

# Hot-Electron-Transfer Enhancement for the Efficient Energy Conversion of Visible Light\*\*

Sungju Yu, Yong Hwa Kim, Su Young Lee, Hyeon Don Song, and Jongheop Yi\*

**Abstract:** Great strides have been made in enhancing solar energy conversion by utilizing plasmonic nanostructures in semiconductors. However, current generation with plasmonic nanostructures is still somewhat inefficient owing to the ultrafast decay of plasmon-induced hot electrons. It is now shown that the ultrafast decay of hot electrons across Au nanoparticles can be significantly reduced by strong coupling with CdS quantum dots and by a Schottky junction with perovskite SrTiO<sub>3</sub> nanoparticles. The designed plasmonic nanostructure with three distinct components enables a hot-electron-assisted energy cascade for electron transfer, CdS → Au → SrTiO<sub>3</sub>, as demonstrated by steady-state and time-resolved photoluminescence spectroscopy. Consequently, hot-electron transfer enabled the efficient production of H<sub>2</sub> from water as well as significant electron harvesting under irradiation with visible light of various wavelengths. These findings provide a new approach for overcoming the low efficiency that is typically associated with plasmonic nanostructures.

**P**lasmonic nanostructures have recently been proposed to enhance the efficiency of solar energy conversion.<sup>[1]</sup> One of the remarkable features of plasmon-induced photocatalysis is localized surface plasmon resonance (LSPR), which arises from the collective oscillation of free electrons at the metallic interface or in small metallic nanostructures.<sup>[2]</sup> The phenomenon confers several distinct advantages to photocatalytic processes. First, plasmonic metal nanoparticles (NPs) act as photosensitizers in metal/semiconductor junctions and strongly absorb at specific wavelengths in the visible region. Second, the metallic NPs effectively act as antennae, which are useful in semiconductors with a short minority carrier diffusion length. The results of femtosecond pump–probe experiments suggest that the hot electrons in Au NPs have an

elastic mean free path of approximately 10 nm.<sup>[3]</sup> However, hot-electron transfer to an adjacent semiconductor still remains a challenge because the hot electrons decay rapidly to lower energy levels through ultrafast electron–electron and electron–phonon scattering on a time scale of a few to several hundred femtoseconds.<sup>[4]</sup> The first demonstration of a plasmon-induced hot-electron transfer process in metal–semiconductor nanostructures by Wu et al. revealed that the plasmon excitation of Au led to the injection of hot electrons into the conduction band (CB) of CdS with an average quantum yield of approximately 2.75(±0.07)%.<sup>[4a]</sup> The low quantum yield was found to be the result of multiple competing pathways for energy dissipation in the hot electron injection process.

Herein, a combinative NP system composed of SrTiO<sub>3</sub> as a high-performance electron filter and a Au@CdS core–shell NP as the plasmonic photosensitizer was found to enhance hot-electron transfer. The ultrafast decay of the resulting hot electrons was efficiently reduced by the strong coupling of Au and CdS. Furthermore, a Schottky junction between Au and SrTiO<sub>3</sub> facilitated the charge transfer to the CB of SrTiO<sub>3</sub>, and in turn, perovskite SrTiO<sub>3</sub> enabled the favorable transfer of charge carriers to active sites for H<sub>2</sub> production. Our findings also indicate the existence of a favorable electron pathway, CdS → Au → SrTiO<sub>3</sub>, as shown by steady-state and time-resolved photoluminescence spectroscopy. This novel plasmonic nanostructure provides a new and effective strategy for the efficient energy conversion of visible light.

