wurde in der vorliegenden Arbeit unternommen, die Trichlormethylmerkaptobenzoesäuren und deren Äthylester darzustellen und auf ihre Fungitoxizität und Phytotoxizität zu undersuchen.

Es soll hier über den präparativen Teil der Arbeit berichtet werden. Die biologischen Versuchsergebnisse werden zu einem späteren Zeitpunkt veröffentlicht werden.

Als Ausgangsmaterial dienten *o*-, *m*- und *p*-Methylmerkaptobenzoesäure und deren Äthylester. *o*-Methylmerkaptobenzoesäure wurde nach D.R.P. 193 800 [9] dargestellt. *m*- und *p*-Methylmerkaptobenzoesäure wurden in Abwandlung des von Wiley [10] für die Merkaptosäuren beschriebenen Verfahrens durch direkte Methylierung des Hydrolysates der Xanthogenate erhalten. Die Säuren fallen in etwas unreinem Zustand an und lassen sich bei Bedarf über die Methyl- oder Äthylester reinigen. Zur Darstellung der Äthylester wurden die Säuren mit Hilfe eines Veresterungsaufsatzes verestert. *o*- und *m*-Methylmerkaptobenzoesäureäthylester sind unseres Wissens bisher noch nicht beschrieben worden.

Die Chlorierung der Verbindungen wurde nach der Vorschrift von Böhme [6] mit in Tetrachlorkohlenstoff oder Chloroform gelöstem Chlor durchgeführt.

Die *m*- und *p*-Trichlormethylmerkaptoderivate wurden in glatter Reaktion erhalten. Der *o*-Methylmerkaptobenzoesäureäthylester liess sich auch unter energischen Bedingungen nicht vollständig chlorieren. Das intensiv gelb gefärbte Chlorierungsprodukt, das in einem Siedepunktsintervall von wenigen Graden überging, hatte einen zu niedrigen Chlorgehalt und war nach dem Infrarotspektrum zu urteilen nicht einheitlich. Die Chlorierung der *o*-Methylmerkaptobenzoesäure führte zu einem Ringschluss und lieferte ein Produkt, dem wir auf Grund der Analysendaten folgende Struktur zuschreiben:

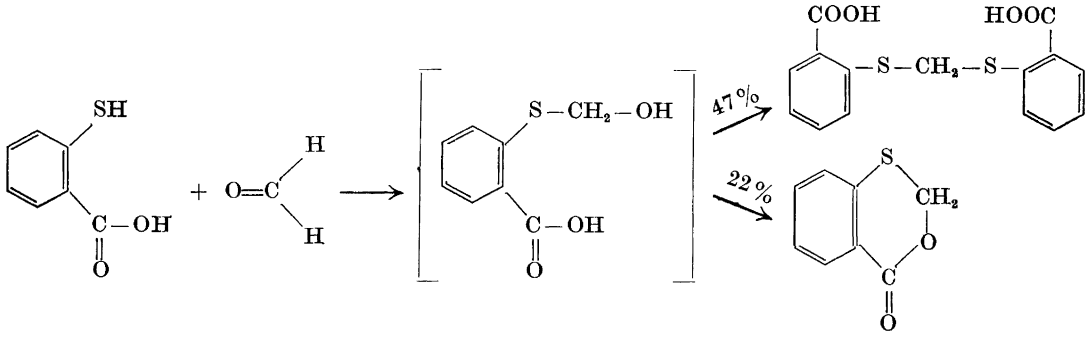


3,3-Dichlor-4-thiaisochromanon-(1)
(2,2-Dichlor-1,3-benzthioxan-4-on)

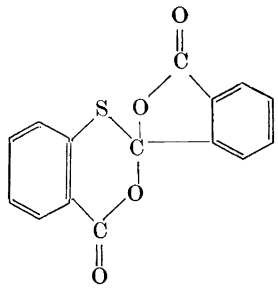
Im Infrarotspektrum des 3,3-Dichlor-4-thiaisochromanons-(1) war die Laktonkarbonylbande charakteristisch verschoben und lag bei 5,63 μ. Adler [11]

beobachtete eine entsprechende Verschiebung bei der 3,4-Dihydroisokumarin-karbonsäure-(3) (Laktonkarbonylbande bei 5,63 μ —5,69 μ).

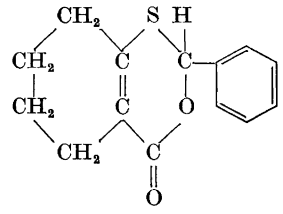
Der Grundkörper, 4-Thiaisochromanon-(1), liess sich durch Einwirkung von trockenem Chlorwasserstoff auf eine siedende Lösung von Thiosalizylsäure und Paraformaldehyd in Eisessig darstellen:



4-Thiaisochromanon-(1) selbst ist unseres Wissens noch nicht dargestellt worden. Dagegen sind Derivate der Tetrahydroverbindung beschrieben sowie eine Spiroverbindung, die das 1,3-Benzthioxanon-(4)-system enthält.



"Thiosalicylsäurephthalidenätherester" Spiro-[1,3-benzthioxan-2,1′(3′H)-isobenzofuran-4,3′-dion] [12]



5,6,7,8-Tetrahydro-2-phenyl-1,3-benzthioxan-4-on [13]

Das Sauerstoffhomologe, 3-Oxachromanon-(4), ist von Calvet [14] und von Borsche [15] dargestellt worden. 1,3-Thioxan- bzw. 1,3-Oxthiophanderivate entstehen durch Umsetzung von Ketonen mit γ-Merkaptopropanol bzw. β-Merkaptoäthanol (Sjöberg [16], Djerassi [17], Marshall [18]), während α-Merkaptokarbonsäuren mit Aldehyden und Ketonen 1,3-Oxthiophanon-(5)-derivate liefern (Bistrzycki [19], Fredga [20]).

Die Untersuchungen in der Verbindungsklasse der Trichlormethylarylsulfide werden fortgesetzt. Gleichzeitig untersuchen wir den Mechanismus der Ringschlussreaktion der *o*-Methylmerkaptobenzoesäure sowie die Möglichkeiten zur Darstellung substituierter 4-Thiaisochromanone-(1).

BESCHREIBUNG DER VERSUCHE

Alle Schmelz- und Siedepunkte sind unkorrigiert. Infrarotspektrogramme wurden mit den Spektrographen Perkin-Elmer Modell 137 und Perkin-Elmer Modell 21 aufgenommen. Die Analysen wurden teils im Institut für Analytische Chemie der Universität Uppsala, teils von der Firma Alfred Bernhardt, Mülheim (Ruhr) ausgeführt.

o-*Methylmerkaptobenzoesäure.* 138,0 g Diphenyldisulfiddikarbonsäure-(2,2′) wurden in einer Lösung von 120,0 g Ätznatron in 750 ml Wasser gelöst und 1 1/2 Stunden mit 139,0 g Dimethylsulfat gekocht. Die *o*-Methylmerkaptobenzoesäure wurde über Nacht im Trockenschrank getrocknet, aus Benzol umkristallisiert und erneut im Trockenschrank getrocknet. Ausbeute: 87,6 g (58 % der Theorie). F: 168°—169° (Literatur: 168°—169°).

m-*Methylmerkaptobenzoesäure.* 109,5 g m-Aminobenzoesäure wurden nach Wiley [10] diazotiert, mit Kaliumxanthogenat umgesetzt und unter Stickstoff hydrolysiert. Anschliessend wurden 200 g Dimethylsulfat und 64 g Ätznatron, gelöst in 165 ml Wasser, zugetropft und anschliessend noch 1 Stunde gekocht. Das Produkt wurde im Trockenschrank bei 90° getrocknet und zur Entfernung anorganischer Verunreinigungen aus Alkohol und Wasser umgefällt. Die bei 90° im Trockenschrank getrocknete *m*-Methylmerkaptobenzoesäure schmolz zwischen 120° und 126° (Literatur: 129°) und wog 109,0 g (82 % der Theorie).

p-*Methylmerkaptobenzoesäure.* Diese Säure wurde analog der *m*-Säure dargestellt. Ausbeute 95 % der Theorie, F: 188°—192° (Literatur: 192°).

o-*Methylmerkaptobenzoesäureäthylester.* 50,0 g *o*-Methylmerkaptobenzoesäure wurden in 800 ml Benzol gelöst und mit Hilfe eines Veresterungsaufsatzes mit 200 ml Äthanol und 20 ml konzentrierter Schwefelsäure bis zur Beendigung der Wasserabscheidung gekocht (100 Stunden). Der Ester wurde auf die übliche Weise isoliert. Zwischen 161°/12 mm und 162°/12 mm gingen 42,3 g (72 % der Theorie) über. *o*-Methylmerkaptobenzoesäureäthylester ist eine farblose Flüssigkeit, Sdp. 129°/0,2 mm, n_D^{20} 1,5784. Der Ester wird im Kühlschrank fest, schmilzt aber unterhalb Zimmertemperatur. (Gef. C 61,02; H 5,89. Ber. für $C_{10}H_{12}O_2S$: C 61,20; H 6,16).

