ABSTRACT

Brain tumors are a diverse group of neoplasms that often carry a poor prognosis for patients. Despite tremendous efforts to develop diagnostic tools and therapeutic avenues, the treatment of brain tumors remains a formidable challenge in the field of neuro-oncology. Physiological barriers including the blood–brain barrier result in insufficient accumulation of therapeutic agents at the site of a tumor, preventing adequate destruction of malignant cells. Furthermore, there is a need for improvements in brain tumor imaging to allow for better characterization and delineation of tumors, visualization of malignant tissue during surgery, and tracking of response to chemotherapy and radiotherapy. Multifunctional nanoparticles offer the potential to improve upon many of these issues and may lead to breakthroughs in brain tumor management. In this review, we discuss the diagnostic and therapeutic applications of nanoparticles for brain tumors with an emphasis on innovative approaches in tumor targeting, tumor imaging, and therapeutic agent delivery. Clinically feasible nanoparticle administration strategies for brain tumor patients are also examined. Furthermore, we address the barriers towards clinical implementation of multifunctional nanoparticles in the context of brain tumor management.

1. Introduction

With the rapid development of nanotechnology for biomedical applications, it is expected that newly developed particle systems can have a revolutionary impact on brain cancer diagnosis and therapy [1–10]. In general, nanotechnology involves the design, synthesis, and application of materials with at least one dimension in the size range of 1–100 nm [3]. Multifunctional nanoparticles containing optical, thermal, and magnetic properties are promising systems that offer new opportunities to overcome the limitations of current brain tumor management options in the clinic. In this review, we begin by introducing the prognostic and biologic features of brain tumors, followed by the major obstacles facing brain tumor management. We then highlight recent advances and clinical applications of nanoparticles in brain tumor therapeutics, focusing on (i) tumor imaging, (ii) treatment and (iii) the combination of both imaging and therapeutic functions (*i.e.* theranostics). Furthermore, strategies for nanoparticle administration and regulation issues surrounding nanoparticle translation to clinic are discussed. Lastly, the barriers towards clinical implementation of these nanoparticles are discussed in order to bring better insight into strategies for developing the most feasible systems for treating brain tumor patients.

2. Brain tumors

Brain tumors, referring to a heterogeneous group of primary and metastatic neoplasms in the central nervous system, are life-threatening diseases characterized by low survival rate [11]. The annual incidence of primary malignant brain tumors is approximately 24,000 cases [11,12]. Malignant gliomas are primary tumors that are derived from glial origin and account for approximately 70% of new primary brain cancer diagnosis [12,13]. Of these, glioblastoma multiforme (GBM), a grade IV astrocytoma according to the World Health Organization (WHO) classification, is the most common and aggressive form in nature [14]. Most patients with brain tumors eventually succumb to the disease despite aggressive treatment approaches. The median survival is only about three years for anaplastic astrocytomas and around 14.6 months for GBM patients [15,16]. Brain metastases are another important class of tumors in the central nervous system originating mainly from systemic cancers in the lung, breast and skin [17]. Metastatic brain tumors occur at a high frequency with an estimated incidence of 100,000–170,000 cases in the USA annually [18].

Today, a multimodality treatment approach including surgical resection, radiotherapy, and chemotherapy is the current standard of care for malignant brain tumor patients [16]. It has been demonstrated that aggressive resection of a brain tumor and postoperative radiation lead to a significant survival advantage [16,19]. Adjuvant chemotherapy can be administered at different time points as well [20,21]. Cytotoxic and cytostatic agents are the two major categories of chemotherapy used to treat brain tumors. The mechanism of these agents involves direct tumor cell death, anti-angiogenesis, pro-differentiation, growth factor pathway disruption, and inhibition of tumor invasion. Temozolomide, an imidazotetrazine derivative, is a first line systemic chemotherapy agent used for patients with brain tumors [22–24]. Unconventional therapies including immunotherapy, gene therapy, and photodynamic therapy (PDT) are potential adjuvant treatments for brain tumors and are under clinical trials. These additive therapies have broadened the spectrum of therapeutic agents for brain tumors to antibodies, genetic material, and photosensitizers.

Furthermore, advancements in anatomical and functional imaging techniques for brain tumors play a critical role in management as it allows for early detection, surgical planning, and follow-up evaluation [25–30]. Imaging techniques including magnetic resonance imaging (MRI), computed tomography (CT), and positron-emission tomography (PET) are the most common modalities for brain tumor diagnosis, characterization and intraoperative imaging [31–34]. Other techniques such as fluorescence imaging have been developed for intraoperative fluorescence-guided tumor resection [35,36]. These imaging modalities can help delineate the boundaries between neoplastic and normal tissue, helping doctors determine the most appropriate course of treatment.

3. Major obstacles in brain tumor treatment

Despite tremendous efforts to develop diagnostic tools and therapeutic avenues, the treatment of brain tumors remains a formidable challenge in the field of neuro-oncology. The major obstacles to the successful treatment of brain tumors include a) the structural complexity of the brain, b) the heterogeneous and invasive nature of many brain tumors, c) difficulty in identifying tumor margins and disseminated tumor burdens, d) insufficient accumulation of therapeutic agents at the site of a tumor, and e) acquired drug resistance to chemotherapy.

The brain, arguably the most complex system in the body, controls a multitude of functions including information processing, perception, motor control, arousal, homeostasis, motivation, as well as learning and memory. Due to the complexity of brain functions, the treatment of brain tumors requires both robust and highly selective elimination of all cancerous tissues including those that invade beyond the main tumor mass into the surrounding normal tissue. Highly skilled surgeons are presented with the difficult task of accurately identifying all the diseased tissue and resecting it from the brain while attempting to preserve surrounding normal, functional tissue. Even after extensive removal, brain tumors usually recur locally within centimeters of the resection margin [37].

Adjuvant treatments including chemotherapy for brain tumors only achieve modest clinical outcomes. The effectiveness of systemic delivery of therapeutic agents to brain tumors is hampered by several physiological barriers. Unlike other organs, the brain is protected by the blood–brain barrier (BBB) [38–40]. The BBB prevents the influx of harmful endogenous and exogenous molecules from the bloodstream but also becomes a major limiting factor for anti-brain tumor therapy. The BBB is composed of tight junctions between endothelial cells, pericytes, a basement membrane, as well as the feet of astrocytes [39]. Normal brain capillaries act as a continuous lipid layer and exhibit selective permeability based on molecular solubility and size. Deficiency of pinocytotic vesicles within the cerebral endothelial cells compromises cellular transcytosis and further contributes to the selectivity of the BBB [39]. Additionally, ATP-binding cassette transporters such as P-glycoprotein act as drug efflux transporters and their high expression limits substrate transportation across the BBB [41–44]. Only small lipophilic molecules, electro-neutral molecules, and nutrients under 400–600 Da in the blood can diffuse passively into the brain [38,45–47].

The second barrier that blocks the passage of systemically administered therapeutic agents is known as the blood–cerebrospinal fluid barrier (CSF) [1,39]. It is formed by tightly bound choroid epithelial cells, which regulate molecule penetration within the interstitial fluid of the brain parenchyma. This barrier prevents most macromolecules from passing into the CSF through the bloodstream. In addition, the intact

blood–CSF barrier is reinforced by active transport systems for weak organic acids, which are mainly located in the choroid plexus [48]. They are capable of actively removing therapeutic organic acids from the CSF and preventing their diffusion into the brain parenchyma [49,50]. Examples include the organic anion transporter 3 (Oat 3), peptide transporter 2 (PEPT2), and P-glycoproteins (P-gp) [50,51]. By working as outward efflux systems, these pumps are able to decrease the CSF concentration of several antibiotics (e.g. penicillins and cephalosporins), chemotherapeutic agents (e.g. methotrexate) [52], and HIV proteinase inhibitors (e.g. ritonavir and atazanavir) [53].