The synthesis of a Au@CdS core–shell NP deposited on the surface of a SrTiO<sub>3</sub> NP (Au@CdS/SrTiO<sub>3</sub>) is schematically shown in Figure 1a. The detailed experimental procedures are given in the Supporting Information. In short, the positively charged surface of SrTiO<sub>3</sub> assists in the adsorption of AuCl<sub>4</sub><sup>−</sup> anions in a pH-controlled environment. Au NPs are deposited on the SrTiO<sub>3</sub> surface using NaBH<sub>4</sub>, a strong reducing agent. Au@CdS core–shell structures are formed in an ethanol suspension containing Au/SrTiO<sub>3</sub>, sulfur, and Cd<sup>2+</sup> cations. Excess sulfur molecules with an affinity for Au are adsorbed on the surface of the Au NPs. When the resulting suspension is irradiated with UV light, the sulfur molecules that are adsorbed on the Au NPs are reduced to S<sup>2−</sup> anions, which instantly react with Cd<sup>2+</sup> cations to form CdS shells around the Au NPs. Although the Au@CdS core–shell structure has been proposed by our group and by Tada et al. for a solid-state Z-scheme under visible-light or UV irradiation,<sup>[5]</sup> the preparation method described in this study was altered so as to optimize the response of the Au NPs to visible-light irradiation by the LSPR effect. For example, the method resulted in Au NPs with a controlled size and the deposited Pt NPs functioned as a co-catalyst on the surface of

**Figure 1.** Morphology and composition of the Au@CdS/SrTiO<sub>3</sub> nanostructures as determined using microscopy techniques. a) Preparation of the Au@CdS/SrTiO<sub>3</sub> nanostructures. The first image (left) indicates the surface state of a SrTiO<sub>3</sub> NP with positive charges in an aqueous suspension at pH 4. The second image illustrates the deposition of Au NPs on the surface of SrTiO<sub>3</sub> by direct reduction of AuCl<sub>4</sub><sup>−</sup> using NaBH<sub>4</sub>. Third, sulfur molecules are adsorbed onto the surface of the Au NPs because of their affinity to Au. Finally, the sulfur molecules are reduced to S<sup>2−</sup> ions, which instantly react with Cd<sup>2+</sup> to form CdS shells under UV irradiation. b) HAADF-STEM image of the Au@CdS core-shell structures distributed on the surface of a SrTiO<sub>3</sub> NP. c) 2D atomic mapping of Sr, Ti, O, Cd, S, and Au obtained by analytical STEM-EDS. d) HR-TEM image of the interface region of SrTiO<sub>3</sub> and Au@CdS.

the SrTiO<sub>3</sub>. Furthermore, the Au@CdS/SrTiO<sub>3</sub> nanostructure entirely reversed the Z-schematic charge-transfer direction and even changed the main active site for H<sub>2</sub> generation from CdS to SrTiO<sub>3</sub>. Notably, whereas two semiconductors that consist of the Z-schematic system should generate electron-hole pairs, SrTiO<sub>3</sub> NPs in the Au@CdS/SrTiO<sub>3</sub> nanostructure do not generate electrons during the H<sub>2</sub> generation but act as an electron filter for efficient hot-electron transfer.

The high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) image in Figure 1b shows that the as-synthesized Au@CdS/SrTiO<sub>3</sub> NPs contain a few Au cores with a diameter of  $11.5 \pm 4.7$  nm (see Figure S1a–e), which are deposited on the surface of the SrTiO<sub>3</sub> NPs (<100 nm); CdS shells with a thickness of 3–5 nm are formed around the Au cores. Figure 1c displays the energy-dispersive X-ray spectroscopy (EDS) results of the core-shell structure marked in Figure 1b, which confirmed that the material is composed of a Au core with a CdS shell deposited on the surface of a SrTiO<sub>3</sub> NP. The high-resolution transmission electron microscopy (HR-TEM) image shown in Figure 1d was taken at the interface region of the SrTiO<sub>3</sub> and the Au@CdS core-shell NP and clearly reveals three distinct types of lattice fringes, which were assigned to SrTiO<sub>3</sub> (JCPDS 01-1018), Au (JCPDS 01-1172), and CdS (JCPDS 41-1049). The interface between the SrTiO<sub>3</sub> and Au core is

believed to be important for the injection of hot electrons from Au to the CB of SrTiO<sub>3</sub> upon LSPR excitation.