m-*Methylmerkaptobenzoesäureäthylester.* Dieser Ester wurde analog dem *o*-Ester dargestellt. Das Produkt ging zwischen 153°/16 mm und 157°/16 mm über. Ausbeute 61 % der Theorie. *m*-Methylmerkaptobenzoesäureäthylester ist eine farblose Flüssigkeit, Sdp. 121°/0,8 mm, n_D^{20} 1,5612. (Gef. C 61,31; H 6,13. Ber. für $C_{10}H_{12}O_2S$: C 61,20; H 6,16).

p-*Methylmerkaptobenzoesäureäthylester.* Dieser Ester wurde analog dem *o*-Ester dargestellt. Das Produkt ging zwischen 165°/16 mm und 171°/16 mm über. Ausbeute 59 % der Theorie. F: 23°—25° (Literatur: 28°).

m-*Trichlormethylmerkaptobenzoesäure.* 10,7 g (0,064 Mol) *m*-Methylmerkaptobenzoesäure (F: 125°—126°) wurden in 100 ml Chloroform suspendiert. Im Laufe von 15 Min. wurden unter Rühren 18,2 g (0,256 Mol) Chlor, gelöst in 400 ml Chloroform, zugegeben. Nach einigen Minuten ging die Säure in Lösung und es entwickelte sich unter mässiger Erwärmung Chlorwasserstoff. Nach weiteren 5 Min. wurde ein Wasserbad von 40° langsam auf 80° aufgeheizt. Nach insgesamt 2 1/2 Stunden war die Chlorwasserstoffentwicklung beendet. Der Kolbeninhalt wurde bis fast zur Trockne eingeengt, abfiltriert und mit wenig leichtsiedendem Petroläther gewaschen. Ausbeute 11,7 g (67 % der Theorie), F: 111°—117°. Das Produkt wurde im Soxhletapparat mit 200 ml leichtsiedendem Petroläther extrahiert und schmolz dann zwischen 119° und 122°. Nach mehrmaligem Umkristallisieren aus Chloroform und Trocknen im Vakuumexsikkator über Paraffin und Kalziumchlorid schmolz die Säure (farblose Rhomben) zwischen 125° und 127°. (Gef. C 35,00; H 1,87; Cl 39,10; S 11,46. Ber. für $C_8H_5Cl_3O_2S$: C 35,38; H 1,86; Cl 39,17; S 11,81).

p-*Trichlormethylmerkaptobenzoesäure.* 42,0 g (0,25 Mol) *p*-Methylmerkaptobenzoesäure wurden in 400 ml Chloroform suspendiert. Zu dieser Suspension wurden unter Rühren im Laufe von 25 Min. 71,0 g (1,00 Mol) Chlor, gelöst in 800 ml Chloroform, zugegeben. Nach weiteren 5 Min. wurde ein Wasserbad von 40° langsam auf 80° aufgeheizt. Nach 70 Min. war die Chlorwasserstoffentwicklung beendet. Nach dem Erkalten wurden 32,0 g Produkt vom Schmelzpunkt 192°—194° abfiltriert. Aus der Mutterlauge wurden durch Einengen weitere 20,0 g vom Schmelzpunkt 182°—188° erhalten. Ausbeute 52,0 g (77 % der Theorie). Nach mehrfachem Umkristallisieren aus Chloroform und Trocknen im Vakuumexsikkator über Paraffin und Kalziumchlorid schmolz die Säure

(feine Nadeln) zwischen 198° und 200° (unter leichter Zersetzung). (Gef. C 35,51 %; H 1,93 %; Cl 39,60 % S 11,69 %. Ber. für $C_8H_6Cl_3O_2S$: C 35,38; H 1,86; Cl 39,17; S 11,81).

m-*Trichlormethylmerkaptobenzoesäureäthylester.* 19,6 g (0,10 Mol) *m*-Methylmerkaptobenzoesäureäthylester wurden in 100 ml Tetrachlorkohlenstoff gelöst und im Laufe von 1/2 Stunde unter Rühren mit 25,5 g (0,36 Mol) Chlor, gelöst in 400 ml Tetrachlorkohlenstoff, versetzt. Darauf wurde 6 Stunden auf dem Wasserbad erwärmt. Das Lösungsmittel wurde abgezogen und der Ester destilliert. Zwischen 192° und 204° (16 mm) gingen 28,9 g (97 % der Theorie) über. *m*-Trichlormethylmerkaptobenzoesäureäthylester ist eine farblose Flüssigkeit (meist von einer schwer zu entfernenden gelben Verunreinigung begleitet), Sdp. 158°/0,6 mm, n_D^{20} 1,5692. (Gef. C 40,75; H 3,19; Cl 34,92; S 10,94. Ber. für $C_{10}H_9Cl_3O_2S$: C 40,09; H 3,03; Cl 35,50; S 10,70).

p-*Trichlormethylmerkaptobenzoesäureäthylester.* Dieser Ester wurde analog dem *m*-Ester dargestellt. Zwischen 160°/0,6 mm und 165°/0,6 mm gingen 24,8 g (83 % der Theorie) über. F: 50°—52°. Nach mehrmaligem Umkristallisieren aus leichtsiedendem Petroläther und Trocknen im Vakuumexsikkator über Paraffin und Kalziumchlorid schmolz der Ester (farblose Säulen) zwischen 55° und 57°. Gef. C 39,74; H 2,85; Cl 35,63; S 10,85. Ber. für $C_{10}H_9Cl_3O_2S$: C 40,09; H 3,03; Cl 35,50; S 10,70).

3,3-Dichlor-4-thiaisochromanon-(1). 27,8 g o-Methylmerkaptobenzoesäure (0,17 Mol) wurden in 100 ml Tetrachlorkohlenstoff suspendiert und unter Rühren mit 60,0 g (0,84 Mol) Chlor, gelöst in 850 ml Tetrachlorkohlenstoff, versetzt. Nach 8 Stunden Erwärmen auf dem Wasserbad war keine Chlorwasserstoffentwicklung mehr zu beobachten. Nach dem Abziehen des Lösungsmittels ging das Produkt zwischen 165°/16 mm und 170°/16 mm über. Ausbeute 25,2 g (65 % der Theorie). 3,3-Dichlor-4-thiaisochromanon-(1) ist eine gelbe Flüssigkeit, die im Kühlschrank fest wird, aber unterhalb Zimmertemperatur schmilzt, Sdp. 97°/0,03 mm, n_D^{20} 1,6196. (Gef. C 40,84; H 1,84; Cl 29,78; S 13,69. Ber. für $C_8H_4Cl_2O_2S$: C 40,87; H 1,72; Cl 30,16; S 13,64).

4-Thiaisochromanon-(1). 15,4 g (0,1 Mol) Thiosalizylsäure und 3,0 g (0,1 Mol) Paraformaldehyd wurden in 150 ml siedendem Eisessig gelöst. In die siedende Lösung wurde 3 Stunden lang trockener Chlorwasserstoff eingeleitet, wobei nach wenigen Minuten ein weisser Niederschlag ausfiel. Anschliessend wurde vom Niederschlag abfiltriert, das Filtrat in ca. 5 l kaltes Wasser gegossen und über Nacht stehen gelassen. Am nächsten Tag war das 4-Thiaisochromanon-(1) in groben Nadeln auskristallisiert. Es wurde abfiltriert, mit 2 %-iger Sodalösung gewaschen und getrocknet. Ausbeute 3,7 g (22 % der Theorie). F: 43°—45°. Nach mehrmaligem Umkristallisieren aus leichtsiedendem Petroläther schmolz die Substanz (farblose Rhomben) zwischen 45° und 47°. (Gef. C 57,74; H 3,66; S 19,24. Ber. für $C_8H_6O_2S$: C 57,81; H 3,64; S 19,29).

Der weisse Niederschlag war Methylen-bis-(*o*-karboxyphenylsulfid), 7,2 g (47 % der Theorie), F: 283°—285°. Nach Umfällen mit Sodalösung und Salzsäure schmolz die Substanz zwischen 286° und 288° (Literatur: 286°—288°). Stevenson und Mitarbeiter [21] haben Thiosalizylsäure und Formalin in Alkohol miteinander umgesetzt und das Merkaptal in 66 %-iger Ausbeute erhalten [22].

Wir danken Herrn Professor A. Fredga für das Interesse, das er unserer Arbeit entgegengebracht hat und für anregende Diskussionen. Wir sind Herrn Professor A. Fredga für die Überlassung des Arbeitsplatzes und *Jordbrukets Forskningsråd* für die finanzielle Unterstützung unserer Arbeit zu Dank verpflichtet.

The Oxidation of Glycosides

XI *. Oxidation of Methyl β-D-xylopyranoside and Methyl β-D-ribopyranoside

EILEEN BRIMACOMBE, JOHN S. BRIMACOMBE and BENGT LINDBERG

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm Ö, Sweden

Methyl β-D-xylopyranoside was oxidised with chromium trioxide in acetone and the resulting oxo-xylosides fractionated. The 2-oxo-, 3-oxo and 4-oxo-methylxylosides were isolated as amorphous materials. Platinum catalysed oxidation of methyl β-D-ribopyranoside gave methyl β-D-3-oxo-xylopyranoside (methyl β-D-3-oxo-ribopyranoside) as the principal oxidation product.