The blood–tumor barrier in the tumor forms a third barrier for transporting therapeutic agents [1,38,39]. Unlike normal brain capillaries, the tight junctions of endothelial cells in the tumor are significantly compromised. The high intratumoral interstitial pressure created by the leaky tumor vasculature limits drug penetration from the bloodstream into the tumor [54]. Moreover, different tumor microvessel populations and spatial variability in capillary functions present in the tumor area also lead to variability in penetration [38]. This can, for example, lead to heterogeneous distribution of drug molecules, which may significantly compromise therapeutic outcome.

4. Key features of nanoparticles

Here, we highlight the key features of nanoparticles including composition, unique physical properties, passive targeting abilities, as well as tunable surface functionality for active targeting. These features enable the detection of brain tumors in a sensitive and specific manner as well as the transportation of diagnostic or therapeutic agents across the BBB.

4.1. Versatile compositions and physical properties

Nanoparticles can be made from a variety of materials such as compositing polymers, lipids, proteins, metals, or semiconductors. A variety of nanoparticles with well-defined shapes such as solid spheres, rods, tubes, and other complex shapes can be designed and synthesized by top–down or bottom–up engineering techniques. Current nanoparticle platforms for brain tumors can be classified into three major categories including organic-based (e.g. liposomes, polymeric nanoparticles, micelles, dendrimers, and solid lipid nanoparticles), inorganic-based (e.g. iron oxide nanoparticles, gold nanoparticles, semiconductor nanocrystals, ceramic nanoparticles, and carbon nanotubes) and hybrid nanoparticles [55–68]. We list examples of currently available

nanoparticle platforms for brain tumors in Table 1. Each nanoparticle system has the luxury of being individually tailored based on size, shape, and surface chemistry to meet the objectives of the proposed function (Table 1).

In general, nanoparticles have large surface to volume ratios that contribute to their high loading capacity. As drug delivery systems, nanoparticles have been shown to improve drug solubility, prolong blood circulation half-life, and control drug-release [3]. Either hydrophilic or hydrophobic therapeutic molecules can be incorporated into nanoparticles to improve the half-life of systemic circulation. Many nanoparticle delivery systems are designed to respond to various environmental stimuli such as pH and temperature, allowing for controlled therapeutic payload release [69,70]. Furthermore, the payload can be extended to include imaging probes and contrast agents. For example, organic fluorescence probes can be incorporated into the nanoparticle structure for particle tracking. More importantly, nanoparticles are easily modified to meet the demands of the intended functionalities with the ability to combine multiple therapeutic agents and imaging probes onto a single platform.

Nanoparticles may also contain intrinsic optical, thermal, electrical, or magnetic properties that can be utilized for imaging or therapeutic purposes. Colloidal gold nanoparticles have been of high interest because their low toxicity, dynamic surface chemistry, size, and shape allow for imaging properties to be attained [70–73]. Gold nanoparticles have high density and extinction coefficients, and therefore can be applied as contrast agents for CT, dark field imaging and photoacoustic imaging. In addition, the nanorod or nanoshell shape of gold nanoparticles allows them to strongly absorb light in the near-infrared range due to surface plasmon resonance and to efficiently convert this energy into heat for photothermal therapy [74–76]. Magnetic nanoparticles such as iron oxide-based nanoparticles are another widely investigated inorganic-based nanoparticle system [10]. Magnetic nanoparticles can be used as contrast agents to produce hypointense regions on T2/T2*-weighted MR images. Magnetic nanomaterials can also either generate heat or mechanical force under an alternating magnetic field to destroy brain tumor cells [77,78]. In comparison to traditional fluorophores, quantum dots made of semiconductor materials with quantum confinement have tunable narrow emission spectra and excellent photostability. They can be used as stable fluorescent probes for brain tumor diagnosis at the molecular level [79]. It has also been demonstrated that quantum dots can act as PDT therapeutic agents to induce cytotoxicity by creating free oxygen radicals under light. Additionally, titanium dioxide nanocrystals are a versatile photoreactive

Table 1
Examples of nanoparticle platforms for brain tumors.

Material	Particle type	Structure formed	Size	Main component	Main applications	Phase of development	Ref.
Organic	Liposomes	Colloid vesicular structure	10 nm–1000 nm	Lipid	Drug carrier	Phase I, II clinical trials	[63]
	Micelles	Nanosphere; cylinder	20 nm–200 nm	Polymer	Drug carrier	Preclinical	[64]

nanomaterial acting as the new generation of photosensitizer for PDT [67,80].

More recently, “hybrid nanoparticles” have been developed to combine the capabilities of different nanomaterials into one platform [68]. Hybrid nanoparticles are synthesized from two or more types of nanomaterials and are generally formed with a metallic or polymeric core covered with a single or multiple lipid coronas to increase the biocompatibility of the system. As a multifunctional platform, they can serve in both diagnostic and therapeutic applications and will be discussed later in this review.

4.2. Passive targeting of brain tumors

The size of a nanoparticle is a fundamental characteristic that determines the passive targeting of and biodistribution within brain tumors. Nanoparticles within the size range of 10–100 nm take advantage of the hyper-vascularized, leaky, and compromised lymphatic drainage system in a brain tumor to passively target and access the intratumoral space while being denied access to healthy brain tissue [1,6]. In other words, nanometer-sized particles accumulate selectively at the site of a brain tumor due to the enhanced permeability and retention (EPR) effect [81]. Such a phenomenon is not observed with small molecular weight compounds like chemotherapeutic agents that rely on free diffusion and therefore cannot discriminate between normal and diseased tissues [82]. The EPR effect in the brain tumor opens many opportunities for nanoparticles to function as diagnostic and therapeutic tools for brain cancer. However, this passive targeting mechanism has its inherent limitations. When given intravascularly, all nanoparticles are susceptible to opsonization and removal by cells of the reticuloendothelial system (RES) [83]. Only a small fraction of administered nanoparticles will therefore reach the tumor. The liver, spleen, lung, kidney, and bone marrow are the most common locations where nanoparticles are trapped [84,85]. Therefore, to achieve an optimal EPR effect, nanoparticles should be less than 100 nm in diameter, and their surfaces should be biocompatible (*i.e.* hydrophilic and almost neutral in electric charge) to avoid removal by cells of the RES.

4.3. Tunable surface functionality for active targeting

Surface functionality, which regulates the interface of nanomaterials and biological systems, is an important factor determining the behavior and the biomedical application of nanomaterials both *in vitro* and *in vivo* [86]. By altering their physiochemical properties (*i.e.* surface charge and hydrophobicity), one can influence the half-life and localization of nanoparticles during circulation. For example, the development of “stealth nanocarriers” that use hydrophilic polymers such as polyethylene glycol (PEG) for surface coating renders nanoparticles with more resistance to protein adsorption and RES uptake [87]. PEGylation prolongs the circulation half-life of nanoparticles, subsequently increasing the chance of reaching distant brain tumor cells.

While the vasculature of a brain tumor may be disturbed to some extent, this disruption is not always consistent throughout a tumor and may not even be extensive in low-grade tumors. For example, high-grade brain tumors display much more vascular permeability than those which are low-grade, illustrating the variability of BBB integrity between different brain tumors [88,89]. However, active targeting of a tumor site can be achieved even without a severely disrupted BBB. Receptors (*e.g.* transferrin and nicotinic acetylcholine receptors) and integrins (*e.g.* $\alpha_v\beta_3$ and Aminopeptidase N) are distributed on brain capillary endothelial cells or on proliferating endothelial cells within a tumor, sites that are in direct contact with circulating nanoparticles in the bloodstream [90–94].

Penetration into a tumor area can therefore be improved by simply targeting receptors that are normally expressed on brain capillary endothelial cells. A number of studies have demonstrated the ability to successfully enhance the delivery of therapeutic nanoparticles to a

brain tumor by targeting transferrin receptors and nicotinic acetylcholine receptors expressed on endothelial cells. Transferrin has been incorporated onto the surface of micelles [95], solid lipid nanoparticles [96], superparamagnetic iron oxide (SPIO) nanoparticles [97], and dendrimers [62,98] for targeting glioma, leading to enhancement in drug efficacy or tumor imaging. Nicotinic acetylcholine receptors have also been used as targets to enhance micelle penetration into the CNS to target glioblastoma [99–101]. Peptides targeting this receptor have been derived from snake neurotoxins including candoxin and *Ophiophagus hannah* toxin b [101,102].