Photocatalytic H<sub>2</sub> production was performed under irradiation with visible light ( $\lambda \geq 400$  nm) in an aqueous suspension (Figure 2). The photocatalytic activities of bare SrTiO<sub>3</sub>, Au/SrTiO<sub>3</sub>, CdS/SrTiO<sub>3</sub>, and Au/CdS/SrTiO<sub>3</sub> were compared with that of Au@CdS/SrTiO<sub>3</sub> by using samples that had almost

**Figure 2.** Photocatalytic H<sub>2</sub> production as a function of time under visible-light irradiation ( $\lambda \geq 400$  nm).

the same Au (1 wt %) and CdS (4 wt %) concentrations, as determined by inductively coupled plasma atomic emission spectroscopy (ICP-AES). The H<sub>2</sub> production of bare SrTiO<sub>3</sub> is negligible because the catalyst can only be excited by UV light. Approximately  $0.4 \mu\text{mol h}^{-1}$  (quantum efficiency, QE = 0.03 %) H<sub>2</sub> molecules were produced by the Au/SrTiO<sub>3</sub> catalyst, despite the poor sensitivity of SrTiO<sub>3</sub> to visible light. The performance of Au/SrTiO<sub>3</sub> can be attributed to the injection of plasmon-induced hot electrons into the CB of SrTiO<sub>3</sub>. CdS/SrTiO<sub>3</sub> produced H<sub>2</sub> at a rate of  $2.5 \mu\text{mol h}^{-1}$  (QE = 0.19 %). It is well-known that CdS-sensitized semiconductor composites (e.g., CdS/TiO<sub>2</sub>) can generate large amounts of H<sub>2</sub> because of the enhanced charge separation that is due to the heterojunction structure.<sup>[6]</sup> Parts of the Au NPs that are not covered with CdS can act as a co-catalyst for H<sub>2</sub> production. A Au/CdS/SrTiO<sub>3</sub> photocatalyst for which Au and CdS NPs were individually deposited on the surface of SrTiO<sub>3</sub>, was examined for the sake of comparison. The photocatalyst produced H<sub>2</sub> at a rate of  $5.0 \mu\text{mol h}^{-1}$  (QE = 0.38 %), which was twice as fast as the rate determined for CdS/SrTiO<sub>3</sub>. This is due to the fact that the photoexcited electrons in the CB of CdS are shuttled to the CB of SrTiO<sub>3</sub>, and are then entrapped by Au NPs, which accelerates H<sub>2</sub> production. Interestingly, Au@CdS/SrTiO<sub>3</sub> showed an impressive photosynthetic H<sub>2</sub> production rate of  $29.1 \mu\text{mol h}^{-1}$  (QE = 2.21 %). This can be attributed to the synergistic effects of 1) the plasmonic photosensitization of the Au@CdS core-shell structure, 2) the formation of a Schottky junction between the Au core and SrTiO<sub>3</sub>, and 3) the high CB of perovskite SrTiO<sub>3</sub> with respect to the water-reduction potential. The efficient H<sub>2</sub> production with Au@CdS/SrTiO<sub>3</sub> is

explained in detail in the Supporting Information (see the Section on synergistic effects, Figure S2–3).

