

Spontaneous Dihydrogen Activation by Neutral TaO₄ Complex at Cryogenic Temperatures**

Mingfei Zhou,* Caixia Wang, Zhen hua Li, Jia Zhuang, Yanying Zhao, Xuming Zheng, and Kangnian Fan

Catalytic hydrogenation is one of the most important reactions in industry.^[1] The activation of dihydrogen by metal centers is a fundamental step in nearly all metal catalytic hydrogenation reactions.^[2] Great efforts have been made to split the H–H bond at metal centers under mild conditions.^[3–8] Traditional homogeneous hydrogenation catalysts are based on precious metals, on which dihydrogen splitting often proceeds by homolytic cleavage to form metal hydride complexes, which can then transfer hydrogen atoms to organic or other substrates.^[9] A second mechanism, heterolytic cleavage of dihydrogen into a hydridic and protic functionality, has also been observed for many transition-metal complexes.^[10]

Transition-metal oxides are vital heterogeneous catalysts or supports in many processes involving H₂. Considerable theoretical investigations have been focused on H₂ adsorption and heterolytic dissociation on metal oxide surfaces.^[2,11] The reactions of bare transition-metal oxide cations with dihydrogen have been studied in the gas phase with mass spectrometric techniques to provide useful insight into the elementary steps of catalytic reactions and to characterize reactive intermediates that have previously not been within reach of condensed-phase techniques.^[12–14] In contrast to cationic reaction systems, neutral transition-metal oxide reactions have gained much less attention, in part because of the experimental challenges faced in detecting neutral species in the gas phase.^[15] Herein we report a joint matrix-isolation infrared spectroscopic and theoretical study of dihydrogen activation by neutral tantalum oxide molecules. We found that, upon annealing, the ground-state TaO₄ d⁰ complex reacts spontaneously with dihydrogen to form [HTaO(OH)(η²-O₂)], which involves both the hydridic (H⁻) and the protic (H⁺) functionalities.

We studied the reactivity of tantalum oxides in different oxidation states (TaO (II), TaO₂ (IV) and TaO₄ (V)) by matrix-isolation infrared absorption spectroscopy, which has previously been described in detail.^[16] The tantalum oxide reactants were prepared either by pulsed laser evaporation of bulk Ta₂O₅ target or by the reactions of laser-evaporated tantalum atoms with dioxygen in solid argon. As has been reported previously,^[17] pulsed laser evaporation of bulk Ta₂O₅ target under controlled laser energy followed by condensation with pure argon formed only the TaO and TaO₂ molecules.^[18] Figure 1 shows the spectra in a selected region

Figure 1. Infrared spectra in 1260–650 cm⁻¹ region from co-deposition of laser-evaporated tantalum oxides with 2.0% H₂ in argon: a) 1 h of sample deposition at 4 K, b) after 25 K annealing, and c) after 20 min of visible-light irradiation (400 < λ < 580 nm).

from co-deposition of laser-evaporated tantalum oxides with a H₂/Ar sample (2.0% H₂ molar ratio). The spectra in other regions are shown in Figure S1 in the Supporting Information. Besides the TaO and TaO₂ absorptions, two groups of new absorptions were produced (labeled as A and B in Figure 1). The group A absorptions were produced on annealing at the expense of the TaO₂ absorptions. When the sample was subjected to broad-band irradiation using the high-pressure mercury arc lamp with a 400 nm long-wavelength pass filter (400 < λ < 580 nm), the group A absorptions were destroyed, whereas the group B absorptions were produced. The experiment was repeated using the bulk Ta₂O₅ target and the mixed H₂/O₂/Ar sample (2.0% H₂ + 0.1% O₂) as reagent gas, and the resulting spectra are shown in Figure 2 and Figure S2 in

Supporting information for this article is available on the WWW under <http://dx.doi.org/10.1002/ange.201003001>.

the Supporting Information. In this experiment, the TaO₂ molecule interacts readily with dioxygen on annealing to form the side-on bonded tantalum dioxide–dioxygen complex, TaO₄, which is trapped in solid argon as a TaO₄(Ar) complex.^[19] Besides the group A and B absorptions, a third group of absorptions (labeled as C) appeared on low-temperature annealing, markedly increased upon high-temperature annealing, and slightly decreased upon irradiation with visible light. Note that the group C absorptions were not observed in the experiment without O₂ doping (Figure 1). Experiments were also performed using a tantalum metal target. The spectra from codeposition of laser-evaporated tantalum atoms with the mixed H₂/O₂/Ar sample (0.05 % O₂ + 2.0 % H₂ molar ratios) show that the ground state tantalum atoms react with dioxygen to give the inserted tantalum dioxide molecules, which further react with additional dioxygen to form TaO₄. The group A, B, and C absorptions were also formed on annealing or photolysis (see Figures S3 and S4 in the Supporting Information). Isotopic substitutions (HD, D₂, and ¹⁸O₂) were employed for product identification based on isotopic shifts and absorption splitting. The spectra are shown in Figures S5–S9 in the Supporting Information.