Oxidation of the anomeric methyl-6-*O*-trityl-D-glucopyranosides with chromium trioxide in acetone [1] yields mainly the 3-oxo-derivative (3—5 %) together with smaller amounts of the 2-oxo- and 4-oxo-derivatives (0.3—0.5 %). Similarly, oxidation of methyl β-D-glucopyranoside with this reagent [2] results in the aforementioned products together with a compound identified as methyl β-D-6-oxo-glucopyranoside (1.3 %). These oxidation studies have now been extended to glycosides of the pentoses and an attempt has been made to localise the oxidation by catalytic methods.

The oxidation procedure used with chromium trioxide in acetone was essentially that described by Theander [1]. The reaction mixture was shown by paper chromatography to contain at least seven products, the principal components of which were separated by chromatography on a carbon-Celite column. The 2-oxo- and 4-oxo-xylosides were eluted from the column together and in a fraction containing unreacted methyl β-D-xyloside. They were subfractionated on thick filter papers (see Experimental). As in the glucoside series [1,2] the 2-oxo- and 4-oxo-xylosides were more labile than the corresponding 3-oxo-xyloside at a pH near the neutral point and readily gave epimerisation and decomposition products. This was particularly noticeable in working up eluates from thick filter papers and in neither case was a chromatographically homogeneous product obtained. Methyl β-D-3-oxo-xylopyranoside, the principal product of the oxidation, was obtained as an amorphous powder ($[\alpha]_D$ −90°) but chromatographically and electrophoretically pure. The yield of oxo-derivatives was essentially the same as found by Theander [1] with methyl

* Part X. *Acta Chem. Scand.* **12** (1958) 1883.

Table 1. Oxo-xylosides; preparation and characteristics.

	Methyl β-D-oxo-xylopyranosides			Methyl β-D-xylopyranoside
	2-oxo	3-oxo	4-oxo	
Yield [a] (%)	0.4	3.5	0.4	43
Percentage of ethanol in the eluate when substance emerged from the column[b]	7.5	12.6	7.5	8.25
Paper chromatography $R_{glucose}$ values [b]				
Irrigant A	1.62	3.48	2.01	1.81
Irrigant B	1.44	2.14	1.63	2.10
Paper electrophoresis M_V values Buffer D at room temperature[b]	1.0	1.0	1.0	0
Products of reduction and hydrolysis	xylose lyxose	xylose ribose	xylose arabinose	

a. The yields are calculated as percentage of the amount of xyloside before oxidation.
b. Data of the carbon column separation and solvents and buffer used for paper chromatoraphy and electrophoresis are given in the Experimental section.

6-*O*-trityl-β-D-glucopyranoside and are recorded in Table 1. The structure of the oxo-xylosides was shown by identifying the sugars obtained on reduction (sodium amalgam) and hydrolysis (see Table 1 for details).

The oxo-xylosides formed strong complexes in hydrogen sulphite buffer at pH 4.7 and all had an M_v value = 1 (migration relative to that of vanillin). This contrasts with the results obtained in the glucoside series [3] where the various isomers showed significant differences in their rates of migration in hydrogen sulphite buffer. The M_v values and $R_{glucose}$ values of the oxo-xylosides are recorded in Table 1. The oxo-xylosides gave strong reducing reactions with silver nitrate-sodium ethoxide reagent and a characteristic yellow colouration (absorption in UV-light) with anisidine hydrogen chloride.

The dehydrogenation of polyols by treatment with oxygen in the presence of platinum catalysts has recently been reviewed by Heyns and Paulsen [4]. In the cyclitol series it has been found that axial hydroxyl groups are preferentially dehydrogenated. *myo*-Inositol has, for example, been selectively dehydrogenated to *myo*-inosose-2. These reactions are generally reversible as axial hydroxyl groups are preferentially formed by platinum catalysed hydrogenation of the corresponding ketones. Theander [5] has shown that platinum catalysed reduction of an oxo-glucoside results in a mixture of glycosides in which the epimer with the axial hydroxyl group predominates. Methyl β-D-ribopyranoside on treatment with oxygen over reduced Adams' catalyst gave a mixture of products, the main component of which was chromatographically indistinguishable from methyl β-D-3-oxo-xylopyranoside (methyl β-D-3-

oxo-ribopyranoside). Carbon column chromatography gave four main fractions (see Experimental) one of which contained relatively pure methyl β-D-3-oxo-xylopyranoside. Reduction of this fraction with sodium amalgam and subsequent hydrolysis gave two sugars indistinguishable from ribose and xylose in irrigants A—C. Another fraction, containing some 3-oxo-derivative together with much unreacted methyl β-D-ribopyranoside, was effectively separated by chromatography on a carbon-Celite column using sodium hydrogen sulphite elution [2]. The yield of methyl β-D-3-oxo-xylopyranoside (*ca.* 6 %) is limited by secondary oxidation and degradation reactions which occur on prolonged oxidation.

In the sterically favoured C-1 conformation of methyl β-D-ribopyranoside only the hydroxyl at $C_{(3)}$ is axially disposed and it seems, as in the cyclitol series, that preferential dehydrogenation occurs at this position. Other experiments, for example with methyl α-L-arabinopyranoside ($C_{(4)}$ hydroxyl group axial), indicated that dehydrogenation occurs at the axial hydroxyl group. This reaction is complicated by the ease of epimerisation and degradation of the initially form oxo-compounds at a pH near the neutral point. Methyl β-D-xylopyranoside (all hydroxyl groups equatorial) was largely unaffected under identical conditions but some slight oxidation was observed. This suggests that either some dehydrogenation occurs at the equatorial hydroxyl groups or that the molecule can react in a sterically unfavourable conformation.

EXPERIMENTAL

Melting points are corrected. All distillations were carried out under reduced pressure (bath temperature < 35°) or by freeze-drying. Whatman 1 filter papers were used for paper chromatography and electrophoresis except for preparative separations which were made on Whatman 3 MM filter papers previously washed thoroughly with water.

Irrigants and buffer used:

A. Ethyl acetate-acetic acid-water, 3:1:3 (upper phase)
B. Butanol-ethanol-water, 10:3:5
C. Ethyl acetate-pyridine-water, 2:1:2
D. Hydrogen sulphite buffer [3] pH 4.7, 0.1 M.

Oxidation of methyl β-D-xylopyranoside with chromium trioxide

The oxidation and fractionation procedures were essentially as described by Theander [1] and an abbreviated description only is given.

Methyl β-D-xylopyranoside (20.0 g) in acetone (1.2 l) was oxidised by treatment under reflux with chromium trioxide (18.3 g) in acetone (1.2 l) for 30 min. The brown chromium oxides were filtered from the oxidation mixture and boiled with acetone (4 × 400 ml) for 10 min with intermediate filtrations. The combined filtrates were evaporated to a dark brown clear solution, adjusted to 500 ml with acetone and treated with 0.5 N alcoholic hydrogen chloride (60 ml) at 25° for 30 min to reduce the chromium in solution to Cr^{3+}. The solution was adjusted (Ag_2CO_3) with agitation and cooling to pH 5. The silver precipitate was filtered, washed with acetone and water and the combined filtrate and washings evaporated to a small volume and deionised [Dowex 50(H^+) and Dowex 3(free base)]. The solution, which had a pH of 5, was evaporated to a semi-crystalline mass (13.6 g) which was fractionated on a carbon-Celite column (70 × 8 cm) using linear gradient elution technique (ethanol: 0—20 %, 16 l). The following main fractions were collected in 50 ml portions.

Fraction I (0.123 g), 120—130, contained a mixture of methyl 2- and 4-oxo-xylosides and was subfractionated on thick filter papers using irrigant A. As the oxo-compounds

were quite labile and further transformed to other products even at pH 4—7, eluates from the thick filter papers were evaporated by freeze-drying in silicone treated flasks.

Fraction II (9.45 g), 132—195, consisted mainly of methyl β-D-xyloside and traces of methyl 2- and 4-oxo-xylosides. The mother-liquors were fractionated on thick filter papers to give further small quantities of 2- and 4-oxo-xylosides after removal of the methyl β-D-xyloside by crystallisation. Fraction III (0.7 g) 202—242 contained methyl β-D-3-oxo-xyloside which was obtained as an amorphous powder $[\alpha]_D^{21.5}$ −90° (*c*, 1.0 in water) after removal of the solvent.

Characterisation of methyl β-oxo-xylosides

Methyl β-D-3-oxo-xylopyranoside (0.2 g) in water (5 ml) was treated over 2 h with 2.5 % sodium amalgam and pH 6 maintained by gradual addition of glacial acetic acid. After deionisation [Dowex 50(H^+) and Dowex 3(free base)] and concentration, the solution was hydrolysed with 0.5 N sulphuric acid for 16 h at 100°. The neutral (Dowex 3) solution was concentrated and the sugars formed were separated on thick filter papers using irrigant A. After elution and evaporation, ribose was obtained as a syrup which failed to crystallise but gave a crystalline 2,4-dinitrophenylhydrazone, m.p. and mixed m.p. 162—163°.