A number of biomolecules have targets that can also be found on proliferating endothelial cells within a tumor. For example, RGD peptide has been found to bind to $\alpha_v\beta_3$ integrin, which is expressed on the periphery of high-grade gliomas as well as on proliferating endothelial cells in the tumor vasculature [93]. This peptide has been incorporated into the design of a broad range of nanoparticles targeting brain tumors including micelles [103,104], iron oxide nanoparticles [105,106], gold nanoparticles [107], dendrimers [108], as well as other types of nanoparticles [109,110]. Aminopeptidase N (CD 13) which is overexpressed on the tumor vasculature [94] has also been targeted with another tripeptide (Asn-Gly-Arg (NGR) peptide) [111]. This NGR peptide has allowed for enhanced targeting of micelles [112,113] and liposomes [114–116] to various brain tumors including glioma and neuroblastoma. Nucleolin is yet another specific marker for angiogenic endothelial cells within the tumor vasculature [117]. F3 peptide was found to bind to this receptor [117], and since this discovery, several nanoparticle systems targeting brain tumors have incorporated this targeting peptide into their design [118,119].

Once nanoparticles have bypassed the BBB, they must be able to target glioma cells in a specific manner. One of the methods to achieve this is to incorporate targeting moieties that bind to receptors that are overexpressed on these cells. Such receptors include $\alpha_v\beta_3$ integrin and CD 13, which have already been mentioned, as well as EGFR [120,121], IL13R α_2 [122–124], and LRP1 [125–127]. Antibodies to EGFR or EGFRvIII have been incorporated into several nanoparticle systems targeted against glioma [128,129]. Anti-IL13R α_2 antibodies [78] and IL13 peptide [130,131] have also been conjugated to the surface of various nanoparticle systems, allowing for the targeting and destruction of glioma cells. LRP1 is a target of angiopep-2 and incorporation of this peptide into the structure of various nanoparticle systems has enhanced therapeutic delivery to brain tumor cells [132–134]. As more glioma-specific receptors are identified, nanoparticles may be able to integrate multiple targeting moieties providing a dynamic platform for targeting heterogeneous brain tumors. Fig. 1 summarizes the variety of mechanisms that nanoparticles can use to target a brain tumor including the EPR effect, carrier-mediated transportation, receptor-mediated endocytosis, and adsorptive-mediated endocytosis.

5. Nanoparticles for brain tumor imaging

Having a high-resolution image before surgery is especially important for GBM, which is characteristically invasive. Such invasiveness makes it quite difficult to accurately determine a clear tumor boundary by eye. Appropriate imaging of a tumor is critical for measuring the extent of tumor distribution preoperatively as well as for determining response to a treatment regimen postoperatively, both being necessary for the successful management of brain tumor patients. By far the most common method for imaging brain tumors is contrast-enhanced T1-weighted MRI [135]. However, this measurement technique can be greatly influenced by vascular leakage that may not be present throughout the entire tumor area [136]. Furthermore, an accurate view of postoperative response can be difficult to acquire, especially with phenomena such as pseudoprogression after radiotherapy [137] and pseudoresponse when using anti-angiogenic therapies [138,139]. Even though it is the contrast agent of choice, gadolinium is nephrotoxic,

Fig. 1. Transportation mechanisms of multifunctional nanoparticles into the brain tumor. (A) Transport of multifunctional nanoparticles across the BBB: 1) receptor-mediated transcytosis, 2) receptor-mediated endocytosis, 3) adsorptive-mediated transcytosis of nanoparticles with cationized ligands. (B) Mechanisms of transportation across the disrupted BBB and selective targeting of brain tumor cells: 1) passive targeting via the EPR effect, 2) adsorptive-mediated endocytosis or 3) receptor-mediated endocytosis. Both mechanisms offer a targeted delivery to brain cancer cells, sparing the normal tissue. NP: nanoparticle.

leading to nephrogenic systemic fibrosis in some patients [140]. Therefore, its use in patients with renal impairment is limited. Other MRI techniques to image a tumor include perfusion-weighted imaging, which can measure blood perfusion and permeability, and diffusion-weighted imaging, which can be helpful for grading gliomas [139,141]. Other modalities such as PET imaging and magnetic resonance spectroscopy (MRS) can allow for the quantification of metabolic activity of tumor cells, potentially allowing for more sensitive measurements of response rates to therapy [139]. ^{11}C -methionine is an example of a radiolabelled amino acid used in PET imaging that demonstrates enhanced uptake by tumor cells compared to normal brain tissue [139,142]. It can be used to measure tumor progression as well as to discriminate between recurrence and radiation necrosis on a scan [139]. Nanoparticles have the potential to enhance the sensitivity and effectiveness of these various imaging techniques. Here, we outline single and multimodal nanoparticles currently in development with an emphasis on MRI, photoacoustic, and intraoperative fluorescence imaging.

5.1. MRI contrast agents

One of the primary imaging modalities used in clinic to assess the extent of a brain tumor is MRI. MRI can provide high spatial resolution and is the usual standard for imaging brain tumors in a clinical setting. Gadolinium chelates such as Gd-DTPA are contrast agents typically used for MRI. Such molecules do not normally cross the BBB but can cause marked signal change in the brain tumor where the BBB is disrupted. They have a short half-life and require repeated injections with high dosages to achieve adequate visualization of a tumor [143,144]. Accurate delineation of tumor boundaries and the quantification of tumor volume are limited due to the spatial variability of BBB disruption in a tumor area and technical difficulties caused by false-positive contrast enhancement [145,146].

Nanoparticle platforms are being developed as contrast agents to provide improvements over those currently used. Various nanoparticle constructs containing magnetic elements such as iron, gadolinium, and manganese are in development or have already made their way to a

clinical setting for use as MRI contrast agents in the imaging of brain tumors [147]. These nanoparticles have been shown to increase signal enhancement for a long period of time and enhance visualization of the tumor border [148]. Iron oxide nanoparticles have been extensively studied as T2/T2* contrast agents for brain tumor imaging. Ferumoxytol, an ultra-small SPIO coated with polyglucose sorbitol carboxymethyl ether, has been used as the MRI contrast agent together with a standard gadolinium chelate for patients with recurrent high grade glioma receiving chemotherapy in phase I clinical trials (ClinicalTrials.gov Identifier: NCT00769093). Quantitative imaging changes of brain tumor vascularity after anti-angiogenic therapy with bevacizumab versus steroid therapy with dexamethasone are being assessed by a dual agent MRI study using gadolinium and ferumoxytol.

Many recent reports describe that targeting peptide modification of iron oxide nanoparticles can enhance uptake at a brain tumor site, resulting in better MRI contrast within a tumor [149,150]. Sun et al. designed PEGylated SPIO nanoparticles possessing a surface-bound brain tumor targeting peptide chlorotoxin (CTX) that showed high selectivity and binding affinity to membrane-bound matrix metalloproteinase-2 (MMP-2) in gliomas [149]. A significant negative contrast enhancement and higher T2 relaxivity were observed in cells when these targeted nanoparticles were used compared to cells that had been incubated with nanoparticles without surface-bound CTX. After retro-orbital injections into mice bearing subcutaneous 9L rat gliosarcoma tumors, the CTX bound nanoparticles served as a MRI contrast enhancement agent accumulating to a greater extent in the tumor when compared to non-CTX bound ones [149]. Although negative contrast agents such as iron oxide particles have been shown to enhance MR imaging of intracranial tumors, a major drawback is that they produce hypointense regions that can often be difficult to distinguish from resident brain iron signal [151]. T2 and T2* weighted imaging in general also provides images of lower resolution than most T1-weighted sequences [152,153].