A: $[\text{TaO}_2(\eta^2\text{-H}_2)_2]$ ($^2\text{A}_1$, C_{2v})

B: $[\text{HTa}(\text{O})\text{OH}]$ (^2A , C_1)

C: $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ (^2A , C_1)

Figure 3. Optimized structures (bond lengths in angstroms, bond angles in degrees) of the species involved in the $\text{TaO}_2 + \text{H}_2$ and $\text{TaO}_4 + \text{H}_2$ reactions.

Absorber B was produced under irradiation with visible light ($400 < \lambda < 580$ nm) at the expense of the group A absorptions, suggesting that the absorber of group B absorptions is due to a structural isomer or photoproduct of species A. The spectral features indicate that the 3715.0, 1780.5, 972.1, and 701.1 cm^{-1} absorptions are due to O-H, Ta-H, Ta=O, and Ta-OH stretching vibrations (Table S3 in the Supporting Information). Therefore, species B should be due to $[\text{HTaO}(\text{OH})]$ or $[\text{HTaO}(\text{OH})(\eta^2\text{-H}_2)]$. Since no obvious H-H stretching absorption was observed, the group B absorptions are attributed to the $[\text{HTaO}(\text{OH})]$ molecule, which was predicted to have a doublet ground state without symmetry (Figure 3).

As shown in Figure 3, the $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ molecule was calculated to have a doublet ground state without

[a] The intensities are listed in parentheses in km mol^{-1} . Only the vibrations above 400 cm^{-1} are listed.

symmetry. The O_2 subunit was predicted to be side-on bonded to the tantalum metal center with two slightly inequivalent Ta–O bonds. The observed O–O stretching vibrational frequency as well as the predicted O–O bond length ($1.326 \text{ \AA}$) indicate that $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ is a superoxide complex.^[23,24] Thus, the complex can be formally described as $[\{\text{HTaO}(\text{OH})\}^+(\eta^2\text{-O}_2)^-]$ with tantalum in its highest +V oxidation state. The calculated vibrational frequencies and intensities for $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ as well as isotopically substituted $[\text{DTaO}(\text{OD})(\eta^2\text{-O}_2)]$ and $[\text{HTa}^{18}\text{O}(\text{OH})(\eta^2\text{-}^{18}\text{O}_2)]$ are also listed in Table 1, which provide strong support for the proposed identification of this complex. The observed Ta–H, Ta=O, and Ta–OH stretching vibrational frequencies of $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ are higher than the corresponding modes of $[\text{HTaO}(\text{OH})]$. These observations suggest that the Ta=O, Ta–OH, and Ta–H bonds in $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ with tantalum in +V oxidation state are stronger than those in $[\text{HTaO}(\text{OH})]$ with tantalum in +IV oxidation state because of increased electrostatic interactions.

The present experiments clearly indicate that the $[\text{TaO}_2(\eta^2\text{-H}_2)]$ complex was formed by the reaction of ground state TaO_2 and dihydrogen [Eq. (1)]. The $[\text{TaO}_2(\eta^2\text{-H}_2)]$ complex can further be transferred to the $[\text{HTaO}(\text{OH})]$ molecule by photoisomerization in combination with H_2 elimination under visible-light irradiation. In the experiments with the $\text{H}_2/\text{O}_2/\text{Ar}$ mixtures, the $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ complex was also produced on annealing after TaO_4 , implying that $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ was formed through the reaction between TaO_4 and H_2 [Eq. (2)].

The potential energy profile for Equation (2) calculated at the B3LYP level of theory is shown in Figure 4. The reaction proceeds with the initial formation of a $[\text{TaO}_4(\text{H}_2)]$ complex without any barrier. Unlike most of previously characterized metal dihydrogen complexes,^[2,21,22] in which H_2 binds side-on to the metal primarily through both donation of the bonding

σ electrons to vacant metal d orbital and back-donation of metal d electrons to the antibonding orbital of H_2 , the bonding interaction between TaO_4 and H_2 only involves σ donation as TaO_4 is a d^0 complex. From the $[\text{TaO}_4(\text{H}_2)]$ complex, one H atom transfers from Ta to one oxygen atom of tantalum dioxide subunit to form $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ via a transition state. The energy barrier from $[\text{TaO}_4(\text{H}_2)]$ to $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ was predicted to be only $6.5 \text{ kcal mol}^{-1}$. The transition state has a four-center struc-

Figure 4. Potential-energy profile (ZPE corrected, in kcal mol^{-1}) for the $\text{TaO}_4 + \text{H}_2 \rightarrow [\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ reaction calculated at the B3LYP/6-311++G**/SDD level of theory.

ture. Similar transition-state structures with low energy barriers have been reported in many metathesis reactions.^[25,26] The overall $\text{TaO}_4 + \text{H}_2 \rightarrow [\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ reaction was predicted to be exothermic by $46.7 \text{ kcal mol}^{-1}$ and proceeds via a transition state that lies $3.7 \text{ kcal mol}^{-1}$ lower in energy than the $\text{TaO}_4 + \text{H}_2$ reactants. The exothermicity of the overall reaction and the negative energy barrier height as compared to the reactants imply that the formation of $[\text{HTaO}(\text{OH})(\eta^2\text{-O}_2)]$ from $\text{TaO}_4 + \text{H}_2$ is both thermodynamically and kinetically favorable, which is consistent with the experimental observations.