To investigate the electron-transfer processes, we prepared control samples of Pt/Au@CdS/SrTiO<sub>3</sub> and Au@CdS/Pt/SrTiO<sub>3</sub> nanocomposites. For the Pt/Au@CdS/SrTiO<sub>3</sub> photocatalyst, Pt NPs (1 wt %) were deposited on the CdS shell by the Z-scheme mechanism for Au@CdS/SrTiO<sub>3</sub> under irradiation with UV light (Figure S4a–c). For the synthesis of Au@CdS/Pt/SrTiO<sub>3</sub>, Pt NPs (1 wt %) were deposited on the surface of the SrTiO<sub>3</sub> by the direct reduction method using NaBH<sub>4</sub> before the formation of Au@CdS core-shell structures on the SrTiO<sub>3</sub> surface (Figure S5a,b). Using Pt/Au@CdS/SrTiO<sub>3</sub> and Au@CdS/Pt/SrTiO<sub>3</sub>, H<sub>2</sub> was produced at a rate of 129.4 (QE = 9.81 %) and 163.6 μmol h<sup>-1</sup> (QE = 12.41 %), respectively. The experimental results imply that most of the photoexcited electrons that originate from the Au@CdS core-shell structures flow to the surface of the SrTiO<sub>3</sub> NP through a cascade of energy states. To further demonstrate the hot-electron-assisted charge dynamics of Au@CdS/SrTiO<sub>3</sub>, we carried out steady-state and time-resolved photoluminescence (PL) measurements. The details of the steady-state PL spectra are provided in the Supporting Information (see the Section on electron-transfer dynamics, Figure S6a–c), where the electron-transfer processes that determine the kinetics of the target system are also explained. Figure 3a and b show the time-resolved PL spectra of the prepared samples suspended in an aqueous solution of rhodamine B (RhB, indicator dye to monitor interfacial charge transfer) with excitation wavelengths of 405 nm (for the excitation of CdS) and 500 nm (for the simultaneous excitation of CdS and Au). The resulting fluorescence was analyzed and fitted to a multi-exponential model. In the model equation, the intensity is assumed to decay as a sum of individual single exponential decays and described as:

$$I(t) = \sum_{i=1}^n A_i e^{-t/\tau_i} \quad (1)$$

where  $\tau_i$  is the decay time,  $A_i$  represents the amplitude of the

components at  $t = 0$ , and  $n$  is the number of decay times. The quality of the fitting was assessed by the reduced  $\chi^2$  value. All of the fitting parameters are summarized in Tables S1 and S2. The fluorescence decays of RhB and of RhB in the presence of CdS can be expressed as single-exponential functions, as CdS hardly emits PL at the excitation wavelength. However, the decay traces of RhB in the presence of SrTiO<sub>3</sub>, Au/SrTiO<sub>3</sub>, CdS/SrTiO<sub>3</sub>, and Au@CdS/SrTiO<sub>3</sub> are expressed as bi-exponential functions as both RhB and SrTiO<sub>3</sub> emit PL at 580 nm. The obtained time-resolved spectra represent the sum of PL<sub>1</sub> of RhB and PL<sub>2</sub> of SrTiO<sub>3</sub>. Therefore, the pre-exponential factors  $A_i$  indicate the relative contribution of PL<sub>1</sub> and PL<sub>2</sub> to the time-resolved PL spectra.  $\tau_1$  and  $\tau_2$  in the exponential term describe the decay of the electron population in photoexcited RhB and in the CB of SrTiO<sub>3</sub>, respectively. The decay rates of the electron populations in RhB and in the CB of SrTiO<sub>3</sub> could be experimentally assessed by fitting the time-resolved PL curve to Eq. (1). In an attempt to understand the kinetics of the process based on the results of the steady-state PL spectroscopy data, electron pathways were constructed with differential equations (see Table S3 and S4). In the schematic representation, R, S, A, and C denote RhB, SrTiO<sub>3</sub>, Au, and CdS, respectively. Furthermore,  $N_R(t)$  and  $N_S(t)$  refer to the time-dependent electron populations of the lowest unoccupied molecular orbital (LUMO) of RhB and the CB of SrTiO<sub>3</sub>, respectively. The rate constants were calculated by comparing the exponents,  $k$ , in the differential equations with the values for  $\tau_i$  that were extracted from the fitted results of the time-resolved PL spectra. Table S5 summarizes the electron-transfer rate constants at the different excitation wavelengths. The fluorescence of pure RhB at the excitation wavelength ( $\lambda_{\text{ex}} = 405$  nm) showed a single-exponential decay with an emission lifetime of 1.711 ns, which was constant at the long excitation wavelength ( $\lambda_{\text{ex}} = 500$  nm), and its recombination rate constant based on the expression  $k_R = 1/\tau_1(\text{RhB})$  was approximately  $5.84 \times 10^8 \text{ s}^{-1}$ . The addition of SrTiO<sub>3</sub> led to faster fluorescence decay of RhB, which could be described by the bi-exponential model. The interfacial charge transfer from the excited RhB to the CB of SrTiO<sub>3</sub> decreased the