Positive contrast agents may therefore be of more benefit as they lead to bright signal enhancement on T1-weighted MRI [152–154]. Gadolinium nanoparticles possess positive contrast properties that

enhance signal by accelerating longitudinal relaxation of water protons and promoting longer retention time at the tumor site. Faucher et al. designed ultra-small paramagnetic gadolinium oxide particles as a T1 contrast agent for brain tumors [153]. The longitudinal relaxivity of these nanoparticles was estimated to be $9.9 \text{ s}^{-1} \text{ mM}^{-1}$ compared to $4.1 \text{ s}^{-1} \text{ mM}^{-1}$ of the Gd-DTPA. These nanoparticles showed a high contrast enhancement in rat brain tumors, increasing over the span of 2 h. Manganese oxide (MnO) nanoparticles are another group of T1-weighted contrast agents that have been developed for the imaging of brain tumors [151,155,156]. Just like gadolinium-based particles, these nanoparticles exert bright contrast on images and can selectively target the brain tumor. Na et al. designed MnO nanoparticles encapsulated in a PEG–phospholipid shell with conjugated Her-2/neu receptor antibody to target EGFRs that were expressed on certain types of breast cancer cells and brain tumors [155]. Using a mouse model of a breast cancer brain metastasis, the authors observed the selective enhancement of tumor cells using T1-weighted MRI. While the non-functionalized MnO particles also accumulated in the tumor due to disrupted tumor vasculature, only the functionalized nanoparticles accumulated at the site for an extended time (up to 24 h was reported) [155].

5.2. Optical imaging probes

A major prognostic factor of patients with malignant gliomas is the extent of removal of malignant tissue during surgery [157,158]. Optical imaging can aid in the intraoperative resection of brain tumors [159], and nanoparticle-based imaging probes with absorption and fluorescence properties have been developed with such capabilities. Quantum dots with intrinsic fluorescent properties allow for cancer targeting and imaging [66]. Cai et al. developed RGD peptide-labeled quantum dots (QD705-RGD) with a maximum emission at 705 nm that could be used to image $\alpha_v\beta_3$ integrin positive tumor vasculature [66]. The greatest contrast was observed around 6 hour post-injection in a subcutaneous U87MG tumor, but no significant fluorescence signal was observed in non-modified QD705 injected mice, demonstrating the importance of the targeting RGD peptide [66]. Nie et al. described tumor-targeting deep-blue polyacrylamide nanoparticles with coomassie blue, PEG, and F3 peptide surface conjugation. These particles could target a tumor effectively and allow for visible color staining of neoplastic tissue. This simple approach could allow for color-guided tumor resection in real time without the need for extra equipment or special lighting conditions [160].

In addition to optical approaches reliant only on light, photoacoustic imaging combining light exposure and sound generation provides higher spatial resolution and deeper tissue penetration. This imaging modality is based on the ability of different types of probes to absorb light and generate transient acoustic signals [161–165]. Exogenous contrast agents such as gold nanoparticles with surface plasmon resonance in the near infrared (NIR) range can be used with this technique to enhance the visualization of different tissue types including brain tumors [65,166–169]. Lu et al. designed a 40 nm hollow gold nanospheres for use with photoacoustic tomography (PAT) to successfully visualize the microvasculature of brain tumor margins [169]. In a follow-up study, Lu et al. used PAT to visualize the targeted accumulation of RGD peptide-modified gold nanoparticles in an intracranial U87 glioma tumor [167]. Quantitative studies demonstrated that the mean contrast-enhanced photoacoustic signal ratio of tumor-to-normal brain 24 h after injection was about twice as high as that seen in pre-contrast images [167]. Gold nanoparticles with a high extinction coefficient can also serve as contrast agents for dark field light scattering imaging, which allow for *ex vivo* diagnosis [76]. Although nanoparticle platforms enable the use of light in the NIR range, the penetration of light through brain tissue is only in the millimeter range. Furthermore, non-invasive optical imaging of brain tumors is severely hampered due to the physical barrier created by the skull. Therefore, the

application's main utility is for the *in vitro* diagnosis and intraoperative localization of brain tumor tissue.

5.3. Nanoparticles for multimodality imaging

More and more studies are starting to design nanoparticles that incorporate the use of multiple imaging modalities [150,168,170–175]. Each imaging modality (e.g. MRI, PET, optical, and SPECT) has its own advantages and drawbacks. However, when used in combination, they may allow for earlier detection of cancer, better characterization of the molecular and metabolic features of a tumor, as well as better tracking of the effects of treatment. Thus, particles with multimodal imaging features may have a role in preoperative delineation of a tumor, intraoperative visualization of malignant tissue location, as well as follow-up during treatment with chemotherapy or radiotherapy.

Veiseth et al. developed a dual-imaging modality nanoparticle to overcome the BBB, allowing for MRI and near-infrared fluorescence (NIRF) imaging of brain tumors [170,172]. In this study, an iron oxide nanoparticle coated with a PEG-grafted chitosan copolymer with the addition of CTX and fluorescent Cy5.5 was synthesized [170]. After intravenous injection of particles into a transgenic mouse model, ND2: SmoA1, which resembles human medulloblastoma, the authors observed the accumulation of nanoparticles in neoplastic tissue but did not observe any significant accumulation of the nanoprobe in healthy tissue. No contrast enhancement was observed with the nanoparticles that lacked the CTX targeting ligand. Signal intensity increased over the first 50 h after injection and then stayed stable for the next 70 h [170]. Lee et al. designed an RGD-conjugated radiolabeled iron oxide nanoparticle for both MRI and PET imaging [171]. MRI signal intensity decreased significantly after tail vein injection of the nanoparticle conjugate compared to the non-targeted nanoparticle and to the nanoparticle co-administered with a $\alpha_v\beta_3$ integrin blocking agent. For PET imaging, these nanoparticles were labeled with ^{64}Cu and provided greater signal-to-noise ratio. Again, the RGD conjugated nanoparticles displayed greater tumor uptake and better visualization upon imaging [171].

Nanoparticles with triple imaging modality capabilities have also been developed and may enhance the ability to visualize the extent of invasive tumors. Kircher et al. developed a gold nanoparticle-based platform with triple-modality MRI, photoacoustic, and Raman imaging capabilities (Fig. 2) [168]. These particles were detected by all three modalities with at least picomolar sensitivity, and co-localization of tumor imaging was observed using all three modalities in an orthotopic U87MG mouse model. Furthermore, the authors demonstrated that tumor resection could be guided using the photoacoustic and Raman signal properties of these nanoparticles 24 h after intravenous injection. Photoacoustic imaging was used to delineate malignant tissue *in situ*, and high-resolution intraoperative Raman images were taken during resection. Such a nanoparticle system could improve both preoperative and intraoperative resection of brain tumors, which may lead to better patient outcomes. However, a current drawback for these particles is that the new instrumentation for endoscopic and intraoperative photoacoustic and Raman imaging that would be required for the approach is still under development [168]. Xie et al. demonstrated another triple-modality imaging using an iron oxide nanoparticle labeled with ^{64}Cu -DOTA and Cy5.5 for MRI, PET and NIRF in a subcutaneous U87MG xenograft mouse model. These particles demonstrated extensive accumulation at the tumor site and led to enhanced visualization of the entire tumor using the combination of all three imaging modalities [176].

6. Therapeutic nanoparticles for brain tumors

Another vital role for nanoparticles is to serve as therapeutic agents, with the potential to overcome many of the hurdles that conventional therapies face. Various nanoparticle systems have been explored as

Fig. 2. Triple-modality MRI-Photoacoustic-Raman nanoparticles (MPRs). MPRs were injected intravenously into mice bearing an orthotopic brain tumor (top). The proposed clinical use is diagrammed at the bottom of the illustration. Detectability of MPRs by MRI allowed for preoperative detection and surgical planning. Photoacoustic imaging, with its relatively high resolution and deep tissue penetration, was then able to guide bulk tumor resection intraoperatively. Raman imaging, with its high sensitivity and spatial resolution, can then be used to remove any residual microscopic tumor burden. The resected specimen can subsequently be examined using a Raman probe *ex vivo* to verify clear tumor margins. Reproduced with permission from Ref. [168].