Methyl β-D-2-oxo-xylopyranoside (20 mg) gave on similar treatment two sugars chromatographically indistinguishable from xylose and lyxose in irrigants A—C.

Methyl β-D-4-oxo-xylopyranoside (20 mg) gave on reduction and hydrolysis two sugars chromatographically indistinguishable from xylose and arabinose in irrigants A—C.

Platinum catalysed oxidation of methyl β-D-ribopyranoside

A stream of hydrogen was passed through a suspension of platinum dioxide (2 g) in water (200 ml) in a 500 ml Kluyver flask until reduction was complete. Excess hydrogen was removed in a stream of nitrogen and oxygen then passed in a rapid stream until the metal was finely suspended; β-methyl-D-ribopyranoside (4 g) was added and oxidised at atmospheric pressure for 5 h at 20°. On paper chromatograms, run in irrigant A, the oxidised solution gave a strong spot with $R_{glucose}$ value 3.48, which showed a characteristic colour reaction with anisidine hydrogen chloride spray and was chromatographically indistinguishable from methyl β-D-3-oxo-xylopyranoside. The oxidised solution was shaken with Dowex 3(free base) to remove any acids produced, filtered and the filtrate concentrated under reduced pressure. The combined yield of two such treatments was chromatographed on a carbon-Celite column (70 × 8 cm) using the linear gradient elution technique (ethanol: 0—20 %, 16 l). The following fractions were collected in 50 ml portions.

Fraction I (0.3 g), 128—160, contained three components, the main component having $R_{glucose}$ value 1.58. This fraction was not further investigated.

Fraction II (0.38 g), 178—187, contained relatively pure methyl β-D-3-oxo-xylopyranoside. It was chromatographically indistinguishable from the methyl β-D-3-oxo-xylopyranoside obtained by chromium trioxide oxidation. Ribose and xylose were the only sugars formed on reduction and hydrolysis.

Fraction III (4.8 g), 188—244, contained a small amount of methyl β-D-3-oxo-xylopyranoside together with unreacted starting material. Separation of 2.3 g of this fraction on a carbon-Celite column (35 × 3 cm) using 0.1 N sodium hydrogen sulphite elution [2] gave a further quantity (42 mg) of the 3-oxo-derivative.

Fraction IV (1.8 g), 246—280, contained mainly methyl β-D-ribopyranoside which crystallised on removal of the solvent.

Short Communications

Studies on Carbamates
XIV. On the Catalytic Action of Metal Ammines on the Process "Carbon Dioxide ⇌ Carbonic Acid"

ERIK JOHANSEN and CARL FAURHOLT

The Royal Danish School of Pharmacy, Copenhagen, Denmark

In a previous investigation [1] from this laboratory it was shown that $Zn(NH_3)_4^{++}$ increases the rate of the process "$NH_2COONH_4 + H_2O = (NH_4)_2CO_3$" which was explained by assuming that the process "$CO_2 + H_2O = H_2CO_3$" is catalyzed by $Zn(NH_3)_4^{++}$.

In the present investigation it is shown that also $Cu(NH_3)_4^{++}$ has some catalytic effect, whereas $Co(NH_3)_6^{+++}$ has no effect.

Experiments with the carbamate of glycine show that the complex zinc glycinate acts as a catalyst to some degree, whereas the complex cupric glycinate has no significant catalytic effect.

1. *Studies on the ammonium carbamate.* In the previous investigation only a single experiment was carried out with $Cu(NH_3)_4^{++}$. The present investigation is supplementary to this experiment. The results of experiments carried out in the buffer 0.5 M NH_4Cl/0.05 M NH_3 are listed in Table 1. The experiments were carried out at 0°C, and the velocity constants were calculated by means of Briggs logarithms. It is seen that the catalytic action is small. Experiments with $Co(NH_3)_6^{+++}$ in the same buffer solution gave no significant effect.

2. *Studies on the carbamate of glycine.* The experiments are carried out in the buffer 0.5 M $+H_3NCH_2COO^-$/0.05 M $H_2NCH_2COO^-$ at 18°C. The reaction was started by addition of K_2CO_3.

The method of analysis was a slight modification of a complexometric titration described by Jørgensen [2].

The reaction was quenched by addition of sodium hydroxide. It was necessary to mask the added catalyst, *e.g.* zinc glycinate or cupric glycinate, in order to titrate excess barium ion. The masking was performed by means of potassium cyanide, since the complex ions, zinc cyanide ion

and cupric cyanide ion, are not titrated together with excess barium ion.

The details are as follows:

20.00 ml of the specimen are run into a flask containing 2.00 ml of a mixture that is 6.4 M in sodium hydroxide and 2 M in potassium cyanide. 8.00 ml of this mixture are precipitated with barium chloride and analysed as described by Jørgensen. It was found that a faint blue colour appeared before the equivalence point was reached, but at the end point a distinct jump in colour intensity was observed.

The complexometric titration gives results which are identical to those obtained by the method previously used.

The experiments are listed in Table 2. It is seen, that the catalytic action of zinc glycinate is significant but it can not be compared in order of magnitude with the catalytic action of zinc tetrammine.

A corresponding experiment with 0.01 M cupric glycinate gave no significant effect.

Acid Soluble Cytidine Nuoleotide Linked Amino Acids in Extracts of Rabbit Liver

GUNNAR ÅGREN

From the Department of Medical Chemistry, University of Uppsala, Sweden

In recent papers [1,2] it was reported that ^{32}P-labeled trichloroacetic acid (TCA) extracts of liver and kidneys of the rat and rabbit contained an ultra violet (UV) absorbing peak (X_I) which contained ninhydrin positive substances. After purification by ionophoresis and paperchromatography the material from the peak still gave a ninhydrin positive reaction. A labeled UV-peak in the same position of the elution curve could also be observed in TCA extracts of ^{32}P-labeled tissue homogenates of rat kidneys. The nucleotide-amino acid complex exhibited changes in UV-absorbtion spectrum characteristic of cytidine nucleotide (CMP). Since CMP-linked amino acids do not seem to have been observed in animal cells previously some properties of the fraction will be described briefly.

In Fig. 1 a section of the elution diagram of the TCA extract is presented consisting of the peaks immediately before and after AMP (adenylic acid). The TCA extract of rabbit livers was eluted according to Hurlbert *et al.*[3] The two first labeled UV-peaks (X_I) appearing with formic acid concentration between 0 and 0.23 M were taken to dryness. At paper electropherograms in

Acid Soluble Cytidine Nuoleotide Linked Amino Acids in Extracts of Rabbit Liver

GUNNAR ÅGREN

From the Department of Medical Chemistry, University of Uppsala, Sweden

In recent papers [1,2] it was reported that ^{32}P-labeled trichloroacetic acid (TCA) extracts of liver and kidneys of the rat and rabbit contained an ultra violet (UV) absorbing peak (X_I) which contained ninhydrin positive substances. After purification by ionophoresis and paperchromatography the material from the peak still gave a ninhydrin positive reaction. A labeled UV-peak in the same position of the elution curve could also be observed in TCA extracts of ^{32}P-labeled tissue homogenates of rat kidneys. The nucleotide-amino acid complex exhibited changes in UV-absorbtion spectrum characteristic of cytidine nucleotide (CMP). Since CMP-linked amino acids do not seem to have been observed in animal cells previously some properties of the fraction will be described briefly.

In Fig. 1 a section of the elution diagram of the TCA extract is presented consisting of the peaks immediately before and after AMP (adenylic acid). The TCA extract of rabbit livers was eluted according to Hurlbert *et al.*[3] The two first labeled UV-peaks (X_I) appearing with formic acid concentration between 0 and 0.23 M were taken to dryness. At paper electropherograms in

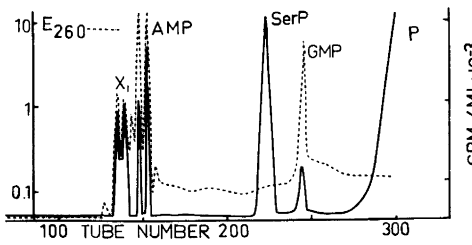

Fig. 1. Acid soluble nucleotides from 7 rabbit livers. The nucleotides were separated on a 6.5 × 45 cm Dowex 1 formate column by gradient elution with reservoir content changed at the tubes numbered as follows: *92*, 1 N formic acid; *250*, 4 N formic acid. The continuous line represents radioactivity and the broken line represents optical density values at 260 mμ.