**Figure 3.** Time-resolved PL spectra of a RhB solution (1 μM) in the presence of the indicated sample with a) excitation at 405 nm and b) excitation at 500 nm, where the emission wavelength is 580 nm. c) Schematic energy band diagram of Au@CdS/SrTiO<sub>3</sub>, showing the proposed electron-transfer processes across the three components responsible for H<sub>2</sub> production. The numbered arrows indicate the following individual electron-transfer steps: 1) Excitation of electrons in the CdS shell, 2) electron injection from the CB of the CdS shell into the Fermi level of the Au core, 3) plasmon-induced hot electron injection from the Au core into the CB of SrTiO<sub>3</sub>, and 4) migration of the hot electrons to active sites at the surface of SrTiO<sub>3</sub>.

lifetime,  $\tau_1$ , of RhB. Its rate constants for the charge transfer,  $k_{R \rightarrow S}$ , were  $0.38 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 405 \text{ nm}$  and  $0.32 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 500 \text{ nm}$ . Furthermore, the recombination rate constants for  $\text{SrTiO}_3$  could be obtained from the second lifetime,  $\tau_2$ , which was affected by the fluorescence decay of  $\text{SrTiO}_3$ . The corresponding rate constants,  $k_s$ , were determined to be  $2.80 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 405 \text{ nm}$  and  $2.90 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 500 \text{ nm}$ . Au/ $\text{SrTiO}_3$  NPs suspended in RhB facilitated the fluorescence decay of RhB, as the photoexcited electrons from RhB were further transferred to the Fermi level of the Au NPs at a rate,  $k_{R \rightarrow A}$ , of approximately  $0.42 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 405 \text{ nm}$ . The rate increased to  $1.17 \times 10^8 \text{ s}^{-1}$  for an excitation wavelength of 500 nm. The increase can be attributed to the LSPR excitation of the Au NPs, leading to hot-electron transfer to the CB of  $\text{SrTiO}_3$ . As Au and CdS did not emit PL, most of the electrons injected into the Au or CdS particles from RhB were assumed to be transferred to the CB of  $\text{SrTiO}_3$ . Therefore, we designated  $k_{R \rightarrow A}$  to be  $k_{R \rightarrow A \rightarrow S}$  at  $\lambda_{\text{ex}} = 500 \text{ nm}$ . However, the deposition of Au NPs caused the electrons in the CB of  $\text{SrTiO}_3$  to recombine at the Fermi level of Au. The rate constant for this process,  $k_{S \rightarrow A}$ , was  $0.04 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 405 \text{ nm}$  and  $0.10 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 500 \text{ nm}$ . CdS/ $\text{SrTiO}_3$  NPs suspended in RhB also promoted the fluorescence decay of RhB as the photoexcited electrons from RhB are sequentially transferred to the CB of CdS and  $\text{SrTiO}_3$  at a rate  $k_{R \rightarrow C \rightarrow S}$ . The rate constant  $k_{R \rightarrow C \rightarrow S}$  ( $0.85 \times 10^8 \text{ s}^{-1}$ ) at  $\lambda_{\text{ex}} = 500 \text{ nm}$  was lower than that ( $1.01 \times 10^8 \text{ s}^{-1}$ ) at  $\lambda_{\text{ex}} = 405 \text{ nm}$  owing to the weak excitation of CdS, and the decay of electrons in the CB of  $\text{SrTiO}_3$  to the VB of CdS,  $k_{S \rightarrow C}$ , occurred at a rate of  $1.28 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 405 \text{ nm}$  and at  $0.04 \times 10^8 \text{ s}^{-1}$  at  $\lambda_{\text{ex}} = 500 \text{ nm}$ . When the Au@CdS/ $\text{SrTiO}_3$  NPs were suspended in RhB, the photoexcited electrons of RhB could be transferred to the CB of  $\text{SrTiO}_3$  and the CdS shell. The electrons in the CB of the CdS shell could be injected into the Au core, which is strongly coupled to the CdS shell (see the Section on optical characterization in the Supporting Information, Figures S7 and S8). Then, the electrons that have been injected into the Au core are likely to decay to the VB of CdS at  $\lambda_{\text{ex}} = 405 \text{ nm}$  with a rate constant  $k_{R \rightarrow C \rightarrow A \rightarrow C}$  ( $1.10 \times 10^8 \text{ s}^{-1}$ ) or quench the remaining positive charges at the Au core upon LSPR excitation at  $\lambda_{\text{ex}} = 500 \text{ nm}$ . At  $\lambda_{\text{ex}} = 500 \text{ nm}$ , the separated hot electrons of the Au core could be sequentially transferred to the CB of  $\text{SrTiO}_3$ , and the rate constant for this process was denoted as  $k_{R \rightarrow C \rightarrow A \rightarrow S}$ . This rate constant ( $1.94 \times 10^8 \text{ s}^{-1}$ ) was even higher than the  $k_{R \rightarrow A \rightarrow S}$  ( $1.17 \times 10^8 \text{ s}^{-1}$ ) rate constant of Au/ $\text{SrTiO}_3$  at  $\lambda_{\text{ex}} = 500 \text{ nm}$ . These observations explain the enhancement of hot-electron transfer with Au@CdS/ $\text{SrTiO}_3$ .