Fig. 3. Schematic structure of different nanocarriers (liposomes, polymeric nanoparticles including nanospheres and nanocapsules, dendrimers, and micelles) for drug delivery to the brain tumor. Reproduced with permission from Ref. [192].

carriers to overcome the BBB for targeted treatment of brain tumors. Additionally, nanoparticles responding to external triggers such as an applied magnetic field and light offer new therapeutic avenues for targeting malignant brain tumors. Here, we focus on novel therapeutic nanoparticles and highlight examples currently under clinical evaluation.

6.1. Nanoparticles as delivery systems

The advantages of nanoparticles as therapeutic carriers are: 1) improved therapeutic agent circulation, 2) targeted drug delivery, 3) controlled drug release, 4) high loading capacity, and 5) co-delivery of more than one therapeutic agent. Nanoparticle-based delivery systems for therapeutic agents such as chemotherapy drugs are expected to have a great clinical impact on brain tumor treatment [130,177,178]. Many hydrophobic agents that normally cannot cross the BBB can accumulate at a tumor site when incorporated into a nanocarrier [108,179,180]. As discussed previously, modification of the nanoparticle surface with targeting moieties that specifically bind to receptors overexpressed on the tumor vasculature and/or cancer cell membrane could provide an effective delivery system for brain tumor therapy. In addition, controlled drug release approaches could further enhance the specificity of the treatment effect to the brain tumor area.

Liposomes, self-assembled spherical phospholipid bilayers, have received a lot of attention as pharmaceutical carriers for brain tumor therapy (Fig. 3) [181,182]. Major advantages of liposomes include selective accumulation within brain tumors by passive and active targeting and improved pharmacokinetic effect [181,183]. There are several liposome-based drug delivery systems under clinical trials. 2B3-101 is a PEGylated liposomal doxorubicin formulation conjugated with glutathione that allows for enhanced drug-delivery to the brain by specialized transporters on the BBB. A phase I/II clinical trial with 2B3-101 was started in 2011 in patients with glioma or breast cancer brain metastasis (ClinicalTrials.gov Identifier: NCT01386580). The purpose of the study was to determine the safety, tolerability and pharmacokinetics of 2B3-101 as a monotherapy and in combination with trastuzumab, a monoclonal antibody that interferes with the human epidermal growth factor receptor. A liposomal encapsulation of the camptothecin derivative and topoisomerase I inhibitor CPT-11 is another delivery system being examined in clinic trials (ClinicalTrials.gov Identifier: NCT00734682) [63,177]. Currently, it is under investigation in a phase I trial to assess the safety, pharmacokinetics, and maximum tolerated dose in patients with recurrent high-grade gliomas who are wild type or heterozygous for the UGT1A1*28 gene. The structural stability, low drug-loading capacity, and scale-up methods are issues of liposomal systems that need to be further improved [184,185].

Other organic-based nanoparticles including micelles, biodegradable polymeric nanoparticles, and dendrimers are also potential candidates for brain tumor treatment (Fig. 3) [64,99,186]. Polymeric micelles are core-shell nanospheres composed of self-assembling amphiphilic block copolymers [187]. Compared to liposomes, micelles are smaller in size and have high solubility with the capacity to deliver hydrophobic drugs to malignant brain tumors. Guo et al. designed an aptamer-functionalized poly(ethylene glycol)-poly (D,L-lactic-co-glycolic acid) PEG-PLGA nanoparticle for anti-glioma delivery of paclitaxel (Ap-PTX-NP) [186]. AS1411, a DNA aptamer specific for nucleolin which was highly expressed in the plasma membrane of both cancer cells and endothelial cells in angiogenic blood vessels, was conjugated to the surface of PEG-PLGA nanoparticle with a final particle size of 156 ± 54.8 nm in diameter. The aptamer-nucleolin interaction significantly enhanced the nanoparticle uptake into C6 glioma cells and resulted in enhanced cytotoxicity of the drug payload. Prolonged circulation and enhanced drug accumulation of Ap-PTX-NP were demonstrated *in vivo* in C6 glioma-bearing mice when compared with Taxol and the unmodified nanoparticle-drug system.

Biodegradable polymeric nanoparticles with nanosphere and nanocapsule structures also show great promise for the delivery of BBB-impenetrable therapeutic agents [59,188–191]. These systems are useful in controlling drug payload release and protect drug from the surrounding environment [192]. Wang et al. evaluated the antitumor effect of 1% polysorbate-80 coated PBCA nanoparticles loaded with a nucleoside reductase inhibitor gemcitabine *in vitro* and *in vivo* in C6 glioma cells [188]. The nanoparticle formulation could inhibit the proliferation of glioma cells and extend the survival time in a rat brain tumor model. Ding et al. demonstrated another polymeric nanopatform incorporating poly (β -L-malic acid) (PMLA) with an antisense oligonucleotide (AON) payload [59]. This system showed pH-regulated release of AON and significant inhibition of intracranial human glioma tumor growth by specifically blocking the synthesis of the tumor neovascular trimer protein laminin-411 [59].

Dendrimers are highly branched polymers with multivalent functional groups, allowing for the easy incorporation of therapeutic agents within their structure [193]. Several studies have demonstrated that dendrimers can overcome the BBB and increase drug accumulation at the site of a brain tumor [62,194]. Controlled drug-release from dendrimers can be achieved using different types of stimulus-sensitive groups [62]. Li et al. developed a pH-sensitive dual-targeting dendrimer conjugated with transferrin and tamoxifen for treating brain gliomas [62]. The anticancer drug doxorubicin was covalently linked to the interior of the poly(amidoamine) (PAMAM) dendrimers via a pH-sensitive hydrazone bond. Only 6% drug release was observed at a pH of 7.4 while 32% release was observed at pH 4.5. Studies in an *in vitro* BBB model indicated that these dual-targeting dendrimers showed an enhanced transport efficiency when compared to the non-targeted and transferrin-targeted dendrimers [62].

Inorganic nanoparticles are physically and chemically more stable compared to the organic nanoparticles, allowing for long-term storage. Most of these nanoparticles are protected by hydrophilic polymers, making them more water-soluble and biocompatible. Studies have shown that magnetic nanoparticles can accumulate within a tumor area after systemic administration with a locally applied magnetic field [57,195,196]. Chertok et al. showed that the iron oxide nanoparticle concentration in glioma tumors could be enhanced by 5-fold when an external magnetic field was applied [57]. Hua et al. demonstrated the effectiveness of a poly[aniline-co-N-(1-one-butyric acid) aniline] (SPANH) coated iron oxide core based delivery system for the chemotherapy drug 1, 3-bis(2-chloroethyl)-1-nitrosourea (BCNU) in the treatment of glioma under external magnetic field [195]. In this system, the bound-BCNU on the nanoparticle was more thermally stable than free BCNU and could be concentrated *in vitro* and *in vivo* at targeted sites upon exposure to the external magnet [195]. Recently, gold nanoparticles with 5 nm core size have been explored as a drug delivery system to overcome the BBB for anti-glioma therapy [71]. Cheng et al. demonstrated that the hydrophobic PDT drug Pc 4 could be attached to the nanoparticle surface via a non-covalent attachment and a 10-fold improvement in the selectivity for a brain tumor was achieved *in vivo* through the use of epidermal growth factor peptide-modified gold nanoparticles. This selectivity was due to the EPR effect within the tumor and receptor-mediated endocytosis of the nanoparticle into the cancer cells [71].