1 M acetic acid most of the free amino acids were carried away leaving a labeled UV-spot which gave a positive ninhydrin reaction. In one dimensional paper chromatography with *iso*butyric acid and ammonia materials from both fractions behaved differently. Only with material from the second X_I peak one sharp spot with congruent UV, ^{32}P-labeling and positive ninhydrin reaction was obtained together with a ninhydrin negative UV-spot. All of the material from the second X_I peak was purified in this way. When this fraction was again run through a Dowex 1 formate column with a gradient 0 → 1 M formic acid concentration a sharp peak giving UV-absorbtion, activity and positive ninhydrin reaction was observed. Both compounds from X_I exhibited changes in their UV-absorbtion spectra characteristic of cytidine nucleotides; namely an absorbtion maximum in acid medium at 280 mμ with an absorption minimum at 240 mμ. The absorption maximum in neutral solution was located at 270 mμ and the minimum at 250 mμ [4]. Following hydrolysis in 0.1 N HCl for 3 min [5] the hydrolysate of the purified material from the second X_I fraction showed the following properties. In electropherograms in 1 N acetic acid a sharp, labeled ninhydrin positive spot with UV-absorbtion was still observed together with three ninhydrin positive spots slowly moving towards the anode and one spot towards the cathode. At pH 5 in 0.1 N pyridine acetate buffer a labeled, ninhydrin positive spot with UV-absorbtion could be observed together with one ninhydrin positive spot moving towards the anode and one to the cathode. After hydrolysis in sealed tubes for 20 h at 120°C the compound was completely hydrolyzed. Electropherograms in acetic acid showed at least seven ninhydrin positive spots all moving towards the cathode and one or two which did not move. Papers run at pH 5 showed two ninhydrin positive spots moving against the anode and several to the cathode. A two dimensional electrophero-chromatogram [5] showed spots corresponding to aspartic acid, glutamic acid, at least six neutral and one basic amino acid. Following hydrolysis in 1 N HCl for 7 min electropherograms in pyridine acetate showed four sharp, labeled spots giving UV-absorbtion and positive ninhydrin reaction. Two spots corresponding to one acid and one basic amino acid were also observed.

All these data taken together seem to prove that extracts from animal tissues contain amino acids linked to CMP-nucleotides probably in peptide combinations. The results with 7 min hydrolysis are rather complicated and do not exclude the possibility that the material may consist of a complex of CMP-nucleotides with adjacent amino acids linked to each other. The partial acid hydrolysis may produce free nucleotides, nucleotides with amino acids, peptides and free amino acids. So far we have not been able to isolate a substance with quite similar properties from *L. casei*.

Synthesis of Compounds Related to Muscarufin

V. Ethyl 5-(5-methoxy-*p*-benzoquinonyl)-valerate *

MARTIN NILSSON and TORBJÖRN NORIN

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Alkyl radicals, obtained by thermal decomposition of diacyl peroxides, may react with quinones to give alkylated products [1,2]. However, no alkylation was observed when bis-(5-ethoxycarbonylvaleryl)-peroxide in acetic acid was thermally decomposed in the presence of dimethyl 2,2′-(*p*-benzoquinon-2,5-ylene)-dibenzoate[3]. Instead the quinone was reduced and converted into the dilactone of 2′,5′-dihydroxy-*p*-terphenyl-2,2″-dicarboxylic acid [3]. Also *p*-benzoquinone was found to be reduced under the same conditions.

However, a 32 % yield of ethyl 5-(5-methoxy-*p*-benzoquinonyl)-valerate was obtained by decomposition of the peroxide in toluene solution in the presence of 2-methoxy-*p*-benzoquinone. The structure of the alkylation product was established by reduction, methylation and oxidation to 2,4,5-trimethoxybenzoic acid. The intermediate 5-(2,4,5-trimethoxyphenyl)-valeric acid could also be obtained, in very good yield, by acylation of 1,2,4-trimethoxybenzene with glutaric anhydride using boron trifluoride as the catalyst, followed by catalytic hydrogenation.

During these studies on the synthesis of compounds related to muscarufin evidence has accumulated which casts some doubt on the correctness of the proposed structure. The work has therefore been discontinued.

Experimental. The melting points were determined on a Kofler block.

*Ethyl 5-(5-methoxy-*p*-benzoquinonyl)-valerate.* 2-Methoxy-*p*-benzoquinone [4] (0.025 mole) in toluene (100 ml, chosen as the solvent because of the sensitivity of the quinone to acids) was heated on a vigorously boiling water bath and a solution of bis(5-ethoxycarbonylvaleryl)-peroxide [2] (0.025 mole) in ether added slowly through a capillary extending to the bottom of the flask while the ether was distilled off. After addition of the peroxide the heating was continued until the evolution of carbon dioxide ceased. The solvent was removed under reduced pressure until the product started to sublime. The mixture was cooled and the crystalline mass collected and recrystallised from methanol, m.p. 100–101° and 112–113° (dimorphism) (yield 32 %). On sublimation the high-melting form was obtained. (Found: C 62.7; H 7.1. Calc. for $C_{14}H_{18}O_5$: C 63.1; H 6.8).

5-(2,4-5-Trimethoxyphenyl)-valeric acid. The quinone (0.27 g) was boiled with acetic anhydride, sodium acetate and zinc dust until the solution was colourless. The mixture was filtered and water was added to precipitate the ethyl 5-(2,5-diacetoxy-4-methoxyphenyl)-valerate, which was recrystallised from methanol, m.p. 41–42.5°. (Found: C 61.1; H 7.0. Calc. for $C_{18}H_{24}O_7$: C 61.4; H 6.9.) The acetate was dissolved in methanol and excess dimethyl sulphate and a concentrated solution of potassium hydroxide added under coal gas. The mixture was then heated to ensure complete saponification of the ester. The reaction product was precipitated and recrystallised from acetic acid-water. The trimethoxyphenylvaleric acid, m.p. 46–47° (0.1 g) was distilled at *ca.* 0.5 mm and then solidified as a higher melting form, m.p. 59–61°. (Found: C 62.7; H 7.4. Calc. for $C_{14}H_{20}O_5$: C 62.7; H 7.5.)

The acid was also prepared by another procedure: A solution of 1,2,4-trimethoxybenzene (0.01 mole) and glutaric anhydride (0.011 mole) in ether was saturated with boron trifluoride and left in the refrigerator for 3 days. The mixture was poured onto ice and the ether evaporated. The 4-(2,4,5-trimethoxybenzoyl-) butyric acid was collected and recrystallised from methanol, m.p. 164–165° (95 %). (Found: C 59.2; H 6.4. Calc. for $C_{14}H_{18}O_6$: C 59.6; H 6.4.)

The synthesis of this acid under somewhat different conditions has been reported but the yield then was lower [5]. A portion (1.03 g) was dissolved in ethanol and hydrogenated over palladised charcoal (0.33 g, 10 %) to absorb 2 mole of hydrogen in 15 h. The 5-(2,4,5-trimethoxyphenyl)-valeric acid was recrystallised from methanol, m.p. 46–48° alone or in admixture with the product obtained from the quinone (95 %). On distillation the same dimorphism was encountered.

Oxidation of 5-(2,4,5-trimethoxyphenyl)-valeric acid with potassium permanganate gave 2,4,5-trimethoxybenzoic acid in 30 % yield,

The Crystal Structure of Hf_2Al_3

LARS-ERIK EDSHAMMAR

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

In the course of phase analyses and crystal structure determinations in the binary metal systems hafnium-aluminium [1-3] and zirconium-aluminium [1], a phase with the composition Hf_2Al_3 has been studied.

The structure has been determined from complete single crystal data using Patterson and electron density maps. The alloy was prepared by arc-melting and single crystals could be obtained from the crushed melt. The single crystal and Guinier powder data showed the structure to be orthorhombic with the following unit cell dimensions:

$a = 9.52_3$ Å $b = 13.76_3$ Å $c = 5.52_2$ Å

The following structure was derived:

Unit cell content: 8 Hf_2Al_3 (observed density 8.00, calculated density 8.04).

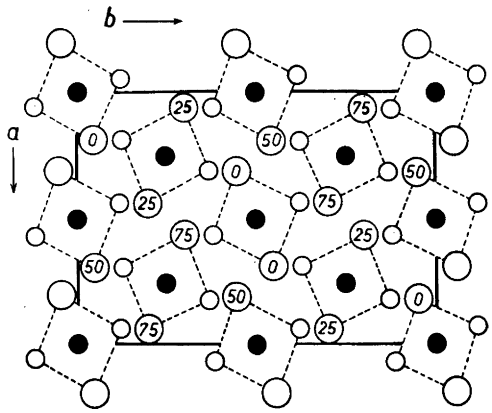

Fig. 1. The structure of Hf_2Al_3 seen along the *c*-axis. The figures in the large circles indicate the height of the Hf-atoms in percent of *c*. Small open circles: Al at *c*/4 above the Hf atoms in the pyramid. Small black circles: Al at 0.39 *c* below the Hf atoms in the pyramid.

Space-group: *Fdd*2 (No. 43).