Regarding the above results, we propose that the following electron-transfer processes occur in Au@CdS/ $\text{SrTiO}_3$  NPs under visible-light irradiation (Figure 3c). The excitation of LSPR in the Au core transiently produces electron-hole pairs with hot electrons at empty states above the Fermi level of the Au core. When a certain number of hot electrons arrive at the interface of the Au core and  $\text{SrTiO}_3$ , a fraction of the hot electrons is injected into the CB of  $\text{SrTiO}_3$ .<sup>[7]</sup> The hot electrons then diffuse to the surface of the  $\text{SrTiO}_3$  and are subsequently entrapped by Pt NPs, which provide active sites for  $\text{H}_2$  production and enhance the charge separation. Meanwhile, a significant fraction of residual holes at the Au core

are removed by the electrons injected from the CdS shell, and the sacrificial ions quench the holes in the CdS shell.

The previous sections focused on the conversion of visible light into chemical energy,  $\text{H}_2$ . Photoexcited electrons in the Au@CdS/ $\text{SrTiO}_3$  nanostructure can also be used to directly generate electrical energy in a photoelectrochemical (PEC) cell. The details of this process are given in the Supporting Information (see the Section on photoelectrochemical performance characterization, Figure S9–S11).

In summary, we have demonstrated an enhancement in the hot-electron transfer of a Au core by strong electronic coupling to a CdS shell that is in direct contact with perovskite  $\text{SrTiO}_3$  NPs for the effective conversion of visible light into clean  $\text{H}_2$  or into electricity. The enhanced  $\text{H}_2$  production can mainly be attributed to the synergistic effects of the following three features: 1) The plasmonic photosensitization of the Au@CdS core-shell NPs generates more active electron-hole pairs. 2) Band bending between the Au core and  $\text{SrTiO}_3$  enables hot electrons to be easily ejected from the Au core into the CB of  $\text{SrTiO}_3$ . 3) Perovskite  $\text{SrTiO}_3$  plays an important role as a high-performance electron filter that is superior to  $\text{TiO}_2$ , and has a sufficiently high CB to produce  $\text{H}_2$ . Consequently, the Au@CdS/ $\text{SrTiO}_3$  nanostructure provided a favorable electron pathway,  $\text{CdS} \rightarrow \text{Au} \rightarrow \text{SrTiO}_3$ , for the efficient separation of electron-hole pairs, although Au, which displays a large work function, was sandwiched in between  $\text{SrTiO}_3$  and CdS. The designed nanostructure achieved a remarkably efficient photocatalytic  $\text{H}_2$  production and electron harvesting at various visible-light wavelengths. The findings from this study will be informative for the design of plasmonic photocatalysts and PEC cells, such as photo-voltaic and water-splitting devices.