6.2. Innovative therapeutic nanoparticles

6.2.1. Magnetic nanomaterials

Nanomaterials with magnetic properties that respond to magnetic fields in a non-invasive manner have been recently explored as therapeutic agents for brain tumors. To date, the most successful application of magnetic nanoparticles is for magnetic hyperthermia. A remarkable example of this involves SPIO nanoparticles, which are in a phase II study for patients with recurrent GBM in Europe [197–199]. The principle of this approach is based on heat generated from the movement of

magnetic nanoparticles under a high frequency alternating magnetic field. Due to the non-invasive nature of this therapy, inaccessible brain tumor tissues can be reached with magnetic nanoparticles. The therapeutic efficacy of magnetic nanoparticles is dependent on several factors including the targeting ability of the nanoparticles to tumor tissue, the magnetization and Curie temperature reached by the magnetic nanoparticle as well as parameters of the magnetic field. Preclinical studies indicate that magnetic hyperthermia achieved by SPIO nanoparticles can effectively promote glioma cell death and increase survival [198]. The safety and efficacy of intratumoral hyperthermia using SPIOs coated with aminosilane under a 2.5–18 kA/m and 100 kHz alternating magnetic field in conjunction with radiotherapy have been investigated in patients with recurrent GBM [198–200]. Results of the study showed that the combination therapy is relatively safe and leads to longer overall survival following tumor recurrence compared to conventional therapies alone. However, an improvement of the nanoparticle composition and intratumoral distribution could lead to further enhancement in future studies.

Recently, magnetic nanomaterials have been utilized under a low frequency magnetic field for the treatment of brain tumors [56,61]. Kim et al. designed anti-IL13R α 2 biofunctionalized magnetic-vortex microdisks for targeted brain cancer therapy [61]. Disks were composed of 20:80% iron–nickel permalloy coated by a 5 nm thick layer of gold and were 60 nm in thickness and 1 μ m in diameter. Under an alternating magnetic field with low frequency, the disks oscillated, creating mechanical torque. The authors demonstrated that the system could selectively destroy N10 glioma cells *via* mechanical stimulus generated by the disk oscillations. The proposed therapeutic mechanism was that membrane integrity was compromised due to mechanical damage and programmed cell death was initiated due to changes in calcium equilibrium. It should be noted that the disks need to be further scaled down into the nanometer range and cell destruction should be tested in other brain cancer cell lines to better support applications for brain tumor treatment [61].

6.2.2. Photosensitive nanomaterials

Semiconductor nanomaterials such as titanium dioxide (TiO₂) and quantum dots possess photosensitive properties and have recently been developed as therapeutic agents for light-mediated glioma treatment [67,201]. One promising application of these photosensitive nanoparticles is to treat a brain tumor with PDT. Under light exposure, these particles absorb energy from light and transfer it to molecular oxygen, generating a variety of cytotoxic reactive oxygen species (ROS) to react with essential cellular components such as DNA, proteins, and lipids [67,80]. Rozhkova et al. demonstrated that a 5 nm anti-IL13R α 2 functionalized 3,4-dihydroxyphenylacetic acid (DOPAC) modified TiO₂ nanoparticle could specifically target brain cancer cells and initiate programmed cell death following visible light treatment [67]. Modification of TiO₂ nanoparticles with electron donating enediol ligands enabled visible light harvesting and generated superoxides [67].

Another potential application of photosensitive nanoparticles is photothermal therapy. It has been demonstrated that gold nanoparticles including gold nanoshells and nanorods can convert absorbed NIR light to heat and induce cell death [58,202]. Day et al. investigated a silica-gold nanoshell, with a 120 nm diameter silica core coated by a 10–20 nm thin layer of gold, as a photothermal cancer therapeutic agent for glioma therapy [58]. Under NIR laser light excitation, successful targeted ablation of glioma cells *in vitro* and *in vivo* was demonstrated in a subcutaneous implanted U373 glioma mouse model. However, photothermal therapy for noninvasive treatment of human brain tumors in an actual clinical setting could be difficult because light cannot penetrate the human skull. During surgery, brain tumors become accessible and light can be introduced to the areas where the tumor cells have been resected. PDT using conventional photosensitizers has been tested on the clinical setting for brain tumors as an intraoperative adjuvant therapy (ClinicalTrials.gov Identifier: NCT01682746,

NCT00118222, NCT01148966). Light can be placed at the surgical cavity through optical fibers to activate the photosensitizers, which can guide the tumor resection as well as help kill any cells that have been left behind.

7. Theranostic nanoparticles for brain tumor treatment

The incorporation of multiple functions into a nanoparticle system would be highly beneficial for clinical translation. With the combination of imaging and carrying capabilities, nanoparticles could allow for the simultaneous delivery of therapeutic agents to the tumor area and real-time tracking of their biodistribution and fate *in vivo* [203,204]. Innovative nanoparticles such as magnetic nanoparticles, gold nanoparticles, and quantum dots, which possess both imaging and therapy functions simultaneously, are emerging systems with theranostic potential [118,149,203,205,206]. Here, we focus on a few reports of nanoparticles that exemplify theranostic systems.

7.1. Combination of MRI and therapy

Liu et al. developed a theranostic system using iron oxide nanoparticles conjugated with the anticancer drug epirubicin for delivery and image tracking functions in a C6 tumor-bearing rat model [207]. In this study, the authors included focused ultrasound to disrupt the BBB at the tumor site to improve nanoparticle accumulation. Drug delivery to the brain tumor was further enhanced by magnetic targeting and monitored in real time. A 2.6 fold increase in relaxation rate with MRI was observed in animals injected with the nanoparticles after focused ultrasound/magnetic targeting treatment compared to the non-treated groups [207].

Reddy et al. demonstrated an example of a theranostic system based on a polymeric nanoparticle formulation containing Photofrin® and iron oxide conjugated with F3 for MRI and PDT in a 9L glioma rat model [118]. Photofrin® was able to generate singlet oxygen (¹O₂) and induce the cytotoxicity under light exposure. The pharmacokinetics of the nanoparticles could be evaluated by MRI due to the magnetic properties of iron oxide. Compared to the untargeted nanoparticles, the F3 modified nanoparticles showed longer retention at the brain tumor area with a 2-fold increase of the contrast enhancement. The authors also demonstrated that the targeted theranostic nanoparticles led to significant survival rate improvements in mice bearing brain tumors after the PDT-mediated laser irradiation compared with the non-targeted theranostic nanoparticles or Photofrin® alone. Forty percent of animals in the targeted theranostic nanoparticle treated group were found to be tumor-free at the end of the study period [118].

In another study, Hadjipanayis et al. developed iron oxide nanoparticles with bound anti-EGFRvIII antibody for targeted glioma imaging and therapy [128]. Glioma cells demonstrated preferential uptake of these functionalized nanoparticles *via* receptor-mediated endocytosis, resulting in caspase-3 activation and strong T2-weighted contrast on MRI. *In vivo* studies revealed increased survival after intratumoral administration of these particles to animals implanted with EGFRvIII-expressing intracranial xenografts [147]. Additional reports have described the use of tumor-specific CTX-peptide conjugated iron oxide nanoparticles to track toxicity and inhibition of glioma cell invasion by MRI, further demonstrating theranostic applications of nanomaterials [172,208].

7.2. Combination of optical imaging and therapy

Optical imaging has demonstrated *ex vivo* and intraoperative applications. Organic fluorescence imaging probes can label therapeutic nanoparticles and allow for *in vitro* and *in vivo* tracking of nanoparticle distribution. Recent studies have been focused on the potential theranostic application of optical nanoprobe such as quantum dots for brain tumors [205]. Jung et al. designed a multifunctional quantum

dot-based siRNA delivery system for brain cancer cells [205]. siRNA was attached through two strategies: 1) enzymatic cleavable disulfide linkage for payload release and 2) a non-cleavable linkage for imaging and tracking. *In vitro* experiments indicated that theranostic nanoparticles selectively inhibited the expression of EGFRvIII in U87 glioblastoma cells. The resulting nanoparticle uptake and localization in the cells were monitored by fluorescence imaging. The potential for targeted delivery was demonstrated at the cellular level by introducing active targeting ligands such as RGD peptide and HIV-derived Tat peptide onto these quantum dots [205]. As most of these combinations are still restricted to preclinical studies, further investigation is necessary in order to establish efficacy and a safety profile of the systems.

8. Administration strategies for nanoparticles

The therapeutic potential of nanoparticles could be improved for clinical translation if the administration method of these particles could 1) allow for specific distribution to and diffuse distribution within a tumor and 2) the neurotoxicity and systemic toxicity could be minimized. Here, we review relevant strategies for nanoparticle administration and discuss their pros and cons for treating brain cancer.