16 Hf in 16(*b*): $x = 0.185$ $y = 0.052$ $z = 0.000$
16 Al in 16(*b*): $x = 0.185$ $y = 0.133$ $z = 0.500$
8 Al in 8(*a*): $x = 0$ $y = 0$ $z = 0.61$

The structure may be described as built up by triangular-bipyramids, Hf_2Al_3, with the hafnium-atoms forming the apices of the pyramids (*cf.* Fig. 1).

An examination of the zirconium-aluminium system shows the existence of an isotypic structure Zr_2Al_3.

Full details on these investigations and a discussion of the structures in the hafnium-aluminium system will be given elsewhere.

The author wishes to express his thanks to Dr. Arne Magnéli for his kind interest in this work.

A Method for the Detection of Oxygen in Organic Compounds

BENGT SMITH and RAGNAR OHLSON

Institutionen för Organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

For the qualitative determination of elements in organic compounds the sodium fusion method of Lassaigne has since long been the most important one. It permits the detection of most common elements occurring in organic compounds. However, neither this nor any other method permits a reliable detection of oxygen, a fact which has been a considerable drawback in qualitative organic analysis. When studying methods for the detection of elements in organic compounds by gas chromatography we found that oxygen could be identified in a simple and reasonably reliable way by cracking the substance over a glowing platinum wire in an atmosphere of helium and analyzing the pyrolysis products for carbon oxide. The new method has been applied to a substantial number of organic compounds of various types including alcohols, phenols, ethers, aldehydes, ketones, carboxylic acids, esters, acetals, amides, anhydrides, carbohydrates, proteins, lignin, nitro compounds, sulphonic acids, oxygen-containing organosilicon compounds and oxygen-containing heterocyclic compounds.

The test was positive in every case. In the pyrolysis of oxygen-containing organosilicon compounds and nitro compounds, a large part of the oxygen was bound up in silicon dioxide and nitrogen oxides, respectively. However, enough carbon oxide was formed, if an adequate amount of substance was used. We have also investigated a number of oxygen-free organic compounds but have not obtained a positive test in any case.

The carbon oxide formed was identified using gel tubes, containing silica gel impregnated with a mixture of palladium sulphate and ammonium molybdate [1]. The yellow silico molybdato complex turns to green or blue in the presence of carbon oxide. Other reducing substances may give a similar test, but the silica gel layer (*cf.* below) placed before the indicating layer is stated to absorb interfering substances [1].

It is also possible to identify the carbon oxide by means of gas chromatography, *e.g.* using columns containing silica gel [2] or molecular sieves [3]. These methods will be discussed in a forthcoming paper, describing the detection of oxygen and other elements in organic compounds by means of gas chromatography.

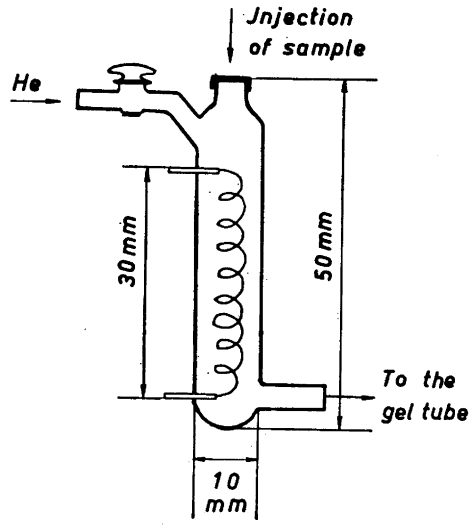

Fig. 1. Pyrolysis apparatus used for the detection of oxygen.

The apparatus used for the pyrolysis is shown in Fig. 1. It consisted of a pyrex glass tube containing a platinum glowing wire. The thin glowing wire (0.35 mm diam.) was welded to two thicker contact wires. The reactor was equipped with inlet and outlet tubes for helium and a tube covered by a serum cap for injecting liquid samples.

An experiment was performed in the following way. The gel tube was connected to the reactor and a stream of helium passed through for some minutes to sweep the air from the reactor. This done, the flow of helium through the reactor was interrupted by turning the three-way stopcock, and a voltage of 3—4 V was applied to the platinum wire causing it to glow. The liquid sample (1—5 μl) was injected through the serum cap and pyrolysed by the glowing wire. After 10 sec the flow of helium was resumed and the pyrolysis products swept through the gel tube. For solid substances the same procedure was followed except that the reactor was used in a horisontal position with the sample in the middle of the reactor at the start.

Instead of helium, oxygen-free nitrogen might be used.

The gel tube * was 100 mm long and had an outer diam. of 4 mm. It was packed to a length of 10 mm with the carbon oxide indicating gel (silica gel impregnated with a mixture of palladium sulphate and ammonium molybdate, *cf.* Ref.[1]). On the inlet side of the indicating layer was placed a 40 mm length and on the outlet side a 10 mm length of silica gel.

The Crystal Structure of Pd_3P

STIG RUNDQVIST and
LARS-OTTO GULLMAN

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

An X-ray investigation of the palladium-phosphorus system was recently begun at this Institute. Preliminary results show that the system is far more complex than is indicated in the equilibrium diagram given by Wiehage *et al.*[1] It is especially noteworthy that at least four intermediate phases seem to exist in the range 0—25 atom % phosphorus. The existence of a phase near the composition Pd_3P, as observed by Wiehage *et al.*[1], was confirmed by our results. A single-crystal investigation showed that Pd_3P has the cementite ($D\,O_{11}$) structure. The homogeneity range, determined from alloys quenched from 740°C, was found to extend from approximately $Pd_3P_{0.75}$ to $Pd_3P_{1.0}$ with the following lattice parameters (accuracy ± 0.05 %): phosphorus-rich limit $a = 5.980$ Å; $b = 7.440$ Å; $c = 5.164$ Å and palladium-rich limit $a = 5.645$ Å; $b = 7.558$ Å; $c = 5.071$ Å.

The crystal structure was determined by examination of single-crystals selected from an alloy with the approximate composition $Pd_3P_{0.95}$. 62 $F(h0l)$-values and 63 $F(0kl)$-values were recorded with niobium-filtered MoK-radiation in a multiple-film Weissenberg camera with thin iron foils between successive films. Atomic parameters were refined from electron density projections and difference syntheses. Fourier summations and structure factor calculations were made on the electronic digital computer BESK with programs devised by Åsbrink *et al.*[2]

The final R-value for the recorded $F(h0l)$-values was 0.087, applying an isotropic temperature factor with $B = 0.72_4$ Å^2; the corresponding figures for the $F(0kl)$-values were $R = 0.088$, $B = 0.67$ Å^2. (The five largest $F(0kl)$-values, which were obviously weakened owing to extinction, were omitted in the final stages of refinement).

The following structural data for $Pd_3P_{0.95}$ were obtained: Space group $Pnma-(D_{2h}^{16})$; $Z = 4$. *(Table 1.)*

The standard deviations quoted were calculated using Cruickshank's formula [3].

Interatomic distances are listed in Table 2.

It is of interest to note that in addition to Pd_3P described above, the compounds Pd_3Si and Pd_3B also possess the cementite structure [4,5]. A case of isomorphism between a boride, a silicide and a phosphide of the same metal is thus demonstrated.

Further reports of the work on palladium phosphides will be published later in this journal.

Table 1. Structural data for $Pd_3P_{0.95}$.

$a = 5.947$ Å; $b = 7.451$ Å; $c = 5.170$ Å; $U = 229.1$ Å^3

The Crystal Structure of Pd_3P

STIG RUNDQVIST and
LARS-OTTO GULLMAN

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

An X-ray investigation of the palladium-phosphorus system was recently begun at this Institute. Preliminary results show that the system is far more complex than is indicated in the equilibrium diagram given by Wiehage *et al.*[1] It is especially noteworthy that at least four intermediate phases seem to exist in the range 0—25 atom % phosphorus. The existence of a phase near the composition Pd_3P, as observed by Wiehage *et al.*[1], was confirmed by our results. A single-crystal investigation showed that Pd_3P has the cementite ($D\,O_{11}$) structure. The homogeneity range, determined from alloys quenched from 740°C, was found to extend from approximately $Pd_3P_{0.75}$ to $Pd_3P_{1.0}$ with the following lattice parameters (accuracy ± 0.05 %): phosphorus-rich limit $a = 5.980$ Å; $b = 7.440$ Å; $c = 5.164$ Å and palladium-rich limit $a = 5.645$ Å; $b = 7.558$ Å; $c = 5.071$ Å.

The crystal structure was determined by examination of single-crystals selected from an alloy with the approximate composition $Pd_3P_{0.95}$. 62 $F(h0l)$-values and 63 $F(0kl)$-values were recorded with niobium-filtered MoK-radiation in a multiple-film Weissenberg camera with thin iron foils between successive films. Atomic parameters were refined from electron density projections and difference syntheses. Fourier summations and structure factor calculations were made on the electronic digital computer BESK with programs devised by Åsbrink *et al.*[2]

The final R-value for the recorded $F(h0l)$-values was 0.087, applying an isotropic temperature factor with $B = 0.72_4$ Å^2; the corresponding figures for the $F(0kl)$-values were $R = 0.088$, $B = 0.67$ Å^2. (The five largest $F(0kl)$-values, which were obviously weakened owing to extinction, were omitted in the final stages of refinement).