In contrast to TaO_4 , which is able to cleave dihydrogen heterolytically and spontaneously at cryogenic temperatures, the cleavage of dihydrogen by TaO_2 requires activation energy. As mentioned above, the formation of $[\text{HTaO}(\text{OH})]$ from $[\text{TaO}_2(\eta^2\text{-H}_2)]$ proceeds only under excitation with visible light. No products due to $\text{TaO} + \text{H}_2$ reaction were observed, indicating that the ground-state TaO molecule is unreactive toward H_2 . These results indicate that the reactivity of tantalum oxides toward dihydrogen increases with the oxidation state, which follows the trend $\text{Ta}^{\text{VO}}\text{O}_4 > \text{Ta}^{\text{IV}}\text{O}_2 > \text{Ta}^{\text{III}}\text{O}$. In the heterolytic cleavage of H_2 on TaO_x ($x = 1, 2, 4$), the reaction is concerted with a four-center cyclic transition state (Figure 4 and Figure S11 in the Supporting Informa-

tion). The activation barriers depend strongly on the strength of the Ta=O bond,^[27] and follows the trend TaO > TaO₂ > TaO₄,^[28] whereas the exothermicity of the reaction increases in the reverse order.

The present experiments clearly show that the neutral TaO₄ d⁰ complex is able to cleave dihydrogen heterolytically and spontaneously at cryogenic temperatures in forming the [HTaO(OH)(η²-O₂)] complex, which involves both the hydridic (H⁻) and the protic (H⁺) functionalities. Thus, the [HTaO(OH)(η²-O₂)] complex may serve as a precursor to transfer hydrogen atoms to organic or other substrates. Theoretical calculations on prototype hydrogenation reaction of formaldehyde mediated by [HTaO(OH)(η²-O₂)] were performed, and the results are summarized in Figure S12 and Tables S4 and S7 in the Supporting Information. The calculated pathway of hydrogen transfer displays a double-well energetic profile involving two complex intermediates, which are linked via a transition state with a six-membered ring structure. A similar transition state has been reported for metal–ligand bifunctional catalyst mediated hydrogenation reactions.^[29] The complete catalytic cycle TaO₄ + H₂ + H₂CO → TaO₄ + CH₃OH is predicted to be exothermic by 18.3 kcal mol⁻¹ and proceeds via two transition states lying 3.7 and 23.9 kcal mol⁻¹ lower in energy than the ground-state reactants: TaO₄ + H₂ + H₂CO. Therefore, the TaO₄ d⁰ complex can serve as a model catalyst for hydrogenation reactions. The results presented herein may help in understanding the dihydrogen activation processes and catalytic mechanisms of hydrogenation reactions at metal centers.

- [20] The density functional theory calculations were performed using the hybrid B3LYP functional (A. D. Becke, *J. Chem. Phys.* **1993**, *98*, 5648; C. Lee, W. Yang, R. G. Parr, *Phys. Rev. B* **1988**, *37*, 785) with the 6-311++G** basis set for the H, C, and O atoms and the SDD pseudopotential and basis set for Ta (M. Dolg, H. Stoll, H. Preuss, *J. Chem. Phys.* **1989**, *90*, 1730; D. Andrae, U. Haussermann, M. Dolg, H. Stoll, H. Preuss, *Theor. Chim. Acta.* **1990**, *77*, 123). The geometries were fully optimized, and the harmonic vibrational frequencies were calculated with analytic second derivatives. The zero-point energies (ZPE) were derived. Transition-state optimizations were performed with the synchronous transit-guided quasi-Newton (STQN) method and were verified through intrinsic reaction coordinate (IRC) calculations. The single-point energies of the structures optimized at the B3LYP/6-311++G**/SDD level were calculated using a more larger basis set: aug-cc-pvtz for H, C, and O, aug-cc-pvtz-PP for Ta (D. Figgen, K. A. Peterson, M. Dolg, H. Stoll, *J. Chem. Phys.* **2009**, *130*, 164108). Further refinement of geometries and energetics was performed using the newly developed and well validated B2PLYP method (S. Grimme, *J. Chem. Phys.* **2006**, *124*, 034108), whereby the geometries were firstly optimized at the B2PLYP/6-311++G**/SDD level of theory and then by single-point energy calculations with the larger basis set. The results indicate that the B3LYP and B2PLYP methods agree well with each other (see the Supporting Information). Thus, the results reported in the text are given by the B3LYP method. All these calculations were performed by using the Gaussian09 program (M. J. Frisch, et al. Gaussian09, revision A02; Gaussian, Inc.: Pittsburgh, PA, **2009**).