8.1. Systemic administration

Systemic administration of nanoparticles is a very convenient strategy for delivery, allowing for repetitive dosing. Despite the diversity of nanoparticle systems in development, most have the potential to target brain tumors through passive and active targeting mechanisms. As previously described, passive targeting occurs through the diffusion of nanosized particles through the disrupted BBB, a phenomenon known as the EPR effect [81]. Active targeting involves functionalizing nanoparticle surfaces with BBB and glioma-specific targeting moieties [1].

One obvious method for the delivery of nanoparticles is *via* intravenous (IV) injections. IV administration of nanoparticles has been used in countless reports including many of those mentioned previously. In the preclinical models, nanoparticle-based therapeutics are often given to the animals in multiple doses with the injection frequency ranging from every 3 days to every 2 weeks to control the tumor growth [179,209]. The maximum tolerated dose for nanoparticle-based therapeutics is usually significantly greater than the free drug [210]. These therapeutics, with lower starting dose in phase I trials compared with the free drugs, are given to patients every three to four weeks (ClinicalTrials.gov Identifier: NCT01386580). Besides tuning of nanoparticle size and surface properties to influence intratumoral accumulation [211], external forces such as a magnetic field and focused ultrasound can also help capture systemically administered nanoparticles at the site of a tumor [207]. Low-frequency focused ultrasound provides local disruption of the BBB [207,212,213], and preclinical studies have shown that this technique can safely enhance the focal delivery of the therapeutic agents into brain tumors [212]. This ultrasound-mediated disruption of the BBB is transient and reversible without permanent neuronal injury or other undesired long-term effects [213]. Magnetic targeting, another noninvasive strategy to facilitate magnetic nanoparticle accumulation at a target site [214,215], has been applied in clinical trials (ClinicalTrials.gov Identifier: NCT0005495, NCT00034333). Based on the FDA guidelines, exposure to magnetic field devices up to 8 T for adults and 4 T for children do not represent any safety concerns. Chertok et al. demonstrated that IV administered iron oxide particles to rodents with 9L-glioma could be monitored by MRI [57]. The authors demonstrated that magnetic targeting induced a 5-fold increase in the total exposure of glioma cells to the nanoparticles over non-targeted tumors and a 3.6 fold enhancement in target selectivity for accumulation in the tumor *versus* normal brain tissue [57]. Although some strategies have been developed for systemic administration to overcome the BBB, the overall percentage of systemically injected nanoparticles found in the brain is typically less than 1% [6,190]. This non-specific accumulation of nanoparticles in normal tissues

may cause severe adverse effects and increase mortality and morbidity in patients.

Intracarotid administration of nanoparticles appears to be a feasible means of ensuring that more nanoparticles accumulate within a brain tumor on the first pass. Han et al. examined the effect of implanted BCNU-loaded wafers and intracarotid perfusion of BCNU-loaded nanoparticles for glioma treatment *in vivo* [216]. BCNU-loaded nanoparticles were made from poly(D,L-lactic acid) (PLA) and coated with transferrin (Tf-PLA-BCNU). Rats with intracranial C6 glioma tumors had improved survival with treatment of Tf-PLA-BCNU delivered *via* intracarotid injections when compared with no treatment controls and even greater survival when intracarotid injections of these nanoparticles were done in conjunction with the implantation of BCNU-loaded wafers. Chertok et al. developed polyethyleneimine-modified magnetic nanoparticles and found that intratumoral levels of the nanoparticles after “active” magnetic capture were increased by 30-fold after intracarotid injections *versus* intravenous injections with the same magnetic capture technique [217].

The major downside of systemic delivery is the risk for accumulation of nanoparticles in non-target organs such as the liver, kidneys, spleen, and lungs. Nanoparticles such as iron oxide and gold nanoparticles are thought to be non-toxic to normal tissues, but the long-term consequences of nanoparticle deposition in the brain have not been fully addressed as of yet. A few studies have shown that nanoparticles can be cleared from the brain [218,219]. Jain et al. studied the biodistribution and clearance of iron oxide nanoparticles in rats [218]. Changes in tissue iron levels including in the brain were analyzed over three weeks after IV injection. The iron concentration in the brain increased 24 h after administration and then decreased after 3 days. Wang et al. studied the fates of gold nanorods in a rat model from 0.5 h to 28 days after IV injection ($0.6 \mu\text{g g}^{-1}$) [219]. Kinetic results demonstrated that gold nanorod accumulation in the brain declined from 0.08 ng g^{-1} to 0.02 ng g^{-1} within 7 days and remained at 0.02 ng g^{-1} after 28 days. However, the clearance mechanism of these nanoparticles in the brain remains unclear and will require further investigation.

8.2. Intracranial administration

Local administration of nanoparticles directly into a tumor site provides another option to overcome the BBB and circumvent non-specific systemic accumulation. Although this method of administration using degradable or non-degradable polymers has shown some ability to destroy tumor cells [220,221], it is characterized by poor drug penetration and dosing limitations [222].

Convection enhanced delivery (CED), another method for intratumoral delivery of nanoparticles, appears to overcome these issues [222]. CED is a means of delivering therapeutic agents directly to the site of the tumor with the benefit of enhancing the distribution of molecules within tumor tissue. This method relies on pressure gradients driving bulk flow of nanoparticles and agents are delivered continuously *via* a catheter connected to a syringe pump which can be implanted during surgery [222]. In this case, higher drug concentrations and more widespread distribution can be achieved in a tumor compared to systemic administration with minimal systemic toxicity [222–224]. CED of therapeutic agents has even made its way into clinical trials, which can be applied for nanoparticle administration [63]. Noble et al. demonstrated that a single CED infusion of 1.6 mg nanoliposomal CPT-11 significantly prolonged median survival over 100 days compared to 28.5 days of the free drug or 19.5 days of the control liposomes in an intracranial U87 xenograft model [63]. In addition, the prolonged exposure to nanoliposomal CPT-11 had no measurable central nervous system toxicity at any of the doses tested [63]. Dendrimers and iron oxide nanoparticles have also been delivered to brain tumors *via* CED [128,225]. While local administration shows the

effectiveness in treating brain tumors, the highly invasive nature of this method is still a major concern.

8.3. Cell-mediated delivery

Stem cells have been found to cross the BBB and have attracted significant attention because of their ability to target brain tumors [226–228]. Mesenchymal stem cells (MSCs) and neural stem cells (NSCs) exhibit tumor-tropic migration towards glioma cells *in vitro* and *in vivo* and may serve as a novel method for targeted delivery of nanoparticles to brain tumor cells [226,229–234]. Versatile image enhancing nanoparticles and therapeutic nanoparticles can be loaded into these cellular carriers for better targeting effect.

Li et al. demonstrated that MSCs with bound silica nanorattle-doxorubicin nanoparticles could migrate towards U251 glioma cells both *in vitro* and *in vivo*. Increased apoptosis was observed after intratumoral injection of silica nanorattle-doxorubicin loaded MSCs when compared to injections of free doxorubicin [235]. Roger et al. demonstrated that marrow-isolated adult multilineage inducible cells loaded with lipid nanocapsules containing ferrociphenol could induce cytotoxicity in U87MG glioma cells [236]. This system was able to slow down tumor growth rate *in vivo* as well. Recently, Cheng et al. demonstrated the use of an FDA-approved NSC cell line to carry silica nanoparticle-doxorubicin (MSN-Dox) conjugates possessing pH-mediated drug release capabilities [237]. *In vivo*, MSN-Dox loaded-NSCs maintained their glioma-homing ability and could deliver doxorubicin conjugates to tumor cells. Both intratumoral and contralateral injections of the MSN-Dox loaded-NSCs were sufficient to achieve significant enhanced therapeutic efficacy compared to using MSN-Dox alone. Results thus far combining stem cells and therapeutic nanoparticles for the treatment of brain cancer are mainly based on local administration methods. Due to their ability to cross the BBB, systemic administration of these stem cell offers promise but warrants further investigation. It has been shown that murine NSCs injected into the systemic circulation via the tail vein of nude mice bearing CNS-1 glioblastoma reach the tumor burden within four days [226]. Furthermore, these administered NSCs did not appear in normal brain tissue. Although systemically delivered NSCs reach the brain tumor, the percentage of stem cells that localize in the brain tumor is currently undetermined [226]. It has been hypothesized that tropic cytokines released from the tumor site may bind to receptors on stem cells to trigger their migration. Of the various signaling proteins that have been suggested to regulate NSC migration, vascular endothelial growth factor that is highly expressed in gliomas is one of the leading candidates [238–240]. A more detailed understanding of the mechanism behind stem cell migration may provide us with the information necessary to increase their migratory efficiency and therefore increase the number of systemically delivered cells that reach a brain tumor.