The following structural data for $Pd_3P_{0.95}$ were obtained: Space group $Pnma-(D_{2h}^{16})$; $Z = 4$. *(Table 1.)*

The standard deviations quoted were calculated using Cruickshank's formula [3].

Interatomic distances are listed in Table 2.

It is of interest to note that in addition to Pd_3P described above, the compounds Pd_3Si and Pd_3B also possess the cementite structure [4,5]. A case of isomorphism between a boride, a silicide and a phosphide of the same metal is thus demonstrated.

Further reports of the work on palladium phosphides will be published later in this journal.

Studies on Rennin

V. Chromatographic Purification of Prorennin

BENT FOLTMANN

Carlsberg Laboratory, Copenhagen, Denmark

The first paper in this series [1] described the preparation of partly purified prorennin obtained from dried calf stomachs by extraction with a 2 % solution of sodium bicarbonate. After clarification with aluminium sulphate and disodium hydrogen phosphate, the extract was precipitated twice by saturation with sodium chloride. Paper electrophoresis indicated that approximately 50 % of the protein in the second precipitate was prorennin, but attempts at further purification by salt fractionation failed.

The investigations have been continued by chromatographic fractionation of the partly purified prorennin on columns of diethylaminoethylcellulose (DEAE-cellulose) as described by Peterson and Sober [2].

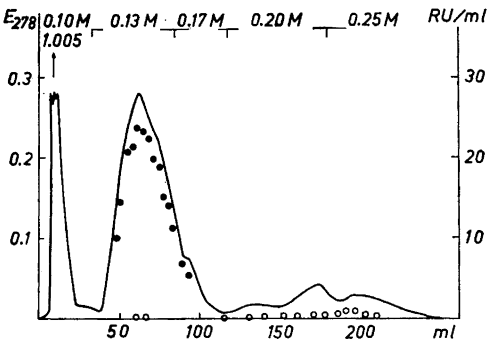

Fig. 1. Chromatography of partly purified prorennin on DEAE-cellulose involving stepwise elution with phosphate buffers of pH 5.8—5.7; 0.10 M, 0.13 M, 0.17 M, 0.20 M, and 0.25 M. Load 20 mg, column 0.9 × 11 cm. Flow rate 4 ml/h; fractions of 2 ml. ○ preformed milk-clotting activity (RU/ml). ● milk-clotting activity after activation. Experimental points have been omitted from the extinction curve of E_{278} for the sake of clarity.

Commercial products of DEAE-cellulose were used (Bio-Rad lot No. CXD $^{59-1}$ and Eastman-Kodak lot No. 7392). The partly purified prorennin was prepared as earlier described. After removal of the NaCl by dialysis the sample was applied to a column of DEAE-cellulose previously equilibrated with 0.10 M phosphate buffer of pH 5.8. Fig. 1 illustrates such an experiment with elution carried out by stepwise increase of the phosphate concentration from 0.10 to 0.25 M. The concentration of protein is expressed by the optical density at 278 mμ. For assay of the potential milk-clotting activity, 200 μl of each fraction was mixed with 200 μl 0.4 M acetate buffer of pH 4.1 and kept 24 h at 25°C to convert the prorennin to active enzyme before the

Studies on Rennin

V. Chromatographic Purification of Prorennin

BENT FOLTMANN

Carlsberg Laboratory, Copenhagen, Denmark

The first paper in this series [1] described the preparation of partly purified prorennin obtained from dried calf stomachs by extraction with a 2 % solution of sodium bicarbonate. After clarification with aluminium sulphate and disodium hydrogen phosphate, the extract was precipitated twice by saturation with sodium chloride. Paper electrophoresis indicated that approximately 50 % of the protein in the second precipitate was prorennin, but attempts at further purification by salt fractionation failed.

The investigations have been continued by chromatographic fractionation of the partly purified prorennin on columns of diethylaminoethylcellulose (DEAE-cellulose) as described by Peterson and Sober [2].

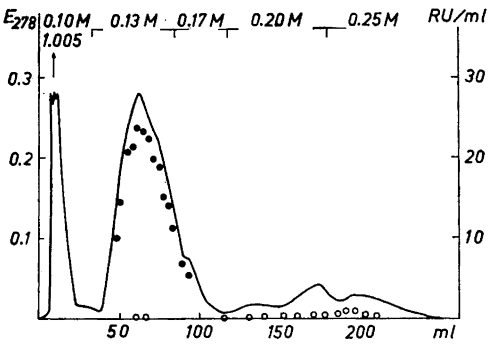

Fig. 1. Chromatography of partly purified prorennin on DEAE-cellulose involving stepwise elution with phosphate buffers of pH 5.8—5.7; 0.10 M, 0.13 M, 0.17 M, 0.20 M, and 0.25 M. Load 20 mg, column 0.9 × 11 cm. Flow rate 4 ml/h; fractions of 2 ml. ○ preformed milk-clotting activity (RU/ml). ● milk-clotting activity after activation. Experimental points have been omitted from the extinction curve of E_{278} for the sake of clarity.

Commercial products of DEAE-cellulose were used (Bio-Rad lot No. CXD $^{59-1}$ and Eastman-Kodak lot No. 7392). The partly purified prorennin was prepared as earlier described. After removal of the NaCl by dialysis the sample was applied to a column of DEAE-cellulose previously equilibrated with 0.10 M phosphate buffer of pH 5.8. Fig. 1 illustrates such an experiment with elution carried out by stepwise increase of the phosphate concentration from 0.10 to 0.25 M. The concentration of protein is expressed by the optical density at 278 mμ. For assay of the potential milk-clotting activity, 200 μl of each fraction was mixed with 200 μl 0.4 M acetate buffer of pH 4.1 and kept 24 h at 25°C to convert the prorennin to active enzyme before the

clotting test was performed. The milk-clotting activities of the activated fractions of prorennin and of preformed rennin are expressed in rennin units (RU) according to Berridge [3].

The chromatogram in Fig. 1 shows that most of the inert material from the partly purified prorennin passed the column as a high, narrow front peak. Without previous activation the peak which was developed after buffer shift to 0.13 and 0.17 M phosphate had only a faint milk-clotting activity (as these tests were carried out with a very high potential activity in the reaction mixture, the clotting observed might be due to activation taking place during the tests). After activation, however, the ratio between potential activity and optical density was constant (within experimental error) across the peak, approximately 90. After further change of the buffer concentration to 0.20 M and 0.25 M phosphate, smaller peaks containing preformed rennin were developed.

For preparation of larger amounts of prorennin, 425 mg freeze-dried, partly purified prorennin was dissolved in 5 ml 0.01 M phosphate buffer of pH 6.1 and applied to a column of DEAE-cellulose (2 × 15 cm) previously equilibrated with 0.1 M phosphate buffer of pH 5.8. The elution was started with 0.1 M phosphate buffer. As expected from the small scale experiment, most of the inert material passed the column in the first 150 ml of eluate. After 280 ml of eluate, the concentration of the eluent buffer was increased to 0.20 M. This rapid increase of the buffer concentration resulted in a very sharp peak with concentrations of prorennin up to 3 mg/ml. The fractions containing the prorennin were pooled, dialysed against 0.001 M phosphate buffer of pH 6.6, and freeze-dried. In this way about 150 mg chromatographically purified prorennin was prepared.

A 16.8 mg sample of this preparation was chromatographed on a column of DEAE-cellulose by the same technique as in the first experiment. The preparation proved to be slightly inhomogeneous, but about 85 % of the total optical density at 278 mμ is represented by the peak containing the prorennin activity (Fig. 2a). Another 13.7 mg of the chromatographically purified prorennin was dissolved in 2 ml of water, and 0.1 N HCl was added to a final pH of 2.1. After 1.5 h at 22°C, the sample was neutralised by addition of 0.1 ml 0.5 M disodium-hydrogenphosphate. The neutralised sample was applied to a column of DEAE-cellulose and chromatographed by the same technique as in the foregoing experiment. The results are illustrated in Fig. 2b.

From Fig. 2 it is seen that the front peak of inactive material is increased from 8 % of the

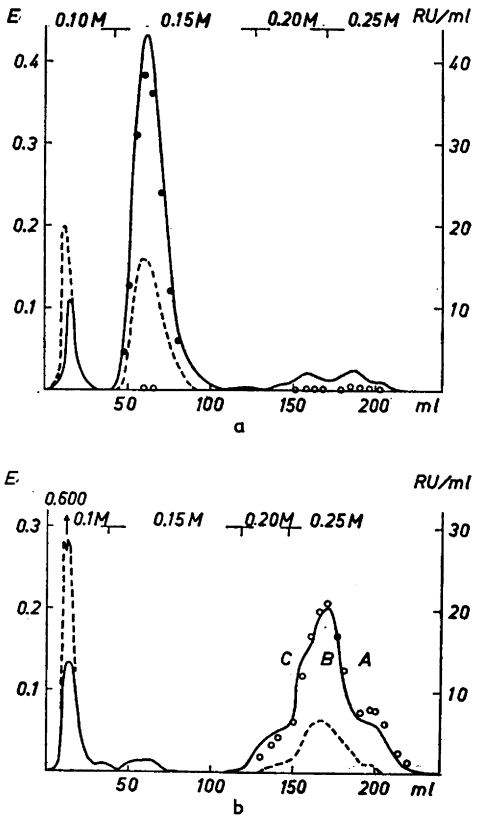

Fig. 2. a. Rechromatography of chromatographically purified prorennin. b. Chromatography of the same preparation after activation at pH 2.1. Columns of DEAE-cellulose (0.9 × 13 cm). Stepwise elution with phosphate buffers, pH 5.8 – 5.7; 0.10 M, 0.15 M, 0.20 M, and 0.25 M. Flow rate 6 ml/h; fractions of 3 ml. ○ milk-clotting activity (RU/ml). ● milk-clotting activity after activation. Solid line: optical density at 278 mμ. Dashed line: ninhydrin color according to Moore and Stein [7] (0.5 ml sample + 0.5 ml reagent diluted with 10 ml of ethanol).

total optical density of the unactivated prorennin (Fig. 2a) to 15 % in the activated sample (Fig. 2b), and further that the ninhydrin reaction of the same peak is much increased, suggesting that one or more tyrosine-containing peptides are split off from the prorennin during the activation.

The prorennin peak has disappeared in Fig. 2b, and in the peak which contains the rennin activity it is possible to recognize three components similar to the A, B, and C rennins obtained from rennin crystals. Furthermore, the specific activity (*i.e.* RU/ml/E_{278}) varies over the rennin peak in a similar way as in chromatography of rennin crystals (Foltmann [4]).

An experiment was carried out after only 15 min. of activation at pH 2. Chromatography of the reaction mixture thus obtained revealed approximately equal amounts of A and B rennins and only traces of C. On the basis of this experience it may be surmised that the different rennins are formed from the same prorennin, perhaps by consecutive reactions as in activation of chymotrypsinogen.

The chromatographically purified prorennin was labelled with fluorodinitrobenzene by the Sanger method [5]. After 7 h of hydrolysis in constant boiling, glass-distilled HCl at 110°C, the DNP-amino acids formed were analysed by paper chromatography according to Levy [6]. In this way alanine was found as NH_2-terminal. With the use of an internal standard of DNP-alanine which was treated in the same way as the DNP-prorennin, a semi-quantitative assay indicated 1 mole of DNP-alanine per 60 000 g of DNP-prorennin. Allowing for the weight increase due to DNP groups, this corresponds to a molecular weight of 40 000—50 000 for the prorennin.

In ultracentrifugation the chromatographically purified prorennin showed one slightly asymmetrical peak. The sedimentation constant was increased by increasing concentrations of prorennin, suggesting the formation of dimers in the more concentrated solutions. By extrapolation to zero concentration, $S_{20,w}$ was found to be 3.5.

The chromatographic behaviour of prorennin and rennin is consistent with the earlier observation (Foltmann [1]) that the isoelectric point of prorennin is higher than that of rennin since compounds with higher isoelectric points would be expected to be eluted first in the technique used.

Further studies on prorennin and its activation will appear in the *Compt. rend. trav. lab. Carlsberg.*

Chromatographic Analysis of Sugars as Complex Borate Ions

ANUND HALLÉN

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

As demonstrated by Khym and Zill [1], neutral sugars can be separated chromatographically on an anion exchange resin as borate complexes, when elution is performed with dilute borate buffers. However, although they used small columns (0.5 × 11 cm) the effluent volumes of the monosaccharides became very large (500 — 1 500 ml). This is obviously a disadvantage in the analysis of small amounts of sugars. A modification involving elution at a higher ionic strength has therefore been worked out. Fig. 1 shows a typical chromatogram, including galacturonic acid and glucuronic acid, of which the separation has been reported by Khym and Doherty [2].

The components were obtained in 100 % yield (error of method ± 10 %). In parallel with the relative rates of migration of the sugar-borate complexes in high-voltage paper electrophoresis [3,4], lyxose was eluted together with mannose, ribose together with fucose, arabinose together with galactose, and xylose together with glucose. It thus seems necessary to use specific colour reactions [5,1] for the differential analysis of such sugar pairs. Keto sugars give a low colour yield in the aniline reaction used.

Experimental. The sugars (0.2—0.8 mg of each component) were dissolved in a total

The prorennin peak has disappeared in Fig. 2b, and in the peak which contains the rennin activity it is possible to recognize three components similar to the A, B, and C rennins obtained from rennin crystals. Furthermore, the specific activity (*i.e.* RU/ml/E_{278}) varies over the rennin peak in a similar way as in chromatography of rennin crystals (Foltmann [4]).

Chromatographic Analysis of Sugars as Complex Borate Ions

ANUND HALLÉN

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

As demonstrated by Khym and Zill [1], neutral sugars can be separated chromatographically on an anion exchange resin as borate complexes, when elution is performed with dilute borate buffers. However, although they used small columns (0.5 × 11 cm) the effluent volumes of the monosaccharides became very large (500 — 1 500 ml). This is obviously a disadvantage in the analysis of small amounts of sugars. A modification involving elution at a higher ionic strength has therefore been worked out. Fig. 1 shows a typical chromatogram, including galacturonic acid and glucuronic acid, of which the separation has been reported by Khym and Doherty [2].

The components were obtained in 100 % yield (error of method ± 10 %). In parallel with the relative rates of migration of the sugar-borate complexes in high-voltage paper electrophoresis [3,4], lyxose was eluted together with mannose, ribose together with fucose, arabinose together with galactose, and xylose together with glucose. It thus seems necessary to use specific colour reactions [5,1] for the differential analysis of such sugar pairs. Keto sugars give a low colour yield in the aniline reaction used.

Experimental. The sugars (0.2—0.8 mg of each component) were dissolved in a total

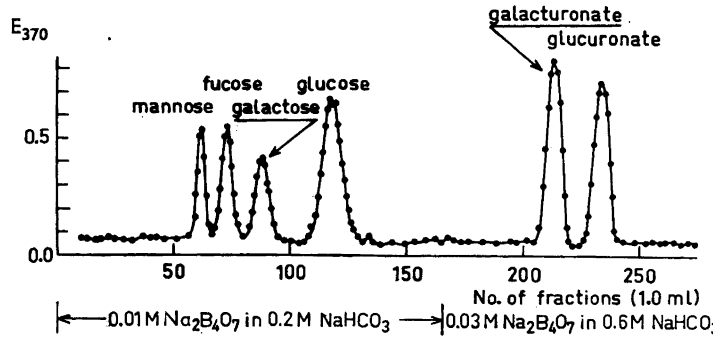

Fig. 1. Chromatography of monosaccharides on a 0.6 × 150 cm Dowex 2 column with borax-bicarbonate solutions. Test mixture: D-mannose (285 μg), L-fucose (298 μg), D-galactose (280 μg), D-glucose (544 μg), D-galacturonic acid (828 μg) and D-glucurone (795 μg).

volume of 0.3 ml of 0.05 M borax (19.1 g $Na_2B_4O_7 \cdot 10\ H_2O$ per liter), and put on the column in the usual way.

The resin, Dowex 2 X 8, 200–400 mesh, was treated with 2 M hydrochloric acid, 2 M sodium hydroxide, 2 M sodium carbonate, and finally 0.03 M borax in 0.60 M sodium bicarbonate, in which solution the resin was stored until used. It was then suspended in a suitable amount of 0.01 M borax in 0.20 M sodium bicarbonate, and was allowed to sediment spontaneously to form a 0.6 × 150 cm column. The column was washed overnight with 0.01 M borax in 0.20 M sodium bicarbonate before application of the sugar mixture. The air present in the solvents was removed by treatment in a suction flask under reduced pressure. Toluene was added to a concentration of 0.5 ml /liter to prevent growth of microorganisms.

The neutral sugars were eluted at room temperature with 0.01 M borax in 0.20 M sodium bicarbonate and, after the appearance of the last neutral sugar peak (glucose), the uronic acids were eluted with 0.03 M borax in 0.60 M sodium bicarbonate. The pH of both solutions was found to be 8.7. The flow rate was adjusted to 1.5 ml/h, and the effluent was collected in 1.0 ml fractions.

A set of standards was prepared for each component. The standards contained 10–100 (150) μg of sugar per ml, dissolved in 0.01 M borax in 0.20 M sodium bicarbonate.

Analysis was performed with a modification of Gardell's aldo sugar method [6]: 3 ml of a freshly prepared mixture of 10 ml of aniline (distilled) and 500 ml of acetic acid was added with an automatic pipette to unknowns and standards. After thorough shaking, the test tubes were provided with aluminium caps, heated for 20 min in a vigorously boiling water bath, and cooled with tap water. The yellow-brown colour was read at 370 mμ in a Beckman B spectrophotometer with water as a blank

The investigation was aided by grants from *Karolinska Institutets reservationsanslag.*