Another prominent way in which cellular carriers and nanoparticles have been combined is for *in vivo* cellular tracking after administration. Magnetic iron oxide nanoparticles for example have been used to track the migration of stem cells towards tumors [233,241,242]. Wu et al. demonstrated the ability to track the course of migrating MSCs after intracranial injections. These cells were monitored over 14 days and distributed to the tumor border in a specific-manner [233]. Thus, such a system in combination with MR imaging may offer a more efficient way of delineating the boundaries of the tumor. Also, tracking the destination and distribution of stem cells will be important as the fate of these cells is of concern for clinical applications.

Although these cell carriers may have the ability to actively deliver the nanoparticles, the role of this innovative combination for brain tumors needs to be further investigated. Nanoparticle loading capacity, targeting efficiency, tumorigenicity originating from the stem cells, controlled nanoparticle release, and clearance are all concerns surrounding the use of this strategy.

9. Regulatory issues surrounding nanoparticle translation to clinic

Complex nanoparticle formulations have shown great promise *in vitro* and in animal models of glioma but the scale of production for these applications is relatively small compared to the size of the production necessary for a clinical trial. Manufacturing nanoparticles on a large scale for clinical trials poses additional challenges that include: 1) efficient and reliable production of the desired nanoparticles and 2) governmental regulations.

First, “scaling-up” of nanomedicines requires a detailed understanding of each component of the system in order to generate a manufacturing protocol that is reproducible and includes checkpoints for the analysis and characterization of products at different stages of the synthesis. Two preparation techniques are often considered: “top-down” and “bottom-up”. Top-down preparation utilizes larger pieces of material to generate the desired nanostructures while bottom-up preparation produces large complex structures through self-assembly of single-molecule components or polymerization of monomers [243]. Regardless of the preparation technique, it is important to select formulation processes (crosslinking, emulsification, sonication, *etc.*) and conditions (reaction time, temperature, pH, pressure, *etc.*) during the early stages of production that can be consistently reproduced on a larger scale and yield a consistent product that has the same structure and properties as the nanoparticles synthesized in the laboratory [244]. Furthermore, if it is required that the nanoparticles are sterile during administration, an appropriate sterilization technique must be selected because nanoparticles are susceptible to damage from gamma irradiation and autoclaving [245–247]. Moreover, in order to regulate the nanoparticles during synthesis, quick and reliable in-process analytic characterization is required to ensure that the manufacturing process does not alter the composition as well as compromise the quality and stability of the final product. Such techniques may include transmission electron microscopy, light scattering, analytic ultracentrifugation, electrophoresis, spectroscopy, and X-ray diffraction [244].

Second, because of the inherent complexity of nanoparticle systems, government regulation is often unclear and difficult to navigate. Today, there is no specific regulation for nanomedicines and therefore the FDA uses an adapted version of the current framework of regulatory standards. The FDA also recognizes that the unique properties of nanoparticles such as their size, robust physiochemical properties, and classification as a combination product make nanoparticles functionally different from their bulk counterparts. Due to this, the FDA agrees that specific regulatory guidelines for nanomedicines are warranted. To address this issue, the FDA established a Nanotechnology Task Force to create a detailed regulatory pathway for the production of safe, novel, and beneficial nanomedicines [248]. Since its conception in 2006, the FDA’s Nanotechnology Task Force has published several draft guidelines. Despite the progress, no official guidelines currently exist and there is a need for the FDA and other regulatory agencies to develop comprehensive guidelines in order to clarify and expedite the production of nanomedicines.

10. Future challenges and perspectives

The ultimate goal of multifunctional nanoparticles for brain tumors is to enhance patient survival and improve their quality of life. As discussed in this review, there are a number of nanomaterials with unique properties that can serve as imaging probes or therapeutic agents for brain tumors. Theranostic nanoparticles will open even more opportunities to create innovative nanomedicines for brain tumors. Despite the tremendous efforts thus far, only a few nanoparticle systems have been approved for clinic trials, illustrating that many obstacles still need to be overcome in order to translate such nanoparticles from the bench to the bedside.

One of major challenges is the development of an effective nanoparticle system that can overcome the BBB and allow for specific yet widespread targeting of brain cancer cells. However, the heterogeneity of malignant brain tumors and the physiological barriers surrounding the central nervous system make this an arduous task. Exclusively targeting overexpressed proteins and receptors on brain cancer cells remains challenging since normal cells may also express these cancer cell-associated targets to some degree. Nanoparticles incorporating multivalent targeting moieties hold the most promise for achieving optimal targeting after systemic administration. Alternatively, local delivery approaches such as CED can be applied for all nanoparticle systems to bypass the BBB and improve the distribution within a brain tumor. Moreover, recent advances in cellular based delivery offer a novel strategy for targeting brain tumors.

A second challenge associated with drug-carrying nanoparticles in brain tumor therapy is controlled drug release. Only after a nanoparticle-based delivery system reaches the tumor site should its therapeutic payload be released. Nanoparticles using non-covalent delivery strategies can preserve active drugs but often suffer from non-specific diffusion during transportation. Enzyme degradable or stimulus-sensitive chemical linkers should be considered to enhance the overall efficacy of the nanoparticle delivery system. Magnetic field, X-ray, light, and heat are promising external triggers which can control drug release in a spatial and temporal manner.

Safety is another concern nanoparticles face. While the unique chemical and physical properties of nanomaterials make them attractive for therapy and diagnosis, potential neurotoxicity and systemic toxicity are concerns related to implementing these particles in actual patients. Current clinical examples using nanoparticles for brain tumors are carried out on patients with recurrent high-grade glioma or patients with brain metastases, both diseases having very poor prognoses. To expand the application of nanoparticles to less aggressive forms of brain cancer is challenging. Although many nanoparticles show low acute systemic toxicity, the long-term side effects are not yet known. In addition, the clearance mechanism of nanoparticles after administration is not fully understood, which makes it unclear as to the long-term consequences of particle accumulation in various tissues. Toxicological profiles and clearance mechanisms in animal models will be needed in order to push the field forward. Other issues such as the long-term stability of nanoparticles, quality control in the synthesis process, and the ability to synthesize these materials on a large scale are practical problems hampering their clinical application. The future design of nanoparticles for brain tumors should take the above challenges into consideration.

Another important direction in the field of nanomedicine will be the development of particles with multiple imaging functionalities. Designing these nanoparticles will require focus on materials that show unique magnetic or optical properties. Integrating more than one imaging probe will further improve the sensitivity for detecting recurrence and tracking patient responses to treatment. Furthermore, they may also allow for new methods of image-guided surgery for brain tumor resection. The field of nanomedicine is also moving towards developing theranostic nanoparticles that combine therapeutic and diagnostic applications. Such systems will be extremely important since they may help in evaluating the tumor status directly in conjunction with therapy. Iron oxide nanoparticle and gold nanoparticles, possessing light- or magnetic field-mediated properties, are distinguished nanomaterials serving as intrinsic theranostic platforms.

Clinical implementation of nanoparticles for patients with brain tumors is still in its infancy. Developing successful systems requires knowledge in a multitude of areas including nanoparticle engineering, medicine, cancer biology, and pharmacokinetics. As our knowledge in these fields expands in the coming years, it will facilitate the creation of innovative and effective nanomaterials for curing patients with brain tumors.
